Other investigators have suggested that lowered but functional levels of ATP are maintained during ischemia and are present at the time of contractile failure.[40,41] ATP that is used during the early phases of development of ischemia is replaced by breakdown of phosphocreatine and, to a lesser degree, by anaerobic glycolysis. This process leads to substantial increases in inorganic phosphate and modest increases in ADP.[17] Increases in inorganic phosphates and ADP limit the free energy available from ATP, resulting in metabolic inefficiency.[19,22]

It has also been proposed that ischemia disrupts the modulatory function of ATP, possibly affecting calcium entry into cells, calcium efflux from the sarcoplasmic reticulum, or both.[20,22] Increased intracellular levels of inorganic phosphates may also contribute to the development of PEA by forming insoluble calcium phosphate precipitates, thus trapping calcium in the sarcoplasmic reticulum and mitochondria.[20,22]

Autonomic nervous system

Kostreva et al. studied the role of the autonomic nervous system in the initiation of PEA during acute cardiac tamponade in a dog model.[42] The onset of PEA in this model was significantly delayed by either surgical or pharmacologic sympathectomy, leading the authors to conclude that the sympathetic efferent component of the autonomic nervous system plays an important role in the initiation of PEA.[42] Cardiac sympathetic efferent stimulation increased the heart rate and double product (Heart rate × Peak left ventricular pressure ÷ 100), thereby increasing cardiac work and oxygen consumption and promoting the initiation of PEA. β-blockade with propranolol decreased the double product and heart rate, significantly delaying the onset of PEA. Although this PEA model did not show any apparent effect on initiation of PEA with bilateral vagotomy, other authors contend that the parasympathetic nervous system also plays an important role.

DeBehnke found that complete loss of vagal tone through surgical vagotomy significantly improved the rate of return of spontaneous circulation from experimental asphyxial PEA cardiac arrest in a dog model.[43] The greater incidence of inferior myocardial infarctions in patients with PEA also suggests a role of the autonomic nervous system.[6,22] Acute increases in parasympathetic activity or withdrawal of sympathetic activity may be partially responsible for initiating the condition. Precipitous decreases in heart rate and blood pressure attributed to the Bezold-Jarish reflex are frequently seen with inferior myocardial infarctions and the development of PEA.[44] The role of the autonomic nervous system in triggering the sequence of events leading to PEA is still undefined and remains a promising area for further research.

Other metabolic derangements

Hypoxia resulting in anaerobic glycolysis and severe lactic acidosis is thought to precipitate PEA in a significant proportion of patients. In an autopsy study, Pirolo et al. reported that approximately 20% of PEA patients had a respiratory cause of cardiac arrest.[8] In a prehospital study, Stueven et al. reported approximately 53% of successfully resuscitated prehospital PEA patients had a probable respiratory cause for their arrest.[4] After the onset of ischemia, cellular action potentials decrease and become sufficiently depolarized to become inexcitable. This depolarization is due almost entirely to an accumulation of extracellular potassium.[45,46]

There are predictable cardiovascular responses to hypothermia.[47] After an initial tachycardia, progressive bradycardia occurs, with a 50% decrease in the palpable pulse at 28 °C.[47] Because the conduction system is more sensitive to cold than is the myocardium, the cardiac cycle is prolonged.[48] The PR, QRS, and QT intervals are sequentially prolonged with reduction of core temperature.[48] Hypothermia decreases the mean arterial pressure and cardiac index. With core temperatures below 25 °C, ventricular fibrillation, PEA, or asystole can occur.[49] The

		Group II			
		Initial		Final	
Rate (beats/min)	Group I(%)	Died (%)	Lived (%)	Died (%)	Lived (%)
Tachycardia (rate ≥ 100)	8.68	22.08	36.36	74.06	25.00
Normal rate (60–100)	28.68	35.06	27.27	18.54	68.75
Bradycardia (rate ≤ 60)	62.64	42.86	36.37	7.40	6.25

mechanism is poorly defined. Tissue hypoxia, acid-base disturbances, and autonomic dysfunction all have been implicated.[47]

A variety of medications reduce myocardial contractility and may result in PEA in drug overdoses. Tricyclic antidepressants, β-blockers, calcium channel blockers, and digitalis can produce PEA.[50]

Coronary perfusion pressure is well established as the most important predictor of return of spontaneous circulation in cardiac arrest patients.[51,52] With gradual loss of myocardial contractility that often occurs before the onset of PEA, myocardial hypoxia and acidosis are further intensified by the corresponding decrease in coronary perfusion pressure.

Effects of metabolic derangements on electrocardiographic characteristics

Aufderheide *et al.* studied the ECG characteristics in PEA in 503 prehospital adult cardiac arrest patients.[2] The initial and final ECG characteristics were compared for unsuccessfully (group I) and successfully (group II) resuscitated patients (Table 22.1). On initial prehospital presentation, patients with PEA who responded to therapy (group II) had significantly faster initial rates, a higher incidence of P waves, and average shorter QRS and QT intervals than did patients not responding to therapy (Group I). Successfully resuscitated patients were capable of increasing heart rates, shortening QT intervals, and developing the new

onset of P waves in response to treatment. Further, successfully resuscitated patients had an average initial and final QRS complex length within normal limits, and these remained unchanged with therapy (Table 22.1).

Successful resuscitations (Group II) were divided into those who lived and those who died. ECG parameters were not significantly different with respect to the presence of P waves or QT or QRS interval. Heart rate was significantly different in these two groups (Table 22.2). Patients who responded to therapy but eventually died increased their heart rate over baseline, and it remained significantly elevated when compared with patients who lived. In the group of patients who died, 74% presented to the emergency department with tachycardias. Conversely, those patients who were successfully resuscitated and lived had faster initial presenting heart rates and these tended to become normal with therapy; that is, bradycardias increased and tachycardias decreased. Nearly 69% of PEA saves (defined as discharged from the hospital alive) arrived at the emergency department with normal rates. Bradycardias were the predominant presenting rhythm in unsuccessful resuscitations (Table 22.2).

There appeared to be a relationship between the presence of sinoatrial activity and the rate of successful resuscitation and saves (Table 22.3). Successfully resuscitated patients had a significantly higher incidence of organized atrial activity on initial ECG than did non-responding patients. In addition, nearly 20% of successful resuscitations and 30% of

Table 22.3. Rhythm type vs. outcome

Rhythm type	Group I (%)	Group II			
		Initial		Final	
		Died (%)	Lived (%)	Died (%)	Lived (%)
Sinus activity related to QRS complex	12.40	32.47	45.46	53.69	75
Second- and third-degree atrioventricular block	7.93	7.79	0	0	0
Atrial fibrillation	0	2.60	4.55	3.70	0
Supraventricular tachycardia	0.99	0	0	12.96	0
Nodal	34.16	25.98	27.28	22.21	25
Wide complex rhythms without P waves	44.57	25.98	22.73	7.14	0

saves developed the new onset of organized atrial activity with treatment. No patient with an initial ECG rhythm of second- or third-degree atrioventricular (AV) block survived to hospital discharge. Similarly, supraventricular tachycardia appeared to be associated with a negative outcome. PEA saves were in those patients who presented to the emergency department following treatment and who had sinus activity related to the QRS complex (75%) or narrow complex nodal rhythms (25%).

The time from onset of cardiac arrest, as estimated by the paramedics, was significantly longer for unsuccessful resuscitations than for successful resuscitations.[2]

Earlier PEA ECG studies performed in animals and humans demonstrated a progression of ECG characteristics with time from onset of anoxia.[7,18,53–67] After the onset of anoxia, the vagi and the electrical cardiac conduction system respond to ever-worsening metabolic events, including lactic acidosis, hypoxia, electrolyte abnormalities, and depletion of intracellular metabolites including ATP and creatine phosphate.[19,25,28,29,39,68–70] These metabolic events worsen with time but are potentially reversible through pharmacologic and non-pharmacologic resuscitative intervention. It is tempting to speculate, therefore, that the observed ECG characteristics in PEA patients are a function of time from onset of anoxia and consequently provide a predictive indicator for successful resuscitation and survival.

Stueven *et al.* classified PEA patients into four groups based on initial ECG morphology and related this classification to patient outcome in 503 PEA patients treated in an emergency medical system.[3] Group 1 and group 2A classifications represented more normal ECG complexes. Thus PEA patients who were successfully resuscitated or saved had initial ECG complexes classified as group 1 or group 2A. Group 2B and group 3 represented more abnormal ECG complexes. Consequently, no PEA patient

Table 22.4. Duration of ECG components in patients with true PEA and pseudo-PEA[a]

	True PEA	Pseudo-PEA	P
QR	0.19 ± 0.13 (0.04–0.56)	0.07 ± 0.05 (0.02–0.20)	0.0004

[a]Values are durations expressed in seconds, with range in parentheses.

classified in group 2B or group 3 was saved or successfully resuscitated. The authors of this study speculated that these four classifications represented progressive stages in the anoxic process, which accounted for their predictive value with respect to outcome or response to therapy (Fig. 22.6).[3]

Paradis *et al.* extended these findings by studying the relationship between the ECG and perfusion by measuring central aortic pressure in patients during PEA.[1] Ninety-four patients with PEA were classified as those with and those without aortic pulse pressures, and the ECG findings and rates of return of spontaneous circulation in the two groups were compared.[1]

Patients whose ECG showed regular, organized depolarizations but who lacked palpable carotid or femoral arterial pulses were designated to be in PEA: those without aortic pulse pressures were defined as being in true PEA ($n = 55$); those with regular aortic pulse pressures less than 60 mm Hg that were synchronous with ECG depolarizations were designated as having pseudo-PEA.

The QR and QRS durations of patients with true PEA and pseudo-PEA are compared in Table 22.4. Patients with pseudo-PEA had shorter QR and QRS durations than did patients with true PEA.
Group 1

Fig. 22.6. PEA morphologic presentation: group 1, normal QRS width, isoelectric ST waves and normal-appearing T waves; group 2A, atrial activity, widened QRS width (≤ 0.12 msec) or abnormal ST or T waves (ST depression, elevation, slurring or T-wave inversion); group 2B, same as 2A but with no atrial activity; group 3, essentially monophasic, slurred RST complexes. These classifications may represent progressive stages in anoxic process of PEA. (From ref. 3.)

A concurrent study of the effect of high-dose epinephrine on CPR coronary perfusion pressure allowed assessment of the effects of standard- and high-dose epinephrine on each type of PEA (71). Eight (15%) of 55 patients in true PEA and 14 (36%) of 39 in pseudo-PEA responded to standard therapy, including epinephrine doses of 1 mg with return of spontaneous circulation ($P=.016$). Six (23%) of the 26 patients in true PEA who received high-dose epinephrine had return of spontaneous circulation. Of the 18 patients with pseudo-PEA who received high-dose epinephrine, 14 (78%) had return of spontaneous circulation. This was significantly greater than the proportion with return of spontaneous circulation after standard doses ($P=0.003$) and was the best outcome among all combinations of PEA type and epinephrine dose ($P=0.001$).

Table 22.5. Characteristics of patients with true PEA and pseudo-PEA

Characteristic	True PEA	Pseudo-PEA	P
Age (yr)	71 ± 15	65 ± 15	0.7
Total arrest time (min)	25 ± 11	21 ± 13	0.44
Witnessed arrests	22/55	26/39	0.01
PO_2 (mm Hg)	237 ± 168	310 ± 134	0.03
PCO_2 (mm Hg)	34 ± 23	24 ± 16	0.04
pH	$7.23 \pm .25$	$7.23 \pm .25$	0.7
Coronary perfusion pressure (mm Hg)	9.9 ± 11.5	19.2 ± 9.5	<0.0001

True and pseudo-pulseless electrical activity

These studies demonstrate that patients with a clinical diagnosis of PEA are in a spectrum of perfusion states that range from normotension to complete absence of perfusion. The fact that many patients clinically in PEA have mechanical cardiac activity should be considered when interpreting the results of cardiac arrest studies. Further, patients with pseudo-PEA appear to have a different short-term prognosis and response to therapy than do patients in true PEA. On the basis of the above preliminary data, administration of high-dose epinephrine may be considered in the treatment of narrow-complex PEA in the hope of improving patient outcome.[1]

Although the minimal perfusion present in patients with pseudo-PEA may be the reason for better short-term outcomes, it is also possible that pseudo-PEA is characterized by a less deranged pathophysiologic state and therefore is more amenable to resuscitation.[1,2] The characteristics of patients with true PEA and pseudo-PEA are shown in Table 22.5. The younger age and higher coronary perfusion pressures in patients with pseudo-PEA are consistent with this conclusion. The greater proportion of witnessed arrests in patients with pseudo-PEA suggests that arrest times are shorter.[1] Further, the estimated time from onset of cardiac arrest to arrival of paramedics has been found to be shorter in PEA patients responding to treatment.[2]

Rapid differentiation of true PEA and pseudo-PEA may be important because of the higher frequency of return of spontaneous circulation with standard and high doses of epinephrine previously mentioned. Consideration of the characteristics of patients with true PEA and pseudo-PEA (Table 22.5) may be helpful, as well as consideration of the ECG characteristics. Patients in PEA who are successfully resuscitated have average QRS intervals that are shorter (0.09 second ± 0.03 second) than those without return of spontaneous circulation (0.12 second ± 0.06 second).[2] The

observation that patients in pseudo-PEA differ in their initial but not terminal QRS deflection indicates the importance of the initial QR deflection (Fig. 22.7).[2] Paradis *et al.* demonstrated that no patient with pseudo-PEA had a QRS interval or initial deflection in the QRS of more than 0.2 second.[1] A QRS duration of 0.12 second or less and especially a normal duration of the initial QR deflection occur most frequently in patients with pseudo-PEA. Nonetheless, there is significant overlap in the average ECG values acquired in PEA patient populations, and these values may not apply in specific cases.

Patients with baseline cardiac contractions (normotensive PEA) probably represent individuals in the first seconds to minutes after the onset of hypovolemia, tension pneumothorax, cardiac tamponade, or other sudden causes for severe preload or afterload reduction. No studies indicate that normotensive PEA represents a significant subset of PEA patients seen by practicing clinicians. It is included as a subset primarily for understanding the pathophysiology and clinical spectrum of PEA. Its detection, however, may assist the clinician in identifying a readily reversible cause for PEA.

Rapid and definitive differentiation among normotensive PEA, pseudo-PEA, and true PEA can be achieved by immediate emergency department echocardiography able to demonstrate myocardial wall motion in patients with clinical PEA. Placement of a Doppler probe over the femoral triangle may rapidly detect pulsatile blood flow. Establishing a peripheral (femoral or radial) arterial line may assist in the differentiation of pseudo-PEA.

Alternatively, placement of a central pressure monitoring catheter may alternatively demonstrate aortic pressures in patients without a clinically detectable pulse.

Causes of pulseless electrical activity

In many patients, PEA is not a primary cardiac arrest but rather a state of severe cardiogenic shock from another etiology. This severe hypotension may propagate the PEA feedback loop: hypotension causes decreased coronary perfusion, which impairs myocardial function, which results in greater hypotension (Fig. 22.5). Indeed, myocardial contractility is normal on initiation of PEA (normotensive PEA). As the process continues, decreased cardiac contractions occur (pseudo-PEA), eventually resulting in absent cardiac contractions (true PEA). The multiple causes of PEA play a central role in therapeutic intervention. Consequently, one major action that must be taken when PEA occurs is the rapid search for possible reversible causes.[50]

Pulmonary causes
The most common cause of PEA is probably severe and sustained respiratory insufficiency or respiratory arrest. Respiratory insufficiency has been implicated as the cause of PEA in 20 to 53% of cases.[4,8]

Preload reduction
Hypovolemia was reported as the cause of PEA in 4.4% of prehospital patients:[4] 3.3% had hemorrhage and 1.1%
Fig. 22.7. Simultaneous aortic arch pressure (expressed in million meters of mercury) and lead II ECG from patient in pseudo-PEA. Total QRS duration of 0.12 msec or less and especially a normal duration of initial QR deflection are more frequently seen in patients with pseudo-PEA. (From ref. 1.)

had functional volume depletion as a result of sepsis.[4] *Pulmonary embolism* results in an increase in pulmonary vascular resistance resulting in an increase in pulmonary arterial pressure. If more than 50% of the pulmonary vascular tree is occluded, left ventricular enddiastolic volume is critically reduced and hemodynamic collapse occurs.

Mechanical causes

Mechanical causes of PEA are so classified because their etiology is related to anatomic structure and their resolution requires mechanical intervention. *Tension pneumothorax* compresses the affected lung, shifting the mediastinum toward the unaffected side and severely reducing cardiac output because of positive intrathoracic pressure decreasing venous return to the heart. *Cardiac tamponade* interferes with normal ventricular filling and results in critically low cardiac output.

Auto-PEEP is a recently described cause of PEA in patients with bronchospastic pulmonary disease during mechanical ventilation. When there is inadequate time for complete exhalation, dynamic forces such as increased respiratory frequency, airway collapse, tidal volume, percentage of inspiratory time (which reduces absolute expiratory time), or a combination of these factors results in air trapping or hyperinflation of the lungs.[72,73] An important consequence of dynamic hyperinflation is that alveolar pressure remains positive throughout expiration, leading to the development of "occult" PEEP. The hemodynamic consequences are identical to those caused by extrinsically applied PEEP that produce increasing intrathoracic pressure, increased pulmonary vascular resistance, and decreased venous return to the heart.[74–76]

Myocardial dysfunction

A direct myocardial dysfunction may cause PEA via a variety of conditions. *Acute myocardial infarction* may cause a critical loss of left ventricular contraction. *Myocardial ischemia* may interfere with normal myocardial function, biochemical processes, and ultrastructure for prolonged periods, resulting in "stunned" myocardium.[29] An autopsy study identified myocardial ischemia as the precipitating cause of PEA in 44% of cases.[8] Patients with end-stage *congestive heart failure* may develop hypotension that causes decreased coronary perfusion and results in myocardial ischemia that further impairs myocardial function. Drug overdoses with *tricyclic antidepressants*, β-*blockers, calcium channel blockers*, and *digitalis* can depress myocardial function and result in hemodynamic collapse. *Hyperkalemia* slows electrical cardiac conduction and depresses myocardial contractility.[77] *Hypothermia*

results in decreased spontaneous depolarization of pacemaker cells, bradydysrhythmias, decreased mean arterial pressure, and decreased cardiac index.[48,49]

Postdefibrillation pulseless electrical activity

Countershock of ventricular fibrillation may be followed by transient PEA in up to 60% of resuscitation attempts.[16] Hoffman and Stevenson reviewed 100 consecutive patients with prehospital ventricular fibrillation receiving countershock.[18] Thirteen (27%) of the forty-nine patients who developed immediate postdefibrillation PEA were admitted to the hospital, and four (8%) were discharged from the hospital alive.[18] These patients had statistically significantly better outcomes than the 25 patients who failed to achieve any organized rhythm in the field. As the initial cardiac arrest rhythm, postcountershock PEA may have a slightly better prognosis than does true PEA. Many patients immediately experiencing postcountershock PEA subsequently develop pulses. Although patients immediately developing supraventricular rhythms with pulses have a better survival rate, the development of postdefibrillation PEA has a prognosis that is neither better nor worse than before defibrillation and statistically better than the prognosis for patients in whom defibrillation fails to produce any organized rhythm. It is therefore postulated that the development of PEA immediately following defibrillation may represent a transient recovery rhythm that, in some cases, spontaneously improves, leading to the appearance of pulses, supraventricular activity, stabilization of hemodynamic status, and possible long-term survival.[18] The variability in return of spontaneous circulation following postcountershock PEA compared with PEA as the initial cardiac arrest rhythm should be considered when interpreting cardiac arrest studies.

Therapy

Therapy for PEA depends on correcting metabolic derangements, correcting anatomic structural derangements, and rapidly reversing underlying causes for PEA.

Correcting metabolic derangements

Because respiratory insufficiency is the cause of PEA in up to 53% of cases, reversal of hypoxia with immediate airway stabilization and hyperventilation with 100% oxygen is indicated in all patients. Maintaining adequate alveolar ventilation and restoration of tissue perfusion, first with chest compressions and then with rapid restoration of spontaneous circulation, should be the primary goal of acid-base therapy in cardiac arrest. Hyperventilation will

partially correct respiratory acidosis by removing carbon dioxide.[78] Laboratory and clinical data fail to show conclusively that low blood pH adversely affects ability to restore spontaneous circulation or short-term survival.[79–81] The use of sodium bicarbonate for treatment of acidosis following return of spontaneous circulation after a long arrest interval is thought to increase cerebrospinal fluid acidosis, is thought to be insufficient to reverse myocardial acidosis, and indeed may be potentially harmful because of its reduction in coronary perfusion pressure.[82–86] The use of bicarbonate may be considered as a therapeutic option with the weight of evidence in favor of its usefulness and efficacy in patients with preexisting metabolic acidosis, hyperkalemia, or tricyclic or phenobarbital overdose.[50]

Treatment of the cardiotoxic effects of various drug overdoses can be effective in the shock state but has not been clearly demonstrated to be effective in cardiac arrest. The direct cardiotoxic effects of tricyclic antidepressant overdose can often be reversed by producing a systemic arterial pH above 7.5 by hyperventilation and the use of intravenous bicarbonate.[50] The cardiosuppressant effects of overdoses of β-blockers respond variably to intravenous glucagon, epinephrine, isoproterenol, and intravascular volume expansion. The cardiac suppressant effects of overdoses of calcium channel blockers can be reversed with intravenous calcium chloride or calcium gluconate. Massive digitalis overdose is treated with intravenous Digabind. The cardiotoxic effects of hyperkalemia are immediately reversed with intravenous calcium chloride or calcium gluconate, followed by intravenous bicarbonate, 10 units of regular insulin, and 1 ampule of intravenous D-50. Therapeutic options for reversing hypothermia include passive external rewarming or active external or core rewarming.[48,49]

Correcting severely reduced preload

Patients with hypotension caused by known hypovolemia should receive rapid intravenous volume expansion. Needle and tube thoracostomies may improve venous return to the heart in patients with tension pneumothorax. Subxiphoid pericardiocentesis may be lifesaving in patients with pericardial tamponade.

Reducing increased vagal tone

Atropine has been recommended by the American Heart Association in cases of bradycardic PEA (below 60 beats/min) or in patients with relative bradycardia.[50] Atropine may reduce increased vagal tone. It has been demonstrated that patients in PEA who respond to treatment with rate normalization have a higher resuscitation and save rate.[2] The atropine dose-response rate for human subjects in PEA has not been established.

Pharmacologically increasing coronary perfusion pressure

α-Adrenergic stimulation improves coronary perfusion pressure, which has been shown experimentally and clinically to predict return of spontaneous circulation.[51,87] Epinephrine has been the adrenergic agent of choice in cardiac arrest. Preliminary information suggests that patients with PEA have a higher rate of return of spontaneous circulation in response to high-dose rather than standard dose epinephrine.[88] Further, patients in pseudo-PEA may benefit from high-dose epinephrine (1). High-dose epinephrine may interrupt the feedback loop of hypotension that causes decreased coronary perfusion and further impairs myocardial function in such patients (Fig. 22.5).

Mechanically increasing coronary perfusion pressure

Maintaining adequate coronary perfusion pressure by utilizing closed chest CPR and intravenous adrenergic agents is the mainstay of therapy for PEA. Modifying existing CPR techniques may improve forward flow, thus increasing coronary perfusion pressure and possibly improving patient outcome. Interopposed abdominal compression CPR, circumferential compression of the chest with use of a pneumatic vest, and active compression-decompression CPR have been shown to improve coronary perfusion pressures and blood flow compared with standard CPR.[89–96]. Cardiopulmonary bypass implemented within 15 minutes after PEA arrest has improved return of spontaneous circulation rates compared with standard- and high-dose epinephrine in an animal postcountershock model.[97] Cardiopulmonary bypass may be a possible therapeutic option in appropriately staffed resuscitation institutions.

Assisting the cardiac electrical conduction system

Transvenous cardiac pacing was studied in a canine model of postcountershock PEA and was found to produce electrical capture but no cardiac contractions.[15] Until cardiac pacing in PEA is studied further, therapy should be aimed at increasing perfusion pressure with other interventions.

The future

PEA remains poorly understood at the biochemical, cellular, and clinical levels. Further investigation into the precise relationships between intracellular biochemical events and myocardial contraction is needed to define the pathologic biochemical cascade leading to uncoupling of excitation and contraction. Characterization of the mechanism for dysfunctional intracellular release and reaccumulation of

Ca^{2+} and the degree of change in affinity for Ca^{2+} during PEA are important areas for investigation. The presence and description of interfering structural changes between actin and myosin cross bridges, including tropomyosin and troponins T, I, and C, at the physiologic extremes seen in PEA may assist understanding of this pathologic process. Further characterization of the biochemical interactions of intracellular high-energy phosphate (ATP) might lead to interventions designed to minimize depletion and facilitate regeneration of myocardial ATP stores.

PEA clinically presents with a spectrum from normotensive to absent myocardial contraction, and there are numerous causes for this condition. Different etiologies may have significantly different pathophysiologic mechanisms and correspondingly different responses to treatment. Study of therapeutic options in PEA is currently limited to asphyxial, tamponade, and postdefibrillation animal models. There is a need to develop and study a much wider variety of animal models that reflect the types of PEA seen clinically, including tension pneumothorax, sepsis/hypovolemia, pulmonary embolus, and drug toxicity PEA animal models.

Perhaps the greatest recent advance in PEA has been the recognition of the important subset of pseudo-PEA patients and their apparent response to high-dose epinephrine therapy. Currently under development, portable and simplified echocardiographic technology may, in the near future, allow hospital and prehospital identification of such patients. Rapid and accurate identification of pseudo-PEA patients will allow clinicians to match PEA therapeutic intervention more accurately with underlying pathophysiology.

Addendum

Volker Wenzel

Innsbruck Medical University, Department of Anesthesiology and Critical Care Medicine, Austria

In a recent study of initial ECG rhythms in out-of-hospital cardiac arrest in Europe, ventricular fibrillation was observed in about 40%, asystole in about 45%, and pulseless electrical activity accounted for about 15%. In contrast, pulseless electrical activity was more likely during in-hospital CPR (children 24%, adults 32%). This is similar to a North American study, when pulseless electrical activity was the initial ECG rhythm in about 20%–40%.[2] Although exact CPR management was not analyzed according to the initial ECG rhythm in the in-hospital CPR study, survival of pulseless electrical activity patients to hospital discharge was relatively good (pediatrics 27%, adults 11%).[3] In a recent study comparing vasopressin vs. epinephrine during CPR ($n=1219$), pulseless electrical activity patients in Europe had a slightly better chance to be discharged from the hospital alive than did asystolic patients (about 6%–8% vs. 2%–5%), but the discharge rate was lower than that for ventricular fibrillation patients (about 18%–19%).[1] While this study was unable to determine an advantage of vasopressin over epinephrine, no pulseless electrical activity patient receiving ≥ 3 mg of epinephrine during CPR ($n=82$) was discharged from the hospital alive, indicating that there may be a critical myocardial ischemia threshold in pulseless electrical activity patients for them to survive.[1] With use of a load-distributing band during out-of-hospital CPR, survival was not improved but differences in survival patterns between initial ECG rhythms (hospital discharge rate, ventricular fibrillation 14%–23%; pulseless electrical activity 3%–9%; asystole 1%–2%)[2] were similar to those in the vasopressin trial in Europe.

Comparable hospital discharge rates for pulseless electrical activity patients were found in Richmond, Virginia, where a load-distributing band was also employed, but survival was not improved over standard manual CPR.[4] When aminophylline vs. placebo was given to patients with bradyasystolic states during out-of-hospital CPR ($n=971$), it was difficult to evaluate effects in pulseless electrical activity patients ($n=222$), because asystolic patients ($n=602$), as well as ventricular fibrillation/tachycardia patients ($n=147$) were included as well. Nonetheless, overall hospital discharge rate in both groups was extremely low (5/971; 0.005%).[5] A different pharmacological strategy, fibrinolysis, was used in pulseless electrical activity victims in a prospective CPR study in Vancouver, Canada. Unfortunately, survival to hospital discharge was again very low (1/117 in the thrombolysis group, and none of 116 of patients receiving placebo), indicating that survival with pulseless electrical activity as initial ECG rhythm was extremely unlikely at least in this trial, and that any statement about treatment strategies was inconclusive.[6]

These clinical studies confirm that survival chances after cardiac arrest with pulseless electrical activity as the initial rhythm are significantly worse than after ventricular fibrillation, and may be only slightly better than survival chances after asystolic cardiac arrest. Moreover, the aforementioned clinical trials further confirm that there is no new promising therapy, such as a "hot track," for this cohort of patients that may be worth follow-up. As pathophysiology indicates, pulseless electrical activity reflects a myocardium that is virtually completely deprived of metabolic activity, and may therefore reflect a setting that is extremely difficult to convert to return of spontaneous circulation with subsequent long-term survival and full neurological recovery.

Therapy of sudden death

Prevention of sudden cardiac death

Catherine Campbell, Ty J. Gluckman, Charles Henrikson, M. Dominique Ashen, and Roger S. Blumenthal

Johns Hopkins Ciccarone Preventive Cardiology Center, Baltimore, MD, USA

Sudden cardiac death (SCD) is defined as death from a cardiac cause that occurs suddenly (usually less than 1 hour) after the onset of symptoms. Most cases of sudden cardiac death are the result of ventricular arrhythmias, which may be the first manifestation of cardiac disease.[1] Chest pain, palpitations, dyspnea, and syncope are common but non-specific prodromal symptoms associated with SCD.

About 400 000–460 000 people in the United States die from SCD each year, accounting for over 60% of all cardiac deaths.[1] Despite the high age-adjusted incidence of SCD (206.5 per 100 000 men, 140.7 per 100 000 women, and 3.0 per 100 000 children and young adults aged $\leq$34 years[2]), it has been a difficult condition to study thus far. In this chapter we review the etiologies of SCD, the tools used to identify and stratify individuals at risk, and strategies for risk reduction.

Etiologies of sudden cardiac death

Coronary artery disease

Because most cases of SCD (approximately 70%) occur in individuals with at least moderate coronary artery disease (CAD), it remains the most common risk factor for this condition.[2] Individuals with a history of myocardial infarction (MI) have a 4- to 6-fold increased risk of SCD[3] due in large part to postinfarction ventricular remodeling.[4] Among patients with left ventricular dysfunction or heart failure, the risk of sudden death is highest (1.4% per month) in the first 30 days after an MI.[5] Coronary artery disease is a less significant risk factor for SCD in young

patients, as only about one fourth of young SCD victims have coronary artery disease.[6]

There are numerous conditions that increase an individual's risk for CAD (Table 23.1).[7] While many of these risk factors are causally linked with CAD, other predisposing and conditional factors are thought to play a role (Table 23.1). Identification of these risk factors is central to CAD risk reduction and, thus, a reduction in the incidence of SCD. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) recommends calculation of the Framingham Risk Prediction Score to provide an estimate of risk for developing an MI or coronary heart disease (CHD) death over the course of 10 years.[8] Importantly, this score is utilized to determine the intensity of pharmacologic risk-reduction therapies. The ATP III also recognizes the impact of the metabolic syndrome on CAD risk, defined by the presence of at least three of the following: abdominal obesity (waist circumference $>$102 cm men, $>$88 cm women), hypertriglyceridemia (triglycerides $\geq$150 mg/dl), low high-density lipoprotein cholesterol (HDL $<$40 mg/dl men, $<$50 mg/dl women), elevated blood pressure ($\geq$130/85 mmHg), and elevated fasting glucose ($\geq$110 mg/dl).

Heart failure and left ventricular hypertrophy

The risk of SCD is increased 6- to 9-fold in individuals with congestive heart failure.[3] Ischemic cardiomyopathy is the most common cause of heart failure in developed countries; however, other cardiomyopathies may also cause heart failure and an increase in the risk of SCD. Structural and functional changes in the failing heart lead to action potential prolongation, abnormal calcium handling, and

Table 23.1. Risk factors for coronary artery disease

Causal	Advancing age (≥45 y men, ≥55 y women)
	Cigarette smoking
	Diabetes mellitus (fasting glucose ≥126 mg/dL; glucose ≥200 mg/dl post-glucose load)
	Elevated blood pressure (>120/80 mmHg)
	Elevated total (≥200 mg/dL) and LDL (≥130 mg/dL) cholesterol
	Low serum HDL cholesterol (<40 mg/dL)
Predisposing	Family history of premature coronary heart disease (first degree relative, <55 y men, <65 y women)
	Overweight and obese states (BMI >25 kg/m^2)
	Abdominal obesity (waist circumference >102 cm M, >88 cm F)
	Physical inactivity
	Ethnic characteristics
	Higher risk than whites:
	African-Americans, South Asians
	Lower risk than whites:
	Hispanics, Asians/Pacific Islanders
	Psychosocial factors (depression, phobias, chronic stressors)
Conditional	Elevated triglycerides (≥150 mg/dL)
	High-sensitivity C-reactive protein (≥2 mg/dL)
	Small LDL particles
	Other possible risk factors:
	• Homocysteine
	• Lipoprotein (a)
	• Lipoprotein-associated phospholipase A$_2$
	B-type natriuretic peptide

aberrant conduction, which are thought to underlie the increased risk of SCD.[9] The degree of functional impairment and left ventricular dysfunction are powerful predictors of the risk of death from an arrhythmic cause.[10–12]

Genetics

Evidence supporting a genetic predisposition for SCD comes from familial associations in population studies and rare genetic disease paradigms. Longitudinal population studies have demonstrated the importance of family history in determining risk for SCD. On the basis of work done in the Seattle[13] and Paris[14] population studies, the relative risk of SCD in an offspring of a parent with a history of SCD is more than 50% higher than the risk in an unaffected family. Of note, in the Paris population study, the relative risk of SCD in offspring with a history of SCD in both parents was 9 times that of the risk in an unaffected family.

Rare genetic disease paradigms also provide evidence for a familial predisposition to life-threatening arrhythmias. Many of these conditions result from mutations in genes that code for channel proteins, non-ion conduction proteins, structural proteins, and contractile proteins, as well as from mutations that alter the interaction of these proteins with regulatory proteins. Management options for these syndromes generally include an implantable cardioverter-defibrillator (ICD) for high-risk patients, and exercise restriction (Table 23.2). In many of these syndromes, β-blockers are also helpful (Table 23.2).

Long QT (LQT) syndrome is an inherited condition characterized by prolonged ventricular repolarization and episodic life-threatening arrhythmias. The autosomal dominant Romano Ward syndrome and the autosomal recessive Jervell and Lange–Nielsen syndromes were the first phenotypes identified.[15,16] It is now apparent that this syndrome is genetically heterogeneous, as more than 10 genes for cardiac ion channel subunits[17] and 1 gene for ankyrin B[18] (a structural protein) have been associated with this condition. Because many carriers of genes associated with long QT syndrome are asymptomatic, there is also variable penetrance.[19] Symptoms, when they do occur, are variable and can occur during sleep (i.e., LQT3), along with emotional stress (i.e., LQT2) and exercise (i.e., LQT1).[20]

The Brugada syndrome is an autosomal dominant disease characterized by right bundle branch block, ST segment elevation in leads V1 to V3, and ventricular tachyarrhythmias that may result in syncope or cardiac arrest.[21] Although an early study suggested that there was an

Table 23.2. Genetic syndromes associated with sudden cardiac death

Syndrome	Genetic mutations	Function Impaired	Management options

Long QT syndrome	Potassium channel:
	  KCNQ1 (LQT1)
	  HERG (LQT2)
	  minK (LQT5)
	  MiRP1 (LQT 6)
	Sodium channel:
	  SCN5A (LQT3)
		Ion channel conduction	• ICD
			• β-blockers
			• avoidance of medications that prolong QT interval
			• LQT1: avoidance of competitive sports, unsupervised swimming

	Ankrin B: ANKB (LQT4)	Anchoring of ion channels to cellular membrane	• LQT2: potassium supplementation; avoidance of alarm clocks, loud telephones • LQT3: mexiletene, pacemaker
Brugada syndrome	SCN5A (sodium channel)	Sodium channel conduction	• ICD
Catecholaminergic polymorphic ventricular tachycardia (CPVT)	RyR2 (ryanodine receptor) CASQ2 (calsequestrin)	Calcium signaling	• ICD • β-blockers • exercise restriction
Arrhythmogenic right ventricular dysplasia (ARVD)	RyR2 (ryanodine receptor) DSP (desmoplakin) JUP (junctional plakoglobin)	Calcium signaling	• ICD • β-blockers (sotalol) • exercise restriction
Hypertrophic cardiomyopathy (HCM)	Sarcomeric myofilament proteins	Muscle contraction, structural stability	• ICD • β-blockers • amiodarone • verapamil • septal ablation, myotomy, or myomectomy • exercise restriction

increased mortality rate (>30% over 3 years) among those not treated with an ICD,[22] more recent data suggest that asymptomatic patients have low mortality rates (0% over 3 years) and may not need an ICD.[23] Unfortunately, the pathogenesis of the Brugada syndrome is poorly understood. In fewer than 25% of cases, there is a mutation in SCN5A,[24] a gene that codes for a sodium channel protein associated with LQT3.

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited disease characterized by stress- or exercise-induced ventricular arrhythmias and an increased risk of sudden cardiac death.[25,26] CPVT may be inherited by an autosomal dominant or autosomal recessive pattern. Genetic mutations in the ryanodine receptor gene (RyR2),[27,28] which encodes a cardiac sarcoplasmic reticulum calcium channel, and the calsequestrin gene (CASQ2),[29,30] which binds calcium and serves as a reservoir within the sarcoplasmic reticulum, are associated with CPVT.

Arrhythmogenic right ventricular dysplasia (ARVD) is a familial disease characterized by fatty-fibrous infiltrate of the right (and less frequently left) ventricular myocardium. The inheritance of ARVD is usually autosomal dominant, with its highest incidence among individuals in the Veneto region of northern Italy (12%–25% of SCD in young patients is associated with ARVD in this area).[31–33] Mutations in desmoplakin (DSP),[34] junctional plakoglobin (JUP),[35] and ryanodine receptor (RyR2)[36] are associated with ARVD. Desmoplakin and plakoglobin are key constituents of desmosomes, with mechanical forces applied to these cell–cell junctions activating calcium channels and calcium release from the ryanodine receptor.[34]

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant genetic disorder characterized by idiopathic left ventricular hypertrophy and marked heterogeneity. The prevalence of HCM in young adults is about 2 per 1000.[37] About 60% of patients have mutations in sarcomeric protein genes, which function in cardiac muscle contraction and structural stability.[38] As most patients are asymptomatic, diagnosis often results from family screening. Sudden cardiac death in patients with HCM is usually due to

ventricular arrrhythmias[38], with an annual risk of 1% in adults, compared with 2%–4% in children and adolescents.[38]

Medications

Further evidence for genetic predisposition to SCD comes from the interaction of drugs with specific genes. Many medications may prolong the QT interval and potentiate torsade de pointes through blockade of the potassium channel in cardiac myocytes.[39] Although antiarrhythmics are the most common offenders, many non-cardiac medications may also produce this effect (Table 23.3). Genetic polymorphisms that increase the risk of drug-induced long QT syndrome have also been identified.[40–42] These include polymorphisms in P450 metabolism pathways, which may lengthen the time that an individual is exposed to a medication that may prolong the QT interval.[41] This idea was first recognized in the early 1970s, when it was noted that certain families (which had a deficiency in the P450 cytokine, CYP2D6) were at higher risk of toxicity from warfarin and anti-seizure medications.[41]

Tools for risk stratification

Patients with a history of CAD, myocardial infarction, heart failure, or certain genetic syndromes should undergo some form of stratification to assess their risk of SCD. This is particularly important for those individuals who are being considered for an ICD.

Ejection fraction (EF) has been the primary SCD risk stratification tool used for inclusion in clinical trials.[43,44] For example, the Marburg Cardiomyopathy Study (MACAS) found that left ventricular EF was the only significant predictor of arrhythmia in patients with idiopathic dilated cardiomyopathy.[45] Despite this, 81% of individuals in the Maastricht prospective registry of cardiac arrest had an EF >30% prior to the event.[46]

Other methods used in SCD risk stratification include Holter monitoring, ECG analysis, and novel tools (Table 23.4).[47] Early studies suggested that ambient ventricular arrhythmias on 24-hour Holter monitoring were predictive of SCD in heart failure patients.[48] More recent studies, however, suggest that ambient ventricular arrhythmias on Holter monitoring are predictive of SCD in patients with HCM[49] but not in patients with heart failure.[50] Holter monitoring also offers the ability to measure reduced heart rate variability, which is associated with an increase in the risk of SCD.[51–55] Baroflex sensitivity, which measures the response to phenylephrine, may also be useful, as decreased sensitivity is associated with an increased risk of SCD.[54]

Table 23.3. Medications that may lead to torsade de pointes through QT prolongation.[39]

Cardiac medications	Non-cardiac medications
Amiodarone	**Anti-infective**
Bepridil	Clarithromycin
Disopyramide	Erythromycin
Dofetilide	Foscarnet
Flecainide	Gatifloxacin
Ibutilide	Halofantrine
Indapamide	Moxifloxacin
Isradipine	Pentamidine
Moexipril/HCTZ	Sparfloxacin
Nicardipine	**Anti-psychotic**
Procainamide	Chlorpromazine
Quinidine	Haloperidol
Sotalol	Mesoridazine
	Pimozide
	Quetiapine
	Risperidone
	Thioridazine
	Ziprasidone
	Anti-nausea
	Dolasetron
	Domperidone
	Droperidol
	Anti-convulsant
	Felbamate
	Fosphenytoin
	Pain control
	Levomethadyl
	Methadone
	GI stimulant
	Cisapride
	Asthma/COPD
	Salmeterol
	Anti-depressant
	Venlafaxine
	Acromegaly/Carcinoid diarrhea
	Octreotide
	Muscle relaxant
	Tizanidine

Finally, implantable loop recorders, which allow extended and continuous ECG monitoring in the evaluation of unexplained syncope[56] and detection of arrhythmias after myocardial infarction,[57] remain to be fully evaluated in identifying individuals at risk for SCD.

Standard ECG analysis, which includes analysis of the ST segment, QT interval, and QRS width and morphology, can be useful in providing clues to structural heart disease and genetic electrophysiologic syndromes. Using the standard

Table 23.4. Tools for risk stratification

	Risk measured	Predictive power
Traditional tools		
CAD risk factors	Underlying disease risk	Low positive predictive value to determine SCD risk in a particular individual
NYHA functional class/ Echocardiography Ejection fraction LVH	Structural disease	High predictive power for sudden cardiac death and overall cardiac death
Holter monitoring Ambient ventricular arrhythmias	SCD triggers	High predictive power in patients with hypertrophic cardiomyopathy; low predictive power in other patients unless combined with other factors
Heart rate variability/baroreflex sensitivity	Conditioning factors	Predictive power unknown
Implantable loop recorders ECG variables	SCD triggers	Predictive power unknown
Standard ECG QRS width QT dispersion	Electrical abnormalities	Low predictive power
Abnormalities suggestive of structural disease (e.g., LVH) or genetic syndromes (e.g., long QT)	Electrical abnormalities	High predictive power in identifying certain diseases
Novel tools High-resolution ECG		
T-wave alternans	Electrical abnormalities	High predictive power in high-risk patients, predictive power unknown for other patients
Late potentials	Electrical abnormalities	Predictive power highest in patients with ischemic cardiomyopathy. Low positive predictive value, high negative predictive value
EP testing: Inducibility of ventricular tachyarrhythmia	Arrhythmogenic substrate	Good positive predictive value in patients with ischemic cardiomyopathy; high rate of false negatives in high-risk patients
Imaging: MRI, MRS, MDCT	Scar tissue, coronary plaque	Predictive power unknown
Genotyping	Genetic predisposition	High predictive power for certain genetic syndromes; predictive power unknown for other patients

Abbreviations: CAD, Coronary artery disease; NYHA, New York Heart Association; LVH, left ventricular hypertrophy; ECG, electrocardiogram; EP, electrophysiologic; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; MDCT, multi-detector computed tomography.

ECG, QT-interval dispersion has been proposed as a useful risk-stratifying tool. Although it measures the difference between minimal and maximal QT intervals in various ECG leads, it lacks accuracy and reliability.[58–60]

Usually, more information can be obtained with high-resolution signal-averaged electrocardiography (SAECG), by evaluating for T-wave alternans and late potentials. T-wave alternans, the beat-to-beat alteration in T-wave

Table 23.5. ABCs of cardiovascular disease risk management

A	Antiplatelet agents	
	Aspirin	• 75–325 mg daily in high-risk patients[81]
		• Controversial for low-risk patients: reduction in CVD risk seen in men,[82] but not in women[83]
	Clopidogrel	• High-risk patients resistant or intolerant to aspirin[84]
		• In addition to aspirin for at least 9–12 months following an acute coronary syndrome, particularly after percutaneous coronary intervention[85–87]
	Anticoagulant therapy: Warfarin	• Post-MI patients intolerant to aspirin[88]
		• Patients with left ventricular thrombus and/or atrial fibrillation
	Angiotensin-converting enzyme inhibitors (ACEIs)	• Patients with recent MI, heart failure, and/or left ventricular systolic dysfunction[89–91]
		• Patients with diabetes mellitus and/or CVD if systolic blood pressure is >120 mmHg[92–94]
	Angiotensin receptor blockers (ARBs)	• Patients with heart failure, diabetic nephropathy, or hypertension[95]
		• In patients with heart failure, primary therapy only in patients intolerant to ACEIs[96]
	Antianginals	• For patients with anginal symptoms: antianginals enable these patients to exercise
B	Blood pressure control	• Initiate blood pressure treatment in low-risk patients if blood pressure ≥140/90 mmHg.[97]
		• Initiate blood pressure treatment in patients with diabetes or chronic kidney disease if blood pressure ≥130/80 mmHg.[97]
		• First-line therapy: ACEIs, beta-blockers, thiazide diuretics
		• Second-line therapy: aldosterone antagonists, ARBs, calcium channel blockers
	β-Blockers	• Post-MI patients[98]
		• Heart failure patients[99]
		• Blood pressure control for CVD patients[97]
C	Cholesterol management	• Statins, ezetimibe, fibrates, nicotinic acid
		• LDL-C goal <100 mg/dL for high-risk patients, <130 mg/dL for intermediate-risk patients, <160 mg/dL for low-risk patients.[100]
		• Lowering LDL even further may reduce risk of CVD.[101–103]
		• Non-HDL-C goal is 30 mg/dL higher than LDL-C goal. Non-HDL-C goal <130 mg/dL for high-risk patients, <160 mg/dL for intermediate-risk patients, <190 mg/dL for low-risk patients. After LDL-C goal met, consider intensifying therapy with LDL-C lowering drug or adding nicotinic acid or fibrate to reach LDL-C goal.[100]
	Cigarette smoking cessation	• Counseling
		• Treatment with buproprion with or without nicotine patch more successful than placebo or nicotine patch alone.[104]
D	Diet and weight management	• ≥500 kcal/d caloric reduction
		• Patients with cardiovascular disease should be encouraged to follow a diet containing whole grains, vegetables, fruits, omega-3 fatty acids and nuts and low in refined grains, cholesterol and saturated fat.[105]
	Diabetes mellitus	• Patients with impaired fasting glucose (110–124 mg/dL) or impaired glucose tolerance (140–199 mg/dL) should be treated aggressively with lifestyle counseling and/or metformin to prevent diabetes.[106,107]
		• Goal hemoglobin A_{1c} <7%, lowest risk when hemoglobin A_{1c} <6%[108]

Table 23.5. (continued)

E	Exercise	• Aerobic, weight training
		• Exercise beneficial for primary[109] and secondary[110] prevention of CVD.
		• Cardiac rehabilitation programs should be considered for patients with left ventricular systolic dysfunction, recent coronary artery bypass surgery, recent MI, and/or chronic stable angina pectoris.[111]
	Ejection fraction	• ACEI and β-blocker for all patients with heart failure.[99]
		• Aldosterone inhibitors (spironolactone,[112] eplerenone[113]) indicated in post-MI patients with severe heart failure.
		• Digitalis can be used to treat symptoms of heart failure.[99]
		• Implantable cardioverter-defibrillator for high-risk patients[114,115]

amplitude, has been found to increase the risk of life-threatening arrhythmia in high-risk patients.[61–63] Late potentials or low-amplitude high-frequency potentials at the end of the QRS complex indicate delayed ventricular activation and have high negative predictive values. The value of late potentials appears to be highest in patients with ischemic cardiomyopathy.[64,65]

Electrophysiologic testing is used for risk stratification because it can assess the inducibility of ventricular tachyarrhythmias. While electrophysiologic testing is most useful in patients with an ischemic cardiomyopathy,[66,67] it is largely limited by a high false negative rate, particularly in high-risk patients.[68,69] In the Multicenter Unsustained Tachycardia Trial (MUSTT), the rate of cardiac arrest was highest in patients with an EF <30% and an inducible tachyarrhythmia. Patients with an EF <30% in whom tachyarrhythmia was not inducible had rates of cardiac arrest similar to those of patients with ejection fraction ≥30% and in whom tachyarrhythmia could be induced.[70]

Significant effort is being focused on novel methods to risk-stratify patients at risk for SCD. Methods include imaging techniques, such as magnetic resonance imaging and spectroscopy (MRI/MRS) and multi-detector computed tomography (MDCT). Genetic and proteomic biomarkers are also being evaluated, helped by the ability now to do large-scale unbiased screens of proteomic expression and genomic information. For example, the Oregon Sudden Unexpected Death Study[71] is collecting risk factor and genetic information for all sudden deaths in the Portland area over a 3-year period. In addition, the Johns Hopkins Donald W. Reynolds Project is utilizing novel technologies, such as whole genome association to identify the genetic determinants of SCD in groups such as the Oregon SUDS and patients with ICDs.

Strategies in the prevention of SCD

Only 1% to 5% of patients with out-of-hospital cardiac arrest survive.[72] Although widespread availability of automatic external defibrillators may increase survival rates,[73] the low survival rate from cardiac arrest requires a preventive focus.

Prevention of coronary artery disease

As patients with CAD are at high risk for SCD, it is imperative that efforts be undertaken to protect against the development of CAD through primary and secondary prevention. Recommended therapies for prevention of CAD are underutilized, with irregular practice patterns.[74–78] Furthermore, the trend towards earlier discharge after myocardial infarction has restricted the opportunity for counseling about modifications of lifestyle such as smoking cessation, diet, and exercise.[79]

A straightforward "ABC" approach to cardiovascular risk reduction may help to narrow the treatment gap in prevention of cardiovascular disease (Table 23.5).[80] This approach provides a checklist to encourage provider adherence to recommended practices. A simplified version of the approach facilitates patient–physician communication about the risk-reducing strategy. For patients at high risk of CHD events (>20% 10-year risk), aggressive risk-reduction therapies should be instituted. For patients at intermediate (10%–20% 10-year risk) or low risk (<10% 10-year risk) of CHD events, less aggressive risk-reduction therapies should be instituted. In addition to managing overall cardiovascular disease risk, lifestyle modifications, medications, and implantable devices can further reduce the risk of sudden cardiac death.

Lifestyle

Smoking is a major CAD risk factor and thus also increases risk for SCD. Smoking cessation should be encouraged in all patients, but particularly in those with CAD. It is also apparent that other lifestyle factors such as circadian variation, anxiety, exercise, and diet influence the risk of SCD. Indeed, SCD risk is increased in the morning[71] and in individuals with phobic anxiety.[116,117] In patients with certain genetic syndromes that increase SCD risk, exercise is generally discouraged as it may further increase risk of SCD (Table 23.2). In nearly all other patients, regular exercise should be encouraged, with participation in cardiac rehabilitation for those at highest risk.[111]

Regular exercise decreases the overall risk of SCD and CHD, but the relative risk of SCD during and shortly after vigorous exertion is greatly increased relative to other times.[118,119] Habitual exercise likely decreases SCD risk by increasing electrical stability through increased basal vagal tone and decreasing risk of plaque rupture through its beneficial effects on lipids and its tendency to decrease the hemodynamic stress experienced at a given workload.[119] The "exercise paradox" likely reflects the increased sympathetic tone of vigorous exertion that increases the risk of ventricular fibrillation and plaque rupture.[119]

Various dietary measures influence the risk of SCD (Table 23.5).[105] Fish consumption and increased levels of the omega-3 polyunsaturated fatty acids (PUFA) found in fish are associated with a reduced risk of SCD, likely because of membrane-stabilizing effects.[120–123] Because alpha-linolenic acid (ALA), an omega-3 fatty acid found in fatty fish and the precursor of eicosapentanoic acid (EPA) and docosahexaenoic acid (DHA), is associated with a reduced risk of SCD[124–126], the American Heart Association recommends regular consumption of fatty fish and other sources of ALA.[127,128] Fish oil capsules can be taken in lieu of fish consumption and may be a useful adjunct because of harm associated with increased mercury levels in fish.[129]

Potassium and magnesium intake and levels should be monitored in patients who are high risk, on diuretics, or are malnourished, because their deficiencies can increase the risk of SCD.[130] In addition, heavy drinking should be discouraged, as heavy alcohol consumption (>5 drinks per day) and, in particular, binge drinking is associated with an increased risk of CHD and SCD.[131,132] This likely results from alcohol's predilection to cause thrombosis and myocardial scarring and through a reduction in the threshold for ventricular arrhythmias.[133]

Medications

Angiotensin converting enzyme inhibitors (ACEIs), β-blockers, and lipid-lowering agents are staples of secondary prevention of CAD and thus SCD. In contrast, nearly all studies have shown a lack of benefit or an increase in mortality with the use of antiarrhythmic medications. The Cardiac Arrhythmia Suppression Trial (CAST) and the survival with d-sotalol (SWORD) trial are clear examples of antiarrhythmic failures. CAST evaluated the efficacy of three class I antiarrhythmic drugs (encainide, flecainide, and moricizine). CAST I was stopped early when encainide and flecainide were found to increase risk of sudden cardiac death relative to placebo.[134] CAST II evaluated moricizine versus placebo and was also stopped early because of a trend toward mortality in the moricizine group.[135] The SWORD trial evaluated the efficacy of the class II agent d-sotalol versus placebo in patients with ischemic cardiomyopathy.[136] The trial was stopped early because of increased mortality in the d-sotalol group. The paradoxical proarrhythmic tendencies of antiarrhythmic medications likely underlie their increased risk of SCD. Of all of the antiarrhythmic medications, only β-blockers and possibly amiodarone (in conjunction with a β-blocker) have shown any promise in reducing risk of SCD.[137,138] β-Blockers are also indicated for many genetic syndromes that predispose to SCD (Table 23.2). Because of the limitations of antiarrhythmics, much of the focus of SCD prevention has shifted to non-pharmacologic therapies.

Device-based therapy

Initial non-pharmacologic therapy involved surgical excision of scar tissue or intraoperative mapping of regions where ventricular tachycardia could be induced.[139,140] Since the development of ICDs, however, interest in these procedures has diminished considerably. ICDs reliably convert ventricular arrhythmias to sinus rhythm and substantially reduce mortality in patients at high risk for SCD. The initial trials, Antiarrhythmics vs. Implantable Defibrillators (AVID),[141] Canadian Implantable Defibrillator Study (CIDS),[142] and Cardiac Arrest Study Hamburg (CASH),[143] demonstrated the efficacy of ICDs in survivors of life-threatening arrhythmias. More recent trials have demonstrated efficacy in a broader group of patients.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT) II included post-MI patients with EF<30% and demonstrated that ICDs reduce mortality by more than 30% when compared to "conventional medical therapy" (lipid-lowering medications, diuretics,

beta-blockers, ACEIs).[43] Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) demonstrated a mortality benefit with ICDs of 23% in patients with New York Heart Association (NYHA) class II or III CHF and an ejection fraction less than 35%.[44] Of note, the Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) found no mortality benefit with ICD implantation 6 to 40 days after MI in patients with EF less than 35%,[144] despite the high risk for sudden death in these patients.[5] Moreover, high-risk patients with genetic predisposition to sudden cardiac death may not be adequately managed with medication and may benefit from an ICD (Table 23.2). The broad categories of patients who may benefit from an ICD and the expense of the devices make risk stratification important. Furthermore, defibrillation is stressful, and many shocks may be inappropriate. Cardiac resynchronization may be less stressful for the patient, and recent trials have demonstrated the benefit of cardiac resynchronization in patients with heart failure and cardiac dyssynchrony.[114,115]

Future investigation

Because of the potential for cell-based therapy to allow for generation of new, functional myocardium, there is hope that this treatment may be useful in those at risk for SCD in years to come. At present, concurrent implantation of ICDs is mandatory as these cells may potentiate arrhythmogenicity by virtue of their limited ability to transmit current.

Conclusions

Sudden cardiac death is a frequent cause of death. CAD, heart failure, and genetic syndromes are the major risk factors for SCD. Assessing risk in these patients is crucial, given the cost implications of both pharmacologic therapies and ICDs. Treatment options include management of cardiovascular disease and heart failure, lifestyle modifications, and, in high-risk patients, implantable devices.

Sequence of therapies during resuscitation: application of CPR

Leonard A. Cobb, M.D.

Harborview Medical Center University of Washington, Seattle, Washington, USA

Introduction

Intuitively, the order in which therapies are applied seems likely to be important for the treatment of many conditions. In the emerging field of cardiac resuscitation such ordering was initially established on the basis of empiricism and on interpretation of animal experiments. In this chapter, a reexamination of two long accepted therapies addresses the possibility that changes might be considered for the sequence of actions in carrying out basic CPR and in the delivery of precordial shocks for ventricular fibrillation.

The worldwide acceptance of the ABC sequence (airway, breathing, circulation) for CPR is impressive. Similarly the emphasis on rapid defibrillation would seem to be logical and has borne the test of time. On the other hand, there is scant evidence for the strict adherence to treatment guidelines in terms of what comes first.

An important reason for reexamining the sequence of steps is that the ground rules have changed over the course of some 40 plus years. CPR was initially developed for use by physicians, nurses, and specially qualified emergency rescue workers.[1] However, resuscitation is now commonly initiated outside the hospital, often by persons with minimal—or even no—formal training in the application of CPR. Notably, the widespread use of automated defibrillators (AEDs) has provided opportunities for new approaches. And clearly, the call for evidence-based medicine is increasingly heard.

The ABC sequence for basic CPR

Prior to 1960, attempts to alter the outcome of cardiac arrest entailed thoracotomy, direct cardiac compression, and internal defibrillation. Whereas open-chest resuscitation could be effective in controlled environments,[2] survivors of such an approach were uncommon. The inventions of effective external techniques to provide circulation, defibrillation, and rescue breathing markedly extended the possibilities for reversing cardiac arrest.[3] The initial steps in cardiac resuscitation were designated ABC shortly after their introduction. That acronym is noteworthy for its simplicity and ease of recall. But why ABC, and not CAB or ACB? The reasoning behind that choice is not clear but might well have been influenced by the possibility of encountering primary ventilatory failure or submersion injury.

Reasons to modify the ABC sequence

For the well-trained healthcare provider, there is probably little reason to modify the ABC sequence for initiating CPR. Thirty years of precedence suggest that immediate change is not mandatory and would likely not be met with enthusiasm. Nonetheless, in considering instruction for the general public, there is at least a practical basis for reexamining alternatives to ABC.

An important reason to replace the current ABC sequence in favor of CAB (or ACB) is to emphasize what is most often the principal goal of CPR: to restore tissue oxygenation as rapidly as possible. The vast majority of adults found in cardiac arrest do not have primary respiratory failure as the mechanism leading to collapse. Thus for most patients with cardiac arrest, efforts to afford oxygenation without circulation can be considered a waste of valuable moments. Furthermore, the difficulties in training persons to perform mouth-to-mouth ventilation correctly are considerable[4]

and contrast with the relative simplicity of teaching and performing sternal chest compression.[5] Finally, at times there may be reluctance to initiate CPR because of perceived hygienic concerns about mouth-to-mouth ventilation.[6,7]

On the other hand, a case for the status quo, i.e., retaining ABC, can be made, particularly in treating infants and some children who are pulseless and unconscious because of primary respiratory failure. Similarly, adults with poisoning or primary ventilatory impairment may be more effectively managed with the ABC sequence.

An exception to the ABC sequence for the lay public was established in the Netherlands in the mid 1980s. CAB was chosen over ABC because of the possible advantage of circulating blood already oxygenated prior to sudden cardiac arrest.[8] It is noteworthy that the CAB sequence for lay public instruction in the Netherlands was recently abandoned in favor of ABC. As far as can be determined, that change was effected largely in an effort to achieve international conformity rather than demonstration of efficacy.[9]

Chest compressions alone

It has been suggested that the provision of chest compressions alone (without ventilation) during the initial minutes of resuscitation may be more efficacious than the ABC sequence, because interruptions of chest compression typically lead to reduced coronary perfusion pressure.[10] The value of chest compression alone has been demonstrated in animal models of cardiac arrest,[11,12] but its role in humans awaits clarification. The production of pulmonary gas exchange with chest compressions has also been demonstrated in experimental animals.[12]

It is relevant to note that EMS dispatchers, when giving transtelephonic instructions, were able to provide instruction more quickly and efficiently when offering instructions for chest compression only, compared to ABC instructions. Importantly, survival of patients in the former group tended to be greater than for those with ABC instruction (14.6% vs. 10.4%).[13]

Staged training for basic life support

Assar and colleagues in the UK have proposed an innovative, phased instructional approach for the training of the general public. Using the bronze, silver, and gold medal designations for the Olympic Games, three instructional programs have been proposed.[14] The bronze level offers instruction in chest compression and opening of the airway (without active ventilation). Silver adds on ventilation at a ratio of 50:5. The gold designation is for the full-course ABC sequence. This remarkably sensible approach was designed

to encourage training of the public in the essentials of chest compression, at the same time making available instruction in the full ABCs whenever practical and desired. Such instructional innovation holds promise for enhancing the participation of the general public, thereby facilitating the primary goal of early intervention for sudden cardiac arrest.[15]

A solution

Whereas the CAB sequence seems to afford theoretical advantage over ABC, there is a likely downside, mainly a reluctance to change without evidence for efficacy. Furthermore, it appears unlikely that robust clinical evidence will soon be forthcoming. On the other hand, the goal of encouraging bystander intervention could be furthered quite simply by implementing the bronze, silver, gold format for training of the public. Ideally most of the public should be equipped and ready to carry out the ABC sequence; unfortunately that expectation has not been realized over the past 25 years.[16] If one considers the ease of teaching and the simplicity of application, widespread knowledge about the use of chest compression, with or without ventilation, appears to offer an opportunity for more of the general public to be prepared and willing to initiate resuscitative measures while awaiting arrival of EMS personnel. That approach to training of the public offers the potential advantage of making chest compressions nearly uniformly available because of the relative ease of training. Although the early implementation of training for the bronze stage was conducted over a course of 2 hours,[15] it is likely that the duration could be substantially reduced. Community-wide studies of staged training programs are highly desirable.

CPR before defibrillation?

For many years CPR guidelines have advocated the need for quick delivery of shocks for all patients discovered to be in cardiac arrest with ventricular fibrillation (or pulseless ventricular tachycardia).[17,18] A widely accepted judgment by many EMS experts was to "zap first."

Two observations, however, led some to question the wisdom of always shocking first:
1. Experiments in animals with induced VF showed that after several minutes of ventricular fibrillation, survival was significantly improved when shocks were delivered after a brief period of CPR (plus administration of epinephrine), compared to attempts at immediate defibrillation.[19,20]

2. In patients with out-of-hospital VF, survival was not improved when first responder AEDs were incorporated into mature tiered EMS systems. Contrary to expectations, exchanging immediate shock for CPR by first responders has not served to improve survival.[21,22]

An additional consideration in questioning the wisdom of always directing primary attention to defibrillation was the simple observation that, for many patients found in cardiac arrest, VF is not the first identified rhythm; **most** patients found in cardiac arrest by EMS responders do not have VF when first examined.[23] In cases with pulseless electric activity or asystole the emphasis on application of an AED would appear to be counterproductive by delaying the institution of potentially useful therapy, i.e., CPR.

Notably, a policy of shocking all VF patients as soon as possible was actually a departure from the then accepted procedure of providing CPR prior to shock in order to coarsen VF and facilitate its conversion (unless a defibrillator was immediately available on the scene).

If countershock and spontaneous pulse do not occur within 60 seconds of collapse, CPR must be started . . . In unwitnessed arrest CPR Steps A-B-C are needed for about 2 minutes (to reoxygenate the myocardium) before an attempt to defibrillate has a chance to succeed. From Safar, P. and Bircher, N.G.[24]

In retrospect one might question the basis for modifying practice guidelines so as to shock first whenever VF was present. The development and widespread availability of AEDs was undoubtedly the principal stimulus for change. It is also likely that other considerations included the recognition that untreated VF is virtually always fatal, and it seemed to follow that the sooner it was removed, the greater the likelihood of survival. And indeed a number of studies had shown that survival was improved with more rapid response of defibrillator-equipped EMS vehicles.[25,26] Additionally, years of experience in hospital coronary care units convincingly demonstrated that recent onset VF in monitored patients was readily managed with the prompt delivery of shocks without need for CPR.[27] Whatever the explanation, most EMS systems adopted, as a number one priority, the deployment of AEDs as quickly as possible for virtually all patients found in cardiac arrest.

Clinical studies

The dictum to rely on the initial use of defibrillator shocks rather than CPR was challenged by the Seattle Medic One EMS providers.[21] In 1994 that group, prompted by the disappointing results after implementing the quick application of AEDs, modified their treatment protocol to provide

1.5 minutes of CPR by first responders prior to use of an AED. The Seattle experience was population-based and utilized a control period immediately before the change in treatment protocol.[21] A randomized trial comparing 3.0 minutes of CPR to immediate defibrillation was conducted in Oslo, Norway,[28] and another randomized trial of 1.5 minutes of CPR was recently performed in Perth, Australia.[29] The Seattle study, the largest to date, but limited by the use of historical controls, showed an overall survival benefit with a CPR-first strategy, restricted entirely to patients with initial response intervals 4 minutes or greater (Fig. 24.1). A qualitatively similar finding was observed in Oslo but without statistically significant benefit overall – only in those with longer initial response intervals (Fig. 24.2). In the Perth study there was no difference in survival rates between the two groups, but response intervals were prolonged to 9 minutes on average, and survival rates were considerably lower than in the other studies. The findings from these three reports are summarized in Table 24.1 below.

Limitations of the clinical studies

The Seattle experience,[21] although population-based, was less robust than a randomized clinical trial, and there is a possibility that the observed benefit could have been due to spontaneous variation in survival rates or that there were other unapparent reasons for increased survival rate. Nonetheless, the *a priori* hypothesis that improvement
Fig. 24.2. Oslo study. Estimated probability of survival to hospital discharge plotted against response time. Average fraction of surviving patients for each 2-minute interval. Lines indicate logistic regression models with time as independent variable fitted separately for each of the two groups. (Reproduced with permission from author and publisher.[28])

would occur mainly in cases with longer response intervals proved to be the case.

The Oslo study[28] was likely underpowered in the number of patients, and the overall benefit of initial CPR did not achieve the generally accepted degree of significance. As in the Seattle study, however, survival benefit was demonstrated in those with longer initial response intervals.

The randomized trial in Perth[29] failed to show any benefit with the introduction of 1.5 minutes of CPR prior to shock. In that study, initial response intervals were lengthy, pharmacologic measures were not used, and tracheal intubation was infrequently employed. The low survival rates in that study raise the possibility that interventions done within those limitations might not be able to improve outcomes.

Thus, each of the three studies cited in Table 24.1 has limitations, and the advisability of extensive and immediate change is not certain. In two of the three reports, however, the findings are consistent with experimental studies in animals.

Three phases of resuscitation

Weisfeldt and Becker have developed an interesting conceptual framework relating to the treatment of VF; they proposed three phases with markedly differing therapeutic implications.[30]

1. *An electrical phase* persisting for a few minutes after onset of VF. The implication here is one of directing immediate attention to the management of the arrhythmia, i.e., prompt delivery of one or more shocks, without incurring delays for CPR or pharmacologic intervention. A relevant clinical scenario describes a patient who is observed to develop unexpected cardiac arrest and can be shocked for VF within 2 or 3 minutes. Prompt defibrillation in this situation has a high likelihood for successful resuscitation. The duration of the electrical phase may be only about 4 minutes.

2. *A proposed circulatory phase* immediately follows the electrical phase. During the circulatory phase the myocardium has become depleted of energy-rich substrates; tissue acidosis has developed; and cellular dysfunction is operative. In this phase, defibrillation attempts without attention to the state of the myocardium are much less effective than in the earlier period, and a shock is likely to result in asystole or to establishment of an organized cardiac rhythm without myocardial contraction. It is during the circulatory phase that oxygen delivery as well as removal of metabolic byproducts by CPR-generated blood flow prior to shock is likely to be of utility. Of note, most victims of out-of-hospital cardiac arrest, when first encountered by EMS, can be considered to be in the circulatory phase. The circulatory phase is estimated to persist for about 10 minutes if VF is not treated.

3. *A metabolic phase* is said to have developed after about 10 minutes of untreated cardiac arrest. In this stage, standard therapies become progressively ineffective, and survival rates are poor. The biochemical alterations leading to this state are not clearly defined, but are postulated to represent factors beyond those immediately due to ischemia or tissue reperfusion. Postresuscitation cooling has been shown to afford benefit;[31,32] other approaches are undergoing study.[33]

Estimating the duration of untreated VF

If the principles described above are accepted, including the position that in some patients it is advisable to provide CPR prior to delivery of shocks, how does one determine the appropriate intervention for the initial management of VF? A tentative estimate of "down time," based on the available clinical history, can sometimes be made on arrival at the scene of cardiac arrest, although the accuracy of that information is often unreliable. Additionally, if bystander

Table 24.1. Summary of three clinical studies: patients with VF on arrival of EMS

Design	Seattle[21] Population-based, historical controls	Oslo[28] Randomized clinical trial	Perth[29] Randomized clinical trial
No. patients			
CPR First	478	104	119
Shock ASAP	639	96	137
Overall survival to hosp.			
Discharge			
CPR First	30% } $p = 0.04$	22% } $p = 0.20$	4.2% } $p = 0.81$
Shock ASAP	24%	15%	5.1%

Survival with shorter response intervals			
Response interval	< 4 min	≤ 5 min	≤ 5 min
CPR First	32% (82/258)	23% (9/40)	12% (3/24)
Shock ASAP	31% (99/318)	29% (12/41)	0% (0/18)

[a] Measured from dispatch time.

[b] Measured from time call received.

[c] 6.5 min for all subjects (L. Wik, pers.commun., 9 October, 2005).

ASAP = as soon as possible.

CPR has been initiated, the qualitative aspects of that are usually not known. Thus, unfortunately, the arriving team has to rely to a certain extent on guesswork to untangle the situation.

Another approach is to examine the VF waveform, which declines in amplitude and frequency over the course of several minutes. To this end, several analytic approaches have been suggested as being helpful. These include measurements of signal amplitude[34,35] waveform frequency/spectral analyses,[35,36] application of chaos theory,[37] and combinations thereof. Such probes have an appeal in that they can be automated and the information transmitted to the EMS personnel, but the clinical utility of these measurements has yet to be established. The influence of time and of CPR on the VF waveform is shown in Fig. 24.3.

Summary

The ABC sequence for basic life support has withstood a test of time for health care professionals. On the other hand, a change in emphasis for the general public deserves consideration. The training requirements for mouth-to-mouth ventilation and the difficulty in its correct performance stand in sharp contrast to the relative ease in teaching and performing chest compressions. Furthermore, the provision of chest compressions appears to be the most vital element in the initial management of cardiac arrest Accordingly the use of staged training for the general public[14] (e.g., bronze, silver, gold) warrants further testing and application.

CPR prior to defibrillation is an attractive, but not fully evaluated, option in patients attended several minutes
Fig. 24.3. From Berg, R.A. *et al.* Typical changes in VF waveform during untreated VF (after 1 and 10 min) and after 3 min. of CPR-first. MF, median frequency (in Hz); AMP, amplitude (in mV). (Reproduced with permission from author and publisher.[35])

after collapse. There are unanswered questions about when "several minutes" starts and how long CPR should continue before rhythm analysis and shock. The widespread acceptance of CPR prior to shock will require modifications in regard to the complete acceptance of the Chain of Survival as now promulgated, yet evidence to date does not support the practice of immediately shocking patients who are no longer in the electrical phase of ventricular fibrillation.[22,23,30,38]

Introduction and history of defibrillation

The passage of electrical current through the myocardium to terminate ventricular fibrillation (VF) or ventricular tachycardia is the definitive treatment and single most important factor in surviving cardiac arrest due to VF. This chapter will review the history and theory of defibrillation, current techniques, and future developments of this critically important therapy.

In 1775, the Danish veterinarian–physician Abildgaard demonstrated that chickens could be stunned and revived by electrical shocks administered to the head and to the heart.[1] Prevost and Batelli in 1899 showed that ventricular fibrillation in dogs could be terminated by electric shocks.[2] In the twentieth century, the Consolidated Edison Company of New York became concerned about the high rate of accidental electrocutions among maintenance workers, and funded research on the cardiac consequences of electrical shocks. Supported by this source, Hooker *et al.* published important studies on defibrillation in animals.[3] The first human defibrillation was performed in 1947 by Beck who administered shocks directly to the exposed epicardium in an operating room.[4] The first closed-chest human defibrillation was achieved by Zoll *et al.* in 1956.[5] Although alternating current was used originally, direct current quickly supplanted alternating current;[6] postshock atrial arrhythmias were found to be reduced by use of direct current.

An important consequence of the early canine studies of defibrillation was the observation that arterial pressure rose when electrodes were pressed against the animal chest. This recognition of the role of chest compression in blood circulation and arterial pressure maintenance ultimately resulted in the development of closed-chest massage by Kouwenhoven *et al.*[7] It is appropriate that the development of contemporary defibrillation techniques should have also resulted in the development of cardiopulmonary resuscitation (CPR), since these two techniques remain cornerstones of cardiac arrest therapy.

Basic science

Theory of defibrillation

Although defibrillation has been an effective cardiac tool for the termination of cardiac arrhythmias for over 45 years, the exact mechanism of defibrillation remains uncertain and controversial. For many years it was believed that a critical mass of myocardium was depolarized by the electrical current traversing the heart; those muscle cells that were not depolarized were thought to be inadequate to sustain the arrhythmia.[8] This hypothesis is supported by the difficulty of initiating and sustaining ventricular fibrillation in the hearts of small animals (e.g., rabbits). More recently, Ideker's group[9] has introduced the "upper limit of vulnerability" hypothesis. This hypothesis suggests that the most important factor in defibrillation is achieving a critical current density throughout the ventricular myocardium; if current density is inadequate, fibrillation may be transiently terminated but then reinitiated. Jones[10] has argued that to achieve defibrillation, shocks must extensively prolong refractoriness so that fibrillation wave fronts are not propagated and VF terminates. Neither Ideker's nor Jones' hypotheses necessarily repudiate the critical mass theory, since a critical mass effect may be important for their mechanisms also.

The metabolic and biochemical environment in which defibrillation occurs is important. Myocardial levels of the so-called "high-energy phosphates" – adenosine triphosphate (ATP), adenosine diphosphate, adenosine monophosphate, and creatine phosphate–appear crucial.[11] These high-energy phosphates are essential for normal regulation of cell volume and maintenance of the normal ionic gradients via the Na^+/K^+ and $Ca^{2+}/ATPase$ pumps. When ventricular fibrillation occurs, myocardial perfusion ceases, myocytes become oxygen-deficient and are unable to continue normal aerobic metabolism, and contractile function stops.[12] Mitochondrial oxidative phosphorylation is inhibited, with uncoupling of high-energy phosphate production and utilization. The levels of the high-energy phosphates decline progressively as tissue lactate and hydrogen ion levels increase. Conversely, after the restoration of circulation, the regeneration of these compounds indicates a return to normal cellular activity and viability.

The depletion of myocardial high-energy phosphates correlates with the onset of myocardial cell injury. Ischemic myocardial contraction develops and ultrastructural studies show progressive evidence of injury such as disruption of the sarcolemma. ATP levels below 10% of normal strongly suggest irreversible myocardial injury.[13,14] Smaller degrees of depletion, such as may occur in the postischemic phase, are associated with myocardial dysfunction or stunning.

During ventricular fibrillation, the decline of ATP levels with time correlates closely with the success of attempted defibrillation. The levels may also predict poor contractile function and hemodynamic status following defibrillation of VF to a potentially perfusing electrocardiographic rhythm.[15,16]

The timing of defibrillation before or, if necessary, after a period of CPR has been debated. Although current guidelines advocate defibrillation as soon as possible, it has been suggested that a period of CPR before defibrillation may achieve better survival. This was first proposed by Cobb in 1999 who reported that the routine provision of approximately 90 seconds of CPR before use of AED was associated with increased survival when response intervals were 4 minutes or longer.[17] More recently, Wik has studied this in greater detail, reporting that CPR before defibrillation did not improve outcome for patients with ambulance response times shorter than 5 minutes, but for patients with ambulance response times longer than 5 minutes, better outcomes were achieved with 3 minutes of CPR before defibrillation.[18,19] It is known that cellular functioning and in particular active transmembrane ion channel functioning deteriorates rapidly during cardiac arrest. With

depletion of high energy ATP reserves, successful defibrillation requires rapidly increasing energy levels. The results of these studies suggest that a period of external chest compression may improve cellular functioning to enable defibrillation to achieve a perfusing rhythm. External chest compression may also reverse distention of both ventricles, particularly the right, which occurs within the first few minutes of VF and subsequently impairs biventricular function after defibrillation.[20]

The ability to defibrillate and subsequent survival correlate with the "coarseness" (amplitude) and the frequency of the ventricular fibrillation waveform. Low-amplitude ventricular fibrillation waveforms are less likely to be associated with restoration of spontaneous circulation and discharge from hospital, and are more likely to convert to asystole following defibrillation.[21] Low-frequency ventricular fibrillation indicates a poor chance of successful resuscitation.[22] The median frequency of the VF waveform correlates with myocardial perfusion during CPR.[23] In an animal model a median frequency of 9.14 Hz or greater had 100% sensitivity in relation to defibrillation success.[23] This type of analysis could possibly be used to determine the most appropriate time to administer a defibrillating shock.[24–26]

Role of transthoracic impedance

Defibrillation involves the delivery of electrical energy across the thorax. Because present defibrillation guidelines specify the delivery of a fixed amount of energy, the magnitude of the transthoracic current (I_m) is determined by transthoracic impedance (TTI).

$$I_m \propto \sqrt{\frac{E}{Z}}$$

where:
I_m = peak discharge current (A)
Z = transthoracic impedance (Ω)
E = electrical energy (J)

The transthoracic impedance is an important determinant of the ensuing defibrillation waveform. The average transthoracic impedance to monophasic defibrillation shocks in adult humans is 70–80 ohms, with a range of 15–150 ohms.[27] Although the total amount of energy delivered is approximately the same, irrespective of the impedance, a low impedance results in a narrow waveform with high current, while high impedance results in a wide waveform with lower current. Excessively high current can cause morphological and physiological myocardial damage associated with postshock arrhythmias, whereas

Table 25.1. Factors that determine and alter human transthoracic impedance

Factor	Effect on impedance
Chest size or interelectrode distance (most important factor)	Larger chest results in higher impedance
Selected energy	Higher energy reduces impedance
Electrode size	Larger electrodes reduce impedance
Couplants between electrodes and chest wall	Failure to use a low resistivity couplant results in very high impedance and low current flow. Gels, electrodes, pastes, and saline-soaked gauze pads are all satisfactory
Multiple shocks	Multiple shocks reduce impedance
Phase of respiration	Inspiration increases impedance, expiration lowers impedance
Electrode-chest wall contact pressure	Firm pressure on hand-held paddles reduces impedance
Sternotomy	Sternotomy lowers impedance
Electrode placement on female breasts	Breast placement increases impedance
Specific arrhythmia (i.e., VF, VT, AFib, AF)*	No effect on impedance

* AFib, atrial fibrillation; AFL, atrial flutter; VF, ventricular fibrillation; VT, ventricular tachycardia.

low current may be inadequate to achieve defibrillation and the longer duration waveform may risk reinduction of ventricular fibrillation. Clinical studies with monophasic waveform defibrillators suggest that optimal success is achieved with a transthoracic current of 30–40 amperes.[27–34]

The challenge in delivering safe defibrillation across a range of impedance is to ensure optimal waveform and current across the entire range. Monophasic defibrillators are unable to adjust for transthoracic impedance and the resultant waveform varies considerably with impedance. Excessively high or low peak transthoracic current is associated with reduced effectiveness of monophasic waveform defibrillation. Minimizing transthoracic impedance will increase the chance of successful defibrillation. Factors affecting transthoracic impedance are listed in Table 25.1 and discussed in more detail below.

Paddle force

When using traditional hand-held defibrillation electrode "paddles," increasing paddle force improves electrical contact at the electrode–skin interface. Optimal paddle force in adults is approximately 8 kg;[35] in children 1–17 years the optimal paddle force is approximately 5 kg and in children <10 kg, approximately 3 kg.[36] Eight kg is a significant force and the physically strongest member of the resuscitation team should therefore be delegated to apply the electrode paddles.

Paddle orientation

Most external defibrillation pads and paddles are asymmetric. Placing the apical electrode in a craniocaudal direction minimizes transthoracic impedance.[37]

Couplant

A couplant is a high conductivity material that minimizes impedance at the electrode-skin interface. Pastes, creams, gels, saline-soaked gauze swabs, or preformed gel pads have all been used for this purpose. Although pastes, creams, and gels all provide good electrical contact, they are prone to be smeared across the chest, making external chest compression slippery and risking arcing between electrodes[38] with the production of a potentially dangerous spark. The low-impedance gel pathway also results in little current traversing the heart.[39] Preformed gel pads as a couplant for hand-held paddle electrodes are quick to apply, provide good electrical contact,[40] and minimize these risks. It is important not to use a high impedance gel (such as some ultrasound gels) since less current is conducted and also since arcing is more likely to occur with associated complications of skin burns or fire.

Shaving the chest

Chest hair increases transthoracic impedance through poor electrode contact and air trapping. Defibrillation across an unshaved chest is likely to result in more severe burns. Shaving the chest prior to defibrillation minimizes transthoracic impedance by improving electrical contact.[41,42] Shaving must not interfere with ongoing external chest compressions.

Lung volume

Lung volume is a major contributor to transthoracic impedance. Firm paddle force (8 kg) during defibrillation reduces overall thoracic volume and reduces transthoracic impedance by 16%.[43] Transthoracic impedance is also lower during the expiratory phase of respiration[31] and increases progressively with increasing positive end-expiratory pressure (PEEP).[44] Patients with acute asthma

may have particularly high transthoracic impedance due to lung hyperinflation and auto-PEEP.

Hypothermia

In swine models of short duration (30 seconds) and long duration (8 minutes) VF, moderate (33.0 °C) and severe (30.0 °C) hypothermia was associated with a higher defibrillation success rate, despite an increase in transthoracic impedance. A higher resumption of spontaneous circulation was achieved. The improved shock success is thought to be due to a hypothermia-induced change in the mechanical or electrophysiological properties of the myocardium.[45,46]

Repeated shocks

Multiple monophasic shocks slightly reduce transthoracic impedance to subsequent shocks.[27,29] The reduced transthoracic impedance will result in a greater transmyocardial current with subsequent shocks even at the same energy. The mechanism for this reduction in impedance may be related to tissue hyperemia and edema in the current pathway.[47] The effect of repeated biphasic shocks on transthoracic impedance is unknown.

Impedance compensating waveforms

Biphasic waveforms are generated using discharge from a capacitor but electronic modification allows manipulation of the waveform. Instantaneous measurement of transthoracic impedance enables the waveform to be controlled by the defibrillator to provide both optimal current and waveform duration. Shock characteristics that may be altered in various commercially available biphasic defibrillators include the duration of the two pulses (individually and in total) and/or the leading-edge voltage of the pulses. This technology, not available on monophasic defibrillators, has resulted in more effective biphasic defibrillation across a wide range of transthoracic impedance, minimizing the effect of impedance on the success of defibrillation.[48]

Therapy

Electrodes

The optimal size of electrodes for adults is thought to be from 8.5 to 12 cm in diameter.[27,49,50] Although impedance can be reduced by using even larger electrodes, if the electrodes are too large, contact with the chest wall may be inadequate if rigid hand-held electrodes are used. Furthermore, with very large electrodes a greater proportion of the current may traverse extracardiac pathways, thereby "missing" the heart.[51]

Traditionally, small electrodes have been used for infants and children, often labeled "pediatric" electrodes. This has primarily been based on the intuitive concept that smaller electrodes are more suitable for children. Very small electrodes may result in excessively high transthoracic impedance and inadequate current flow, however.[52] Larger "adult" electrodes are therefore more appropriate if the electrode paddles will fit completely on the child's thorax, which, for most children, is true at or above 1 year of age or 10 kg weight. Current flow is improved by using "adult" paddle electrodes in children.[53]

Electrodes should be placed so that the heart is located between them. The polarity of the paddles is unimportant.[54,55] It is now understood that current does not follow a straight line through the chest between electrodes, and a surprisingly low portion of the total current flow – only about 4% – actually traverses the myocardium during transthoracic defibrillation.[56] The most common electrode placement is apex-anterior: the anterior electrode is placed anteriorly to the right of the upper sternum below the clavicle, while the apical electrode is placed to the left of the nipple, just outside the position of the normal cardiac apex (V_{4-5} position)[57] (Fig. 25.1). The apical electrode must be placed sufficiently laterally to optimize transmyocardial current flow and prevent arcing of current across the chest wall.

It is important in female patients to avoid placing the defibrillator paddles or self-adhesive pads directly on the left breast. The breast should be elevated and the paddle or pad placed on the chest wall lateral to the breast in the expectation that this will reduce impedance and improve current flow.[34]

Other electrode positions have been used successfully: an anterior-posterior position where one electrode is placed anteriorly over the left precordium and the other posteriorly in the right or left infrascapular position or an apex-posterior position where the anterior paddle is placed over the cardiac apex with a posterior paddle in the right infrascapular location (Fig. 25.1). In any individual patient one position may be superior to others; in our experience, a shock will occasionally achieve defibrillation when electrode positions are altered and a new position is used, after several shocks have been administered unsuccessfully from a previously used position.

Putting the electrodes nearer the heart to increase the electrical field strength will increase success and may be achieved by a more invasive defibrillation route. Examples of this include epicardial or endocardial electrodes applied

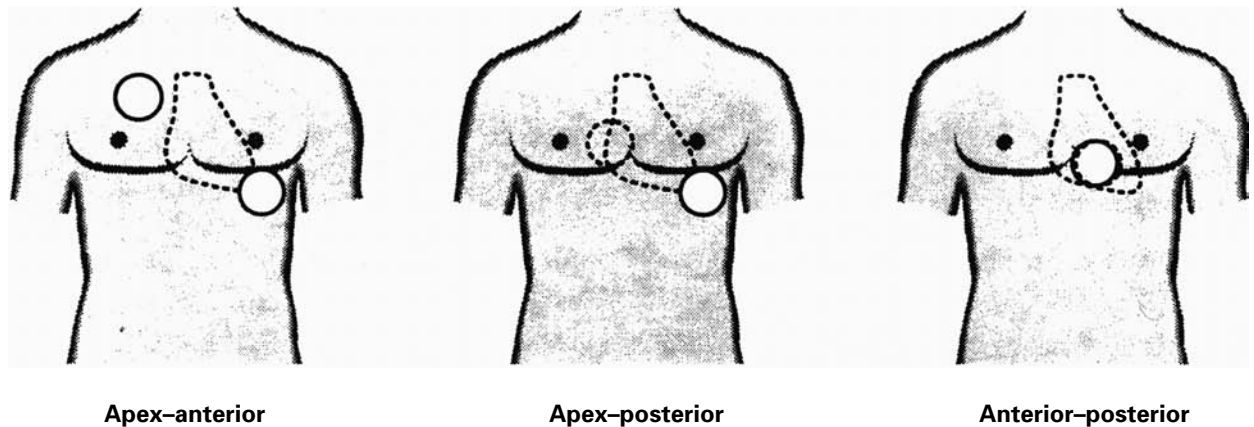
Apex–anterior   **Apex–posterior**   **Anterior–posterior**


Fig. 25.1. Recommended electrode placement for defibrillation. (From Tacker, W.A., ed., *Defibrillation of the Heart*. St. Louis, Mosby-Year Book, 1994:1630.)

either during open-chest resuscitation or by surgical implantation of automatic defibrillators. This also will lower impedance because the electrodes will be closer together. With invasive techniques, energy levels between 5 J and 25 J may be adequate.

Transesophageal electrode placement permits successful defibrillation of ventricular tachycardia and ventricular fibrillation at relatively low energy levels (100 J or less).[58] The technique, however, is unlikely to be applicable for routine resuscitation, and esophageal injury has been reported with higher energies.[59]

Defibrillation can also be performed by using disposable self-adhesive monitoring defibrillation pads that incorporate a conductive gel between the electrode and skin surface.[49,60,61] This is an attractive option: the pads enhance operator safety by physically separating the operator from the patient. In elective situations (electrophysiologic studies, cardiac catheterization laboratory, elective cardioversion) they can be preplaced, facilitating optimal placement without the extreme stress of an ongoing cardiac arrest. Transthoracic impedance is similar to that of standard hand-held electrodes.[49] Self-adhesive pads are routinely supplied with automatic external defibrillators, and are used to detect the surface electrocardiogram and permit its analysis and then to deliver the defibrillating shock.

Present recommendations for the size of pads used with these automatic external defibrillators are that the total area of the two electrodes be at least 150 cm[2].[50]

Defibrillation waveforms

The monophasic damped sinusoidal (MDS) waveform for defibrillation was introduced by Lown in 1962,[62] and remained the standard waveform for transthoracic defibrillation for 30 years. Monophasic truncated exponential waveform defibrillators were used less frequently,[63] and may be less effective.[64] More recently, biphasic truncated exponential waveforms have supplanted the damped sinusoidal monophasic waveform as the standard waveform for transthoracic defibrillation. Shocks given by using the BTE waveform have been shown to achieve higher rates of VF termination than MDS waveforms at equivalent energy levels.[65–67] Furthermore, there is experimental evidence that the BTE waveform is less damaging, as it is associated with less myocardial depression and fewer postshock arrhythmias.[68]

An available variant of the BTE waveform is characterized by a rectilinear (near-rectangular) first pulse followed after polarity reversal by a truncated exponential second pulse.[69]

Energy guidelines for defibrillation by use of monophasic waveform defibrillators have for many years emphasized a "stacked shocks" approach: 200 J, 200–300 J, 360 J. This was based on several studies which found that initial shocks of less than 200 J may generate inadequate current to defibrillate,[70] while higher energy initial shocks did not achieve higher initial success.[71] The newer biphasic truncated exponential waveforms, however, have been found to have much higher success rates (up to 98%) than monophasic waveforms at relatively low shock energies.[66,67,72,73] In view of this, a single-shock strategy might be preferable to three standard shocks, i.e., if the first shock fails to terminate VF, external chest compressions should be immediately resumed, rather than applying additional biphasic shocks which take time and are unlikely to be effective until a period of closed-chest compression has been administered.

Elapsed time during a cardiac arrest is a particularly important consideration when the new automated external defibrillators (AEDs) that analyze the ECG signal are used and, if an algorithm for VF detection is satisfied, the operator is advised to deliver a shock. No CPR can be performed while the analysis is in progress, because CPR produces artifacts in the ECG. The AED algorithms typically require 30 or more seconds for each analysis/charging cycle. Thus, requiring three failed stacked shocks before resuming CPR and administering agents such as epinephrine or vasopressin, could require as long as 1½–2 minutes during which no CPR was administered, thus reducing the chance of success of the resuscitation effort.

"Thumpversion" (precordial thump)

Ventricular tachycardia and, rarely, ventricular fibrillation can be terminated by striking the precordium with a closed fist – so-called "thumpversion" or precordial thump.[74–77] The success rate of this maneuver in terminating the arrhythmia is from 11 to 25% for ventricular tachycardia, and approximately 2% in ventricular fibrillation. However, such a thump can accelerate ventricular tachycardia or convert it to ventricular fibrillation, asystole, or electromechanical dissociation, thereby substantially worsening the patient's condition. "Thumpversion" should be considered in a witnessed cardiac arrest where the patient is pulseless and a defibrillator is not immediately available. If the patient has a pulse, the precordial thump should not be employed unless a defibrillator is immediately available.

Safety of defibrillation

Whereas the use of a defibrillator may be lifesaving for the patient, safety must not be compromised during defibrillation attempts. There are three significant areas of risk during defibrillation: risk to the patient, to the user, and to the equipment/environment. There is obviously some overlap between these.

Risk to the patient
Defibrillation of supraventricular arrhythmias should be synchronized to avoid delivering a shock on the "T" wave of the ECG, which may induce ventricular fibrillation. It is important to avoid inadvertent use of synchronization when shocking ventricular fibrillation in order to avoid delay in delivering a shock.

When paddles are used for monitoring, after one or more shocks an electrical voltage "offset" can result in the monitor incorrectly displaying an ECG trace mimicking asystole, even when the patient remains in VF.[78] This spurious appearance of asystole may last long enough to delay further shocks, because it may mislead rescuers who rely on monitoring through the paddles. Spurious asystole is more likely to occur after several successive shocks have been applied through gel pads and in the presence of high transthoracic impedance. This is probably due to the higher voltages applied with successive shocks. If asystole is seen following a shock while gel pads or paddles ("quick look paddles") are used, the rhythm must be confirmed immediately by attaching standard ECG electrodes.[78] They are less likely to have a prolonged voltage offset.

Increasing numbers of patients requiring defibrillation may have an implanted pacemaker or a cardioverter defibrillator. Both these devices may be damaged by the high current associated with defibrillation (this is one example of risk to equipment and to patient). Placing the electrodes 12–15 cm away from the device has been recommended to ensure both that the sensitive electrical components of the ICD are not damaged and that the defibrillation current does not stray down the low-impedance pathway of the internal pacing/defibrillation electrode.[79–81] This is not difficult to achieve in the majority of such patients, where the pacemaker generator is placed in a subcutaneous pocket in the left pectoral area. In these situations where a right pectoral location is present, anterior–posterior electrode placement can be used safely. All implanted cardioverter defibrillators and pacemakers should be checked promptly in patients after they have been defibrillated, because transient disturbances in sensing, capture, and pacing may occur.

Risk to the user

Accidental shock to the rescuer
The rate of accidental shocks during defibrillation by emergency medical technicians has been reported to be 1/1000 compared with 1/1700 for paramedics, fortunately without morbidity or mortality.[82] When defibrillation is carried out, it is important that no one is physically in direct contact with the patient. The operator must shout "stand clear" and check that all those present have done so before giving the shock. With automated systems, the team leader must ensure that voice commands from the machine are followed. Contact with intravenous infusions, wet clothing, and metallic contact with the patient (e.g., from a bed or trolley) must also be excluded. Electrode pastes can spread across the chest wall and/or onto the operator's hands, leading to arcing of the current and the potential for spark formation.

Risks to equipment and environment (also may carry risk to patient and user)

Oxygen   High oxygen concentrations may be present around patients during resuscitation attempts.[83] Sparks generated during defibrillation may ignite the oxygen and cause a fire and burns to the patient.[84,85] It is recommended that oxygen concentrations around the chest during defibrillation be minimized by avoiding disconnection of the ventilation circuit and ensuring that any free-flowing oxygen is moved away from the patient.

Transdermal drug patches   Nitroglycerine patches may explode if a defibrillating electrode is placed directly over the patch. The explosion is due to arcing and breakdown of the metal backing of the patch rather than explosion of the nitroglycerine itself.[86,87] Metal backing is present in other transdermal drug patches and therefore all should be removed before defibrillation.

Aircraft avionics   Defibrillation in aircraft is normally safe, provided that standard precautions are observed. Leakage currents of less than 1.5 mA have been recorded from standard battery-operated defibrillators and should cause no interference with avionic equipment.[88]

The future of defibrillation

Automated external defibrillators

The development of AEDs has revolutionized out-of-hospital resuscitation.

AEDs monitor the ECG via self-adhesive electrodes applied to the patient's chest. The rhythm is analyzed by a microprocessor in the defibrillator. If the algorithm for ventricular fibrillation is satisfied, semiautomatic versions of these devices sound an alarm and advise the operator to deliver a shock. In fully automatic systems, the defibrillation shock is applied without further input from the operator, but an audible warning is given for safety of any nearby personnel. An example of defibrillation accomplished by lay rescuers using an AED is shown in Fig. 25.2.

The algorithms used are accurate when tested against field-recorded electrocardiograms.[89,90] Specificity rates for diagnosing ventricular fibrillation approach 100%, i.e., that the machine will not shock non-VF rhythms. Sensitivity rates are somewhat lower, particularly with low-amplitude ventricular fibrillation waveforms.[91,92] AEDs may also fail to interpret the pacing "spike" of an implanted defibrillator pacemaker correctly, but instead recognize it incorrectly as
Fig. 25.2. Defibrillation by a volunteer (lay) first responder emergency medical service using an automated external defibrillator. A single 200 J shock terminates ventricular fibrillation (VF); a brief period of asystole is followed by a perfusing rhythm. The patient survived.

a QRS complex.[93] Lower sensitivity rates can result in failure to shock ventricular fibrillation.

Emergency service personnel equipped with such automated defibrillators achieve higher resuscitation and survival rates than do those equipped with manual defibrillators or no defibrillators at all.[94] This is primarily due to the reduced time for delivery of the first shock when an AED is used. Also, AEDs have significant advantages over manual defibrillators in terms of reducing time and resources for initial training and periodic retraining.

The International Liaison Committee on Resuscitation (ILCOR), of which the American Heart Association is a member, has promulgated the concept of the "chain of survival" – early activation of the emergency medical service system, early CPR, early defibrillation, early advanced cardiac care – and strongly endorses and encourages the use of automated or manual defibrillators by all emergency personnel who may be called to diagnose and treat cardiac arrests: physicians, nurses, emergency medical technicians, and first responders, such as firefighters and police officers.[95]

Widespread availability of AEDs in the community, with selected lay personnel trained in the use of these devices, was shown to be practical and to offer a promising approach to improving survival from prehospital cardiac arrest.[95–97] In a subsequent large public access defibrillation (PAD) study, there were substantially more survivors to hospital discharge in scenarios where lay volunteers were trained in the use of AEDs plus CPR (23% survival), rather than CPR only (14%).[98]

Automatic implantable defibrillators

Fewer than half of the individuals who survive out-of-hospital resuscitation for sudden cardiac death have evidence of acute myocardial infarction. Ambulatory ECG recording indicates that ventricular fibrillation is often the terminal event, frequently preceded by ventricular tachycardia or multiple ventricular ectopic activities.[99,100] In an attempt to reduce the frequency of recurrent ventricular arrhythmias, antiarrhythmic drug therapy has been used, but these drugs are not always effective, have side effects, and can themselves be proarrhythmic (i.e., can cause life-threatening arrhythmias). Recent reports indicating an increase in mortality in patients taking drugs for arrhythmia control have highlighted this problem.[101]

A fully automatic implantable defibrillator (AID) was first described for use in treatment of sudden cardiac death in 1986.[102] These first devices were inserted by thoracotomy, but transvenous systems are now used for nearly all patients. They consist of a pulse generator that resembles a pacemaker and have electrodes for sensing the ECG and shocking the heart, with the electrodes located on leads that are usually positioned in the cardiac chambers and superior vena cava. Newer implantable devices have both pacing and defibrillation capability and are referred to as ICDs (implantable cardioverter defibrillators). The sensing electrodes detect occurrence of a dangerous arrhythmia and the device automatically applies pacing pulses (for ventricular tachycardia) or defibrillation shocks (for rapid ventricular tachycardia or ventricular fibrillation) to treat the disorder. Many patients are treated with both an ICD and antiarrhythmic drugs.

At the time of implantation, the patient's shock intensity required for defibrillation is determined by test shocks, because there is considerable patient-to-patient variability in shock intensity needed. Also, the ICDs allow for progressive increases with each shock in the event that the first shock(s) are unsuccessful. The intensity of shocks can be reprogrammed non-invasively at a later date if the patient's requirements change. If they are conscious, patients report that a shock feels like being hit or kicked in the chest.

Because many of these patients have extensive ischemic heart disease and poor ventricular function, mortality from heart failure remains high, but sudden death from arrhythmias is dramatically reduced and overall survival is improved after device implantation.[103]

Implantation of these devices has greatly increased as indications for use have increased and implantation has become easier. Three large trials have shown the effectiveness of ICDs to reduce mortality. The MADIT (multicenter automatic defibrillator implantation trial) and MUSTT (multicenter unsustained tachycardia trial) trials[104,105] showed that mortality decreased in patients who had ischemic heart disease, a reduced ejection fraction, non-sustained ventricular tachycardia and inducible sustained VT. The MADIT II study did not require non-sustained VT or electrophysiology testing, but did require a previous myocardial infarction and an ejection fraction <30%.[106] Notably, MADIT II showed that prophylactic ICD implantation, sometimes in combination with drug therapy, reduced patient mortality by 31%. This finding almost certainly will further increase the use of ICDs.

Home defibrillators

The great majority of prehospital sudden cardiac deaths occur in the home, not in public places.[107] AEDs are approved for use in a home setting. However, certain requirements for successful AED use must be present: the arrest must be witnessed (family members or spouses may be asleep or away) and the rescuer must be trained and able to locate the AED, apply the electrodes and operate the

device correctly (a particular challenge for elderly or infirm spouses). The recent introduction of wearable defibrillators, which continuously monitor the ECG and which are fully automated, offers potential for overcoming some of these problems.[108] Possibly such devices could be provided to intermediate risk patients on a temporary lease basis to reduce costs – perhaps for several months after a myocardial infarction, or as a bridge before heart transplant in patients with severe dilated cardiomyopathy (such patients have high rates of sudden death while awaiting heart transplantation). Clearly, patients known to be a high risk for sudden cardiac death (previous cardiac arrests, malignant ventricular arrhythmias) should receive an implantable defibrillator.

Developing strategies for prompt diagnosis and treatment of VF occurring in the home remains a major challenge if we are to improve survival from cardiac arrest.

History of AEDs

Automated external defibrillators (AEDs) as we now know them have had a rapid and interesting evolution. The first report of an "automatic cardiac resuscitator" was made by Diack *et al.* in 1979, who had developed the defibrillator, the Heart-Aid.[1] A first clinical report on successful ambulance use was published in 1982.[2] The design of this defibrillator was unusual for several reasons. First, it used a tongue electrode together with a chest electrode for defibrillation. Second, the tongue blade also contained a sensor for respiration, which prevented the defibrillator from delivering a shock as long as an air stream was detected over the tongue. Confidence in the algorithm to detect ventricular fibrillation (VF) by the ECG was not sufficient: a second independent sign of circulatory arrest was desired. Further automated analysis of the ECG and defibrillation in cardiac arrest was investigated first in defibrillators that were used by traditional responders such as Emergency Medical Technicians.[3,4] Then, when safety and efficacy were confirmed, the use was extended to fire fighters[5] who were already part of the Emergency Medical Services (EMS) and to police squads who had never been part of the EMS.[6] It became clear that the future of automated defibrillation was with lay rescuers with limited training, without the ability to interpret ECGs. Ease of use was paramount.

Therefore, new AEDs were designed with the lay rescuer in mind, with increasing simplicity and decreasing weight, volume, and cost. Also, these new AEDs offered assistance to the rescuer with voice prompts that could talk the rescuer through the still complicated process of applying defibrillation pads, defibrillation, checks for return of circulation, and resuming CPR when needed. The process could be repeated according to agreed protocols. These AEDs received rapid acceptance, especially when experiences were published with police[7,8] airline personnel,[9] casino attendants[10] airports[11] and the public domain.[12] Use of AEDs in pediatric cardiac arrest became better accepted when energy attenuators became available, limiting the energy delivered,[13] and the VF detection algorithm proved reliable in children.[14] Limitations in the delivering of the voice prompts became clear however,[15] they markedly curtailed the time during which CPR could be administered, thus decreasing the life-saving potential of AEDs. The 2005 AHA and ERC guidelines on resuscitation[16,17] suggest revision of voice prompts according to accumulated experience and new understanding of the prime importance of chest compressions.

Another trend is the addition of new tools to assist the rescuer in performing Basic Life Support, such as a metronome to enforce an optimal rate of chest compression and a displacement transducer that gives feedback on speed and depth of chest compressions.

AEDs have evolved into highly sophisticated, small, simple, and cheaper devices that are now applied in increasing numbers in out-of-hospital cardiac arrest.[18] The technological developments will clearly continue with new capabilities to optimize the chance of successful resuscitation.

The clinical application of AEDs

The principal applications of AEDs are for use by operators with modest training, although they have been used

increasingly by healthcare professionals, including physicians and nurses, whose work does not bring them into frequent contact with cardiac emergencies so that they lack relevant experience for dealing with cardiac arrest.

AEDs are deployed in two strategies: "on-site," in which any use is expected to be close to where the device is kept; and "transported" in which the device is intended to be taken to an emergency remote from where it is kept.

On-site AEDs

The most obvious on-site use of AEDs is within the home, a concept that has been likened to keeping a fire extinguisher for an unlikely but grave emergency. But it is not an exact analogy. Even an AED requires both training and refresher training as well as battery maintenance. Moreover, the cost for *routine* home use would be prohibitive and many would find its presence intrusive. Thus the perceived risk of a family member developing a malignant arrhythmia must be great enough to justify its purchase for both reassurance and protection. Here, too, there is a caveat; if the risk is very great – as for example for an individual who has already suffered such an event – then an implantable defibrillator would be the usual strategy. Vest devices[19] also compete for favor if protection is required as a bridge whilst an implant is awaited. No consensus yet exists on the level of risk that might call for protection to be immediately available yet not merit implantation. One early small study showed no survival benefit.[20] Moreover, the psychological aspects cannot be assumed to be favorable. How many deemed at risk might fear to venture far from what may be perceived as a life-line? The strategy is currently being investigated comprehensively in the HAT (home external automatic defibrillator trial) trial that is expected to report in 2007.[21] Until more evidence is available, home applications should be regarded as of unproven value.

An extension of the home concept has been investigated as part of a larger trial that involved placement of units not only in public places, but also in blocks of dwellings. The need here was therefore based on a large number of individuals at relatively low risk rather than on single persons at high risk. The Public Access Defibrillation (PAD) trial[12] included 80 apartment complexes with volunteers trained to provide CPR for cardiac arrest and, for comparison, 77 others in which the volunteers also had the potential to deliver an AED within 3 minutes. Only a single individual survived in each group from a total of 70 definite cardiac arrests. The issues of ownership, training, and response times would inevitably have posed challenges that may have accounted for the poor result in the AED arm of the study. The declared target to have defibrillation available

within 3 minutes would also be difficult to achieve in this situation, so that the strategy does not provide a typical example of "on-site" use.

The considerations are quite different in relation to the protection of individuals not known to be at high risk, but who are in areas remote from any chance of conventional rescue. Typical examples have been reported in relation to commercial aviation[9,22–25] but could apply equally well to ships, long distance trains, expeditions, and even remote settlements. Here, the problem of responsibility for using the device in an emergency can be settled readily because selected individuals will have a "duty to respond." The case for this strategy cannot generally be made on economic grounds unless, as was the situation aircraft, experience shows that expensive diversions can be avoided. Few AEDs would ever be used successfully to treat cardiac arrest during flight. A review of in-flight deaths reported to the International Air Transport Association suggested that cardiac arrest might occur once in every 3 million passenger flights.[26] The QANTAS experience[22] of one in a million passenger flights was higher; this may represent only statistical chance in small numbers, but under-reporting of events by airlines is also possible. The case for AEDs on aircraft, now adopted by almost all major carriers, was based in part on medicolegal considerations, because of the risk of liability arising from not having facilities available for defibrillation. More recently, in the United States the Federal Aviation Agency (FAA) has ruled that all commercial aircraft with at least one flight attendant must carry an AED: the law now adds an even more powerful motive.[27] The principle of equity might also be cited. All these reasons are valid and powerful: benefit cannot always be judged on clinical results alone.

The likelihood of need is clearly greatest where large numbers of sick patients are likely to be found. Whereas high dependency clinical areas are generally equipped with defibrillators with staff experienced in their use, most healthcare areas do not have resuscitation equipment available routinely – more than a decade after the first description of AEDs in hospital.[28] Many non-critical hospital wards, nursing homes, clinics, and physician or paramedical premises are also likely to have patients, either resident or visiting, who are at risk of sudden cardiac death. The use of automated defibrillation is ideal in such areas but has been unevenly exploited. All hospital areas with vulnerable patients should have defibrillation facilities immediately to hand, certainly sufficiently close to permit application within a couple of minutes in order to achieve defibrillation within the few minutes of the 'electrical phase' of cardiac arrest[29] while the prospects of success remain optimal. The notion that collapse in a ward area is

a signal for summoning a remote cardiac arrest team is a recipe for unnecessary deaths! AEDs can provide a very desirable solution because all professional ward staff should then be able to provide immediate definitive treatment. Although observational studies attest to its value,[30,31] the strategy has not yet been widely implemented in some countries, nor fully in all. It should be seen as a priority. Primary care is another area where availability of defibrillation facilities has been disappointingly low. One can only regret that the excellent results obtained from the use of AEDs in the offices of general practitioners have not prompted a demand for the defibrillator being universally available.[32]

The concept of "on-site" defibrillators in public places is developed in Chapter 27 where Public Access Defibrillation is considered in greater detail. It has been a success story for the implementation of AEDs, with use in casinos,[10,33] airports, bus or ferry terminals, railway stations,[11,34] shopping malls,[12] and sports facilities.[35–39] Remarkable success for on-site defibrillation was also reported from a survey of rehabilitation programs even before devices were automated;[40] such equipment should now should be available routinely where cardiac rehabilitation is practiced. Authorities should consider carefully where else in the community they should be deployed. A survey in 1998 examined the annual incidence of cardiac arrest in public places.[41] A county jail came second only to an international airport; the needs of defibrillation facilities in detention centers can readily be overlooked! Data from emergency services should be used more frequently to guide community policies with regard to prompt defibrillation.

Vulnerability of any given population must be a key issue, but even the apparently fit merit consideration. At present we have no consensus on the numbers of healthy people gathered in one place that might constitute a recognized need for availability of defibrillation facilities. Numbers alone provide an insufficient guide, however, in assessing community risk. Average age of a population clearly has a bearing, but more important is the type of environment. In particular, environments that trigger high adrenergic drive have a disproportionately high incidence of cardiac arrest, but also an unusually high incidence of arrests with shockable rhythms, with fibrillation found in over 80% of cases in airports and railway stations[34] and over 90% of cases in a casino.[10] Moreover, where adrenergic drive is a major factor, a high proportion of arrests may occur in the absence of fresh infarction, so that resuscitation may have a greater chance of success. Although this is a reasonable hypothesis that is in keeping with observed data, it has not been studied formally.

Transported AEDs

Lay first-responder schemes are probably the most important area of development in which the use of AEDs could counter an important proportion of cases of sudden cardiac death. Although response times will generally be longer than for on-site defibrillation, they can still be appreciably shorter than those achieved by conventional emergency systems. This is hugely important when every minute of delay has been shown in a large database to reduce the average success rate in comparison with that of the previous minute by no less than 23%.[42] The strategy has not been adequately exploited for various reasons, but none of them is insuperable nor should any be seen as an overly daunting challenge in comparison with the size and nature of the problem that it could address. Complacency, lack of vision, and even ignorance within the medical community pose the greatest barriers.

The major barrier to reducing community mortality by first-responder defibrillation is perceived to be the site of most unexpected cardiac arrests. They do not occur in hospital, or even in public places. A large majority of persons die at home; in one epidemiological survey this was reported to be as high as 80%,[43] although it was appreciably lower at 61% in another study.[44] Not surprisingly, older people are more likely to suffer sudden cardiac arrest at home than are younger ones.[44,45] Most are witnessed by sight or by sound but the survival rate is poor, with prospects regarded as gloomy because of the belief that most patients with cardiac arrest outside hospital will never be in reach of publicly accessible defibrillators.[46]

The current situation is indeed unsatisfactory, particularly since most statistics for out-of-hospital cardiac arrest relate only to cases in which an attempt at resuscitation was made. In some areas this is close to zero, but even in areas with highly developed emergency services there is another problem. The proportion of victims found with shockable rhythms is usually reported to be about 40%.[47,48] Such unpromising figures are, however, due in large measure to slow response times that permitted the decay of fibrillation into asystole. Indeed, data from Gothenburg have suggested that the initial incidence of fibrillation is about 80%,[49] a percentage that has been exceeded in some studies of on-site AEDs as quoted above. The figure was derived by extrapolating backwards to zero time from the falling incidence found as delays increase. Although the proportion of cases with fibrillation has been noted to fall in recent years, defibrillation should be the appropriate option for far more victims than is currently observed: short response times are the

key. An important concept must be accepted: *cardiac arrest in the community is a problem for the community and not primarily for ambulances*. It remains, however, a problem for the emergency services because it is the conventional emergency control systems that must activate responders in the shortest possible time. But if responders are activated only for cases believed to involve cardiac arrest, then at least half will be missed, and the responders will never develop the competence that comes from experience and confidence. Few data have yet been published to confirm that community responders can achieve greater success by attending all reported major emergencies. One study from Piacenza[50] in Italy, however, has attracted interest by showing that implementation of a scheme in which volunteers trained in AED use, but not CPR, tripled the community survival rate. Further detailed studies of well organized community schemes are urgently needed.

Far more extensively studied have been schemes in which non-healthcare professionals 'with a duty to respond' have been equipped with AEDs and given the remit of attending cardiac emergencies. These have largely been fire service and police personnel. In the United States and some other countries, the fire service is generally part of a unified emergency service but, where this is not the case, firemen could supplement ambulances and indeed can often reach victims sooner.[51] Fire services must be adequately staffed at all times for emergencies that are relatively infrequent. It therefore makes abundant sense to equip them with AEDs and use them as coresponders in order to achieve good response times at relatively modest cost. In some countries, however, the strategy has not been adopted or has been adopted imperfectly. Within the United Kingdom, union reservations from the professional fire service has held up progress. In other countries, interservice rivalry has lessened the beneficial impact.

Police forces offer another obvious method of rapid response to life-threatening emergencies. The highly successful experience by police in Rochester (Minnesota,[6,52] described in Chapter 27) shows how dramatically successful this can be. But even well-organized schemes[53,54] cannot match this success unless an effective system is in place to ensure that police are alerted as quickly as the regular ambulance service. When this is achieved, response times can be appreciably reduced.[55] Any shortcomings in this area may not be due to lack of cooperation. Apart from the complexities of linking control centers and the resultant delay, incidents of cardiac arrest cannot be identified accurately from public emergency calls, and few police services have the capacity or will to act as a routine

backup ambulance service. Moreover, one survey found that most law enforcement officers would not feel comfortable using an AED.[56] This area requires more research by those willing to follow the lead given by the 'gold-standard' Rochester co-responder scheme.

AEDs were not initially designed for healthcare professionals, but some of their most valuable contributions have been made by such personnel. Reference has already been made to their use by physicians and hospital staff with access to "on-site" units. Apart from general practitioner physicians who travel to emergencies equipped with their office AEDs,[32] they have found a role in the conventional or statutory ambulance services as well as independent private services and those provided by voluntary groups. The obvious benefit comes from the reduced training required compared with that for manual defibrillators, so that the use of ambulance defibrillation can be greatly extended. But there are other benefits. The algorithm decision plus screen interpretation of the waveform offers a double check that many believed would hasten decisions to shock. Some reports, however, showed that the adoption of AEDs in ambulances did not improve results overall[57] even when the previous option had been to provide CPR and await a second tier ambulance.[58] This is probably due to the considerable delays that have been required by AED algorithms before a shock can be given, comprising 'hands-off' analysis time, charge time, and human delay after the shock instruction is issued.[15] Experimental evidence now indicates that after cardiac arrest has been present for a very few minutes, any delay between compressions and shock greatly reduces the likelihood of a return of spontaneous circulation.[59] At present, this can reduce the efficacy of AEDs in comparison with manual defibrillation.[60] Improvements in design of the devices will shortly overcome this disadvantage. Once this has been achieved, we anticipate that AEDs will eventually displace manual units even for skilled professional use.

The inestimable value of AEDs has been shown in many different spheres of resuscitation. The role of automated and perhaps automatic (self-discharging) units is set to increase, both in terms of the numbers that a community will expect to have available and also for expanding indications for their use.

AED in children

As the advantages and availability of automated external defibrillators (AEDS) in both out-of-hospital and in-hospital sites increased, it became apparent that children were not eligible for this potential therapy. Since AEDs

were not approved for use in young children, a child could receive only CPR and initial airway management by first responders. Rhythm analysis and defibrillation were delayed until the arrival of advanced paramedics with a variable dose manual defibrillator. The energy dose was substantially higher than recommended doses for children and the rhythm detection algorithms had been developed with adult rhythms only. Over the last 5 years, there has been an increasing effort to understand these risks and modify the AEDs to optimize use in children.

Cardiac arrest in infants and children: is there a need for AEDs?

The etiology of pediatric cardiac arrest differs from cardiac arrest in adults.[61-70] Primary respiratory arrest is more common than primary cardiac arrest, and is the leading cause of cardiac arrest in children less than 5 years. The most frequent rhythm observed in patients 0–17 years old is asystole or pulseless electrical activity (PEA). Successful resuscitation rates are distressingly low (less than 10%), costs are extremely high, and permanent neurological sequelae are common.[65,67,70]

Because of the high frequency of respiratory arrest and asystole in children, the emphasis of resuscitation efforts has been on effective ventilation and oxygenation, whereas rhythm assessment and defibrillation, despite their importance, have received less emphasis. Rapid rhythm evaluation is not routinely performed in pediatric patients as[66,71] first responders evaluated rhythm in only 44% of pulseless children.[66]

We now recognize that the frequency of ventricular fibrillation may have been under-estimated during pediatric arrest. In studies of out-of-hospital pediatric arrest, ventricular fibrillation was present in 9 to 22% of those in whom an ECG was obtained.[61-66,68-70,72,73] Two out-of-hospital, population-based studies demonstrate ventricular fibrillation in 9–19% of children suffering pulseless arrest from any etiology. Mogayzel *et al.* reported ventricular fibrillation as the initial rhythm in 19% of children (5–18 years) who experienced an out-of-hospital cardiac arrest.[66] The presence of ventricular fibrillation was evenly distributed among all categories of arrest: drowning, overdose, trauma, and medical illness. Young *et al.*[70] found ventricular fibrillation in 9% of pediatric cardiac arrest victims. The disparity in frequency can probably be explained by different populations: Mogazel's study was limited to children 5–18 years; Young's study included children and infants 0–12 years as well as those diagnosed with sudden infant death syndrome (SIDS). Interestingly, 6% of the patients categorized as having SIDS had VF reported as the presenting rhythm. Two recent in-hospital studies have also documented an 11%–14% incidence of ventricular fibrillation in pediatric arrest.[72,74] Thus, ventricular fibrillation, although not common, occurs in pediatric arrest and should *not* be considered rare.

The presence of ventricular fibrillation as the initial rhythm, compared with asystole or PEA, predicts hospital discharge, improved survival, and/or neurological outcome in both in-hospital and pre-hospital situations. Long-term survival of 25%–40% has been reported in the studies cited above.[64-66,75,76]

Because of this new information, early recognition and treatment of ventricular fibrillation have been identified as one factor that could improve pediatric resuscitation rates[70,73,77] and this has also prompted the need for modification of AEDs to permit pediatric use.

Equipment design and modification for pediatric use

Potentially, adult-only AEDs could be applied to children, but there were unknown risks associated with this practice. In order to extend the new technology to children, modifications to the existing devices were necessary. The rhythm identification algorithms needed validation and a pediatric energy dose established. The rhythm identification algorithms had been validated from libraries of adult rhythms, but the rhythm algorithms from electrograms recorded from young children also needed validation. The AED energy doses were all programmed to adult energies of 150–360 J shocks and a mechanism to deliver lower energies was required. These modifications were needed without increasing the complexity of the AED operation for adult use.

Several manufacturers have tested or developed modifications of their AEDs to permit safe and effective use in children < 8 years. Adult algorithms have been validated with pediatric rhythms, or modified specifically for pediatric patients.[14,78,79] In 2001, the first pediatric pad and cable system was granted market release by the United States Food and Drug Administration and several manufacturers followed with comparable systems. Typically, the modifications utilize separate pediatric pads with an attenuator that automatically absorbs a portion of energy when the AED delivers a shock. The attenuator lowers the nominal energy delivered to the patient from 150–200 J to approximately 50 J.[80] As a result, scaled energy and current are delivered to pediatric patients. The pediatric pads are designed for use on children 0–8 years or up to 25 kg. The American Heart Association strongly recommends the use of the pediatric pads with attenuated dosing for children 1–8 years.[16,81]

Modification of energy dosing

The energy dose recommendation of 2–4 J/kg for children was derived from animal data[82,83] and one small retrospective review of in-hospital short-duration pediatric ventricular fibrillation.[84] That these doses were effective or safe in humans has not been confirmed, especially for long-duration ventricular fibrillation. Recent animal and human data indicate that 2–4 J/kg may be inadequate. Clark *et al.*[85] concluded that although biphasic waveforms were superior to monophasic waveforms in both infant and child swine models, successful biphasic defibrillation required energy doses of 3–4 J/kg. Berg *et al.* demonstrated that in 4–24 kg piglets, 2 J/kg monophasic waveforms failed to defibrillate any animal with the initial shock.[86] In a small case series from Tucson, Arizona, only 50% of children who received 2 J/kg ± 10 J were successfully defibrillated, but six had asystole and one had PEA. In the remaining 50% of children ventricular fibrillation was not terminated.

There appears to be a wide therapeutic range for energy dosing, especially with biphasic waveforms. Tang and colleagues[87] delivered 50 J to piglets weighing 3.5–25 kg. All animals were successfully defibrillated to an organized rhythm and survived for 72 hours. There were no differences in fractional area change or echocardiographic ejection fraction among the different weight groups 4 hours after the shocks. Berg *et al.* observed good survival and 24-hour neurological outcomes in 4–24 kg animals with escalating attenuated biphasic waveforms compared to monophasic doses of 2–4 J/kg.[86] Two studies of biphasic defibrillation delivered very large doses to small animals without obvious damage to the heart. Killingsworth et al. detected no abnormalities of cardiac rhythm or left ventricular function with very high-energy doses, 20–360 J delivered to animals weighing 3.8–20 kg.[88] In an animal model of *commotio cordis,* blunt trauma to the chest, small dogs received 200–360 J after ventricular fibrillation had been produced.[89] These energy doses were highly effective at terminating VF, although 17 of 26 animals died.

There are two case reports and a case series of effective pediatric defibrillation with high dosing.[90–92] Rossano *et al.* reviewed defibrillation dosing during out-of-hospital pediatric cardiac resuscitation.[92] Of 57 patients under age 18 years, the median dose for the first shock was 3.63 J/kg, range 0.67–14.29 J/kg, and 49% of patients received more than 4 J/kg as the first dose. Nineteen (33%) patients survived to hospital discharge. Energy dose did not predict survival, and some of the survivors received extremely high doses.

Is it necessary to provide attenuated energy dosing to children given the apparent wide therapeutic range?

Table 26.1. Sensitivity and specificity of AEDs for pediatric cardiac rhythms

	Philips[a]	Medtronic Physio-Control[a]	Zoll[b]
Number of patients	191	203	220
Number of rhythms	696	1561	693
Sensitivity (%)	100	99.5	99.8
Specificity VF (%)	96	99	100
Specificity VT (%)	75	70	93.9

VF Ventricular fibrillation, VT Ventricular tachycardia.
[a] Adult algorithm validated with pediatric rhythms.
[b] Algorithm developed with pediatric rhythms.

Excessive energy doses, even with biphasic waveforms, can be detrimental to myocardial tissue and may result in serious dysfunction or serologic evidence of damage.[93,94] Defibrillation with full adult dosing doubles troponin levels in small swine who receive even biphasic adult dose defibrillation compared to the animals who received the attenuated dosing. As with any other therapy, the application and energy dose should be optimized for the patient. Since pediatric pads are available and deliver an appropriate dose for children, their use should be strongly encouraged, rather than settling for adult pads that deliver larger doses than are necessary. Children deserve the same standard of care as adults receive. An adult AED should only be used if the pediatric pads are not available.[16]

Arrhythmia identification

Theoretical concerns exist concerning the capacity of AEDs to detect VF in the pediatric patient because of smaller cardiac mass in children. The American Heart Association recommends that manufacturers document the sensitivity and specificity of the algorithm for pediatric arrhythmias. Recent reports indicate high sensitivity and specificity of adult algorithms within two commercially available AEDs.[14,79] (Table 26.1) Both studies surpassed the recommendations of the AHA for specificity and sensitivity in all but one category.[95]

Analysis of the electrogram characteristics of rate, stability, and conduction as determined by one AED algorithm did demonstrate differences between shockable and non-shockable rhythms recorded from adults and children. (Fig. 26.1) Heart rate of both shockable and non-shockable rhythms and conduction scores were statistically higher in children than in adults. (Fig. 26.2) These data highlight the importance of using multiple criteria to make a shock designation in children. A third manufacturer has developed
Fig. 26.1. Electrogram characteristics between pediatric and adult shockable rhythms. *P* < 0.0001. Rate is the frequency of ECG complex occurrence, stability is the morphologic stability of the ECT complexes, and conduction is a measure of rapidly conducted signals. Stability and conduction are measured from 0 to 1 and a higher number indicates less variability in the electrogram and faster conduction. The three measures are performed concurrently to make a shock decision; no one measure independently generates a shock decision. Reprinted with permission from ref. 14.

an algorithm based solely on pediatric rhythms, which is activated when the pediatric pads are attached to the device.[78] This algorithm, although not yet field-tested, also demonstrates very high sensitivity and specificity (Table 26.1).

Simplistic algorithms with only rate criteria will likely provide a lower specificity for children, potentially resulting in inappropriate shocks. It is vitally important that each manufacturer test its algorithm against a database of pediatric rhythms that includes multiple age groups, especially infants less than 1 year and rhythms with heart rates greater than 250 bpm.

Field use of AEDs in children

Field data of AED use in children has been difficult to collect, because cardiac arrest in children is an uncommon event. Thus, retrospective and postmarketing studies

become important. Using the cardiac arrest database established by the Emergency Services Learning Resource Center at the University of Iowa, we performed a retrospective study of AED use during out-of-hospital cardiac arrest in patients less than 16 years old.[76] We reviewed the years 1988–1997, when AEDs were first coming into widespread use in Iowa. Eighteen instances of AED application were reviewed. Average patient age was 12 years (range, 5–16 years). AEDs had a sensitivity of 88% and specificity of 100%. There were no instances of a shock recommendation for a non-shockable rhythm. We observed 33% survival in patients who received a shock as opposed to 11% survival with non-shockable rhythms.

More recently, the results of a postmarketing survey of the attenuated pads have established accurate rhythm detection with substantial survival. By voluntary reports of use, 27 patients with cardiac arrest (0 days to 23 years, median 2 years), were confirmed. Ventricular fibrillation was reported
Fig. 26.2. Heart rates of non-shockable rhythms from adults and children. Data normalized to compensate for different numbers in database. Reprinted with permission from ref. 14.

in 8 cases (age range, 4.5 months to 10 years, median 3 years). Shocks were delivered to all VF patients, average shock number 1.9, range 1–4. All patients had termination of VF, were admitted to the hospital, and five survived to hospital discharge. Non-shockable rhythms were reported in 16 patients, and the AED appropriately did not advise a shock. Eleven of these patients had asystole or PEA as their initial rhythm and did not survive to hospital discharge. One report contained no additional information other than that the patient did not survive, and in two other reports, the pads were not applied to patients. More details about the youngest patient have been described in a separate report.[96]

Implications

Although children are less likely to suffer from ventricular fibrillation than are adults, it does occur in 10%–20% of pediatric cardiac arrests. The technology is now available to recognize and treat ventricular fibrillation in children as quickly as we can for adults. As this technology gains increased acceptance, resuscitation rates and outcomes for VF in children should approach those now seen in adults.

Cost-effectiveness

Introducing AEDs somewhere in the community will generate questions of cost to set up and to maintain the program. Also, questions may arise as to whether this money is wisely spent. Such questions of the relationship between the cost of a program and the effectiveness of that program, cost-effectiveness, are common in decisions in medical programs: not all decisions on AED programs are made within the framework of the medical domain. Examples are the airport act and the public building act, in which the US government enforced implementation of AEDs by law. Also, the decision of individuals acquiring an AED for their offices or home may be guided more by feelings of responsibility towards their employees or their family, without explicit or implicit cost-effectiveness considerations. After one airline showed the effectiveness of AED use on board airplanes(9), other airlines may have adopted AED programs more out of fear of litigation or consideration of marketing than consideration of cost-effectiveness.

For medical decisions regarding treatment choices, however, considerations of cost-effectiveness are more

common and the principles can also be applied to AEDs in the community, especially when financial resources in a country are limited. Data are available for estimates of the costs of introduction of AEDs. These costs must be separated into the cost for the organization that purchases the AED and maintains the program, and the medical costs that will be incurred when a patient is brought to the hospital when resuscitation is successful. From the moment ambulance help is requested, the subsequent costs of emergency room care and hospital care are no longer borne by the organization that decided on the AED program. Nevertheless, these costs must be taken together for a complete analysis, because costs should be analyzed from the perspective of society.

It is difficult to attribute accurately those costs to an AED program, that are made after resuscitation and hospital admission to an AED program, even assuming the need to do so. Costs may increase: indeed, that the patient survived to admission and medical costs were incurred may be attributed to the use of the AED. Some costs may decrease: for example, earlier defibrillation may result in better neurological condition on admission and thus result in avoidance of, or a shorter stay in intensive care.[97]

The effectiveness of introducing AEDs in the community should lead to increased survival. In general, this is expressed in added quality-adjusted life–years. None of the studies that investigated the benefit of AEDs has extended the endpoint beyond discharge from the hospital, an endpoint that may not completely reflect the effect of AED use, as the cost of long-term care will not be included. When cost-effectiveness analysis is done, many components of cost or effectiveness must be derived from other studies, assumptions, or models.

When calculating effectiveness, the effect from the AED program on the survival rate observed in the specific population must be distinguished from the effect on the general population. Public Access Programs targeted to specific groups in specific places may have a significant survival benefit to that group, but may have very little effect on the survival rate for cardiac arrest in the general population. In general, PAD programs are targeted at victims in public places, where large groups are gathered and can be reached with a relatively small number of AEDs and trained rescuers: casinos, airports, public buildings, offices, sport arenas, and others. In these kinds of location, the collapse is generally witnessed, AEDs are close by and response times are short. Nonetheless, as at most 20% of victims of cardiac arrest are in these locations and 80% suffer a cardiac arrest in residential areas not suitable for PAD programs, the impact on the survival in the general population by these programs is necessarily limited. The

PAD trial included 16% of the AEDs placed in residential areas and showed no survival benefit for victims in those residential areas, although the overall survival doubled in the trial.[12] An analysis of cardiac arrests in Scotland suggested that the great majority of victims (79%) suffered their cardiac arrest in places not suitable for PAD programs.[98]

Determinants of cost-effectiveness of AED implementation

Analysis of cost-effectiveness establishes that incidence rate of cardiac arrest and response times are the main determinants of cost-effectiveness.[99] When rates are high (about > 0.5 incident per AED per year) and response times to defibrillation by rescuers with an AED are short (< 5–6 minutes), then implementing a PAD program can be expected to be cost-effective.

Will AED programs designed for victims in residential areas be cost-effective? From the possible settings of AED implementation (dispatched (non-traditional) first responders, on-site responders, home use with high-risk patients and PAD), only dispatched first responders or home AEDs would potentially be suitable for victims in residential areas and therefore might be cost-effective. There are no studies published in this domain that allow a direct estimate of cost-effectiveness, but comparing key figures from the PAD trial and three controlled dispatched first responder studies may give some insight in the relative cost-effectiveness of the two strategies.

Table 26.2 compares the key resources used (number of AEDs used and number of rescuers trained) and the absolute number of victims saved (difference in survival to discharge among groups) by the institution of the AED program. Although the costs of resources may differ, the numbers suggest that dispatched first responders may be more cost-effective than PAD programs and have the added important benefit that they can reach all victims, at home and in public areas. With less than one-tenth of the rescuers required to be trained and with a few percent of the AEDs needed by dispatched first responders compared to those in the PAD study, about the same number of patients were saved by the program. Although all studies were controlled with the associated possible Hawthorne effect, they are real population-based studies, so that the comparison can be translated to routine use. Importantly, in many countries, dispatched first responders do not exist as part of EMS. In that situation, a dispatched first responder program with AED such as police, is a real addition to existing EMS and can be expected to be beneficial. When a dispatched first responder program already exists (e.g., fire fighters in the

Table 26.2. Comparison of key resources and outcome between the PAD trial and three controlled dispatched first responder studies

Study	Number of AEDs used	Number of rescuers trained	Duration of study (months)	Number of victims saved in the study period (no. experimental minus no. control)
PAD trial[12]	1650	19,376	21	15
Myerburg[8]	1900[a]	1900	20[b]	13
Capucci[50]	39	1285	22	8
Van Alem[54]	50	1650	24	11

[a] Each police officer retained his own AED, also off duty; [b] control period and experimental period not concurrent, calculated as if concurrent.

US), however, then adding another dispatched first responder may not have much added value.[100]

AEDs for home use will be purchased by individuals based on considerations other than cost-effectiveness. The effectiveness of such programs is as yet unknown and the outcome of the "HAT trial" will be the first information from a large scale study in that domain. The results are not expected before 2007. Until then, the cost-effectiveness of such a program cannot be considered.

The AED in the Guidelines 2005

In December 2005 new guidelines for cardiopulmonary resuscitation were published, with special reference to the use of the AED in several chapters.[17,101] Several changes in the guidelines are also reflected in the settings of the AED.

The defibrillation energy settings of the AED are now similar to the recommended energy settings of the manual defibrillator, both for monophasic waveform and biphasic waveform AEDs.

As one of the very important elements of the new guidelines, the significance of rapid institution of chest compressions and immediate resumption of chest compressions after a defibrillation shock, is emphasized. From experience with the AED we have learned that the modern biphasic defibrillators have a very high success rate in termination of VF, whereas immediately after the shock the probability of detecting return of perfusion is low, even when the rhythm after the shock is an organized one. As a consequence, the shock algorithm now includes only one shock, which is immediately followed by a period of chest compressions. Only after 2 minutes of uninterrupted chest compressions is the rhythm checked again, a second defibrillation shock is delivered when VF is present at that time or CPR resumed again for 2 minutes when VF is not present. There is no pulse check for lay rescuers after the shock and no lengthy assessment of signs of life. Only

when spontaneous breathing appears to be normal, are assessment of signs of life or signs of a circulation recommended, postponing chest compressions and ventilation while the signs of life or return of a pulse is confirmed.

These changes in the algorithm have profound implications for the voice prompts that guide the rescuer in the actions during the use of the AED. It is expected that these changes in the voice prompts will reduce the hands-off time as previously instructed by the voice prompts that had resulted in unnecessarily long periods without CPR.[15]

Future developments

As described in the first part of this chapter, AEDs have developed into highly sophisticated tools and can hardly be compared with the first devices of 30 years ago, which could do no more than detect and treat a shockable rhythm. It is certain, however, that developments will not stop now; some new developments are already being applied to current models.

The ability to assist the rescuer in doing Basic Life Support will become more prominent. As the importance of continued chest compressions, even when an AED is used, is now recognized, both speed of chest compressions and compression depth will be monitored by transducers and the rescuers will be aided by a metronome and voice prompts or other signals to keep the chest compressions optimal in rate and depth. As chests are not uniform in size, shape, and compliance, however, other tools to give feedback for optimal chest compressions should be developed. Potentially, feedback from blood flow resulting from chest compressions will be more informative than the mechanics of the compression. These are complex and yet unresolved biomedical problems, but the work must be done.

Finding better ways to diagnose circulatory arrest are needed. Our lay criteria of unconsciousness and absence of normal breathing are quite limited in their ability to

identify a victim of circulatory arrest and tools that can identify the absence of blood flow could be very helpful, as many victims of cardiac arrest are not immediately recognized. It is possible that AEDs of the future will recognize gasping, and prompt initiation of CPR when a gasping breathing pattern is recognized.

Although AEDs are designed to shock, none is designed to pace the heart. Although asystole from prolonged VF is probably not responsive to pacing, asystole during complete heart block may well be. Also, postshock asystole may respond to pacing and it must be investigated whether this paced organized rhythm will also result in a paced perfusing rhythm, as already known and implemented in the Implantable Cardioverter Defibrillator.

There is no doubt that AEDs will be cheaper in the future. It will be important to distinguish true reduction in production costs from savings made by reducing or not including valuable features. As the volume of sales increases, larger scale production will lower these production costs. Reducing cost should then further increase their wider use. Nonetheless, as the survival rate from circulatory arrest remains low, even when AEDs are available, new developments of proven benefit should not be held back by cost considerations.

There will be many more developments not yet visible on the horizon. The hope now is that there will remain sufficient profit from AED manufacturing to provide adequate funding for the research that is needed to make the AED of the future even better than the current excellent machines.

Introduction

The development of automated external defibrillators (AEDs) enabled the potential life-saving benefit of rapid defibrillation to be extended into locations outside traditional boundaries. Defibrillation with these devices could now be provided by minimally medically trained persons such as firefighters and police officers. The survival benefit from AED deployment by such users led to the presumption that even more rapid defibrillation might be provided by placement of AEDs in public settings where large numbers of persons are present, and where defibrillation might be accomplished by even less-trained persons, and possibly even by persons not trained at all in AED use. And thus emerged the initiative known as public access defibrillation, or PAD. In this chapter, experience with PAD is described in several different settings, fortunately with acquisition and reporting of data to permit analysis of outcomes. Experience to date is surely encouraging, yet questions remain. Pell and colleagues have raised such questions pertaining to cost-effectiveness and have recommended expansion of first-responder defibrillation such as by police or firefighters and bystander cardiopulmonary resuscitation as more defensible options to PAD.[1–3]

In the PAD Trial reported by Peberdy in this chapter the low number of events is disheartening in light of the magnitude of the commitment in terms of numbers of persons trained and devices deployed, and the multiple locations in which AEDs were deployed. This observation may reflect yet another reality: the incidence of ventricular fibrillation (VF) as the presenting rhythm in out-of-hospital arrest settings is declining at an impressive rate, as reported now by several cardiac arrest investigators.[4–11] This reality imposes new obligations on those who advocate widespread deployment of AEDs in public settings. It will be necessary to define strategic locations where event rates are likely to confer cost-effective and life-saving benefit. The experience from the UK reported in this chapter appears to affirm that such locations can be identified.

Experience with PAD in the USA

Historical perspective

Public access defibrillation was first conceptualized by the American Heart Association's (AHA) "Future of CPR" Task Force in 1990. Although it was well recognized that the majority of cardiac arrests occur in the home, the thought of having lay persons respond with an AED to victims of cardiac arrest in public places was enticing. This model created the possibility for delivering defibrillation faster than most traditional EMS responses, and carried with it the hopes for substantial improvements in survival from out of hospital cardiac arrest. On the basis of recommendations of this task force, the AHA created an "AED Task Force" under the leadership of Dr. Myron Weisfeldt. This task force was responsible for the inclusion of the PAD concept in the 1992 AHA Guidelines on Cardiopulmonary Resuscitation and Emergency Cardiac Care. The following statement from the 1992 Guidelines provided a "large picture" view for what would be needed to begin to promote the concept of early defibrillation by non-traditional first responders.[12]

The placement of automated external defibrillators (AEDs) in the hands of large numbers of people trained in their use may be the key

intervention to increase the survival chances of out-of-hospital cardiac arrest patients ... The widespread effectiveness and demonstrated safety of the AED have made it acceptable for nonprofessionals to effectively operate the device. Such persons must still be trained in CPR and use of defibrillators. In the near future, more creative use of AEDs by nonprofessionals may result in improved survival ... Participants in the national conference recommended that (1) AEDs be widely available for appropriately trained people, (2) all fire-fighting units that perform CPR and first aid be equipped with and trained to operate AEDs, (3) AEDs be placed in gathering places of more than 10,000 people, and (4) legislation be enacted to allow all EMS personnel to perform early defibrillation.

The first PAD conference was held in Washington, DC in 1994. Scientists, clinicians, members of the American Heart Association, representatives of the National Heart Lung and Blood Institute, and industry leadership met and collectively confirmed the need for future research and investigation in this area. Again, on the basis of the discussions during this conference, an official AHA Statement on Public Access Defibrillation was published in 1995.[13] This statement both supported the concept and began to develop a defined scope for PAD.

Early bystander cardiopulmonary resuscitation (CPR) and rapid defibrillation are the two major contributors to survival of adult victims of sudden cardiac arrest. The AHA supports efforts to provide prompt defibrillation to victims of cardiac arrest. Automatic external defibrillation is one of the most promising methods for achieving rapid defibrillation. In public access defibrillation, the technology of defibrillation and training in its use are accessible to the community. The AHA believes that this is the next step in strengthening the chain of survival. Public access defibrillation will involve considerable societal change and will succeed only through the strong efforts of the AHA and others with a commitment to improving emergency cardiac care.

Public access defibrillation will include (1) performance of defibrillation by laypersons at home and by firefighters, police, security personnel, and non-physician care providers in the community; and (2) exploration of the use of bystander-initiated automatic external defibrillation in rural communities and congested urban areas where resuscitation strategies have had little success.

The second PAD conference was held in 1997 and the recommendations published in 1998.[14] This international meeting further defined several details of implementation of the early PAD program and defined the original "four levels" of responders:

Level 1: Traditional first-responder defibrillation
This level includes defibrillation efforts by police, highway patrol personnel, and firefighter personnel. In many locations, firefighters are the first responders to cardiac emergencies, and yet they are often prohibited by regulations and state codes from providing early defibrillation.

Level 2: Non-traditional first-responder defibrillation
This level includes defibrillation efforts by lifeguards, security personnel, and airline flight attendants.

Level 3: Citizen CPR defibrillation
This level refers to citizens and laypeople that have received AED training. These individuals are interested in providing emergency cardiac care, usually in the setting of a home in which a family member who is a high-risk patient resides.

Level 4: Minimally trained witness defibrillation
This level refers to individuals who happen to witness a cardiopulmonary emergency and have an AED available (for example, through a worksite defibrillation program). In general, this level occurs most commonly in the home or at a worksite where one group of people has been trained and other groups have not. The untrained witness wants to help out and assist, but she has not yet received formal AED training. Another example of this level is possible if AEDs become accessible in the so-called "fire-extinguisher mode," in which the AED location is displayed prominently and any witness to an emergency has access to these devices. At present, both Food and Drug Administration and state regulations permit physician prescription of AEDs to individual homes. This level will become more feasible with the introduction of newer technology that provides more voice prompts to the user, automatic 911 dialing, and possibly 911 dispatcher-assisted defibrillation.

This leveling system divided potential responders into two main categories of "public safety responders" (Levels 1 and 2) and "lay citizen responders" (Levels 3 and 4). Attention was initially focused on increasing the numbers of public safety responders, since these persons may already be called upon as part of their job to respond to a potential cardiac arrest emergency. As efforts to implement widespread PAD programs at all levels continued it became clear that there were substantial regulatory barriers that negatively affected the ease and rapidity with which these programs could be developed. The Cardiac Arrest Survival Act (CASA) was passed into law in 2000. This act called for recommendations for the placement of AEDs in all Federal buildings and addressed the issue of partial immunity under the Good Samaritan Law. It also called for the publishing of training and implementation guidelines in the Federal Register, and served as the first Federal recognition of the importance of PAD. Much legal progress has been made since the passing of the CASA in the USA. Every state now has its own legislation supporting PAD, and also has specific wording in the local Good Samaritan

laws for lay first responders and those acting in good faith while responding to cardiac arrest emergencies.

Other regulatory decisions have also assisted in promoting the widespread implementation of PAD throughout the USA. The Rural AED Bill was passed in 2000, which authorizes the use of up to $25 million in federal funds to help rural communities purchase AEDs and train first responders how to use them. In 2001, the Federal Aviation Administration ruled that all commercial aircraft carrying at least 30 passengers and one flight attendant are required to have an AED on board. The law also required the training of all flight attendants in how to perform CPR and use an AED. Final compliance for this ruling was in 2004. Also in 2001, the government released new guidelines for the placement of AEDs in federal facilities such as post offices, military bases, and federal parks to stress the importance of an optimal response time of less than 3 minutes.

Until recently, AEDs could only be purchased with a prescription and had to be used under the medical direction of a physician. This potential barrier for widespread placement of AEDs in public places was overcome in September, 2004 when for the first time the Food and Drug Administration granted marketing clearance for the over-the-counter sale of one manufacturer's AED designed specifically for lay users. AEDs can now be purchased and used in the USA without prescription or physician oversight.

Clinical perspective

Clinical adoption of early defibrillation with AEDs has evolved tremendously in the United States, and has demonstrated a multipronged approach to delivering defibrillation as early as possible to victims of cardiac arrest. Many EMS systems did not have first responder defibrillation capability as recently as a decade ago. One of the first mechanisms for implementation of PAD was to focus on early defibrillation by public safety personnel, such as emergency medical technicians, paramedics, and fire and police first responders, and eventually equipping nearly all ambulances throughout the country with AEDs. Fire department personnel and police are the backbone of the public safety primary response in the USA. Over 80% of police and fire agencies respond to medical emergencies and provide some level of clinical care. Adding defibrillation with AEDs theoretically should improve survival by reducing the time from collapse to first shock. White and colleagues studied the outcome of adult cardiac arrest patients in Rochester, Minnesota from 1990 through 1995.[15] The first arriving personnel delivered the shock. Of the 84 patients in the study, 31 (37%) were initially shocked by police. Thirteen of the 31 had return of spontaneous circulation and all survived to discharge. The remaining 18 patients required ACLS and had a 27% survival to discharge. Fifty-three patients were shocked by paramedics and 14 survived without the need for ACLS. There were 9 survivors from the 38 patients who required ACLS. This study showed the effectiveness of early defibrillation with AEDs by both police and paramedics, and demonstrated that it is the rapidity with which the shock is delivered that determines the outcome, irrespective of who delivers the shock. Other results evaluating first responder defibrillation with law enforcement officials have varied, depending on factors such as the efficiency of the control systems, distance traveled to rural areas, absence of a medical response culture, unease with acting as a medical care provider, variable medical direction, and frequency of refresher training.[16,17] Most cities and larger suburban areas in the USA now use public safety personnel as first responders to deliver early defibrillation.

As the concept of PAD became more widely accepted, the effort to involve more truly "lay" first responders increased. The next level of penetration for AEDs was in equipping first responders who have a "duty to act" in public places as part of their job but not necessarily with a medical response. On-site security officials and flight attendants became the next level of personnel to be trained in the use of an AED to respond to victims of cardiac arrest. American Airlines was the first US-based airline to equip its aircraft with AEDs, train flight attendants how to use them, and publish their results. There were 36 cardiac arrests in the first 2 years of the program, with 15 in documented (13) or presumed (2) VF.[18] Forty percent (6/15) of subjects with VF survived. All 6 survivors were among the 11 VF arrests that occurred in the aircraft. One of the major dilemmas to improving survival from cardiac arrest in the air is that many cases are not acted upon quickly, because the person may be assumed to be sleeping. For further improvement of the impact of AEDs in the airline industry, AEDs began to be placed in airport terminals much in the way that fire extinguishers are distributed throughout a facility. Chicago's O'Hare and Midway airports were the first to describe their findings from placing 59 AEDs throughout their terminals spaced for a retrieval time of less than 3 minutes.[19] Although security officials were trained in how to use the AEDs, almost all of the devices were in glass-faced cabinets accessible to the public. Of the 80 million passengers that pass through these airports annually, 21 suffered a cardiac arrest (18 VF) in the first 2 years of the program. Eleven were successfully resuscitated and all but one had long-term neurologically intact

survival. Half of the rescuers had no training or previous experience in the use of an AED.

Valenzuela *et al.* trained security officers in US casinos to perform CPR and use an AED.[20] They reported a survival to hospital discharge rate of 53% in the 105 patients suffering a VF arrest. Of those cases that were witnessed (86%), the mean time interval from collapse to attachment of the defibrillator was 3.5 ± 2.9 minutes, from collapse to first shock was 4.4 ± 2.9 minutes, and from collapse to arrival of EMS was 9.8 ± 4.3 minutes. This was one of the first large-scale trials of non-traditional first responders improving survival with on-site, early layperson defibrillation.

In an effort to acquire further data on more widespread use of AEDs by true laypersons in a variety of public places, the Public Access Defibrillation Trial was undertaken.[21] The PAD trial was a prospective, community-based, multi-center study that randomized public and multifamily residential locations from 24 cities throughout the United States and Canada to have lay, on-site volunteers trained in CPR alone vs. CPR plus an AED. The purpose of this trial was to determine whether or not trained laypersons without a duty to act would save more lives from out of hospital cardiac arrest by using an AED in addition to CPR compared with CPR alone. Sites qualified for participation if they had the equivalent of ≥ 250 adults over the age of 50 for 16 hours per day, or a history of one or more cardiac arrests in 2 years. Locations with on-site personnel with a duty to respond to medical emergencies, such as law enforcement officers or nurses, were excluded. Over 20 000 volunteers from 993 community units were trained to perform CPR and access EMS, with additional training in the use of the AED in the units randomized to this intervention. The AED arm received 1600 AEDs that were distributed at a density to achieve retrieval and return to the victim within 3 minutes or less. Sixteen percent of the study units were residential, and 84% were in public places and facilities. A total of 526 presumed cardiac arrests occurred during the study period, yielding 235 definite cardiac arrests after blinded review. Survival was achieved in 31 cases in the CPR + AED arm and 16 cases in the CPR only arm (RR = 2.0, CI = 1.07–3.77). Adverse events were rare and consisted mostly of device theft and varying levels of emotional distress on the part of the volunteer responder. There were no failures to shock when indicated, and no inappropriate shocks. No patient or volunteer was harmed by the use of an AED.

The PAD trial provides the first large-scale, randomized, controlled study that not only documents improved survival, but also demonstrates the safety of AEDs when used by trained lay volunteers in public locations. Evidence from the PAD trial should be generalized with caution. The sites chosen to participate had a significant percentage of people over the age of 55, who therefore were at higher risk for cardiac arrest. This, coupled with the unexpectedly low event rate, could lead to difficulties in prospectively determining the optimal public places for PAD programs. Since all volunteers were trained in both CPR and the use of an AED, when appropriate, these data should not be extrapolated to programs using untrained lay first responders. Finally, the true impact of PAD programs should be considered in relation to overall survival from cardiac arrest. Numerous studies have previously determined that approximately 80% of cardiac arrests occur in the home. PAD trial data show that only 0.6% of cardiac arrest victims in residential locations survived to hospital discharge, compared to 29.9% for those arresting in a public place. If nationwide PAD implementation occurred throughout the USA and a similar doubling of survival was seen, an add-itional 2000 to 4000 lives would be saved out of the more than 450 000 out-of-hospital cardiac arrests that occur annually.

The National Institutes of Health is currently sponsoring the Home AED Trial (HAT), scheduled to complete enrollment in late 2005 and to conclude in 2007. HAT is a randomized, controlled unblinded investigation evaluating the impact of home AED placement on survival of patients at high risk of sudden death. Eligible persons must have had a previous anterior wall myocardial infarction, no ICD placement, and have a live-in companion willing to use the AED if needed. The HAT provides first responder instruction via video, rather than traditional "hands-on" training. Information from this trial will help determine the safety and effectiveness of home AED use in high-risk patients with first responders who have not had mandatory traditional training in CPR or use of the AED.

Experience with PAD in Europe

From a technical perspective, the performance of defibrillation by minimally trained operators including laypersons became possible with the development of reliable automated external defibrillators in the late 1980s.[22,23] At that time a scheme to investigate this strategy was established in Europe by Douglas Chamberlain at Victoria Station, one of London's principal railway termini. Members of the British Transport Police working at the station were taught basic resuscitation techniques and how to use an automated defibrillator. During the first year of operation, five lives were saved by what was probably the first PAD scheme in the World.[23]

Subsequent guidance documents and position statements published by resuscitation authorities and applica-

ble to Europe have aimed to guide the adoption of PAD 2000.[24] With the exception of England, however, progress in Europe has been limited. Several reasons have been advanced for this and are well summarized in the European Society of Cardiology – European Resuscitation Council recommendations for the use of AEDs.[25] This policy document was developed from the proceedings of an international conference on PAD held in 2002, which included resuscitation experts from most European countries. Problems with the initiation of PAD schemes and reasons for the slow initial progress in Europe identified at this conference include the following.

1. A lack of generally applicable models or defined strategies for community resuscitation schemes and their likely effectiveness.

2. Regulations in some countries that seriously limit or even forbid the use of defibrillators by lay responders. Fortunately these outdated laws are gradually being replaced by more appropriate contemporary legislation.

3. Lack of clear guidance about who should be responsible for providing equipment and for administering such programs or who should act as responders.

4. Concerns about the cost of implementing PAD schemes and a lack of evidence about cost effectiveness.

5. A lack of consensus on training requirements. Common International standards have been proposed as an ideal but have yet to be agreed or implemented.[26]

6. Uncertainty about the legal status of operators of AEDs with the possibility in some countries that a civil claim for damages might be bought against the user. These concerns have been assessed as a major problem to the implementation of PAD schemes in general and have been identified as a very important issue in Germany.[27] In contrast, a detailed analysis undertaken in England by lawyers with the help of expert medical advisors raised only minor concerns.[28,29]

7. The need for common definitions and audit standards. Although there has been little international discussion about this, the issue has been addressed in detail in England.[30,31]

Such schemes that have been reported from European centers have evolved to suit the requirements and conditions of individual countries or locations.[30–36] Other reports have investigated the feasibility and potential benefit of introducing PAD, in some cases as a prelude to their introduction.[2,8,34–40] These surveys, often based on theoretical projections based on epidemiological data, have reported variable results.

One established strategy is to place AEDs in high-risk locations where they are operated by trained lay persons who work at the site.[33,41,42] This arrangement has come to be known as "on-site" defibrillation, and dramatically successful results have been reported.[41,42]

The alternative strategy is to equip trained "first responders" who are usually despatched by ambulance control centers with AEDs.[32] This is common practice in the UK, particularly in remote rural areas of England and Wales. The responder may be a lay volunteer or a member of the police or fire service; a report from Austria has even described patrol members in alpine skiing resorts acting in this role.[43] Some workers have reported schemes that use a mixture of first responder and on-site defibrillation.[33,35] The important distinction is that "first responder" has to travel to a potential casualty; they may reach the scene more quickly than a conventional EMS response, but can only rarely match the response intervals seen with "on-site" schemes. The results have been less favorable, particularly when the response is delayed.[32,44]

Public access defibrillation in England: evolution towards a national scheme

Of importance is that there are different arrangements for the administration of health services in the individual countries that constitute the United Kingdom. The largest proportion of the population (49 million) live in England with health services administered by the Department of Health (DH) in London. In Scotland (5 million) and Wales (2.9 million) the responsibility rests with devolved national administrations. Decisions made in London for England may or may not be adopted by the other countries.

During the 1990s, PAD in the UK gradually evolved along the two major pathways described, largely through the generosity of the British Heart Foundation (BHF), a major national charity. AEDs were supplied to ambulance services for use by lay first responders, to some individual police forces, and to a few fire services. In most cases, the introduction depended on the enthusiasm of individual services, but in the fire service there was considerable opposition from one of the fire brigade trade unions that restricted deployment to a limited number of services.

At the same time AEDs were also supplied by the BHF for use in an "on-site" role. Managers of exhibition halls, concert venues, sporting stadia, shopping centers, and gymnasiums / leisure centers all installed AEDs, very often with the help of the BHF, and arranged training for their staff. This deployment was largely "reactive" and carried out according to the applications received.

During this time, the voluntary first aid societies, particularly St. John Ambulance, acquired AEDs and

arranged their deployment among their trained members (usually, but not exclusively, lay first-aiders) undertaking public duties on their behalf; again the BHF provided a major source of funding. Many of these constituted an "on-site" strategy, with the operator deployed with an AED at the site of an event attended by large numbers of the general public. Many anecdotal accounts of successful resuscitation at sporting events, Remembrance Day services, and other events testified to the value of having an AED available.

Audit of these schemes was at first carried out by some individual organizations for their own purposes, and later systematic audit was established when a national scheme for the audit of all lay AED use was established by the Resuscitation Council (UK). This employs a specially designed computer database and report form described elsewhere.[31]

The English National Defibrillator Program

The major boost to PAD, and one of the principal reasons why the concept is so far advanced in the UK, came when the Government of England announced in 1999 the introduction of a scheme to place AEDs in busy public places so that some victims of sudden cardiac death could be resuscitated.[45] Funding was allocated at the outset for both the purchase of equipment and training.

The first phase of the program, which concerned the location of almost 700 AEDs, was administered by full-time staff working from central government offices in London. Considerable input to the planning, administration, and audit of the scheme came from medical advisors. The details of this scheme and its introduction have been described in detail previously.[29] Briefly, AEDs were located in busy public places identified from routine ambulance service data as sites where cardiac arrest commonly occurred. Staff who worked at these sites volunteered to be trained in basic life support and the use of an AED in classes lasting 4 hours. A standardized competency-based curriculum with adequate manikin practice is taught at each location, supplemented by the use of simulated cardiac arrest scenarios. Whereas in London, trainers from St. John Ambulance undertake the classes, at sites outside London, training is provided by the statutory ambulance services.

AEDs are located in unlocked protective cabinets at the selected locations in a density that ensures that equipment is available within notional 2 minutes' walk from any part of the premises to which the public has access.

Biphasic waveforms were used in all the defibrillators. Data about each resuscitation attempt are recorded at the location in a format compatible with the Utstein system for uniform recording of prehospital resuscitation attempts. Experience gained during this phase of auditing the program led to the design of the report form and audit methods described in detail elsewhere. The intervals between collapse and the institution of basic life support (BLS) and defibrillation are usually estimated, but are sometimes supported by data from ambulance dispatch centers or other control systems. The data on the report form is analyzed in conjunction with a download of data stored electronically in the memory chip in the AED, so that detailed analysis can be undertaken of both the electrocardiogram and the procedures undertaken during each event.

Results

The detailed audit possible with a scheme that formed a part of routine healthcare provision provided by the National Health Service has yielded valuable information.[38,39] The ambulance services consulted had indicated that the most common public places where they attended patients with cardiac arrest were transport facilities, particularly airports and mainline railway stations. Ferry terminals, underground railway stations, and bus stations were also identified. Many such sites were duly equipped with AEDs and reported every deployment of the equipment to a potential patient. In the first 250 such deployments,[41] 182 were to actual cases of cardiac arrest. The remaining 68 deployments were either as a precaution to casualties who had been taken ill for other reasons, or because initial reports had suggested the possibility of cardiac arrest. In one case, an AED was attached to a passenger who although conscious, looked very unwell. The AED subsequently documented the onset of ventricular tachycardia which degenerated into VF that responded to a single shock with the restoration of a perfusing rhythm.

As would be expected, the great majority (177/182) of arrests were witnessed. A high proportion (82%) showed VF as the first recorded rhythm; 8% showed asystole; 7% severe bradycardia; and the remainder idioventricular rhythm. The overall survival rate after defibrillation was impressive: 29% in patients presenting with VF/VT and 25% when all rhythms are considered (Table 27.1).

Of 143 cases of VF/VT where downloads were available, one or more shocks were administered (range 1–16) in 140 cases. One VF waveform was below the sensitivity of the device and equipment or operator failure occurred twice. The first shock terminated the arrhythmia at least transiently (at least 5 seconds) in 132 cases. In 74, only 1 shock was required before the patient was transferred to the

Table 27.1. Outcome of cardiac arrest by type of site and initial rhythm

| Patient group Type of site | Known VF/VT | | All rhythms |
	Proportion surviving (%)	95% confidence interval (%)	Proportion surviving (%)
Airports	21/83 (25)	17–35	22/101 (22)
Railway stations	19/50 (38)	26–52	19/58 (33)
Other	3/13 (23)	8–50	3/18 (17)
Total	43/146 (29)	23–37	44/177 (25)

Percentages are shown in parentheses, with 95% confidence intervals for survival proportions of those with known VF/VT by tape of site.

care of paramedics. None of the patients without first shock success survived to discharge. Of 44 survivors, 32 only required 1 shock on site; the remainder required 2 or more.

In most cases, the electrodes were attached to the casualties an estimated 3–5 minutes after collapse. Data obtained from ambulance services attending the sites showed average response times of 8–12 minutes. "Response time" is the interval between identification of the main complaint in the control center and the arrival of the ambulance at the scene. It does not take into account the time taken to locate a telephone and make the emergency call, interrogation by the call taker, or the time taken to reach and assess the patient after arrival (likely to be a few further minutes at a large station or airport). The use of AEDs by those working at the site is likely to have reduced the time between collapse and defibrillation considerably and is doubtless a major factor behind the excellent results achieved.

The figures presented here are the first formal evaluation of a European "on-site" PAD scheme. The results are comparable with those reported from other schemes, predominantly in the USA.[18–21] None of this evidence was published at the time that the English scheme was initiated (1999) and it represented a bold move on the part of the relevant government agencies involved.

Further evidence about the effectiveness of on-site defibrillation is available from the Resuscitation Council (UK) database.[30] This incorporates the DH data mentioned above with the results from several hundred AEDs supplied by the BHF. In 317 resuscitation attempts using AEDs placed in public places, shocks were administered in 247 (78%), ROSC occurred in 114 (36%), and 62 (20%) were discharged from hospital. Once again, the electrodes were placed on the casualty promptly, within 3–5 minutes of collapse. These figures were obtained from 138 arrests at airports, 69 at railway stations, 66 where members of the voluntary first aid societies provided an AED at a public

event, 8 at underground railway stations, 7 at other transport facilities, 11 at shopping centers, and 18 at gymnasia or other sporting facilities.

The English National Defibrillator Program (NDP): The next stages

The original proposal for the implementation of PAD on a national basis in England included the siting of a total of 3000 AEDs in the community. The second phase of the NDP began in 2004 and saw an important change of direction, with the provision of PAD becoming the responsibility of the 31 local ambulance services in the country and a core part of their NHS service provision. Funding was supplied through an award from the Big Lottery Fund (a National Lottery, some of the proceeds of which are used for community projects), and a close working relationship was established between the BHF and the DH who became partners in the administration of the next phase of the program. The funding was allocated to the procurement of the additional 2700 AEDs, to funding additional staff in ambulance services, and for administration and training.

The responsibility for implementation at a local level rests with the individual ambulance services, the additional AEDs being allocated according to a "needs assessment" undertaken by each service. Some will be used in an "on-site" role to build on the experience obtained during the first stage of the program. Others will be used by lay first responders under the control of the local ambulance service. At the time of writing, this process is at an early stage of implementation and no results are yet available. Audit is expected to be carried out as a routine in each service, however, and results should therefore be available in the future.

The partnership between the BHF and the DH also provides the opportunity to incorporate the AEDs already donated by the BHF (around 2000 by 2005) into the national strategy for PAD.

Table 27.2.

	Lay ambulance Responders	Fire service Responders	Total
Number	533	118	651
Time [a] (min)	8	12	
Shocked	186	36	222 (34%)
ROSC	68	12	80 (12%)
Discharged	21[b] (3.9%)	2 (1.7%)	23 (3.5%)

Outcome of cardiac arrests attended by first responders.

[a] Median time from receipt of call to placement of AED pads, estimated in some cases.

[b] Some arrests witnessed by a first responder dispatched to a patient judged at risk of cardiac arrest.

Percentages are shown in parentheses.

First responders in England

While there now exists a firm evidence base for the use of static AEDs installed in busy public places, the situation is less clear for their use by first responders in Europe. One prospective randomized trial in Amsterdam[32] that used police or fire personnel as first responders reported higher rates of ROSC and admission to hospital, but numbers surviving to discharge were not increased. Delays in calling for help, in handling emergency calls and in despatching were thought to have been the factors that reduced the potential effectiveness of first responders. Another study carried out in Piacenza, Italy has shown a tripling of survival (from 3.3 to 10.5%) with the introduction of 39 AEDs used by lay volunteers who achieved a reduction in response time of slightly more than 1 minute compared to that of the local EMS.[33] 12 of the AEDs were placed in lay-staffed ambulances, 15 in police cars, and 12 were installed "on-site" at high-risk locations. It is not clear how many of the arrests were actually treated by first responders and how many were treated "on-site," but the fact that 86.7% of the arrests occurred at home suggests the majority were "first responder" resuscitations.

The Resuscitation Council (UK) database contains records of arrests attended by first responders before the arrival of EMS, and a preliminary report has been presented.[44] A preliminary analysis of a more extensive series of 651 arrests attended by lay or fire service first responders dispatched by ambulance control centers, is shown in Table 27.2. In the UK, patient confidentiality issues prevent the methodical collection of hospital outcome data. Every patient in whom ROSC is achieved is followed up, but it is not always possible to establish whether or not they survived. The numbers of survivors may therefore be slightly higher than shown in the table. It is clear, however, that the results are very much poorer than those achieved by

on-site responders, almost certainly related to the much longer time taken to reach the patient and attach the AED.

PAD in other locations

In 2002, Capucci and colleagues reported their first experience with deployment of AEDs in Piacenza and the surrounding region in Italy.[35] Lay responders trained in AED operation were added to those deployed by police and fire vehicles and in public assistance volunteer groups who assisted in the care and transportation of the ill. These agencies and responses were grouped collectively under the designation Piacenza Progretto Vita (PPV). During the first 22 months of this initiative, 34/143 (23%) of the patients in the PPV group were in ventricular fibrillation and 33/211 (15.6%) of those in the EMS group. Neurologically intact survival in the PPV group was 12/34 (35%) and 5/33 (15%) in the EMS group. This difference was of borderline statistical significance ($P = 0.058$), although the number of patients in each group is small.

In 2000, Wassertheil *et al.* published their experience with early defibrillation using a tiered response strategy in two public locations in Australia (the Melbourne Cricket Ground and the Shrine of Remembrance). Manual defibrillators were used during the first half of the study by ambulance officers and certified nurses. In all 28 arrests, VF was the presenting rhythm and 20 (71%) were discharged.[46] This study might be considered a precursor to what is now known as PAD.

Kuisma and colleagues described preliminary results in a community-based pilot study in Helsinki.[34] AEDs were placed in seven public locations where the event rate was predicted to justify inclusion in such a trial. Over the 3-year period of study there were only 7 events in the PAD

locations, and only 4 of these were in VF. None were discharged from the hospital. There were 13 patients in the control group, 6 of whom were in VF on EMS arrival. Four were discharged. Obviously the numbers are very small and thus it is not possible to draw definitive conclusions. The authors pointed out an important observation: only 50% of the patients were in VF, again raising the question of cost-effectiveness in the presence of a declining incidence of VF.

In Brazil, a number of PAD initiatives are being undertaken, with legislation supporting such initiatives. At this time no patient outcome data have been reported. Varig Airlines, the Brazilian national air carrier, was one of the early commercial air carriers to equip its aircraft with AEDs. To date there is only one very preliminary reported experience with this approach, confirming the feasibility of equipping aircraft with AEDs and training flight attendants in their operation. Patient outcome data, however, are too limited to permit conclusions regarding overall cost-effective benefit.[47]

Conclusions

The results reported in this chapter provide important insights into the potential benefit of deployment of AEDs in public settings. The acquisition and reporting of accurate, credible incidence and survival data from PAD experience will provide a definitive process for assessing benefit from PAD programs in various locations. Without such data we will be left with anecdotal accounts of success, and such accounts will not in themselves be of benefit in defining the most cost-effective, durable lifesaving approaches to provision of defibrillation in various out-of-hospital cardiac arrest settings. Benefit of deployment of AEDs in home settings remains a completely unanswered question at this time. It is to be hoped that results from the Home Automated Defibrillation Trial (HAT Trial) will provide insight into this question, but that study will not be concluded until 2007.

The physiology of ventilation during cardiac arrest and other low blood flow states

Ahamed H. Idris and Andrea Gabrielli

University of Texas Southwestern Medical Center at Dallas, TX, USA
Division of Critical Care Medicine, University of Florida, Gainesville, FL, USA

Introduction

Ventilation – the movement of fresh air or other gas from the outside into the lungs and alveoli in close proximity to blood for the efficient exchange of gases – enriches blood with O_2 and rids the body of CO_2 by movement of alveolar gas out of the lungs to the outside.[1]

The importance of ventilation in resuscitation is reflected in the "ABCs" (airway, breathing, circulation), which is the recommended sequence of resuscitation practiced in a broad spectrum of illnesses including traumatic injury, unconsciousness, and respiratory and cardiac arrest. Since the modern era of cardiopulmonary resuscitation (CPR) began in the early 1960s, ventilation of the lungs of a victim of cardiac arrest has been assumed to be important for successful resuscitation.

This assumption has been questioned and the role of ventilation during resuscitation has been the subject of much research for more than a decade.[2] A number of laboratory studies of CPR have shown no clear benefit to ventilation during the early stages of cardiac arrest with ventricular fibrillation.[3–5] Furthermore, exhaled gas contains approximately 4% CO_2 and 17% O_2, thus making mouth-to-mouth ventilation the only circumstance in which a hypoxic and hypercarbic gas mixture is given as recommended therapy.[6] With the introduction of the *2000 Guidelines for Cardiopulmonary Resuscitation*, a new, evidence-based approach to the science of ventilation during CPR was introduced and continues with the publication of the 2005 edition. New evidence from laboratory and clinical science has led to less emphasis being placed on the role of ventilation following a dysrhythmic cardiac arrest (arrest primarily resulting from a cardiovascular event, such as ventricular fibrillation or asystole). Nevertheless, the classic airway patency, breathing, and circulation CPR sequence remains a fundamental factor for the immediate survival and neurological outcome of patients after asphyxial cardiac arrest (cardiac arrest primarily resulting from respiratory arrest).

This chapter reviews pulmonary anatomy and physiology, key historical studies of ventilation in respiratory and cardiac arrest, the effect of ventilation on acid–base conditions and oxygenation during low blood flow states, the effect of ventilation on resuscitation from cardiac arrest, manual, mouth-to-mouth, and newer techniques of ventilation, and current recommendations for ventilation during CPR.

History of artificial ventilation and CPR techniques

With the onset of cardiac arrest, effective spontaneous respiration quickly ceases. Attempts to provide ventilation for victims of respiratory and cardiac arrest have been described throughout history. Early descriptions are found in the Bible[7] and in anecdotal reports in the medical literature of resuscitation of victims of accidents and illness. Early examples of mouth-to-mouth ventilation are described in the resuscitation of a coal miner in 1744,[8] and in an experiment in 1796 demonstrating that expired air was safe for breathing.[9] In 1954, Elam and colleagues described artificial respiration with the exhaled gas of a rescuer using a mouth-to-mask ventilation method.[10,11]

Descriptions of chest compression to provide circulation[12] can be found in the historical literature of more than 100 years ago. Electrical defibrillation had been applied in animal laboratory research since the early 1900s and by Kouwenhoven in 1928.[11]

The modern era of CPR began when artificial ventilation, closed-chest cardiac massage, and electrical defibrillation were combined into a set of practical techniques to initiate the reversal of death from respiratory or cardiac arrest. Resuscitation is associated with hypoperfusion and consequent ischemia. Recent studies suggest dual defects of hypoxia and hypercarbia during ischemia.[13] Thus, the primary purpose of CPR is to bring oxygenated blood to the tissues and to remove carbon dioxide from the tissues until spontaneous circulation is restored. In turn, the purpose of ventilation is to oxygenate and to remove carbon dioxide from blood. The "gold standard" of providing ventilation during CPR is direct intubation of the trachea, which not only affords a means of getting gas to the lungs, but also protects the airway from aspiration of gastric contents and prevents insufflation of the stomach. Because this technique requires skill and can be difficult during cardiac arrest, other airway adjuncts have been developed when intubation is contraindicated or impractical because of lack of user skill.

Before the arrival of an ambulance, ventilation given by bystanders must employ techniques that do not require special equipment. Manual methods of ventilation (i.e., the Sylvester method, the Shafer prone pressure method, and others) consisting of the rhythmic application and release of pressure to the chest or back and lifting of the arms had been in widespread use for 40 to 50 years prior to the rediscovery of mouth-to-mouth ventilation. These manual techniques had been taught in Red Cross classes, to lifeguards, in the military, and in the Boy Scouts as recently as the 1960s, before being replaced by mouth-to-mouth ventilation as the standard for rescue breathing. Safar and Elam first showed that obstruction of the upper airway by the tongue and soft palate occurs commonly in victims who lose consciousness or muscle tone and that ventilation with manual techniques is markedly reduced or prevented altogether by such obstruction.[14,15] Subsequently, Safar and colleagues developed techniques that prevent obstruction by extending the neck and jaw and applying this in conjunction with mouth-to-mouth ventilation.[16] Although mouth-to-mouth ventilation has been studied extensively in human respiratory arrest and has been shown to maintain acceptable oxygenation and CO_2 levels, its evaluation in laboratory models of cardiac arrest and in actual human cardiac arrest has been limited.

Pulmonary physiology during low blood flow conditions

Effects of hypoxemia and hypercarbia on pulmonary airways

During respiratory and cardiac arrest, hypoxemia and hypercarbia gradually increase over time. The concentrations of both oxygen and carbon dioxide affect ventilation and gas exchange. Hypoxemia has variable effects on airway resistance, which is the frictional resistance of the airway to gas flow and is expressed by:

$$\text{Airway resistance (cm H}_2\text{O/l/s)} = \text{pressure difference} \\ \text{(cm H}_2\text{O)/flow rate (l/s)}$$

A number of studies in animals and humans, albeit with effective circulation, have shown that hypocapnia causes bronchoconstriction resulting in increased airway resistance, while the effect of hypercapnia on the airways is inconclusive.[17–22] In one study, when end-tidal CO_2 was increased from between 20 and 27 mmHg to between 44 and 51 mmHg, airflow resistance decreased to 29% of the initial mean.[17] Other studies have shown, however, that hypercapnia causes an increase in airflow resistance through a central nervous system effect mediated by the vagus nerve.[18–22] It appears that hypocapnia causes bronchoconstriction and increased resistance to flow through a direct local effect on airways, whereas hypercapnia causes increased airway resistance through action on the central nervous system.[18–22]

Hypoxic pulmonary vasoconstriction

Hypoxic pulmonary vasoconstriction is a physiologic mechanism that minimizes venous admixture by diverting blood from underventilated, hypoxic areas of the lung to areas that are better ventilated.[23] Pulmonary vessels perfusing underventilated alveoli are normally vasoconstricted. This effect is opposed by increases in the partial pressure of O_2. Hypoxic pulmonary vasoconstriction matches local perfusion to ventilation, increasing with low airway PO_2 and low mixed venous PO_2. The greater the hypoxia, the greater the pulmonary vasoconstriction until a point is reached where vasoconstriction becomes so intense and widespread that the response becomes pathologic and pulmonary hypertension develops.[24,25]

Hypoxic pulmonary vasoconstriction is inhibited by respiratory and metabolic alkalosis and potentiated by metabolic acidosis.[26] In addition, pulmonary vasoconstriction is more pronounced when pulmonary artery pressure is low and is attenuated by increased pulmonary vascular

pressure.[26] Hence, a consequence of low inspired O_2 concentration, as occurs during mouth-to-mouth ventilation, could be decreased blood flow caused by increased pulmonary vascular resistance. Whether hypoxic pulmonary vasoconstriction occurs during cardiac arrest and CPR is unknown, and warrants evaluation because hypoxemia occurs commonly.

The ventilation/perfusion ratio ($\dot{V}/\dot{Q}$ ratio): the relationship of blood flow and ventilation during low flow conditions

During normal cardiac output, ventilation is closely matched with perfusion through a series of physiologic mechanisms exemplified by the maintenance of alveolar and arterial PCO_2 within a range close to 40 mmHg at rest. But during low blood flow states, the ventilation–perfusion relationship becomes altered.

When systemic blood flow decreases, the flow of blood through the lungs decreases as well. With less venous CO_2 delivered to the lungs, less is available for elimination via exhalation and the concentration of CO_2 in exhaled gas decreases. Because CO_2 elimination is diminished, CO_2 accumulates in venous blood and in the tissues. Mixed venous PCO_2 thus reflects primarily systemic and pulmonary perfusion and is an indicator of the tissue acid–base environment. On the other hand, during low flow conditions arterial PCO_2 and PO_2 reflect primarily the adequacy of alveolar ventilation. During low rates of blood flow, if alveolar ventilation is adequate, blood flowing through the pulmonary capillary bed is overventilated because of a large ventilation–perfusion mismatch. The relationship between alveolar ventilation and pulmonary blood flow is expressed in the ventilation–perfusion ratio equation:[27]

$$\dot{V}a/\dot{Q} = 8.63 \cdot R \cdot (CaO_2 - C\bar{v}O_2)/PaCO_2$$

where $\dot{V}a$ is alveolar ventilation; $\dot{Q}$ is the volume of blood flowing through the lungs each minute; 8.63 is a factor relating measurements made at body temperature, ambient pressure, and saturated with water vapor (BTPS) to measurements made at standard temperature, pressure, and dry (STPD); R is the respiratory exchange ratio (CO_2 minute production/O_2 consumption); CaO_2 is arterial oxygen content; $C\bar{v}O_2$ is mixed venous oxygen content and $PaCO_2$ is the partial pressure of alveolar CO_2.

This equation appears simple, but it can be solved only by numerical analysis with a computer because alveolar PO_2 is an implicit variable (i.e., alveolar PO_2 decreases when alveolar PCO_2 increases) (Fig. 28.1). The ventilation perfusion ratio equation predicts that as pulmonary blood flow decreases (increasing $\dot{V}a/\dot{Q}$ ratio), arterial PO_2 and mixed venous PCO_2 will increase and arterial PCO_2 will decrease (Fig. 28.2). It predicts that, as pulmonary perfusion is further reduced ($\dot{V}a/\dot{Q}$ ratio approaches infinity), arterial PO_2 and PCO_2 approach the composition of inspired gas. In contrast, if blood flow is present, but alveolar ventilation is absent ($\dot{V}a/\dot{Q}$ ratio is zero), arterial PO_2 and PCO_2 approach the composition of mixed venous blood. A study of ventilation during precisely controlled low blood flow conditions found that arterial and mixed venous blood gases behaved as the equation predicts: as blood flow decreased, arterial PCO_2 decreased and PO_2 increased.[28]

Although mixed venous blood gases provide more accurate assessment of perfusion during resuscitation, it can be obtained during CPR only rarely; usually a pulmonary artery catheter is already present. Animal laboratory work seems to suggest that the intraosseous blood gas analysis can be a viable alternative to venous pH and PCO_2 measurements during cardiopulmonary resuscitation. In a swine pediatric model of hypoxic cardiac arrest, the intraosseous blood gas correlated closely to the mixed venous gas within 15 minutes of cardiopulmonary resuscitation. Beyond this time, the intraosseous blood gas reflected more local acid–base conditions or the effect of intraosseous administration of medications than mixed venous blood gas.[29]

Gas exchange and the transport of oxygen and carbon dioxide in blood

Hemoglobin is the principal protein of red blood cells and functions importantly in the transport of O_2 and in the elimination of CO_2 through the carbamate and bicarbonate pathways.[30] Although hemoglobin is usually considered solely in its role as a carrier of oxygen from the lungs to the tissues, it has an equally important role as a carrier of CO_2 from the tissues to the lungs. Deoxyhemoglobin binds about 40% more CO_2 than oxyhemoglobin and, conversely, when hemoglobin becomes oxygenated during passage through the lungs, CO_2 is actively driven off (Fig. 28.3). This mechanism is referred to as the Bohr–Haldane effect and is responsible for about 50% of the total CO_2 excreted by the lungs during each circulation cycle.[31,32] The principle mechanism of the Bohr-Haldane effect is the binding of CO_2 as carbamate compounds to the alpha-amino groups of hemoglobin.[33,34] When oxygen is released by hemoglobin in the tissues, a change takes place in the shape of the hemoglobin molecule, making binding sites available for the uptake of CO_2.[35] When hemoglobin takes up O_2 in the lungs, the change in hemoglobin conformation repels
Fig. 28.1. Changes in the PO_2, PCO_2, and end-capillary oxygen content in a lung unit as its ventilation-perfusion ratio is increased. The lung is assumed to be breathing air, and the PO_2, and PCO_2 of mixed venous blood are 40 and 45 mmHg, respectively. The hemoglobin concentration is 14.8 g/100 ml. (From West JB Ventilation-perfusion relationships. Am Rev Respir Dis 1977; 116: 919–943.)
Fig. 28.2. Oxygen-carbon dioxide diagram showing a ventilation-perfusion ratio $\dot{V}a/\dot{Q}$ line. The PO_2 and PCO_2 of a lung unit move along this line from the mixed venous point, $\bar{v}$, to the inspired gas point; I, as its ventilation-perfusion ratio is increased; A, alveolar gas for a lung unit with a normal ventilation-perfusion ratio. (From ref. 27.)
Fig.28.3 Reciprocating engine serves as a model of the cooperative effects of hemoglobin. The piston is driven to the right by the energy liberated in the reaction of hemoglobin with oxygen (*O₂*) and to the left by the protons (*H⁺*) and carbon dioxide (*CO₂*) liberated by respiring tissues. Diphosphoglycerate (*DPG*) and chloride ions (*Cl*) are passengers riding in company with protons and carbon dioxide. (From ref. 30.)

CO_2 and promotes its excretion. Plasma proteins also function in the transport of CO_2, but have only one-eighth the buffering capacity of hemoglobin.[36]

A small amount of CO_2 dissolves in plasma (5% to 10% of total CO_2) and a much larger amount (60%) is converted to carbonic acid intracellularly in red blood cells (RBC) through catalytic hydration. Cellular membranes are extremely permeable to CO_2. As RBCs traverse the tissue capillary bed, CO_2 diffuses into them where it is converted by carbonic anhydrase to carbonic acid, which then dissociates to bicarbonate and proton. The conversion of CO_2 to bicarbonate would soon stop if protons were not buffered by hemoglobin, and bicarbonate would otherwise be trapped within the RBC because of its polarity, preventing diffusion through the RBC membrane. A membrane transport system rapidly exchanges plasma chloride for intracellular bicarbonate, however, and preserves the CO_2-carbonic acid-bicarbonate gradient.[36] Another important aspect of the interaction of proton with hemoglobin is its effect on lowering the affinity of hemoglobin for oxygen and, by the law of action and reaction, oxygenation of hemoglobin lowers its affinity for proton. When hemoglobin is exposed to higher concentrations of CO_2 from respiring tissues, the formation of protons helps to unload O_2, which becomes available to tissues. When hemoglobin is oxygenated in the pulmonary capillaries, protons are released from hemoglobin, and bicarbonate is converted back to water and CO_2, which then diffuses out of the blood into the alveoli. Thus, oxygenation of hemoglobin actively promotes excretion of CO_2 from the lungs, and CO_2 from tissues promotes the release of O_2 from hemoglobin at the tissue level.

In summary, hemoglobin is the principal protein responsible for lung-to-tissue transport of O_2 and tissue-to-lung transport of carbon dioxide. Hemoglobin transports CO_2 as carbamino compounds and in the form of bicarbonate. These mechanisms of CO_2 exchange and O_2 transport establish that alveolar oxygenation and ventilation as well as pulmonary blood flow play crucial roles in the removal of CO_2 from the tissues. Because pH and CO_2 levels affect the affinity of hemoglobin for O_2, these factors are important during the treatment of cardiac arrest.

Ventilation during low blood flow conditions

Effect of ventilation on acid–base conditions and oxygenation

Acid–base conditions and oxygenation are important factors in resuscitation from low blood flow states such as shock[37–42] and cardiac arrest.[43–48] Hypoxemia and hypercarbic acidosis critically reduce the force of myocardial contractions,[49–53] make defibrillation difficult,[54,55] and are associated with poor outcome.[54,55] It has been observed that, during cardiac arrest, arterial blood gases do not reflect tissue conditions and that mixed venous blood has a level of CO_2 that is frequently twice the level of the arterial side.[51,52,58]

Arterial and mixed venous metabolic acidosis and mixed venous hypercarbic acidosis are associated with failure of resuscitation from cardiac arrest.[43,46,48] Studies of both human and animal cardiac arrest have shown that during CPR, the pH of blood is largely determined by the concentration of CO_2[56–71] and that arterial blood is often alkalemic whereas mixed venous blood is acidemic because of differences in CO_2 levels. A recent Norwegian study measured arterial PCO_2 and pH in patients receiving tidal volumes of 500 ml vs. 1000 ml several minutes after intubation during

out-of-hospital cardiac arrest (mean time, approximately 15 minutes).[72] The study showed that mean PCO_2 was 28 and 56 mmHg with 1000 ml and 500 ml tidal volume, respectively. These results indicate that tidal volume affects arterial PCO_2 and pH significantly: larger tidal volume is associated with respiratory alkalosis and smaller tidal volume is associated with respiratory acidosis.

The arteriovenous PCO_2 gradient increases substantially during CPR and returns to near normal when spontaneous circulation is restored.[13,38,57,62,64,73–75] The CO_2 gradient likely results from reduced blood flow through the lungs, decreased pulmonary elimination of CO_2, accumulation of CO_2 on the venous side of the circulatory system, and overventilation of blood entering the arterial side (Fig. 28.4).[13,56,62,73] A recent study showed that changes in ventilation could affect excretion of CO_2 even when blood flow rate is as low as 12% of normal.[28] In addition, with decreasing blood flow, the decrease in end-tidal CO_2 parallels the decrease in arterial PCO_2. Thus, both arterial PCO_2 and end-tidal CO_2 vary directly with blood flow, while mixed venous PCO_2 varies inversely with blood flow.

Mixed venous PCO_2 and pH can be improved with proper ventilation and become worse with hypoventilation. Nevertheless, there are major interactions among the mechanics of positive pressure ventilation, intrathoracic pressure, and blood flow. Positive pressure ventilation can have such a profound effect on hemodynamics that overventilation can result in decreased blood flow and worse tissue hypoxia and hypercarbia. This issue is discussed in greater detail in the section on ventilation and hemodynamics.

Effect of ventilation on ventricular fibrillation and defibrillation

Sudden death is thought to be a primary cardiac electrical event and may not be a result of myocardial injury, although there is often underlying myocardial ischemia, which can reduce electrical stability and lead to ventricular ectopy. The event is often fatal and is probably initiated by ventricular tachycardia, or ventricular fibrillation. Investigations have shown that hypoventilation, hypoxemia, hypercarbia, and metabolic acidosis can lower the threshold for ventricular fibrillation as well as affect the tendency of the heart to develop ventricular arrhythmias. Further, arterial hypoxemia has been shown to cause arrhythmia by excitation of the autonomic nervous system and by affecting vagal tone.[76] Both hyperventilation and hypoventilation are associated with severe ventricular and supraventricular arrhythmias.[77] Hypoxemia and other factors such as hypoglycemia, hyper- and hypokalemia
Fig.28.4. The relationship of the arteriovenous carbon dioxide gradient and cardiac index follows the form of a modified Fick equation: (mixed venous CO – arterial CO_2) × cardiac index – k, where $k < 0$. During control minute ventilation, $k = 20.2 = 2.1$ (95% confidence limits = 16.0 to 24.5), concordance n = 0.82, ($P < 0001$). (From ref. 28.)

cause ventricular fibrillation by shortening the duration of the cardiac action potential.[78] Hypercarbia without hypoxemia has been shown to lower the ventricular fibrillation threshold and respiratory alkalosis raises the ventricular fibrillation threshold and enhances spontaneous recovery from ventricular fibrillation.[79] In another study, ischemia, but not hypoxemia, lowered the ventricular fibrillation threshold.[80]

The effect of ventilation on the defibrillation threshold, which is the minimum electrical energy required for defibrillation of a fibrillating ventricle, has not been studied directly. Instead, the defibrillation threshold has been investigated under conditions of hypoxemia, and metabolic and hypercarbic acidosis, either alone or in combination.[46,48,54,81] The findings of different studies have been somewhat contradictory, but generally show that the defibrillation threshold is unaffected by acid-base conditions existing either before or during CPR. However, more recent studies using animal models of cardiac arrest suggest that hypercarbia is associated with ventricular fibrillation refractory to defibrillation.[46,52,55] Coronary

perfusion pressure, duration of untreated ventricular fibrillation, and duration of CPR are critical factors known to affect success of defibrillation.[82]

A human study of factors that influenced the success of defibrillation found that arterial hypoxemia and acidemia, and delay in defibrillation attempts were associated with failure to defibrillate,[54] but it was not possible to distinguish the effect of these factors independently because they tended to occur together. A canine study, in which ischemia, ventricular hypertrophy, hypoxemia, acidosis, and alkalosis were well-controlled independent variables, did not find an adverse effect of these factors on defibrillation threshold.[81] Surprisingly, hypoxemia was found to lower the threshold for defibrillation. Another study found that metabolic acidosis, but not metabolic alkalosis or respiratory acidosis or alkalosis, lowered the threshold for ventricular fibrillation.[83] More recent laboratory CPR studies of hypercarbic acidosis found a substantial reduction in rate of resuscitation. Although the defibrillation threshold was not investigated, four of six animals ventilated with 50% CO_2 had refractory ventricular fibrillation.[46] In other studies of acid-base conditions, most animals with sufficient coronary perfusion pressure during CPR were defibrillated, but only animals without substantial hypercarbia recovered adequate cardiac output.[52,55,84–88] A recent study of human CPR also found that return of spontaneous circulation was associated with improved levels of arterial and mixed venous PO_2 and PCO_2.[44]

There are important differences in physiology during normal cardiac output and CPR that may not be widely appreciated. For example, high levels of arterial and mixed venous hypercarbia are usually tolerated by humans[89] and animals[46,90–93] when there is normal spontaneous cardiac output. Nevertheless, during cardiac arrest, hypercarbia substantially reduces success of resuscitation by adversely affecting myocardial contractility.[46,52,55,84–88] At least one laboratory study found that hypercarbia was associated with refractory ventricular fibrillation.[55] In this rat model, very high levels of inspired and thus, myocardial, PCO_2 were produced and may help explain the difference in findings of another study[81] that used more modest levels of hypercarbia and failed to find an effect on defibrillation threshold.

Among factors that can affect the likelihood of defibrillation, the duration of ventricular fibrillation is known to be of great importance.[94] In human CPR, the rate of successful defibrillation is approximately 80% or more if it is administered immediately after onset of witnessed ventricular fibrillation, but the chance of survival decreases 7 to 10% for each additional minute of ventricular fibrillation.[95,96] When bystander CPR is provided, the decrease in survival is more gradual, about 3% to 4% per minute from collapse to defibrillation. A similar effect of duration of ventricular fibrillation is seen in laboratory CPR models[97–99] and may be explained, in part, by the gradual depletion of myocardial adenosine triphosphate, which is thought to be a marker for ischemic tissue damage and the metabolic state of the myocardium.[100] In addition, potassium uptake by myocardial cells is increased during ventricular fibrillation and is related to hydrogen ion, CO_2, and lactate production.[101] Earlier work found that the ratio of intracellular to extracellular potassium concentration affected the defibrillation threshold.[102]

In summary, hypoxemia and hypercarbia decrease the threshold for ventricular fibrillation. Hypoxemia and hypercarbia have a negligible effect on the defibrillation threshold when the duration of ventricular fibrillation is brief. Recent studies suggest that hypoxemia and hypercarbia make defibrillation more difficult when ventricular fibrillation persists for several minutes or more.

Effect of ventilation on myocardial force and rate of contraction

Studies with an isolated heart model demonstrated that hypoxia and hypercarbia caused a profound decrease in myocardial force of contraction independent of pH (Fig. 28.5).[53,103–106] In studies that examined the effect of hypercarbia on isolated spontaneously contracting myocytes, the rate and force of contraction are inhibited by modestly increased concentrations of CO_2, with pH held at 7.40 and PO_2 at 142 mmHg.[107] The model demonstrated a rapid and profound effect of CO_2 independent of pH, PO_2, vascular tone, neuroendocrine factors, or inflammatory mediators. In contrast, isolated decreased blood or perfusate pH is not associated with reduced ventricular force of contraction.[49–53] The reason for these differences in myocardial response to extracellular CO_2 and hydrogen ion is that CO_2 is a non-polar, lipid-soluble molecule that is permeable to cellular membranes and diffuses rapidly into the intracellular space. Once CO_2 enters the cell, it lowers intracellular pH by dissociating to hydrogen ion and bicarbonate. In contrast, hydrogen ion is polar, diffusing at a very slow rate through cell membranes, and this may account for its lack of effect on myocardial dynamics under most experimental conditions.[108] There is accumulating evidence that reduced intracellular pH affects calcium ion flux, exchange, and binding, and ultimately affects excitation-contraction coupling and myocardial contractility.[108]

During ventricular fibrillation, the heart continues to perform work and very likely has energy utilization
Fig.28.5. Peak isovolumic left ventricular pressure (*LVP*) expressed as percentage of value at zero time. Zero time is at 10 minutes of perfusion under ischemic conditions (33 mmHg) and at time of alteration of perfusate. In control hearts, perfusate was not altered (From ref. 53.)

greater than during normal contractions; metabolites in the form of hydrogen ion, lactate, and CO_2 continue to be produced. With the onset of ventricular fibrillation, myocardial CO_2 tension increases rapidly from a normal value of approximately 50 mmHg to 350 mmHg and there is a parallel increase in hydrogen ion concentration (Fig. 28.6).[74,103] As noted above, the removal of CO_2 from tissues depends upon blood flow; thus, coronary blood flow is an important co-factor influencing levels of myocardial CO_2. A coronary perfusion pressure of less than 10 mmHg was associated with myocardial CO_2 tensions >400 mmHg and failure of resuscitation, while a coronary perfusion pressure of greater than 10 mmHg was associated with myocardial CO_2 tensions <400 mmHg and successful resuscitation.[109] Decreased intracellular pH is associated with changes to the structure and function of regulatory and enzyme proteins and, if not corrected soon enough, leads to irreversible loss of cell function and cell death.[110]

In summary, both isolated hypoxemia and isolated hypercarbia have a negative inotropic effect on the heart.

Ischemia would be predicted to be a more injurious event than hypoxemia or hypercarbia alone, because ischemia causes both decreased delivery of O_2 and decreased elimination of tissue CO_2. To the extent that ventilation can affect the elimination of CO_2 and enhance tissue oxygenation, it can likely provide some benefit during cardiac arrest and CPR. There are promising therapies that perfuse the heart with oxygen-containing fluorocarbon compounds (SAPO: selective aortic arch perfusion and oxygenation) resulting in higher rates of restoration of spontaneous circulation after prolonged cardiac arrest and CPR.[111]

Interaction of hypoxemia and hypercarbia with the vasopressor effect of catecholamines

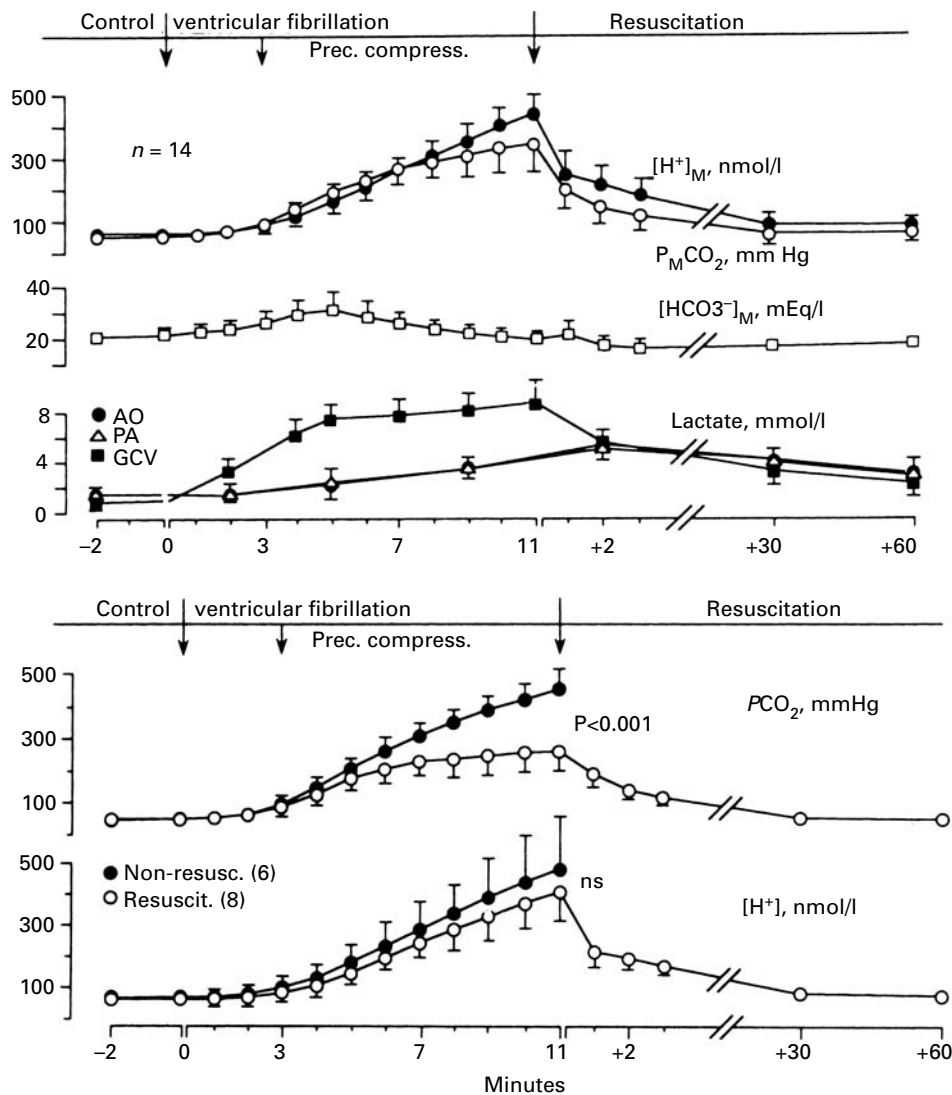
The administration of such catecholamines as epinephrine during CPR has been considered essential for successful resuscitation. Numerous studies and years of experience treating cardiac arrest have shown that adrenaline is often a pivotal factor in reversing sudden death by


Fig. 28.6. *Top:* Increases in myocardial hydrogen ion [H^+] and myocardial PCO_2 (P_MCO_2) together with increases in lactate content in blood sampled from the great cardiac vein. More moderate increases in lactate content of systemic blood were documented. Values are mean = SD. *Bottom:* Myocardial PCO_2 and [H^+] in resuscitated and non-resuscitated animals. *Prec. increasing coronary perfusion pressure and the likelihood of defibrillation.[112] The efficacy of pressors on later outcome measures such as survival to discharge or neurological outcome, however, is less certain. The purpose of this section is to review and analyze the interaction of ventilation with the vasopressor activity of epinephrine and other catecholamines.

A number of studies have shown that increases in blood PCO_2 in animal models and in humans results in a

decrease in the pressor response to epinephrine and norepinephrine by more than 50%.[113–115] The mechanism for the failure of blood pressure to increase is primarily decreased peripheral vasoconstriction and vascular resistance[113–119] with a smaller contribution from a cardiac arrhythmia other than tachycardia[113–115] Metabolic acidosis (i.e., increased hydrogen ion concentration) has also been found to inhibit vasoconstriction, but to a much smaller degree than "respiratory" acidosis (i.e., increased

PCO_2).[119] With return of CO_2 to normal levels, the inhibitory effect of hypercarbia on epinephrine activity is reversed completely within 10 minutes in human volunteers with normal cardiac function.[118]

Hypoxemia also has been found to decrease the pressor response to epinephrine.[51] Hypoventilation, through simultaneous hypoxemia and retention of CO_2, causes greater peripheral vasodilation and loss of the pressor effect of epinephrine than does isolated hypercarbia or hypoxemia alone.[51] Few studies specifically examine the effect of ventilation on the pressor response to catecholamines during cardiac arrest and CPR. Successful resuscitation is associated with epinephrine-induced increases in coronary perfusion pressure, and there are data suggesting that hypoxemia and hypercarbia may modulate the increase.[120,121]

Respiratory and circulatory system interactions

Spontaneous breathing produces negative intrathoracic pressure during inspiration. Therefore, beyond respiratory functions of gas exchange, spontaneous ventilation plays an important role in maintaining cardiac output by enhancing venous return to the chest and heart.[122–124] Venous return to the heart is greatest during inspiration because negative intrathoracic pressure creates a pressure gradient between thoracic blood vessels and those outside the chest. In contrast, assisted positive pressure ventilation with mechanical ventilators and self-inflating bags produces positive intrathoracic pressure during inspiration, reducing venous return to the chest and, as a result, reducing cardiac preload and subsequent cardiac output. For a given airway pressure, pleural pressure depends on the compliance of the lung and chest wall. According to the mode of ventilation, airway pressure can be dependent on a number of variables, including inspiratory flow rate and time, tidal volume, ventilation rate, and degree of intrinsic positive end-expiratory pressure (auto-PEEP). Holding all other factors constant, the higher the ventilatory rate, the greater the proportion of time with positive intrathoracic pressure and thus the greater is the potential for hemodynamic compromise (Fig. 28.7). For example, assuming an inspiratory:expiratory ratio of 1:1, and an inspiratory time of 1 second, positive intrathoracic pressure is present 40% of the time with a ventilation rate of 12/min; 66% at 20/min; and 100% of the time with a rate of 30/min. Auto-PEEP can even occur with ventilation rates of 30 in normal lungs, or even at lower rates when the lungs are compromised from such conditions as obstructive lung disease, or other conditions with impaired expiratory flow.[125,126]
Fig. 28.7. Illustration of the effect of positive-pressure ventilation on intrathoracic pressure during ventilation rates of 12, 20, and 30 breaths per minute in a hypothetical patient with normal lungs. Positive intrathoracic pressure is present 40% of the time with a ventilation rate of 12/min, 66% of the time at a rate of 20/min, and 100% of the time at 30/min. (Original illustration by AH Idris.)

Excessive assisted ventilation can impair cardiac preload and output

The potential detrimental effects of positive pressure ventilation on hemodynamics have been well-known since the seminal description by Cournand *et al.* more than a half century ago, which demonstrated proportionate reductions in cardiac output as airway pressure increased.[127] A number of studies have shown that both intermittent PPV and positive end-expiratory pressure (PEEP) can impair cardiac output even in normally functioning hearts because of reduced venous return,[125–130] A critical factor in the development of auto-PEEP is the minute ventilation (due to excessive tidal volume, and/or increased respiratory rate) and decreased expiratory time, and it has been described as a common etiology of pulseless electrical activity during resuscitation.[125,126] Again, the major mechanism of cardiac output impairment is diminished cardiac

preload, and the effects are even more pronounced in progressively hypovolemic states.[127,129,130]

Excessive assisted ventilation can lead to brain ischemia and hypoxia

In the U.S., blunt trauma accounts for approximately 80% of severe injuries, and frequently is associated with traumatic brain injury (TBI).[131] Every year, TBI results in 52 000 deaths and 90 000 people with permanent neurological disability.[132] Secondary insults such as hypoxemia and hypotension occur frequently in severe TBI, and are associated with worse outcomes. Although "therapeutic hyperventilation" has been recommended in the past to reduce intracranial pressure, it has been shown to reduce cerebral blood flow enough to cause brain tissue ischemia, especially when the patient is in shock.[133–140] Therefore, the American Association of Neurological Surgeons now recommends that hyperventilation ($PaCO_2$ < 35 mmHg) should be avoided during the first 24 hours after TBI except when signs of brain herniation are present or when specialized monitoring is available, thus excluding the prehospital setting.[141] Nevertheless, hyperventilation not only occurs very commonly in the prehospital setting, but often remains the perceived mandate for patients with TBI.[142,143] Hyperventilation during conditions of low blood flow, such as traumatic hypotension and cardiac arrest, also may further decrease blood flow to an already ischemic brain.[134,135,138,139,144–146] A number of recent studies have shown that excessive ventilation, as indicated by $ETCO_2$ levels < 30 mmHg, is associated with increased mortality rates.[147,148] Large volume crystalloid fluid resuscitation, which is used for hemorrhagic hypotension, also is associated with increased mortality in the presence of TBI.[149] Therefore, avoidance of hyperventilation may be a useful strategy to avert secondary brain injury, improve perfusion, and to decrease the volume of crystalloid necessary for resuscitation of severely injured people.

Excessive assisted ventilation during shock and cardiac arrest

Rescuers often are unable to judge appropriate timing and have a tendency to use excessive ventilation rates in stressful situations.[142,150,151] For example, although the American Heart Association had recommended about 12 breaths/minute during non-traumatic CPR, respiratory therapists have been observed to use a mean ventilation rate of 37/minute (range, 24 to 68/minute).[150] Other studies have documented ventilation rates greater than 20 breaths/minute during in-hospital CPR.[152,153] Similarly, in a recent study of cardiac arrest, the investigators observed that EMTs were using an average rate of 34 breaths/ minute despite focused training directives not to do so.[151]

Positive pressure ventilation rate during low blood flow conditions

During hemorrhagic hypotension, blood pressure is substantially affected by the rate of positive pressure ventilation. In one study, systolic blood pressure decreased significantly when ventilation rate was changed from 12 to 20 breaths/minute and decreased further with 30 breaths/ minute;[130] however, blood pressure increased when ventilation rate was decreased from 12 to 6 breaths/minute. The study emphasizes the principle that the duration of increased intrathoracic pressure is proportional to the ventilation rate when positive pressure ventilation is used. Another principle is that blood pressure is inversely proportional to ventilation rate.

A study of cardiac arrest and CPR showed that 24-hour survival was only 1 of 8 animals by using 20 breaths/ minute, and was substantially improved to 7 of 8 animals when a ventilation rate of 12 breaths/minute was used.[151] Other studies showed the best improvement in 24-hour survival from cardiac arrest occurred with ventilation rates of 4 to 6 breaths/minute and the greatest oxygen delivery to tissues occurs with a ventilation rate of 6 breaths/ minute during CPR.[154–160] A recent laboratory study of cardiac arrest compared CPR that used a compression:ventilation ratio of 15:2 with that of a ratio of 30:2. The study showed improved coronary and cerebral perfusion pressures and 24-hour survival with the 30:2 ratio without significant differences in arterial PO_2 or PCO_2.[161]

Recognition of the substantial problem of excessive ventilation rate during low blood flow conditions such as cardiac arrest, the good sense of trying to match ventilation with perfusion, and the importance of chest compressions has resulted in significant changes in guidelines for CPR. The American Heart Association Guidelines 2005 now recommend that rescuers use a compression:ventilation ratio of 30:2 during CPR when the victim does not have an advanced airway (endotracheal tube, laryngeal mask airway, Combitube, or other device) in place.[162] Once an advanced airway is placed, chest compressions should be given continuously without interruption for ventilation and no more than 8–10 ventilations/minute are now recommended.

When the victim has been resuscitated with return of a pulse, the recommended ventilation rate is 10–12 breaths/minute.

Tidal volume, pulmonary vascular resistance, and intrathoracic pressure

The effect of lung inflation on pulmonary vessels is complex. At abnormally low lung volumes, vessels are collapsed and pulmonary vascular resistance is increased.[27] When the lung is inflated, collapsed vessels open and resistance decreases. But at high inflation volumes, alveolar capillaries are compressed and resistance increases. Underventilation and ventilation perfusion mismatch at low lung volumes result in a progressive decrease in lung compliance and an increase in alveolar–arterial oxygen tension difference. Because blood flow is inversely related to pulmonary vascular resistance, if the lungs are poorly inflated during CPR, pulmonary blood flow may possibly decrease further. The alpha-adrenergic effect of adrenaline during cardiac arrest specifically depresses PO$_2$ absorption and CO$_2$ elimination of low $\dot{V}/\dot{Q}$ lung units. Vasopressin has significantly less adverse effect on pulmonary gas exchange after CPR. It has been speculated that vasopressin could exert rehabilitation to pulmonary circulation through the agonist effect of the V2 vasopressinergic receptor,[163] but few data are available in this area.

Continuous positive airway pressure ventilation (i.e., CPAP or PEEP) given during both the compression and release phase of chest compression would be expected to interfere with venous return and to decrease blood flow just as it does during spontaneous circulation.[164] PEEP can also be the inadvertent result of excessive tidal volume, increased respiratory rate, and reduced inspiratory time (auto PEEP) and has been related to increased incidence of pulseless electrical activity during resuscitation.[125]

An impedance threshold device that causes negative intrathoracic pressure during CPR and hemorrhagic shock has been shown to increase venous return, right myocardial pre-load, blood pressure, and blood flow to the heart and brain.[165–168] It also has been shown to improve survival from cardiac arrest and hemorrhagic shock. The device is based on the physiologic principle that negative intrathoracic pressure enhances venous blood return to the chest and heart, thus making increased cardiac output possible.

Application of continuous positive airway pressure (CPAP) without active ventilation has been recently studied in CPR. In a pig model of cardiac arrest, CPAP titrated to achieve 75% of a baseline end-tidal CO$_2$ was compared with intermittent positive pressure ventilation.[169] A significant difference in both airway pressure and

diastolic blood pressure was detected between the two techniques (27 ± 58 mmHg in CPR vs. 13 ± 11 mmHg in CPR$_{CPAP}$), and arterial and mixed venous pH, O$_2$ saturation, and CO$_2$ were improved in the CPR$_{CPAP}$ animals. Cardiac output did not change significantly between the two methods. This technique has the potential advantage of simplifying CPR, decreasing pulmonary atelectasis, and improving both oxygenation and ventilation. Nevertheless, it can also have a negative effect on diastolic blood pressure and, thus, on both coronary and cerebral blood flow.

Despite the potential for decreased venous return, it is possible that very small amounts of positive airway pressure may decrease intrapulmonary shunting, pulmonary vascular collapse, and atelectasis without adverse hemodynamic effects. Indeed, recent use of a multi-slice CT scanner to allow dynamic imaging of tridimensional volume of the lung during CPR suggested that CPAP was superior to simple volume controlled ventilation or no-ventilation CPR in maintaining better lung distension and preventing atelectasis.[170]

In conclusion, movement of venous blood into the lungs takes place during the release phase of external chest compression when intrathoracic pressure is low. When the chest is compressed, intrathoracic pressure rises and blood moves out of the lungs and heart and into the systemic circulation. Negative airway pressure enhances blood flow and venous return to the chest, while continuous positive airway pressure ventilation inhibits venous return and blood flow but decreases lung atelectasis. These studies emphasize the crucial relationship between ventilation mechanics and circulation.

Effect of ventilation on outcome from resuscitation

For over 30 years, emergency ventilation has been considered an essential component of CPR. There are few studies and little direct evidence that ventilation affects outcome from cardiac arrest, although it has been assumed crucial for resuscitation. Recommendations for ventilation were based on studies performed in the 1950s and 1960s in living humans with normal cardiac output.[14–16] These studies presumed that the goal of ventilation during CPR was to achieve near "normal" tidal volumes and minute ventilation. Substantially less ventilation may be sufficient for gas exchange during CPR, however, because cardiac output and pulmonary blood flow are only 10% to 15% of normal during manual chest compression.[171] As a consequence, the amount of hemoglobin passing through the pulmonary bed is reduced and the amount of oxygen necessary to saturate hemoglobin is also reduced if there is not a large ventilation/perfusion mismatch. Because

venous return and thus the quantity of CO_2 delivered to the lungs are decreased, the amount of ventilation necessary to remove CO_2 is presumably reduced as well.

The time when ventilation must be initiated during CPR and the quantity needed to achieve satisfactory results are unclear. In a canine model of cardiac arrest, arterial pH, PCO_2, and PO_2 had no significant change after 5 minutes of untreated ventricular fibrillation,[172] while arterial PO_2 decreased from 81 to 69 mmHg under similar conditions in a swine model.[173] In the canine study, there was no significant change in arterial PO_2 and PCO_2 for 30 seconds after initiation of chest compressions without ventilation. At 45 seconds, arterial PO_2 was 52 mmHg, a significant decline. Another canine study showed that chest compression alone without assisted ventilation will produce a minute ventilation of 5.2 ± 1.1 l/min and will maintain O_2 saturation $> 90\%$ for more than 4 minutes.[4] A murine study found that chest compression alone produced tidal volumes of 26% of baseline and, although arterial PCO_2 increased to 80 mmHg after 9 minutes, resuscitation rate was not impaired.[5,174] The animals were intubated in all of these studies. It is likely that ventilation induced by chest compression would be less in non-intubated models, but this would affect blood gases is unknown.

Other studies have shown that ventilation has an important role in resuscitation. An early study showed that well oxygenated dogs had better carotid artery blood flow than did asphyxiated dogs. This was attributed to loss of peripheral vascular tone.[175] Weil and colleagues showed that spontaneous gasping during cardiac arrest in a swine model favored successful resuscitation, and also showed that both the frequency and duration of gasps correlated with coronary perfusion pressure and predicted outcome.[176]

More recent studies were specifically designed to test the effect of ventilation on outcome in swine models of CPR. One study compared a group receiving mechanical ventilation during CPR with a group receiving chest compression alone and a group without chest compression or ventilation. The duration of untreated ventricular fibrillation was 30 seconds, followed by 12 minutes of CPR in the treatment groups. All animals were successfully defibrillated and entered a 2-hour intensive care period. After 24 hours, however, only two of eight animals that had no CPR survived, while all 16 animals survived in the groups receiving chest compression with and without ventilation.[3] Another study allocated 24 swine to groups with and without ventilation during 10 minutes of chest compression following 6 minutes of untreated ventricular fibrillation. Nine of 12 ventilated animals and only 1 of 12 non-ventilated animals had return of spontaneous circulation. The non-ventilated animals died with significantly

greater arterial and mixed venous hypoxemia and hypercarbia.[177] A follow-up study was done to test whether hypoxemia or hypercarbia independently affects survival from cardiac arrest. By using a swine model of isolated arterial and mixed venous hypoxemia without hypercarbia in one group, and isolated hypercarbia without hypoxemia in another group, only 1 of 10 animals had return of spontaneous circulation in each group.[121]

Other experimental work in large animals showed that survival and neurological outcome up to 48 hours were not different when ventilation was withheld during resuscitation. These initial studies, although clearly de-emphasizing the importance of ventilation during the first few minutes of CPR, were limited by the persistence of an "artificial" patent airway in the animal, which resulted from the presence of an endotracheal tube allowing exchange of ventilations from gasping and chest compressions/decompressions.[178,179]

More recent studies eliminated the possible influence of an artificial patent airway in animal models during CPR. When standard CPR was compared with compression-only CPR in a pig model in which the airway was occluded, no difference was found in 24-hour outcome.[180] Of note, a supine, unconscious dog or pig usually has a patent airway, whereas a supine, unconscious human has an obstructed airway resulting from the kinked nature of the human airway. These model differences are rarely discerned in CPR ventilation experiments, but do have fundamental clinical importance. These latest observations confirmed that ventilation for a few minutes after dysrhythmic cardiac arrest was not fundamental and suggested the need to test the no-ventilation hypothesis in humans.[181]

There are important differences among all these studies, including duration of untreated ventricular fibrillation, the use of 100% O_2 before cardiac arrest, and whether or not agonal respirations were prevented with a paralytic agent. Nonetheless, taken together, these studies provide some evidence that ventilation may possibly be withheld when chest compression is initiated promptly after cardiac arrest, but that ventilation is important for survival when chest compression is delayed.

There are even fewer human studies of the role of ventilation during cardiac arrest. Because ventilation is such a well-accepted intervention, the ethical considerations of doing a controlled study by withholding ventilation in one group have been difficult to overcome. Indirect evidence pointing to a less important role of ventilation immediately after cardiac arrest has existed since the early 1990s. For example, in Seattle, where ambulance response time is short, patients who were seen to have spontaneous agonal respiratory efforts immediately after cardiac arrest had a higher rate of successful resuscitation.[182] Another study

found that hypoxemia and hypercarbia was associated with the use of the esophageal obturator airway in the field and also a lower resuscitation rate.[65] Mixed venous hemoglobin oxygen saturation is associated with prognosis for survival from cardiac arrest; mixed venous pH, PO_2, and PCO_2 measured during hemorrhagic shock and cardiac arrest were significantly better in those with return of spontaneous circulation.[44,183] In the Netherlands, clinical CPR is given in the order "CAB" (chest compression–airway–breathing) with ventilation being delayed and chest compression being initiated as soon as possible. With use of "CAB," CPR survival data from the Netherlands are comparable to those reported in the USA.[184] Human data also suggest that prompt chest compression after cardiac arrest improves brain and heart perfusion and the success of defibrillation.[185]

More human studies have become available in the last few years. In a prospective, observational study of CPR and ventilation, chest compression-only CPR, and no CPR, survival from CPR (i.e., return of spontaneous circulation) was found to be 16%, 15%, and 6%, respectively.[186] Although both forms of basic life support (BLS) were significantly better than no CPR, there were no differences between CPR with or without ventilation. Similar results were reported more recently in North America in a study of telephone dispatcher-assisted BLS–CPR in which survival of chest compression-only CPR vs. mouth-to-mouth ventilation and chest compression CPR was 14% vs. 10%, respectively, with a slight trend of survival favoring chest compression-only CPR.[187] Although this study emphasized that CPR without ventilation is better than nothing, it presents several limitations in design. Mouth-to-mouth ventilation performed by a bystander was assumed to be done and was not observed directly by the investigator at the scene; the patency of the airway was unclear in some patients, and primary respiratory arrests were excluded. In addition, if the bystander knew how to perform CPR, then the patient also was excluded from the study. Nevertheless, the study suggested a need to reconsider BLS with a goal of minimizing the time to onset of CPR in the cardiac arrest victim and maximizing the efficacy of chest compression. When the concept of this "simplified CPR" was tested in a mannequin, effective compression was achieved an average of 30 seconds earlier than with the standard technique, and the number of compressions per minute were approximately doubled.[188] Dispatcher instructions for chest compression-only CPR is quite sensible, considering the difficulty of trying to teach mouth-to-mouth ventilation in addition to chest compression over the telephone to an anxious rescuer. Also, trying to teach how to perform ventilation over the telephone takes as much as 1–2 minutes of time away from doing CPR.

Despite the overall enthusiasm for the relatively positive results of dispatcher-assisted CPR instructions without ventilation as described by the providers[186,187] it has been emphasized by independent observers that the concept of no-ventilation CPR could be a misnomer, because, provided that the airway is open, patients with ventricular fibrillation cardiac arrest often exchange a significant amount of air through gasping.[189] Therefore, the term "CPR without assisted ventilation" has been suggested. Although the North American literature seems to de-emphasize the importance of ventilation in the first few minutes after cardiac arrest, a recent Swedish report of 14 000 patients showed increased survival to 1 month for "complete CPR" (both chest compressions and ventilation) versus "incomplete CPR" (compression only) (survival, 9.7% vs. 5.1%; $P < 0.001$).[190]

In that study, ventilation, and duration of less than 2 minutes between patient collapse and the beginning of lay bystander CPR, were both powerful modifying factors on survival at 30 days, emphasizing the need for better and earlier CPR. A limitation of these out-of-hospital studies is the lack of proper neurological examination during or immediately after resuscitation. Therefore, the relative influence of ventilation on cerebral perfusion is unclear. In swine models, pupillary diameter light reaction was used and found to have a reasonable correlation with cerebral perfusion pressure. However, the animal was ventilated during resuscitation with a tidal volume of 15 ml/kg at an FiO_2 of 1.0. It is unknown whether these clinical findings could be used in a human prospective randomized study during CPR to evaluate the level of influence of ventilation on neurological outcome.[191]

It is logical that ventilation should be matched with perfusion of blood through the lungs and the systemic circulation. Thus, when blood flow is zero, ventilation is unnecessary because it would not affect tissue oxygenation and CO_2 removal. Nonetheless, with CPR techniques that improve blood flow, such as use of device adjuncts for chest compression, more ventilation may be necessary.

The duration of ventricular fibrillation before the start of chest compression is likely to be of significance regarding the need for ventilation, although the importance of ventilation in CPR has been de-emphasized in favor of the need for more effective chest compression and early defibrillation. Indeed, it is likely that time of defibrillation is an important factor in determining whether ventilation is necessary for successful resuscitation. The etiology of cardiac arrest is another very important factor related to the role of ventilation in CPR. Ventilation has primary importance when cardiac arrest occurs from asphyxia,

such as in drowning, and is the most frequent cause of pediatric cardiac arrest.

In summary, recommendations for ventilation during CPR are based on numerous laboratory studies that are somewhat contradictory, computer models, and limited human studies. After evaluating the sum of available evidence, a consensus of international experts continues to recommend ventilation, although at a reduced rate and minute volume during CPR and in the postresuscitation period.[162]

Techniques of ventilation during CPR

Ventilation techniques that can be used for basic CPR by the lay public: manual, mouth-to-mouth, and mouth-to-mask ventilation

In the 1950s and early 1960s alternative methods of artificial respiration were investigated in addition to mouth-to-mouth ventilation. A number of studies showed that the application of external pressure to the chest during manual maneuvers in normal volunteers caused substantial respiratory tidal volumes that ranged from 50 to 1114 ml (Fig. 28.8).[10,14–16,192–197] The rate of manual ventilation was 10 to 12 compressions/minute and total minute ventilation (the product of tidal volume and respiratory rate per minute) provided by these techniques was 0.5 to 11.1 l/min. When these techniques were applied to patients with pre-existing pulmonary disease, tidal volumes were considerably lower (50 to 540 ml) than in healthy subjects.[197] These studies also noted that tidal volumes generated by actively expanding the chest with arm-lift or hip-lift techniques were 20 to 40% greater when compared with passive chest expansion.[195] Techniques that relied exclusively on passive chest expansion were ineffective for adequate ventilation and resulted in mean arterial oxygen saturations of 67% in normal volunteer subjects.[192] Manual techniques that included active chest expansion produced mean arterial oxygen saturations of 93% in human subjects, and thus were able to maintain acceptable gas exchange without positive pressure ventilation.[192] In contrast with the manual techniques previously mentioned, pressure applied directly over the sternum of curarized, intubated volunteers produced mean tidal volumes of only 156 ml. Furthermore, without intubation, sternal pressure produced no tidal exchange because of airway obstruction by the tongue.[15] With the head extended to prevent airway obstruction, however, five of six patients had tidal volumes greater than 340 ml and three of six had tidal volumes in excess of 500 ml.

Simultaneous with studies of manual ventilation techniques, mouth-to-mouth ventilation was also studied extensively. Several research projects were funded by the Department of the Army because of the urgency of problems of resuscitation in nerve gas poisoning. In one study, 29 volunteers were paralyzed with curare, and mouth-to-mask resuscitation was started before the onset of cyanosis.[198] The arterial oxygen saturation of the volunteers receiving artificial ventilation was never below 85% and the mean oxygen saturation was 94%. Alveolar CO_2 tensions, measured in 21 patients, were maintained at or below 50 mmHg. The mean alveolar CO_2 concentration was 5.6% before resuscitation and 3.9% during resuscitation. Expired gas resuscitation produced a fall in alveolar CO_2 concentration in all 12 patients. The authors concluded that with mild hyperventilation, the rescuer readily converted his exhaled gas to a suitable resuscitation gas. These experiments were designed to simulate a respiratory arrest and only healthy volunteers were studied. Whether exhaled gas would benefit a patient who suffers cardiac arrest was not considered and has not been investigated.

Because exhaled gas contains CO_2, it may have adverse cardiovascular effects during CPR, but few investigations have addressed this issue. A study of the effect of ventilation on resuscitation during CPR in an animal model showed that both hypoxemia and hypercarbia independently have an adverse effect on outcome from cardiac arrest. Swine were ventilated with experimental gas mixtures consisting of 85% oxygen in a control group, 95% O_2 and 5% CO_2 in a hypercarbic group, and 10% O_2 and 90% N_2 in a hypoxic group. The model succeeded in producing isolated hypoxemia without hypercarbia and isolated hypercarbia without hypoxemia. Only one of 10 (10%) animals could be resuscitated in each of the hypercarbic and hypoxic groups, while 9 of 12 (75%) animals were resuscitated in the control group.[121]

A study of the composition of gas given by mouth-to-mouth ventilation during simulated one- and two-rescuer CPR showed that the rescuers exhaled a mean concentration of CO_2 of 3.5 to 4.1% and a mean concentration of O_2 of 16.6 to 17.8%.[6] Therefore, the gas given by mouth-to-mouth ventilation has a similar concentration of CO_2 and is more hypoxic than the gas shown to be deleterious in the above-cited animal study. When compared with mouth-to-mouth ventilation, room air is a superior gas for ventilation, because it contains 21% oxygen and a negligible amount of CO_2 (0.03%).

Furthermore, when these gas concentrations were used in a swine model with 6 ml/kg ventilation, profound arterial desaturation was noted and was shortly followed by hemodynamic instability and hypotension.[199] This instability and

desaturation were not observed if the tidal volume was increased to 12 ml/kg, or if a fraction of inspired oxygen of 0.70 was used with a tidal volume of 6 ml/kg. Two main features make older human studies different from more recent animal laboratory experiences: the patients described in the original case reports were typically paralyzed, and the rescuer hyperventilated to the point of feeling dizzy, and had an arterial partial pressure of CO_2 of about 20mmHg.[10]

These differences highlight the need for more controlled human studies before recommending withholding mouth-to-mouth ventilation during cardiac arrest.

Of note, an important factor might affect the feasibility of such studies: a widespread fear of acquiring contagious diseases from victims of cardiac arrest that has recently resulted in reluctance among the lay public, and even some health professionals, to perform mouth-to-mouth ventilation.

Infectious disease concerns published in the literature include *Helicobacter pylori*, *Salmonella*, *Herpes simplex* virus, tuberculosis, HIV, and the hepatitides.[200–203] Being repulsed by the sight of a victim in agony and the fear of doing harm may also affect the decision to provide mouth-to-mouth ventilation. Recent surveys of CPR instructors reported that all would perform mouth-to-mouth ventilation on a 4-year-old drowned child, but only 54% on a college student, 35% on a hemophiliac, 18% on a stranger in a bus in San Francisco, and 10% on a person who had overdosed on heroin.[204,205] Awareness of new infectious disease issues, if not new infectious diseases, has resulted in the current recommendation of the AHA to use barrier devices to protect the rescuer against contamination with any infective secretions.[203] Effective barriers against contamination increase efficacy and effectiveness of CPR, helping the rescuer to overcome fear of contamination and immediately to start resuscitation. The overall willingness to perform bystander CPR is disappointingly low in the United States, Europe, and Japan, however, for laypersons and healthcare providers alike. Different reasons are likely responsible for this widespread attitude. In the United States and Europe, the factor deterring performance of mouth-to-mouth ventilation by a bystander or health care provider is fear of contracting infectious diseases. This differs from the situation in Japan, where unwillingness to perform mouth-to-mouth ventilation is mostly a result of lack of confidence in a person's ability to perform CPR properly.[206] The difference may be related to the 200-fold lower incidence of HIV in Japan, as compared with the United States.[207]

Education and increased retention of proper mouth-to-mouth ventilation technique is fundamental but difficult to apply to all populations. The use of television spots as a means of teaching basic skills of CPR in at-risk populations has been explored in Brazil. Although television spots seem to increase skill retention over 1 year, mouth-to-mouth ventilation and effective external cardiac compression are recognized as skills that depend on supervised practice with mannequins. Although the study is limited, it makes sense to use an alternative methodology to promote resuscitation skills in the lay population, including the use of educational clips or scenarios in entertaining and motivating television spots.[208] Recently, a 20-minute video-based basic life support course with a new, inexpensive manikin was studied in two cities and showed skill retention rates at 2 and 6 months that were as good as those seen in students who took the standard 4-hour course.[209,210] In addition, A 5-minute course on use of an automated external defibrillator (AED), when combined with the 20-minute CPR course, showed equivalent skill retention for correct AED use 6 months after training when compared with a standard 4-hour course.[211]

While recent evidence-based literature acknowledges the importance and efficacy of CPR without ventilation, the need for assisted ventilation in cardiac arrest with asphyxia (cardiac arrest primarily resulting from respiratory arrest) or in pediatric populations (generally younger than 8 years of age) cannot be overemphasized.[212] Cardiac arrest with asphyxia was originally illustrated in the first case of external chest compressions.[213] The rationale of ventilation during CPR for cardiac arrest is based on the assumption that CPR delays brain death in no-flow situations, and that hypoxia and respiratory acidosis can aggravate the injury. A critical decrease of brain ATP of 25% below the normal level has been observed after 4 minutes in an animal model of decapitated normothermic dog.[214]

In general, arterial partial pressure of oxygen is maintained within the normal range for approximately 1 minute in a dog model of chest compressions without ventilation.[215] Furthermore, when asphyxia is the cause of cardiac arrest, oxygen consumption has reached near complete exhaustion, and CO_2 and lactate have significantly accumulated just before cardiac arrest. This is in contrast to ventricular fibrillation, in which hypoxemia and acidemia become significant only several minutes after the onset of cardiac arrest. In a model of resuscitation after asphyxia (clamping of the endotracheal tube in an anesthetized pig), the animal subjects were randomly selected to receive resuscitation with and without simulated mouth-to-mouth ventilation. Return of spontaneous circulation was noted only when ventilation was added to chest compression.[216] Successful chest compressions and mouth-to-mouth rescue breathing allowed complete neurological recovery in 90% of the animals.

The presence of a foreign body obstructing the airway is an uncommon but important cause of cardiac arrest with asphyxia, with an incidence of 0.65 to 0.9 per 100 000 cardiac arrests.[217] A recent study seems to support in part the original investigation of Ruben and MacNaughton,[218] in that abdominal thrust is not necessary in foreign body

choking, and that chest compressions can achieve higher airway pressure than the Heimlich maneuver.[219] Indeed, when CPR was performed and compared with an abdominal thrust in the cadaver, median and peak airway pressure reached a value of 30 cm H_2O vs. 18 cm H_2O and 41 cm H_2O vs. 26 cm H_2O, respectively. Only in a moderately obese cadaver was the mean airway pressure produced by the Heimlich maneuver higher than that produced with chest compression. The European Resuscitation Council (ERC) also addressed acute asphyxia from airway obstruction.[220]

Despite recent knowledge that occurrence of ventricular fibrillation in children may be more frequent than was previously thought,[221] asphyxia is still the most common cause of cardiac arrest in the pediatric population. The Pediatric Resuscitation Subcommittee of the Emergency Cardiovascular Care Committee of the American Heart Association (AHA) worked with the Neonatal Resuscitation Program Steering Committee (American Academic of Pediatrics) and the Pediatric Working Group of the International Liaison Committee on Resuscitation to review recommendations on oxygenation and ventilation in neonatal resuscitation.[222] The approach to the recommendations has been the same as that described in the AHA Guidelines 2000 for adults, which uses five classes of recommendations centered on evidence-based reviews of scientific reports. Up to 10% of newborn infants require resuscitation at birth. The majority, because of meconium airway obstruction/aspiration, require immediate intervention and assisted ventilation. Because of their unique physiology, the importance of ventilation/oxygenation in newborns cannot be overemphasized. Fluid-filled lungs and intra- as well as extracardiac shunts at birth are physiologically reversed in the first few minutes of extrauterine life with either spontan-eous or assisted vigorous chest expansion. Failure to normalize this function may result in persistence of right-to-left, intra- and extracardiac shunt, pulmonary hypertension, and systemic cyanosis. Bradycardia usually follows, with severe hemodynamic instability and rapid deterioration to cardiac arrest. Although these physiologic characteristics are typical of the newborn (minutes to hours after birth), similar events can be triggered by hypoxia in neonates (first 28 days of life) and infants (up to 12 months of age). The importance of proper ventilation/oxygenation and the small margin of safety resulting from the unique physiology and high oxygen consumption of the newborn mandate the need for immediate ventilation and the presence of skilled personnel at the bedside to perform proper basic steps of resuscitation. Clearance of meconium fluid should be immediately performed, upon birth, and providing positive pressure ventilation should be considered within 30 seconds when bradycardia or apnea is present. Tracheal intubation remains the gold standard for providing immediate ventilation/oxygenation to the newborn. European and American guidelines have essentially the same sequence of resuscitative events in neonates, recommending a chest compression–to-ventilation ratio of 3:1, with about 90 compressions and 30 breaths per minute with emphasis on quality of ventilation and compressions.[223,224]

A major change to guidelines for CPR occurred with publication of the 2005 International Consensus Conference on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science With Treatment Recommendations.[224] It is now recommended that lay rescuers or a lone professional rescuer use a 30:2 compression:ventilation ratio for infants, children, and adults. This recommendation is intended to simplify training and reduce interruptions of chest compression, which is known to have a negative effect on outcome. When two or more professional rescuers are present, a compression:ventilation ratio of 15:2 is recommended for infants and children.[224,225] The airway patency, breathing, and circulation approach to CPR sequencing was not modified The sequence of when to call 911 (activate the EMS system) has also been modified and is now based on presumed etiology of the cardiac arrest (dysrhythmic vs. asphyxial). For *unwitnessed* or non-sudden collapse, start CPR immediately, give 5 cycles of chest compressions and ventilation, then activate EMS and get an AED. For *witnessed* sudden collapse, activate EMS/get an AED, start CPR, then attempt defibrillation.[225]

In summary, ventilation remains essential in cardiac arrest with asphyxia in both adult and pediatric patients. The need for immediate ventilation in dysrhythmic cardiac arrest is less clear, however, and has less emphasis in CPR guidelines since 2005. It is clear that future studies are needed to address the ideal compression:ventilation ratio, the ideal minute volume, and whether mouth-to-mouth ventilation during cardiac arrest is any better than chest compression without rescue breathing, and the optimal "exhaled" volume to be provided to the victim.

Positive pressure ventilation in an unprotected airway: the problem of gastric insufflation and pulmonary aspiration

Manual techniques of ventilation used for rescue breathing were in widespread use from the early 1900s to the early 1960s, when they were replaced with mouth-to-mouth ventilation. Although manual techniques were capable of providing reasonably good tidal volume and

minute ventilation in patients with patent airways, a major drawback was that prevention of upper airway obstruction was not an integral part of the technique, and airway obstruction could prevent movement of air. The principal advantage of mouth-to-mouth ventilation is that providing an open airway through backward tilt of the head and lifting of the mandible is part of the technique. Also, because the provider is immediately aware of upper airway obstruction when increased resistance to

ventilation is encountered, further steps can be taken to relieve the obstruction.

Upper airway obstruction in an unconscious patient is caused by occlusion of the oropharynx by the relaxed tongue (Figs. 28.9 and 28.10). The base of the tongue is retracted against the posterior wall of the pharynx when the head is in a flexed position and occurs whether the patient is in a supine or prone position. Extension of the head can relieve obstruction in most patients and the addition of forward displacement of the mandible and/or an oropharyngeal airway opens the airway completely in 88 to 98% of subjects.[226–228] Studies of manual techniques of ventilation showed that the back-pressure-arm-lift method produced a mean tidal volume of only 126 ml when the head was allowed to remain in a natural position, but with extension of the head, tidal volume increased to 520 ml and only one of six subjects (17%) had a tidal volume that was less than dead space (Fig. 28.11).[228]

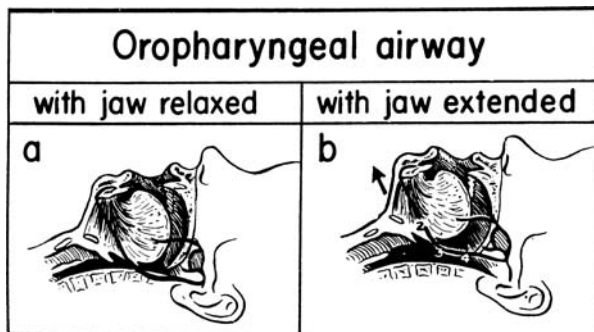
Unlike manual techniques of ventilation that produce negative intrathoracic pressure to move air into the lungs, mouth-to-mouth ventilation uses positive pressure to inflate the lungs. Because air under pressure can flow into the esophagus as well as the trachea, a frequent complication of mouth-to-mouth ventilation is gastric insufflation. Peak inflation pressure is directly related to the product of inspiratory flow rate and airways resistance. Delivering a


Fig. 28.9. When the mandible is extended by lifting it upward, the hyoid bone and floor of mouth are also drawn upward. This maneuver makes forward displacement of the tongue obligatory, since it is attached to the mandible, hyoid bone, and floor of mouth. (From ref. 198.)

large tidal volume over a brief inspiratory time results in increased peak inflation pressure and leads to gastric insufflation and hypoventilation in victims with an unprotected (not intubated) airway. The volume delivered to the lungs can be increased by using a longer duration of inspiration and a lower inspiratory flow rate.[229] The pressure necessary to move gas into the lungs depends on airway resistance and total thoracic compliance, which is equal to the sum of chest and lung compliance:

$$\text{Compliance (l/cm H}_2\text{O)} = \text{change in volume (l) / change in pressure (cm H}_2\text{O)}$$

Lung compliance decreases with decreasing lung volume and the tidal volume necessary to prevent decreased compliance is approximately 7 ml/kg of body weight in patients with normal lungs. Lung compliance also is decreased by pulmonary edema and atelectasis. Chest compliance is decreased by kyphoscoliosis, scleroderma, obesity, and the supine position.

Chest compression has been shown to affect compliance during cardiac arrest and compliance decreases with each minute of chest compression.[230] Compliance becomes a crucial factor for ventilation when the upper airway is not intubated. Because the trachea, pharynx, and esophagus are all exposed to the same positive pressure during mouth-to-mouth ventilation, or bag-mask ventilation, air could preferentially enter the stomach via the esophagus. During cardiac arrest and CPR, chest compliance decreases and thus greater pressure is needed to inflate the lungs adequately. At the same time, lower esophageal sphincter tone decreases during cardiac arrest and there is less resistance for air to enter the stomach.[231,232]

Work done in anesthetized patients found that the pressure needed to produce gastric insufflation ranged from 10 to 35 cm H_2O with a face mask technique of ventilation and the most frequent pressure needed for insufflation was 15 cm H_2O.[233] Regurgitation of gastric contents and pulmonary aspiration does not occur with chest compressions alone, but requires inflation of the stomach.[234,235] Mouth-to-mouth ventilation was shown to cause regurgitation in 48% of patients, probably because of gastric insufflation.[235] In a study of non-survivors of cardiac arrest, 46% were found to have full stomachs and at least 29% had evidence of pulmonary aspiration of gastric contents.[236] Similar complications occur with the use of a bag-mask ventilation device in patients with unprotected airways.[238] Aside from pulmonary aspiration of gastric contents, gastric insufflation, if sufficient, causes elevation and splinting of the diaphragm with consequent loss of lung volume, decreased compliance, hypoventilation, and greater risk of further

gastric insufflation. Gastric insufflation can be prevented in many patients by applying pressure over the cricoid to seal off the esophagus.[237] In addition, manual techniques of ventilation would not be expected to produce gastric insufflation, because inspiratory airflow is caused by negative airway pressure and airflow during expiration is associated with very low airway pressures of approximately 0 to 1 cm H_2O.[238,239]

Effectiveness and safety of ventilation of the unprotected airway have been extensively studied in bench models. When a mechanical ventilator was used to provide tidal volumes of 500 ml and 1000 ml, respectively, in an in vitro model of an unprotected airway, significantly less stomach inflation was found when a smaller tidal volume (approximately 500 ml) was applied with a mechanical ventilator compared with a tidal volume of approximately 1000 ml.[241] For the same reason, the use of a smaller, pediatric, self-inflating bag delivering a maximal volume of 500 ml showed less gastric inflation in the same model when compared with the large adult bag.[199,241] All of these studies suggest that when the peak airway pressure exceeds lower esophageal sphincter pressure during ventilation of an unprotected airway, the stomach is likely to be inflated. As a result, a tidal volume of 6 to 7 ml/kg body weight (approximately 500 ml) and an inspiratory time of 1 second is recommended for assisted ventilation.[162,224]

The performance of the apparatus used to deliver bag-valve mask (BVM) ventilation has recently been reviewed extensively. Seven commercially available models of ventilating bags used on an advanced cardiac life support training mannequin connected to an artificial lung, in which compliance and resistance were set at normal, have been evaluated for the tidal volume achieved.[242] Interestingly, standard ventilations with one hand averaged a tidal volume between 450 to 600 ml in both genders, despite significant differences in the size of male and female hands. When the technique was modified to open palm and total squeezing of the self-inflating bag against the flexed rescuer's knee, next to the patient's head, total volume ranged from 888 to 1192 ml. This study seems to indicate that most of the commercially available ventilating bags can provide both 6 ml/kg to 12 ml/kg tidal volume, with and without available oxygen, in a reliable manner. This study was performed on a mannequin with normal compliance and resistance, however, and gastric inflation was not measured.

When ventilation is provided to a victim of cardiac arrest, proper tidal volume cannot be easily assessed. Excitement and overenthusiasm of the professional rescuer at the scene of cardiac arrest can increase the chance of gastric inflation.[243] In a recent intriguing paper from Austria, it was shown that the stomach inflation of the victim, as assessed by postresuscitation chest radiograph, was minimal and statistically lower (15%) when the lay bystander provided mouth-to-mouth ventilation versus when professional paramedics ventilated the victim with a BVM device.[244] There are many possible explanations for these results, which are partially related to the limitation of the chest radiograph as a test to assess gastric inflation and the lack of autopsy reports from the non-surviving victims. It is also possible that "extreme efficiency" of ventilation by the paramedics as compared with the bystander's mouth-to-mouth ventilation determined the difference. This finding, combined with the observation that professional rescuers tend to squeeze the bag very rapidly during the excitement of CPR (generally in < 0.5 s and with power), suggests the need for better teaching of basic manual resuscitation skills.[241]

Limiting the size of the ventilating bag to a pediatric volume could theoretically decrease the danger of delivering an exaggerated tidal volume during CPR. If oxygen is not available at the scene of an emergency, and small tidal volumes are given during BLS ventilation with a pediatric self-inflatable bag and room air (21% oxygen), insufficient oxygenation and/or inadequate ventilation may result. Recently, 80 patients were studied who were randomly allocated to receive ventilation with either an adult (maximum volume, 1500 ml) or pediatric (maximum volume, 700 ml) self-inflatable bag for 5 minutes while apneic after induction of general anesthesia and before intubation. The study used ventilation with 40% O_2 and showed no significant difference in mean arterial O_2 saturation (98% vs. 97%) or $ETCO_2$ (26 vs. 33 mmHg) with the adult or pediatric bag, respectively.[245] The investigators did a follow-up study using the same methodology, but this time they used room air instead of 40% O_2 as the ventilating gas.[246] When using an adult ($n = 20$) versus pediatric ($n = 20$) self-inflatable bag, tidal volumes and tidal volumes per kilogram (mean ± standard error) were significantly larger (719 ± 22 ml/kg vs. 455 ± 23 ml/kg and 10.5 ± 0.4 ml/kg vs. 6.2 ± 0.4 ml/kg, respectively; $P < 0.0001$). Compared with an adult self-inflatable bag, BVM ventilation with room air and use of a pediatric self-inflatable bag resulted in lower arterial PO_2 values (73 ± 4 mmHg vs. 87 ± 4 mmHg; $P < 0.01$), but comparable CO_2 elimination (40 ± 2 mmHg vs. 37 ± 1 mmHg; not significant), indicating that smaller tidal volumes of about 6 ml/kg (approximately 500 ml) given with a pediatric self-inflatable bag and room air maintain adequate CO_2 elimination, but decrease oxygenation during simulated BLS ventilation. This study confirms previous observations that if small (6 ml/kg) tidal volumes are used during BLS ventilation, supplemental oxygen is needed, and when oxygen is not available, larger tidal volumes of about 8 to 10 ml/kg should

be used to maintain both sufficient oxygenation and CO_2 elimination when circulation is normal.[199]

In conclusion, proper mask ventilation is a fundamental skill of resuscitation and should receive a high priority in training of both adult and pediatric providers.[249,250] Using recommended guidelines for tidal volume and inspiratory time, pulmonary ventilation can be maximized and gastric inflation can be minimized. However, gastric inflation and pulmonary aspiration can be completely prevented only when the airway is protected with endotracheal intubation, always regarded as the "gold standard" of providing ventilation during CPR.

Ventilation caused by chest compression: standard and active chest compression–decompression

When the chest is pressed with the hands or a mechanical device, intrathoracic pressure increases above atmospheric pressure and air flows out of the lungs if the upper airway is unobstructed. Air flows back into the lungs when pressure on the chest is released and the thorax recoils passively, creating negative intrathoracic pressure. Although the tidal volume caused by chest compression usually is less than the dead space, effective gas exchange can take place under certain conditions, particularly if the frequency of compression is high enough.

Knowledge of dead space is helpful in understanding high frequency ventilation. Inhaled air passes through the conducting airways to the alveoli where gas exchange takes place. The conducting airways (the nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles) do not participate in gas exchange and have a volume, termed anatomic dead space, of about 150 to 180 ml in the adult human.[1] The total volume of alveoli not perfused with blood and thus not participating in gas exchange is called alveolar dead space. Physiologic dead space is the sum of anatomic and alveolar dead space, and is the volume of the lung that does not eliminate CO_2. Physiological dead space is a functional measurement, approximating 2.2 ml/kg of lean body weight. Physiological dead space increases during conditions of ventilation-perfusion inequality. During conventional ventilation, tidal volume must exceed physiological dead space for effective delivery of O_2 and elimination of CO_2. During high frequency ventilation, gas exchange can take place when tidal volume is less than physiologic dead space, presumably because of enhanced diffusion and mixing of gases.

Ventilation caused by chest compression is a form of high frequency ventilation, which is defined as lung ventilation at a frequency of at least four times the normal breathing frequency, usually with tidal volumes less than anatomical

dead space.[249] Gas exchange depends on several mechanisms, including bulk flow of gases, molecular diffusion, asymmetric velocity profiles where the profile is direction-dependent, cardiogenic mixing, mixing caused by turbulent airflow, and inter-regional "pendelluft" due to time-constant inequalities, which results in gas from fast-filling lung units redistributing into slow-filling units.[249,250]

High frequency ventilation has been produced by applying external pressure to the chest by means of a pressure cuff around the thorax. In a canine experiment, high frequency ventilation with use of chest compression with tidal volumes of approximately 50 ml and frequencies of 3 to 5 Hz (180 to 300 compressions per minute) produced better arterial oxygenation and elimination of CO_2 than did conventional ventilation at standard tidal volumes and rate.[251] The effectiveness of high frequency ventilation depends on where compression is applied to the body. One study found that it is more effective when applied to the abdomen.[252] High frequency ventilation was found to have equally efficient gas exchange when applied at the trachea or the chest[253] and provided enhanced ventilation in a model of airway obstruction.[254–256] Adequate gas exchange can take place with tidal volumes as low as 12% of dead space.[257]

There is a striking similarity between high frequency ventilation with chest compression and chest compression during cardiac arrest. The recommended frequency of chest compression during CPR is approximately 2 Hz (100 compressions per minute). If obstruction of the upper airway can be prevented, then tidal volume can be produced during sternal compression. In an intubated swine cardiac arrest model, a study showed that sternal compression with a mechanical device produced ventilation with a mean tidal volume of 45 ml during the first minute of resuscitation that decreased to 16 ml during the 10 minute (Fig. 28.12). Because chest compressions were given at a rate of 100 per minute, minute ventilation was 4.5 l during the first minute of resuscitation and 1.6 l during the 10 minute. When compared with conventional ventilation, however, CO_2 elimination was less with chest compression ventilation, resulting in significantly greater hypercarbic acidosis.[238]

Active compression–decompression CPR is a technique of chest compression in which force is applied to the chest during both downward compression and upward lifting decompression by means of a suction cup applied to the chest. Thus, the chest is actively re-expanded with this technique instead of passively recoiling as in conventional CPR. It has been shown that during CPR, thorax and lung compliance gradually decrease over time, thus explaining, in part, why ventilation produced by conventional chest
Fig. 28.12. Minute ventilation (L/min + SD) caused by external chest compression in swine without additional mechanical ventilation. Animals received either standard mechanical chest compression (*Standard*) (n = 8) or mechanical active chest compression–decompression (*ACD*) (n = 8) (Data from Idris AH. Wenzel V. Tucker KJ. Orban DJ. Chest compression ventilation: a comparison of standard CPR and active-compression/decompression CPR. Acad Emerg. Med 1994; 1: A17 refs. and 240).

compression decreases over a 10-minute period. Active compression–decompression CPR may overcome the loss of compliance because the chest is forcibly re-expanded. In another swine study of CPR, active compression–decompression chest compression was compared with conventional chest compression (Fig. 28.12).[239] The tidal volume and minute ventilation caused by active compression–decompression were twice that of standard chest compression, did not decrease during 10 minutes of CPR, and produced significantly better arterial pH, PO_2, and PCO_2.

An interesting recent application has been the use of adjunct CPAP and pressure support ventilation (CPAP-PSV) during the decompression phase. In a swine model of cardiac arrest, CPAP-PSV showed a significantly higher PaO_2 and lower A-aDO$_2$, maintaining moderate hypercarbia when compared with control animals. Remarkably, an unexplained increase of VO_2 was observed in all the animals with applied CPAP-PSV.[258]

Gasping ventilation

Gasping appears to be much more common than previously thought within the first few minutes of cardiac arrest.

Investigators reported the presence of gasping or agonal respiration in as many as 55% of witnessed cardiac arrest victims.[259–261] Gasping is often mistaken for normal breathing, with the unfortunate consequence that bystanders withhold CPR for up to 40% of victims with confirmed cardiac arrest. The American Heart Association Guidelines 2005 now emphasize recognition of gasping breaths and initiating CPR if the rescuer is unsure if the person is breathing normally.[162]

Current standards for ventilation during CPR and adjunct devices for ventilation

The American Heart Association has developed a set of training tools and guidelines for cardiopulmonary resuscitation and emergency cardiovascular care.[262] Control of the airway during cardiopulmonary resuscitation is divided into three general categories: basic airway management, advanced airway control, and postresuscitation airway management.

Basic management of the airway entails establishing unresponsiveness, calling for help, opening the airway with various maneuvers, maintenance of airway patency, determination of apnea, and provision of ventilation and

oxygenation in conjunction with chest compression. Advanced airway control requires endotracheal intubation and use of ancillary equipment to support ventilation and oxygenation. Following successful resuscitation, the patient may remain supported by endotracheal intubation and mechanical ventilation.

Basic airway management

Basic airway management is indicated for patients who suffer respiratory and/or cardiac arrest. Primary respiratory arrest may occur during drowning, foreign body obstruction, smoke inhalation, drug overdose or anaphylactic reaction, cerebrovascular accident, thermal or electrical injury, trauma, acute myocardial infarction, epiglottitis, sepsis, and coma of whatever cause. Early initiation of rescue breathing may improve survival and prevent cardiac arrest.

The goal of basic airway management is to provide enough oxygen to the brain and heart until definitive medical treatment can restore normal heart and ventilatory activity.[262] Rescue breathing brings oxygen into the lungs while chest compression promotes oxygen transport from the lungs to vital tissues. Immediate initiation of resuscitation is necessary, because the highest rate and quality of survival are achieved when basic life support is started within 4 minutes from the time of arrest and when advanced cardiac life support is initiated within 8 minutes.[263]

Provision and maintenance of a patent upper airway

The maneuvers utilized to provide a patent upper airway in an unconscious patient are designed primarily to relieve obstruction by the tongue gravitating toward the posterior pharyngeal wall. Relaxation of the head and neck muscles supporting the mandible during loss of consciousness results in the loss of the tongue's muscular tone. When the tongue falls against the posterior pharynx, it causes obstruction of the upper airway. Airway obstruction is aggravated in a comatose patient by a semi-flexed neck, which causes narrowing of the distance from the tongue to the posterior pharynx. The epiglottis also tends to fall back onto the glottis. Furthermore, breathing against an obstructed upper airway pulls the tongue toward the airway, worsening the obstruction. The negative pressure generated in the airway during inspiration causes a ball valve type of tracheal obstruction. Even in normal, spontaneously breathing anesthetized patients, some airway obstruction occurs in 90% when the head is in neutral position and the airway is unsupported.[226]

Unless contraindicated, the victim should be properly positioned, before resuscitation is started: a firm, flat surface, with the arms alongside the body, is preferred. The patient's head should be below the level of the thorax. If the victim is prone, the patient should be moved supine as a unit to avoid twisting the head neck or back. The rescuer should kneel beside the patient's shoulder. Spontaneous breathing should be ascertained. Several maneuvers are utilized to open the airway. In Europe, it is taught that breathing should be ascertained in the position the victim is found. The victim is positioned supine if respirations cannot be assessed or if they are absent.

Head tilt/chin lift maneuver

In the absence of head and neck trauma, the head tilt/chin lift maneuver is utilized to open the airway (Fig. 28.13(a)).[264] This maneuver is also referred to as the "sniffing position" and is considered to be the most effective method of opening the airway of an unconscious victim. A roll or towel may be placed under the victim's occiput to maintain this position. The victim's mouth should be examined for dentures and debris. A piece of cloth is used to wipe out fluid or semi-liquid material. Solid materials are removed with a hooked index finger. Dentures may be left in place to maintain a normal facial shape, facilitating adequate lip seal and mouth-to-mouth breathing. But if dentures obstruct the airway, they must be removed. One hand is placed on the patient's forehead and the head is tilted backward with firm pressure. The fingers of the other hand are positioned firmly beneath the chin's bony portion, lifting it upward. This brings the chin forward and the teeth almost to occlusion, supporting the jaw and helping to tilt the head backward. Pressure on the soft tissue under the chin should be avoided because it can aggravate airway obstruction. Unless mouth-to-nose breathing is indicated, the mouth should not be completely closed. During mouth-to-nose breathing, the mouth can be closed by increasing the pressure on the hand that is already on the chin. This technique is the recommended maneuver of choice because of its simplicity, safety, effectiveness, and ease of learning. The maneuver was found to be superior in opening the airway during mouth-to-mouth resuscitation of apneic patients, achieving airway patency in 91% of cases vs. 78% with the jaw thrust and 39% with simple neck lift.[265] Greater tidal volume was also delivered during head tilt/chin lift maneuver when compared to other techniques.

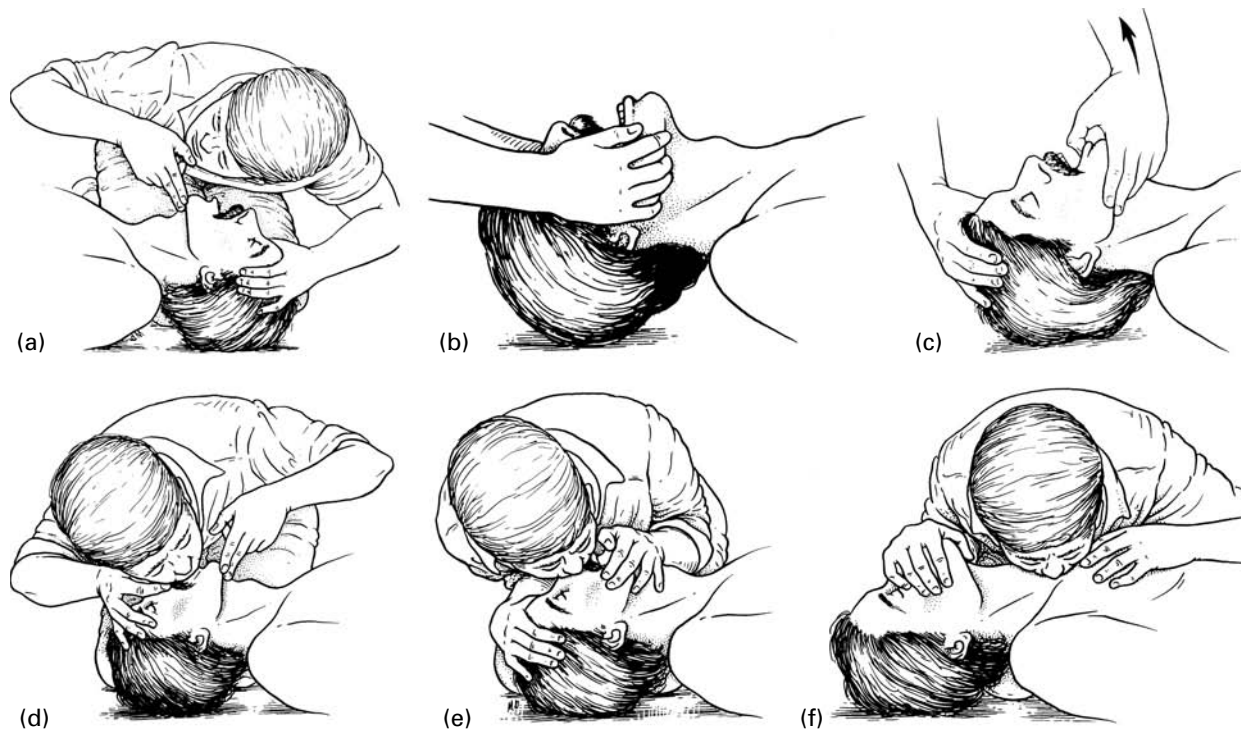
In pediatric victims, airway patency is also established by maintaining the head in the sniffing position, but direct pressure on the trachea or hyperextension of the head should be avoided. The pediatric trachea is not yet fully


Fig. 28.13. (a) Head-tilt-chin-lift maneuver. (b) Jaw-thrust maneuver and triple airway maneuver. (c) Mandibular displacement. Arrow indicates that the mandible is pulled upward. (d) Rescue breathing. (e) Mouth-to-nose ventilation. (f) Mouth-to-stoma ventilation. (From ref. 266.)

developed and does not have a well-formed rigid cartilaginous ring. Any direct or indirect pressure on this structure causes it to collapse.

Jaw-thrust maneuver

The angles of the mandible may be displaced anteriorly by grasping the lower jaw with both hands from one side and pulling forward, and simultaneously tilting the head backwards (Fig. 28.13(b)). The elbows of the CPR provider should rest on the surface on which the patient is lying. To open the lips, the lower lip can be retracted with the thumb. Mouth-to-mouth breathing can be delivered by occluding the victim's nostrils with the rescuer's cheek pressed tightly against them. To avoid extension of the neck in patients with suspected neck injury, a modified jaw thrust maneuver is performed. Forward traction is applied on the mandible without head tilt and care must be taken to avoid moving the head from side to side. If this maneuver is unsuccessful in opening the airway, the head may be slightly tilted with care. Although jaw thrust maneuver is highly effective in providing upper airway patency, the technique may be technically problematic and the rescuer tires easily. It is considered as an ancillary method and is utilized as a secondary method by professional rescuers.

Triple airway maneuver

This is a modification of the head tilt-lift maneuver whereby the lower lip is retracted with the thumb to open the mouth after tilting the head backward and lifting the chin upward. This maneuver is usually utilized by a more experienced rescuer.

Mandibular displacement

Another method to open the upper airway is to pull the mandible forward by placing the rescuer's thumb in the patient's mouth and putting the fingers underneath the chin to pull the lower jaw upward (Fig. 28.13(c)). Although effective in opening the airway in spontaneously breathing, edentulous patients, it can cause injury to the rescuer if the patient wakes up and suddenly bites rescuer's thumb.

Determination of apnea

There are several recommended methods of determining the absence of spontaneous breathing in an unconscious patient. Spontaneous respiration may be difficult to observe unless the airway is opened. Once airway patency is established, the rescuer should place his or her ear over the victim's mouth and nose. The rise and fall of the chest

should be noted. One must listen for breath sounds and feel for expired air. The absence of these signs is indicative of apnea. Frequently, gasping, gurgling, or snoring sounds or agonal respiratory efforts may be observed during cardiac arrest, especially within the first few minutes of collapse. This is not sustained, the respiratory rate is 6/minute or less, and should not be mistaken for spontaneous respiration. In some instances, the victim may show respiratory efforts but no air exchange is observed. This indicates upper airway obstruction and opening the airway facilitates resumption of air movement.

Once spontaneous respiration and pulse are established during resuscitation, the CPR provider should continue maintaining a patent airway. To reduce the likelihood of aspiration and obstruction, the patient should be rolled on his or her side. This is called the recovery position. The victim must be rolled as a unit, moving the head, shoulders and torso simultaneously without twisting. If trauma is suspected, however, the patient should not be moved unless absolutely necessary. There are several options on how the dependent arm may be placed in the recovery position: (a) it may be bent at the elbow, and alongside the victim while the other hand rests under the cheek of the victim; (b) the dependent arm may be alongside the victim; or (c) the dependent arm may be bent at the elbow with the hand under the face. The fundamental goal of the recovery position is to have the patient on his/her side so that aspiration and accidental airway obstruction is prevented.

Initiation of respiration (rescue breathing)

Delivery of an adequate tidal volume is required during rescue breathing. Usually, 500 ml to 600 ml of tidal volume is considered adequate for an adult. It is difficult for the rescuer to know exactly how much tidal volume is given during mouth-to-mouth ventilation. Therefore, it is recommended that the rescuer give just enough tidal volume with each breath to make the chest rise visibly.

The oxygen concentration of expired air is approximately 16% to 17%. With this oxygen concentration, the maximum alveolar oxygen partial pressure is about 80 mmHg, enough to meet the victim's oxygen need. It is recommended that two initial breaths should each be delivered over 1 second. Sufficient time should be allowed for exhalation between breaths. Using this inspiratory time (1 second) in conjunction with a tidal volume of about 500 ml produces a lower inspiratory flow rate, and reduces the chances of exceeding opening pressure of the esophageal sphincter, thereby decreasing the chance of gastric distention, the most common major problem associated with rescue breathing. Gastric distention elevates

the diaphragm, reduces lung volume, and promotes regurgitation and aspiration. Sellick's maneuver, the application of cricoid pressure against the cervical vertebra, helps prevent regurgitation against esophageal pressure of up to 100 cm water. This technique requires an assistant and is recommended only to be used by trained professionals. If regurgitation is observed during CPR, the victim's entire body should be turned to the side and the mouth wiped clean. The patient is then turned back to supine position and CPR is resumed. Additionally, excessive peak airway pressures may be generated during exhaled oxygenation (rescue breathing), increasing the risk of barotrauma.

Basic life support CPR can be performed either by one or two rescuers. During both one- and two-rescuer CPR, 2 breaths are given during a pause after every 30th chest compression. Exhalation occurs passively after each breath and during chest compression. Rescue breathing can be delivered through mouth-to-mouth, mouth-to-nose, mouth-to-stoma, and mouth-to-barrier devices.

After opening the airway by the head-tilt-chin lift maneuver, the rescuer can seal the nose by pinching it with the thumb and index finger of the hand on the victim's forehead (Fig. 28.13(d)). The rescuer inhales and puts his or her lips around the patient's mouth, creating an airtight seal. Two breaths are delivered at a chest compression/ventilation ratio of 30:2 with one- or two-rescuer CPR; the ratio is the same for adults, children, and infants. If two or more professional rescuers are present, the ratio is 15:2 for children and infants. Upward movement of the chest and sensing the escape of air during exhalation assure the rescuer that adequate ventilation has been delivered. ***The most common cause of failure to ventilate is improper positioning of the head and chin.*** If attempts to ventilate fail, the patient's head and chin should be repositioned. If after repositioning, the patient cannot be ventilated, the airway should be evaluated for the presence of foreign bodies. These maneuvers will be discussed later in this chapter. Also, it should be emphasized that pauses for ventilation pertain only to subjects with an unprotected airway (i.e., unintubated). Once the airway is intubated, chest compressions are given continuously, at a rate of 100 compressions/minute without interruption for ventilation. A ventilation rate of 8 – 10 breaths/minute should be used, which is less than was recommended prior to 2005.[162] When circulation is present with a pulse, about 10 to 12 breaths/minute should be used.[266] If an end-tidal CO_2 monitor is available, ventilation rate should be adjusted to maintain end-tidal CO_2 within a range of about 35 mmHg to 45 mmHg. In patients with obstructive pulmonary disease and increased resistance to exhalation, a lower ventilation rate should be used (e.g., 6 to 8 breaths/minute)

to prevent air-trapping and to allow enough time for complete exhalation.[266] Recent studies suggest that fewer breaths/min may improve blood flow during shock or cardiac arrest and provide a better ventilation/perfusion match. This is an important area of active investigation and randomized controlled trials are currently being planned.

If it is difficult or contraindicated to deliver mouth-to-mouth breathing, mouth-to-nose breathing can be performed. It is indicated in patients with mouth trauma, trismus, or in those where a tight mouth-to-mouth seal is impossible to achieve. After the head is properly positioned and the mouth closed (as previously described), the rescuer inhales, puts his or her mouth in a tight seal around the victim's nose, and breaths out into it (Fig. 28.13(e)). The rescuer then removes his or her lips from the patient's nose and lets exhalation occur passively. The mouth may also be opened after breath delivery to allow air to escape through the mouth.

If the patient has a previous laryngectomy and has a permanent opening connecting the trachea to the front base of the neck, ventilation during CPR can be performed by delivering the breath through the stomal opening (Fig. 28.13(f)). In a similar fashion to mouth-to-mouth or mouth-to-nose breathing, the rescuer's mouth is arranged to form a tight seal around the stoma and two breaths are delivered. When the rescuer stops breathing into the stoma, air passively escapes from the opening.

The presence of vomitus and fear of infectious contamination may affect the willingness of rescuers to perform mouth-to-mouth resuscitation. Lawrence and Sivaneswaran showed that only 13% of 70 hospital staff members surveyed would use mouth-to-mouth ventilation and 59% would prefer to use mouth-to-mask ventilation.[269] Specialized masks with a one-way valve are currently utilized during CPR. The valve prevents the exhaled air from entering the rescuer's mouth. Additionally, bacterial filters are incorporated in some of the commercially available masks to prevent contamination of the rescuer. Moreover, some resuscitation masks can deliver as much as 50% oxygen.[267] Mouth-to-mask ventilation can provide adequate tidal volume at a significantly lower airway pressure when compared to mouth-to-mouth resuscitation.[9] Other barrier devices such as face shields are also available. Unlike the masks, many face shields do not have a one-way valve and air may leak around the shield. If a barrier device is used during rescue breathing, it must be placed tightly around the patient's mouth and slow, deep breaths should be delivered in a manner similar to mouth-to-mouth ventilation.

Cardiopulmonary arrest occurring in the hospital setting is often initially managed with bag-valve-mask ventilation. There are studies reporting that this device cannot deliver adequate tidal volume when only one person is doing pulmonary resuscitation.[268–271] The basic problem arises from the need to provide an adequate seal between the face and the mask while controlling the airway by head extension at the same time. Additionally, familiarity with the use of the equipment requires special training and additional manpower. It has been shown that this technique is more effective in delivering adequate ventilation when two rescuers are supporting the airway.[271,272] One rescuer effectively seals the mask to the mouth and maintains head extension while the other squeezes the bag with both hands to deliver adequate tidal volume. The central issue is that the individual providing BVM ventilation must be well-trained in the proper use of this instrument before attempting to control the airway in an arrested patient for the first time.

Oxygen supplementation can be provided during BVM ventilation, which delivers 40% to 60% O_2 without and with an oxygen reservoir, respectively.[273] Complications associated with the use of a BVM are primarily due to excessively high ventilating pressures and include pneumothorax, pneumomediastinum, pneumocephalus, and gastric rupture.[274] When oxygen is available, ventilation should be limited to approximately one-third of the total bag volume (about 600 ml in the 1.8 l adult bag) and delivered (over 1 second; the recommended inspiratory time is a little faster because of the smaller tidal volume). Unless the rescuer is proficient in the use of anesthesia bags, it is preferable to use self-inflating hand-held resuscitator bags during CPR. Anesthesia bags such as the Mapleson system are not self-inflating and require a continuous oxygen source.[275] Some resuscitator bags have a pressure relief valve, a safety feature designed to limit the maximum pressure that can be delivered, thereby preventing gastric insufflation and hyperinflation of the lungs and subsequent pulmonary barotrauma. These valves may malfunction, however, and it must be emphasized that improper venting can cause inadequate ventilation. This can be recognized by the sound of air escaping through the relief valve when the bag is squeezed. Adjusting or partially occluding the valve may be life-saving.

The basic principles governing rescue breathing of pediatric patients are the same as those of adults, although the pediatric airway may be flattened by excessive extension of the cervical spine during the head tilt-chin lift maneuver. In infants and smaller children, mouth-to-nose ventilation may be necessary during CPR. Smaller breaths must be used to avoid abdominal distention, regurgitation, and pulmonary barotrauma. Ventilation in the newborn needs special consideration. Indeed, as already stated, appropriate ventilation is essential for the survival of the newborn infant.

While hypoxia before delivery can influence the time of successful resuscitation of a newborn, it is recommended

that adequate ventilation should be assessed immediately and endotracheal intubations should be carried out within 30 to 60 seconds of birth.[276] This time should be reduced to < 30 seconds in preterm babies, although no clear literature exists on this situation.[277] Trauma should be avoided by maintaining inflation volume at about 6 ml/kg.[278] Physiologic considerations in the newborn seem to confirm that this volume for resuscitation is probably adequate. It is known that a first breath with use of a medium tidal volume of 5 ml/kg is usually sufficient to achieve a functional residual capacity (FRC) lung volume almost immediately (reaching a total FRC volume of 28 to 30 ml/kg).[279] Furthermore, it is possible that a small tidal volume would stimulate the newborn to breathe spontaneously through a reverse Hering-Breuer reflex (called head paradoxical reflex).[280] This level of tidal volume and a real mask inflation pressure to less than 20 cm H_2O can usually limit gastric inflation.[281,282]

Adjunctive airway equipment

Airway control may be facilitated with the use of adjunctive airway devices. This equipment is generally available to the rescuing paramedics or hospital personnel. It is mandatory that people using these devices be familiar with their use and potential problems. They should be regarded as a "bridge to" rather than "alternate to" endotracheal intubation.

Oxygen source

Oxygen supplementation should be initiated as soon as possible during CPR by the trained rescuer, to avoid the adverse effects of hypoxemia. If oxygen is inadequate, all other resuscitation efforts will fail; 100% oxygen should be utilized during resuscitation. If available, pulse oximeter should be used to determine oxygen saturation.

Oxygen is generally stored either in liquid form or in cylinder reservoirs. A portable oxygen tank is color-coded green in the United States. It is provided with a regulator and flowmeter. The regulator reduces the pressure to 50 psig for delivery to the flowmeter. Most emergency medical technicians carry the smaller E cylinder. This is pressurized to 1800 to 2400 psig at 70 °F and 14.7 psig absolute pressure. The cylinder holds 659 liters of oxygen and lasts about 1 hour when the flow rate is set at 10 liters per minute. Oxygen is considered a "drug," hence its use is regulated by agencies in most states.

Face masks

A pocket facemask is the simplest adjunct beyond mouth-to-mouth resuscitation. An ideal facemask should be colorless to provide direct visualization of the mouth, lips, nose, and the presence of vomitus or secretions. It should have a soft pliable edge to create an effective seal against the face. To assure proper ventilation, an airtight seal is necessary to avoid oxygen and air escaping during supportive ventilation. The mask should provide an oxygen inlet with a standard 15 mm/22 mm coupling size. Various sizes should be available for adults and children. A reservoir bag with a one-way valve may be attached to the mask for manual ventilation of the lungs.

Placement of the face mask is best achieved when the operator is positioned at the top of the patient's head. An airtight seal can be provided by single handed or double handed technique. Single-handed technique requires that the rescuer fits the mask snugly on the victim's face, using the thumb and the index finger in a pincer grip while simultaneously displacing the mandible upward and lifting the chin with the other three fingers. The middle finger should rest on the mandible, the ring finger is positioned midway between the chin and the angle of the jaw, and the little finger is on the mandibular angle. Pressure on the soft tissue should be avoided, because it is uncomfortable and can lift the base of the tongue and cause upper airway obstruction.

Mouth-to-mask ventilation can be achieved by the rescuer sealing his/her lips around the coupling adapter of the mask. If ventilation is inadequate or if airway obstruction is unrelieved, a double-handed technique should be utilized. The fingers are placed on the same position as the single handed method but applied on both sides of the face. However, a second rescuer is necessary to deliver exhaled or manual ventilation. Care must be observed to avoid pressure damage to the eyes and soft tissues.

Manual resuscitators (bag valve devices)

Bag valve devices of various designs are available for adults and children, but a self-inflating, manually operated bag with a non-rebreathing valve is preferable because it allows ventilation even if there is no connecting oxygen supply. This device may be used in conjunction with a face mask, endotracheal tube, or other invasive airway device.

The standard parts include a delivery port with a 15 mm/22 mm adapter coupling size that can be connected to the mask or tracheal tube. It is provided with a one-way, non-jam valve that allows a minimum of 15-liter per minute oxygen flow rate for spontaneous and controlled ventilation. It should also have a system for delivering high oxygen concentration through an auxiliary oxygen inlet at the back of the bag or by an oxygen reservoir. A positive end-expiratory pressure (PEEP) valve can also be

incorporated. The bag should be a self-refilling one that can be readily cleaned and sterilized. The bag usually holds a volume of up to 1600 ml. Some pediatric resuscitator bags are provided with a 25 to 30 cm H_2O pop-off valve to avoid excessive positive airway pressure. This device is expected to perform satisfactorily under all common environmental conditions and extremes of temperature.

To operate this equipment properly the operator must be positioned at the top of the victim's head. After correct head positioning as previously described, appropriate tidal volume should be delivered (6 to 7 ml/kg, sufficient to produce visible chest rise) with oxygen supplementation, if available. An oropharyngeal airway may be used to open the mouth. A single rescuer may have difficulty maintaining the head position and delivering adequate tidal volume at the same time. It is therefore recommended that two rescuers operate this device: one to hold an airtight seal over the face, the other to squeeze the bag manually. The proper use of this device requires training, practice, and familiarity with the equipment.

Oxygen-powered manually triggered devices

Oxygen-powered breathing devices have also been used by EMS personnel during CPR. These machines are expensive, and require high oxygen flow rates to overcome air leak.[267] Although they may be able to deliver adequate tidal volumes, oxygen-powered devices carry the risk of gastric distention and regurgitation. Most of these devices are time-cycled and deliver high instantaneous flow rates by a manual control button. They can be used in conjunction with a face mask, endotracheal tube, esophageal airway, or tracheostomy tube.

Parts of an oxygen-powered manually triggered device include a standard 15 mm/22 mm adapter coupling, a compact, rugged, breakable-resistant mechanical design that is easy to hold, and a trigger arranged so that both hands of the rescuer can remain on the face mask to hold it in position. It should also have the following characteristics: a constant flow rate of 100% oxygen at less than 40 liters per minute, and an inspiratory pressure relief valve that opens at approximately 60 cm H_2O and vents any remaining volume to the atmosphere or ceases gas flow. Furthermore, an alarm sound system is provided to alert the rescuer that the pressure relief valve has been activated, indicating that the patient requires high inflationary pressure and may not be receiving adequate tidal volume. It should be able to operate satisfactorily under common environmental conditions and extremes of temperature. It should be provided with a demand flow system that does not impose additional work.[217] These devices are contraindicated in children and spontaneously breathing patients. The potential for complications is high and its use requires training and familiarity.

Suction devices

A suction apparatus is essential during advanced airway support. Suction may be provided by portable battery-operated or electrically powered equipment. In the hospital, wall vacuum outlets are available for suctioning. This device should be available during resuscitation prior to airway instrumentation. Vomitus, secretions, or blood may occlude the airway and can be aspirated into the lungs, compromising the ability to adequately ventilate and oxygenate the victim. In addition to a suction apparatus, a flexible catheter or a rigid tonsillar suction tip should be attached to large bore, non-kinking suction tubing that should be 14 French or greater internal diameter. A rigid tonsillar tip can rapidly suction particulate materials or large volumes of fluid from the pharynx. Flexible catheters are available in various sizes for children and adults and are used to decompress the stomach, suction the esophagus, pharynx, and endotracheal tube.

The wall suction units should provide airflow of more than 30 l/minute at the end of the delivery tube and a vacuum of more than 300 mmHg when the tube is clamped. The suction apparatus should have an adjustable knob to control the amount of suctioning power, especially in children. It must be designed for easy cleaning and subsequent decontamination. Suctioning may damage the teeth and surrounding structures. Prolonged suctioning can cause deoxygenation. It is recommended that the procedure be limited to less than 10 seconds at a time and that the patient receive 100% O_2 in the intervals between suctioning.

Alternative methods of ventilation after successful endotracheal intubation

The relation between airway pressure, intrathoracic pressure, and circulation during CPR has been recently studied.[283] During the decompression phase of CPR, venous return is enhanced. A small inspiratory impedance valve has recently been introduced to occlude the airway selectively during the decompression phase of CPR without interfering with exhalation or active ventilation. The effect of this device on venous return, coronary perfusion pressure, and blood flow during resuscitation has been studied in animals and humans. A remarkable improvement in all of the physiologic parameters usually associated with restoration of spontaneous circulation after defibrillation was demonstrated (end-tidal CO_2, systolic blood pressure, diastolic blood pressure). Furthermore, the beneficial effect of this valve could be seen in models of both protected and

unprotected ventilation.[284,285] Remarkably, when the effect of PEEP was combined with negative inspiratory pressure produced with the inspiratory threshold valve (CPAP level up to 10 cm H_2O), the increase in oxygenation was still appreciated with improved respiratory system compliance, but without the detrimental effect on hemodynamics expected with the use of CPAP.[286] Negative pressure pulmonary edema is one possible complication of that and can occur during airway obstruction or an exaggerated Mueller maneuver.[287]

Transport ventilators

Although the introduction of transport ventilators for pre-hospital and hospital care was typically aimed at providing mechanical ventilation in patients with an endotracheal tube in place, some of their features can be used to provide ventilation of the unprotected airway during and after CPR. These devices are typically compact, lightweight, time-cycled or flow-controlled, durable, pneumatically or electronically powered, easy to operate, and low maintenance. An excellent review is available in the literature.[288]

During transport of artificially ventilated patients, automatic transport ventilators (ATVs) are found to be superior at maintaining constant minute ventilation and adequate arterial blood gases when compared with BVM devices.[289] Advantages of ATVs include allowing the rescuer to do other tasks when the patient is intubated, and allowing the rescuer to use both hands to hold the mask in patients not intubated. The rescuer can also perform the Sellick maneuver with one hand while holding the mask in the other hand. ATVs can provide a specific tidal volume, respiratory rate, and minute ventilation.

It is recommended that ATVs should function as constant inspiratory flow rate generators and should have the following features: (1) a lightweight connector with a standard 15 mm/22 mm adapter coupling for a mask, endotracheal tube, or other airway adjunct; (2) a lightweight (2 to 5 kg) compact, rugged design; (3) capability of operating under all common environmental conditions and extremes of temperatures; (4) a peak inspiratory pressure limiting valve set at 60 cm H_2O with an option of an 80 cm H_2O pressure that is easily accessible to the user; (5) an audible alarm that sounds when the peak inspiratory limiting pressure is generated to alert the rescuer that low compliance or high airway resistance is resulting in a diminished tidal volume delivery; (6) minimal gas consumption allowing the device to run for a minimum of 45 minutes on an E cylinder; (7) minimal gas compression volume in the breathing circuit; (8) ability to deliver 100% oxygen; (9) an inspiratory time of 1 second , and maximal inspiratory flow rates of approximately 30 l/minute in adults and 15 l/ minute in

children; (10) at least two rates, 10 breaths/minute for adults and 20 breaths/minute in children. If a demand flow valve is incorporated, it should deliver a peak inspiratory flow rate on demand of at least 100 l/minute at -2 cm H_2O triggering pressure to minimize the work of breathing.[217] Additional desirable features include a pressure gauge, provision for continuous positive airway pressure, controls for rate and tidal volume, and low pressure alarms to indicate low oxygen pressure either from disconnection or depletion of the gas source. Theoretically, both time or flow cycle transport ventilators can replace BVM ventilation during CPR. One particular model, the Ohmeda HARV or pneuPAC 2-R (Ohmeda Emergency Care, Orchard Park, NY), is commercially available for either transport ventilation or assisted mask ventilation. HARV produces a rectangular flow waveform that is time-triggered, flow- or pressure-limited, and time-cycled. A single control sets one of seven rate/tidal volume combinations.[288]

Mechanically operated mask ventilation undoubtedly presents advantages during CPR, because it frees the resuscitator's hand that typically is involved in squeezing the bag. The use of a pressure-powered mechanical ventilator that operates from an external pneumatic source (wall pressured oxygen or portable oxygen tank) also has the advantages of providing constant tidal volume, flow rate, inspiratory time, and ventilation rate, once it is set. These devices may help to reduce the frequency of hyperventilation that is associated with manual bag resuscitators.

Monitoring ventilation during CPR

End-tidal carbon dioxide as a tool for monitoring the progress of CPR

A number of studies have shown that end-tidal CO_2 varies directly with cardiac output during cardiac arrest,[47,290–292] provides a useful indicator of the efficacy of resuscitation efforts, and also predicts outcome.[293–301] The presence of end-tidal CO_2 has been investigated as a guide to correct placement of endotracheal intubation.[302–305] Additionally, capnography has been used in resuscitation research as an indication of pulmonary blood flow, which serves as a proxy for the direct measurement of cardiac output.[306–309]

Aerobic and anaerobic cellular metabolism generate CO_2, which diffuses out of the cell into tissue capillaries, and is transported to the lungs, exhaled, and can be measured as end-tidal CO_2.[310,311] Under normal conditions, end-tidal CO_2 is 2 to 5 mmHg less than the $PaCO_2$. Systemic metabolism changes little during CPR, which is usually relatively brief, although ischemic hypoxia can alter the

respiratory quotient.[312,314] The concentration of exhaled CO_2 changes when blood flow to the lungs changes and is an indirect indicator of cardiac output and systemic blood flow. Under conditions of constant minute ventilation, end-tidal CO_2 is linearly related to cardiac output, even during extremely low blood flow rates (Fig. 28.14).[313] The decrease in end-tidal CO_2 parallels closely the decrease in $PaCO_2$ that occurs when blood flow decreases, and is therefore useful clinically as a monitor of perfusion during shock and CPR. End-tidal CO_2 changes rapidly with changes in flow, changing one breath after a change in perfusion and almost reaching a new steady state within 30 seconds (Fig. 28.15). After administration of epinephrine, however, the prior relationships of end-tidal CO_2 may be altered because of the changes in pulmonary and peripheral vascular resistance and preferential redirection of blood flow.[302] In some instances, epinephrine may cause decreased pulmonary blood flow and end-tidal CO_2, while at the same time coronary perfusion pressure increases because of increased peripheral vascular resistance (Fig. 28.16).[314]

During the past two decades, there has been great interest in the physiology of end-tidal CO_2, especially in low blood flow states. The primary reason for this interest is the difficulty in directly measuring low rates of blood flow, particularly during human cardiac arrest. Because it is much easier to measure, end-tidal CO_2 has been used as

an indicator of pulmonary blood flow, which serves as a proxy or substitute for the direct measurement of cardiac output.

In animal models of cardiac arrest and resuscitation, end-tidal CO_2 has been shown to vary directly with cardiac output.[47,290,291] Coronary artery perfusion pressure, one of the best prognostic indicators of survival in cardiac arrest,[315] correlates closely with end-tidal CO_2.[297,298] For example, end-tidal CO_2 was higher during CPR in 17 animals that survived when compared to five animals that failed resuscitation.[292] Thus, end-tidal CO_2 is correlated with blood flow and successful resuscitation from cardiac arrest.

Investigators have used end-tidal CO_2 as a substitute for the measurement of blood flow in studies of CPR techniques.[306,309] End-tidal CO_2 levels were found to increase when greater force was applied during external chest compression force in humans,[306] while changes in compression rate had little effect on end-tidal CO_2.[307] Because end-tidal CO_2 is directly related to cardiac output when minute ventilation is held constant, it is a useful tool in CPR research as a substitute for the direct measurement of cardiac output. Because lack of end tidal CO_2 may simply represent inefficient chest compression during CPR, however, new devices have been introduced to confirm endotracheal intubation in a setting of cardiac arrest. A suction bulb and a large syringe, both with standard fitting
Fig. 28.14. The relationship of the partial pressure of end-tidal carbon dioxide (P_aCO_2) to cardiac index (*CI*) under conditions of constant minute ventilation (r – 0.82, *P* < 0001) in swine (n – 10) on biventricular bypass devices. (From ref.315.)
Fig. 28.15. End-tidal CO_2 (mmHg) blood flow (produced with biventricular bypass devices; cardiac output measured with a magnetic flow probe expressed as a percent of baseline; and aortic blood pressure (B/P) mmHg rate calf (125 kg). Blood flow in a rate was reduced to 10% of baseline and then back to baseline. The second half of the recording was made at a higher speed. Original data from A.H. Idris.
Fig. 28.16. Aortic blood flow expressed as a percent of of baseline, end-tidal CO_2 (mmHg), aortic pressure (mmHg), and pulmonary artery pressure (mmHg) in a calf (125 kg) with blood flow produced by biventricular assist devices. Epinephrine 2.0 mg was given (*arroic*) through the proximal port of the pulmonary artery catheter. Both aortic and pulmonary artery pressures increased dramatically following administration of epinephrine, probably because of increased pulmonary and peripheral vascular resistance. At the same time, aortic blood flow decreased transiently, probably because of decreased pulmonary blood flow, decreased return of blood to the left ventricular assist device, and increased peripheral vascular resistance. End-tidal CO_2 decreased approximately 5 mmHg after epinephrine. (Original data from AH Idris.)

for an endotracheal tube adaptor have been used to recognize the tracheal versus a "virtual and collapsible lumen" represented by the esophagus. At the time of this writing, the sensitivity and specificity of these devices during CPR have not been well established.[316]

Several studies of end-tidal CO_2 during low blood flow states found that levels changed significantly with changes in minute ventilation.[28,317] When minute ventilation doubled, end-tidal CO_2 decreased 50% and when minute ventilation decreased 50%, end-tidal CO_2 doubled. Thus, end-tidal CO_2 varies inversely with minute ventilation and can be used to monitor ventilation during low flow conditions. If both perfusion and ventilation are not constant, end-tidal CO_2 levels can be difficult to interpret.

The use of arterial and central venous blood gases during CPR

It has been a longstanding practice to use arterial blood pH, PO_2, PCO_2, and HCO_3 to monitor ventilation and to guide therapeutic interventions for abnormalities in acid–base conditions during CPR.[217] While $PaCO_2$ and PaO_2 are useful for monitoring pulmonary ventilation, there is mounting evidence that arterial blood may not reliably reflect tissue acid–base conditions during low blood flow states and that central venous blood more accurately reflects conditions at the tissue level.

One study showed that after 5 minutes of untreated ventricular fibrillation, arterial and mixed venous blood gases remained nearly unchanged from baseline pre-arrest values.[173] Only the PaO_2 decreased by 10 mmHg, but it was still within the normal range. This demonstrates an important relationship among blood flow, tissue perfusion, and acid–base conditions. Blood that is contained within the large arteries under no-flow conditions is static and does not reflect ongoing intracellular metabolism until some perfusion is restored so that blood at the tissue level is mobilized back into circulation. Thus, if blood flow is sufficiently low, pHa, PaO_2, and $PaCO_2$ might remain "normal" for a prolonged period of time. Moreover, if ventilation is held constant, pHa and PaO_2 will increase and $PaCO_2$ will decrease as perfusion becomes worse.[56]

A number of investigations support the view that pHa and $PaCO_2$ can be used for monitoring the effectiveness of resuscitation efforts during cardiac arrest.[28,56,318,319] Arterial PCO_2 has been shown to correlate closely with cardiac output and coronary perfusion pressure, which is known to be a good predictor of success of resuscitation. Nevertheless, changes must be interpreted differently from those in conventional practice: when perfusion improves, arterial blood becomes more acidemic, $PaCO_2$ increases, and PaO_2 may decrease; when perfusion becomes worse, arterial blood becomes more alkalemic, $PaCO_2$ decreases, and PaO_2 increases.[28,66,318]

In addition, the timing of blood sampling is another variable that must be considered. If arterial blood gases are measured during CPR within 8 minutes of cardiac arrest, pH is usually normal or alkaline because significant metabolic acidosis has not yet developed and $PaCO_2$ is lower than normal. As the duration of CPR progresses, increasing blood lactate and decreasing bicarbonate concentrations ultimately cause an acidemic arterial pH.[67] Administration of sodium bicarbonate, which has been shown to cause an increased pHa and $PaCO_2$, must also be considered when interpreting blood gases.[59,68]

Another important consideration when using arterial blood gases is that $PaCO_2$ and PaO_2 values respond quickly to changes in minute ventilation. In one study, $PaCO_2$ increased by approximately 85% when minute ventilation was decreased to 25% of the previous setting; similar changes were observed with blood flow rates as low as 12% of normal.[28] Therefore, arterial blood gas analysis can be used to assess perfusion when minute ventilation is held constant, or to assess minute ventilation when perfusion is held constant. When both perfusion and minute ventilation are uncontrolled, it is difficult to interpret arterial blood gases.

Mixed venous pH, PO_2, and PCO_2 are more useful than arterial gases for assessing acid–base status and perfusion during low flow states because they more closely reflect the tissue environment.[13,46,55,56,62,64,70,320] One study of hemorrhagic shock showed that mixed venous oxygen saturation averaged 46% in survivors and only 25% in non-survivors;[183] others have found a similar relationship.[321,322] A study of human cardiac arrest found that mixed venous oxygen saturation was associated with prognosis for survival and mixed venous pH, PO_2, and PCO_2 measured during cardiac arrest was substantially better in those who ultimately had return of spontaneous circulation.[44] Additionally, mixed venous blood gases are more useful than arterial blood gases for assessing perfusion during CPR, because they are much less affected than arterial gases by changes in minute ventilation.[28] Because of the great difficulty in obtaining mixed venous blood samples during CPR, other venous sites may be used as a substitute. Evidence exists that central, femoral, intraosseous, and mixed venous blood gas values are very similar, even during prolonged cardiac arrest and CPR.[323–325]

In summary, $PaCO_2$, mixed venous pH and PO_2, and end-tidal CO_2 vary directly with blood flow, while mixed venous PCO_2 varies inversely with blood flow. Arterial PO_2 and pH vary directly with minute ventilation, while arterial and

mixed venous PCO$_2$ vary inversely with minute ventilation. Both arterial and mixed venous blood gases are useful for assessing the efficacy of resuscitation efforts. Arterial PO$_2$ and PCO$_2$ are most useful for assessing the adequacy of ventilation, whereas mixed venous PO$_2$ and PCO$_2$ are most useful for assessing the adequacy of circulation. At the present time, there are no conclusive data that allow recommendations on how frequently arterial or venous gases should be monitored during resuscitation.

Conclusions

During normal cardiac activity, ventilation serves to remove CO_2 from and provide oxygen to tissues. The effect of ventilation on tissues continues even during low flow states, although its ability to provide oxygen and remove CO_2 is diminished and limited by blood flow. Ventilation during the first few minutes of dysrhythmic adult cardiac arrest has been somewhat de-emphasized in favor of more effective chest compression. Manual techniques of ventilation have a number of advantages over mouth-to-mouth ventilation, including safety from transmission of infectious diseases and a superior ventilation gas (i.e., room air). If obstruction of the airway could be prevented, manual ventilation may be a useful alternative and should be studied. In addition, chest compression alone can provide some ventilation, provided that the upper airway is unobstructed. The relationship between ventilation mechanics and circulation has been studied in cardiac arrest and hemorrhagic shock. Rescuers often inadvertently use excessively high ventilation rates. Studies have found that positive pressure ventilation may decrease blood flow by decreasing venous return to the heart. Excessive ventilation has a detrimental effect in cardiac arrest, shock, and traumatic brain injury and should be avoided. Since 2005, lower ventilation rates are now recommended.

Chest compression alone may be effective for the first few minutes of witnessed sudden cardiac arrest. This would certainly be an advantage because chest compression without ventilation could be more easily mastered by lay CPR providers and there would be less hesitation in providing bystander chest compression without mouth-to-mouth ventilation. Although the few studies of ventilation and its effect on outcome from cardiac arrest in humans are promising, they are inconclusive. The issues surrounding ventilation in resuscitation are critical and involve more than 300 000 cardiac patients per year in United States, and even more victims of severe traumatic injury. The scientific community must respond to this challenge with a targeted, multidisciplinary research effort.

Airway techniques and airway devices

Jerry P. Nolan and David A. Gabbott

Anaesthesia and Intensive Care Medicine, Royal United Hospital, Bath, UK
Department of Anaesthetics, Gloucester Royal Hospital, Gloucester, UK

". . . with a slight breath the lung will swell and the heart becomes strong . . . and as I do this and take care that the lung is inflated at intervals, the motion of the heart does not stop . . ." Vesalius *(1514–1564)*

Introduction

Maintaining a patent airway is of paramount importance if the lungs are to be inflated successfully with high inspired oxygen concentration during cardiopulmonary resuscitation (CPR) attempts. The association between delivering adequate breaths via a patent airway and maintenance of cardiac function was clearly recognized by Vesalius in the sixteenth century. Patients requiring CPR often have an obstructed airway, usually caused by loss of consciousness, but occasionally it may be the primary cause of cardiopulmonary arrest. Prompt assessment, with control of the airway and ventilation of the lungs is essential. This will help to prevent secondary hypoxic damage to the brain and other vital organs as well as maintaining cardiac function. Without adequate oxygenation it may be impossible to restore a spontaneous cardiac output from a myocardium in cardiac arrest.

An extensive review of the science behind airway management during cardiac arrest was published recently: the 2005 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations (CoSTR).[1] The European Resuscitation Council (ERC) Basic Life Support (BLS) and Advanced Life Support (ALS) Working Parties have recently published new guidelines on management of the airway during cardiac arrest and these were based partly on the recommendations published in CoSTR.[2,3]

Airway obstruction

Causes of airway obstruction

Obstruction of the airway may be partial or complete. It may occur at any level from the nose and mouth down to the trachea (Fig. 29.1). In the unconscious patient, the commonest site of airway obstruction is at the level of the pharynx. The precise cause of airway obstruction in the unconscious state has been identified by studying patients under general anesthesia.[4–6] Until recently, this obstruction had been attributed to posterior displacement of the tongue caused by decreased muscle tone, with the tongue ultimately touching the posterior pharyngeal wall.[7,8] These studies of anesthetised patients have suggested that the site of airway obstruction is primarily at the soft palate and epiglottis and not the tongue. Obstruction may be caused also by vomit or blood, as a result of regurgitation of gastric contents or trauma, or by foreign bodies. Laryngeal obstruction may be caused by edema from burns, infection, inflammation, or anaphylaxis. Laryngeal spasm may be the result of an inappropriate response to upper airway stimulation, or caused by an inhaled foreign body. Obstruction of the airway below the larynx is less common, but it may arise from excessive bronchial secretions, mucosal edema, bronchospasm, pulmonary edema, or aspiration of gastric contents.

If airway obstruction is left unattended or allowed to progress, the consequences are progressive hypoxia, an increased work load for the patient, fatigue, hypercarbia, pulmonary edema, and ultimately complete airway obstruction leading to cardiopulmonary arrest. Furthermore, attempting to ventilate the lungs of a patient with an obstructed airway generates a cycle of gastric inflation

and worsening respiratory system compliance as gas is forced down the esophagus and into the stomach.[9] Such an unfortunate sequence is further compounded by reduced pressure on the lower esophageal sphincter seen shortly after loss of consciousness during cardiopulmonary arrest.[10]

Assessment and recognition of airway obstruction

Airway obstruction can be subtle and is often missed by many healthcare professionals as well as by laypeople. The look, listen, and feel approach is a simple, systematic method of detecting airway obstruction:
- *look* for chest and abdominal movements
- *listen* and *feel* for airflow at the mouth and nose.

In partial airway obstruction, air entry is diminished and usually noisy. Inspiratory stridor is caused by obstruction at the laryngeal level or above. Expiratory wheeze implies obstruction of the lower airways, which tend to collapse and obstruct during expiration. Other characteristic sounds include:
- gurgling: caused by liquid or semisolid foreign material in the main airways
- snoring: arises when the pharynx is partially occluded by the soft palate or epiglottis
- crowing: is the sound of laryngeal spasm.

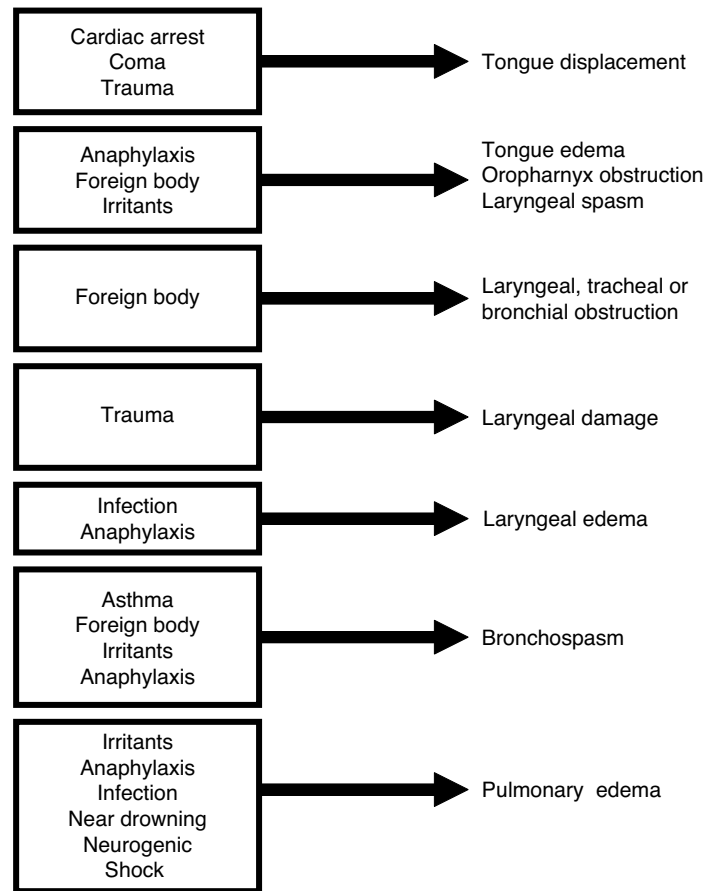
In a patient who is making respiratory efforts, complete airway obstruction causes paradoxical chest and abdominal movement, often described as "see–saw breathing." As the patient attempts to breathe in, the chest is drawn in and the abdomen expands, with the opposite in expiration. This is in contrast to the normal breathing pattern of synchronous movement upwards and outwards of the abdomen (pushed down by the diaphragm) with the lifting of the chest wall. During airway obstruction, other accessory muscles of respiration are used, with the neck and the shoulder muscles contracting to assist movement of the thoracic cage. Full examination of the neck, chest, and abdomen is required to differentiate the paradoxical movements that may mimic normal respiration. The examination must include listening for the absence of breath sounds in order to diagnose complete airway obstruction reliably; any noisy breathing indicates partial airway obstruction. During apnea, when spontaneous breathing movements are absent, complete airway obstruction can be recognized by failure to inflate the lungs during attempted positive pressure ventilation. Unless airway patency can be re-established to enable adequate lung ventilation within a very few minutes, neurological and other vital organ injury may occur, leading to cardiac arrest.


Fig. 29.1. Common causes of airway obstruction.

In patients who have complete airway obstruction, the continued uptake of oxygen from the gas remaining within the lungs can generate negative pressure within the chest cavity ("hypobaric thorax"). When airway obstruction is relieved, upper airway gases from within the mouth and pharynx may be sucked into the lungs by this negative pressure. The application of high inspired oxygen levels under these circumstances may greatly increase the pulmonary and blood oxygen levels as the airway obstruction is relieved.[11,12]

Basic airway management

Once any degree of obstruction is recognized, immediate measures must be taken to create and maintain a clear airway. There are three manoeuvres that can be used to improve an airway obstructed by the tongue or other upper airway structures: head tilt, chin lift, and jaw thrust.

Fig. 29.2. Head tilt and chin lift. (Reproduced with permission from Dr. Mike Scott.)

Head tilt and chin lift

The rescuer's hand is placed on the patient's forehead and the head is gently tilted back; the fingertips of the other hand are placed under the point of the patient's chin, which is gently lifted to stretch the anterior neck structures (Fig. 29.2).[13–18]

Jaw thrust

Jaw thrust is an alternative maneuver for bringing the mandible forward and relieving obstruction by the soft palate and epiglottis; it was described first in 1874.[5] The rescuer's index and other fingers are placed behind the angle of the mandible, and pressure is applied upwards and forwards. Using the thumbs, the mouth is opened slightly by downward displacement of the chin (Fig. 29.3).

These simple positional methods are successful in most cases in which airway obstruction is caused by relaxation of the soft tissues. If a clear airway cannot be achieved,

Fig. 29.3. Jaw thrust. (Reproduced with permission from Dr. Mike Scott.)

other causes of airway obstruction must be sought. A solid foreign body visible in the mouth should be removed using a finger sweep. Broken or displaced dentures should be removed, but well-fitting dentures are best left in place as they help to maintain the contours of the mouth, facilitating a good seal for ventilation.

Airway management in patients with suspected cervical spine injury

If spinal injury is suspected (e.g., if the victim has fallen, been struck on the head or neck, or has been rescued after diving into shallow water) the head, neck, chest, and lumbar region should be maintained in the neutral position during resuscitation. Excessive head tilt could aggravate the injury and damage the cervical spinal cord;[19–23] however, this complication has not been documented and the relative risk is unknown. When there is a risk of cervical spine injury, a clear upper airway should be established by using jaw thrust or chin lift in combination with manual in-line stabilization (MILS) of the head and neck by an assistant.[24,25] If life-threatening airway obstruction persists despite effective application of jaw thrust or chin lift, head tilt should be added, a little at a time, until the airway is open; establishing a patent airway takes priority over concerns about a potential cervical spine injury.

Adjuncts to basic airway techniques

Simple airway adjuncts are often helpful, and sometimes essential to maintain an open airway, particularly when

resuscitation is prolonged. The position of the head and neck must be maintained to keep the airway aligned. Oropharyngeal and nasopharyngeal airways are designed to overcome backward displacement of the soft palate and tongue in an unconscious patient, but head tilt and jaw thrust may also be required.

Oropharyngeal airways

Oropharyngeal (Guedel) airways (Fig. 29.4) are available in sizes suitable for newborns to those required for large adults. An *estimate* of the size required may be obtained by selecting an airway with a length corresponding to the vertical distance between the patient's incisors and the angle of the jaw. The most common adult sizes are 2, 3, and 4.

If the glossopharyngeal and laryngeal reflexes are present, retching, vomiting, or laryngospasm may occur during insertion of an oropharyngeal airway; thus, insertion should be attempted only in comatose patients.

The procedure for insertion is as follows.

- Open the patient's mouth and insert the airway in the "upside-down" position as far as the junction between the hard and soft palate and then rotate it through 180°; it is then inserted further until it lies in the oropharynx. This rotation technique minimizes the chance of pushing the tongue backwards and downwards. A tongue depressor may also be used to facilitate insertion.
- After insertion, maintain head tilt/chin lift or jaw thrust, and check the patency of the airway.

The oropharyngeal airway can become obstructed at three possible sites:[26] part of the tongue can occlude the end of the airway, the airway can lodge in the vallecula, and it can be obstructed by the epiglottis.

Nasopharyngeal airways

In patients who are not deeply unconscious, a nasopharyngeal airway is tolerated better than an oropharyngeal airway. The nasopharyngeal airway may be life-saving in patients with clenched jaws, trismus, or maxillofacial injuries, when insertion of an oral airway is impossible. Inadvertent insertion of a nasopharyngeal airway through a fracture of the skull base and into the cranial vault is possible, but extremely rare.[27,28] In the presence of a known or suspected basal skull fracture an oral airway is preferred, but if this is not possible, and the airway is obstructed, gentle insertion of a nasopharyngeal airway may be life-saving (i.e., the benefits may far outweigh the risks).

The tubes are sized in millimeters according to their internal diameter, and the length increases with diameter.
Fig. 29.4. Oropharyngeal airway. (Reproduced with permission from Dr. Mike Scott.)

Fig. 29.5. Insertion of nasopharyngeal airway. (Reproduced with permission from Dr. Mike Scott.)

The traditional methods of sizing a nasopharyngeal airway (measurement against the patient's little finger or anterior nares) do not correlate with the airway anatomy and are unreliable.[29] Sizes 6–7 mm are suitable for adults. Insertion can damage the mucosal lining of the nasal airway, causing bleeding in up to 30% of cases.[30] If the tube is too long it may stimulate the laryngeal or glossopharyngeal reflexes to produce laryngospasm or vomiting.

The procedure for insertion is as follows (Fig. 29.5).

- Check for patency of the right nostril.
- Lubricate the airway thoroughly using water-soluble jelly
- Insert the airway bevel end first, vertically along the floor of the nose with a slight twisting action. The curve of the airway should direct it towards the patient's feet. If any obstruction is met, remove the tube and try the left nostril.
- Once in place, check the patency of the airway and adequacy of ventilation by the look, listen, and feel technique. Chin lift or jaw thrust may still be required to maintain airway patency. When there is suspicion of an injury to the cervical spine, maintain correct alignment of the head and neck.

Supraglottic airway devices

The tracheal tube has generally been considered as the optimal method of managing the airway during cardiac arrest. But there is evidence that, without adequate training and experience, the incidence of complications, such as unrecognized esophageal intubation (6%–14% in some studies)[31–34] and dislodgement, is unacceptably high.[35] Prolonged attempts at tracheal intubation are harmful: the cessation of chest compressions during this time will compromise coronary and cerebral perfusion. Several alternative airway devices have been considered for airway management during CPR.[36] Many of these devices are designed to enable ventilation through apertures situated above the laryngeal inlet. Some have perilaryngeal cuffs and some have pharyngeal cuffs. Many also have

Fig. 29.6. Laryngeal mask airway. (Reproduced with permission from Dr. Mike Scott.)

esophageal drain tubes, whereas others are simply placed as esophageal obturators.

The Combitube, the classic laryngeal mask airway (cLMA), and the laryngeal tube (LT) are the only alternative devices that have been studied during CPR, but none of these studies has been powered adequately to enable survival to be studied as a primary endpoint; instead, most researchers have studied insertion and ventilation success rates. There are no data supporting the routine use of any specific approach to airway management during cardiac arrest. The best technique depends on the precise circumstances of the cardiac arrest and the competence of the rescuer.

Laryngeal mask airway and variants

Classic LMA
The cLMA was introduced in 1988 and comprises a wide bore tube with an elliptical inflated cuff designed to seal around the laryngeal opening (Fig. 29.6). When positioned correctly, the cLMA tip lies within the top of the esophagus. Experience with its use is extensive, with 2500 publications and an estimated 200 million insertions worldwide.[36] The cLMA is easier to insert than a tracheal tube.[37–43]

On the basis of data from anesthetic practice, the cLMA establishes an airway in more than 99% of cases; when attempted bag-mask ventilation fails, the cLMA will resolve airway obstruction in more than 95% of cases.[44]

The LMA has been studied during CPR but none of these studies has compared it directly with the tracheal tube. During CPR, successful ventilation was achieved with the LMA in 72%–98% of cases (Table 29.1).[45–51]

Ventilation with the LMA is more efficient and easier than with a bag-mask.[52] When an LMA can be inserted without delay it is preferable to avoid bag-mask ventilation altogether. When used for intermittent positive pressure ventilation, provided that high inflation pressures ($>20\,\mathrm{cm\,H_2O}$) are avoided, gastric inflation can be minimized. In comparison with bag-mask ventilation, use of a self-inflating bag and LMA during cardiac arrest reduces the incidence of regurgitation from 12% to 3%.[53] In cases of suspected neck injury, the cLMA can be inserted easily with the head and neck maintained in a neutral position.[54,55]

In comparison with tracheal intubation, the perceived disadvantages of the LMA are the increased risk of aspiration and inability to provide adequate ventilation in patients with low lung and/or chest wall compliance. There are remarkably few cases of pulmonary aspiration reported in the studies of the LMA during CPR. Rumball and MacDonald reported 1 aspiration out of 15 cases that were autopsied,[45] Tanigawa and Shigematsu reported six
Table 29.1. The success rates for insertion and/or ventilation with the LMA during CPR

Study	In-/out-of-hospital	n	Insertion (%)	Ventilation (%)
Baskett, 1994[48]	In	164	100	86
Kokkinis, 1994[50]	In	50	N/A	98
Leach *et al.*, 1993[51]	In	40	N/A	95

Tanigawa & Shigematsu, 1998[47]	Out	2701	89.5	71.5

cases of aspiration (almost certainly under-reported), [47] and Baskett reported just one case and this patient survived to discharge.[48] There are no data demonstrating whether or not it is possible to provide adequate ventilation via an LMA without interruption of chest compressions. The ability to ventilate the lungs adequately while continuing to compress the chest may be one of the main benefits of a tracheal tube. There has been one case report describing gastric rupture associated with use of the LMA during CPR;[56] however, this complication is more likely to have been caused during the period of layperson CPR before arrival healthcare professionals.[57]

Although often taught as a method for helping to protect the airway from esophageal and gastric sources of aspiration, cricoid pressure is problematic when used with the LMA. Evidence clearly suggests that application of cricoid pressure impairs the correct positioning and function of the LMA.[58–60] The tip of the LMA normally sits within the upper esophageal sphincter where studies on cadavers have shown that acts as an "obturator" preventing, to a certain degree, overspill of esophageal contents into the larynx. This position is important when the LMA is used as a ventilation device. The application of cricoid pressure prevents the LMA from adopting its correct location in relation to the larynx, and the aperture of the LMA is pushed out towards the base of the tongue.

Technique for insertion of a laryngeal mask airway
- Select an LMA of appropriate size for the patient and deflate the cuff fully. A size 5 will be correct for most men and a size 4 for most women. Lubricate the outer face of the cuff area (the part that will not be in contact with the larynx) with water-soluble gel.
Fig. 29.7. Technique for insertion of laryngeal mask airway. (Reproduced with permission from Dr. Mike Scott.)

- Flex the patient's neck slightly and extend the head (try to maintain neutral alignment of the head neck if there is suspicion of cervical spine injury).
- Holding the LMA like a pen, insert it into the mouth (Fig. 29.7). Advance the tip behind the upper incisors with the upper surface applied to the palate until it reaches the posterior pharyngeal wall. Press the mask backwards and downwards around the corner of the pharynx until resistance is felt as it locates in the back of the pharynx. If possible, get an assistant to apply a jaw thrust after the LMA has been inserted into the mouth – this increases the space in the posterior pharynx and makes successful placement easier.
- Connect the inflating syringe and inflate the cuff with air (40 ml for a size 5 LMA and 30 ml for a size 4 LMA); alternatively, inflate the cuff to a pressure of 60 cm H_2O. If insertion is satisfactory, the tube will lift 1–2 cm out of the mouth as the cuff finds its correct position and the larynx is pushed forward.

- If the LMA has not been inserted successfully after 30 seconds, oxygenate the patient by using a pocket mask or bag-mask before reattempting LMA insertion.
- Confirm a clear airway by listening over the chest during inflation and observing bilateral chest movement. A large, audible leak suggests malposition of the LMA, but a small leak is acceptable provided that chest rise is adequate.
- Insert a bite block alongside the tube if available and secure the LMA with a bandage or tape.

Single-use LMA

The cLMA can be reused up to 40 times after sterilization. After the patent for the basic design of the cLMA expired in 2003, several companies have manufactured single-use versions, many of which are currently available. All differ slightly from the cLMA. Several reports indicate slightly increased difficulty with insertion of the single-use variants,[61–63] although seal pressure may be slightly higher in some models.[62–64] There are no studies of single-use laryngeal masks during resuscitation either in or out of hospital and their routine use during CPR cannot necessarily be extrapolated from the data acquired when using the cLMA. Single-use airway devices may have advantages when they are likely to be used infrequently and where there are problems accessing sterilizing services, e.g., out-of-hospital.

ProSeal LMA

The ProSeal LMA (PLMA) is a modified version of the original LMA. It has an additional posterior cuff and a gastric

Fig. 29.8. ProSeal laryngeal mask airway. (Reproduced with permission from Dr. Mike Scott.)

drain tube (Fig. 29.8). The device has been studied extensively in anesthetized patients,[65] but there are no studies of its function and performance during CPR. It has several attributes that, in theory, make it more suitable than the original LMA for use during CPR. Nine comparative studies of 1470 patients indicate that the airway seal pressure is approximately 50% higher with the PLMA than the cLMA (PLMA 27–31 cm H_2O vs. cLMA 16–22 cm H_2O).[65] The inclusion of a gastric drain tube enables venting of liquid gastric contents regurgitated from the upper esophagus and passage of a gastric tube to drain liquid gastric contents. The in-built bite block prevents occlusion of the airway tube. The higher seal pressures achieved with the ProSeal may enable ventilation volume to be maintained during uninterrupted chest compressions. At pressures above 30 cm H_2O, leak-free ventilation should be achievable in 48% of patients with the PLMA, but in only 4% with the cLMA.[66] Potential weaknesses of the ProSeal LMA as an airway device for CPR are that it is slightly more difficult to insert than is the original LMA, it is not available in disposable form at present (although expected to be available in 2007), it is relatively expensive, and that solid regurgitated gastric contents could block the gastric drainage tube. There are no data on its performance during CPR in humans, but the cLMA, PLMA, intubating LMA (ILMA), LMA Unique (single-use), facemask and tracheal tube have been evaluated in a manikin with chest compressions given by a mechanical chest thumper.[67] Ventilation was measured both during interrupted and uninterrupted chest compressions. When chest compressions were paused for ventilation, all airway devices performed adequately. When chest compressions were uninterrupted, only the PLMA, ILMA, and tracheal tube (TT) enabled effective ventilation of the manikin; excessive gastric inflation occurred with the other airway devices. The Proseal LMA is also inserted easily with the head and neck maintained in a neutral position, making it useful in suspected cases of cervical spine injury.[68]

Intubating LMA

The intubating LMA (ILMA) is valuable for managing the difficult airway during anesthesia, but it has not been studied during CPR. Although it is relatively easy to insert the ILMA,[69,70] reliable, blind insertion of a tracheal tube requires considerable training[71] and, for this reason, it is not an ideal technique for the inexperienced provider. The ILMA provides a slightly higher airway seal pressure than the cLMA (ILMA 34 cm H_2O vs. cLMA 27 cm H_2O) enabling leak-free ventilation in a higher proportion of patients. [70] Further improvements in the seal pressure are possible by pushing the ILMA onto the laryngeal inlet after first optimizing its

position. The device can also be inserted successfully with the head and neck maintained in a neutral position in suspected cases of cervical spine injury.[72] Concerns surrounding the pressure applied to the cervical spine by the rigid metal tube of the ILMA have not been substantiated and there are no case reports of neurological deterioration after ILMA insertion in patients with known cervical spine injury.[73,74] Like the cLMA, cricoid pressure significantly impairs the ability to place the ILMA correctly.[75] A single-use version of the ILMA is now available, which may make it a useful option for managing the airway during CPR.

Combitube

The Combitube is a double-lumen airway available in two sizes (37F SA and 41F).[76] It is passed blindly into the mouth, over the tongue and into the pharynx. It enables ventilation of the patient's lungs whether the tube enters the esophagus or trachea. The tracheal channel has an open distal end. The esophageal tube has no terminal opening, but has several small side-holes located between two cuffs. A large volume pharyngeal cuff (85–100 ml) and a small volume distal cuff (12–15 ml) are used to create seals so that the device may function correctly. Each cuff has an independent pilot balloon. The Combitube is positioned by opening the mouth and manually lifting the jaw. Prior bending of the device into a "hockey stick" configuration aids placement. A laryngoscope is not necessary and, if the Combitube is inserted correctly, no fixation is required. When introduced blindly, the tube usually enters the esophagus (in 95% of cases), and the patient's lungs are ventilated through the esophageal channel via the side holes located at, or above, the larynx (Fig. 29.9(a)). Gas cannot pass down the esophagus because of the blind end of the esophageal channel, and the distal cuff, which is positioned just proximal to the blind end. If the tube enters the trachea, ventilation is achieved via the tracheal port through its open distal end (Fig. 29.9(b)).

The Combitube may have some distinct advantages over other available airway adjuncts. It occludes the esophagus with a distal cuff and allows "venting" of esophageal and gastric contents via one of the two lumens. This may also protect against gastric rupture. Ventilation with high airway pressures is possible, furthermore, the Combitube functions well with the neck maintained in a neutral position making it potentially useful in victims of trauma.[77]

Early published data with use of the device showed an improvement in arterial oxygenation when compared with ventilation via a tracheal tube at equivalent oxygen concentrations.[78] This is probably a consequence of positive end expiratory pressure in the trachea generated via increased

(a)

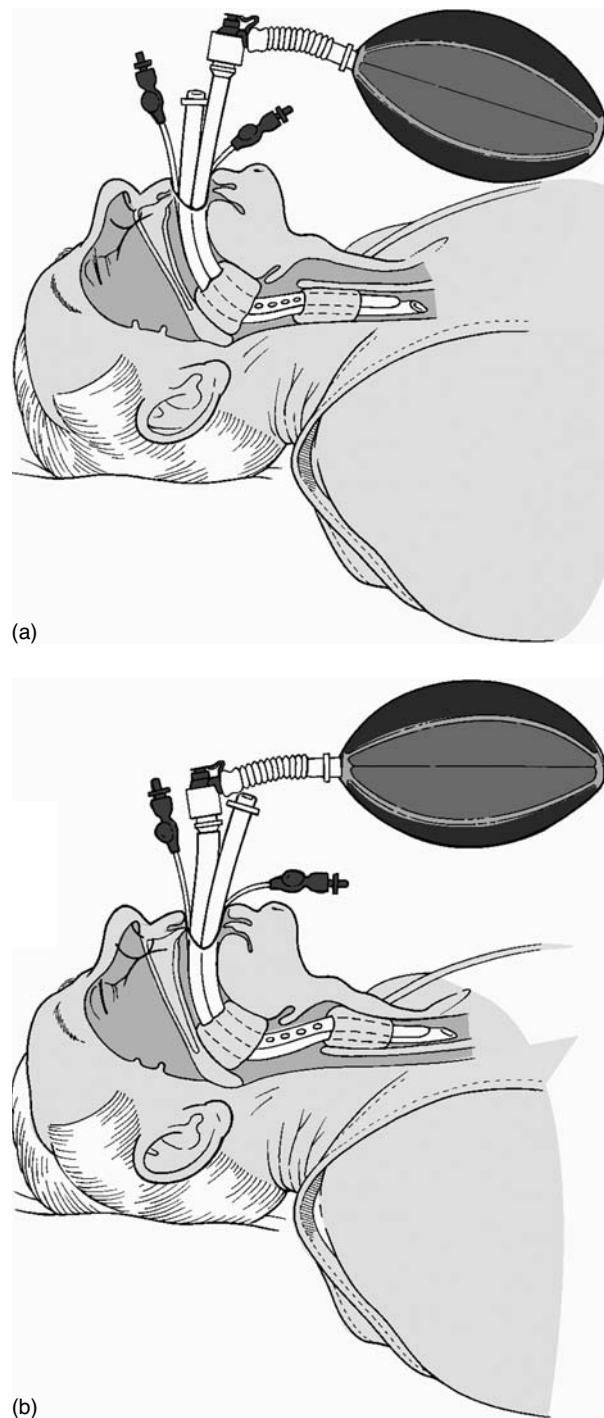
(b)


Fig. 29.9. Combitube in (a) esophageal and, (b) tracheal positions.

resistance to expiration through the small supraglottic apertures. There may also be some degree of glottic closure.

There are many studies of the Combitube in CPR and successful ventilation was achieved in 79%–98% of patients

Table 29.2. The success rates for insertion and/or ventilation with the Combitube during CPR. All except that of Staudinger *et al.** are out-of-hospital studies

(Table 29.2).[47,79–85] All except one[79] of these studies involved out-of-hospital cardiac arrest, which reflects the infrequency with which the Combitube is used in hospitals. The Combitube has been compared directly with the tracheal tube during CPR in four controlled studies (Table 29.3). On the basis of these studies, the Combitube appears as safe and effective as tracheal intubation for airway management during cardiac arrest; however, there are inadequate survival data to permit us to comment with certainty on the impact on outcome. The relatively poor success rates in both studies by Rumball and colleagues' probably reflects the relatively short period of manikin-only training;[45,84] however, the physicians in the Rabitsch study received just 2 hours of manikin training with the Combitube (they were already skilled in tracheal intubation).[85] It is possible to attempt to ventilate the lungs through the wrong port of the Combitube (2.2% in one study):[80] this is equivalent to unrecognized esophageal intubation with a standard tracheal tube.

Recent work has suggested that higher airway pressures (up to 30 cm H_2O) can be generated with the Combitube than with the cLMA.[87] Furthermore, drug access to the trachea via the Combitube has been demonstrated successfully with both lidocaine and adrenaline.[88] One other major advantage of the Combitube is the ability to deflate the pharyngeal balloon while keeping the esophageal balloon inflated. The trachea can thus be safely intubated and protected from esophageal contents when the device needs to be exchanged for a tracheal tube. Finally, it appears that the Combitube protects the larynx well from soiling above the larynx. A study of methylene blue instilled above the inflated pharyngeal balloon has demonstrated little staining of the trachea.[89]

Limitations of the Combitube

Much of the recent work has also highlighted problems with the Combitube. The device may be difficult to insert without correct training. Since it is not in daily use for non-emergencies, teaching is limited to manikins. It also causes a degree of pharyngeal or laryngeal trauma during insertion. In two studies, the incidence of blood staining the Combitube after removal was 24% and 45%.[89,90] Some trauma may be related to overdistension of the pharyngeal balloon and consequent stretching of the pharyngeal mucosa. It would seem prudent therefore to recommend that the proximal cuff is inflated sufficiently only to create the best pharyngeal seal possible. More recently this suggestion has been supported with pharyngeal cuff volumes for the Combitube correlating well with patient height when titrated to leak pressure.[87,91] Furthermore, esophageal rupture,[82,92] mucosal tears and hematomas[91] have been reported after Combitube insertion. Studies in cadavers have demonstrated significant distortion to the esophagus by the Combitube, thought to be due to pressure exerted by its tip which is angulated anteriorly.[93] This may, in part, explain some of the reported cases of esophageal perforation.

There are also reports of a complete inability to ventilate the lungs by using the Combitube. This is usually caused by the device being inserted too far, with the pharyngeal cuff sitting directly over the laryngeal inlet. Withdrawing the tube a small distance easily overcomes the problem. Finally, while it has been shown that ventilation in the presence of a cervical collar is adequate, insertion of the Combitube with the patient wearing a cervical collar is very difficult. One study demonstrated a complete inability to insert the device in 10/15 patients when a rigid cervical collar was in place.[77] This was probably caused by poor mouth opening and the size of the device. In half of these failures insertion was possible with the aid of a laryngoscope. Other studies have demonstrated that, in comparison with several other supraglottic airway devices, the Combitube potentially causes the most cervical spine movement.[23]

Laryngeal tube

The laryngeal tube (LT) is a relatively new airway device (Fig. 29.10); its function in anesthetized patients has been reported in several studies.[94,95] The performance of the LT is favorable in comparison with the classic LMA and ProSeal LMA[96–99] and successful insertion rates have been reported even in studies of paramedics and emergency medical technicians.[100,101] There are sporadic case reports relating to use of the LT during CPR.[102,103] In a recent study, the LT was placed in 30 patients in cardiac arrest out-of-hospital by minimally trained nurses.[104] Insertion of the laryngeal tube was successful within two attempts in 90% of patients, and ventilation was adequate in 80% of cases. No regurgitation occurred in any patient.

Table 29.3. Controlled studies comparing the Combitube with the tracheal tube during CPR

Study	n	Ventilation success Combitube	Ventilation success Tracheal tube	Comments
Staudinger et al., 1993[79]	37	16/17 (94%)	19/20 (95%)	In-hospital, better P_aO_2 with Combitube

Rabitsch et al., 2003[85]	172	87/89 (98%)	78/83 (94%)	5 intubation fails had Combitube OK 2, Combitube fails were intubated Insertion time shorter with Combitube (12 s vs. 18 s) – Physicians
Rumball et al., 2004[84]	357	62//95 (65%)	175/250 (70%)	Minimal training

There are three other modified versions of the LT: the single-use LT, the LT-Suction II, and the single-use LT-Suction II.[95] The LT-Suction II has a suction tube located behind the airway tube. Two studies of the first version of this device in anesthetized patients indicate that its performance is similar to the ProSeal LMA[105,106], but one study concluded that the quality of the airway achieved with the LT-Suction was inferior to that achieved with the ProSeal LMA.[107] The LT-Suction II has yet to be studied during CPR.

Other new supraglottic airway devices

There are now a large variety of commercially available new airway devices. All are designed in some way to be placed above the larynx and allow a blind insertion technique. Current manufacturing legislation allows such devices to be sold for clinical use without any properly conducted human trial data as to their efficacy. Many of the new devices are marketed for use during cardiopulmonary resuscitation, but until reliable data are available, they should be used with caution. Recent work and subsequent correspondence concerning where some of these new devices are positioned within the pharynx has highlighted some of the issues.[108,109]

Tracheal intubation

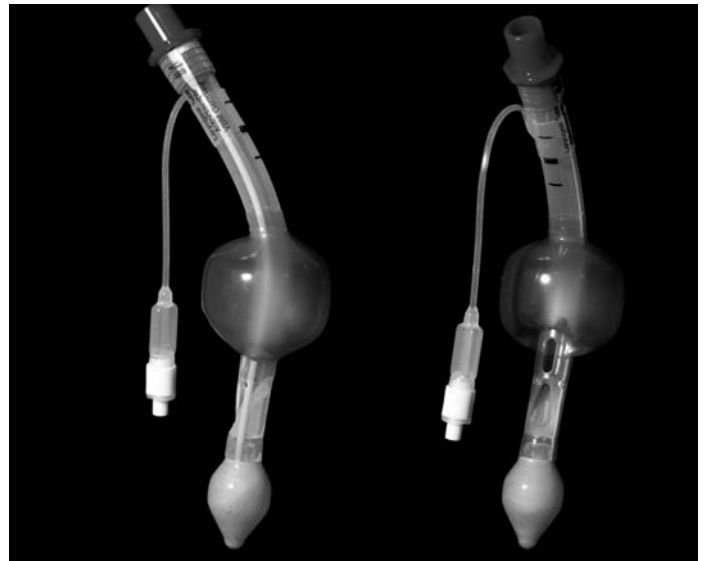
There is insufficient evidence to support or refute the use of any specific technique to maintain an airway and provide ventilation in adults with cardiopulmonary arrest. Despite this, tracheal intubation is perceived as the optimal method of providing and maintaining a clear and secure airway. It should be used only when highly skilled, confident personnel are available to carry out the procedure. The only


Fig. 29.10. Laryngeal tube. (Reproduced with permission from Dr. Mike Scott.)

randomized controlled trial comparing tracheal intubation with bag-mask ventilation (BMV) was undertaken in children requiring airway management out-of-hospital.[110] There was no difference in survival to discharge: 123/404 (30%) in the bag-mask group vs. 110/416 (26%) in the intubation group (OR 0.82 (95% CI 0.61–1.11)). In the children with a diagnosis of cardiopulmonary arrest ($n = 591$) the survival to hospital discharge was 24/290 (8%) in the bag-mask group vs. 24/301 (8%) in the tracheal intubation group. Of the 420 children in the intubation group, paramedics attempted intubation in 305 (73%) and, of these, 174 (57%) were intubated successfully. There were three

(2%) unrecognized esophageal intubations and 12 (6%) unrecognized tube dislodgements. The incidence of vomiting (14%) and aspiration (14%–15%) was no different between the groups, but gastric distention was more common in the bag-mask group (31% vs. 7%). It is very difficult to extrapolate these data to adult cardiac arrest: children are more difficult to intubate and tube dislodgement is probably more likely, paramedic training was suboptimal (6 h of classroom training in pediatric airway management; they were already trained in and practiced adult tracheal intubation), and the etiology of cardiac arrest in children is different from that in adults. Two studies compared outcomes from out-of-hospital cardiac arrest in adults when treated by either emergency medical technicians or paramedics.[111,112] The skills provided by the paramedics, including intubation and intravenous cannulation[111,112] and drug administration,[112] made no difference to survival to hospital discharge.

The perceived advantages of tracheal intubation over bag-mask include: maintenance of a patent airway, which is protected from aspiration of gastric contents or blood from the oropharynx; ability to provide an adequate tidal volume reliably, even when chest compressions are uninterrupted; the ability to generate high airway pressures where significant resistance is encountered, e.g., asthma; the potential to free the rescuers' hands for other tasks; the ability to suction airway secretions; and the provision of a route for giving drugs. Use of the bag-mask is more likely to cause gastric distension, which, theoretically, is more likely to cause regurgitation with risk of aspiration; however, the higher incidence of regurgitation occurred in a study of the laryngeal mask airway vs. bag-mask.[53] Nonetheless, there are no reliable data to indicate that the incidence of aspiration is any lower in cardiac arrest Patients ventilated with bag-mask versus those who are ventilated via tracheal tube.

The perceived disadvantages of tracheal intubation over the bag-mask include: the risk of an unrecognized misplaced tracheal tube, which in patients with out-of-hospital cardiac arrest is as high as 6%[31–33] to 14% (Table 29.4);[34] a prolonged time without chest compressions while intubation is attempted; and a comparatively high failure rate. Intubation success rates correlate with the intubation experience attained by individual paramedics.[113] Rates for failure to intubate are as high as 50% in prehospital systems with a low patient volume and providers who do not perform intubation frequently.[33] The cost of training prehospital staff to undertake intubation should also be considered. Healthcare personnel who undertake prehospital intubation should do so only within a structured, monitored program, which should include comprehensive competency-based training and regular opportunities to refresh skills.

Table 29.4. Reported rates of unrecognized esophageal intubation after out-of-hospital cardiac arrest

Study	Number (%)

In some cases, laryngoscopy and attempted intubation may prove impossible or cause life-threatening deterioration in the patient's condition. Such circumstances include acute epiglottitis, pharyngeal pathology, head injury (where straining may occur, further raising intracranial pressure), or in patients with cervical spine injury. In these circumstances, specialist skills such as the use of anesthetic drugs or fiberoptic laryngoscopy may be required. These techniques require a high level of skill and training.

Rescuers must weigh the risks and benefits of intubation against the need to provide effective chest compressions. The intubation attempt will require interruption of chest compressions, but once an advanced airway is in place, ventilation will not require interruption of chest compressions. Personnel skilled in advanced airway management should be able to perform laryngoscopy without stopping chest compressions – a brief pause in chest compressions will be required as the tube is passed through the vocal cords. Alternatively, to avoid any interruptions in chest compressions, the intubation attempt may be deferred until return of spontaneous circulation. No intubation attempt should take longer than 30 seconds: if intubation has not been achieved after this time, bag-mask ventilation should be restarted.[3] After intubation, tube placement must be confirmed and the tube secured adequately.

Aids to intubation

Alternative laryngoscope blades

The Macintosh blade is a good general-purpose blade and size 3 is suitable for most adults. Occasionally a longer (size 4) blade is better for very large, long-necked patients. The McCoy levering laryngoscope has a hinged tip, and will often improve the view at laryngoscopy.[114] Use of the straight blade is occasionally necessary and often preferred by some, particularly in the United States.[115,116]

Introducers

If visualization is difficult, a gum elastic bougie may be helpful to guide the tracheal tube into the larynx.[117–120] It is best inserted into the larynx separately – the tube is then passed over it into the trachea. When correctly placed, a bougie will demonstrate "hold up" within the bronchial tree.[121] A bougie placed accidentally in the esophagus will pass without obvious resistance.

Newer single-use bougies are now widely available. They do not possess the same memory, i.e., retain the shape into which they are preformed before insertion into the trachea, and their performance is inferior to the reusable device.[122,123]

Confirmation of correct placement of the tracheal tube

Unrecognized esophageal intubation is the most serious complication of attempted tracheal intubation – routine use of primary and secondary techniques to confirm correct placement of the tracheal tube should reduce this risk. Primary assessment includes observation of chest expansion bilaterally, auscultation over the lung fields bilaterally in the axillae (breath sounds should be equal and adequate) and over the epigastrium (breath sounds should not be heard). Clinical signs of correct tube placement (condensation in the tube, chest rise, breath sounds on auscultation of lungs, and inability to hear gas entering the stomach) are not completely reliable. Secondary confirmation of tracheal tube placement by an exhaled CO_2 or esophageal detection device should reduce the risk of unrecognized esophageal intubation. If there is doubt about correct tube placement, the laryngoscope should be used to see if the tube passes through the vocal cords.

None of the secondary confirmation techniques will differentiate a tube placed in a main bronchus from one placed correctly in the trachea. Data are currently inadequate to identify the optimal method of confirming tube placement during cardiac arrest and all devices should be considered as adjuncts to other confirmatory techniques.[1,124]

Esophageal detector device

The esophageal detector device creates a suction force at the tracheal end of the tracheal tube, either from pulling back the plunger on a large syringe or releasing a compressed flexible bulb. Air is aspirated easily from the lower airways through a tracheal tube placed in the cartilage-supported rigid trachea. When the tube is in the esophagus, air cannot be aspirated because the esophagus collapses when aspiration is attempted. The esophageal detector device is generally reliable in patients with both a perfusing and a non-perfusing rhythm, but it may be misleading in patients with morbid obesity, late pregnancy, or severe asthma, or when there are copious tracheal secretions; in these conditions the trachea may collapse when aspiration is attempted.[33,125–129]

The esophageal detector device is highly sensitive for detecting misplaced tracheal tubes in the esophagus.[129–133] But in two studies of patients in cardiac arrest, the esophageal detector device had poor sensitivity for confirming tracheal placement of a tracheal tube:[125,126] up to 30% of correctly placed tubes may have been removed because the esophageal detector device suggested esophageal placement of a tube.[134]

Carbon dioxide detector devices

Carbon dioxide detector devices (waveform, colorimetry, or digital) measure the concentration of CO_2 exhaled from the lungs and may be useful as adjuncts to confirm tracheal tube placement during cardiac arrest.[124,126,134–144] The persistence of exhaled CO_2 after six ventilations indicates placement of the tracheal tube in the trachea or a main bronchus.[135] Confirmation of correct placement above the carina will require auscultation of the chest bilaterally in the mid-axillary lines. In patients with a spontaneous circulation, a lack of exhaled CO_2 indicates that the tube is in the esophagus. During cardiac arrest, pulmonary blood flow may be so low that there is insufficient exhaled CO_2, so the detector does not identify a correctly placed tracheal tube. When exhaled CO_2 is detected in cardiac arrest, it indicates reliably that the tube is in the trachea or main bronchus, but when it is absent, placement of the tracheal tube is best confirmed with an esophageal detector device. A variety of electronic as well as simple, inexpensive, colorimetric CO_2 detectors are available for both in-hospital and out-of-hospital use. Again data from cardiac arrests are insufficient to enable any firm recommendations for any particular one of these techniques.

If there is a perfusing rhythm, detection of exhaled CO_2 can be used to monitor tracheal tube position during transport. [145]

Cricoid pressure

During bag-mask ventilation and attempted intubation, cricoid pressure applied by a trained assistant should prevent passive regurgitation of gastric contents and the consequent risk of pulmonary aspiration.[146–150]

The cricoid cartilage is identified immediately below the thyroid cartilage where it forms a complete ring at the upper end of the trachea. A pressure of 30 newtons (3 kg) is

Fig. 29.11. Application of cricoid pressure. (Reproduced with permission from Dr. Mike Scott.)

applied anteroposteriorly, forcing the cricoid ring backwards to press the esophagus against the vertebral column (Fig. 29.11).[151,152] Pressure should be maintained continuously until a tracheal tube is inserted through the vocal cords and the cuff has been inflated. Although effective at preventing passive regurgitation, cricoid pressure should not be used in cases of active vomiting or retching, as it could result in damage/rupture to the esophagus, particularly in the presence of esophageal pathology.[153] In patients with suspected cervical spine injury, counter-pressure may be applied to the back of the neck to reduce movement of the cervical spine.[154] If the technique is applied imprecisely or with excessive force, ventilation with a bag–valve–mask and tracheal intubation can be made significantly more difficult. Application of cricoid pressure at 30 N causes airway obstruction in 3% of patients compared with 35% when 40 N are applied.[155] If ventilation of the patient's lungs is not possible, reduce the pressure applied to the cricoid cartilage or remove it completely.

It is also important to apply the cricoid pressure in the correct direction. If the true perpendicular anterior–posterior position is not used, significant problems may occur. Pushing the larynx in an upward direction (a technique often used to improve the view at laryngoscopy) will cause closure of the vocal cords and worsen any attempts at ventilation.[152] If the patient's head and neck are not aligned correctly, e.g., during lateral tilting of the pregnant patient, the view at laryngoscopy may be made worse if the cricoid is displaced to the left.

Securing the tracheal tube

Accidental dislodgement of a tracheal tube can occur at any time, but may be more likely during resuscitation and during transport. There are no studies comparing different strategies for securing the tracheal tube during CPR. Two studies undertaken in intensive care units,[156,157] comparing commercial devices with traditional taping for securing tracheal tubes, reported no difference in rates of accidental tube displacement. Thus, either conventional tapes or ties, or purpose-made tracheal tube holders can be used to secure the tracheal tube during CPR.

Cricothyroidotomy

Occasionally it will be impossible to ventilate an apnoeic patient with a bag-mask, or to pass a tracheal tube or alternative airway device. This may occur in patients with extensive facial trauma or laryngeal obstruction caused by edema or foreign material. In these circumstances, delivery of oxygen through a needle or surgical cricothyroidotomy may be life-saving.[158–160] A tracheostomy is contraindicated in an emergency as it is time-consuming, hazardous, and requires considerable surgical skill and equipment.

Surgical cricothyroidotomy provides a definitive airway that can be used to ventilate the patient's lungs until semielective intubation or tracheostomy is performed. Needle cricothyroidotomy is a much more temporary procedure providing only short term oxygenation.[161] It requires a

wide-bore non-kinking cannula, a high pressure oxygen source, runs the risk of barotrauma, and can be particularly ineffective in patients with chest trauma. It is also prone to failure because of kinking of the cannula, and is unsuitable for patient transfer. A recent cadaver study indicated that a Seldinger technique cricothyroidotomy was quicker to achieve than a standard surgical technique;[162] however, an animal study indicated that a cannula-over-needle technique (Quicktrach) was better than a wire-guided technique (Mini-trach).[163]

Several new purpose-built cricothyroidotomy devices are now available, e.g., PCT (Portex), Quicktrach II (VBM), cuffed Melker (Cook). These are manufactured to enable quick and easy insertion, they have a short wide-bore tube permitting ventilation with a self-inflating bag, and they have cuffs to enable both high airway pressure ventilation and airway protection.

Summary

Airway obstruction is common during cardiopulmonary arrest; establishing and maintaining a patent airway is a fundamental component of cardiopulmonary resuscitation. Basic airway maneuvers with or without the use of simple adjuncts will often enable airway patency to be established. In the hands of highly skilled personnel, tracheal intubation should provide the most reliable protection of the airway and route for ventilation of the lungs during cardiac arrest. The time taken to insert the tracheal tube and the risk of unrecognized esophageal intubation, however, are significant disadvantages. Supraglottic airway devices, such as the LMA and Combitube, are easier to insert than a tracheal tube and may be a better option for personnel who are not skilled in tracheal intubation. Several other supraglottic devices are available, but there are insufficient data to recommend their use during CPR.

External chest compression: standard and alternative techniques

Manual cardiopulmonary resuscitation techniques

Henry R. Halperin and Barry K. Rayburn

Johns Hopkins University School of Medicine, Baltimore, MD, USA
University of Alabama School of Medicine, Birmingham, AL, USA

The standard technique of external chest compression in cardiopulmonary resuscitation (CPR) has changed little since the landmark paper of Kouwenhoven *et al.* in 1960 (Fig. 30.1).[1] This is despite the fact that a variety of alternate techniques have been proposed as providing an advantage over the standard method. The rhythmic application of force to the body of the patient is fundamental to the process of generating blood flow in CPR, but there is little agreement as to the optimal technique for applying that force. There is a great need for improved external chest compression techniques since only an average of 15% of patients treated with standard CPR survive cardiac arrest,[2,3] and it is widely agreed that increasing the blood flow generated by chest compression will improve survival.

This chapter will review the standard external chest compression technique as it is currently taught, including its origins and its rather scant scientific basis. It will also explore in detail the origins, physiology, and applicability of some alternate manual techniques that have been proposed.

Standard external chest compression

According to the most recently published guidelines of the Emergency Cardiac Care Committee of the American Heart Association,[4] external chest compressions are applied by the rescuer who places the heel of one hand over the victim's sternum. The second hand is placed on top of the first in such a way that the fingers do not touch the chest. The fingers may be interlocked if desired. Force is applied straight down with the elbows locked and the shoulders in line with the hands. The goal is to displace the sternum

1 1/2 to 2 inches for an average sized adult victim. The compressions are repeated at a rate of 100 times/minute regardless of whether there are one or two rescuers. Compression is maintained for 50% of each cycle to maximize arterial pressures, but is released completely between cycles without removing the hands from the chest. The Emergency Cardiac Care Committee guidelines provide specific recommendations for the integration of compressions with artificial respiration. Without endotracheal intubation, it is recommended that there be cycles of 30 compressions followed by two ventilations. With endotracheal intubation, it is recommended that compressions not be interrupted for ventilation. Additional guidelines specify the optimal method for two rescuers to switch roles during a resuscitation and also for the introduction of a second rescuer to ongoing one-rescuer CPR. Readers are referred to the latest published manuals on basic and advanced life support for full details and the most up-to-date recommendations regarding the performance of CPR. Although training programs in CPR are widespread, little is known about how often chest compressions are performed correctly in actual resuscitations or how this affects survival.

Origin

In the article by Kouwenhoven *et al.*,[1] two earlier investigators were cited who described external chest compression in a limited fashion. Boehm in 1878 described a study in which he applied pressure to the thorax of cats by wrapping his hands around the chest (analogous to the current recommendations for infant external chest compression).[5] In 1934, Tournade *et al.* described the hemodynamic

Fig. 30.1. (**a**) Illustration from the original article by Kouwenhoven *et al.* describing the technique of external chest compression. (**b**) Illustration from the latest published guidelines for the performance of chest compressions. Note the similarity between the illustrations even though they were published over 30 years apart. (b)
results of a sudden compression of the chest in a dog.[6] The extent to which Kouwenhoven was influenced by these studies is unclear. In a review of the history of cardiopulmonary resuscitation research, Criley *et al.* described Kouwenhoven's discovery of closed-chest massage as "the serendipitous by-product of defibrillation studies in animals."[7] Regardless of these earlier studies, 1960 was the dawn of modern CPR and specifically of the standard technique of external chest compression as it is currently used.

In the many years since the article by Kouwenhoven and colleagues, the details of how external chest compressions are integrated into the technique we know as CPR have changed somewhat in response both to anecdotal observations and to sound research in the field. In general, changes have become accepted into standard practice by their adoption by an organization, and incorporated into that organization's teaching standards for CPR.

The first widely disseminated guidelines for the performance of CPR, including external chest compression, were published in 1966,[8] a mere 6 years after the original description of CPR in the literature. These guidelines were written by an ad hoc committee of the National Academy of Sciences – National Research Council. Widespread interest in CPR prompted rapid, national attention. The salient points for chest compression in these first guidelines were (*a*) compression to a depth of 1 1/2 to 2 inches over the lower half of the sternum; (*b*) avoidance of compression over the xiphoid process; (*c*) a firm support behind the patient; and finally (*d*) equal duration of compression and relaxation phases. Although these guidelines were not specifically referenced, many stem from the original article

of Kouwenhoven et al. and seem to be based mostly on empiric observations.[1]

The guidelines that were published in 1974 introduced the American Heart Association (AHA) as a cosponsor,[9] by which time the AHA and the American Red Cross had already become leaders in education in the technique of CPR. The guidelines for external chest compression changed only minimally in this publication, with new emphasis placed on moving the victim to a horizontal position before initiating compressions and a more refined technique for identifying the correct position of the hands while avoiding compression of the xiphoid. These guidelines were the first to instruct the rescuer not to remove his hands from the chest wall during relaxation, a variance from the original technique introduced by Kouwenhoven *et al*. Once again, this suggestion was not specifically referenced and its origin is uncertain. In 1979 a conference to update these guidelines was convened, and the results were published in 1980;[10] external chest compression was codified into 11 steps, but few changes were added to the existing recommendations. These guidelines were the first to mention the importance of keeping the fingers off the chest while performing compressions but again do not cite a reference for this recommendation. All of the published guidelines up to this point had maintained a recommended compression rate of 60 per minute for two-person CPR and 80 per minute for one-person CPR (the latter yielding 60 actual compressions because of the mandatory pause for ventilation). In 1986, the guidelines were again revised, but the only change made was an increase in the recommended rate of compressions to 80 to 100 per minute for both one- and two-rescuer CPR.[11] This change was made based on the basis of strong recommendations from several researchers in the field. Despite a disagreement on the exact mechanism of blood flow during CPR (Chapter 17), most researchers agreed that a faster compression rate would improve blood flow. Those who favored direct cardiac compression as the dominant mechanism of blood flow believed that more compressions per minute would yield more blood flow. Likewise, those who favored changes in intrathoracic pressure as the dominant mechanism sought to assure that compression and relaxation were equal in duration. This was much more easily accomplished by rescuers at a rate of 80 to 100 per minute than at 60 per minute. The most recent guidelines for the performance of CPR, joint publication by the American Heart Association and the International Liaison Committee on Resuscitation (ILCOR), were published in 2005.[4] Those latter guidelines had a number of changes: (1) The rate of compressions should be 100/min, (2) During the decompression phase of the chest compression cycle,

there should be complete recoil of the chest with no residual force being applied by the rescuer, (3) There should be as few interruptions as possible, and (4) The hands should be placed over the mid sternum, rather than trying to measure the placement with respect to the xiphoid.[4]

Physiology

Developments in the field of closed-chest defibrillation served as a driving force in the rapid acceptance of external chest compression as a beneficial technique. Kouwenhoven and others recognized that closed-chest defibrillation provided an opportunity to reverse a process that was previously irreversible. Further, it was recognized in early studies of defibrillation that it was only successful if applied during the first few minutes after the onset of ventricular fibrillation, which was assumed to be due to the effects of lack of blood flow to the heart itself during fibrillation. Thus, the primary physiologic goal of external chest compression was to maintain the heart in a state where external defibrillation would be effective for as long as possible.

In their original paper, Kouwenhoven *et al.* stated that chest compression "compresses the heart between [the sternum] and the spine, forcing out blood."[1] From the data presented in that paper, it is clear that this statement was fundamentally an assumption on the part of the investigators, based on the anatomical relationships of the heart and bony thoracic structures. Despite this lack of rigorous scientific data, and a certain amount of skepticism, the concept of direct cardiac compression as the sole explanation for the movement of blood during standard external chest compression was widely taught for nearly two-and-a-half decades. In the last 20 years, this assumption has come under rigorous investigation. It is now apparent that the exact mechanism by which blood moves in response to externally applied force is complicated, and probably involves a combination of mechanisms. A detailed discussion of the controversies surrounding the mechanisms of blood flow in CPR is presented in Chapter 17.

Discussions of the efficacy of various techniques of CPR usually focus on either hemodynamic considerations (blood flow, perfusion pressures, and others), on initial survival (also known as return of spontaneous circulation), or on long-term survival (survival to hospital discharge and beyond). In order to provide a basis of comparison for alternative techniques of external chest compression, we will briefly review the results of the standard technique in these terms. Much of the available data regarding the hemodynamics and outcome of standard CPR come from the control groups of studies of various alternate techniques, raising concern that some bias against the standard

[b] NA, not available.

technique may be present. Some investigators have attempted to minimize bias by measuring and controlling the amount of compression force or displacement.

Although small amounts of data are available for a wide variety of species, the dog model of cardiac arrest is most widely used in CPR research. Table 30.1 lists the results obtained by several investigators during standard external chest compression in dogs. The wide variation in the data highlights the difficulty in comparing CPR studies; "conventional" or "standard" external chest compression is described in a similar fashion in all the publications. It has been shown that critical determinants of blood flow during chest compression include the sternal compression force (or depth of compression; Chapter 17)[12,13], the duration of compression (percent of the compression cycle during which compression occurs),[12] and the use of vasopressors.[14] Not all authors, however, control for or even measure these variables. In addition, even the methods used for determining perfusion pressures and flows differ greatly. While such ambiguities make direct comparisons difficult, some general conclusions can be drawn from the data. The very highest coronary perfusion pressure in these studies resulted in only 30% of control myocardial blood flow. Most of the results were, or would be expected to be, considerably worse than this (based on lower perfusion pressures). Cerebral blood flow is likewise poor, attaining less than 60% of control level in all dog studies of standard external chest compression reviewed. The wide variation among peak or systolic aortic pressures in these studies likely reflects variations in the force applied during compression as well as the effects of using epinephrine. This suggests that an improvement in perfusion pressures and flow could be attained by applying higher force in standard external chest compression. In both animals and man,

trauma becomes the limiting factor in applying excessive force to the sternum. Fig. 30.2 shows several pressure tracings of standard external chest compression in dogs. The differences in these tracings further illustrate the difficulty in comparing studies and the need for rigorous standardization of external chest compression in laboratory models of CPR.

Survival studies in animal models of CPR have been performed, but are of somewhat limited utility. True long-term survival is not an available endpoint in an instrumented animal model. At best, 24-hour survival has been measured with an attempt to look at some type of neurologic outcome. Available 24-hour survival studies with standard external chest compression demonstrate that between 14 and 50% of animals survive.[15–18] Again, differences in the experimental protocols as well as subtle differences in the application of "standard" CPR likely account for this variability. In any case, 24-hour survival in animal models of cardiac arrest receiving standard external chest compression is probably better than can be expected in large populations of human cardiac arrest patients, simply because of the inherent absence of underlying pathology in the study animals, and less time between the onset of arrest and the start of CPR. Animal survival data are perhaps most useful in estimating the best possible human outcome from a CPR technique. These studies are done by highly motivated and trained investigators in well-equipped laboratories, and it is unlikely that most human resuscitation efforts will have such advantages.

All of the difficulties that exist in comparing one animal study to another are magnified in studies of human CPR. When considering hemodynamic outcomes and survival data, it is critical to take into account that the exact method of applied force is only one of many variables that may

influence the results. The population studied, other components of the resuscitation protocol, the time between arrest and intervention, and a host of other factors influence the final outcome.

Unlike comparable animal studies, direct measurements of myocardial and cerebral blood flow are not available in human CPR. Surrogate measures of efficacy include peak compression-phase (systolic) pressure, myocardial and cerebral perfusion pressures, and direct and indirect measures of cardiac output (Table 30.2; Fig. 30.3). Several animal studies have shown that the myocardial perfusion pressure (typically defined as the difference between aortic

release phase (diastolic) pressure and right atrial pressure) is a predictor of return of spontaneous circulation.[19–22] Paradis *et al.* were also able to demonstrate this in humans undergoing CPR.[23] In their study of 100 patients, only patients who could achieve a maximum myocardial perfusion pressure of greater than or equal to 15 mm Hg had return of spontaneous circulation. This finding is consistent with the results from animal studies and serves as a useful benchmark for assessing alternative external compression techniques.

The clinically important results from human CPR studies are long-term survival and neurologic function.
Fig. 30.3. Hemodynamic tracing from a patient undergoing standard external chest compressions. Note the relatively low coronary perfusion pressure despite similar compression phase pressures when compared with Fig. 30.2 in a dog model. (From Halperin, H.R., Tsitlik, .J.E., Gelfand, M., *et al.* A preliminary study of cardiopulmonary resuscitation by circumferential compression of the chest with the use of a pneumatic vest. *N Engl J Med* 1993; **329**: 762–768. Reprinted by permission of *The New England Journal of Medicine.* Copyright 1993 *Massachusetts Medical Society.* All rights reserved.)

Notably, despite the large number of variables that play a role in the outcome of CPR, several studies have achieved similar results. Schneider *et al.* have provided one of the most comprehensive reviews on survival following in-hospital standard CPR (including standard external chest compression).[2] Their review of 98 reports of clinical outcomes in CPR includes nearly 20 000 patients. A meta-analysis of these reports showed that overall survival-to-hospital discharge in this group of patients was 15%. An additional 3765 patients reported from a British registry had a survival-to-hospital discharge of approximately 20% with a 1-year survival of 15%.[3] Among the noteworthy findings of the analysis by Schneider et al. was the absence of any significant trend in survival-to-hospital discharge across the years from 1960 to 1990. This disputes individual, smaller reports that concluded that there was a generalized decrease in success rates of resuscitation over time,[24–27] possibly attributable to a change in the composition of in-hospital populations over time. Several reports, including the metaanalysis conducted by Schneider *et al.*, have concluded that the success rate of in-hospital resuscitation declines in an elderly population.[25,26,28] Data for out-of-hospital cardiac arrests suggest that, for large, unselected populations, the overall survival-to-hospital discharge is lower than for in-hospital arrests. Several large studies report survival-to-hospital discharge rates of 8 to 10% of all patients receiving CPR in the pre-hospital setting.[29–36] In a study performed in King County, Washington, 2043 patients cared for by paramedics in the prehospital setting were found to have a survival-to-discharge rate of 18%.[35]

Complications

Trauma is the major complication from manual CPR. The reported incidence of trauma, as the result of manual CPR, ranges from 21% to more than 65%.[37–45] The most frequent thoracic injuries, occurring more than 20% of the time, include chest abrasions or contusions, defibrillator burns, sternal and rib fractures, gastric dilation, and pulmonary edema. Even properly executed manual CPR can lead to injury. A comprehensive list of the types of trauma associated with standard CPR is presented in Table 30.3.

Applicability

The single most striking feature of standard external chest compression is its inherent ability to be applied in cardiac arrest. Thousands of people are saved each year by standard CPR, but this represents only a small fraction of the patients who suffer a cardiac arrest. Manual CPR has the disadvantage that its effectiveness can be compromised by misapplication of the technique resulting from such factors as operator fatigue and operator error. Standard CPR can be difficult to apply correctly, since in most instances a gauge is not available to assure that the operator applies the recommended 1 1/2 to 2 inches of sternal displacement. In addition, there are a significant number of manual CPR-related injuries. Despite these limitations, however, any CPR is probably better than no CPR.[30,34,35] The detrimental effects of trauma are unclear, since most research on the incidence of CPR-related trauma has focused on non-survivors of CPR, who might have died even if no trauma had occurred. Improvements in outcome may be achieved by external CPR techniques that improve blood flow; these external techniques could be available to larger numbers of rescuers than are those requiring invasive measures. Some alternative manual techniques have been studied, and are discussed below. Alternative techniques that use mechanical devices are discussed in Chapter 31.

Table 30.3. Complications reported for standard cardiopulmonary resuscitation

Thorax (42%)	Heart and great vessels (11%)	Skin (66%)
Rib fracture (31–52%)	Pericardial sac blood (8%)	Chest abrasion/contusion (59%)
Sternal fracture (21–22%)	Epicardial hematoma (3%)	Defibrillator burns (31%)
Anterior mediastinal hemorrhage (18%)	Myocardial contusion (1%)	Miscellaneous
Pneumothorax (3%)	Vena cava injury (1%)	Air embolus to coronary (1%)
Hemothorax (1%)	Myocardial laceration (0.1%)	Air – other locations (1%)
Flail chest (0.5%)	Upper airway (20%)	Retroperitoneal hemorrhage (0.1%)
C-spine fracture (0.1%)[a]	Oropharynx vomitus (10%)	Bladder wall hemorrhage (0.1%)
Lacerations of the diaphragm	Tracheal vomitus (9%)	Bone marrow embolus
Abdomen (31%)	Endotracheal tube misplacement (4%)	Vertebral fractures
Gastric dilation (29%)	Tongue laceration	Ruptured tympanic membrane
Liver rupture (2%)	Oropharynx injury (2%)	
Other liver injury (1%)	Larynx injury (2%)	
Spleen rupture (0.3%)	Dental injury (1%)	
Gastric rupture (0.1%)	Tracheal injury (1%)	
Omentum hemorrhage (0.1%)	Hemorrhage of vocal cords (0.5%)	
Abdominal distension	Misplaced nasogastric tube (0.5%)	
Ischemic bowel	Fractured thyroid cartilage (0.1%)	
Lung (13%)	Contusion – epiglottis/esophagus (0.1%)	
Pulmonary edema (44–46%)	Hypopharyngeal hematoma (0.1%)	
Aspiration (11%)	Hemorrhage of cricoid (0.1%)	
Interstitial emphysema (1%)	Lip injury (8%)	
Contusion/puncture (1%)	Dislocated mandible	
Infiltrates (0.6%)	Dislocated C-spine/neck strain	
Atelectasis (0.6%)	Esophageal rupture	
Pulmonary embolus

Interposed abdominal compression

Interposed abdominal compression (IAC)-CPR (or abdominal counterpulsation CPR) includes an additional rescuer (for a total of two or three) positioned alongside or opposite the rescuer applying chest compressions. This additional rescuer places his or her hands on the abdomen, usually near the umbilicus, and compresses the abdomen during the relaxation-phase of chest compression (Fig. 30.4). The ratio of abdominal to chest compressions is one to one, so the rate of abdominal compressions is also 100/min. Some authors place a blood pressure cuff or another measuring device between the hands and the abdominal wall in order to measure the amount of force applied to the abdomen. Exact guidelines as to how much to compress the abdomen, or how much force to apply if measured, have not been proposed. In studies of this technique, the forces measured from air-filled measuring devices have ranged from 20 to 150 mm Hg. Most authors describe abdominal compression as lasting through the entire release phase of chest compression, resulting in a 50% compression duration for each.

Ohomoto *et al.* first published a description of interposed abdominal compression using a mechanical device with two pistons (one for the chest, one for the abdomen) in 1976[46]. Since that time, there has been ongoing and extensive research into this method[47–74].

Physiology

IAC-CPR may improve blood flow in CPR by a number of mechanisms. First and foremost, IAC-CPR may act in a fashion analogous with intraaortic balloon pumping, where abdominal and aortic compressions would result in greater retrograde aortic flow into the chest and greater aortic pressure between chest compressions, with greater coronary flow and survival. Second, abdominal pressure by itself increases intrathoracic pressure, even without chest compression. Interposed abdominal compression could therefore either (a) optimize the duration of the rise in intrathoracic pressure since durations of compression longer than those usually present during manual CPR are known to improve flow, or (b) increase the rise of
Fig. 30.4. IAC-CPR with three rescuers. This technique could also be performed by two rescuers with one rescuer performing both chest compressions and artificial ventilation. The arrows depict how one rescuer pushes while the other relaxes and vice versa. (From ref. 65. Copyright 1992, American Medical Association.)

Fig. 30.5. Hemodynamic tracings in a dog undergoing CPR. Beginning about halfway across the recording, mechanical CPR was augmented with IAC-CPR. Abdominal aorta (*AA*), thoracic aorta (*TA*), intra-abdominal (*ABD*) and right atrial (*RA*) pressures, and common carotid blood flow (*CCBF*) are shown. Note that the majority of intravascular pressure as well as carotid flow seems to occur coincident with abdominal compression rather than with thoracic compression in this model. (From ref. 70.)

intrathoracic pressure as a result of moving the diaphragm and abdominal contents upward. In addition, during the diastolic phase (i.e., relaxation of chest compression), compression of the abdomen "charges" the intrathoracic compliance in preparation for the next chest-compression cycle. This coincides with work in our laboratory that shows, in a model of the canine circulation, that an intrathoracic pump would be optimized by minimizing the compliance of the vessels inside the thorax and maximizing the compliance of vessels in the abdomen during compression. During the relaxation phase, this extrathoracic compliance would then discharge into the intrathoracic vessels, thus maintaining myocardial blood flow during diastole. Of potential concern is that compression of the abdomen during the relaxation phase of chest compression can raise the pressure inside the thorax, since the abdominal and thoracic compartments are contiguous. This rise in intrathoracic pressure could raise right atrial and aortic pressures to an equal extent, which could actually decrease coronary perfusion pressure[14]. A pressure waveform during IAC-CPR is shown in Fig. 30.5.

Ralston *et al.* compared standard CPR with mechanical (Piston) external chest compression, with and without the addition of IAC.[75] They showed that with no other changes in the technique, the addition of IAC increased cardiac output, and systolic and diastolic arterial pressures in 10 dogs. Eight of 10 dogs had an increase in the arteriovenous difference (myocardial perfusion pressure). Walker *et al.*[76], Voorhees *et al.*,[77] and Einagle *et al.*[70] all demonstrated an increase in either brain or carotid blood flow with IAC-CPR. Despite the similarity of conclusions among these studies, however, these data are somewhat difficult to interpret.

Studies by Walker and Voorhees and colleagues do show a statistically significant increase in brain blood flow versus standard CPR, but in the study by Voorhees *et al.* this difference is physiologically trivial (0.03 ml/min/g). Alternatively, the study by Walker *et al.* showed a substantial increase in brain blood flow (0.21 ml/min/g), but had extremely low brain blood flow in the standard CPR group, raising concern about the quality of the standard CPR. Of note, no study looking at myocardial blood flow showed a statistically significant difference between standard CPR and IAC-CPR. Kern *et al.* studied 24-hour survival in a dog model of cardiac arrest comparing standard external chest compression, IAC-CPR, and high-impulse CPR and found no difference among the groups.

Several trials have looked at human hemodynamics or survival with IAC-CPR. Studies by Berryman and Phillips[69] and Howard *et al.*[78] at the end of conventional resuscitation showed an increase in mean arterial pressure with the addition of IAC-CPR. Despite these increases, Howard *et al.* did not find a significant difference in the myocardial perfusion pressure. Berryman and Phillips reported this information in only a single patient in whom it was increased.

McDonald[79] reported on six patients, also late in resuscitation, in whom there was no difference in any measured variable with the addition of IAC. Mateer *et al.*[68] described a large field trial of IAC-CPR conducted by paramedics in Milwaukee: no difference in initial resuscitation was found after randomizing medical arrest patients to either standard external chest compression or IAC-CPR after intubation. In an in-hospital trial of IAC-CPR, Sack *et al.*[65] reported the results of 135 resuscitation attempts in 103 patients who had been randomized on admission to the hospital to receive either IAC-CPR or standard CPR should they arrest. In this study, they reported an increase in initial resuscitation (51% vs. 27%), discharge from the hospital (25% vs. 7%), and discharge neurologically intact (17% vs. 6%) with IAC-CPR. Conducting this type of randomized trial in a hospital setting is in itself a considerable accomplishment. Obviously a CPR trial cannot be a blind study, and this is one of the self-criticisms mentioned by the investigators. In addition, no attempt was made to control for the force of sternal compression used in either group, which may account in part for the rather marked difference seen in this study. Of greater concern is the relatively low survival rate of the standard CPR group. Only 7% of these patients survived to hospital discharge, which is roughly half the survival-to-discharge rate typically reported by large studies of CPR in hospitalized patients. Again, this may reflect a subtle difference in the standard CPR technique utilized during the study, or may reflect some bias in the group of patients included in the study. In a follow-up study of 143 hospitalized patients with either pulseless electrical activity or asystole, the same group demonstrated improved initial resuscitation and 24-hour survival with IAC-CPR compared with standard CPR.[64] Survival-to-hospital discharge was not an endpoint in this study, although the investigators noted that no patients survived to discharge neurologically intact. These results from a technique that is easy to apply should encourage ongoing investigation.

Although the incidence of abdominal trauma could be increased with IAC-CPR, specific data are limited. Kern et al. in one trial compared three methods of manually applied CPR, including IAC-CPR, and noted no difference in the incidence of trauma with the addition of abdominal counterpulsations.[63] In their most recent study, Sack et al. noted no clinically obvious difference in abdominal trauma between the groups, and none of the five IAC-CPR patients who underwent autopsy had any abdominal trauma.[64]

Applicability

IAC-CPR requires at least two rescuers. Beyond this requirement, it is a manually applied technique that requires no specialized equipment. The ability of rescuers in general to perform the technique correctly has not been determined. Hemodynamic data in humans are less convincing than those in animals, although this may reflect a limited ability to look at brain blood flow in humans. If IAC-CPR does improve brain perfusion as suggested by animal models, then it may well have clinical utility. Provided that it does not adversely affect the myocardial perfusion and therefore the chances of establishing return of spontaneous circulation, additional brain blood flow may improve the neurologic outcome of those patients who do survive resuscitation. The study reported by Sack *et al.*, despite its limitations, may address these facts.[65] They showed a survival-to-hospital discharge of 25%, which is higher than historical controls, suggesting a benefit over standard CPR. Larger trials of IAC-CPR will be needed, however, before its true clinical utility can be determined.

High-impulse external chest compression

High-impulse external chest compression is performed by placing the hands in a position identical with that of standard external chest compression. The compression itself, however, is done at a higher rate (typically 120 to 150/minute) and with a very quick, jabbing onset and offset. Ventilation is provided as with standard CPR, at a rate of 12/minute.

Investigators at Duke University first proposed high-impulse chest compression as a replacement for standard external chest compressions in 1984.[80] Despite one reference cited for rapid compressions from the 1890s, these authors were clearly the major force that brought this technique into the modern era of CPR research. High-impulse CPR became one of the focal points of the debate between the two schools of thought (direct cardiac compression vs. intrathoracic pressure fluctuations) on the mechanism of blood flow in CPR.[12,18,80–87] Those investigations led to a significantly improved understanding of the physiology of blood movement during chest compression.

Physiology

In studies of the physiology of blood flow during external chest compression in dogs, Maier *et al.* noted that increasing the rate of compressions resulted in increased cardiac output and increased coronary flow compared with slower rates.[80] They showed that stroke volume stayed constant, while cardiac output rose. Coronary blood flow tended to be higher, although not significantly, at a compression rate of 150/minute vs. 60/minute.[80] These data were
Fig. 30.6. Hemodynamic tracings from a patient undergoing CPR. The top tracing shows CPR at a rate of 60/min, the middle at 100/min, and the bottom at 150/min or high-impulse CPR. Note on each tracing the amount of time spent during the compression and relaxation phases. Only the third tracing appears consistent with the recommended 50% compression duration. (Reproduced with permission from ref. 80. Copyright 1984 American Heart Association.)

interpreted as showing that direct cardiac compression was the predominant mechanism of blood flow since stroke volume was constant for each compression, and cardiac output rose at higher rates as more stroke volumes were delivered per unit time. The investigators attempted to control compression force by measuring intrapleural pressure with micromanometers in the intrapleural space. This was one of the two major criticisms of the work since measurements of intrapleural pressure are difficult and often inaccurate. Nevertheless, they did achieve the same reading in a given animal for each compression rate.

The second major criticism is illustrated in Fig. 30.6: a variable not controlled by the investigators in these initial studies was the compression duration, or the percent of the compression–decompression cycle during which compression occurs. At low compression rates, the duration of compression appeared to be approximately 20% of the cycle; at high rates, it was much closer to 50%, the currently recommended standard. This provided a potential mechanism for the increase in cardiac output, even if an intrathoracic pump mechanism was operative since compression duration does affect blood flow in the intrathoracic pump model. Subsequent animal studies examined survival differences between high-impulse external chest compression and standard CPR. Kern *et al.* found no dif-

ference in 24-hour survival between a group receiving standard external chest compression and a group receiving high-impulse CPR.[63] A later study by Feneley *et al.* did show improved survival in a group of animals receiving high-impulse CPR compared with standard manual CPR.[18] In this latter study, the authors attempted to control for duty cycle between the two groups. Compression force was not quantitatively reported, however, and pressures generated in the control group were substantially lower than in other studies of standard external compression done by the same research group.[80]

A number of case-report type studies of high-impulse CPR have been published.[80,88] Minimal quantitative analysis of these data are available, however, and no controlled trials of standard vs. high-impulse CPR in humans have been reported.

Applicability

High-impulse CPR requires little more than an alteration in training from that in standard external chest compression. None of the data reported for high-impulse CPR, however, provide convincing evidence that this technique would provide substantial benefit over standard CPR in the general population. There may be subsets of patients in whom the jabbing chest compressions of high-impulse CPR are beneficial. These chest compressions may alter airway mechanics in these patients to produce higher intrathoracic pressure, or alternatively, may enhance cardiac compression. If these groups can be identified, it is conceivable that high-impulse CPR could provide a hemodynamic benefit over standard external chest compression.

Future directions

Research aimed at improving survival from cardiac arrest both in- and out-of-hospital continues. The first 30 years of external chest compression have been marked by enthusiasm, disappointment, innovation, and speculation, but to date no technique has convincingly positioned itself to replace standard CPR as we now know it. Research has contributed a great deal to the science of CPR and set the stage for real advancement in the resuscitation of cardiac arrest victims. The critical importance of early defibrillation is now clearly recognized. Likewise, the criteria used to judge a new CPR method have been defined. These measures – coronary perfusion pressure (important in predicting return of spontaneous circulation), systolic arterial pressure (predictive of cerebral blood flow and likely of neurologic recovery), and ultimately survival-to-hospital

discharge – will drive the search for the best method or methods of applying force to the human body over the next several years. The future may lie not so much in a replacement of current CPR as in evolution to differing types of CPR under different circumstances. Resuscitation initiated by lay persons will by necessity remain a manual technique, but some other form of CPR may be used once qualified rescuers are on the scene. The use of gauges to assure that manual CPR is performed correctly, and a reduction in interruptions in chest compression, may improve the efficacy of manual CPR dramatically. Currently the distinction between basic and advanced life support involves the availability of drugs, mechanical airways, and defibrillation. It is very possible that the form of CPR utilized may also become part of this distinction.

Finally, with several of the techniques discussed in this chapter providing some promise for improved survival from cardiac arrest, we are entering an era where small trials will be unlikely to add significantly to our knowledge. For a new technique of external chest compression to be widely accepted, it will need to be tested in a sufficiently large population to produce statistically significant as well as clinically significant data, much as thrombolytic therapy and angiotensin-converting enzyme inhibitors have been tested in mega-trials. These trials, both in-hospital and in the field, should provide the information needed for a technique to be judged for its long-term benefits. Smaller trials can be useful, as still other alternate techniques are developed. In small human survival trials, it is critical for authors to know and report the baseline survival data from their institution by using standard CPR in a nearly identical population *before* the onset of the study. Control groups are always subject to bias in studies that are not performed blind. Knowing the existing survival data from standard CPR at the same institution before the study begins will allow the investigators to judge whether a bias was introduced into their control group during the study.

Mechanical devices for cardiopulmonary resuscitation

Henry R. Halperin

Johns Hopkins University School of Medicine, Baltimore, MD, USA

The rhythmic application of force to the body of the patient is fundamental to the process of generating blood flow in CPR, but there is little agreement as to the optimal technique for applying that force. There is a great need for improved external chest compression techniques since only an average of 5%–15% of patients treated with standard CPR survive cardiac arrest,[1,2] and it is widely agreed that increasing the blood flow generated by chest compression will improve survival. Given the potential importance of newer devices and techniques that may augment blood flow, this chapter will explore several alternate devices and techniques that have been studied.

Piston chest compression

According to the most recently published guidelines of the Emergency Cardiac Care Committee of the American Heart Association,[3] external chest compressions are applied by the rescuer who places the hands over the victim's sternum. Force is applied straight down with the rescuer's elbows locked and the shoulders in line with the hands. The goal is to displace the sternum 1 1/2 to 2 inches for an average-sized adult victim, 100 times per minute, with compression maintained for 50% of each cycle. Unfortunately, compressions are often done incorrectly,[4,5] and incorrect chest compression can compromise survival.[6,7] One way of improving the quality of chest compression is with automatic mechanical devices, which can potentially apply compression more consistently than by manual compression. Another way of potentially improving the quality of chest compression is to use gauges that provide feedback to the rescuer on the depth and rate of compressions, allowing the

rescuer to adjust the application of force to produce compressions that have the correct depth and rate.

One type of automatic mechanical device uses a pneumatic piston (Fig. 31.1) to administer external chest compressions at a specified rate, compression depth, and duty cycle (percent of time compression is held during each cycle). The piston is located at the end of an arm that extends over the patient's chest, and is based on a board which provides a firm surface under the patient's back. In addition, a ventilation circuit is integrated into the device, which allows for continuous CPR with minimal operator input once the device is set up. Although there are some differences between mechanical and manual external chest compression in the time course of application of force, which may affect hemodynamics,[8,9] one small study showed no difference in survival with use of the two techniques.[9] Two additional small studies suggested a slight hemodynamic benefit to CPR performed by the pneumatic piston, one using end-tidal CO_2 as a surrogate measure for cardiac output,[10] and the other showing a slight improvement in mean arterial pressure (25 versus 31 mm Hg), although no statistical analysis was provided.[9] An updated version of the piston compression device moves the piston with higher velocity, and in an animal model produces increased vascular pressures compared to the earlier version.[11] Despite these slight differences in hemodynamics, chest compression performed by a pneumatic device probably has the same physiology as manual chest compression and is generally considered an extension of the standard technique.

Trauma is the major complication from piston CPR. The reported incidence of trauma, as the result of piston CPR, can be as high as 65%.[12,13] The most frequent thoracic
Fig. 31.1. Piston device used for performing mechanical external chest compressions. (Thumper, Courtesy of Michigan Instruments, Grand Rapids, MI.)

injuries, occurring more than 20% of the time, include chest abrasions or contusions, defibrillator burns, sternal and rib fractures, gastric dilation, and pulmonary edema. Even properly executed CPR can lead to injury.

Despite the substantial amount of trauma, however, the detrimental effects of trauma are unclear, because most research on the incidence of CPR-related trauma has focused on non-survivors of CPR, who might have died even if no trauma had occurred. Improvements in outcome may be achieved by external CPR techniques that enhance blood flow; but such improvement has not been convincingly demonstrated for piston-type devices. These devices do, however, allow CPR to be performed in situations where standard manual CPR would be difficult, such as in moving ambulances, and where personnel are limited.

Simultaneous compression and ventilation

Simultaneous compression and ventilation (SCV), as originally described, requires the subject to be endotracheally intubated or to have a tracheostomy.[14–16] Compressions are administered as with standard external chest compression, but at a slower rate (typically 40 compressions/minute). Instead of interposed ventilation between appropriate compressions, ventilation to a high airway pressure (typically 60 to 100 mm Hg) is performed synchronously with each compression. Some authors have modified this technique slightly, compressing at faster rates or adding an abdominal binder.[14,16,17] Most studies of this technique in both animal models and humans were

performed using a mechanical compression device with an integrated system to deliver ventilation to the endotracheal tube.

In 1967 Wilder *et al.* reported an increase in blood flow in dogs by using simultaneous ventilation and external chest compression at low airway pressures.[18] This phenomenon was left unexplained and largely unexplored, however, until the late 1970s when it was studied by a group of investigators at Johns Hopkins,[14,15] and subsequently by other groups.[17,19–21]

Physiology

Simultaneous compression–ventilation CPR (SCV-CPR) was a direct by-product of the theory that intrathoracic pressure fluctuations are responsible for blood movement during CPR. The assumption was that if blood flow is due to fluctuations in intrathoracic pressure, then anything that makes those fluctuations larger should increase blood flow. Many authors went a step beyond this and added abdominal binding to the technique, assuming that binding the abdomen would restrict the motion of the diaphragm, and thus result in higher intrathoracic pressure for a given applied force.[14,16,22,23]

Animal studies of the hemodynamics of SCV-CPR resulted in a number of observations that were unanticipated by the investigators, but ultimately led to an increased understanding of the determinants of blood flow during chest compression. For example, when electromagnetic flow probes around the carotid artery were used as an estimate of cerebral blood flow in animals,[16] administration of epinephrine resulted in a paradoxical decrease in carotid flow, despite an increase in cerebral perfusion pressure. This observation led investigators to seek alternative techniques for measuring cerebral blood flow and resulted in the routine use of radioactive microspheres during animal studies of CPR. Such studies showed that carotid flow measurements in dogs estimate blood flow to the facial muscles and tongue, and not to the brain.[14] Brain flow was actually augmented by epinephrine, as was myocardial blood flow.[24] Another observation that resulted from animal studies of SCV-CPR was that excessively high airway pressures (100 mm Hg) could cause carotid collapse, which can reduce blood flow,[24] and that negative airway pressure in-between compressions can augment blood flow.[16] Although not recognized at the time, this latter mechanism may be operative in other forms of CPR that induce negative intrathoracic pressure in-between compressions.

Another somewhat surprising observation was that abdominal binding can actually reduce coronary perfusion

pressure.[23,25] The mechanism of this phenomenon remains incompletely understood, but it is probably the result of an alteration of the distribution of vascular compliance (see Chapter 17). During the compression phase of CPR, blood moves out of the thorax into a relatively compliant set of vessels, mostly in the abdomen. This blood is then readily available for redistribution to the thoracic vasculature to provide for coronary blood flow during the release phase. Abdominal binding seems to reduce this extrathoracic arterial compliance, thus reducing the amount of blood available for coronary perfusion.

In human studies of SCV-CPR, Chandra et al. reported an increase in radial artery pressure and carotid flow velocity in a hemodynamic study of 11 patients at the end of failed conventional resuscitation.[15] Martin *et al.* examined hemodynamics in five patients and found a decrease in coronary perfusion pressure with SCV-CPR.[21] These patients were very late in resuscitation, which may have adversely affected the outcome. A major clinical trial of SCV-CPR was reported by Krischer et al., where 994 patients with out-of-hospital cardiac arrest were treated with either SCV-CPR or standard CPR.[26] The ambulance crews, rather than the patients, were randomized, so that the crews knew which form of CPR was going to be administered prior to arrival at the scene of the arrest. This block randomization method was criticized for its potential for adding bias. The survival (to hospital admission) was greater with standard CPR than with SCV-CPR (26% vs. 19%). This study did utilize abdominal binding with the SCV-CPR, which as noted could have had a deleterious effect on coronary perfusion. Because of the lack of significant resuscitation survival benefit in any study, there is little active research on this technique.

Active compression–decompression (ACD) CPR

In this technique, CPR is applied by using a compression device (either manual or mechanical) with an integral suction cup (Fig. 31.2). The suction cup allows for active decompression of the chest in-between compressions. Investigators studying this technique have used standard guidelines for the rate and duration of compressions. The decompression phase actively returns the chest wall to its expanded position without breaking contact. In human studies, ventilation has been performed according to the usual guidelines, but some animal studies have omitted ventilation except that caused by the compression–decompression itself.

ACD-CPR research began with a report of an elderly man resuscitated by his uninitiated son with a bath-

Fig. 31.2. Device for performing active compression–decompression CPR. The upper part is a handle, while the lower part is a suction cup. (Courtesy AMBU Corporation).

room plunger.[27] Lurie *et al.* at the University of California at San Francisco then began active research into the technique in both humans and an animal model. A device to perform ACD-CPR was developed by Ambu International (Copenhagen, Denmark), and numerous investigations have been performed with this technique.[28–48]

Physiology

ACD-CPR likely works in a fashion not dissimilar to interposed abdominal CPR where the active decompressions serve to prime the intrathoracic pump mechanism.[49–52] The active decompressions could result in greater chest expansion and filling with air between compressions, so that the next compression results in a greater rise in intrathoracic pressure and greater flow. A greater rise in intrathoracic pressure could be mediated through increased trapping of air in the lungs,[53] or simply increased application of force. Of note, chest compression force has not been measured in control groups undergoing standard manual CPR. Even if the peak compression forces used during active-decompression CPR and standard CPR were comparable, it would still not be known whether the reported benefit for active-decompression CPR results from the active decompressions, or from the increased force change (peak compression-to-peak decompression force) applied. For example, if 400 N compression force and 100 N decompression force were applied to the chest, is it equivalent simply to applying 500 N of compression force, or does the decompression force have unique physiologic effects that improve blood flow?

The active decompressions could produce negative intrathoracic pressure between compressions and greater venous return, even without increasing the right atrial pressure relative to aortic pressure, which would impede coronary flow. Alternatively, there may be better right heart flow into the pulmonary bed between compressions. Additionally, the design of the device used for ACD-CPR results in the potential for a mechanism in the application of compression force that is slightly different from that in conventional CPR. In standard external chest compression, the hands never lose contact with the thorax, and therefore the onset of application of force is gradual. The ACD-CPR device provides an air space of a few inches between the location of the hands and the chest wall. This allows some acceleration to take place before the force of compression actually reaches the chest, resulting in a slight impact on the chest wall. The significance of this with regard to the physiology of ACD-CPR is unknown. Studies reported to date have not resolved these issues. One study in pigs showed, in the absence of vasoconstrictors, increased coronary blood flow for active-decompression CPR for a standardized amount of chest compression from a mechanical chest compressor.[54] Nevertheless, that same study showed no difference in coronary flow when vaso-constrictors were used.

A number of clinical trials have been reported with ACD-CPR. In the first clinical study, it was reported that 18 of 29 (62%) patients treated with active-decompression CPR had return of spontaneous circulation, compared with 10 of 33 (30%) patients treated with standard CPR. A number of larger clinical trials have been reported since that time. Most of the trials have shown no difference in survival for patients treated with standard CPR or ACD-CPR.[38,55–58]

In one trial of 512 patients in Paris, France,[43] there was an improvement in survival (ACD vs. standard CPR) at 1 hour (36.6% vs. 24.8%, $P = 0.003$), 24 hours (26% vs. 13.6%, $P = 0.002$), and at hospital discharge (5.5% vs. 1.9%, $P = 0.03$). Mean time from collapse to basic cardiac life support CPR was 9 minutes and from collapse to ACLS CPR was 21 minutes. A more recent report of 750 patients from that latter group showed that survival was also improved at 1 year (5% vs. 2%, $P = 0.03$).[45] All patients who survived to 1 year had cardiac arrests that were witnessed.

It is unclear why most trials showed no benefit for ACD-CPR over standard CPR, and that there was a statistically significant, albeit small, benefit in the Paris study. It has been speculated that ACD-CPR may be of more benefit if administered relatively late in the course of cardiac arrest, as was done in Paris, and that the level of training and retraining is important.

There is a possibility that the high velocity of impact of the device at the start of chest compression could cause additional trauma as compared to conventional chest compressions.[59,60] In addition, the increased chest excursions produced by the active decompressions could cause increased flexing of the ribs, and increased trauma.

Applicability

ACD-CPR shares the advantages of all manual techniques in that it is readily applied in a wide variety of circumstances. The device required to perform this technique could be made widely available should it prove significantly beneficial. The technique itself is not appreciably more difficult than standard external chest compression, although it may prove substantially more tiring, given that the rescuer is required to be active during both phases (compression and decompression) of each cycle.[61] The disadvantages of manual devices, however, are that an operator can perform the compressions incorrectly and chest compression must be interrupted for defibrillation. Finally, the combination of the Impedance Threshold Device (see below) with the Active Compression Decompression Device seems to improve its hemodynamics and efficacy substantially.

Impedance threshold device

The impedance threshold device (valve), is placed in the airway circuit to impede the flow of air into the chest during chest decompression (Fig. 31.3). Its goal is to increase the level of negative intrathoracic pressure generated during chest decompression, and thereby augment the beneficial effects of that negative intrathoracic pressure.

The impedance threshold device (ITD) has been studied with standard CPR in a porcine model of cardiac arrest. In one study, coronary perfusion pressure (CPP) (diastolic aortic minus right atrial pressure) was the primary endpoint. After 2 minutes of CPR, mean $+/-$ SEM CPP was $14 +/- 2$ mm Hg with a sham valve versus $20 +/- 2$ mm Hg in the ITD group ($P < 0.006$).[62] Significantly higher CPPs were maintained throughout the study when the ITD was used. In another study, microsphere-measured myocardial blood flow was higher with the use of the impedance threshold valve ($0.32 +/- 0.04$ vs. $0.23 +/- 0.03$ ml/min per g, $P < 0.05$), as was cerebral blood flow ($0.23 +/- 0.02$ vs. $0.19 +/- 0.02$; $P < 0.05$).[63] In a third study, the use of the ITD was evaluated to determine the potential to improve 24-hour survival and neurological function in a pig model of cardiac arrest. That study used a randomized, prospective, and blinded design, where the effect of a sham versus
Fig. 31.3. Schematic diagram of impedance threshold device. The components of the device are shown on the upper left panel. During chest compression or exhalation(upper right panel) air moves freely through the valve. During chest decompression (lower left panel) airflow is impeded by the device to increase the level of negative intrathoracic pressure generated. During rescuer ventilation or spontaneous inhalation (lower middle and right panels) air also moves freely through the valve. (From ref. 63.)

active ITD was evaluated on 24-hour survival and neurological function. After 6 minutes of ventricular fibrillation, followed by 6 minutes of standard CPR with either a sham or an active valve, advanced life support was performed. A total of 11 of 20 pigs (55%) in the sham vs. 17 of 20 (85%) in the active valve group survived for 24 hours ($P<0.05$). Neurological scores were significantly higher with the active valve; the cerebral performance score ($1 =$ normal, $5 =$ brain death) was $2.2+/-0.2$ with the sham ITD versus $1.4+/-0.2$ with the active valve ($P<0.05$).[64] Thus, with standard CPR in animal models, the ITD improved coronary perfusion pressure, microsphere-determined myocardial and cerebral blood flows, and 24-hour survival and neurologic function.

Similar to the animal studies, clinical studies during manual cardiopulmonary resuscitation have shown a hemodynamic benefit for the impedance threshold device,[65] as well as improved short-term survival for patients with pulseless electrical activity with use of the ITD.[66]

The impedance threshold device has also been studied in conjunction with active compression–decompression cardiopulmonary resuscitation.[64,67,68] In a prospective, randomized, blinded trial performed in Paris, France, patients in non-traumatic cardiac arrest received ACD-CPR plus the valve or ACD-CPR alone for 30 minutes during advanced cardiac life support.[67] With the use of the impedance threshold device (Fig. 31.4) there were increases in end tidal carbon dioxide pressure ($19.1+/-1.0$ vs. $13.1+/-0.9$ mm Hg, $P<0.001$), diastolic blood pressure ($56.4+/-1.7$ vs. $36.5+/-1.5$ mmHg, $P<0.001$), and coronary perfusion pressure ($43.3+/-1.6$ vs. $25.0+/-1.4$ mmHg, $P<0.001$). In addition, return of spontaneous circulation was observed in 2 of 10 patients with ACD-CPR alone after $26.5+/-0.7$ minutes versus 4 of 11 patients with ACD-CPR plus the impedance threshold device after $19.8+/-2.8$ minutes ($P<0.05$).

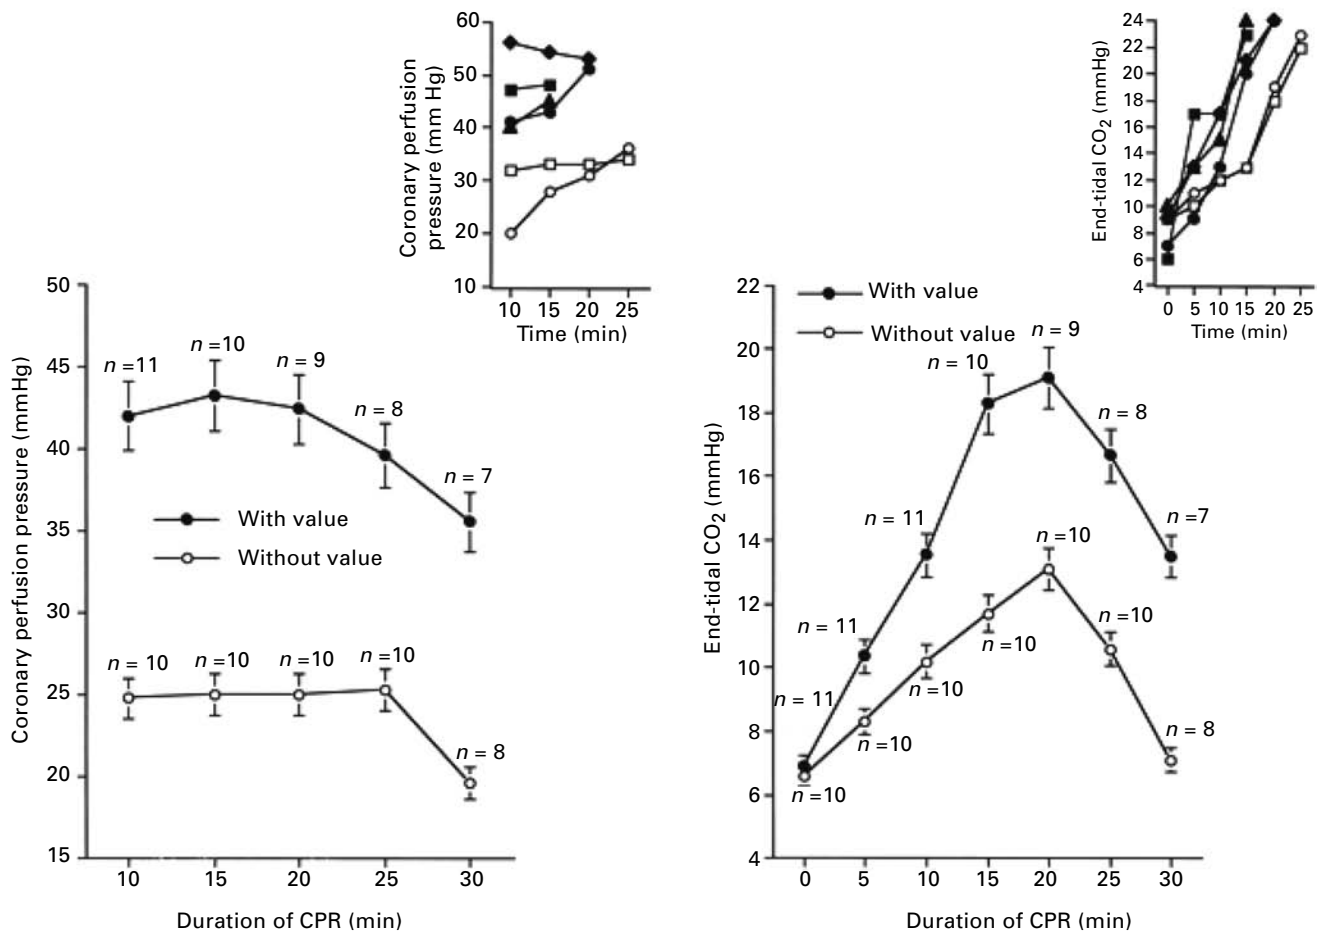
A prospective trial of ACD-CPR with the ITD vs. standard CPR was performed in Mainz, Germany. Patients with


Fig. 31.4. Coronary perfusion pressures (left), and end tidal CO_2 (right) in patients during active compression–decompression CPR without (lower tracing) and with (upper tracing) the use of the impedance threshold device. (From ref. 67.)

out-of-hospital arrest of presumed cardiac pathogenesis were randomized to ACD + ITD CPR or standard-CPR. The randomization was by rescuer crews, not individual patients. With ACD + ITD CPR (n=103), return of spontaneous circulation and 1- and 24-hour survival rates were 55%, 51%, and 37% vs. 37%, 32%, and 22% with standard-CPR (n=107) (P=0.016, 0.006, and 0.033, respectively). One- and 24-hour survival rates in witnessed arrests were 55% and 41% with ACD + ITD CPR vs. 33% and 23% in control subjects (P=0.011 and 0.019), respectively. One- and 24-hour survival rates in patients with a witnessed arrest in ventricular fibrillation were 68% and 58% after ACD + ITD CPR vs. 27% and 23% after standard-CPR (P=0.002 and P=0.009), respectively. Hospital discharge rates were 18% after ACD + ITD CPR versus 13% in control subjects (P=0.41). In witnessed arrests, overall neurological function trended higher with ACD + ITD CPR vs. control subjects (P=0.07).[69]

A subsequent, blinded, multicenter study was done to determine whether an inspiratory impedance threshold device, when used in combination with active compression–decompression cardiopulmonary resuscitation, would improve survival rates in patients with out-of-hospital cardiac arrest. Patients were randomized to receive either a sham (n = 200) or an active impedance threshold device (n = 200) during advanced cardiac life support performed with active compression–decompression cardiopulmonary resuscitation. The primary endpoint of this study was 24-hour survival. The 24-hour survival rates were 44/200 (22%) with the sham valve and 64/200 (32%) with the active valve (P = 0.02). The number of patients who had return of spontaneous circulation (ROSC), intensive care unit (ICU) admission, and hospital discharge rates was 77 (39%), 57 (29%), and 8 (4%) in the sham valve group vs. 96 (48%) (P = 0.05), 79 (40%) (P = 0.02), and 10 (5%) (P = 0.6) in the active valve group.[70] Thus, whether the control group

was standard CPR or ACD-CPR, the use of the ITD improved short-term survival.

Thus, the results with the impedance threshold device are very promising, particularly since the device can be used with standard CPR as well as more advanced forms of CPR. There appears to be a clear hemodynamic benefit and short-term survival benefit with use of the device. Further studies are needed to determine if the valve can be used successfully in larger studies of cardiac arrest, and whether the improved hemodynamics and short term survival will translate into improved long-term survival.

Phased chest and abdominal compression

A mechanical device is being developed that allows for active compression and decompression of the chest as well as for active compression and decompression of the abdomen. The device consists of two adhesive pads that are connected to a mechanical linkage. The pads are attached to the chest and abdomen, respectively. The linkage has two handles that are held by the rescuer. The rescuer pushes or pulls on the chest handle to compress or decompress the chest, and alternately pushes or pulls on the abdominal handle to compress or decompress the abdomen.

Laboratory studies of phased chest and abdominal compression has shown an increase in coronary perfusion pressure, as well as an increase in the number of animals resuscitated over that with standard cardiopulmonary resuscitation.[71] Kern *et al.* studied different types of ventilation, and showed that the type of ventilation could have a serious impact on the hemodynamics produced by this type of resuscitation.[72]

In a clinical study of phased chest and abdominal compression CPR, 54 patients were studied.[73] More patients treated with standard CPR survived to hospital discharge (7 vs. 0), but fewer patients treated with phased chest and abdominal compression had significant trauma at autopsy.

Since there are only small studies of phased chest and abdominal compression, further studies are needed to determine if this device will be useful in the treatment of cardiac arrest victims.

Vest cardiopulmonary resuscitation

With vest CPR, a bladder-containing vest (analogous to a large blood pressure cuff) is placed circumferentially around the patient's chest (Fig. 31.5) and cyclically inflated and deflated by an automated pneumatic system. In this manner, the chest is compressed cyclically. The device permits control of rate, compression duration, and inflation pressure. The vest also maintains a small amount of positive pressure on the chest between compressions to keep the vest snugly against the chest, except during the built-in pause for ventilation, at which time the vest completely deflates. The vest is generally inflated to a pressure of approximately 250 mm Hg, 60 times/ minute, with 40% to 50% of each cycle in compression. Adherent defibrillation pads are placed on the chest before applying the vest to allow for defibrillation without having to remove the vest or interrupt CPR.

As with SCV-CPR, vest CPR was developed as a means for augmenting intrathoracic pressure over that which could be produced by standard CPR. Vest CPR was largely developed by a group of investigators at Johns Hopkins University,[53,74–84] although other groups also made contributions.[23,85–93]

Physiology

Vest CPR is designed to maximize the intrathoracic pressure rises generated for a given force applied to the chest. By encircling the chest (Fig. 31.5), force can be applied evenly, thus resulting in a large decrement in the volume of the chest with minimal displacement of an individual point on the chest wall. This circumferential compression allows for large increases in intrathoracic pressure without the trauma inherent in applying force to a single point, as with standard chest compression.

Many generations of vest CPR systems have been developed and tested. Studies with an early vest device reported by Luce *et al.* in 1983 and 1984 showed that hemodynamics in a dog model of CPR were only minimally if at all improved with vest CPR compared with mechanically performed standard external chest compression.[92,93] Niemann *et al.*[91] and Halperin *et al.*[74] used an improved system and showed augmentation of perfusion pressures and blood flows with vest CPR either with or without simultaneous ventilation. In the study by Halperin's group, survival was also better in the group of dogs receiving vest CPR. At high vest pressures, they produced myocardial and brain blood flows equivalent to that in control animals, although they noted some trauma. At somewhat lower vest pressures, myocardial blood flow was 40% of prearrest flow, and cerebral blood flow was essentially equal to prearrest flow, with no trauma. These latter flows were greater than had been reported previously with standard external chest compression by any author.

Swenson et al. reported a study of vest CPR in 10 patients late in cardiac arrest[85]; they found no improvement in
Fig. 31.5. Comparison of vest CPR and manual CPR. The vest is like a large blood pressure cuff that encircles the chest. A pneumatic system inflates and deflates the vest to compress and release the chest. Flat defibrillator (defib) pads can be placed beneath the vest so that defibrillation can be performed during compressions. The vest compresses most of the circumference of the chest (lower panels), compared with a point compression of standard CPR. (From ref. 78.) Copyright 1993, *N. Engl. J. Med.*

coronary perfusion pressure produced with that vest CPR system. Halperin et al. subsequently reported a two-phase study of vest CPR using an improved vest CPR system, which incorporated a vest that covered more of the chest than did previous systems.[78] This system also included a small positive pressure on the chest in-between compressions to keep the vest tight against the chest. With the improved vest CPR system, hemodynamics in humans were significantly improved over those of standard external chest compression. Peak aortic pressure was nearly doubled (up to an average of 138 mm Hg), and coronary perfusion pressure increased by 50%. A hemodynamic tracing during manual and vest CPR in a patient is shown in Fig. 31.6. In addition, 4 of the 29 patients had return of spontaneous circulation during vest CPR despite being treated late (50 ± 22 min) in resuscitation. The second phase of the study randomized patients to either vest CPR or standard external chest compression after initial (11 ± 4 min) advanced cardiac life support failed to resuscitate the patients. There was a trend toward improved initial resus-

citation in the vest CPR group, but the trial was too small to show a statistically significant benefit.

If the vest is applied below the desired thoracic region, increased abdominal trauma could be expected. The vest does not, however, appear to increase the incidence of trauma over that of manual CPR,[78] although only limited data are available.

Applicability

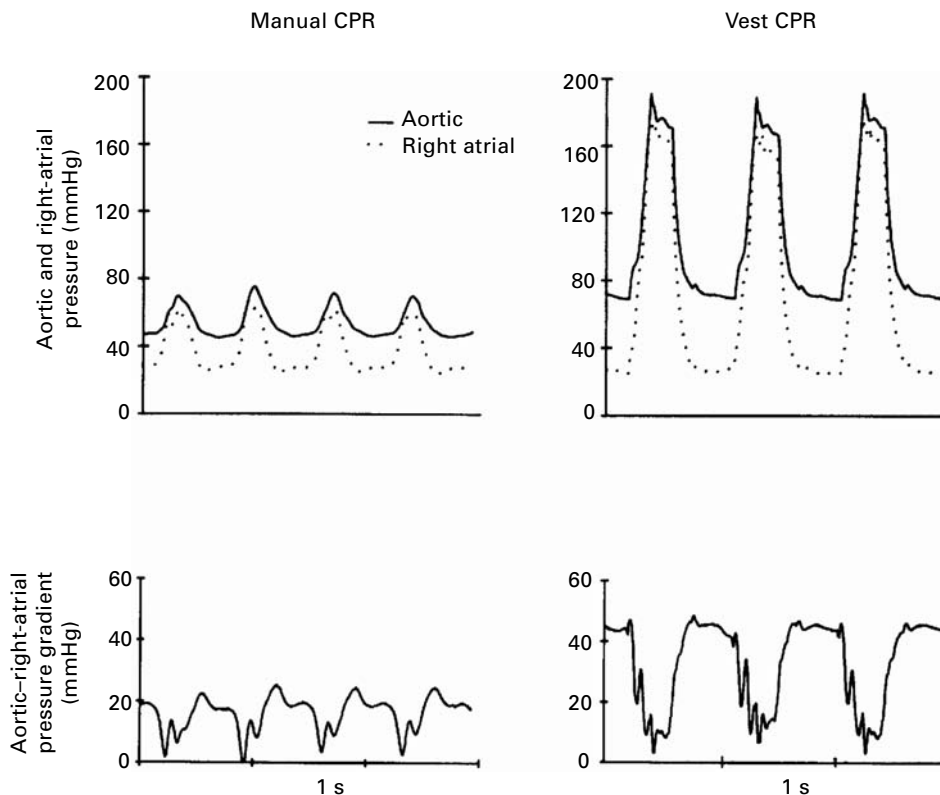
Vest CPR requires a sophisticated device for its administration, which limits its use to locations where the device would be readily available. Application of the vest itself is not difficult and can be performed successfully by nurses, given only a few minutes instruction in its use. It is likely that, if vest CPR proves successful in improving survival from cardiac arrest, it will remain predominantly in the hands of health care professionals. It will serve as a supplement, therefore, to the best form of standard CPR available for out-of-hospital arrests. Both animal and


Fig. 31.6. Hemodynamic tracing during vest and manual CPR. Aortic, right atrial, and aortic minus right atrial pressures are shown. (From ref. 78.) Copyright 1993, *N. Engl. J. Med.*

human data show rather dramatic improvements in hemodynamics with vest CPR. If vest CPR can routinely raise the coronary perfusion gradient above the threshold required for late defibrillation to be successful, then it could make a measurable impact on the ability to achieve return of spontaneous circulation. Until sufficient human studies are done, however, we will not know whether or not this will result in improved long-term survival and neurologic recovery.

Load distributing band (LDB) cardiopulmonary resuscitation

It had previously been shown that the circumferential vest device, analogous to a large blood pressure cuff that was inflated and deflated, could generate pressures during CPR that were substantially improved over those generated by standard CPR.[74,78] That vest device, however, was too large, and consumed too much power to be easily portable, and it has not been tested in large clinical trials. An improved device, based on a band that distributed the compression load over the entire anterior chest (load distributing band, LDB) was subsequently developed.

Physiology

The LDB device probably has similar physiology to the vest CPR device, given that the compressive load is distributed over a large portion of the chest with both devices. An initial animal trial showed that the LDB device generated peak aortic and coronary perfusion pressures that were improved over those generated with standard CPR.[94] An improved device was subsequently developed and was named the AutoPulse™ (Fig. 31.7). In a study with an improved LDB device, 30 pigs (16 ± 4 kg) were investigated, comparing LDB-CPR to conventional CPR with the piston device (C-CPR). LDB-CPR improved coronary perfusion pressure without epinephrine (LDB-CPR 21 ± 8 vs. C-CPR 14 ± 6 mmHg, mean $\pm$ SD, $P<0.0001$) and with epinephrine (LDB-CPR 45 ± 11 vs. C-CPR 17 ± 6 mmHg, $P<0.0001$). LDB-CPR improved myocardial flow without epinephrine, and cerebral and myocardial flow with epinephrine ($P<0.05$). LDB-CPR

also produced greater myocardial flow at every coronary perfusion pressure ($P<0.01$). One of the mechanisms for the improved hemodynamics with LDB-CPR appears to be airway collapse (Fig. 31.8) that occurs with LDB-CPR, trapping air in the lungs resulting in higher and more sustained intrathoracic pressure generation, and not present with C-CPR.[95]

In a preliminary trial in terminally ill patients, after a minimum of 10 minutes of failed advanced life support, subjects received alternating periods of manual and LDB chest compressions for 90 seconds each. Peak aortic
Fig. 31.7. Operation of the load distributing band device. During compression (left) the band is tightened by a motor, and compression force is directed inward. During relaxation (right), the band is released, and the chest expands.

pressures were higher with LDB CPR when compared with manual CPR (150 ± 8 vs. 122 ± 11 mm Hg, $P<0.05$, mean $\pm$ SEM), as was coronary perfusion pressure (20 ± 3 vs. 15 ± 3 mm Hg, $P<0.02$), even though the manual chest compressions were of consistently high quality (51 ± 20 kg) and in all cases met or exceeded American Heart Association guidelines for depth of compression.[96] In that latter study, coronary perfusion pressure was raised above the level generally associated with improved survival.[97]

In a case control study of LDB-CPR, a retrospective chart review was undertaken where a manual CPR comparison group was case-matched for age, gender, initial presenting ECG rhythm, and the number of doses of ACLS medications as a proxy for treatment time. Matching was performed by an investigator blinded to outcome and treatment group. Sixty-nine LDB-CPR cases were matched to 93 manual CPR only cases. LDB-CPR showed improvement in the primary outcome of survival to arrival at the emergency department, when compared to manual CPR with any presenting rhythm (LDB-CPR 39%, manual 29%, $P=0.003$). When patients were classified by first presenting rhythm, shockable rhythms showed no difference in outcome (LDB-CPR 44%, manual 50%, $P=0.340$). Outcome was improved with LDB-CPR in initial presenting asystole and approached significance with pulseless electrical activity (asystole: A-CPR 37%, manual 22%, $P=0.008$; PEA: A-CPR 38%, manual 23%, $P=0.079$).[98]
Fig. 31.8. Magnetic resonance imaging of the thorax during Load Distributing Band cardiopulmonary resuscitation in a pig. The trachea is widely patent in the uncompressed state (A, arrow) but is nearly fully collapsed during peak compression (B, arrow). (From ref. 95.)

A prospective trial (ASPIRE trial) compared resuscitation outcomes following out-of-hospital cardiac arrest when an automated LDB-CPR device was added to standard emergency medical services (EMS) care with manual CPR. The trial included 5 centers and enrolled 1071 patients. Block randomization was done, in which a specific EMS crew would perform either LDB-CPR or manual CPR on a specific number of patients (block size), then perform the other type on a subsequent block of patients. In addition, the crews had the discretion of whether or not to enroll specific patients. The primary end point was survival to 4 hours after the 911 call. Following the first planned interim monitoring conducted by an independent data and safety monitoring board, study enrollment was terminated. No difference existed in the primary end point of survival to 4 hours between the manual CPR group and the LDB-CPR group overall ($N = 1071$; 30% vs. 29%; $P = 0.74$). However, among the patients who were felt to have primary cardiac arrests, survival to hospital discharge was 9.9% in the manual CPR group and 5.8% in the LDB-CPR group ($P = 0.06$, adjusted for covariates and clustering). A cerebral performance category of 1 or 2 at hospital discharge was recorded in 7.5% of patients in the manual CPR group and in 3.1% of the LDB-CPR group ($P = 0.006$).[99]

There are a number of issues that make interpretation of the results of the ASPIRE trial problematic. Statistical analysis showed that the study sites were not statistically homogeneous, in that one site was statistically different from the other four sites. The statistically different site had much higher survival rates for both manual CPR and LDB-CPR than the other four sites, prior to a protocol change that occurred in the middle of the trial. The survival with LDB-CPR and manual CPR were similar before the protocol change, but the survival with LDB-CPR decreased dramatically after the protocol change. The one statistically different site was responsible for the overall decrease in survival noted in the study. In addition to the change in protocol, other factors that could explain the decreased survival with LDB-CPR in the ASPIRE include: (1) bias that could be introduced by the block randomization and crew enrollment discretion, (2) delays in performing defibrillation, and (3) inadequate training.

A prospective and retrospective trial (Richmond trial) was conducted in Richmond, Virginia, comparing LDB-CPR with manual CPR after the emergency medical services system there switched from manual cardiopulmonary resuscitation (CPR) to load-distributing band (LDB) CPR. A total of 499 patients were included in the manual CPR phase (January 1, 2001, to March 31, 2003) and 284 patients in the LDB-CPR phase (December 20, 2003, to March 31,

2005); of these patients, the LDB device was applied in 210 patients. Patients in the manual CPR and LDB-CPR phases were comparable except for a faster response time interval (mean difference, 26 seconds) and more EMS-witnessed arrests (18.7% vs. 12.6%) with LDB. Rates for ROSC and survival were increased with LDB-CPR compared with manual CPR (for ROSC, 34.5% vs. 20.2%; and for survival to hospital discharge, 9.7%; 95% CI, 6.7%–13.8% vs. 2.9%; 95% CI, 1.7%–4.8%; adjusted OR, 2.27; 95% CI, 1.11–4.77). In a secondary analysis of the 210 patients in whom the LDB device was applied, 38 patients (18.1%) survived to hospital admission (95% CI, 13.4%–23.9%) and 12 patients (5.7%) survived to hospital discharge (95% CI, 3.0%–9.3%).[100] A weakness of the Richmond trial is that there is a historical control group. A major strength is that all patients treated for cardiac arrest were included.

Applicability

Like vest CPR, LDB-CPR requires a sophisticated device for its administration, which limits its use to locations where the device would be readily available. The LDB device is, however, readily portable and can be applied in as little as 30 seconds. The LDB device will likely serve as a supplement, therefore, to the best form of standard CPR available for out-of-hospital arrests. Both animal and human data show rather dramatic improvements in hemodynamics with LDB-CPR, and there are mechanistic explanations for those improvements. If LDB-CPR can routinely raise the coronary perfusion pressure above the threshold required for resuscitation, then it could make a measurable impact on the ability to achieve return of spontaneous circulation. LDB-CPR significantly improved survival in the Richmond trial, but not in the ASPIRE trial. The reasons that these two trials showed such differences in survival are unclear. There are likely to be implementation and training issues that have to be addressed. In addition, one site was responsible for the overall decrease in survival noted for the ASPIRE trial, which was probably due to that site's change in protocol midway through the trial. Another trial is commencing that will address the issues noted in the previous trials and should be large enough to determine the true clinical utility of LDB-CPR.

The future

Research aimed at improving survival from cardiac arrest both in- and out-of-hospital continues. The first 45 years of external chest compression have been marked by enthusiasm, disappointment, innovation, and specula-

tion, but to date no technique has convincingly positioned itself to replace standard CPR as we now know it. Research has contributed a great deal to the science of CPR and set the stage for real advancement in the resuscitation of cardiac arrest victims. The critical importance of early defibrillation is now clearly recognized, as is the importance of improved blood flow. Likewise, the criteria used to judge a new CPR method have been defined. These measures – coronary perfusion pressure (important in predicting return of spontaneous circulation), systolic arterial pressure (predictive of cerebral blood flow and likely of neurologic recovery), and ultimately survival-to-hospital discharge – will drive the search for the best method or methods of applying force to the human body over the next several years. The future may lie not so much in a replacement of current CPR as in evolution to differing types of CPR under different circumstances, as well as improving the quality of standard CPR. Small hand-held devices are already under development that measure chest compression depth and compression rate to provide even lay rescuers with feedback to help them perform chest compressions at the specified 1.5–2 in of displacement and 100 compressions/ minute. Resuscitation initiated by lay persons will by necessity remain a manual technique, but some other form of CPR may be used once qualified rescuers are on the scene. Currently the distinction between basic and advanced life support involves the availability of drugs, mechanical airways, and defibrillation. It is very possible that the form of CPR utilized may also become part of this distinction, as well as the concomitant use of more advance strategies such as hypothermia.

Invasive reperfusion techniques

Mark G. Angelos

Department of Emergency Medicine, The Ohio State University, OH, USA

Standard external cardiopulmonary resuscitation (CPR) generates at best, 20% to 25% of normal cardiac output and is frequently inadequate to restore initial cardiac activity. Furthermore, this limited blood flow during CPR decreases as either the time of arrest is prolonged[1] or the time of CPR is increased.[2] When sudden death is the result of ventricular fibrillation, immediate countershock is very effective not only in defibrillating the heart but also in restoring effective myocardial contractions.[3] As the time in which the heart fibrillates in a non-perfused state increases, however, the likelihood of successful defibrillation with restoration of adequate contractile function diminishes.[4] At some point, the heart reaches an irreversible resuscitation state. It is this limited reperfusion capability of standard CPR techniques that continues to drive the search for newer reperfusion techniques following cardiac arrest.

Cardiopulmonary bypass in animal models

Cardiopulmonary bypass has been investigated as a means to reperfuse the non-working heart in cardiac arrest. Cardiopulmonary bypass can generate much higher flows than traditional external chest compression, allowing for resuscitation after prolonged cardiac arrest. Even with the capability of restoring full flow, there are still limits to myocardial resuscitability after long periods of cardiac arrest. In the canine model, normal levels of reperfusion flow generated by cardiopulmonary bypass after 15 and 20 minutes of untreated ventricular fibrillation resulted in successful resuscitation in all animals.[5] After 30 minutes of non-perfused ventricular fibrillation, however, full flow cardiopulmonary bypass was successful in restoring ROSC

in only 50% of animals.[5] During cardiac arrest, coronary perfusion pressure has been noted to correlate with myocardial blood flow.[6,7] The minimum coronary perfusion pressures necessary for ROSC have been estimated at greater than 18 mm Hg in canine models,[8] and greater than 15 mm Hg in humans.[9] With cardiopulmonary bypass, much higher coronary perfusion pressures can be achieved. In a ventricular fibrillation model, coronary perfusion pressure was noted to improve from 18 ± 8 mmHg during standard external CPR, to 27 ± 10 mmHg after adrenaline administration, to 58 ± 6 mmHg after institution of cardiopulmonary bypass (Fig. 32.1).[10]

Although high flows can be achieved, perfusion pressures while subjects are on cardiopulmonary bypass generally do not return to baseline levels unless an adrenergic agent is used, particularly after prolonged ischemia. The previously reported correlation between coronary perfusion pressure and myocardial blood flow seems to be lost with cardiopulmonary bypass reperfusion following cardiac arrest. Despite normal flows, coronary perfusion pressure may be subnormal. This is similar to the intra-operative experience of central cardiopulmonary bypass, where the mean arterial pressure is noted to fall after the patient is placed on cardiopulmonary bypass. Perfusion pressures of 40 to 60 mm Hg are tolerated without adverse consequences.[11] The significance of subnormal coronary perfusion pressures in the face of normal or supranormal organ blood flow during acute resuscitation is unclear. When epinephrine, either as a bolus or continuous infusion, is given in conjunction with cardiopulmonary bypass, normal or even supranormal coronary perfusion pressures can be generated while the heart is fibrillating.[12,13] In "high flow" reperfusion states after prolonged
Fig. 32.1. Coronary perfusion pressure with standard external CPR (*Group I*) and cardiopulmonary bypass (*Group II*). All animals received adrenaline 0.05 mg/kg at 10 minutes. (From Angelos, M.G., Gaddis, M., Gaddis, S., Leasure, J.E. Improved survival and reduced myocardial necrosis with cardiopulmonary bypass reperfusion in a canine model of coronary occlusion and cardiac arrest. *Ann. Emerg. Med.* 1990;**19**:1126.)

cardiac arrest, the β-adrenergic effects of adrenaline may be more important in reversing postresuscitation myocardial dysfunction than α-adrenergic effects in raising coronary perfusion pressure.[13, 14]

The main benefit of cardiopulmonary bypass in cardiac arrest seems to be its ability to restore flow. Cardiopulmonary bypass can provide flows that approximate baseline cardiac output. During reperfusion of ventricular fibrillation, flows of 80 to 100 ml/kg per min have been reported in canine cardiac arrest models[15] and flows above 200 ml/kg per min have been reported in swine cardiac arrest models.[12,16] These flows far exceed those generated by standard CPR and its variations. With the use of peripheral cardiopulmonary bypass during ventricular fibrillation, there is retrograde perfusion of the aorta from the femoral arteries and antegrade perfusion of the coronary and cerebral arteries.[17,18] Organ blood flow patterns seem to be altered when cardiopulmonary bypass is instituted after the global ischemia of cardiac arrest. An early hyperemia is seen in some organs, particularly the brain and the

heart, and is probably secondary to ischemic vasodilation with loss of vascular autoregulation.[19]

In canine cardiac arrest models, cardiopulmonary bypass has shown improved ROSC rates when compared to standard CPR with advanced life support after non-perfused ventricular fibrillation of 10 minutes,[20] 12 minutes,[21] 12.5 minutes,[22] and 4 minutes of ventricular fibrillation plus 30 minutes of CPR.[23] Cardiopulmonary bypass survivors in these studies showed improved neurologic outcome at 72 hours, when compared to survivors of CPR and advanced life support. Similar results have been reported in the swine model. Cardiopulmonary bypass was successful in achieving ROSC in 8/8 swine after 10 minutes of ventricular fibrillation and 5 minutes of failed conventional CPR therapy.[12] The utilization of an adrenaline infusion (3 μg/kg per min) during cardiopulmonary bypass resulted in normalization of coronary perfusion pressure and re-establishment of spontaneous circulation after an average of 23 minutes compared to 152 minutes without adrenaline.[12]

In a comparison of cardiopulmonary bypass with open-chest CPR and closed-chest CPR (in a canine ventricular fibrillation model), improved rates of ROSC were obtained with cardiopulmonary bypass.[24] Furthermore, cardiopulmonary bypass showed improved ROSC rates when compared with standard and high-dose adrenaline in a canine postcountershock model of pulseless electrical activity.[25] In both of these studies, however, there was no statistical improvement in 2-hour survival. Safar *et al.* reviewed their work with cardiopulmonary bypass in cardiac arrest animal models at the University of Pittsburgh Resuscitation Center from 1982 to 1988. Of 221 dogs from six cardiac arrest studies, 179 received cardiopulmonary bypass during ventricular fibrillation. All animals receiving cardiopulmonary bypass achieved ROSC after ventricular fibrillation times ranging from 10 to 30 minutes prior to the onset of cardiopulmonary bypass.[15]

Human resuscitation applications of percutaneous cardiopulmonary bypass

Currently, there is growing experience with the use of cardiopulmonary bypass for the acute resuscitation of cardiac arrest patients. This has been facilitated by the availability of smaller, more portable centrifugal pumps and the utilization of percutaneous cardiopulmonary bypass performed by cannulation of the femoral vessels. Reference to the most recent American Society for Artificial Internal Organs Registry indicates a trend toward centrifugal pumps even for the more standard indication of postcardiotomy cardiogenic shock cases, with about 70% of cases

treated with centrifugal pumps.[26] To date, no controlled studies have examined the use of cardiopulmonary bypass in cardiac arrest, but there are a growing number of case series.[27–34]

The first successful complete bypass of the heart and lungs in a human was reported by Gibbon in 1954.[35] For acute resuscitation, the use of cardiopulmonary bypass was first reported in 1961 for successful pulmonary thrombolectomy.[36] In 1967, two cases of hypothermia treated with cardiopulmonary bypass were reported.[37,38] In 1976, Mattox and Beal reported a series of 39 moribund patients resuscitated with portable cardiopulmonary bypass by using femoral artery and vein access.[27] Etiologies of shock or arrest state included massive pulmonary embolus, trauma, drug overdose, myocardial infarction, and cardiac arrest of unclear origin. Of the 39 patients, 15 were long-term survivors, 13 of whom were patients with pulmonary embolus.

Utilizing femorofemoral bypass, Phillips *et al.* reported on five patients with cardiac arrest who, after failing conventional therapy, achieved ROSC with cardiopulmonary bypass.[28] Three patients survived. The investigators reported flows on bypass of 2.0 to 2.5 l/min. Interestingly, they reported that the procedure took less than 5 minutes in all patients. The ease and speed of cannulation for femorofemoral bypass seems to be quite variable, with other groups reporting much longer cannulation and set-up times. In a later report, Phillips *et al.* reported on 22 additional patients, of whom 15 were in cardiac arrest at the time of femorofemoral cardiopulmonary bypass. All cardiac arrest patients except the four trauma patients were initially resuscitated and six were long-term survivors.[29] Again they noted application times of less than 5 minutes.

Attempts have been made to use cardiopulmonary bypass in out-of-hospital cardiac arrest patients once they arrive in the emergency department.[30] Key elements in successful resuscitation with cardiopulmonary bypass are the ischemia time prior to institution of cardiopulmonary bypass, time and success of cannulae placement, and availability of an on-call bypass team within the hospital.

The most extensive experience with the use of cardiopulmonary bypass in cardiac arrest has been with in-hospital cardiac arrests. Reported outcomes have been variable. In a series of 11 patients in cardiac arrest who received percutaneous cardiopulmonary bypass, 2 patients were long-term survivors. The two survivors were significantly younger and without atherosclerotic heart disease when compared with the non-survivors.[31] In another series of 32 patients receiving cardiopulmonary bypass, the overall survival rate was 12.5%, and only 1 (3.4%) of the 29 patients presenting in cardiac arrest left the hospital.[32] In this series, cardiopulmonary bypass was instituted within 15 minutes of cardiac arrest in 10/29 patients, within 15 to 30 minutes in 9 patients, and in more than 30 minutes in 10 patients. The time to place patients on bypass after the request was received ranged from 5 to 35 minutes.

In another series of patients from Sharp Memorial Hospital in San Diego, California, the experience of 38 hospitalized patients receiving emergent cardiopulmonary bypass was reported. Patients had cardiac arrest and failure of standard CPR prior to the onset of portable cardiopulmonary bypass. Thirty-six of 38 patients were successfully resuscitated to a stable heart rhythm. Two patients could not be cannulated. Bypass support allowed eight diagnostic angiographic procedures to be performed. Twenty-four of the 36 patients underwent operative procedures and 18 of the 36 patients were successfully weaned from bypass. Six (17%) of 36 were long-term survivors.[33]

In the largest series to date, the National Cardiopulmonary Support Registry for Emergency Applications in 1992 reported a total of 187 patients from 17 institutions who were treated with emergent portable cardiopulmonary bypass.[34] Of the 187 patients, 116 patients had witnessed cardiac arrest and 14 had unwitnessed cardiac arrest. In the witnessed cardiac arrests, the time in arrest before bypass ranged from 5 to 272 minutes, with a mean time of 45 ± 43 minutes. Other emergent indications for bypass were cardiogenic shock, profound hypothermia, and pulmonary insufficiency. The registry defined successful bypass as a mean arterial pressure of >60 mm Hg together with flows > 2.0 l/m². One of the key advantages to the use of bypass in these patients appeared to be the capability of supporting the patient so that various diagnostic and therapeutic procedures could be performed. This occurred in 74.9% of the total patients. Bypass times ranged from 5 to 4,500 minutes, with 36 patients having bypass times of more than 8 hours. In patients suffering cardiac arrest, 30-day survival was 15.5%, with overall survival in all patients of 21.4%. The authors concluded that patients with unwitnessed cardiac arrest and patients with refractory cardiac arrest who have received more than 30 minutes of CPR are poor candidates for emergent cardiopulmonary bypass. Good candidates for emergent cardiopulmonary bypass are patients with anatomically correctable problems and patients for whom therapeutic procedures such as angioplasty can be performed. The other small but important group that should benefit from emergency cardiopulmonary bypass are patients with hypothermic cardiac arrest.

Both femorofemoral bypass[39] and central cardiopulmonary bypass with median sternotomy have been used[40]

in the successful treatment of hypothermic cardiac arrest patients. A number of case studies and reports in the literature describe successful outcome with bypass-assisted perfusion and rewarming.[41,42] Such cases include the resuscitation of a child submersed for 66 minutes in cold water, with subsequent normal neurologic outcome.[43] A case series from Finland of 23 patients with hypothermia-generated cardiac arrest (mean temperature, 24.4 ºC) were placed on cardiopulmonary bypass after a mean of 106 min of CPR. Fourteen of the 23 patients (61%) were resuscitated and discharged from the hospital.[44] A recent follow-up report on 15 young, severely hypothermic patients (core temperature 17.1 ºC–25 ºC) in cardiac arrest who were resuscitated using cardiopulmonary bypass found minimal or no cerebral impairment, despite the long cardiac arrest times.[45] There is general consensus that severe hypothermia with refractory cardiac arrest is an indication for emergent cardiopulmonary bypass. Nevertheless, no controlled studies have been performed, nor are they likely to be done, given the small number of available cases at single institutions.

Percutaneous cardiopulmonary bypass has also been used in elective high-risk coronary intervention, including valvuloplasty, coronary arthrectomy, or coronary angioplasty.[46] Patients are instrumented for bypass before the procedure. If cardiovascular collapse or cardiac arrest should occur during the procedure, bypass can be initiated immediately. There are reports of successful implementation of cardiopulmonary bypass in cardiac arrest patients who fail to respond to advanced cardiac life support allowing transfer to the operating room for coronary artery bypass graft surgery or emergent coronary angioplasty.[47] Shawl *et al.* reported that 4 of 7 patients had good long-term survival.[47] The location of the cardiac arrest has been noted to be a significant factor, with the best survival rates in patients suffering cardiac arrest near the cardiac catheterization laboratory.[48] Presumably, the coronary anatomy of these patients was rapidly defined and could be followed by a therapeutic procedure if a reversible lesion were present. In the National Cardiopulmonary Support Registry report of 187 patients (125 patients in cardiac arrest), bypass was initiated in the cardiac catheterization laboratory in 33% of the total patients. Another 28% of these patients had bypass started in the operating room, 26% in the intensive care unit, 5% in the emergency department, and 5% on the hospital floor.[34]

In pediatric patients, veno-arterial extracorporeal membrane oxygenation (ECMO) has been used successfully for resuscitation from shock and cardiac arrest. Although analogous to cardiopulmonary bypass, generally lower flows are used to assist the intact but dysfunctional circulatory system. In a report of more than 600 children receiving ECMO, specific indications for instituting ECMO included cardiopulmonary arrest unresponsive to standard therapy, inability to wean from cardiopulmonary bypass following surgery, and refractory hypotension with blood pressure <50 mm Hg.[49] The University of Michigan reported their experience with either veno-venal bypass or veno-arterial bypass in severe pediatric respiratory failure in which 15/25 patients were long-term survivors.[50] Veno-venous bypass was used for respiratory failure without concomitant cardiac failure. This has little, if any, application during cardiac arrest. Flow rates were titrated to maintain arterial oxyhemoglobin saturation around 90%. Required flows were generally similar to full cardiopulmonary bypass flows, ranging from 100 to 150 ml/kg per min for veno-arterial bypass and 80 to 100 ml/kg per min for veno-venal bypass. The hematocrit was maintained at 45% and continuous heparinization was used to maintain anticoagulation. The Children's Hospital of Pittsburgh reported their experience with ECMO in 33 children between 1981 to 1991. Eleven of these patients suffered sudden cardiac arrest after open-heart surgery and were placed on ECMO after unsuccessful CPR; there were 7/11 early survivors, 6 (55%) of whom were long-term neurologically intact. Overall long-term survival in all patients receiving ECMO was 14/33 (42%). The duration of CPR prior to institution of ECMO ranged from 20 to 110 minutes, with an average time of 65 ± 9 minutes.[51] The application of ECMO to cardiac arrest patients is limited by the time needed to institute therapy. The authors report the time required to set up and prime an ECMO circuit is 20 to 30 minutes with a separate perfusion team on call at all times for ECMO.

Recently a combination of therapies has shown a surprisingly high resuscitation rate with good neurologic outcome. Two recent series from Japan in out-of-hospital cardiac arrest patients combined the use of cardiopulmonary bypass for resuscitation with emergent percutaneous coronary intervention (PCI) in suspected acute coronary syndrome (ACS) and then mild induced hypothermia to 34 ºC.[52,53] Both noted higher resuscitation rates in patients found to have coronary lesions amenable to PCI than cardiac arrest of undetermined cardiac etiology. The survival rate was 40% with 25% having good neurologic outcome in one study[53] and 30% survival with 24% good neurologic outcome in the other study.[52]

In summary, percutaneous cardiopulmonary bypass for resuscitation from cardiac arrest can provide near normal flow even after prolonged cardiac arrest periods, with improved outcome compared with standard CPR and ALS.
Fig. 32.2. Cardiopulmonary bypass system for use in humans. (From Ott RA, Gutfinger DE, Gazzaniga AB, eds. Cardiac surgery: state of arts review. Philadelphia: Hanley & Belfus, 1993.)

Nonetheless, based on work to date, this methodology is likely to be successful only under specific cardiac arrest situations, namely profound hypothermia or cardiac arrest due to ACS responsive to PCI, or another surgical emergency such as valvular dysfunction. Non-discriminate use of percutaneous cardiopulmonary bypass is unlikely to improve outcome and becomes cost- and labor-prohibitive.

Implementation of emergent cardiopulmonary bypass

Much of what we know about the technical considerations of providing emergent cardiopulmonary extracorporeal support to cardiac arrest patients comes from cardiopulmonary bypass-supported angioplasty.[54–59] Although it might be possible to use the equipment and techniques found in the open-heart surgical arena for elective high-risk angioplasty procedures, emergency support requires alterations in traditional techniques. For example, the preparation time required to set up equipment and devices associated with conventional bypass surgery would prohibit success in emergency procedures. Cannulation techniques resulting in a large diameter, unrestricted venous outflow into hard-shell or collapsible reservoirs make the use of gravity venous drainage possible in the operating room, but impractical to use in emergency situations. Bulky equipment and devices also make adaptability and portability to sites outside the operating room difficult.

Many of the limitations of conventional bypass techniques have been resolved with the use of preassembled

membrane oxygenator circuits, percutaneous cannulation, and centrifugal pumps (see schematic Fig. 32.2). Preassembled circuits, with only the devices and connections required to perform emergency bypass support, have allowed preparation time to be shortened to as little as 5 minutes.[28,60,61] Centrifugal pumps not only move the blood forward through the membrane oxygenator and into the patient, but also serve to aspirate the venous blood from the patient. This allows venous cannulation to be performed with smaller diameter cannulae, which would be unsuitable for gravity venous drainage. As a result, both arterial and venous cannulae can be inserted percutaneously in a time frame suitable for emergency situations.

Circuits used for emergency support, therefore, are typically simple, closed non-compliant systems, but with this lack of complexity comes an element of risk if they are operated by personnel who are unaware of the inherent dangers (e.g., massive air embolism, hemolysis, thrombotic incident, or disseminated intravascular coagulopathy). It is essential that the team assembled to provide emergency support include perfusionists who have experience with operating the pump and oxygenator and monitoring the hemodynamic, oxygenation, and anticoagulation status of patients undergoing extracorporeal circulation.[55,61–63] Careful attention must be given to the development of protocols for each application of these devices and for each potential complication. These techniques can only be successful if all team members have a clear understanding of their role and responsibility in the initiation and maintenance of emergent cardiopulmonary bypass.

Equipment and circuit

The hardware and circuits needed for successful emergency support can be either designed and constructed by the institution or commercially purchased. A centrifugal pump is required both to aspirate venous blood from the patient and to drive the blood through the oxygenator to the patient. Currently, centrifugal pumps are found in a constrained vortex or impeller design. Both can provide full bypass flow as long as the cannulae selected are appropriate for the size of the patient and oxygen delivery requirement. A calibrated flow meter, either electromagnetic or ultrasonic, must be included in the line distal to the pump to allow blood flow to be monitored and adjusted. The pump console (Fig. 32.3) consists of a magnetic coupling drive motor and measures both flow and revolutions per minute (rpm) of the pump head. Each of the pump designs has safety features that are helpful in emergency support applications. They appear to be less traumatic to blood over extended support periods and air

locks will form if they are deprimed with large quantities of air. They are also considered to be afterload- and preload-dependent pumps. As an afterload-dependent pump, if the resistance to outflow is increased by any means (e.g., a change in patient vascular resistance), the flow will decrease. This adds an important safety element. If the bypass line returning blood to the patient should kink or inadvertently be clamped, the line will not be disrupted. As a preload-dependent pump, the volume must be continuously provided in an unrestricted way to the pump head in order for outflow to occur. The perfusionist must continuously monitor the rpm of the pump and patient flow in order to adjust for probable changes in pump afterloading (change in arterial vascular resistance) or preloading (change in venous volume).

A second hardware item required is a water bath system designed to deliver thermoregulated water to the heat exchanger of the circuit. This is necessary in order to maintain or adjust the patient's blood temperature. This system may be either a simple water bath that heats to a narrow normothermic temperature range with no potential for adjustment, or a more complicated heating/cooling system with an adjustable water temperature ranging from normothermia to deep hypothermia. For many emergency procedures, maintaining normal body temperature will be all that is required. For emergency support procedures involving rewarming the core of hypothermic patients, some option in the adjustment of water temperature for heat exchange will be desired. In these situations, careful regulation of the temperature gradient between the water and inlet blood temperature will allow for controlled rewarming.[43,64]

A gas supply is also required for emergency support systems. Although some adaptation of wall gas supply is desired, portability of the equipment necessitates that E or D cylinders be available. Oxygen can be used alone as a gas source, but mixing of oxygen and compressed air allows adjustment of the fractional inspiratory oxygen (FIO_2) of the gas source to the membrane oxygenator. A flowmeter and gas blender must be used to adjust and monitor both total gas flow and FIO_2.

Additional equipment includes arterial and venous temperature probes that are inserted into thermowells in the circuit for temperature monitoring. External battery systems must be integral to all of the equipment to make portability to other areas of the hospital possible (e.g., intensive care unit, catheterization laboratory, or operating room). All of this equipment should be housed in a cart that allows portability and provides storage space for disposable supplies for circuit construction and replacement.
Fig. 32.3. Pump console. *Medtronic* PBS portable bypass system (Courtesy of Medtronic Inc., Anaheim, CA.)

The disposable circuit is made up of a membrane oxygenator and centrifugal pump head (Fig. 32.4) connected with appropriate lengths of polyvinyl chloride tubing. This tubing also makes up an arteriovenous loop, which connects to the vascular cannulae. The membrane lung is often a polypropylene or polyethylene hollow fiber design that directs blood flow around the outside of a fiber bundle and gas flow to the inside of each fiber. This outside fiber blood flow design provides excellent gas exchange and minimizes resistance to blood flow from the centrifugal pump. The membrane oxygenator may have a heat exchanger, proximal to or integral with the fiber bundle, to maintain or adjust the patient's blood temperature. If not part of the oxygenator, the heat exchanger must be added as a separate device in the circuit. In some cases, a membrane oxygenator is chosen

Fig. 32.4. Centrifugal pump. Need updated photo of Medtronic Biopump Plus Centrifugal Blood Pump. (Courtesy of Medtronic Inc., Anaheim, CA.)

with design features that allow it to act as a safety device in case of accidental introduction of air. It is possible that air, inadvertently introduced into the venous side of a membrane oxygenator, can be trapped in the device and perhaps be eliminated by diffusing to the gas path. This eliminates the need for air-trapping devices placed distal to the oxygenator, which would add complexity to the circuit design and priming procedures.

A fluid administration line is located proximal to the centrifugal pump head. This is used to prime the circuit prior to bypass and may be opened during the procedure for rapidly administering replacement volume to the patient. Approximately 350 ml of fluid are required to prime most systems. Sampling sites should be provided for access to arterial and venous blood. Often a tubing bridge, located close to the patient, connects the arterial and venous lines. This bridge is helpful in the priming procedure, for oxygenator change-out procedures, to eliminate air that may enter the circuit after bypass has begun, and often is used to circulate the circuit volume to minimize stasis at times when bypass is discontinued. Lastly, a line pressure monitoring device may be incorporated in the circuit at the oxygenator or at some point in the arterial line. This is usually a small piece of tubing connecting the circuit to an aneroid pressure gauge.

Concerns about the use of anticoagulants in these patients has led to attempts to provide support with circuits that have been precoated with heparin.[65,66] This likely reduces the risk of heparin-induced hemorrhage and the complications associated with heparin reversal requiring protamine.

Patient preparation and management with cardiopulmonary bypass

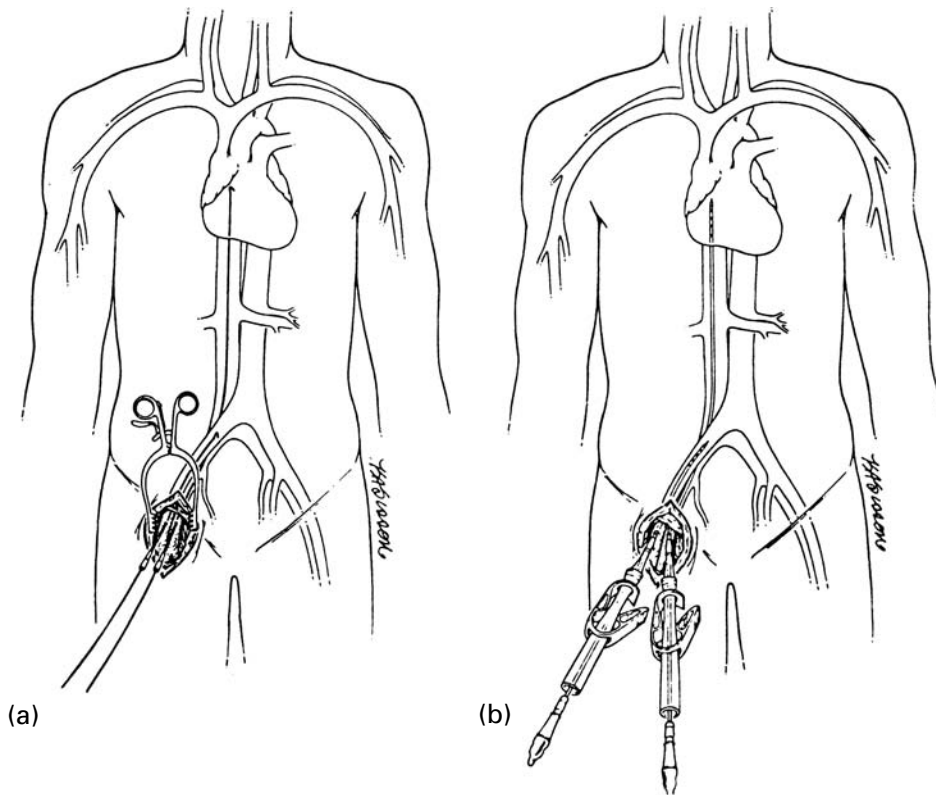
Rapid cannulation and initiation of cardiopulmonary bypass is key to the success of extracorporeal emergency support. Thin-walled polyurethane cannulae are available that can be inserted percutaneously into the femoral artery and vein by the Seldinger technique or directly inserted by a modified Seldinger technique or complete cutdown.[28,57] The more direct approach, with some level of cutdown, may be required in patients with complete circulatory collapse.[67] Other cannulation sites (e.g., the internal jugular vein) may be used if needed. The venous cannula is available in 17 to 30 F sizes and is long enough (50 to 60 cm) to advance the tip to the venocaval-atrial junction. The end of the cannula is multiholed to minimize tissue obstruction to venous flow. The arterial cannula is available in 12 to 21 F (15 to 30 cm) sizes and is advanced to the common iliac artery (Fig. 32.5) Both cannulae must be sized to the patient in order to ensure minimal obstruction to preloading and afterloading of the centrifugal pump. Iliofemoral angiography is helpful in elective cases (e.g., angioplasty)


Fig. 32.5. Peripheral cannulation of femoral vessels for CPB. A. A right groin cutdown is followed by systemic heparinization. 18-gauge femoral venipuncture and arterial puncture are performed with insertion of guidewires. B. A 20F, thin-walled cannula is placed with end holes in the right atrium and a short 20F cannula is placed into the common iliac artery. (Reprinted with permission from the Society of Thoracic Surgeons from Hartz R, LoCicero J, Sanders JH, Frederiksen JW, Joob AW, Michaelis LL. Clinical experience with portable cardiopulmonary bypass in cardiac arrest patients. Ann Thorac Surg 1990;50:438.)

to ensure an unobstructed course for arterial cannula advancement and blood flow, but is not practical for emergent procedures. Heparin is administered (300 U/kg) to the patient after guidewire placement but before vessel dilatation and cannula insertion.[28,61,68,69]

Since the venous volume is aspirated from the patient with the centrifugal pump, it is essential that all central and peripheral venous infusion and monitoring lines be checked for proper functioning prior to initiation of bypass.[67] Central monitoring catheters must be closed systems and peripheral administration lines must be closed or placed on occlusive infusion pumps. It is possible that an open peripheral line used for drug delivery could be rapidly emptied of its volume because of the aspiration that will occur in the venous vascular system. Venipuncture during the bypass procedure could result in a massive venous air embolism. All venous cannulae must be properly secured in the patient to avoid movement of

the cannula and exposure of the end holes to air, which would lead to depriming of the circuit.

Initiation of bypass is performed slowly, especially in patients who are conscious. This minimizes sudden shifts in temperature or the consequences of hemodilution.[62] The circuit bypass is clamped and the venous and arterial cannulae are unclamped (in that order) with the centrifugal pump operating at low rpm to ensure displacement of the prime volume to the patient. If the centrifugal pump is not on, or is set at an rpm value too low to overcome the afterload of the patient and circuit, retrograde flow will occur from arterial to venous cannula. Flow should be increased to the predetermined target over several minutes. As the speed of the pump increases, flow will also increase until there is insufficient preload of the centrifugal pump head with volume. At this point, further increases in rpm will not produce increases in flow and the perfusionist will note decreased flow if the rpm is further adjusted upward. A

vibration in the venous line and low or negative central venous pressures are additional signs that the pump head is not adequately preloaded. If additional flow is required, volume may be administered to determine if the problem is inadequate preload or obstruction of the venous cannula.[55,61] Fluid additions through the administration line proximal to the pump must be monitored carefully since fluid will be aspirated into the circuit at a rapid rate. When fluid bags are being changed, all air must be evacuated from the bag and administration line before they are opened to the patient. Only collapsible fluid containers are acceptable for use.

Full flow may not be required if the patient is able to provide some cardiac output and does not show symptoms of hypoxia or hypotension. If this is the case, some pulsatility in the arterial pressure waveform will be noted and some ventilation of the patient's lungs must be maintained in order to ensure that the blood that is ejected to the proximal aorta is arterial. The ventilation of the membrane lung can be adjusted downward to avoid hypocarbia. If, however, bypass is supporting the entire cardiac output, no pulsatility will be noted in the arterial waveform. It is likely that the pulmonary artery and capillary wedge pressures will also be low under these circumstances. Flow rates achieving full support should be possible as long as the cannulae are properly sized to the patient and aspiration of the venous volume is unobstructed.

Typical measures that are monitored to assess bypass flow include arterial and central venous pressures, systemic vascular resistance, venous oxygen saturation, and rpm. As patients regain consciousness, systemic vascular resistance may increase. High rpm values with low flow may suggest a high systemic vascular resistance.[70] Blood gases, activated clotting time, hematocrit, electrolytes, and urinary output are also monitored. Changing the flow rate and FIo_2 on the gas source to the membrane oxygenator will affect arterial Pco_2 and Po_2, respectively. Arterial Pco_2 is inversely related to gas flow rate. As the gas flow rate is increased, more carbon dioxide is removed from the gas path of the membrane oxygenator, thus increasing the gradient for carbon dioxide transfer and lowering arterial Pco_2. Gas flow should be initiated at a rate equal to blood flow (a 1:1 ratio) with subsequent adjustments made based on blood gas analysis. Arterial Po_2 is directly related to ventilating gas Fio_2. Precise control of arterial blood gases, acid–base balance, electrolyte levels, and volume is possible with extracorporeal support. This precision is a distinct advantage over other techniques used to resuscitate the arrest patient or rewarm the hypothermic patient.[71,72] The activated clotting time should be maintained at levels in excess of 400 seconds,[56,58,61,68,69] which can be accomplished with inter-mittent administration of heparin. Since most emergency support procedures are performed at normothermia, heparin metabolism will likely be more rapid than is found in conventional open-heart bypass. Frequent measurements of activated clotting time are required by the perfusionist to avoid a thrombotic incident.

As flow is reduced, more volume will enter the right side of the heart with eventual ejection from the left side. Arterial waveform pulsatility will reappear. Volume can be added to the patient by aspirating through the administration line until the central venous or pulmonary capillary wedge pressures are increased to predetermined targets. As the flow is decreased below 0.5 l/min, the arterial line will require clamping to avoid retrograde flow through the arterial line from the patient. Once the patient is off bypass and the line leading to the centrifugal pump is clamped, additional volume can be administered from the administration line into the venous cannula. When the arterial and venous cannulae are both clamped, the bypass bridge can be opened to recirculate the blood slowly through the circuit to avoid stasis while the patient's hemodynamic stability is assessed. Residual volume in the bypass circuit can be drained into blood transfer bags or centrifuged to recover the cells for later infusion to the patient.

Open chest cardiac massage

Despite improved hemodynamics during cardiac arrest with open chest cardiac massage in animal models, at present open chest cardiac massage is mainly of historical interest. The current indications for opening the chest during cardiac arrest in order to perform direct cardiac massage are limited to very specific traumatic arrests. Current recommendations advocate emergency thoracotomy only for trauma patients with recent loss of vital signs (cardiac arrest within approximately 5 minutes) and penetrating chest injury. While thoracotomy and open chest cardiac massage have been done after longer cardiac arrests and following blunt trauma, no survival benefit has been noted. Earlier reported series of cardiac arrest patients who received open chest cardiac massage involved primarily intraoperative patients who arrested[73] many predating the seminal work of Kouwenhoven et al.[74] describing closed chest CPR. More recently a few small series have been described in which open chest cardiac massage was performed on out-of-hospital cardiac arrests. In a study from Brussels in which a physician-staffed mobile intensive care unit was dispatched to the scene of the cardiac arrest victim, over a 12-year period (1984–1996) open chest CPR was instituted at the scene in 33 of 2212

patients who received out-of-hospital closed chest CPR.[75] In these 33 patients ROSC was obtained in 13 (39%) and survival to hospital discharge in 2 patients. At present, efforts to improve CPR outcome continue to be directed away from open chest cardiac massage except in very specific and infrequent situations.

Ventricular assist devices

A number of left, right, and biventricular assist devices have been used for support in profound heart failure after various cardiac surgical procedures, and cardiogenic shock following acute myocardial infarction.[76–78] These devices have demonstrated the ability to sustain circulation even during ventricular fibrillation. Because of the technical difficulty in applying these devices, however, such devices are not currently viewed as a therapeutic option for cardiac arrest patients, unless some degree of circulatory support is already present. The time constraints of global ischemia induced by cardiac arrest do not allow for application of these devices in a reasonable time period.

Ventricular assist devices that have been utilized in cardiac arrest are known as direct mechanical ventricular assistance (DMVA) devices. DMVA was first described in 1966[79] and consists of a heart assist cup and a pneumatic driving system. The heart assist cup is constructed of a rigid translucent shell containing an inner elastic diaphragm which is placed around the ventricles after a thoracotomy has been performed. The outer portion of the cup communicates with the pneumatic drive system through two ports. A sustained negative pressure exerted from the driving system holds the cup securely in place on the ventricles. Through the second port, alternating positive and negative pressures are pulsed to actuate the myocardium in systole and diastole. DMVA has shown increased perfusion pressures and cardiac output in canine cardiac arrest models when compared with both closed- and open-chest CPR.[80,81] Myocardial blood flow was measured in a swine model of 10-minute ventricular fibrillation arrest and reperfusion with 3 minutes of external CPR, followed by DMVA. Myocardial blood flow was significantly elevated above CPR levels and probably approached baseline levels, although the study did not report baseline levels or controls.[82] Four of the seven animals were successfully defibrillated.

Potential advantages of DMVA when compared to cardiopulmonary bypass include no interface of blood with a foreign surface, which precludes the need for anticoagulation, and perfusion with pulsatile flow, which may be more beneficial than non-pulsatile cardiopulmonary bypass flow. Moreover, since the DMVA device is placed directly over the ventricles after a thoracotomy is performed, the technique does not rely on obtaining vascular access.

Comparisons between DMVA and cardiopulmonary bypass in the canine model have not shown one technique to be clearly superior over the other. In a comparison of 20 dogs with 10 in each group, 4 hours of DMVA was compared to 4 hours of cardiopulmonary bypass while the heart remained in ventricular fibrillation. Time-to-peak contracture at the end of the 4-hour perfusion period was longer in the DMVA group. High-energy phosphate depletion was assessed through myocardial biopsies. A significant delay in depletion of left ventricular subendocardial adenosine phosphate (ATP) was noted in the DMVA animals. There were no significant changes in ATP between groups in left ventricular epicardial, right ventricular, or septal regions of the heart.[83] Although both groups received 4 hours of augmented perfusion, there were differences in perfusion between groups. Mean arterial pressure during perfusion was significantly higher in the DMVA group than in the cardiopulmonary bypass group.[83] Central venous pressures were higher in the DMVA group, however, so that the arteriovenous pressure difference was similar in the two groups. In assessing organ blood flow during the 4-hour perfusion period, organ flows with cardiopulmonary bypass were increased significantly over DMVA (cardiopulmonary bypass 110% of normal versus DMVA 75% of control), while at the same time the DMVA group had a mean arterial pressure significantly higher than did the cardiopulmonary bypass group.[84]

Clinical experience with use of DMVA is very limited. A single trial with DMVA in human cardiac arrests has been reported.[85] Twenty-two patients had institution of DMVA after failure of conventional cardiac arrest therapy. Twenty of the 22 patients presented to the emergency department in cardiac arrest. The average time in cardiac arrest until application of DMVA was 81 ± 9 minutes. Four of the 22 patients were initially defibrillated; however, two died within the first hour. The other two died in hospital before discharge. The authors noted that DMVA could be applied within 2 to 3 minutes, including thoracotomy time. Because the time of cardiac arrest before application of DMVA is not known, it is difficult to determine whether the device conferred any clinical benefit.

The future

The greatest laboratory and clinical experience to date with perfusion-augmenting devices and therapy has been

with cardiopulmonary bypass. Both laboratory and clinical studies have demonstrated the ability to restore normal levels of circulation after prolonged periods of cardiac arrest. What has become clear, however, is that successful restoration of perfusion is not always sufficient to restart the heart or ensure good neurologic outcome. There are time limits to global ischemia beyond which normal or even greater than normal reperfusion and circulatory support are insufficient to reverse ischemic damage. When therapy is started late, the efficiency of treatment in reversing the arrest state to a good long-term outcome cannot be evaluated accurately. Late therapy, no matter how good, is never effective once the ischemic capability of the heart and brain is exceeded. Nevertheless, the window for recovery may be lengthened by circulatory support, thereby allowing the administration of reperfusion agents that may be important in ameliorating ischemic and reperfusion injury. Cardiopulmonary bypass and other circulation assist therapies may facilitate delivery of such agents and compensate for any hypotensive effects or reduced perfusion that these agents might cause.

The future use of cardiopulmonary bypass in the setting of cardiac arrest depends on being able to institute cardiopulmonary bypass quickly after the onset of cardiac arrest refractory to initial treatment. The best outcomes in cardiac arrest with this therapy seem to be in patients with cardiac arrest due to profound hypothermia or secondary to acute coronary syndrome with coronary lesions amenable to PCI or surgical repair. Given that specific subpopulations of cardiac arrest patients may be more likely to respond to this therapy and it is not feasible to institute such therapy in every cardiac arrest patient, strict criteria for patient selection are needed. Criteria for starting and stopping these therapies after both successful and unsuccessful ROSC must also be developed.

Future use of cardiopulmonary bypass early in cardiac arrest may be effective with only partial reperfusion support, rather than requiring flows equivalent to normal cardiac output. Early partial circulatory assistance may permit the attainment of ROSC with continued partial assistance after circulation has returned. Partial circulatory support would allow the use of much smaller cannulae, which would greatly facilitate placement. Lower flow requirements would permit further modification and presumably miniaturization of current pumping systems. In order to utilize this technology effectively, future cardiopulmonary bypass systems must be smaller, more mobile and allow for easy set-up and rapid insertion of percutaneous cannulas. Eventually this technology must be capable of transport to the patient's side in the field prior to arrival to the hospital, to maximize outcome success. Currently the time to implement cardiopulmonary bypass and the resources required constitute the foremost obstacles hindering the utilization of this methodology in cardiac arrest.

Summary

Generally global ischemia of >10 minutes is thought to be universally fatal. Earlier large animal cardiac arrest studies, however, have shown good neurologic and cardiac recovery after cardiac arrests of 12–30 minutes duration prior to any resuscitative attempts. The key determinant of successful reperfusion in these prolonged cardiac arrest situations is controlled reperfusion with use of cardiopulmonary bypass. Cardiopulmonary bypass allows for much higher reperfusion flows, reperfusion pressures, and oxygen delivery than any available CPR methods. Although this level of reperfusion clearly seems to be superior to the much lower reperfusion provided by CPR techniques, there are very significant limitations of the technique, which continue to preclude its widespread use. The primary limitations of cardiopulmonary bypass with cardiac arrest consist of: (a) the duration of time necessary to bring a portable device to the patient's side; (b) time and difficulty to cannulate the patient's large vessels under arrest conditions; (c) time to prime the circuit; (d) large expenditure of resources for this equipment; (e) the availability of adequately trained personnel to monitor and run the equipment; and (f) determining the subpopulation of cardiac arrest victims that might benefit from this intervention. At present, we are not able to overcome these limitations on a widespread scale, although it is likely these obstacles can be overcome in the future. The promise of this therapy is the capability of providing controlled, near normal circulation despite the absence of functional cardiac pumping.

Historical review of routes of drug administration

Baggellardus, a contemporary of Columbus, observed Indians applying fumigation to the mouth or anus of apparently dead persons and brought the technique to Europe.[1] In the aftermath, during the seventeenth and eighteenth century, scientific societies all over Europe recommended warmth, artificial respiration, rectal fumigation with tobacco smoke, friction, and bleeding for resuscitation purposes.[2,3] Insufflation of air, tobacco smoke, or vaporized aromatic plants either by mouth, the nostrils, or the rectum was common,[4] stimulants were administered by nasogastric or rectal tubes, and topical application with "spirits of wine, hartshorn, or, which is perhaps the most powerful, the spirits of sal ammoniac" were used .[5] Eventually, tobacco insufflation was abandoned when Brodie in 1811 published his observations that even a dog was easily killed by injection of smoke into the rectum.[2]

History of intravenous techniques

Bronze syringes had been known since antiquity,[6] when Heron of Alexandria had recommended his pus extractor for injection of fluids.[7] Blood circulation was discovered in 1616 by William Harvey,[8] and in 1656 the British astronomer Sir Percival Christopher Wren (1632 to 1723) first demonstrated intravenous therapy by injecting wine and beer into a dog.[9] He noted that "the opium. . . did within a short time stupefy, though not kill the dog." Three other physicians, acting independently of Wren, described intravenous (iv) therapy: Johann Sigismund Elsholtz (1623 to 1688), who infused water into the brachial artery of a drowned woman in 1661, the surgeon Carlo Fracassati (ar. 1630 to 1672), and lastly Johann David Major (1634 to 1693), a medical doctor. Intravenous drug injection was supposedly first attempted in man in the failed execution of a servant of the French envoy to London in 1657.[10] A silver syringe and cannula were first described by Elsholtz in 1667.[11] In the years following, Richard Lower (1631 to 1691) performed the first transfusion from animal to animal in 1666, while Jean-Baptiste Denis (ar. 1615 to 1704) attempted animal to human transfusion. As Denis' patient died one night after the transfusion, the court of Paris interdicted all transfusions in 1670. Because of the observed complications (thrombosis, hemolysis, embolism), intravenous techniques played only a marginal role until the nineteenth century. Intra-arterial injections for the purpose of resuscitation were then performed by Moritz Schiff.[12] In 1891, Arnaud injected blood directly into the coronary arteries and showed that defibrinated and oxygenated blood could revive an arrested heart.[13]

In 1929, Forssmann started percutaneous techniques when he catheterized his own right ventricle.[14] Intravenous catheters were tested by Cournand and Ranges[15] and Meyers.[16] Duffy described the use of the external jugular vein in 1949,[17] Aubaniac[18] reported cannulation of the subclavian vein in 1952, and in 1953 Seldinger described his technique for catheterization.[19] Despite all these advances, Kouwenhoven, Jude, and Knickerbocker[20,21] in the 1960s still recommended a venous cut-down for drug therapy after emergency treatment with intracardiac injections. Swan *et al.*[22] reported on the use of pulmonary artery catheters in 1970, when Jernigan et al. also published their experiences with the internal jugular vein approach.[23]

History of intracardiac injection

The anatomical features of intracardiac injections were described by Steiner[24] in 1871. Intracardiac injection of epinephrine probably was first done by Latzko[12] in 1904 and Crile and Dolley[25] in 1906. In 1919, von den Velden[26] reported on 45 cases of intracardiac injections that he had performed since 1906. Intracardiac (or intraarterial) injections were used mainly for blood transfusion, however, until 1921 when several authors reported the successful use of intracardiac epinephrine.[27–29] In their important papers, Kouwenhoven et al.[21,21] recommended intracardiac vasopressor injections "since the drug should be injected into the blood stream for immediate effect."[20] The common perception was that peripheral iv injections had no effect in the low flow state of CPR, although sparse data supported this view:[12] "Many physicians are under the impression that intracardiac injections should be more effective than intravenous. . . they are reluctant to use them intravenously even with an intravenous route immediately available."[30] In addition to the pharmacologic effect, insertion of the needle itself was deemed to affect the heart.[24,26,31] Fontana[32] in 1775 had provoked a heart beat simply by inserting a needle, and in 1829 Krimer[33] combined the technique with electricity to resuscitate drowned patients, thereby introducing some sort of intracardiac pacemaker for the first time. In 1871, Steiner[24] published extensive historical, anatomical, and physiologic studies recommending "electropuncture" of the heart for cardiac arrest during chloroform anesthesia. By the end of the nineteenth century, however, electrical therapy of cardiac arrest was no longer practiced.

History of endotracheal administration

Endotracheal (ET) intubation was first performed by the Belgian anatomist Andreas Vesalius[34] in 1543. The absorption capacity of the lungs was demonstrated by the french physiologist Claude Bernard[35] in 1857 with the administration of curare to dogs by way of tracheostomy. Several years later, resorption of many more drugs administered by the ET-route was reported[36,37] Kline and Winternitz in 1915 were the first to recommend the ET route for administering medication.[38] In 1935, Graeser and Rowe[39] recommended inhalation of epinephrine for treatment of bronchial asthma, and direct aerosolized drug delivery was broadly used for antibiotic therapy of lung infections.[40–45] From the 1940s until the 1970s, numerous reports established that substantial uptake of local anesthetics occurs during topical anesthesia of the larynx and trachea, as even occasional deaths were reported.[46–52]

History of intraosseous routes

The intraosseous route was introduced after the description of the circulation within mammalian bone by Drinker et al.[53] and Doan in 1922.[54] The first site chosen was the sternum, but this was quickly abandoned in preference for the tibia or femur. In 1940, Tocantins showed that substances injected into the bone marrow appeared almost immediately in the circulation.[55] The intraosseous technique fell from favor, however, with the introduction and improvement of intravascular catheters that allowed for more permanent peripheral intravenous access but was reinstated in 1983 after a letter to the editor about intraosseous infusion by Turkel,[56] which was followed by a plethora of clinical and experimental reports.

Peripheral venous routes

Basic physiology

In animal studies with indocyanine green dye, the time from dye injection to appearance at the aortic root was 94 seconds.[57] Peak dye concentration following peripheral injection was lower than that following central injection and time-to-peak concentration was delayed. In another study, lidocaine time-to-peak following peripheral injection was 42 seconds, with therapeutic lidocaine levels persisting for 9.6 minutes.[58] Peak lidocaine levels averaged 22 μg/ml following peripheral injection compared to 34.5 μg/ml when given by central venous injection. Open-chest massage reduced circulation time compared to closed-chest compression.[57] For example, while circulation time after peripheral injection during closed-chest CPR averaged 94 seconds, it was only 31 seconds with open-chest massage. Dye concentration curves obtained during open-chest CPR have a sharp peak with rapid decay, comparable to those observed during spontaneous circulation and in contrast to those obtained during closed-chest CPR (Fig. 33.1). The route of administration is probably less critical during open-chest CPR as there are only small differences in circulation times between sites. For example, there is an average difference of only 10 seconds in circulation time between central and femoral injection during open-chest CPR in dogs. It is unlikely that there are clinically significant differences in man. Although peripheral injection somehow delays the drug effect, one clinical study suggests that this does not alter clinical outcome.[59] Gueugniaud et al. reviewed 233 patients given either peripheral epinephrine (175 patients) or central injection of
Fig. 33.1. Dye dilution curve after central venous injection during open chest CPR (paper speed 1 mm/s). *Arrow* indicates dye injection.

epinephrine (58 patients). Of these patients, 51% receiving peripheral injection had temporary return of spontaneous circulation (ROSC) compared to 38% of patients receiving central injection; 13 patients were alive after 21 days, including 12 who received peripheral injection and 1 who received central injection. With this sample size, this study would have a power of 36% to detect a difference in survival.

Drug delivery after peripheral injection is enhanced by following the injection with a saline flush.[60] After a 20-ml flush, circulation times are 40% shorter than those without a saline flush (Fig. 33.2),[61] and correspond to those seen after central injection.[62,63] Yet peak dye concentrations show no differences.[60] Varying the bolus size from 10 to 30 ml also was without significant effect on either circulation time or peak dye concentration. Virtually all of the studies have been performed in animal models and there are no data providing a reliable basis for clinical use. Nevertheless, since preliminary results in dogs have indicated that 10- to 30-ml boluses result in similar circulation times, it seems reasonable to assume that, for clinical use, a bolus of about 20 ml is appropriate. Peripheral

venous access is the least invasive and safest means of administering medication during cardiac arrest and does not interfere with CPR.

Drugs

Injection of epinephrine into the antecubital vein has been demonstrated to lead to a marked rise in epinephrine levels within 2 minutes after injection.[64] Quinton *et al.* randomized 12 patients to receive intravenous epinephrine administered either in an antecubital vein or via an endotracheal tube. The injection of 1 mg of epinephrine IV increased serum epinephrine levels up to three times the level before administration. By comparison, the maximal increase in levels after ET administration was less than half the minimal increase in epinephrine levels after iv administration. In dogs, an increase in coronary perfusion pressure occurs within 1 minute after injection and reaches a peak around 3 minutes, after which the coronary perfusion pressure begins to return to baseline.[65] iv Injection of 0.015 mg/ kg of epinephrine was found to increase coronary perfusion pressure from 16.9 mmHg to a peak of 22.5 mmHg.

Femoral injection

There is broad, especially military, experience in using the femoral vein for resuscitation. These lines can provide a route for fluid administration, although the incidence of complications increases the longer the line is in place. Experience during the Vietnam war showed that the femoral vein could be catheterized successfully 95% of the time even in patients without palpable pulses.[66] The technique was associated with arterial puncture in approximately 6% of patients, hematoma formation in 1%, and wound infection in 1%. No instances of retroperitoneal hematoma formation in this large series were observed. At least one civilian study has demonstrated that 89% of attempts at femoral vein catheterization in patients either in cardiac arrest or requiring fluid perfusion for shock were successful.[67] Femoral venous access was particularly useful for rapid fluid infusion, although this is not a consideration, and indeed may be deleterious, in cardiac resuscitation.

There has been some concern that drugs administered near the femoral route may not circulate to the central compartment during CPR.[68] A canine CPR model did not demonstrate a pressure gradient between the inferior vena cava and right atrium, and cineangiographic studies revealed significant reflux into the inferior vena cava during compression. In another canine arrest model, measurements with radioisotopes established that the time-to-reach half-peak count over both the right and left ventricles was markedly delayed for injection into the inferior vena cava compared to superior vena cava injection. When corrected for cardiac output during CPR, the times to right and -left ventricle peaks and half-peaks were all significantly delayed after inferior vena cava injection.[69]

In two studies of femoral vein catheterization during human cardiac arrest, the success rate for correct placement was low. Jastremski et al. found that physicians of various backgrounds correctly placed catheters in the femoral vein in only 31% of cases.[70] In a larger study with injection of radiopaque dye to verify catheter placement, femoral vein catheters were placed correctly 77% of the time as compared to 94% of subclavian vein catheters.[71] The femoral route has never been compared to other routes during CPR in humans. An older study compared dogs given epinephrine by a variety of routes: ROSC-time was 127 seconds for the femoral route, compared to 139 seconds for the intracardiac route, and 116 seconds for endotracheal administration.[30] Recently, Chiang and Baskin reported that in 121 critically ill infants, children, or young adults, placement of femoral central venous catheters was successful in 83% of all cases. Twenty of their patients were in cardiac/respiratory arrest.[72] In summary, femoral venous injection during cardiac arrest is limited by a low chance of successful cannulation as well as prolonged circulation times. Its use should be limited to situations in which other routes of administration are unavailable.

Central venous injection

Peak dye concentrations after central injection in animal studies were 40%[57] or 270%[73] greater than those seen after peripheral injection. Circulation times after central venous injection are 30%–50% shorter compared to peripheral injection. In human studies, peak lidocaine levels were four times greater after central injection than after peripheral injection.[74] Lidocaine levels reached a peak 30 seconds after central injection, whereas lidocaine was not detected until 90 seconds after peripheral injection and did not reach a peak during the 5-minute study period after peripheral injection. In a review of 554 catheterizations, including shock patients, the overall complication rate was 13.7%.[75] Normally, the complication rate of placing subclavian catheters can be as low as 1%,[76] and differences may be related to the higher accuracy of prospective studies, urgency of the situation, and level of physician training.[75] Most of these studies have been performed when circulation was spontaneous and the results may not be directly applicable to the difficult situation of central vein catheterization during ongoing CPR.

Few studies have examined central venous catheterization during human CPR. Dronen et al. compared the superior and inferior approaches to the subclavian vein in 76 patients undergoing CPR, and found no difference in the overall success rate, although malpositioning was more frequent with the inferior approach.[77] Moreover, the inferior approach led to more frequent interruptions in chest compression. Emerman et al. found that 94% of attempts at infraclavicular approaches to the subclavian vein were successful in human CPR.[71] In that study, 11% of catheters were malpositioned in the venous system, and 6% of the catheters were inadvertently placed into the arterial system. Our personal experience is that the supraclavicular approach to the subclavian vein provides less interference with ongoing CPR with a high rate of success. Nevertheless, the approach chosen should be related to the

individual operator's personal experience and expertise. There is little evidence to suggest that any one approach is mandated during CPR.

An alternative approach to the central circulation is cannulation of the external jugular vein, which is generally engorged during CPR and is easily cannulated. If desired, a wire can be passed through the catheter allowing subsequent placement of a longer catheter into the superior vena cava, although venous valves occasionally limit the success of this maneuver.

Intraosseous injection

Rationale

Successful resuscitation has been shown to depend on the time to achieve intravascular access, but this is a major problem, especially in pediatric CPR. Rossetti and coworkers[78] reported that placement of an intravenous catheter required at least 10 minutes in 24% of the children in cardiac arrest. Lillis and Jaffe[79] found that more than half of the children younger than 6 years who required intravascular access did not receive an IV line in the prehospital setting, and that only 4% of children under 6 years with absent vital signs had successful placement of an IV line. Unlike iv access, studies of intraosseous infusions have shown overall success rates of 76%, and 85% of infusions were achieved in less than 1 minute.[80] Therefore, it is recommended that in children under 3 years old, attempts at peripheral access not be sustained beyond 90 seconds before an alternative route for drug administration is sought.[81] Although intraosseous infusion is generally considered a technique for pediatric resuscitation, it can also be used in adults. Valdes reported no complications in 15 adults, none of whom were in cardiac arrest, who received 2–42 liters via the intraosseous route over a period of 3.5–30 days.[82] Iserson used the intraosseous route successfully in 22 adults who were in cardiac arrest.[83] Temporally related pharmacologic effects were observed after administration of sodium bicarbonate, lidocaine, atropine, and vasopressors. Based on experience on adult cadavers, Clem and Tierney recommended using the calcaneus as the preferred site for intraosseous infusion in adults.[84]

Flow rates of 10 ml/min with gravity and 41 ml/min with 300 mmHg pressure have been demonstrated with a 13-gauge needle in the medial malleolus of calves.[85] In vivo flow rates depend on the flow through the bone marrow, e.g., the characteristics of the medullary space, rather than on the size of the needle.[86] Similar flow rates were also attained in humans.[87] Laspada and coworkers used a piglet model to compare the extravasation rates and insertion complications under gravity and 300 mmHg pressure infusion of threaded and nonthreaded needles and found no significant differences.[88]

Physiology

A rich network of medullary sinusoids in the long bones is drained by numerous venous channels that empty into a solitary longitudinal central venous sinus. From there, the blood enters the central venous circulation.[89] The marrow cavity functions as a rigid vein and does not collapse during hypovolemia or circulatory shock.[90] After intraosseous injection, the distribution of drugs and fluids appears to be very similar to that after iv injection.

Technique

The proximal tibia is the optimal site for the insertion of the intraosseous needle in children. This site is approximately 1 cm below the tibial tuberosity and medially on the tibial plateau, and it permits concomitant ventilation or chest compression during placement.

Other sites for intraosseous infusions include the sternum, humerus, clavicle, distal tibia, iliac crests, and femur. Drug absorption and fluid infusion are equally effective from either site.[91] If the distal tibia is used, the optimal location is in the medial surface of the tibia proximal to the medial malleolus.[89] The distal femur site is just about 1 cm above the patella and in the midline. The sternum, humerus, and clavicle cannot be used during CPR.

A number of commercially available bone marrow needles exist for intraosseous access and infusion.[92,93] In the absence of a bone marrow needle, a strong, large bore needle with a stylet, such as a lumbar puncture needle, should be used[94] and inserted perpendicular to the bone, with the bevel pointing away from the joint space. Entry into the marrow space is confirmed by noting a lack of resistance after passing through the cortex.[95] Aspiration of blood marrow with a syringe confirms the correct position. After conventional vascular access is established, the intraosseous infusion should be discontinued.

Complications

The complication rate for this technique is low. Difficulty or inability to enter the marrow cavity is the most common problem, whereby, the needle is accidentally forced through the opposite site of the bone. Extravasation of fluid around the puncture site is a minor but frequently

reported problem and can occur at any site where there has been a break in the cortex, e.g., around the puncture site, or from holes from unsuccessful attempts or fractures in the cortex.[89]

Potential hazards include fat embolization, cellulitis, abscess, subperiosteal infiltration or hematoma, and subcutaneous infiltration. Risk of osteomyelitis is low: of 4270 cases reported between 1942–1977, only 27 cases of infections were reported.[89] Bowley *et al.* reported an iatrogenic fracture of the proximal tibia caused by the use of a bone injection gun device, and suggested performing follow-up radiographs for all children in whom intraosseous insertion had been attempted.[96] Damage to the epiphyseal plate is at least of theoretical concern, although it has never been reported and may be avoided by placing the needle several centimeters away, and pointed away from the joint space.[89] Follow-up studies after intraosseous infusion have shown only short-term periostitis and no long-term sequelae. One study reported 72 patients followed-up with radiographs and showed no adverse effects 1–2 years after intraosseous infusions.[97] Fatalities attributed to intraosseous infusions were all related to sternal puncture with associated mediastinitis or injury to the heart or great vessels.[98] Therefore, the sternal site should be avoided altogether. Multiple insertion attempts can significantly decrease vascular drug levels, presumably due to extravasation.

Clinical applications

Only a few human studies are available, most of which compared intraosseous, intravenous, and endotracheal drug administration.

Orlowski *et al.* studied the pharmacokinetics of epinephrine hydrochloride, sodium bicarbonate, calcium chloride, hydroxyethyl starch, 50% dextrose in water, and lidocaine hydrochloride in normotensive anesthetized dogs.[99] Each animal was treated with all three routes of administration (central iv, peripheral iv, and intraosseous) in a randomized sequence. Effects of adrenaline were also assessed in a shock model. The IO route was comparable with the central and peripheral iv routes for all drugs, with equivalent magnitudes of peak effect or drug level and equal or longer durations of action.

Time-to-peak plasma concentration of atropine in anesthetized monkeys was shortest with iv administration and longest with endotracheal administration, with intraosseous administration in-between.[100] The mean concentration of atropine in plasma was significantly higher in the iv group than in the endotracheal group at 0.75 and 2 minutes, and the concentration was sig-

nificantly higher only at 0.75 minute compared to intraosseous administration. Its mean plasma concentration was, however, significantly higher than that of endotracheal administration at 5 minutes and it was greater than that of iv and endotracheal administrations for the samples collected over 5–30 minutes.

In another study, Orlowski *et al.* compared central iv, peripheral iv, intraosseous, and intratracheal administration of epinephrine in both normotensive and hemorrhagic shock dogs.[101] Epinephrine was equally effective by the intraosseous, central iv, and peripheral iv routes in terms of time-to-onset of action, time-to-peak effect, and magnitude of effect on systolic, diastolic, and mean arterial pressures in both the shock and non-shock animals. The duration of effect was significantly longer for the intraosseous route of administration.

Several studies used radioactive isotopes to compare peripheral and central delivery times by iv and intraosseous infusion. Cameron et al. injected a radionuclide tracer and showed that intraosseous infusion achieved peripheral and central circulation transit times comparable to those achieved by the iv route during both normovolemic and hypovolemic states.[102] Warren and coworkers studied the pharmacokinetics from multiple intraosseous sites, including tibial, medial malleolar, distal femoral, and humeral, as well as from peripheral iv site injections in normovolemic and hypovolemic pigs. They demonstrated similarly rapid transit times and proportions of bicarbonate and radioactive tracers from all sites.[103]

In summary, the above-cited studies demonstrate that intraosseous drug delivery is comparable to both the peripheral and central venous routes, with equivalent magnitudes of peak drug effect and levels, and equal or longer durations of action. Most of these studies, however, were performed when circulation was spontaneous and therefore the results may not be directly applicable to a cardiac arrest setting.

Cardiac arrest

There are only isolated case reports describing successful resuscitation after intraosseous infusion of epinephrine, albumin, and bicarbonate in humans.[104–106] Ryder *et al.* reported on an 11-week-old infant who suffered cardiac arrest secondary to gastrointestinal hemorrhage and was successfully treated by intraosseous infusion and discharged with no apparent neurological deficit.[105]

McNamara *et al.* reported on a 3-month-old in asystole who achieved a stable rhythm and blood pressure before iv access had been obtained following after administration of epinephrine and atropine via the endotracheal

route and sodium bicarbonate through intraosseous infusion.[106]

In a porcine resuscitation model, Spivey compared intraosseous and central and peripheral iv bicarbonate injection after CPR. The peak increase in pH after intraosseous administration was greater than that after peripheral iv injection, although both were somewhat lower than that after central iv injection.[107] In another swine CPR study, intraosseous injection of 0.01 mg/kg of epinephrine increased plasma epinephrine levels without effects on diastolic or mean blood pressure. Injection of a 10-fold dose led to an increase in blood pressure, suggesting that intraosseous administration requires larger than currently recommended doses to produce a significant change in blood pressure.[108] Similarly, injection of epinephrine via both the intraosseous and central venous route in a lamb CPR model led to significant increases in plasma epinephrine levels. Peak concentrations were similar for both routes, although the peak for the intraosseous route was delayed by 15 seconds compared with that following central venous injection.[109]

Recommendations and summary

Intraosseous drug administration offers an alternative means of administering drugs, and is now standard emergency care. The technique is simple, rapid and rarely associated with major complications. Considering the difficulty in securing vascular access during low-flow states, current recommendations of the European Resuscitation Council consider intraosseous administration the method of choice of emergency drugs and fluids when iv access cannot be achieved.[110]

Endotracheal administration

Advantages

Endobronchial drug administration is a simple and rapid alternative during CPR when intubation is performed before intravenous cannulation,[111] when the time interval to intravenous access is prolonged, or when attempts to establish intravenous access are unsuccessful.[112]

Basic physiology

The lung with its capillary surface of about $70\,m^2$ plays a major role in drug uptake.[113] Absorption of water occurs at all levels of the upper airway and lungs, but drug absorp-tion[114] depends on particle size, thickness of absorption membrane, area of membrane surface, drug conversion or degradation by lung tissue, the ventilation/perfusion ratio, drug dilution with saline or water, volume of dilution carrier, and depth of drug administration into the bronchial tree.[115–120] Small particles, up to a diameter of $6\,\mu m$ or a molecular weight of $75\,000$,[121] are absorbed similarly to gas molecules by a simple diffusion process, and drugs have to be aerosolized to particles of 1 to $10\,\mu m$ in diameter to reach the presumed site of absorption.[122] Larger molecules (more than $6\,\mu m$) are absorbed via the bronchial mucosa (Fig. 33.3). A small amount of drug may be resorbed by the lymphatic system.[123]

Method of application

It would be expected that deep endobronchial injection close to the alveoli would result in a more rapid absorption than shallow injection. Unfortunately, study data are contradictory, and several studies suggest varying tracheal or bronchial uptake of non-aerosolized drugs; e.g., after injection of 4 ml of dye in 12 cadavers via a specially designed catheter, followed by three-to-five manual hyperinflations, (Fig. 33.4) all right main bronchi and 90% of the left main bronchi are stained by the dye within 24 hours.[124]

Likewise, shallow injection results in drug delivery only to the main bronchi, even when followed by manual hyperinflation.[117,125] Even when the saline solution was administered into the proximal aperture of the tube, the results were similar to those seen with injection under bronchoscopic control into the trachea, right main bronchus, or the right lower lobe bronchus.[117] Arterial lidocaine or epinephrine levels tended to be higher after shallow administration.[119,126]

Therefore, adequate drug dilution may be more important than the method of application. Dilution of lidocaine with normal saline to a total volume of 6 ml is more effective than any other application method.[127,128] Lidocaine levels in anesthetized adults are higher with 10 ml of fluid than with 3 or 5 ml.[115] More recent studies recommend dilution of epinephrine in at least 5 ml of saline.[129]

Results in patients with low pulmonary blood flow may be different. In the study by Ralston *et al.* on dogs in ventricular fibrillation (VF), 0.2 mg/kg of epinephrine diluted in 10 ml of saline produced no change in blood pressure after shallow injection.[130] Conversely, a lower dose of 0.1 mg/kg of epinephrine in 10 ml of saline, injected via a catheter wedged deep into the bronchial tree and followed by three hyperinflations, elevated both systolic and diastolic blood pressure. Therefore, the guidelines in 2000
Fig. 33.3. Upper airway and respiratory units. Absorption rate of particles depends on their nature and size, as well as on ventilation and conditions of the respiratory tract. (from ref. 23.)

recommend passing a catheter beyond the tip of the tube and hyperventilating the patient after administration via the catheter, although this is estimated to interrupt oxygen supply and chest compressions significantly longer.[131] To avoid this, in neonatal cardiac arrest, direct drug application into the tube is recommended by some authors.[132]

Diluent

For choosing the ideal type and amount of diluent for ET therapy, the effects on blood gases, pulmonary surfactant, and rapidity of absorption, as well as possible short- and long-term sequelae should be considered. Some investigators have advocated the use of normal saline.[133] In one study in dogs, arterial PCO_2 increased and PO_2 was

depressed after water was used, whereas no significant change was observed after ET instillation of normal saline.[134] Yet, as 2 ml/kg of endotracheal fluid were used which correspond to 140 ml in humans, the results might not be transferable to humans. No adverse effects of up to 25 ml of normal saline on blood gases were reported.[135] Gas exchange is not impaired during CPR in dogs when 10 ml of saline are instilled endobronchially.[130]

In contrast, Redding *et al.* in 1967 found that dilution of 1 mg of epinephrine in 10 ml of water achieved ROSC faster than in 10 ml of normal saline, which was similar to iv or intracardiac injection.[136] Naganobu *et al.* reported that in dogs, 20 μg/kg of epinephrine given endobronchially in 2 ml of distilled water increased both levels of epinephrine in plasma and blood pressure significantly better than did 2 ml of normal saline as diluent, indicating that distilled water provided a "solvent drag" for endobronchial epinephrine.[137] Although distilled water administered into the endo-bronchial tree may decrease partial pressure oxygen significantly more than normal does saline, these changes could be judged to be acceptable.[138] As a compromise, Orlowski *et al.* suggested one-fourth or one-half normal saline. In their study, intrapulmonary shunt increased to almost 50% with the use of water and to a lesser extent with normal saline, whereas use of 0.225% NaCl solution was least injurious and approximated the control with no fluid in the trachea.[133]

There are no data analyzing the adequate volume of diluent for pediatric patients, and only case reports exist for this group of patients.[111,139] It is possible that the volume administered to children should be correlated to alveolar surface size, but this requires further investigation.

Drugs

Epinephrine

As early as 1967, Redding and colleagues reported on the endotracheal route for systemic administration of epinephrine during resuscitation.[30] The onset of action for ET therapy starts after seconds and lasts for 18 to 20 minutes, whereas onset of IV therapy starts after seconds and lasts for 2 to 3 minutes.[140] When blood levels from the femoral artery are compared, maximal epinephrine concentrations are achieved 15 seconds after either iv or ET administration. Schuettler *et al.* observed maximal heart rate 0.5 minute after IV and 1 to 2 minutes after ET administration.[141]

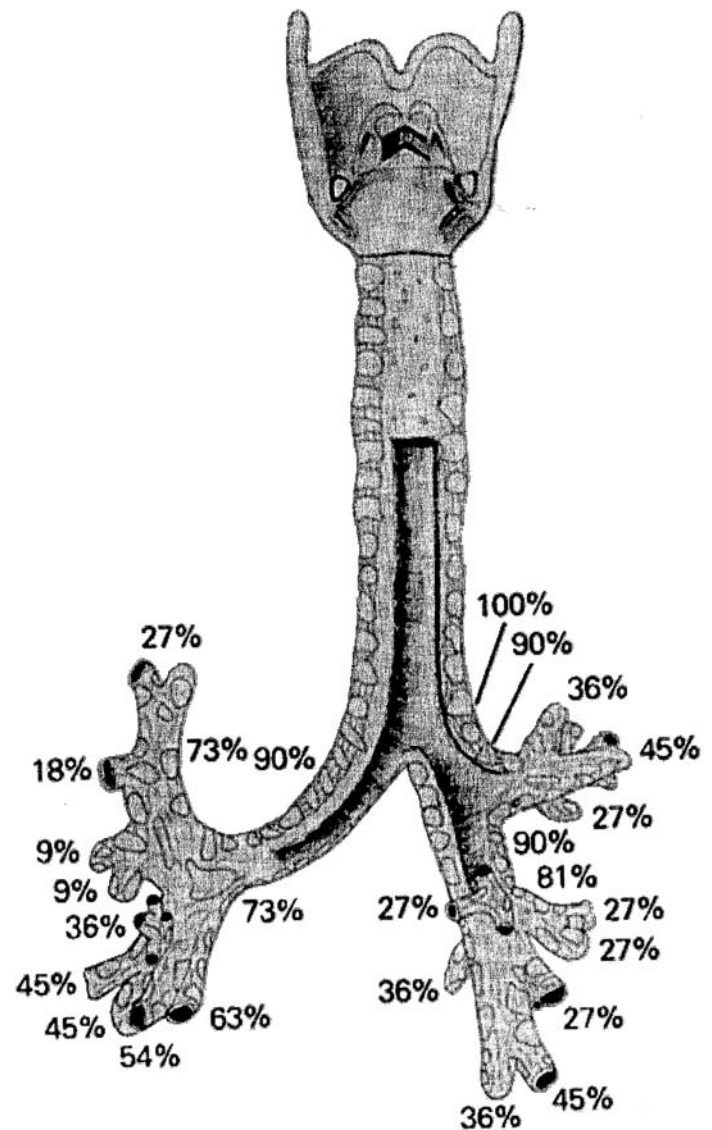
In a study by Crespo[142] standard dosing of epinephrine through the endotracheal tube (0.01 mg/kg) produced only a small rise of epinephrine blood levels. When common iv-doses are used endotracheally, the beta-receptor effect is unopposed by alpha-adrenergic vasoconstriction which


Fig. 33.4. Distribution of dye in the bronchial tree.

can result in decreases in blood pressure[143,144] In models with spontaneous circulation, a ten-fold higher dose usually is necessary to produce effects similar to iv therapy.[141] During CPR, the "equipotent epinephrine dose" administered endobronchially is approximately 3 to 10 times higher than the intravenous dose.[145,146]

Schuettler *et al.* prospectively compared peripheral venous plasma epinephrine levels after intravenous or deep endobronchial drug therapy in patients with out-of-hospital ventricular fibrillation, (Fig. 33.5). Intravenous epinephrine resulted in mean plasma levels 70% higher than endobronchial therapy, was more rapidly detected, and fell more rapidly below therapeutic levels than did epinephrine

(a)

(b)
Fig. 33.5 (a) Mean plasma concentration in 28 out-of-hospital patients in VF after endobronchial administration of 2.5 mg epinephrine in 5–10 ml of normal saline. **(b)** Mean plasma concentration in 8 out-of-hospital patients in VF after intravenous administration of 1 mg epinephrine (From ref. 147)

given endobronchially.[147] The investigators considered endobronchial administration a reliable alternative to iv injection. Earlier, Schuettler *et al.* had reported successful resuscitation of 7 of 19 out-of-hospital cardiac arrest victims who received only ET epinephrine.[146] Several case reports document the feasibility of ET therapy in children as well as in adults, recommending an ET dose of 0.1 mg/kg of epinephrine.[148–150]

A side effect of endotracheal epinephrine therapy is the "depot-like" effect.[146] Five minutes after ET administration, blood concentrations were 80% of the initial value, and this high level persisted for 30 minutes, whereas only

20% of the initial maximal concentration was detected 5 minutes after iv injection.[151] This may provide evidence of poor initial absorption as lung perfusion is only approximately 10%–30% of normal during CPR. With restoration of spontaneous circulation, perfusion improves and a washout effect occurs, resulting in arterial hypertension, malignant arrhythmias, and recurrence of ventricular fibrillation. Therefore, some investigators advise against repeated administration of ET epinephrine.[112]

Accordingly, intravenous drug administration remains the first-line strategy during CPR. Administration of drugs via an endotracheal tube during CPR is only a second-line approach.

Vasopressin

When endobronchial vasopressin is diluted with normal saline,[152] identical dosages of vasopressin result in comparable blood pressure responses, irrespective of endobronchial, intraosseous,[153] or intravenous administration.[154] Coronary perfusion pressure increased 2 to 3 minutes later after endobronchial than after intravenous vasopressin.[154] In animal studies, vasopressin accomplished its effect on diastolic blood pressure more rapidly, vigorously, and protractedly compared to epinephrine.[155] To avoid bradycardia after cardiopulmonary resuscitation, some authors propose to use vasopressin with atropine.[156] The ILCOR guidelines 2000[150] called for vasopressin as an alternative to epinephrine in shock-refractory ventricular fibrillation, and the 2005 guidelines concluded that there is insufficient evidence to support or refute the use of vasopressin as an alternative to adrenaline.[157]

Lidocaine

Use of lidocaine during CPR is debatable, yet many studies have documented its rapid uptake from the respiratory tract.[147] In animal studies, bioavailability of ET lidocaine is 90%. In patients undergoing elective surgery, lidocaine levels reached therapeutic plasma levels comparable to iv administration, albeit more slowly, but within minutes.[158] Endotracheal administration of 2 mg/kg of lidocaine, diluted with normal saline to a total volume of 10 ml, resulted in therapeutic action after 30 seconds.[159] One of the few studies undertaken under CPR conditions was Elam's bradycardia/ ventricular standstill model in which ET lidocaine suppressed premature ventricular contractions (PVCs) after 11 seconds, while the same dose of IV lidocaine took 43 seconds.[140] The duration of action was 43 versus 17 minutes, respectively. Therapeutic levels were not achieved in plasma in all animals treated with ET lidocaine.[160] In a human study of 17 patients with ET therapy, 14 were found to have insufficient plasma levels of lidocaine (below

1.5 mg/ml), whereas 1 patient had more than the therapeutic value of 5 mg/ml.[161]

In summary, clinically significant lidocaine levels can be achieved by ET therapy when a large bolus is administered, but plasma lidocaine levels are not exactly predictable. The ILCOR Guidelines 2000 recommended a 2 to 2.5 times larger bolus endotracheally than intravenously (2–3.2 mg/kg).[150] Endotracheal application of other antiarrythmics, e.g., amiodarone, is not feasible.

Atropine

Elam found that ET administration of 2 mg of atropine in 10 ml of water produced an ECG-response after 16 seconds, compared to 54 seconds for IV delivery. This effect lasted for 10 vs. 6 minutes.[140] Nevertheless, ET atropine doses were up to 0.8 mg higher than those given iv. Fifteen minutes after endobronchial application, atropine levels were almost four times higher than after IV application. As a clinical response can be found even with low plasma atropine levels, the clinical significance of measuring atropine levels is not clear.

Bray *et al.*[162] administered 0.6 mg of atropine to anesthetized patients either iv or ET (1 ml of solution deep endobronchially followed by five manual hyperinflations). The maximal increase in heart rate was similar in ET- or iv-treated patients. The effect of endobronchial atropine persisted for only 4 minutes in contrast to 9 minutes after IV application.

A few case reports are available on the ET use of atropine in human CPR,[163] but prospective studies did not demonstrate any efficacy of atropine.[164] In one study with 170 patients in asystole, 43 patients received atropine. Six (14%) were resuscitated, compared with none of 37 patients in the control group.[165]

Even though atropine is recommended early in the treatment of cardiac arrest, it is usually not given until 2 to 3 minutes into resuscitation.[150] Consequently, in most cases an iv line will be established when administration of atropine is considered, and this route should be used. Alternatively, 2 to 3 mg can be given ET, but few data support this method of application. Use of atropine for treatment of bradycardia or heart block, however, is strongly recommended.[150]

Sodium bicarbonate

In one study by Bauer in an animal model, as reported by Elam, inactivation of surfactant by alkalinization rendered the lung atelectatic. High levels of positive end-expiratory pressure resulted in circulatory deterioration, and the endotracheal application of sodium bicarbonate was discouraged.[140]

Summary

Whenever possible, iv or io application is favored because there is no evidence of benefit by endotracheal drug administration.[166,167] In congruence with ILCOR and ERC guidelines, we recommend this method of drug administration during CPR whenever an iv line is not in place before the arrest and the establishment of other routes is delayed.[110,150,157]

Intracardiac administration

Advantages

Promoters of this technique have stressed the ease of injection[168] and the low risk.[169,170] There are no clinical outcome data, however, that have demonstrated an advantage for the IC route over intravascular or ET routes[30,171] in spite of the extensive use of IC routes for CPR over many years. Administration of drugs to the left ventricle should reduce the time-to-peak interval to a minimum, but autopsy studies in 18 cadavers after CPR with 46 intracardiac (IC) injections (5 subxiphoid punctures) revealed left ventricular puncture in only 5 (11%) cases. All other injections ended either in the right ventricule in (28%), the pulmonary trunk, the ascending aorta, the lung, or were untraceable.[172] Thus, in most instances the effect at best will be similar to central venous administration. In the few cases of successful left ventricular injection, this means of drug administration might be superior to administration to the right side of the heart.[173]

Techniques

Either the subxiphoid or the left sternal approach are commonly recommended for intracardiac injections.

Subxiphoid

The subxiphoid injection is considered safer than a transthoracic injection. A long needle is inserted from 1 cm left of the xiphoid process at a 20°- to 30°-angle in both the sagittal and vertical plane, with continuous withdrawal of the plunger on needle insertion. If no blood appears as the needle is fully inserted, the needle is withdrawn under suction and redirected in another angle. No injections should be performed without prior aspiration of blood, as it is essential to inject into the ventricular lumen.

Left sternal

In the left sternal approach, the needle is inserted from the fourth or fifth left intercostal space, immediately left of the sternum. It should be directed toward the vertebral column

of the patient. Laceration of the left anterior descending artery or the internal mammary artery is a special hazard of this approach.[174,175]

Complications

Intramyocardial injections of epinephrine or sodium bicarbonate inevitably lead to extensive myocardial necrosis. Interestingly, Forssman's development of right ventricle catheterization in 1929 was originally stimulated by the need to replace IC injections because of the high rates of laceration of the coronary artery and subsequent hemopericardium associated with the method.[14] Because of difficulties in placing the needle in a ventricular cavity, there is a possibility for delay.[30] In one study, all patients developed serosanguineous pericardial fluid after ic injections, whereas patients without this route of drug delivery exhibited almost no pericardial fluid after CPR.[176] In that study, cardiac puncture was documented in only 3 of 65 cases at autopsy. With right ventricular puncture, there is no self-sealing as occurs with left ventricular puncture.[177] Even when only a small amount of fluid is present in the cardiac sac, hemopericardium can further compromise the already reduced cardiac output.[170] Other complications include pneumothorax,[178] pneumopericardium, cardiac tamponade[179] and successive death,[180] laceration of the myocardium, coronary artery, and internal mammary artery, intramyocardial injection with ventricular arrhythmia,[181] intractable ventricular fibrillation,[182] persisting total arteriovenous block after injection into the interventricular septum,[183] and bacterial endocarditis.

Animal studies

Three well-performed studies have been published claiming the superiority of left ventricular injection of epinephrine. Showen *et al.* demonstrated a faster onset of action for the left vs. the right ventricular route for dogs with pulseless electrical activity.[184] Left ventricular but not aortic injection of epinephrine in dogs was superior with respect to time to reach a 20% increase in heart rate and a 10% increase in mean arterial pressure, but not in peak mean artery pressure itself when compared to right ventricular injection.[185] In mongrel dogs, injection of 1 mg of epinephrine into the descending aortic arch during CPR resulted in a doubling of coronary perfusion pressure within 10 seconds, whereas administration to the superior vena cava was not followed by a detectable change.[173] Nevertheless, this approach is highly impracticable in the CPR setting as most ic injections result in right ventricular drug delivery,[172] whereas left ventricular catheterization would result

in an unacceptable delay compared to ET or IV routes. In addition, in another study on dogs, time-to-therapeutic level in the aorta during CPR was about 30 seconds after both right and left ventricular injection.[58]

Human studies

Several older studies in patients with out-of-hospital CPR have claimed that IC injections can be done with an acceptable rate of (noted) side effects, but none has prospectively demonstrated the superiority of this method over another.[169,170,186,187] In one study, as many as 24% of patients with intracardiac medication developed pneumothoraces, compared to only 3% in the group with iv therapy.[186] Davison *et al.*[170] reported that 31% of patients developed hemopericardium after ic injection.

Comparisons with intravenous/endotracheal access

In dogs, the time from intracardiac administration of 1 mg of epinephrine to ROSC was marginally slower than with peripheral intravenous injection (139 ± 34 vs. 127 ± 76 seconds).[30] ET access resulted in a mean time to ROSC of 132 ± 44 seconds when 1 mg of epinephrine was diluted with water and 217 ± 142 seconds when it was diluted with saline. The investigators' conclusion was that "intratracheal (diluted), intravenous, and intracardiac routes are equally effective." When central venous administration of lidocaine in dogs with open-chest CPR was compared to left ventricular and peripheral venous administration, there were no differences in the appearance of significant amounts at the level of the coronary artery ostia.[58,106]

Recommendations/summary

AHA guidelines indicate that the intracardiac route should be used during open chest massage or when other routes are unavailable.[188] In our opinion, IV, ET, and intraosseous routes with well-documented effectiveness have fewer side effects, and IC injections during CPR should be avoided.

Other routes of drug administration

Oral transmucosal drug absorption (sublingual and buccal)

Systemic effects are known to occur quickly following sublingual drug administration. Captopril, beta agonists, and benzodiazepines have all been shown to enter the central circulation rapidly when placed in liquid form under the

tongue.[189] Several transmucosally administered cardiovascular drugs have been studied extensively, e.g., nitroglycerin.[190] Research on captopril, verapamil, nifedipine, propafenone, and others has proven promising.[191–193] Arnold *et al.* used intraglossal atropine in a large series of children undergoing strabismus surgery, and have shown better effects through this route than through the intravenous route.[194]

Epinephrine

Limited data are available on intralingual administration of epinephrine. Ordog and coworkers[195] used a goat model to simulate the effect of sublingual injections on pediatric patients. Sublingual injection of Cardio-Green in kid goats undergoing internal cardiac massage is associated with a tenfold lower central blood level compared to that after peripheral injection, and the authors recommended obtaining a central line. Rothrock *et al.* reported on a 7-month-old successfully resuscitated with intralingual epinephrine and atropine injected into the midline of the sublingual tissues.[196] Redding and coworkers reported that the injection of 1 mg/1ml of epinephrine into the tongues of dogs undergoing CPR resulted in ROSC in only 2 of 10 animals, whereas injection into the thigh muscles saved 4 of 10 dogs. The mean time from injection to ROSC was 292 (intralingual) versus 50 (intramuscular) seconds.[30]

Given the ease of administration of epinephrine via the endotracheal and intraosseous routes, the potential necrosis of sublingual tissues, and the limited experience with intralingual epinephrine, this route cannot be recommended as an alternative for drug administration.

Vasopressin

A synthetic form of vasopressin, desmopressin, has been used to treat diabetes insipidus. The sublingual route of administration has been suggested as an alternative to the usual one via intranasal administration.[197] In a study comparing pharmacokinetics and biological effects of vasopressin in eight healthy volunteers who were administered desmopressin by several routes, including sublingual, bioavailability was found to be 3.4% after intranasal administration and 0.1% after oral administration.[198]

De Groot and coworkers assessed the bioavailability and pharmacokinetics of oxytocin in six male subjects after sublingual dose of 400 IU (684 μg) and after an intravenous dose of 1 IU (1.71 μg).[199] After sublingual administration, poor bioavailability with 10-fold variation between 0.007%–0.07% was observed. The authors suggested that the sublingual route of administration with its "long" lag time and "long" absorption half-life does not seem to

provide reliable, accurate high dosing for immediate prevention of postpartum hemorrhage.

Naloxone

A rapid effect of intralingual naloxone was demonstrated in dogs by Maio *et al.*[200] Ventilation increased well above baseline and control levels at 1 minute after administration. In a human study, Maio *et al.* reported a reversal of narcotic-induced respiratory depression in a 25-year-old man following the administration of intralingual naloxone.[201] Wasserberger *et al.* recommended intralingual naloxone injections only when patients are in shock, have a systolic blood pressure <80 mmHg, and there is no iv line or endotracheal tube in place.[202]

Midazolam

Buccal administration of midazolam has been shown to be very effective when compared with nasal and rectal formulations. High bioavailability and reliable plasma concentrations after buccal administration of midazolam have been reported in healthy volunteers by Schwagmeier *et al.*[203] Scott *et al.* aimed to determine whether there are differences in efficacy and adverse events between buccal administration of liquid midazolam and rectal administration of liquid diazepam in the acute treatment of seizures.[204] They found the buccal cavity easy to reach safely, and suggest that the buccal administration of midazolam seems to have some distinct advantages over rectal administration of diazepam. Geldner and coworkers[205] found plasma concentrations of midazolam were significantly higher following sublingual administration compared with nasal administration with better acceptance by patients.

Intranasal drug delivery

The nasal mucosal surface provides a suitable route for many drugs with molecular weights <1000.[206] Drugs sprayed into the nasal mucosa are rapidly absorbed by three routes: the olfactory neurons, the supporting cells and the surrounding capillary bed, and by the transneuronal route through the cerebrospinal fluid. Transneuronal absorption is generally slow, whereas absorption by the supporting cells and the capillary bed is rapid.[207]

For some drugs, administration by nasal spray results in a greater CSF-to-plasma concentration than does iv administration, providing evidence for diffusion of these compounds through the perineural space around the olfactory nerves, a compartment known to be continuous with the subarachnoid space.[208,209] In one study, drops were found to cover the wall of the nasal cavity more effectively than nasal sprays, independent of the volume adminis-

tered, while another study reported that both forms were equally effective.[210] Absorption rates are also influenced by the site of deposition and by concomitant pathologic conditions, such as rhinitis.[211]

Vasopressin and corticosteroids were among the first drugs to be administered by this route.[212,213] Sedatives,[214–216] potent narcotics, and a variety of drugs that are used in emergency medicine such as ketamine,[217] sufentanil, verapamil, metoclopramide,[218] nitroglycerin, salbutamol,[219] digoxin,[220] atropine,[221] and anticonvulsants[222] have been employed.

Drug administration

Epinephrine

Early animal studies found that sympathomimetics, such as adrenaline and ephedrine, did not penetrate the nasal mucosa of the frontal sinuses of cats and dogs.[223] Similarly, Myers and Iazzetta found no significant changes in heart rate and blood pressure in humans after intranasal administration of phenylephrine.[224] Shapiro and Grenvik, however, described a patient with C1 tetraplegia who responded to nasal phenylephrine,[225] and differing results from several other animal studies have also been published. Yamada demonstrated that epinephrine plasma concentrations increased substantially following administration of epinephrine in the nasal septal mucosa:[226] the mean peak value of the plasma epinephrine (20.1 ± 12.4 ng/ml) was obtained after 15 seconds, and the peak systolic pressure was 200% of the control value after 60 seconds.

In a dog model of closed chest CPR, intranasal delivery of epinephrine (28 mg) produced the same increase in aortic systolic and aortic diastolic perfusion pressures as did 0.015 mg/kg of iv epinephrine.[65] Further studies by the same group suggested that the optimal combinations of nasally administered epinephrine and phentolamine to improve coronary perfusion pressure in a canine model were 0.25 and 7.5 mg/kg/nostril, respectively.[227] In addition, continuous nasal absorption of epinephrine maintained pressures over a prolonged period of time.

Naloxone

Loimer *et al.* compared intranasal naloxone to other routes (intravenous/intramuscular) in 17 opiate-dependent patients and found the nasal route to be as effective as the iv route.[228] In the study by Barton *et al.*, a total of 30 patients received intranasal naloxone by paramedics in the field: 11 responded to either intranasal or iv naloxone. Ten of these 11 (91%) patients responded to intranasal naloxone alone, with an average response time of 3.4 minutes and seven (7/11, 64%) did not require an iv line.[229]

When intranasal was compared to intramuscular naloxone for treatment of respiratory depression due to suspected opiate overdose in the prehospital setting, intranasal delivery was less effective as than intramuscular treatment.[230]

Further research and recommendations

The sublingual/intralingual and the intranasal routes offer a variety of opportunities for drug delivery, including bypassing the gastrointestinal tract and first-pass metabolism in the liver. There are, however, no validated studies addressing the pharmacokinetic and pharmacodynamic issues, such as optimal injection site, circulation times, time-to-peak effect, duration of action, and ROSC. Optimal volume and concentration levels need to be determined. The nasal route could be important for drugs that are used in crisis treatments, such as for pain, and for centrally acting drugs where the putative pathway from the nose to the brain might provide a more rapid and more specific effect. Explorations for novel nasal and transmucosal drug delivery systems, drug carriers and their exploitation for their administration of drugs are being actively pursued.[231] The products developed will first comprise products for crisis management, such as sleep induction, acute pain, nausea, and heart attacks.[232] Until appropriate studies have been completed, however, it is advisable not to administer resuscitation drugs through this route.

Experimental techniques

Several additional routes that are not currently in clinical use are available for drug administration during CPR. In animal studies, selective perfusion of the aortic arch has been shown to improve aortic pressures and carotid artery flow.[233] By occluding the distal aorta with a balloon catheter and infusing normal saline, the aortic arch to right atrial pressure gradient increased from 2 mmHg before infusion to 9 mmHg after 60 seconds. The investigators concluded that solutions that could improve cardiac and cerebral function can be delivered by this method. In another study, aortic arch instillation of epinephrine led to greater improvement in coronary perfusion pressures than did administration by superior vena cava.[173] The time to achieve a postarrest systolic blood pressure of 60 mmHg was shortest for the animals given aortic epinephrine, and the aortic arch pressure consistently rose within 10 seconds to a plateau after 40 to 60 seconds. ROSC was seen in all eight animals given epinephrine via the aortic arch, and time-to-ROSC was short-

Table 33.1. Cardiopulmonary drugs: routes of administration and recommended dosages

	Intravenous/Intraosseous	Endobronchial	Sub-/intralingual	Intranasal
Epinephrine	1 mg	2–3 mg	1 mg[a]	Not recommended
Lidocaine	1.5 mg/kg	400–500 mg[a]	Not recommended	Not recommended
Atropine	1 mg	2.5 mg[a]	Not recommended	Not recommended
Naloxone	0.4–0.8 mg	1.2–2.4 mg[a]	0.4 mg[a]	Not recommended

[a] Insufficient data, not routinely recommended.

est with epinephrine given via the aortic arch rather than via the superior vena cava. In contrast, Rubertsson *et al.* found no difference in coronary perfusion pressures or survival in dogs when 100 μg/kg of intra-aortic or central venous epinephrine was given combined with aortic occlusion during experimental CPR.[234] When central venous and left atrial infusion of norepinephrine were compared in a canine model of cardiopulmonary bypass,[235] there was no difference in hemodynamic efficacy over a wide range of three doses in a model with normal lungs. In one study by Fullerton's *et al.*, on aorto-coronary bypass patients, left atrial administration of epinephrine produced a 35% greater cardiac output, 25% lower pulmonary artery pressure, and 32% lower pulmonary vascular resistance than did central venous administration.[236] Cardiopulmonary bypass has been utilized in canine resuscitation models,[237] which provides another mechanism to administer medication to the central circulation. Notably, these techniques, while interesting, remain experimental and have not been proven outside of the laboratory at this time.

Summary (Table 33.1)

The choice of route for drug administration during CPR must be made on an individual basis and requires consideration of the speed with which access can be obtained, the technical difficulties with performing the procedure, associated risk of complications, delays in drug delivery to the central circulation, duration of effective drug levels following their injection, and magnitude of peak drug levels. The peripheral venous route is the safest method and drug delivery can be enhanced by saline bolus after medication injection. Central venous cannulation provides more direct access to the central circulation, although with some risk of complications. Circulation time is shortest and drug concentrations are highest when this route is used. The femoral route is associated with delays in drug delivery and a higher incidence of unsuccessful catheterization. Its use should be reserved for instances when other routes of drug

administration are not available. The endotracheal tube is a route for administration of most drugs, but peak concentrations are lower than those obtained by other routes. The intraosseous route should be utilized in resuscitation of children when iv access cannot be obtained promptly. Intraosseous injection can also be an option in adults.

The ultimate goal of vascular access during CPR should be to contribute to oxygen delivery to the cardiac and cerebral circulation at a sufficiently high pressure to ensure perfusion. Although almost all administration routes can deliver drugs to the central circulation, there are only limited human data comparing the effectiveness of one route over another and at establishing ROSC. The few available studies either had limited numbers of subjects or had not controlled for confounding variables. Even adequate animal models comparing resuscitation rates among different routes of venous access are lacking. The information given above can provide some guidelines to aid in the choice of routes for administration. The goal of future studies should be to determine which routes of administration provide the best opportunity for ROSC. New techniques such as aortic arch perfusion, combined with the development of resuscitation fluids and medications that can establish critical coronary and cerebral perfusion, offer other promising areas for research.

Recommendations

We prefer to initiate drug therapy with the first available route. In adults this generally means administering endotracheal drugs while peripheral access is attempted. Endotracheal administration is accompanied by a 10-ml flush with either saline or water and followed by forceful hyperinflations. Peripheral catheterization is attempted during or immediately after intubation. Administration by this route is followed by a 20-ml saline bolus. If peripheral access is not rapidly accomplished after intubation, an attempt is made to cannulate the external jugular vein. Central venous cannulation is almost always unwarranted in the acute setting. Very exceptionally, a venous cutdown

will be needed. Percutaneous cannulation of the femoral vein has a low success rate but may also be used if no other route is available. Finally, in the patient with no other access, medications may be administered by intraosseous injection.

In children, drug therapy is initiated through the endotracheal tube, while attempts are made to obtain peripheral placement. If peripheral access is not obtained within a few minutes, an intraosseous line is placed. Central venous and external jugular lines or venous cutdown are used rarely in children and only when the peripheral and intraosseous routes cannot be used.

The above constitutes our personal preferences. The more invasive procedures carry risks that some practitioners would not consider justifiable. Given the lack of evidence to establish the importance of utilizing a particular protocol for venous access, it is difficult to argue against another, less invasive approach. Finally, even more aggressive approaches exist, such as the use of intraaortic injection, along with balloon counterpulsation or cardiopulmonary bypass, but these approaches currently remain within the investigator's domain.

Vasopressor therapy during cardiac arrest

Adrenergic agonists

Max Harry Weil, Shijie Sun, and Wanchun Tang

Keck School of Medicine of the University of Southern California, Los Angeles, CA, USA

Introduction

Although there is persuasive evidence that the administration of adrenaline during CPR favors the success of electrical defibrillation as well as the return of pulsatile rhythm, its more ultimate benefit on survival is unproven. To the contrary, the more recent discovery of reversible myocardial dysfunction after successful resuscitation from cardiac arrest initially in experimental models[1] and subsequently in human patients[2] led to a re-examination of its role. Although there is only indirect evidence that impaired myocardial function accounts for early death, the high correlation between the severity of myocardial impairment and decreased survival supports this assumption. Accordingly, postresuscitation myocardial dysfunction may therefore explain, at least in part, the high fatality rate within the initial 72 hours after successful resuscitation from cardiac arrest such that fewer than 5% of victims recover to be discharged from the hospital without major impairment.[3]

The immediate effort during CPR is to restore blood flows to sustain the functions of vital organs, and most especially, to the heart and the brain prior to successful restoration of spontaneous circulation. Blood flow to the vital organs during CPR is contingent primarily on the cardiac output generated by precordial or direct cardiac compression and by the resistance in the systemic arterial bed. Yet the cardiac output that is generated by precordial compression represents only approximately 25% to 30% of normal values.[4] Vasopressor drugs increase arterial and arteriolar vasoconstriction, and thereby produce increases in aortic diastolic pressure. The increases in aortic diastolic pressure in turn produce increases in coronary and cerebral perfusion pressures, in part "borrowing" from blood flow to viscera and muscle.[5] Restoration of threshold levels of coronary perfusion pressure with corresponding augmentation of myocardial blood flow has been a consistent predictor of successful restoration of spontaneous circulation during CPR.[1,6] Electrical defibrillation is itself facilitated after coronary perfusion pressures are increased above such thresholds, especially after prolonged, untreated cardiac arrest.[7] Cerebral "survival" in relation to vasopressor therapy during CPR has been less intensely studied, but it is also an ultimate criterion of outcome following cardiac arrest. Although the focus of this chapter is on the role of adrenergic vasopressor agents for resuscitation of the heart, including effects on postresuscitation myocardial function and survival, we recognize that long term survival is appropriately defined in terms of *both* cardiac and cerebral survival.

Epinephrine

Pharmacological actions of epinephrine are mediated by adrenergic receptors. Ahlquist first demonstrated in 1948 that epinephrine, and endogenous catecholamines more generally, act through alpha- and beta-adrenergic receptors.[8] In the years that followed, $alpha_1$ and $alpha_2$ subtype receptors and $beta_1$, $beta_2$, and $beta_3$ subtype receptors were identified.[9] Currently available adrenergic vasopressor agonists are summarized in Table 34.1 in relation to their receptor function.[10]

Epinephrine has both alpha- and beta-adrenergic actions, and has been the preferred adrenergic agent for the management of cardiac arrest for almost 40 years.[11,12] The pressor effects of epinephrine follow alpha-adrenergic

Table 34.1. Adrenergic vasopressor agents in relation to their receptor function

Agent	Receptors
Epinephrine	Alpha, beta
Methoxamine	Alpha$_1$
Phenylephrine	
Clonidine (crosses blood–brain barrier, vasodilator)	Alpha$_2$
Alpha-methylnorepinephrine (selective peripheral vasoconstrictor)	

receptor activation.[13–17] Beta-adrenergic effects, which are inotropic and chronotropic, have unfavorable actions in that they produce substantial increases in myocardial oxygen consumption. Epinephrine therefore increases the severity of ischemic injury of the myocardium during resuscitation. If the patient is subsequently resuscitated, it increases the severity of postresuscitation myocardial dysfunction.[18,19] The chronotropic effects of epinephrine are equally striking. They account for both increases in heart rate and ectopic ventricular arrhythmias leading to recurrent ventricular tachycardia and ventricular fibrillation.[19,20] Quite apart from its cardiac action, epinephrine also reduces arterial oxygen saturation and therefore oxygen delivery. This phenomenon has been studied by our group, which identified ventilation-perfusion mismatch as accounting for pulmonary arteriovenous shunting.[18]

The issue is especially important because during the chaotic and disorganized contraction of the heart during VF, there are dramatic increases in the myocardial demands for oxygen. Human data reported in a paper by Holmberg *et al.*[21] were based on 14 065 patients during cardiac arrest. Among 10 966 resuscitated patients, epinephrine had been administered to 4566 or 42.4% of cases, but only 156 (3.4%) patients survived for 1 month. This contrasted with 6207 patients who received no epinephrine of whom 388 (6.3%) were survivors. Treatment with epinephrine was an independent predictor of lower likelihood of survival ($P < 0.0001$), independently of gender, incidence of arrhythmias, witnessed or unwitnessed arrest, and bystander CPR. These data are supported by those of Laurent *et al.*,[22] who reported that administration of epinephrine was associated with a lower postresuscitation cardiac output in survivors of out-of-hospital cardiac arrest. Gonzales *et al.*[23] confirmed decreases in end-tidal carbon dioxide with increased doses of epinephrine, a finding explained by both pulmonary arteriovenous shunting produced by epinephrine and decreases in pulmonary blood flow also observed by our group.[18]

Objective evidence of the failure of epinephrine to improve the balance between myocardial oxygen supply and demand during closed-chest cardiopulmonary resuscitation in dogs was reported in 1988 by Ditchey and Lindenfeld.[17] The late Dr. Joseph S. Redding in collaboration with Pearson in 1963 had already identified potential benefits of more selective alpha-adrenergic agonists including phenylephrine and methoxamine when compared to epinephrine.[5] In 1990, Roberts *et al.*[24] further demonstrated that methoxamine, a selective alpha$_1$-agonist, produced significantly greater myocardial and cerebral blood flows during CPR in dogs than did epinephrine, with more optimal postresuscitation cardiac output and greater survival.

Beta-adrenergic blocking agents

Studies by Ditchey *et al.*[19] demonstrated improved resuscitability and better postresuscitation myocardial function in dogs after pretreatment with a non-specific β-adrenergic blocking agent, namely, propranolol.[25] Propranolol has also been shown by Maroko *et al.*[26,27] to decrease electrocardiographic evidence of ischemic myocardial cell damage in both experimental and clinical settings. Ischemic cells had less mitochondrial swelling in propranolol-pretreated animals. Obeid *et al.*[28] reported that propranolol preserved ATP stores in ischemic myocardium. In brief, we can now conclude that beta-adrenergic stimulation is adverse to the globally ischemic heart and this concept applies to the global ischemic injury during cardiac arrest and resuscitation.

In subsequent animal studies, a short acting beta$_1$-selective adrenergic blocking agent, esmolol, was administered during cardiopulmonary resuscitation. Esmolol significantly improved initial cardiac resuscitation, minimized postresuscitation myocardial dysfunction, and increased the duration of postresuscitation survival.[29] Current evidence suggests that there is likely to be an important role for beta-adrenergic blockade during CPR as it is now used for routine management of acute coronary syndromes and acute myocardial infarction.

With special focus on postresuscitation myocardial dysfunction, major decreases in myocardial contractile function followed successful restoration of spontaneous circulation. When the effects of epinephrine were compared with a more selective alpha-adrenergic agonist, phenylephrine, outcomes of cardiac resuscitation were improved with phenylephrine.[20] In experiments on a rat model of cardiac arrest and CPR, epinephrine was combined with the beta$_1$-adrenergic blocking agent, esmolol. Restoration of spontaneous circulation, postresuscitation

myocardial function, and survival were each improved,[20] and these benefits were subsequently confirmed in a cardiac arrest-CPR model in pigs.[30]

It is now apparent that beta-adrenergic effects of adrenergic agonists administered during CPR are detrimental. Although this is now established in both experimental and clinical settings of coronary artery disease with regional myocardial ischemia, there was relatively slow acceptance of the practice. While epinephrine improves the success of initial resuscitation attempts, the evidence that it is adverse to ultimate survival is persuasive to us and that this dichotomy is best explained by its detrimental effects on postresuscitation myocardial function cited above. It is these adverse pharmacological actions of epinephrine that have increasingly called into question the highly traditional and widely accepted use of epinephrine as the preferred adrenergic vasopressor agent for management of advanced cardiac life support. The current American Heart Association Guidelines specifically point to the unproven value of epinephrine.[31]

Both experimental studies and a small series of clinical reports first published in the mid-1980s held that as much as 10-fold higher doses of epinephrine yielded greater coronary perfusion pressure, myocardial and cerebral blood flows, and the success rates of initial resuscitation. Nevertheless, no improvement in long-term survival was confirmed.[32–34] Three large, randomized clinical studies were subsequently reported in which the effects of high-dose epinephrine were compared with standard-dose epinephrine on outcomes of CPR.[35–37] In one study, either 1- or 7-mg bolus doses of epinephrine were administered during both in-hospital and out-of-hospital settings of cardiac resuscitation. There were no significant differences in initial return of spontaneous circulation, neurological outcomes, and hospital survivals. In two additional studies in which standard and high doses of epinephrine were compared during out-of-hospital CPR, again there were no statistically significant differences in the return of spontaneous circulation and no difference in in-hospital survival. On the basis of these reports, the recommended dose of epinephrine has been maintained as 1.0 mg administered intravenously (or by intraosseous route) every 3 to 5 minutes during resuscitation. High-dose epinephrine (0.1 mg/kg) in adults would best be reserved for treatment of overdose of beta-adrenergic blocking agents or calcium channel blockers.[11]

Alpha$_1$-adrenergic agonists

After the adverse effects of beta-adrenergic agonists on cardiopulmonary resuscitation were exposed, the more selective role of alpha-adrenergic receptors with respect to CPR were explored. The extent to which peripheral vascular resistance, and therefore myocardial and cerebral perfusion pressure and blood flows, could be increased by alpha-adrenergic agonists during resuscitation was investigated. The favorable effects of non-specific alpha-agonists were confirmed in part.[19,20,24] Observations on the relatively selective alpha$_1$-adrenergic agonists methoxamine and phenylephrine had earlier indicated diminished effectiveness in comparison with epinephrine in settings of prolonged cardiac arrest.[38] These observations pointed to selectively lesser effects, especially on alpha$_1$-adrenergic receptor responses, in settings of myocardial ischemia.[39,40] This loss of effectiveness was subsequently traced to desensitization of the alpha$_1$-receptor after prolongation of cardiac arrest.[41] It was also recognized that alpha$_1$-adrenergic receptors reside in the myocardium and, like beta-receptors, account for inotropic effects.[42] Alpha$_1$-agonists therefore also increased myocardial oxygen requirements at the very time that supply was reduced and consequently that they increased the severity of global ischemic injury during cardiac arrest. When alpha$_1$-adrenergic receptors were blocked by either a selective or non-selective alpha-adrenergic blocking agent when cardiac arrest was induced following experimental coronary occlusion, myocardial function was significantly improved.[43] Alpha$_1$-adrenergic agonists have also been shown to constrict coronary arteries such that additional reductions in myocardial perfusion may be superimposed on already reduced coronary blood flows.[43]

Alpha$_2$-adrenergic agonists

After the limitations of epinephrine for management of cardiac resuscitation were recognized, and specifically the adverse effects of beta- and to a lesser extent alpha$_1$-receptor agonists, the role of selective alpha$_2$-adrenoceptor agonists was investigated by our group. Three subtypes of alpha$_2$-receptors are now identified, namely alpha$_{2A}$, alpha$_{2B}$, and alpha$_{2C}$ as shown in Table 34.2.[45] Alpha$_{2A}$-agonists act centrally on the medulla and mediate a tonic sympatho-inhibitory effect. These central effects account for reductions in arterial blood pressure, myocardial contractility, and heart rate. This contrasts with alpha$_{2B}$ actions which are primarily arterial and arteriolar vasoconstrictor. Alpha$_{2B}$ subtype receptors are also present but are less abundant in brain tissue and do not appear to diminish a predominant peripheral vasoconstrictor response.[46,47] Alpha$_{2C}$ is a third subclass which, like alpha$_{2A}$, has a predominant central nervous system effect, including a so-called stress response, but as yet it has no defined cardiovascular actions.[48] As of the

Table 34.2. Subgroup classification of alpha-adrenergic receptors

	Site	Action	Additional effects
Alpha $_1$	Arterial Myocardial Coronary	Vasoconstriction Inotropic Vasoconstriction	Early desensitization
Alpha$_{2A}$	CNS (medulla) (Crosses blood-brain barrier)	Vasodilatation	Reduced heart rate and arterial pressure, reduced myocardial contractility
Alpha$_{2B}$	Arterial, arteriolar (Does not cross into CNS)	Vasoconstriction	
Alpha$_{2C}$	CNS	Stress response	No overt cardiovascular effects

present writing, we identify only alpha$_2$ receptors as a group pertinent to the management of CPR. The potential roles of individual alpha$_2$ subtypes have not yet been addressed in these settings.

When alpha$_2$-receptor agonists act centrally and produce vasodilator effects, they may override peripherally acting vasoconstrictor effects. Accordingly, only the peripheral actions are regarded as beneficial for the initial management of cardiac arrest. This prompted a search for a selective alpha$_2$-adrenergic agonist that had peripheral vasoconstrictor actions and led our group to identify alpha-methylnorepinephrine (alpha-MNE). Alpha-MNE does not cross the blood-brain barrier.[49] The vasoconstrictor effects of alpha-MNE were associated with significant improvement in the likelihood of initial resuscitation, better postresuscitation myocardial function, and increased postresuscitation survival when tested in a rat model of cardiac arrest and resuscitation (Fig. 34.1). Alpha$_2$-MNE produced neither transient hypoxemia nor did it increase the incidence of postresuscitation ventricular arrhythmias in comparison with epinephrine. Accordingly, a selective alpha$_2$-agonist proved to be as effective as epinephrine for initial cardiac resuscitation and there was evidence that this occurred without disproportionate increases in myocardial oxygen consumption, without compromise of postresuscitation myocardial function, or of survival. More recent evidence that alpha$_2$-adrenergic agonists increase endothelial nitric oxide production is also of interest since such activity would mitigate any alpha$_2$-adrenergic vasoconstrictor effects on coronary arteries.[44] At the time of this writing, alpha-MNE is not commercially available nor is it an approved drug in the United States.

The effects of epinephrine on microvascular cerebral blood flow were more recently reported from studies in anesthetized pigs. When epinephrine was administered during CPR, there was a striking decrease in capillary blood flow but not in the carotid artery flow. Decreases in capillary flow were documented in both sublingual sites[50] and at the surface of the frontoparietal cortex.[51] The preliminary experimental observations indicate surprising dissociation between large vessel and microcirculatory flow. For the present, we cannot assume that large vessel and, specifically, arterial blood flow is itself predictive of flow to sustain microvascular blood flow and delivery of substrates to the capillary exchange beds.

Adrenergic vasopressors compared to vasopressin

The relationships between equipressor doses of epinephrine, vasopressin, and epinephrine after alpha$_1$- and beta-adrenergic blockade have also been examined. Each was comparably effective for restoring spontaneous circulation in a pig model of cardiac arrest.[51] Combined alpha$_1$- and beta-adrenergic blockade, however, which represented the equivalent of administering selective alpha$_2$ vasopressor agonists, resulted in better postresuscitation cardiac and neurological recovery. In these experiments, we identified an adverse effect in the postresuscitation period, by which vasopressin produced more myocardial dysfunction. This may be explained by its prolonged action, in which increases in afterload impose more prolonged increases in workloads on the stunned heart and after postresuscitation contractile function has already been impaired.

Discussion

A large number of pharmaceuticals were initially recommended for routine use during CPR. Except for selective management of hypocalcemia, hyperkalemia, heart block, or other unique mechanisms of cardiac arrest, only agents that increase peripheral vasoconstriction are of proven

Changes in myocardial function, %
Fig. 34.1. Ventricular fibrillation was untreated for 8 minutes. (From ref. 48.)

benefit and in most instances only for initial resuscitation. Adrenergic vasopressors, which increase myocardial oxygen consumption by their beta and alpha$_1$ actions, increase ectopic ventricular arrhythmias, and transient hypoxemia. Although epinephrine may improve initial resuscitation and return of spontaneous circulation, there is no secure evidence of improved postresuscitation outcomes in terms of survival, as cited above. The major adverse effects are admittedly the inotropic and chronotropic beta-adrenergic actions of epinephrine. Although alpha$_1$ and alpha$_2$-adrenergic agonists increase peripheral vascular resistance and therefore favor myocardial coronary and cerebral perfusion, the inotropic and chronotropic actions of alpha$_1$-adrenergic agonists also increase myocardial oxygen consumption. To that extent,

they act much like beta-adrenergic agonists, whereby postresuscitation myocardial dysfunction is increased. Alpha$_2$-adrenoceptor agonists that do not cross the blood brain–barrier are promising. These agonists acting peripherally have improved outcomes of CPR, based entirely on experimental studies, however. In comparison, vasopressin is also effective for initial resuscitation, but its prolonged vasopressor action after successful restoration of spontaneous circulation has potential adverse effects when it imposes increased workloads on the heart at a time when work capability is already impaired.

The primary goal of chest compression or open chest cardiac message is to re-establish the flow of blood to vital organs until spontaneous circulation is restored to these organs. Blood flow to the heart itself, and specifically the

restoration of blood flow to the coronary arteries to sustain myocardial blood flow, is of predominant import for successful restoration of spontaneous circulation. When adrenergic vasopressor agents produce systemic vasoconstriction they are intended to increase aortic diastolic pressure and consequently coronary and cerebral perfusion pressures. We have described in detail the pharmacological actions of adrenergic agents and how they are mediated by receptors and specifically alpha, including alpha$_1$ and alpha$_2$, and beta, including beta$_1$, beta$_2$, and beta$_3$. Epinephrine has each of these adrenergic actions, and was the predominant adrenergic drug used during CPR for more than a century. Its primary effect is alpha-adrenergic vasoconstriction. This contrasts with its beta-adrenergic actions, which are mildly vasodilatory and more strikingly inotropic and chronotropic. Beta-adrenergic actions result in increases in myocardial oxygen demands and consumption, and increases in heart rate and ventricular premature beats. The beta-adrenergic effects of epinephrine also account for transient hypoxemia caused by pulmonary arteriovenous shunting. There is no evidence that epinephrine improves ultimate survival in human victims of cardiac arrest.

More selective alpha-adrenergic agonists have been investigated to minimize these adverse beta-adrenergic effects. Both alpha$_1$- and alpha$_2$-agonists have peripheral vasopressor actions. Nevertheless, desensitization of alpha$_1$-adrenergic receptors during CPR may account for lesser vasopressor potency. In addition, alpha$_1$-adrenergic receptors in the myocardium, like beta-adrenergic agonists, increase myocardial oxygen demands. Alpha$_2$-adrenoceptor agonists act in the central nervous system where they produce vasodilatory effects, but only if they cross the blood–brain barrier. If an alpha$_2$-agonist does not have central nervous system access, it produces selective peripheral vasoconstrictive effects. Experimentally, during CPR, selective alpha$_2$-agonists that do not gain entrance into the brain therefore may produce more optimal systemic vasoconstriction. Selective alpha$_2$-agonists have as a major advantage that they do not increase myocardial oxygen consumption and thereby increase ischemic injury during the reduced low flow state of cardiac resuscitation. Myocardial ischemic injury during CPR is therefore minimized and myocardial function after successful restoration of spontaneous circulation is better preserved with improved survival in animals. The issues are of substantial clinical importance, for clinical studies have as yet failed to confirm neither an optimal drug nor an optimal dose of either adrenergic vasopressor amines or vasopressin of proven benefit for increased survival in settings of cardiac resuscitation.

These observations prompt re-examination of adrenergic agents for routine management of cardiac resuscitation and invite clinical studies on the patented benefits of selective alpha$_2$-agonists.

Vasopressin and other non-adrenergic vasopressors

Anette C. Krismer, Martin Dunser, Karl H. Stadlbauer, Karl H. Lindner and Volker Wenzel

Department of Anesthesiology and Critical Care Medicine, Innsbruck Medical University, Austria

Basic science

The importance of arterial vascular tone in resuscitation from cardiac arrest has been described in detail in the previous chapters of this book.

Efficacy of non-adrenergic pressors

There is a longstanding concern that administration of adrenaline during resuscitation may result in detrimental effects during the postresuscitation period. For example, laboratory studies with adrenaline during cardiopulmonary resuscitation (CPR) showed increased myocardial oxygen consumption,[1] ventricular arrhythmias,[2] ventilation–perfusion defects,[3] and postresuscitation myocardial dysfunction.[4] Therefore, non-adrenergic vasoactive peptides such as vasopressin hold considerable promise, since they may raise perfusion pressure without the β-receptor-mediated side effects of adrenergic vasopressors. Another intriguing possibility is that they may act synergistically when administered together with catecholamines, and that concomitant use of adrenergic drugs and nonadrenergic vasoactive peptides may allow lowering of the dose of each agent.

Vasopressin, an endogenous stress hormone

A number of fundamental endocrine responses of the human body to cardiac arrest and CPR have been investigated in past years,[5–8] and are summarized in another chapter of this book. Circulating endogenous vasopressin concentrations were high in patients undergoing CPR, and levels in successfully resuscitated patients have been shown to be significantly higher than those in patients who died.[5] This may indicate that the human body discharges vasopressin as an adjunct endogenous vasopressor to epinephrine in life-threatening situations such as cardiac arrest in order to preserve homeostasis. In a clinical study of 60 out-of-hospital cardiac arrest patients, parallel increases in plasma vasopressin and endothelin during CPR were found only in surviving patients.[6] Thus, plasma concentrations of vasopressin may have a more important effect on CPR outcome than was previously thought. These observations prompted several investigations to assess the role of arginine vasopressin in the management of CPR in order to improve patient outcome.

Arginine vasopressin physiology

Arginine vasopressin is an endogenous hormone with osmoregulatory, vasopressor, hemostatic, endocrinologic, thermoregulatory, and central nervous effects (Fig. 35.1). The hormone is produced in the magnocellular nuclei of the hypothalamus, and stored in neurosecretory vesicles of the neurohypophysis. It is secreted upon osmotic, hemodynamic, and endocrinologic stimuli. Although only 10%–20% of the total hormonal pool of arginine vasopressin in the neurohypophysis can be readily released, the time from synthesis to secretion into the circulation is ~1.5 hours.[9] Once released, the plasma half-life of arginine vasopressin is 5–15 minutes. Dose-dependent clearance occurs through vasopressinases in the liver and the kidneys.[10]

The most important hemodynamic signals for secretion are reduced atrial filling and lower arterial blood pressure.
Fig. 35.1. Amino acid sequence of arginine-vasopressin. (From ref. 107.)

Any reduction in blood volume or venous return stimulates secretion of arginine vasopressin *via* activation of stretch receptors located in the left atrium and pulmonary arteries (Gauer–Henry reflex). Activation of baroreceptors in the aortic arch and carotid sinus further augments secretion of arginine vasopressin *via* the glossopharyngeus and vagal nerves. Baroreceptor stimulation is the primary and most important mechanism for release of this hormone in hypotensive states and cardiac arrest.[11] In acute hypotension, there is an exponential relationship between levels of arginine vasopressin in plasma and the decrease in arterial blood pressure. Whereas small reductions in blood pressure (∼5–10% from baseline) usually have only minor or no effect on arginine vasopressin levels in plasma, a 20%–30% decline in arterial pressure results in arginine vasopressin concentrations that are severalfold higher.[12] Similarly, volume depletion produces little elevation in plasma levels of this hormone unless blood volume decreases by more than 10% and results in diminished arterial blood pressure.[11,13] Nevertheless, secretion of argin-ine vasopressin can also be directly stimulated by hypoxia, endotoxin, low concentrations of norepinephrine and angiotensin, or hypoglycemia.[14]

Pharmacological effects of arginine vasopressin

Peripheral effects of arginine vasopressin are mediated by different vasopressin receptors: namely V_{1a}, V_{1b}, and V_2 arginine vasopressin receptors. V_{1a} receptors are located on smooth muscle cells in arterial blood vessels, and induce vasoconstriction by an increase in cytoplasmic ionized calcium *via* the phosphatidyl-inositol-bisphosphonate cascade.[15] On a molar basis, arginine vasopressin was shown to be a severalfold more potent vasoconstrictor than were norepinephrine and angiotensin II.[16] In contrast to catecholamine-mediated vasoconstriction, effects of arginine vasopressin are preserved during hypoxia and severe acidosis.[17]

Vascular effects mediated by vasopressin differ substantially within particular vascular beds, however. Physiologically, most arterial beds exhibit vasoconstriction in response to vasopressin.[18,19] Vasopressor effects are strongest in the muscular, adipose, cutaneous, and probably also the splanchnic vasculature. In a porcine CPR model, Voelckel *et al.*[20] found a significantly lower blood flow in the superior mesenteric artery in pigs resuscitated with arginine vasopressin when compared to epinephrine; there were no differences in hepatic or renal blood flow. Similar to oxytocin-mediated paradoxical vasodilatation of vascular smooth muscle, vasodilatation after arginine vasopressin has not only been described in the pulmonary, coronary, and vertebrobasilar circulation, but interestingly also in the mesenteric vascular bed, suggesting a dose-dependent response.[21–24] The underlying mechanisms for such an arginine vasopressin-mediated vasodilatation seem to be nitric oxide dependent.[22] Russ and Walker reported that stimulation of V_1-receptors can release nitric oxide, presumably from the endothelium of some vascular regions.[25] There is increasing evidence of hemodynamically

relevant V_1-receptors on cardiomyocytes. In vitro and animal experi-ments have demonstrated an increase of intracellular calcium concentration and inotropy after stimulation of myocardial V_1-receptors.[26,27]

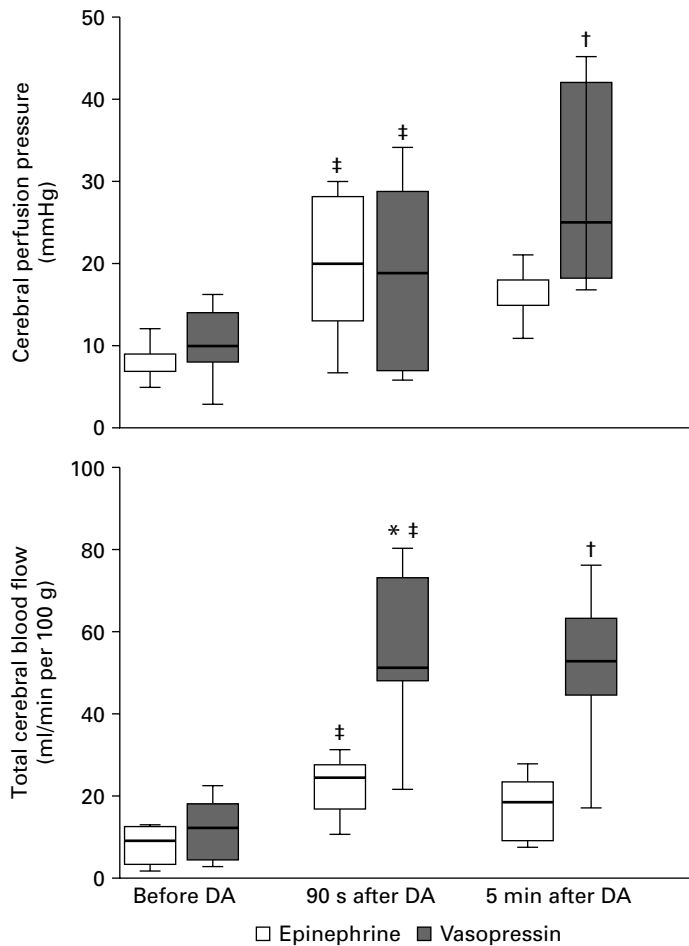
In the kidney, V_2-receptors are located on distal tubules and collecting ducts. Upon stimulation, they facilitate integration of aquaporines into the luminal cell membrane of the collecting ducts, leading to increased resorption of free water *via* an adenylate cyclase-dependent mechanism.[28] Despite its antidiuretic effect, a paradoxical increase of urine output has been reported during continuous infusion of arginine vasopressin in patients with advanced vasodilatory shock.[29–31] It is hypothesized that together with increased renal perfusion pressure, arginine vasopressin selectively constricts efferent glomerular arterioles, whereas it dilates afferent vessels, thus increasing effective filtration pressure in the glomerulus.[29]

V_{1b} receptors are located on the anterior hypophysis; stimulation induces liberation of ACTH and prolactin.[32] Accordingly, Kornberger *et al.*[33] reported significantly higher ACTH and cortisol concentrations in serum from animals resuscitated from cardiac arrest with arginine vasopressin when compared to epinephrine. In patients with advanced vasodilatory shock, however, a continuous infusion of arginine vasopressin at dosages of 4 IU/h affected neither serum ACTH nor cortisol concentrations.[34] A complex dysfunction of the hypophyseal–adrenal axis in critical illness may explain the lack of effects of the potent stimulator arginine vasopressin on ACTH-producing cells. Nonetheless, arginine vasopressin seems to be able to promote prolactin excretion by V_{1b} receptor stimulation. Additional V_{1b} receptors are expressed on pancreatic islet cells where they enhance insulin secretion in the presence of high glycemic levels.[35]

Arginine vasopressin during CPR in laboratory models

In a porcine model simulating ventricular fibrillation, a dose–response investigation of three arginine vasopressin dosages (0.2; 0.4; 0.8 U/kg) compared with the maximum effective dose of 200 µg/kg epinephrine showed that 0.8 U/kg of arginine vasopressin was the most effective drug for increasing blood flow to vital organs and coronary perfusion pressure (Figs. 35.2 and 35.3).[36] Correspondingly, arginine vasopressin significantly improved cerebral oxygen delivery, and mean frequency of ventricular fibrillation during CPR when compared with a maximum dose of epinephrine[37] (Fig. 35.4). Furthermore,
Fig. 35.2. Effects of different doses of vasopressin vs. high dose epinephrine on systolic and diastolic blood pressure. (From ref. 36.)

the effects on vital organ blood flow lasted longer after administration of arginine vasopressin than after treatment with epinephrine (~4 vs. ~1.5 min); significantly more arginine vasopressin animals could be resuscitated.[38] The same dose of intravenous and endobronchial arginine vasopressin resulted in similar coronary perfusion pressures 4 minutes after drug administration.[39,40] Intraosseous vs. intravenous arginine vasopressin lead to comparable levels of arginine vasopressin in plasma, hemodynamic variables, coronary perfusion pressure, and rates of return of spontaneous circulation (Fig. 35.5).[41] Therefore, the intraosseous route might be a valuable alternative for administration of arginine vasopressin during CPR, when intravenous access is delayed, or not available.

After repeated dosages of arginine vasopressin vs. epinephrine were administered in a porcine model, coronary perfusion pressure increased only after the first of three epinephrine injections, but increased after each of three arginine vasopressin injections; accordingly, all arginine vasopressin-treated animals survived, whereas all pigs resuscitated with epinephrine died (Fig. 35.6).[42] In the early postresuscitation phase of the same model, arginine
Fig. 35.3. Effects of different doses of vasopressin vs. high dose epinephrine on left ventricular blood flow. (From ref. 36.)


vasopressin administration resulted in higher arterial blood pressure, but a lower cardiac index; a reversible depressant but not critical effect on myocardial function by arginine vasopressin was observed when compared with epinephrine.[43] Renal and splanchnic perfusion may be impaired during[44] and after[45] successful resuscitation from cardiac arrest. Arginine vasopressin impaired mesenteric blood flow during CPR and in the early postresuscitation phase.[20] Neither renal blood flow, nor renal function, however, was influenced by arginine vasopressin or epinephrine in this investigation.[20]

In a model of prolonged advanced cardiac life support (22 minutes), all arginine vasopressin animals had return of spontaneous circulation, whereas all pigs in the epinephrine and saline placebo group died. Twenty-four hours after return of spontaneous circulation, the only neurological deficit of pigs resuscitated with arginine vasopressin was an unsteady gait, which disappeared within another 3 days. Subsequently performed magnetic resonance imaging revealed no cerebral cortical or subcortical edema, intraparenchymal hemorrhage, ischemic brain lesions, or cerebral infarction, indicating that arginine vasopressin- but not epinephrine-treated pigs recovered fully from cardiac arrest in both anatomical and physiological terms even after prolonged CPR.[46]

Fig. 35.4. Effects of different doses of vasopressin vs. high dose epinephrine on total cerebral blood flow and cerebral perfusion pressure. (From ref. 37.)
Fig. 35.5. Intravenous vs. intraosseous vasopressin during CPR. Individual coronary perfusion pressure tracings after intravenous (■) and intraosseous (▲) vasopressin administration during CPR. No statistical analysis was performed for this figure. Some tracings may be superimposed on each other; defibrillation was performed approximately at 5 min and 15 s after drug administration. (From ref. 41.)

Clinical studies with arginine vasopressin during cardiac arrest

In patients with refractory cardiac arrest, arginine vasopressin induced an increase in arterial blood pressure, and in some cases, return of spontaneous circulation, where standard therapy with chest compressions, ventilation, defibrillation, and epinephrine had failed.[47] In a small ($n = 40$) prospective, randomized investigation of patients with shock-refractory out-of-hospital ventricular fibrillation, a significantly larger proportion of patients treated with arginine vasopressin were successfully resuscitated and survived for 24 hours compared with patients treated with epinephrine.[48] In 1999, a Chinese study group reported a prospective, randomized trial comparing two different dosages of arginine vasopressin and two different dosages of epinephrine in 83 patients with in-hospital cardiac arrest. Their findings indicated that high-dose arginine vasopressin (1 IU/kg) significantly increased the rate of return of spontaneous circulation, and improved the survival rate compared with standard (1 mg) and high dosages

(5 mg) of epinephrine.[49] In a large ($n = 200$) in-hospital CPR trial from Ottawa, Canada, comparable short-term survival was found in both groups treated with either arginine vasopressin or epinephrine, indicating that these drugs may be equipotent when response times of rescuers are short.[50] In another clinical evaluation in Detroit, Michigan, 4 of 10 patients responded to arginine vasopressin administration after ~45 minutes of unsuccessful advanced cardiac life support, and had a mean increase in coronary perfusion pressure of 28 mmHg.[51] This is surprising, because an increase in arterial blood pressure with any drug after such a long period of ineffective CPR management is expected to be minimal.

From June 1999 to March 2002, we conducted a large multicenter trial in Austria, Germany, and Switzerland, and randomized 1219 out-of-hospital cardiac arrest patients to be treated with epinephrine or arginine vasopressin[52] (Fig. 35.7). Hospital admission and discharge rates were comparable between treatment arms for patients with ventricular fibrillation and for pulseless electrical activity, but patients with asystole were more likely
Fig. 35.6. Vasopressin vs. epinephrine during prolonged CPR. Administration of repeated doses of vasopressin (■), but not epinephrine (♦) given early during basic life support CPR maintained mean ± SEM CPP above the threshold of ~20 to 30 mmHg (dashed lines) that is needed for successful defibrillation with return of spontaneous circulation. DA 1 indicates drug administration of 0.4 U/kg of vasopressin vs. 45 μg/kg of epinephrine; DA 2, 0.4 U/kg of vasopressin vs. 45 μg/kg of epinephrine; DA 3, 0.8 U/kg of vasopressin vs. 200 μg/kg of epinephrine; *$P < 0.05$ vs. epinephrine; ROSC, return of spontaneous circulation; VF, ventricular fibrillation; and ACLS, advanced cardiac life support. Time is given in minutes (') and seconds ("). (From ref. 53.)

to survive when primarily treated with arginine vasopressin (Table 35.1, Fig. 35.8). If patients could not be successfully resuscitated with two injections of arginine vasopressin, however, additional epinephrine significantly improved hospital admission ($p = 0.002$) and discharge rates ($p = 0.002$) when compared to epinephrine-treated patients (Table 35.2, Fig. 35.9). There was no difference in cerebral performance between groups for the entire trial.

These results did not confirm earlier data suggesting that arginine vasopressin was more effective than epinephrine as a first-line vasopressor drug in the treatment of ventricular fibrillation, pulseless electrical activity, or asystole.[36–38,46,48,53] Criticism has been raised that arginine vasopressin may improve coronary and cerebral perfusion pressures during CPR with refractory ventricular fibrillation and pulseless electrical activity, but not outcome. Unfortunately, we are unable to state whether this phenomenon may be similar to the observations described with high-dose epinephrine during CPR, when increasing epinephrine dosages were effective in the laboratory,[54] but not in clinical practice.[55] It is clearly a virtually impossible

problem to extrapolate laboratory CPR to the clinical setting since species differences, comparing diseased patients with healthy laboratory animals, or differences in out-of-hospital CPR compared to laboratory conditions cannot be controlled adequately.

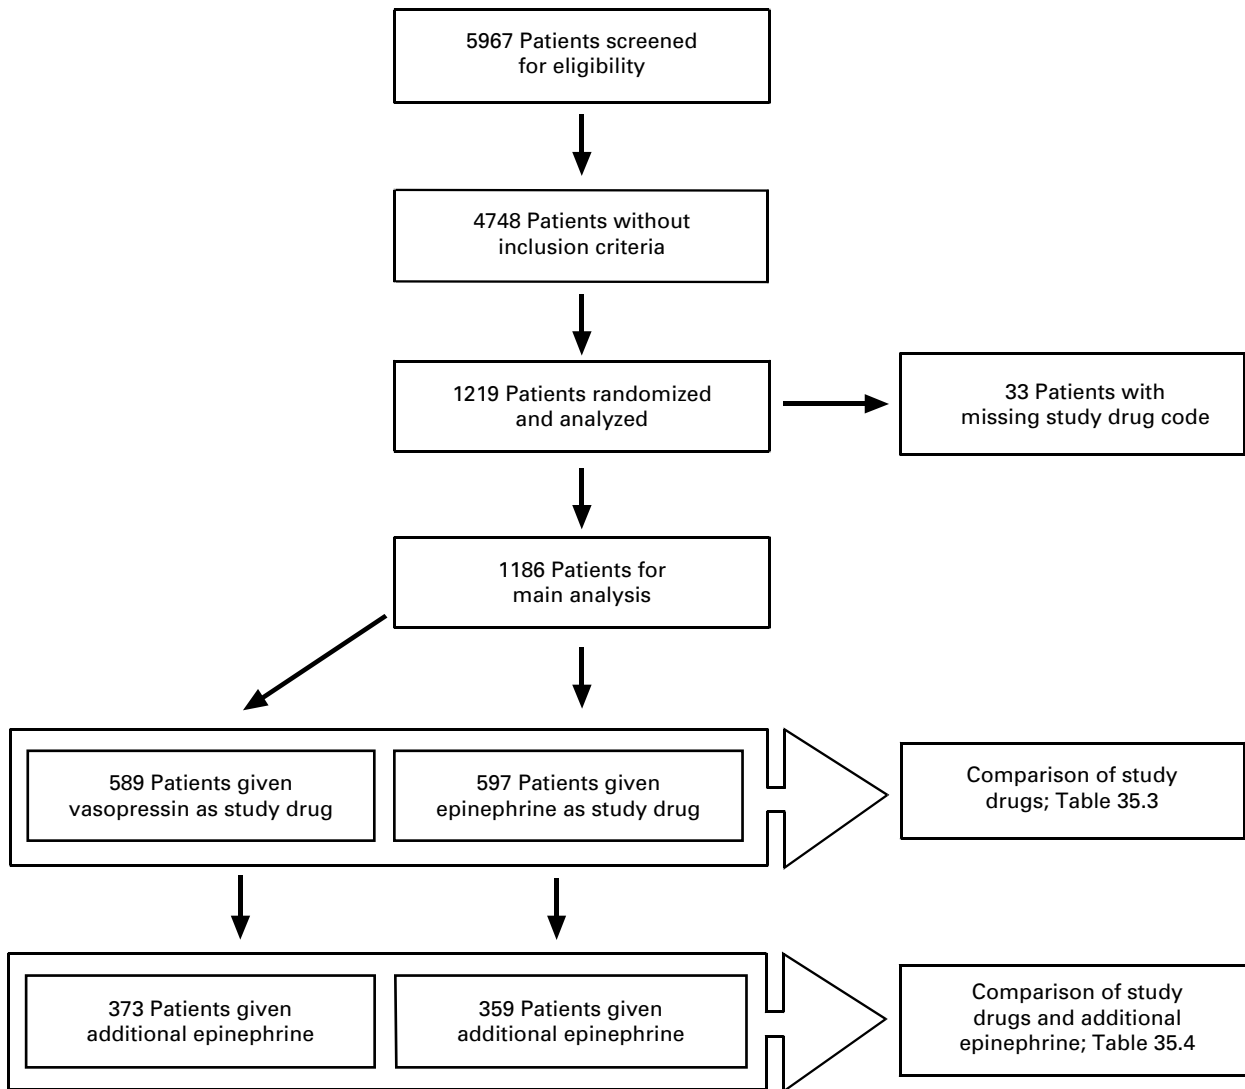
In contrast to ventricular fibrillation and pulseless electrical activity, in the multicenter study, arginine vasopressin improved the likelihood of asystolic patients reaching the hospital alive by about 40% over epinephrine. A possible explanation may be profound ischemia which is frequently present in asystolic patients. This is in accordance with a study *in vitro*, where it was demonstrated that arginine vasopressin has vasoconstricting efficacy even in severe acidosis, when catecholamines are less potent.[17] Thus, arginine vasopressin seems to be more effective than epinephrine in asystolic patients, thereby resulting in better coronary perfusion pressure during cardiac resuscitation. Since improved coronary perfusion pressure during CPR improves survival,[56] arginine vasopressin may be a better option than epinephrine for asystolic patients, who normally have the worst chance of survival. Also, improvement


Fig. 35.7. Flowchart of the European multicenter study and analysis. (From ref. 52.)

in hospital discharge after treatment with epinephrine following arginine vasopressin may indicate that interactions among arginine vasopressin, epinephrine, and the underlying degree of ischemia during CPR may be more complex than was previously thought. When prolonged asphyxia had depleted endogenous epinephrine levels and caused profound ischemia in pigs, arginine vasopressin combined with epinephrine tripled coronary perfusion pressure over either epinephrine or arginine vasopressin alone (Fig. 35.10).[57] This suggests that the presence of arginine vasopressin may enhance the effects of epinephrine or *vice versa,* especially during prolonged ischemia.[57,58]

In an in-hospital CPR study reporting comparable effects of arginine vasopressin and epinephrine, 87%

of arginine vasopressin patients received additional epinephrine.[50] The concept of deliberate administration of arginine vasopressin combined with epinephrine during CPR is also supported by clinical observations that epinephrine followed by arginine vasopressin significantly improved coronary perfusion pressure,[51] return of spontaneous circulation,[47,58] and 24-hour survival rates.[59] This was also confirmed by a retrospective review that compared arginine vasopressin after epinephrine *vs.* epinephrine only, in a subset of patients with out-of-hospital cardiac arrest who did not respond to immediate therapy with epinephrine (Fig. 35.11).[58]

Although half of the survivors in the multicenter study with good neurological outcome received the combi-

European multicenter study.

nation of arginine vasopressin and epinephrine, this strategy also resulted in more, albeit not statistically significant, patients in coma than after epinephrine alone. This indicates that the combination of arginine vasopressin and epinephrine effectively resuscitated the heart, but was too late to resuscitate the brain in some patients. When starting CPR, it is difficult to predict postresuscitation brain function.[60] Although our hospital discharge rate (9.7%) compares favorably with that in other reports, 2.2% of our patients had severe neurological impairment. Thus, combining arginine vasopressin and epinephrine improved survival rates, but resulted in unfavorable neurological outcome in some patients. In patients treated with arginine vasopressin, unfavorable neurological outcome was observed in 5 of 10 patients who were first found to be in asystole or pulseless electrical activity; in contrast, no asystole or pulseless electrical activity patient receiving ≥ 3 mg epinephrine had unfavorable neurological outcome since all died before being discharged.

While an unfavorable ECG diagnosis upon starting CPR, such as asystole, may be one important surrogate for unfavorable neurological outcome, we should not forget that duration of ischemia reflects vital organ injury, and the required vasopressor dosage reflects the organism's ability to respond to CPR efforts. For example, both witnessed cardiac arrest and basic life support within 10 min was highly significant ($p < 0.001$) in predicting hospital admission in the European multicenter study. Patients who needed only one or two injections of the study drugs had a hospital discharge rate of 19.5%, whereas patients requiring two injections of either one of the study drugs and additional epinephrine had a hospital discharge rate of only 4%. A final judgment whether combining arginine vasopressin and epinephrine is beneficial, especially when administered earlier, as in our investigation, requires confirmation in a prospective study, which is currently under way in France. More than 1500 patients have already been randomized (PY Gueugniaud, personal communication, 2005).

Limitations of arginine vasopressin during CPR

The promising news about vasopressin CPR studies cannot disguise the fact that many issues have not been addressed as of today. For example, there is still lack of large clinical studies. This may be the reason why a recently conducted meta-analysis[61] did not show statistically significant differences between arginine vasopressin and epinephrine in return of spontaneous circulation, hospital admission, and discharge rates (Tables 35.3–35.5). It is to be hoped that the ongoing French vasopressin study will answer these questions decisively.

Further, extrapolating experience with arginine vasopressin from the adult to the pediatric setting is difficult, and needs to be investigated.[62] Preliminary laboratory

evidence suggests beneficial effects of a combination of arginine vasopressin with epinephrine in asphyxic cardiac arrest; however, this observation is inconsistent with reports in a postcountershock, pulseless electrical activity preparation. Although preliminary experimental data suggest coronary vasodilatation after arginine vasopressin, this model may not reflect diffuse coronary artery disease of humans with possibly different physiology of the

Fig. 35.11. Retrospective study comparing the effects of arginine vasopressin after epinephrine vs. epinephrine only. Asystolic patients treated with arginine-vasopressin after epinephrine had a better short-term survival compared to patients treated with epinephrine only. (From ref. 58.)

coronary arteries.[63,64] Currently, we do not know whether arginine vasopressin acts simply as a back-up for the vasopressor epinephrine during life-threatening shock states, whether arginine vasopressin or epinephrine alone is better in certain situations, or whether these two hormones have unique adjunct features that we are only beginning to understand. Better knowledge of these underlying mechanisms would most likely save many

patients, who at this point in time have relatively little chance of survival.[65]

Arginine vasopressin in hemorrhagic shock

In 1990, about 5 million people died worldwide as a result of injury, and it seems likely that the global epidemic of deadly

trauma is only beginning. By 2020, deaths from injury are expected to increase to 8 million worldwide,[66] and 30% of these fatalities will be attributable to uncontrolled hemorrhagic shock.[67] Resuscitation of patients in uncontrolled hemorrhagic shock remains one of the most challenging aspects of emergency care, and trauma patients with complete cardiovascular collapse have an extremely poor chance of survival. For example, in a 1993 study of 138 trauma patients requiring cardiopulmonary resuscitation at the accident scene or during transport, none of the initially successfully resuscitated patients survived to hospital discharge.[68] Accordingly, prevention of cardiac arrest has been considered to be the primary goal of trauma care.[69] Unfortunately, trauma-related cardiac arrest is only the tip of the iceberg. Because hemorrhage-induced hypotension in trauma patients is predictive of frequent mortality and morbidity, managing prolonged hypotension aggressively may be equally important.

For hemodynamic stabilization of critically injured patients with uncontrolled hemorrhagic shock, current trauma guidelines recommend infusion of crystalloid or colloid solutions in addition to catecholamine vasopressors. In a large clinical study of penetrating torso trauma, patients receiving delayed fluid resuscitation had better survival rates than did those receiving immediate fluid resuscitation.[70] Roberts et al.[71] further found no scientific evidence for the effectiveness of immediate fluid resuscitation in uncontrolled hemorrhagic shock. Also, a Cochrane review of randomized controlled trials found no evidence either for or against early or large volume IV fluid administration in uncontrolled hemorrhage.[72] At present, therefore, we have no clearly proven fluid resuscitation strategy for uncontrolled hemorrhagic shock, and it seems expedient to consider alternative strategies to prevent immediate or delayed cardiac arrest in these patients. Moreover, during the late phase of hemorrhagic shock when cardiac arrest may occur at any time, replacement of fluids and blood may become ineffective even when supported by conventional vasopressors such as norepinephrine.[73] In an experimental shock model in dogs, arginine vasopressin has been shown effectively to restore circulation in the late phase of hemorrhagic shock that was unresponsive to blood replacement and catecholamines.[73] Furthermore, arginine vasopressin enabled short- and long-term survival in a porcine model of uncontrolled hemorrhagic shock after penetrating liver trauma (Fig. 35.12)[74–77] and after traumatic brain injury.[78] Arginine vasopressin has also been used in a small number of non-trauma patients with upper gastrointestinal bleeding and subsequent shock that was unresponsive to volume replacement.[79] In the clinical setting, positive effects of arginine vasopressin were observed in some patients with life-threatening hemorrhagic shock with collapsing arterial blood pressure, who did not continue to respond to adrenergic catecholamines and fluid resuscitation (Fig. 35.13).[80–83] Interestingly, all patients in these case reports received a combination of vasopressin and catecholamines during the late phase of uncontrolled hemorrhagic shock, which may be more effective than either drug alone. This enhancing effect of a combination of vasopressin and catecholamines is in accord with our evidence in settings of severe shock such as cardiac arrest and septic shock.[52,57,80,82,84] Furthermore, these case reports demonstrate that prolonged hemorrhagic shock with severe hypotension managed with vasopressin can result in fully conscious patients with intact cardiocirculatory function and full neurological recovery. This is in agreement with a case report[80] of a patient with multiple fractures of the pelvis, spine, and legs, as well as a severe head trauma after a fall from a roof (fourth floor), resulting in uncontrolled hemorrhagic shock and severe hypotension that was refractory to massive infusion of fluids, blood products and norepinephrine. Subsequent infusion of vasopressin prevented cardiocirculatory collapse, resulted in a stable hemodynamic function, and enabled emergency surgery. This patient made a full neurological recovery (Fig. 35.13).[80]

The case reports also provide valuable information, because the successful treatment of uncontrolled hemorrhagic shock with vasopressin was reproducible and reported by different observers. We believe that in patients with uncontrolled hemorrhagic shock, infusing vasopressin may be an option for stabilizing cardiocirculatory function and prevent cardiac arrest. In the absence of randomized controlled trials investigating the role of vasopressin in uncontrolled hemorrhagic shock today, even the currently limited clinical data available may support treatment decisions in selected patients who would otherwise die rapidly. In the future, we need to assess whether the existing laboratory[74–78] and limited clinical data[80–83] on treating uncontrolled hemorrhagic shock successfully with vasopressin can be confirmed in a randomized controlled clinical trial. In addition, the best timing of application and optimal dose of this form of therapy need to be addressed.

Angiotensin II

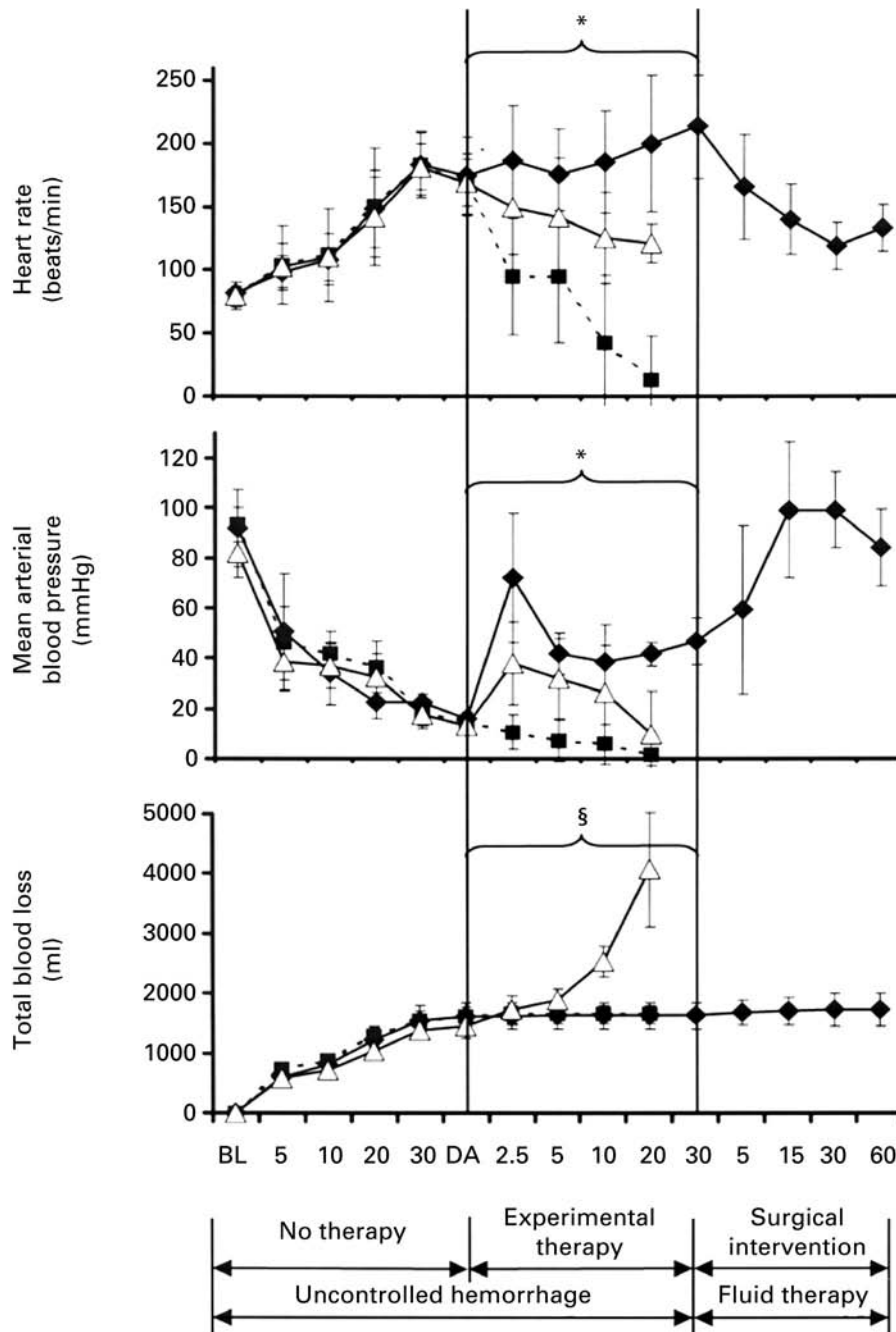
Angiotensin II is a potent vasoconstricting octapeptide. As an intermediary in the renin-angiotensin-aldosterone system, angiotensin II has received much attention as a mediator of hypertension and congestive heart failure.


Fig. 35.12. Mean ± SD heart rate, mean arterial blood pressure, and total blood loss before, during, and after administration of a 0.4 U/kg bolus dose, and 0.08 U/ kg/min continuous infusion of vasopressin (closed diamond, continuous line) vs. fluid resuscitation (closed triangle, continuous line) with 25 ml/kg lactated Ringer's solution and 25 ml/kg 3% gelatin solution vs. saline placebo (closed square, dotted line). Uncontrolled hemorrhage = the non-intervention interval after liver injury; experimental therapy = vasopressin or fluid resuscitation or saline placebo administration without bleeding control; surgical intervention = surgical management of the liver lobe to control bleeding; fluid therapy = infusion of lactated Ringer's solution, 3% gelatin solution, and transfusion of blood; BL = baseline; DA = drug administration; *$P < 0.05$ between groups for differences between all groups during the experimental protocol; §$P < 0.05$ for differences between the fluid resuscitation, and vasopressin and saline placebo group during the experimental protocol. No statistical comparison was performed after 20 min of experimental therapy because of death of all fluid resuscitation and saline placebo pigs, respectively. (From ref. 74.)
Fig. 35.13. A 41-year-old woman fell off a roof (height ~15 m), and was transported to the next county hospital. Because of an unstable pelvic fracture, the patient became hemodynamically unstable; therefore, an arterial cannula, and a large-bore central venous catheter were placed, and four units of packed red cells and coagulation factors were administered, and the patient was airlifted to a university hospital. After arrival in the emergency room of the level one trauma center, hemodynamic stability could not be maintained despite massive infusion of fluids and norepinephrine (50 μg/min). The patient had a TRISS score-predicted death rate of 84.9%. An infusion of vasopressin was then started (10 IU/min), and blood pressure was stabilized, thus allowing emergent angiography and application of a pelvic clamp. Angiography revealed a ruptured left internal iliac, and left pudendal artery; both blood vessels were successfully coiled and the patient was stabilized. Subsequent CT scanning revealed an injury pattern consisting of complex facial injuries, subdural hematoma, diffuse edema of the brain, spine and rib fractures, hemothorax and hemomediastinum, rupture of the right bronchus, central hematoma of the liver, massive retroperitoneal hematoma, pelvic fractures, open fracture of the left femur, open fractures of both tibias, and fractures of both ankles, and the right upper arm. The patient underwent several surgical procedures to repair fractures, developed a systemic inflammatory response and a multiple organ dysfunction syndrome, but was discharged from the critical care unit to the ward without neurological damage 39 days after the accident. (From ref. 80.)

Renin, on secretion by the renal juxtaglomerular cells, catalyzes the cleavage of angiotensinogen to angiotensin I, which is only a weak vasopressor.[85] Angiotensin II is formed by cleavage of angiotensin I by angiotensin-converting enzyme. Angiotensin II is then converted to angiotensin III, which stimulates aldosterone release by the adrenal cortex. Angiotensin II has a very short serum half-life as it is quickly converted to angiotensin III and broken down by serum and tissue peptidases.[85]

Angiotensin II has unique receptors, designated AT_1 and AT_2, of which AT_1-receptors mediate the vasopressor and chronotropic effects of angiotensin II.[86,87] The second-messenger system of the AT_1-receptor appears to involve activation of phospholipases C and D leading to increased inositol phosphates.[85,87,88] This increase in inositol phosphates increases intracellular calcium and leads to smooth muscle contraction. The second-messenger system is distinct from that of the adrenergic system, which utilizes cyclic adenosine monophosphate (cAMP).

The vascular response to angiotensin II infusion is generalized vasoconstriction. On a molar basis, angiotensin II is approximately 30 times more potent than norepinephrine.[85] It produces a dose-dependent increase in blood pressure in humans and animals.[88–90] It acts in conjunction with the adrenergic system and vasopressin to maintain mean arterial pressure during a variety of physiologic insults, including hemorrhage, sepsis, adrenal insufficiency, and other hypotensive states.[91–95]

Angiotensin II has been used experimentally as a vasopressor since the 1950s. The effect of pharmacologic doses of angiotensin II in the setting of hypotension and shock, however, has not been well studied. There are case reports

of use of angiotensin II in individual patients, but no comprehensive physiologic assessment. Much of the use of angiotensin II occurred before invasive hemodynamic monitoring became routine. The relative contribution of direct vasoconstriction by angiotensin II compared to its effects on adrenal catecholamine release was not examined. The effects of angiotensin II on myocardial blood flow have been tested in a swine model of cardiac arrest with open-chest cardiac compressions. After administration of angiotensin II, myocardial blood flow was 118 ml/min per 100 g, which is near normal, compared to 56 ml/min per 100 g for the placebo group. Myocardial oxygen delivery and oxygen-extraction ratio were improved in the angiotensin II group.[96] Cerebral oxygen delivery and extraction ratios were also improved by angiotensin II in a porcine cardiac arrest model.[97] A porcine study described the effects of angiotensin II (50 μg/kg) compared to epinephrine (20 μg/kg), and a group receiving the two agents in combination.[98] All groups had a significant increase in myocardial blood flow during CPR following drug administration, but there was a trend toward higher flows in the epinephrine-treated animals. Furthermore, both groups that received epinephrine had significantly higher myocardial blood flow after return of spontaneous circulation when compared with those treated with angiotensin II.[98] Further studies will be needed to determine whether angiotensin II may have a role as a vasopressor in the therapy of cardiac arrest. At this time, clinical evidence is not sufficient to support use of angiotensin II during CPR.

Endothelin

Endothelin has been identified as a powerful vasoconstricting hormone secreted by endothelial cells.[99–101] DeBehnke *et al.*[102] reported that compared with endothelin or epinephrine, the combination of endothelin-1 plus epinephrine improved coronary perfusion pressure in a canine model of CPR. It was further shown that endothelin may significantly improve cerebral perfusion.[103,104] Another porcine model studied the effects of a combination of epinephrine and endothelin.[105] Although more animals that received the combination of endothelin-1 plus epinephrine had return of spontaneous circulation, fewer animals survived to 1 or 24 hours.[105] This was the result of a marked vasoconstricting effect of the combination of epinephrine and endothelin-1 in the doses used. There was a marked increase in the coronary perfusion pressure, but a dramatic narrowing of the pulse pressure, and a marked drop in the end-tidal carbon dioxide level, indicating a marked decrease in forward blood flow. Results from a canine study suggested that endothelin-1 may contribute to the failure of cerebral circulation after cardiac arrest.[106]

In summary, it had been axiomatic that increased vasoconstriction during CPR improves coronary perfusion pressure, and thereby immediate resuscitation success; however, data indicate that vasoconstriction can be excessive. Postresuscitation left ventricular dysfunction is well documented, and is difficult to manage in the intensive care unit. Accordingly, the stunned left ventricle may be unable to tolerate the increased systemic vascular resistance immediately after resuscitation and, therefore, heart failure and malignant ventricular arrhythmias may occur. Accordingly, use of endothelin during CPR is not beneficial.

Practice points

CPR

Both angiotensin II and endothelin should not be administered during CPR. According to the new data from the European arginine vasopressin study,[52] we recommend administering first, 1 mg of epinephrine followed alternately by 40 IU of vasopressin and 1 mg of epinephrine
Fig. 35.14. Algorithm according to the new data from the European arginine vasopressin study.[52] We recommend administering 1 mg of epinephrine first, followed alternately by 40 IU vasopressin and 1 mg epinephrine every 3 minutes in adult cardiac arrest victims, regardless of the initial ECG rhythm. (From ref. 52.)

every 3 minutes in adult cardiac arrest victims, regardless of the initial ECG rhythm (Fig. 35.14).

Hemorrhagic shock

Although promising at present observations made with arginine vasopressin in hemorrhagic shock and collapsing blood pressure in the laboratory and in individual patients, need to be confirmed in future prospective, randomized clinical trials. In selected patients with massive bleeding and intractable hemorrhagic shock resulting in collapsing blood pressure despite advanced trauma life support, 5–10 IU vasopressin may be injected; the cumulative dose should be titrated according to arterial blood pressure.

Most cases of sudden cardiac death (SCD) are due to malignant ventricular tachyarrhythmias, such as ventricular tachycardia (VT) and ventricular fibrillation (VF)(see Fig. 36.1).[1,2] Both VF and pulseless VT require defibrillation as definitive therapy. If these or other arrhythmias persist despite basic life support and defibrillation, the current international advanced cardiac life support guidelines (ILCOR 2005)[3] recommend administration of pharmacologic agents to help stabilize rhythm and restore cardiac output.

The pathophysiologic substrate of cardiac arrest: therapeutic implications

The pathophysiology of sudden cardiac death is relevant to both acute and long-term management. In most instances, the underlying cardiac pathology is ischemia and coronary artery disease. For instance, Liberthson and coworkers[4] reported that 81% of a series of SCD victims had significant coronary artery disease. In another series, up to 50% of the victims of out-of-hospital cardiac arrest had suffered a recent acute myocardial infarction.[5] Although the majority have a coronary disease etiology, numerous other pathologies can be involved in the genesis of sudden cardiac death, such as ventricular hypertrophy, cardiomyopathies, congenital disorders of ion channels ("channelopathies"), but also massive pulmonary embolism, as well as coronary dissection, and coronary inflammation or embolism to the coronary arteries. From a clinical perspective, it is appropriate to assume that the cause of sudden death is coronary artery disease unless circumstances suggest otherwise.

Although the creatine kinase (CK) and its MB fraction may not be diagnostic of acute myocardial ischemia, cardiac troponins can identify myocardial ischemic damage and thus prompt invasive coronary studies, which may make long-term antiarrhythmic treatment irrelevant. A study by Spaulding et al.[6] demonstrated that even without positive cardiac markers, significant coronary disease and coronary occlusions are frequently found in patients with cardiac arrest. These authors reported that 60 of 84 (71%) patients they investigated after out-of-hospital cardiac arrest had significant coronary artery disease and that 40 patients (47%) had coronary occlusions – supporting a more general application of coronary angiography in this situation. In addition to acute myocardial ischemia due to coronary artery disease, hypertrophic or dilated cardiomyopathy are relatively frequent causes of unexpected malignant arrhythmias.

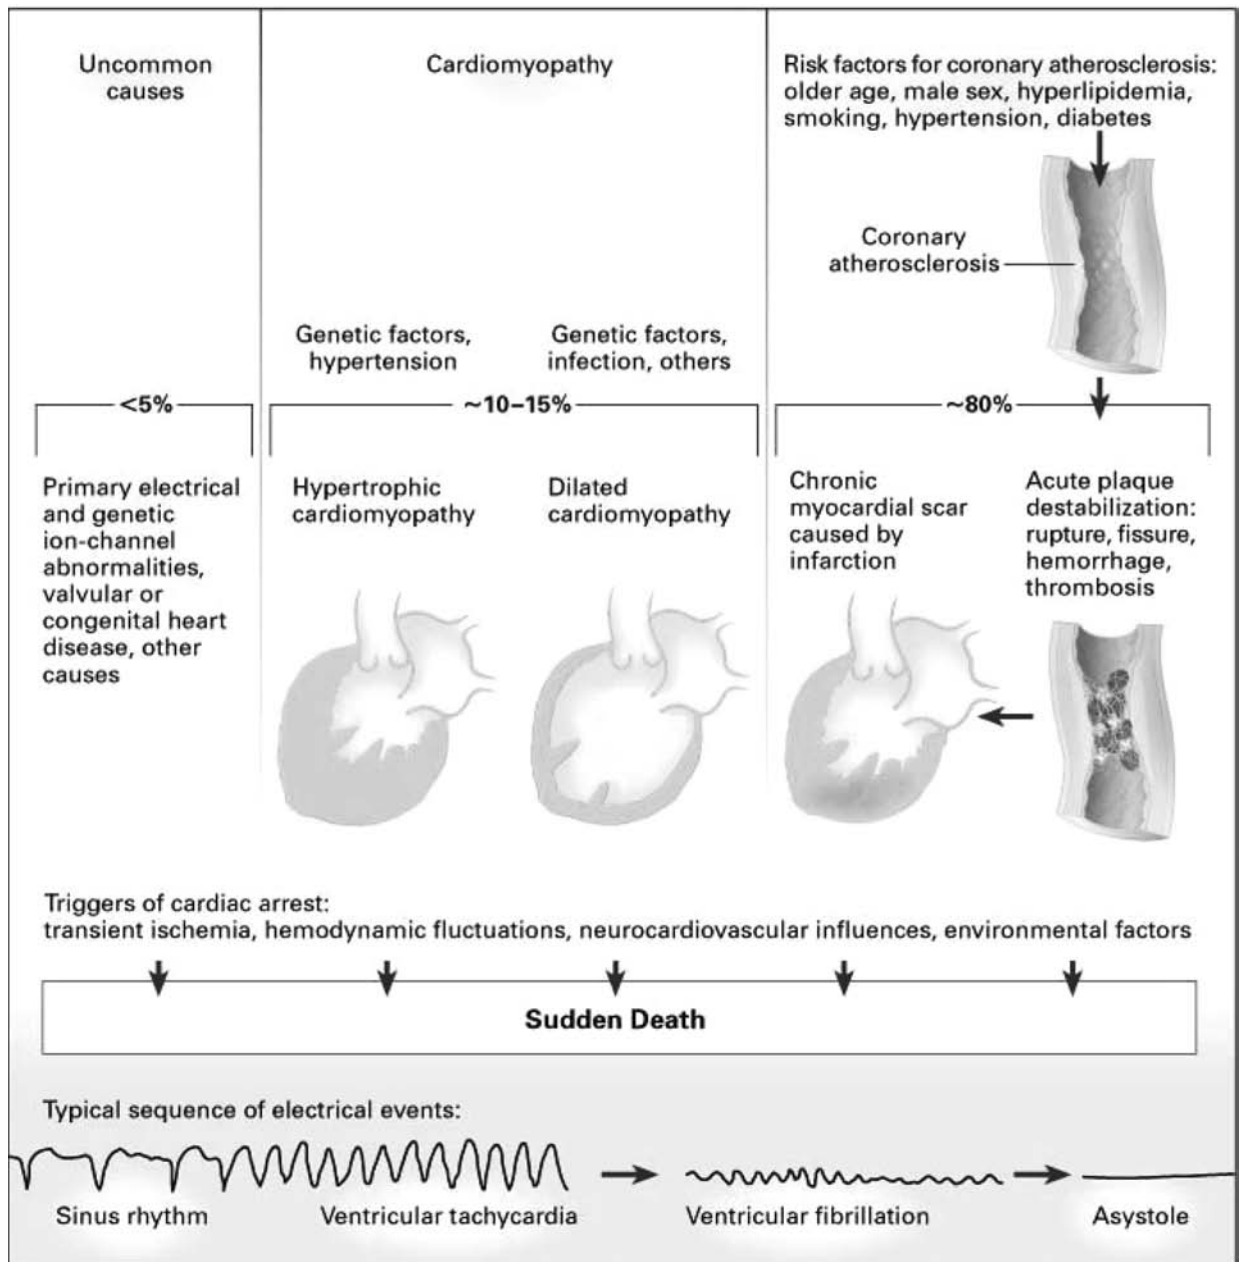
All antiarrhythmics have the potential to increase the risk of cardiac arrest; those that affect repolarization are particularly important in this regard, especially if the substrate for which they are used also involves ion channels. This has been shown for the Class I sodium channel blocking agents encainide and flecainide in the CAST study,[7] which found a significant excess mortality in patients with chronic coronary artery disease, mostly due to ventricular fibrillation. Moreover, Class III drugs that prolong the action potential – such as sotalol, dofetilide, or ibutilide – can directly cause torsades de pointes that may then degenerate into ventricular fibrillation.[8–13] Whether or not patients have received antiarrhythmics, channelopathies have to be considered if no coronary or myocardial abnormality can be identified. They comprise the congenital long QT syndrome,[14] the Brugada syndrome,[15] and other less well recognized


Fig. 36.1. Pathophysiology and epidemiology of sudden death from cardiac causes. (From ref. 1, with permission.)

disorders.[16] Not only patients, but also their siblings, should be investigated if a channelopathy is likely, so that their genotype and phenotype can be characterized. Other specific causes for VT/VF and consecutive cardiac arrest are severe electrolyte abnormalities that are of particular risk in individuals who are vulnerable for other reasons.

Non-cardiac causes that lead to cardiac arrest are usually associated with electromechanical dissociation, which is

the most profound form of pulseless electrical activity, rather than to ventricular fibrillation or fast and degenerating ventricular tachycardia.

Irrespective of the pathophysiology, the patient's long-term risk of malignant ventricular arrhythmias needs to be assessed after hemodynamic stabilization and successful management of the acute hospital phase. Treatment with an automatic implantable cardioverter-defibrillator

(ICD) should generally be considered to be mandatory following a clinical event such as resuscitation from cardiac arrest. An exception is the acute phase of myocardial infarction. If VT/VF occurs within the first 48 hours of a transmural acute myocardial infarction, then the long-term risk of sudden cardiac death for a given patient is not increased compared with that in other similar patients.[17–19]

Other rhythms during cardiac arrest and resuscitation

Pulseless electrical activity (PEA) is defined as cardiac electrical activity in the absence of any palpable pulses. It occurs not only in cases without a primary cardiac cause, but also in patients with very severe underlying myocardial disease. If PEA or asystole is seen, or even if bradycardic rhythms are present, antiarrhythmic agents should be avoided because of their side effects including negative inotropic effects and further exacerbation of bradycardia and asystole. Intravenous administration of atropine (3 mg) is recommended,[3] because its strong vagal blocking effect offers a clear benefit in bradycardia, and an occasional apparent beneficial effect in an asystolic patient. Human studies have failed, however, to demonstrate a systematic advantage in cardiac arrest with PEA or asystole.[20,21] Similarly, the phosphodiasterase inhibitor aminophylline has shown some positive clinical effects in asystole, but cannot be generally recommended on the basis of the available clinical evidence.[22–24]

Amiodarone treatment during cardiac arrest and resuscitation

Amiodarone is an antiarrhythmic drug with multiple complex actions that may potentiate each other. It is one of the most powerful antiarrhythmic drugs both at atrial and ventricular levels. It is highly lipophilic and has a very long half-life. It prolongs the cardiac action potential and the QT interval on the surface ECG (Class III in the Vaughan-Williams classification), and in addition exerts conduction-prolonging effects (Class I), non-competitive beta-blocking activity (Class II), and calcium antagonism (Class IV). A central line should be available for intravenous use, because the solvent (polysorbate 80) is an irritant as well as having some antiarrhythmic and negative inotropic activity of its own.

The amiodarone in resuscitation of refractory sustained ventricular tachyarrhythmias (ARREST) study,[25] was the first to investigate an antiarrhythmic drug in a double-blind placebo-controlled trial in the setting of cardiac arrest. In this study, patients with shock-refractory ventricular fibrillation were given amiodarone or matching placebo during continued CPR efforts. Three shocks were delivered before randomization. Survival to discharge was similar in both groups (13.4% vs. 13.2%, *P=NS*, see Fig. 36.2), but there was a highly significant advantage in survival to hospital admission (44% vs. 34%, *P*= 0.03).

A second important randomized study, the amiodarone vs. lidocaine in prehospital ventricular fibrillation evaluation trial (ALIVE)[26] randomized 347 patients with cardiac arrest and ventricular fibrillation to lidocaine or amio-

	All patients	VF	Asystole of PEA converting to VF	ROSC	No ROSC
No. Surviving/Total No.	108/246 89/258	101/205 84/216	7/41 5/42	35/55 22/53	73/191 67/205
Fig. 36.2. The ARREST trial: effect of treatment with amiodarone on survival to hospital admission in all patients and subgroups of patients. VF = ventricular fibrillation, PEA = pulseless electrical activity, ROSC = return of spontaneous circulation before the study. (From ref. 25, with permission.)

darone given intravenously. With a primary endpoint of survival to hospital admission, a clear advantage for amiodarone was found for the main study population but also within many subgroups. For example, patients with asystole recorded as the initial rhythm and ventricular fibrillation later showed a benefit similar to patients with ventricular fibrillation as the initial rhythm on the scene. Survival to admission in the amiodarone-treated patients was 23% compared with 12% in patients treated with lidocaine ($P =$ 0.009)(see Fig. 36.3). Survival to discharge, however, was only 5% and 3%, respectively, in the two groups ($P =$NS). The results of this study significantly changed the practice of using lidocaine as the primary antiarrhythmic agent in patients with cardiac arrest and ventricular fibrillation.

Thus, conclusion from the ARREST and ALIVE trials is that for refractory ventricular fibrillation the administration of intravenous lidocaine may be an alternative only if amiodarone is not available at the resuscitation scene. Importantly, however, the data do not show a survival benefit for amiodarone beyond hospital discharge. Consequently, administration of amiodarone during resuscitation is considered useful but not mandatory, and the decision is at the discretion of the emergency physician. Since data were accumulated in patients with VF refractory to three shocks, they may not apply to VF resistant to a single shock. The 2005 ILCOR consensus[3] recommends amiodarone as a possible and useful antiarrhythmic agent in shock-refractory VF. Lidocaine, however, is not recommended in the consensus document.

The administration of amiodarone or other antiarrhythmic agents should not interfere with other CPR efforts. In addition to the advantages shown in the randomized studies, amiodarone may have theoretical advantages in cardiac arrest patients. First, it has no negative inotropic action in contrast to Class I antiarrhythmic agents (although its solvent does); and secondly it is not a vasodilator, unlike procainamide, for example.

Treatment with other antiarrhythmic agents

Lidocaine

Lidocaine is an antiarrhythmic agent with Class Ib action that prolongs conduction and has a membrane-stabilizing effect without a major influence on the cardiac action potential. Because of its ease of administration, its rapid onset and short action, and a good side effect profile, it was previously considered the antiarrhythmic agent of first choice in patients undergoing resuscitation from cardiac arrest due to ventricular fibrillation. This widely

accepted practice was first questioned by a meta-analysis of a number of previous studies of lidocaine in this setting.[27] In a subsequent study by Weaver *et al.*[28] 199 patients with prehospital cardiac arrest due to ventricular fibrillation were randomized to lidocaine 100 mg vs. adrenaline (epinephrine). Initial resuscitation and discharge alive from the hospital were not significantly different in this study. Interestingly, the number of patients discharged from the hospital alive was higher if *no* pharmacologic therapy was administered between repetitive defibrillation shocks in these patients.

Procainamide and bretylium

Because procainamide is an antiarrhythmic agent that prolongs action-potential activity (class III of the Vaughan Williams classification), it should not be given in addition to amiodarone. Another disadvantage is that it can only be infused slowly at a rate of 30 mg/min. Although procainamide has major antiarrhythmic activity, clinical evidence is at best anecdotal and not nearly as strong as that for amiodarone. Previously the guidelines recommended procainamide as an alternative agent if amiodarone is unavailable, but the new ILCOR consensus[3] no longer includes it. Similarly, bretylium (also with class III antiarrhythmic action), which had been widely used in the United States for the treatment of ventricular fibrillation is no longer recommended for lack of favorable evidence.

Intravenous administration of magnesium

Magnesium plays a role in many enzyme systems, for neurochemical transmission, and for myocardial contraction. The acute administration of intravenous magnesium may therefore exert a number of beneficial effects in the patient with VT/VF. There is a direct beneficial effect on afterdepolarizations associated with QT prolongation that can precipitate torsades de pointes type of arrhythmias, and in arrhythmias caused by digitalis toxicity. There may also be stabilizing effects in arrhythmias due to hypokalemia and hypomagnesemia, both of which occur quite frequently in resuscitated patients. The only transient side effect may be hypotension. In several controlled and randomized trials in the cardiac arrest setting, magnesium has failed, however, to demonstrate a clear-cut clinical advantage except for one study in shock-refractory VF[29–32]. Therefore, the new ILCOR consensus[3] recommends intravenous magnesium only for torsades de pointes arrhythmias, in arrhythmias due to digitalis toxicity, and in VT/VF that is shock-refractory or due to possible hypomagnesemia.

No. surviving/Total no
	All patients	Initial rhythm VF	Initial rhythm asystole or pulseless electrical activity	Return of spontaneous circulation	No return of spontaneous circulation
Amiodarone	41/80	35/141	4/34	10/24	31/156
Lidocaine	20/167	16/134	1/27	3/11	17/156

Fig. 36.3. The ALIVE study: effect of treatment with amiodarone or lidocaine on survival to hospital admission in all patients and in selected subgroups. VF = ventricular fibrillation. (From ref. 26, with permission.)

Effects of concomitant adrenaline and vasopressin treatment

Vasopressor agents such as adrenaline or vasopressin, which may be used concomitantly with antiarrhythmics, may influence their efficacy or have proarrhythmic effects. Notably, high dose adrenaline does not compare favorably with conventional doses when given for cardiac arrest outside the hospital.[33] These data should be considered together with the study by Weaver et al.[28] that showed no benefit from adrenaline or lidocaine treatment during cardiac arrest. Since patients receiving no drugs showed improved survival, it was concluded that the delay in resuscitation efforts caused by drug preparation and drug administration was detrimental.

A recent randomized study by Wenzel et al.[34] compared the effect of intravenous vasopressin and intravenous adrenaline in 1219 patients with prehospital cardiac arrest. Overall, there was a similar survival in the two groups; but in a post-hoc subgroup analysis of those with asystole, survival to admission (29% vs. 20%) as well as survival to discharge (4.7% vs. 1.5%) was significantly improved by vasopressin compared with adrenaline. Furthermore, if patients were treated with additional non-randomized adrenaline after

the trial vasopressin, there was also a survival benefit both to admission (26% vs. 16%, P=0.002) and survival to discharge (4.7% vs. 1.5%, P=0.002) suggesting that the combination of the two drugs is potentially useful.

Vasopressin is a non-adrenergic vasopeptide with significant vasoconstricting activity that might be responsible for a lower incidence of arrhythmias during resuscitation efforts.

Cardiac arrest and resuscitation in ICD patients

Although the ICD was designed specifically to detect and to provide immediate treatment for malignant ventricular arrhythmias, these devices cannot prevent their occurrence.[35] Even when they are in place, repetitive arrhythmias may be associated with a high mortality,[36] and therefore immediate antiarrhythmic treatment and admission to an intensive care monitoring unit is justified before cardiac arrest and the need for resuscitation is reached. The term "electrical storm" or "arrhythmic storm" has been defined as a series of two or more shocks for different arrhythmic episodes within any 24 hours. The situation is similar to shock-refractory cardiac arrest discussed above. Generally, intravenous amiodarone is recommended,[37–39]

while class I antiarrhythmics may be detrimental. The administration of beta-blockers has also proved to be useful if the hemodynamic state permits their use.[38]

Acute treatment of supraventricular arrhythmias

On rare occasions, supraventricular arrhythmias may play an important role in cardiac arrest. For this reason, the 2000 guidelines called for cardioversion of patients with narrow complex supraventricular tachycardia at a rate of more than 250 bpm. Such underlying rhythms may be explained by atrial flutter with 1:1 conduction to the ventricles, by fast AV reciprocating tachycardias in patients with accessory pathways, and by fast AV nodal reentry tachycardias. In the absence of a bypass tract, atrial fibrillation is unable to generate such rapid ventricular rates. No definite rate, however, is set as a marker in the European Resuscitation 2005 guidelines:[40] the markers of instability relate to consciousness levels, hypotension, failure, or cardiac pain. Supraventricular arrhythmia may also present as broad complex tachycardia as a result of aberrant conduction or pre-existing bundle branch block, and constitute an important differential diagnosis to ventricular tachycardia. If a broad complex tachycardia is seen in an emergency setting with acute hemodynamic compromise, however, time should not be wasted in attempting to differentiate between SVT and VT: instead, ventricular tachycardia should be assumed and the appropriate algorithm should be followed. If, however, the rate is less than 250 bpm in suspected SVT and hemodynamic collapse has not yet occurred, vagal maneuvers such as the Valsalva maneuver or carotid massage may be attempted. Such treatment may terminate the arrhythmia directly or slow the rate and thereby unmask the underlying rhythm. If unsuccessful, intravenous adenosine in increasing doses is the agent of choice and is recommended in the 2005 consensus document.[3] The administration of adenosine will result in the prompt termination of the SVT (AVNRT, AVRT) at no major risk because of the short half-life of the agent, or at least provide a clue to the diagnosis. As an alternative to intravenous adenosine, the consensus document also mentions verapamil or diltiazem if adenosine is not successful, and cardioversion if the patient is unstable. Where the rates of SVT are sufficiently slow to permit hemodynamic stability, the use of i.v. beta blockers, digoxin, or amiodarone may also be appropriate.

Summary

Amiodarone has several advantages as an antiarrhythmic agent for use during cardiac arrest. Importantly, it improves survival to hospital admission, although it has not been shown to have a survival advantage to discharge. Other antiarrhythmic drugs may also be used empirically on an individual basis. Lidocaine has the advantages of ease of use and wide availability. Magnesium has beneficial actions without doing harm and can be useful in some situations. Procainamide and bretylium have little scientific support and should no longer be used. The administration of antiarrhythmics should never be allowed to hinder other resuscitation efforts. As a vasopressor agent, vasopressin has the advantage of lack of proarrhythmic activity, but its role has not yet been well defined.

Introduction

Both respiratory (hypercarbic) and metabolic acidosis are important components of cardiac arrest pathophysiology, and resuscitation measures aim to ameliorate or to counteract their potentially harmful effects. The acid–base derangements of cardiac arrest and CPR are exceptionally complicated because of the distinctive kinetics of carbon dioxide during the low-flow state of CPR. On the basis of this physiology, far-reaching hypotheses regarding buffer therapy in general and bicarbonate in particular have been considered and have profoundly affected clinical practice for the past two decades. These hypotheses, however, have not been substantiated by firm published data, resulting in rather ambiguous official recommendations and an atmosphere of uncertainty in the field.

The main objectives of this chapter are to discuss the complicated acid–base derangements of cardiac arrest and CPR and their effects on critical body systems, and to clarify ambiguities regarding buffer therapy.

The discussion in this chapter is limited to acid–base considerations in the context of cardiac arrest and CPR, and not in other contexts of metabolic acidosis, such as hypoxia with adequate tissue perfusion, shock, or ketoacidosis. Despite some similarities, the pathophysiology of these conditions differs markedly from that of cardiac arrest and direct extrapolation might lead to erroneous conclusions.

Historical perspectives

In their original 1961 "Report of Application of External Cardiac Massage in 118 Patients"[1] Jude, Kouwenhoven and Knickerbocker wrote: "Continued cardiac arrest, even though the circulation is artificially maintained, will result in metabolic acidosis. Sodium bicarbonate is beneficial in maintaining blood pH close to the normal value . . ." Since the accompanying metabolic acidosis was believed to be detrimental to outcome, sodium bicarbonate (SB) – the prime representative of buffer therapy – has become part of the basic therapeutic armamentarium of modern CPR. Subsequently, SB was introduced in 1974 as a first line drug in the first Standards for Cardiopulmonary Resuscitation and Emergency Cardiac Care of the American Heart Association.[2]

Reservations about the necessity, efficacy, and side effects of SB and a newly drafted hypothesis on the kinetics of carbon dioxide in very low-flow states resulted in a rather drastic change towards the use of SB in the 1986 update of the Standards and Guidelines for CPR and ACLS.[3] The "low-flow state" hypothesis postulated that the very limited tissue perfusion generated by external cardiac massage is insufficient to transport all of the CO_2 produced from the tissues to the lungs. Hence, CO_2 remains "trapped" at the tissue level, and tissue perfusion – rather than alveolar ventilation – limits its elimination. It was further hypothesized that the administration of "CO_2 producing" buffers, such as SB, will further increase tissue CO_2 concentrations, and CO_2 molecules will rapidly diffuse into the cells, cause "paradoxical" intracellular acidosis and thus might worsen CPR outcome.[3–7] This attractive, although (at best) only partially substantiated hypothesis, prompted the 1986 Guidelines no longer to recommend the use of SB, but rather left its use to "the discretion of the team leader".[3]

This approach was only slightly modified in the 1992 version of the AHA ACLS Guidelines[8] and by the 1998

European Resuscitation Council Guidelines.[9] The 2000 International ACLS Guidelines did not offer any new discussion of buffer therapy and this section was basically copied from the 1992 version.[10]

Thus, the 2000 Guidelines regarding buffer therapy state: "In certain circumstances, such as patients with pre-existing metabolic acidosis, hyperkalemia, or tricyclic or phenobarbitone overdose, bicarbonate can be beneficial. After protracted arrest or long resuscitative efforts, bicarbonate possibly benefits the patient. However, bicarbonate therapy should be considered only after confirmed interventions, such as defibrillation, cardiac compression, intubation, ventilation and vasopressor therapy, have been ineffective".[10]

Acid–base changes during cardiac arrest and CPR

Definitions of acid–base changes

Acidity of the blood (and of other body fluids) is customarily expressed as pH, which represents the negative logarithm of the measured hydrogen ion, or proton, concentration $[H^+]$. $[H^+]$ can also be conveniently expressed in nanomoles (10^{-9} mol) per liter. Normal values of arterial pH and of $[H^+]$ are 7.42 ± 0.04 and 40 ± 4 nmol/l, respectively. Any increase in measured blood $[H^+]$ (i.e., a decrease in blood pH value) is termed acidemia, and any decrease in blood $[H^+]$ (i.e., an increase in its pH) is termed alkalemia. Acidosis and alkalosis are the processes that change hydrogen ion concentrations: acidosis will increase, whereas alkalosis will decrease $[H^+]$.

Respiratory processes change $[H^+]$ through changes in carbon dioxide concentrations (conveniently expressed as PCO_2). Thus, any increase in PCO_2 (normal arterial values are 40 ± 4 torr) will be interpreted as respiratory acidosis, and any decrease in PCO_2 as respiratory alkalosis.

Metabolic changes in $[H^+]$ are mediated through changes in fixed (non-volatile) acids or bases. Conventionally, metabolic processes are assessed by the readily calculated value of bicarbonate ion concentration $[HCO_3^-]$. Such a straightforward assessment is inaccurate, however, since $[HCO_3^-]$ is also directly influenced by changes in PCO_2. According to the formula

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$
every molecule of CO_2 that reacts with H_2O will produce one ion of HCO_3^- (and one H^+). This represents a respiratory, rather than a metabolic, change in HCO_3^-. Several methods were devised to dissociate the respiratory effects from the "true" metabolic effects on HCO_3^-, one of which is the calculation of base excess (BE).[11,12] Although BE has been recently criticized,[13,14] it can be conveniently used in the cardiac arrest/CPR scenario as it is automatically calculated with every blood gas analysis. "Normal" BE is 0 ± 2 mmol/L: a positive BE denotes metabolic alkalosis and a negative BE ("base deficit") denotes metabolic acidosis.

Nature of acidosis of cardiac arrest and CPR and its rate of development

CO_2 and lactic acid are the predominant determinants of extra- and intracellular pH during CPR. Extracellular HCO_3^- (such as $NaHCO_3$ intravenously) increases intracellular pH only after some delay because of its slow distribution by low blood flow and the transfer time from the blood into the intracellular space.

Metabolic (lactic) acidosis in the cardiac arrest setting

At what rate does significant metabolic (lactic) acidosis develop during arrest and CPR? This question is not academic as it has a direct impact on the issue of buffer therapy and its timing.

The development rate of lactic acidosis depends on both severity and duration of tissue hypoxia. During circulatory arrest, acids remain confined to the tissues, and will not be detected in peripheral blood.[15–18] Only after the establishment of at least some tissue perfusion by CPR or after return of spontaneous circulation (ROSC), will acidemia be detected in peripheral blood.[15–18] The magnitude of the detected acidemia depends on the degree of tissue acidosis, the rate of acid washout, and the timing of blood sampling. These complicated dynamics partly explain the marked variability in the reported data about both severity of metabolic acidosis and the effectiveness of buffer therapy in treating it.[15]

Retrospective clinical studies reporting acid–base data are difficult to interpret as major variables, such as "downtimes," location of arrest, duration and quality of CPR, buffers administration, and timing of blood sampling, were not controlled. During in-hospital resuscitations with relatively short response times, rapid increases in serum lactate[19] and in the metabolic component of acidosis[20] were observed. Serum $[HCO_3^-]$ of 14–15 mmol/l and $[H^+]$ of 68–85 nmol/l were found in patients undergoing CPR in the emergency department, even though most patients received large bicarbonate doses within 10 minutes of CPR.[21] Children presenting to the emergency department in respiratory or cardiac arrest had

initial mean arterial pH values of 7.05 and base deficits of −15 mmol/l in survivors, and 6.94 and −18 mmol/l, respectively, in non-survivors.[22]

More rigorous data were provided by controlled laboratory experiments. pH values < 7.10 and base deficits of −17 mmol/l were demonstrated after 10 minutes of ventricular fibrillation (VF) and 5 minutes of CPR.[17] Serum base deficits increased by 1.1 to 1.5 mmol/l for every minute of circulatory arrest.[17,18,23,24] Arterial lactate increased by 0.3 mmol/l for every minute of cardiac arrest and CPR when epinephrine was used,[17,24] and by almost 0.6 mmol/l when epinephrine was not used.[23] In the fibrillating heart, myocardial lactate concentrations, as reflected in great cardiac vein blood, increased approximately three times faster than systemic lactate concentrations.[16,23,25] Myocardial lactate increased about tenfold in 10 minutes of untreated VF.[26]

Carbon dioxide and acid–base physiology during the low-flow state of ACLS

In 1976, Bishop and Weisfeldt[27] showed in a canine model that arterial pH could be maintained at approximately normal levels during the initial 13 minutes of cardiac arrest and CPR with hyperventilation to a $PaCO_2$ of around 15 torr. Similarly, Sanders *et al.*[28] documented almost normal arterial pH during the initial 18 minutes of ventricular fibrillation (VF) and CPR by hyperventilating dogs to $PaCO_2$ values of 10 to 18 torr.

Subsequently, Weil and his group highlighted the exceptional acid–base and carbon dioxide dynamics during the very-low-flow state of CPR. In a porcine model, Grundler *et al.*[5] demonstrated that arterial pH remained alkalemic during 11 minutes of cardiac arrest and CPR by maintaining $PaCO_2$ of 20–23 torr. Nevertheless, mixed venous blood disclosed pH values lower by 0.27–0.3 units compared to prearrest and to the concurrent arterial values. These differences were mainly due to increases in venous PCO_2, resulting in widening of the veno-arterial PCO_2 differences to 34.2–39.4 torr.[5]

The same investigators supported these experimental findings with clinical observations in a group of 16 patients during CPR.[29] Over a median interval of 23 minutes from onset of cardiac arrest and blood sampling, the patients received on average 130 meq of SB. At the time of sampling, arterial pH and PCO_2 averaged 7.41 and 32 torr, respectively, while mixed venous pH and PCO_2 averaged 7.15 and 74 torr, respectively. Calculated bicarbonate concentrations were equal in arterial and venous samples. Thus, arterial blood tended towards alkalemia and venous blood showed acidemia.

These findings were explained by the unique physiology of the "very low flow state":[6,10,29] with normal or moderately reduced tissue perfusion, CO_2 elimination depends only on alveolar ventilation; whereas under conditions of very low flow, tissue perfusion becomes the rate-limiting step of CO_2 elimination. External chest compressions generate at best only 25%–30% of normal cardiac output,[30,31] insufficient to carry all of the produced CO_2 to the pulmonary circulation. CO_2 remains partly "trapped" at the tissue level, and the increased tissue PCO_2 is reflected as increased venous PCO_2 ($PvCO_2$). Pulmonary blood flow and CO_2 transport to the lungs are very low, as detected by decreased end-tidal CO_2.[32–34] The high ventilation:perfusion ratio leads to arterial hypocarbia and to elevated arterial pH,[29,35–38] which further widens the veno-arterial differences. This phenomenon of hypercarbic venous acidemia coincident with normo- to hypocarbic arterial alkalemia was termed the "arterio-venous paradox."[5,29]

This phenomenon was subsequently demonstrated in other clinical studies[39] and in various models of cardiac arrest and CPR[18,23,37,38,40] (Fig. 37.1), and was investigated thoroughly by Adrogue *et al.*[35,36] The phenomenon was also observed, but to a somewhat lesser degree, in dogs during hemorrhagic shock.[41,42] In an experimental model of progressive pericardial tamponade, arterial-venous pH and PCO_2 gradients increased proportionally with the reduction in cardiac output.[43] Venous hypercarbia developed
Fig. 37.1. Relationship of the arteriovenous CO_2 gradient and cardiac index follows the form of a modified Fick equation. (From ref. 38. Copyright Williams & Wilkins.)

during septic shock with systemic hypoperfusion.[44–46] By using tissue electrodes, tissue hypercarbia was demonstrated during shock in the kidney,[46,47] liver, and brain.[46] In the myocardial circulation, cardiac venous PCO_2 and the cardiac venous to arterial PCO_2 differences were greater than were the concurrent systemic differences.[16,23,25,48]

Of note, however, there is nothing really "paradoxical" about this phenomenon, and it can be accurately predicted by the Fick principle.[15,40] Tissue and venous hypercarbia are common pathophysiological phenomena, and basically characterize any global or regional ischemia.[38,40,49] The magnitudes of the veno-arterial pH and PCO_2 gradients are inversely related to the cardiac output[18,38–40] (Fig. 37.1) and they may actually provide an index of the severity of the perfusion defect.[35,36,38,39,49]

Of note, in CPR animal models, markedly increased $PvCO_2$ and veno-arterial PCO_2 gradients were observed mainly when no epinephrine was used and tissue perfusion pressures were extremely low.[5,50–53] When epinephrine or other measures were used to produce higher perfusion pressures, P_vCO_2 increased only moderately.[17,54–56]

Hypothesis regarding bicarbonate and other alkalinizing agents in the low flow state

On the basis of these observations, Weil's group postulated a far-reaching, encompassing hypothesis regarding buffer therapy during CPR.[4,5,16,29,57] The hypothesis consisted basically of four consecutive elements: (1) During the very low flow state of CPR, CO_2 elimination is determined mainly by tissue perfusion rather than by alveolar ventilation. (2) SB administration will result in excessive carbon dioxide production, which cannot be eliminated effectively and will accumulate in the tissues. (3) As CO_2 penetrates cellular membranes more rapidly than bicarbonate ions, it will accumulate intracellularly and will paradoxically aggravate intracellular acidosis by enhancing its hypercarbic ("respiratory") component. (4) Intracellular (myocardial) hypercarbic acidosis is detrimental and therefore SB administration might worsen CPR outcome.[3–10,16,29,57,58]

In the mid-1980s this hypothesis triggered the controversy around the use of SB and had a profound clinical impact, causing a sharp decline in the utilization SB in both out- and in-hospital resuscitations. In the early 1980s, SB was the most frequently used medication during CPR – administered to 84.7% of patients undergoing in-hospital CPR.[59] Aufderheide et al. found a 79.9% bicarbonate usage rate among resuscitated patients in a single emergency medical service during 1982–1984.[60] In a large, multicenter clinical trial performed between 1989 and 1992, Bar-Joseph et al. reported that SB was administered in only 54.5% of the resuscitations,[61] and its usage rate by the various study sites ranged between 3.9% and 98.3% of CPR attempts.[62] Levy et al. audited SB usage for CPR in a single district hospital in England, and found that it decreased progressively from 1986 to no usage at all by 1991.[63]

Nevertheless, as will be described later (Buffer Therapy in CPR), steps 2, 3, and 4 of this far-reaching hypothesis were not really supported by the available evidence, which points out that SB either increases or does not decrease intracellular pH and that it does not worsen CPR outcome.

Role of (arterial) blood gas monitoring during CPR

Historically, arterial blood gas (ABG) determination during CPR was recommended, as it may provide information on the adequacy of ventilation and oxygenation, the magnitude of metabolic acidosis, and an indirect estimate of tissue perfusion. Our current understanding of the pathophysiology of the low-flow-state, however, has greatly modified the practical value of ABG determination.

The high pO_2 measured in ABGs in patients ventilated with supplemental oxygen does not reflect tissue hypoxia and the very low venous pO_2.[21,23,29,35]

Although ABGs accurately reflect "adequacy" of ventilation in arterial blood,[64] they do not reflect conditions at the tissue level, as evidenced by the large differences between arterial and venous values of PCO_2 and pH because of the low tissue perfusion and the high ventilation:perfusion ratios characterizing CPR.[5,16,21,23,25,29,39]

Arterial PCO_2 was shown to correlate well with end-tidal CO_2 ($EtCO_2$) which in turn correlates with coronary perfusion pressure – the major determinant of tissue (myocardial) perfusion.[65,66] It was therefore thought that $PaCO_2$ could provide an indirect estimate of the perfusion generated during CPR. Although $PaCO_2$ correlated well with $EtCO_2$ during CPR in animals,[65] it did not correlate well in humans.[67] Furthermore, while in some animal studies $PaCO_2$ correlated to a certain degree with coronary perfusion pressure,[65,68,69] Barton et al.[70] failed to demonstrate such a positive correlation in humans undergoing CPR, and $PaCO_2$ could not differentiate between resuscitated and non-resuscitated patients. Thus, ABGs apparently do not provide a useful estimate of tissue perfusion.

What about metabolic acidosis? We are used to thinking of serum bicarbonate [HCO_3^-] as the marker of metabolic acidosis. [HCO_3^-] changes by 1 to 2 meq/l for every 10 torr change in PCO_2. The markedly elevated venous PCO_2, "elevates" the calculated venous [HCO_3^-] and the arteriovenous [HCO_3^-] differences are numerically less

prominent than the PCO_2 differences.[16,21,23,25,35,40,71,72] This "respiratory" contribution may be misleading if we regard $[HCO_3^-]$ as the only marker of metabolic acidosis. This phenomenon was even more prominent in the coronary venous blood, where despite extreme combined acidosis (pH 6.62 and 6.75, lactate 7.6 and 8.2 mmol/l) and extreme hypercarbia (PCO_2 177 and 150 torr), the $[HCO_3^-]$ values were 18 and 20 meq/l.[25]

Base excess (or deficit), on the other hand, provides a straightforward estimate of the metabolic component of the acid–base imbalance and it does not vary markedly between arterial and venous blood.[54,73,74] Base excess was shown to be an excellent predictor of resuscitability in dogs undergoing CPR.[17]

Lactate concentrations are equal in arterial and in mixed venous blood.[16,23,25,52,75] Many modern blood gas analyzers measure lactate concentration. Nevertheless, changes in blood lactate are also flow-dependent and do not necessarily reflect concurrent tissue concentrations. It should be kept in mind that the physiologic effects of (metabolic) acidosis are determined by H^+ ion concentrations and the lactate anion has no significant physiologic effect. H^+ ion concentration is obviously affected by other factors, such as ventilation, natural buffer systems, and buffer therapy. Therefore, the clinical applicability of "lactate concentration" during CPR is rather limited (Fig. 37.2).

Thus, the use of ABGs to monitor or guide therapy during CPR is of very limited, if any, clinical value, as they do not reflect tissue hypoxia, pH, or PCO_2. The question of whether the measurement of ABGs has any effect on the clinical management of CPR or on CPR outcome, however, was never subjected to a proper clinical trial.

Effects of acidosis on critical organs – is the acidosis of cardiac arrest detrimental?

This is a highly controversial question. On the one hand, intuitively and "teleologically," the answer should be "yes": if our organism functions optimally at an extracellular $[H^+]$ of 40 nmol/l, and exquisite mechanisms are utilized to maintain it within a very narrow range, why should it be expected to function even better (i.e., resume sinus rhythm and effective spontaneous circulation) under the extremely unfavorable conditions of both tissue hypoxia and much higher acidity? As mentioned, this was the basic approach during the first 25 years of modern CPR.

On the other hand, researchers have claimed that acidosis is not detrimental,[76] and may even be protective.[7,57,77]

This ambiguity is seemingly reflected in the text of the 2000 Guidelines,[8,10] which state that "laboratory and clinical data fail to conclusively show that low blood pH adversely affects ability to defibrillate, ability to restore spontaneous circulation, or short-term survival. Adrenergic responsiveness also appears to be unaffected by tissue acidosis."[10] The same Guidelines, however,
Fig. 37.2. Correlation between great cardiac vein PCO_2 and lactate. (Adapted from ref. 48. Copyright American Physiological Society).

recommend bicarbonate (Class IIa recommendation) for pre-existing metabolic acidosis and upon return of spontaneous circulation[78] – apparently because metabolic acidosis is considered harmful. Furthermore, the postulation that bicarbonate paradoxically worsens intracellular acidosis (and therefore outcome) is obviously based on the premise that acidosis is harmful and will impede resuscitation.

The ambiguity surrounding the potential detrimental effects of acidosis in CPR has several sources. One is the inability to differentiate precisely the detrimental effects of hypoxia from those of acidosis. Second, attempts to resolve the issue in experimental studies by comparing the effects of buffers to those of placebo yielded equivocal results, as they depend largely on the model and study design (see below, under "Buffer therapy in CPR").

The following discussion of the effects of acidosis in cardiac arrest and CPR will concentrate mainly on the two major "target organs" – the heart and the brain.

Cardiac acid–base changes

Myocardial acidosis

During CPR, anaerobic myocardial metabolism generates hydrogen ions, CO_2, and lactate. Myocardial CO_2 accumulation stems from local CO_2 production, dissociation of endogenous myocardial bicarbonate when buffering anaerobically generated hydrogen ions, and from reduced clearance of CO_2 due to low blood flow. Therefore, intramyocardial CO_2 ($PmCO_2$) increases when coronary blood flow (CBF) is impaired and is negatively correlated to the coronary perfusion pressure (CPP) during CPR (Fig. 37.3).

Capparelli et al.[23] and Gudipati et al.[48] demonstrated that changes in the cardiac venous pH and PCO_2 are much more prominent than the concurrent changes in mixed venous blood. After 5 minutes of VF and 7 minutes of CPR, great cardiac vein pH declined from 7.3 to 6.7 and PCO_2 increased from 50 to 140 mmHg with marked increases in the arterial-coronary vein pH and PCO_2 gradients.[48] After ROSC, cardiac venous pH and PCO_2 returned to near normal levels within minutes. It was hypothesized that such high CO_2 levels may reflect an even more profound acidosis within myocardial tissue.[16]

This was indeed confirmed by von Planta et al.[16] who used a miniature electrode to measure intramyocardial tissue pH. Following 3 minutes of untreated VF and 8 minutes of CPR, intramyocardial pH declined from 7.27 to 6.88, and returned to pre-arrest levels 60 minutes after ROSC.
Fig. 37.3. The relationship between myocardial PCO_2 and coronary perfusion pressure (CPP) documented a critical threshold for myocardial PCO_2 of approximately 400 torr and for CPP of approximately 10 mmHg which predicted failure of successful resuscitation. (From ref. 25. Copyright Williams & Wilkins).

Subsequently, Kette et al.[25] measured both myocardial pH and $PmCO_2$ in the same model. Myocardial pH decreased to 7.05 and $PmCO_2$ increased to 97 torr following 3 minutes of untreated VF. Eight minutes after initiation of CPR, myocardial pH declined further to 6.38 and $PmCO_2$ increased to 346 torr. $PmCO_2$ returned to normal levels 30 minutes after ROSC (Fig. 37.4).

Lactate production is the second cause of myocardial acidosis. In the same VF models, great cardiac vein lactate increased approximately three times faster than systemic lactate.[16,23,25,48] Myocardial content of lactate increased about tenfold by 10 minutes of untreated VF.[26]

With initiation of chest compressions, a sharp increase in lactate concentration is observed, reflecting myocardial washout of lactate. Subsequently, cardiac venous lactate concentrations, as well as PCO_2, increase slowly and tend to reach a plateau.[16,25,48,50] Possibly the minimal perfusion and oxygenation generated by CPR result in partial aerobic metabolism, mitigating further lactate production. That CO_2 and H^+ continue to accumulate in the myocardium[25] supports this possibility of incomplete myocardial ischemia.

Coronary perfusion pressure, myocardial acidosis and resuscitability

Myocardial blood flow correlates closely with CPP which is considered the most important determinant of cardiac resuscitability.[79] CPP levels above 20 mmHg in dogs,[80] 20 mmHg in rats,[81] 10 mmHg in minipigs,[51,52] and 15 mmHg in human patients[82] predicted outcome. Kette et al. showed an inverse correlation between CPP and $PmCO_2$, and
Fig. 37.4. Marked hypercarbia is associated with low pH levels within the myocardium. Restoration of spontaneous circulation is followed by prompt return of pH and PCO_2 to normal levels. (Adapted from ref. 25. Copyright Williams & Wilkins).

demonstrated a threshold level of CPP and $PmCO_2$ for ROSC in pigs[25] (Fig. 37.3): resuscitated animals had CPP >10 mmHg and $PmCO_2$ <400 torr, while non-resuscitated animals had CPP <10 mmHg and $PmCO_2$ >400 torr.

Likewise, MacGregor *et al.*[83] demonstrated in a canine anoxic arrest model, a critical $PmCO_2$ threshold of 416 torr as predicting failure of cardiac resuscitation.

Effects of acidosis on the heart

Multiple adverse effects of severe acidosis – either hypercarbic ("respiratory") or metabolic – on cardiac function, resuscitability, and viability were reported and reviewed,[84–88] many of them relevant to the cardiac arrest/CPR scenario. It has been known for well over 100 years that acidosis decreases cardiac contractility.[89] Extensive review pointed out that acidosis interferes with almost every step in the excitation–contraction coupling, and that H^+ metabolism is intimately linked to the cellular handling of Na^+ and Ca^{2+}.[84] Acidosis can lead to arrhythmias, mainly to slow heart rates, by interfering with both pacemaker activity and the conduction system.[88,90] Recently, a direct correlation between low pH and induction of apoptosis in cardiac samples from human patients and porcine subjects was reported.[91]

Assessing the effects of acidosis on CPR outcome in uncontrolled, retrospective clinical studies is basically impossible, as the intensity of metabolic acidosis correlates directly with the duration and magnitude of tissue hypoxia, which determines CPR outcome. For this reason, the presence of acidosis or the need for buffer therapy was repeatedly found to be associated with worse CPR outcome.[92–96] In a prospective clinical trial, Tribonate® failed to improve

survival.[97] In a recent post-hoc analysis of the BRCT III trial data, SB use in association with epinephrine resulted in better resuscitability and long-term outcomes.[62]

In the laboratory, the effects of acidosis on hemodynamics, response to epinephrine, and resuscitability depend largely on the model.[98] The effects of metabolic and respiratory acidosis are not necessarily identical. Metabolic acidosis arising from cellular hypoxia during cardiac arrest differs substantially from acidosis induced by external administration of acids[98,99] or from hypoxic lactic acidosis with normal circulation.[100]

Gerst *et al.* showed that metabolic acidosis lowered the cardiac fibrillation threshold, whereas respiratory acidosis had no effect.[101] Defibrillation threshold was not affected by mild (pH < 7.25)[102] or moderate (pH = 7.12)[103] respiratory or metabolic acidosis induced by external administration of acid, although in the latter study fewer animals with metabolic acidosis resumed spontaneous circulation.[103] In isolated, perfused rat hearts, Morimoto *et al.*[104] found that extramyocardial metabolic acidosis (pH < 7.1) decreased resuscitability and cardiac performance after VF. No hearts recovered after perfusion below pH 6.5. Mandolano *et al.* found that hypercarbic acidosis, induced during reperfusion in a ventricular fibrillation model, reduced early resuscitability.[105] Administration of buffer during CPR improved resuscitability[17,54,55,106] and postresuscitation myocardial dysfunction.[107]

Response to catecholamines

Several reports have shown that, in states of acidosis, the ability of catecholamines to attenuate or reverse the

contractile impairment induced by acidosis is substantially reduced.[108–111]

In the cardiac arrest setting, the reports are equivocal: whereas one study[54] found higher systemic and coronary perfusion pressures in dogs treated with SB during CPR, others did not show an enhanced vasopressor effect of epinephrine following administration of buffers.[17,52,112]

These discrepancies may be explained by the model (spontaneously beating hearts vs. hearts in VF)[98], by the epinephrine dosage, or by the combination of hypoxia and acidosis. Preziosi *et al.*[113] found that induced metabolic acidemia had no effect on the hemodynamic response to epinephrine, but when animals were made hypoxic, acidemia attenuated the vasopressor response to epinephrine, which was restored only after correction of hypoxia.

Acid–base changes and the brain

Since the introduction of modern CPR in the 1960s, survival with good neurological activity of patients not responding to early defibrillation remains a most yearned for, but still unaccomplished goal.

Cerebral tissue pH and bicarbonate, as well as cerebrospinal fluid pH, decrease sharply after cessation of blood flow to the brain.[114,115] This occurs parallel to decreases in cerebral tissue pO_2, cerebral oxygen metabolic rate, and cellular adenylate charge (i.e., decrease in ATP and increase in AMP), and to increases in cerebral tissue lactate and Pco_2.[114–116] These processes depend mainly on the duration of the hypoxic-ischemic event and on its intensity (i.e., complete cessation of blood flow vs. variable degrees of low blood flow, such as those generated during CPR).[114,116]

An intriguing aspect of the acid–base status of the brain is concerned with the different permeability characteristics of carbon dioxide and bicarbonate ions through the blood–brain barrier.[117] This relates to the discussion of acid–base and buffer therapy in CPR, as cerebrospinal fluid (CSF) acid–base status is thought to represent intracellular acid–base status. This basic premise, however, may be wrong.[118,119]

An excellent review of pH-associated brain injury in cerebral ischemia and circulatory arrest was published by Hurn and Traystman.[120] Energy depletion is the most critically damaging event in brain ischemia/hypoxia. Protons (H$^+$) are generated in large amounts through hydrolysis of ATP, unbalanced by the normal uptake of H$^+$ during formation of new ATP in the creatine kinase reaction, and through (anaerobic) lactate production.

Intracellular brain pH (pHi) decreases to approximately 6.2 within 6 minutes[115,121] and to 6.0 by 10–12 minutes[122] of complete ischemia (circulatory arrest), and extracellular pH (pHe) decreases generally in parallel to pHi.[123]

Severe cerebral acidosis enhances ischemic brain damage,[124,125] and these effects are intensified by the "glucose paradox of cerebral ischemia":[126] as brain metabolism depends largely on glucose oxidation, increased tissue glucose content or continued glucose delivery to hypoxic, energy-depleted brain tissue exacerbates lactic acidosis. Originally, Siesjo's group[127,128] showed that a high blood glucose during hypoxia simultaneously decreased cerebral tissue pH and the cellular content of ATP, and Myers and Yamaguchi[129] showed that administration of glucose just before arrest markedly augments the severity of brain injury and alters its distribution.

It is now well established that hyperglycemia or increased tissue glycogen stores or the administration of glucose-containing solutions before, during, or after the ischemic insult (in both cardiac arrest and stroke models) result in significantly elevated cerebral lactate and lower tissue pH. This profound brain acidosis causes reduction of ATP synthesis and impaired energy metabolism,[130,131] endothelial and glial swelling,[132] and enhanced brain edema[132–134] which hampers postischemic perfusion and recovery of regional blood flow,[132,135,136] and worsens histopathologic damage[133,137] and neurological outcome.[134,138,139] In patients, a strong association exists between hyperglycemia and poor neurologic outcome following cardiac arrest[140,141] and stroke.[142,143]

The next question is whether buffer therapy can enhance recovery of brain acidosis and improve cellular function and neurological outcome. Restoration of circulation sets the stage for recovery of pHi and pHe by removing accumulated CO_2 and lactate and by providing oxygen to promote oxidative phosphorylation and ATP production.[144] ATP reactivates energy-dependent transmembrane ion exchange mechanisms, particularly H$^+$ extrusion by Na$^+$/H$^+$ exchange.[145] This high capacity antiporter system is operating below its maximal capacity when pHe is very low, as H$^+$ competes with Na$^+$ at the external side of the exchanger. Thus, measures that reduce pHe are expected to facilitate normalization of pHi.[145,146]

Buffers were shown to correct cerebral acidosis in various CPR models.[68,146–148] Using a pH/PCO_2 electrode, Liu *et al.*[148] confirmed that the profound acidosis developing during circulatory arrest was associated with a rapid increase of cerebral tissue PCO_2. Buffer (SB or Tribonate®) administration during CPR increased cerebral cortical blood flow during the initial reperfusion phase after ROSC, and prevented the development of secondary cerebral tissue acidosis during the subsequent period of low systemic perfusion pressure.

Hyperventilation to counteract metabolic acidosis

ACLS Guidelines[3,8,10] stressed the importance of "adequate alveolar ventilation," which, together with restoration of tissue perfusion "are the mainstays of control of acid–base balance during cardiac arrest." Guidelines also state that hyperventilation corrects respiratory acidosis by removing carbon dioxide, which is freely diffusible across cellular and organ membranes.[3,8,10] These statements imply that acidosis of cardiac arrest is mainly respiratory and not metabolic, and that hyperventilation can correct the entire acid–base derangements,[6,27,28,76,149] despite the official recommendation to ventilate at 12–15 times per minute.

Clearly, "adequate" ventilation can effectively eliminate CO_2 from the diminished blood flow reaching the pulmonary circulation. To correct arterial academia temporarily, Bishop and Weisfeldt, in their often-quoted study,[27] hyperventilated dogs to $PaCO_2$ below 20 torr. Sanders *et al.* "adequately" ventilated dogs to $PaCO_2$ of 10 torr[28] and Capparelli *et al.* to 16.6 torr.[23] Still, concomitant mixed venous pH and PCO_2 were 7.09 and 72 torr and cardiac venous pH and PCO_2 were 6.76 and 128 torr, respectively.[23] Thus, hyperventilation cannot correct whole body acidosis when tissue perfusion becomes the limiting step in CO_2 elimination.[15,68,69]

Moreover, hyperventilation may be deleterious during CPR: Aufderheide *et al.* observed that professional rescuers ventilated patients excessively during out-of-hospital CPR.[150] Subsequent animal studies demonstrated that similar excessive ventilation rates resulted in significantly increased positive intrathoracic pressures and markedly decreased coronary perfusion pressures and survival rates.[150] Aside from potential detrimental mechanical effects,[151] hyperventilation causes cerebral vasoconstriction and can reduce cerebral perfusion, which may be particularly deleterious in low flow states. This was demonstrated in traumatic brain injury,[152] and may also be applicable to the cardiac arrest victim. A human study suggested that cerebrovascular reactivity to changes in $PaCO_2$ is preserved in comatose adults following CPR.[153]

Buffer therapy during cardiopulmonary resuscitation

The discussion of buffer therapy during CPR should address several issues: first, is the metabolic acidosis detrimental? This issue was discussed above. Second, does buffer therapy improve CPR outcome? Third, is buffer therapy safe, especially with SB, as so many concerns about putative deleterious effects have been raised. And finally, how do various buffer agents compare in the context of CPR outcome?

Does buffer therapy improve CPR outcome?

An attempt to answer this question is severely hampered by the paucity of adequate clinical studies. Therefore, most of the evidence available is based on animal experiments, which varied markedly in their design. To appraise correctly their results careful attention should be paid to details such as arrest time, timing and dosage of buffer administration, the use of epinephrine, and other measures affecting tissue perfusion and outcome endpoints.

Clinical studies

No large, prospective randomized clinical trial (RCT) on buffers during CPR has ever been conducted.

Several retrospective studies attempted to analyze the outcome effects of buffers (mainly SB), administered in an uncontrolled fashion.[60,94–96,154,155] These studies were all inconclusive because of an inherent bias: patients who had longer resuscitation attempts and had worse outcome also received buffers more frequently. Thus, buffer administration was an epiphenomenon of prolonged arrest and CPR.

The only prospective RCT was published by Dybvik *et al.*[97] 502 patients received either Tribonat® (a mixture of SB, tromethanol, phosphate, and acetate, used frequently in Scandinavia) or normal saline during out-of-hospital CPR. Buffer therapy did not improve immediate resuscitability or long-term outcome. However, the response time in this study was short, only moderate acidosis was detected in both treatment arms on hospital admission, the number of patients was relatively small, and the odds ratio was very wide.[156]

Bar-Joseph *et al.* recently reported a post hoc analysis of bicarbonate usage among 16 emergency medical services (EMS) systems that participated in the BRCT III trial – a clinical trial that compared primarily standard-dose and high-dose epinephrine.[62] SB usage was optional and its usage rates and timing of administration varied widely among the EMS systems. A total of 2122 patients undergoing out-of-hospital CPR were analyzed. SB usage rates correlated inversely with the sites' timing of bicarbonate administration (Fig. 37.5). Study sites were divided according to their SB usage profile: "high SB user" sites administered SB in over 50% of CPRs and within 10 minutes of the first epinephrine dose, while "low SB user" sites administered SB in < 50% of CPRs and beyond 10 minutes of the first epinephrine. "High SB user" sites had significantly higher ROSC and hospital discharge rates and better long-term neurological outcome.

This study, however, was not a randomized controlled trial of buffer use, and it suffered from some expected limitations of a post-hoc analysis.[157] The information it provides can, and should, be used to set up a proper prospective clinical trial.[62,157]

Laboratory studies

At least eight animal studies demonstrated a clear beneficial effect of SB or other buffers on ROSC, post-resuscitation myocardial function, or neurological outcome,[17,54,55,106,107,158–160] while a significant number of other studies were "neutral," i.e., not showing such beneficial effects.[37,50–52,56,73,161–165] Study design plays a major role. The more "mechanism"-oriented studies utilized models with relatively brief untreated arrest times, administered unrealistically large buffer doses, and did not use vasopressors. The "outcome"-oriented studies utilized experimental protocols better resembling realistic cardiac arrest and CPR conditions. Some of the studies included only 5 animals in each group, a number too small to permit conclusions to be drawn.

In their "classical" studies on resuscitation drugs, Redding and Pearson[106] found that the combination of SB and epinephrine yielded significantly better short- and long-term outcome than no drugs or either drug alone. Interestingly, they administered large sodium SB doses (approximately 1.5 to 3 meq/kg) and their animals had rather extreme arterial alkalemia.

Vukmir *et al.*[54] demonstrated higher survival rates and reduced neurological deficit with the combination of SB and epinephrine in dogs resuscitated after 5 and 15 minutes of VF.

Bar-Joseph *et al.*[17] found that SB, and to a somewhat lesser degree Carbicarb (a mixture of sodium carbonate and sodium bicarbonate), increased resuscitability rate and shortened the time to ROSC in dogs subjected to 10 minutes of VF. Arterial pH and base deficit were the best predictors of ROSC. In a similar model, Leong *et al.*[55] found that administration of epinephrine and SB before defibrillation attempts was associated with increased ROSC rates compared to administration of epinephrine and saline. ROSC was achieved with fewer shocks and in a shorter time. Coronary perfusion pressures were significantly higher in SB-treated animals than in controls.

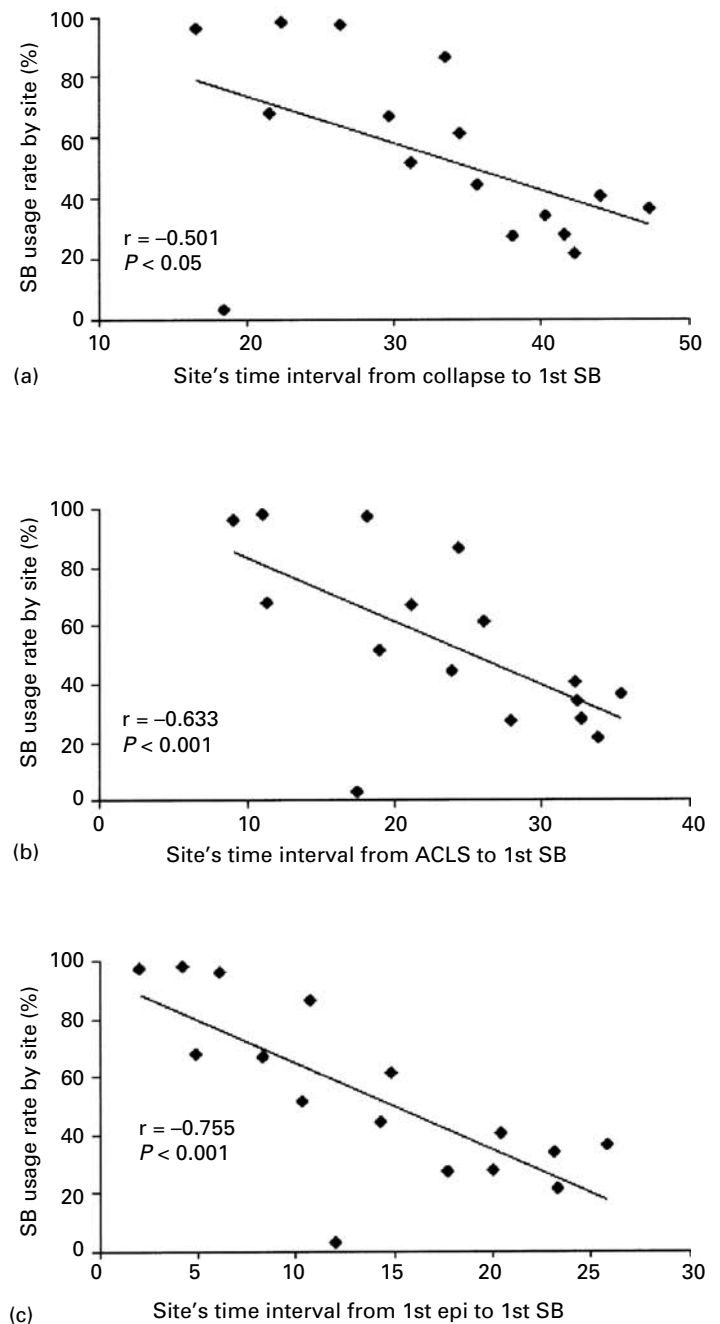
Katz *et al.*[160] compared the effects of "low dose" Carbicarb, "high-dose" Carbicarb, and saline on neurological outcome in a rat asphyxial arrest model. Importantly, the buffer dose administered as a bolus in the "low" and "high dose" Carbicarb groups was equivalent to approximately 1.3 and 2.6 meq/kg of SB, respectively. "Low dose" Carbicarb attenuated acidosis,


Fig. 37.5. Sodium bicarbonate (SB) usage rates for each of the 16 Brain Resuscitation Clinical Trial III (BRCT III) study sites vs. time intervals to sodium bicarbonate (SB) administration: (a) from collapse, (b) from initiation of advanced cardiac life support (ACLS), and (c) from administration of the first epinephrine (Epi) dose. Significant inverse correlations were found between SB usage rates and the timing of its administration: Study sites with higher SB usage rates administered it significantly earlier. (From ref. 62. Copyright Blackwell Publishing).

improved resuscitation, reduced neurologic deficits, and reduced the number of dead hippocampal neurons. Neutralization of cerebral acidosis with "high-dose" Carbicarb increased the number of dead hippocampal neurons and neurologic deficits.

In a rat VF model, Sun *et al.*[107] found that buffers administered during CPR reduced coronary perfusion pressure due to their hypertonicity and did not affect immediate resuscitability ($n = 5$ in each group). Nevertheless, buffers ameliorated postresuscitation myocardial dysfunction and increased postresuscitation survival. "CO_2 consuming" buffers (Tromethamine and Carbicarb) were more effective than SB. Of note: no vasopressors were used and animals received a buffer dose of 2.5 meq/kg.

Kette *et al.*[51] studied the effects of SB, Carbicarb, and hypertonic saline on myocardial acid–base status. Defibrillation attempts were successful in each animal, but spontaneous circulation was reestablished in a smaller number of animals treated with SB compared to those treated with Carbicarb or saline. This was a typical "mechanism"-oriented study: buffer doses were very large, no vasopressors were used, and the coronary perfusion pressures (CPP) during CPR were very low.

Liu *et al.*[148] explored the effects of SB, Tribonat®, and hypertonic saline on cerebral perfusion and cerebral

acidosis during CPR. ROSC was achieved in a significantly smaller proportion of piglets treated with SB. During CPR and following ROSC, buffer-treated animals had significantly higher arterial, mixed venous, internal jugular, and cerebral tissue pH values compared to saline. Cerebral cortical blood flow following ROSC was higher and of longer duration in the buffer-treated animals (Fig. 37.6).

Other laboratory studies found neither beneficial nor detrimental effects of buffer therapy on CPR outcome.[37,50,52,56,73,161–165] In most of these studies, cardiac arrest with no CPR was rather brief[37,50,52,73,161,162] and buffers were administered very early in the course of CPR.[50,52,73] Such experimental protocols deviate markedly from actual timeline of the common clinical scenario[61] and have a rather unsound physiologic logic: i.e., with no significant metabolic acidosis, buffer therapy is not indicated and cannot be expected to prove beneficial. In most of these studies a very large dose of buffer (2.5–3 meq/kg) was administered[50,52,73,162,163] and in some[50,52,163] epinephrine was not used, resulting in extremely low perfusion pressures. The combination of large doses (2.5 meq/kg) of hypertonic buffers or NaCl with no epinephrine was shown to decrease CPP,[163] which has been repeatedly shown to be an important determinant of ROSC.[163]
Fig. 37.6. Cerebral cortical blood flow during CPR and after ROSC. The values were expressed as means ± SD in percent of the baseline values. O Bicarbonate group; • Tribonat® Group: ▲ Saline group. (From ref. 148. Copyright Elsevier).

Is SB therapy during CPR detrimental?

Since 1986,[3] a rather long list of presumptive detrimental effects of buffer therapy in general and SB in particular has been repeatedly cited,[3,6–10,58,99,166,167] and consequently it has been "insinuated" that SB therapy worsens CPR outcome. The 2000 Guidelines assert that bicarbonate "can compromise coronary perfusion pressure; may cause adverse effects due to extracellular alkalosis, including shifting the oxyhemoglobin saturation curve or inhibiting the release of oxygen; may induce hyperosmolarity and hypernatremia; produces carbon dioxide, which is freely diffusible into myocardial and cerebral cells and may paradoxically contribute to intracellular acidosis; exacerbates central venous acidosis; and may inactivate simultaneously administered catecholamines."[10] The following section analyzes the evidence underlying these assertions.

"SB can compromise coronary perfusion pressure"
This variably seen effect is apparently "model-dependent:" CPP decreased only when no vasopressor preceded buffer and when the buffer dose was very large (2.5–3 meq/kg)[51,52,107,163,168] but not when either a vasopressor preceded SB or when clinically "reasonable" SB doses (i.e. 1–1.5 meq/kg) were administered.[17,54,73,159,161,162,165,168] Sun *et al.* showed that both SB and tromethamine decreased CPP when given before vasopressor, but not when vasopressor preceded the buffers.[168] The hypotensive effect of the large SB doses is secondary to the high sodium load rather than to the alkalinizing effect, as equivalent loads of hypertonic saline resulted in the same effect.[163]

"Bicarbonate may induce alkalosis which may shift oxyhemoglobin saturation curve to the left or inhibit oxygen release"
This repeatedly mentioned claim[3,7,8,10,76,169] was postulated based on the physiologic leftward shift of the oxyhemoglobin saturation curve with alkalemia. A single reference[170] is mentioned (in ref. 8) as presumably supporting this hypothesis. In this study, investigators used a "near drowning" (not CPR) hypoxemia model, where swine received massive SB loading (8 meq/kg over 1 minute). Arterial pH increased to 7.75, arterial saturation increased from 38.2% to 65.3% and venous saturation decreased from 34.3% to 28.4%. Thus, the calculated oxygen extraction increased almost tenfold, from 3.9% before to 36.9% after SB. Using an indirect, convoluted reasoning, however, the authors concluded that "these findings suggest that bicarbonate caused a distinct leftward shift . . . which could impair tissue oxygenation."[170]

In cardiac arrest/CPR models, increased oxygen release and oxygen uptake at the tissue level were observed following administration of SB or other buffers.[17,171] Other data on oxygen extraction, mixed venous PO_2, or saturation did not support the notion that buffer therapy impairs tissue oxygenation.[54,68,112] Moreover, buffer therapy, and specifically SB, did not increase arterial or coronary sinus lactate in CPR models.[17,50–52] Cerebral oxygen extraction did not change after SB, but tended to decrease after Tribonate®.[148]

"SB may induce hyperosmolarity and hypernatremia"
This can certainly happen – depending on the amount of SB given. In the often-quoted paper by Mattar *et al.*[172] patients became severely alkalemic, hypernatremic, and hyperosmotic following massive doses of SB during prolonged CPR (mean of 338 meq SB per patient). Bishop and Weisfeldt[27] found transient increases in serum osmolarity (from 308–309 to 343–349 mOsm/kg) 2 minutes after the administration of 0.7–1 meq/kg of SB. Serum osmolarity declined rapidly within the next 3 minutes. Other clinical[60,173] and experimental[165] studies showed no significant increases in serum sodium if recommended doses (ca. 1 meq/kg) of SB were used.

"SB may inactivate simultaneously administered adrenaline"
This was never shown to be true: mixing epinephrine with SB (or Tris buffer) in the same syringe caused a slight decrease in its biological activity.[174] After administering a very high SB dose (3 meq/kg) and making the animals extremely alkalotic (pH 7.7), the response to epinephrine did not differ from that of the control group.[175]

"SB produces carbon dioxide, which is freely diffusible into myocardial and cerebral cells and may paradoxically contribute to intracellular acidosis; exacerbates central venous acidosis"
Based on the findings of increased central venous PCO_2 ($PvCO_2$) in the "low flow state", this postulation has stirred up the "SB controversy" during CPR.[3,4,6,8,16,58]

No RCT reported values of $Pvco_2$ following SB administration. In the original reports by Weil *et al.*[29] and Nowak *et al.*[39] $PvCO_2$ values were elevated, but most of the patients received SB during CPR and no comparison with patients not receiving SB was reported. In previously ventilated patients undergoing CPR, Adrogue' *et al.* actually found lower $PvCO_2$ in those who received SB than in those who did not.[36] In previously unventilated patients, both $PaCO_2$ and $PvCO_2$ were higher in those who received SB during CPR. The authors concluded that hypoventilation on top of severe circulatory failure is required for CO_2

accumulation.[36] Barton and Callaham[70] found similar arterial PCO_2 values in patients who received SB during CPR and in those who did not.

In animal studies, $PvCO_2$ transiently increased when SB doses ≥2 meq/kg were administered[51,52,55,107,162,163,54] but not when doses < 2 meq/kg were used.[17,54,73,176] These increased $PvCO_2$ values were observed only within 3 minutes of SB administration.[17,50–52,54,161–163,148,176,177] CO_2 elimination during CPR follows a bi-exponential function, with an initial fast phase representing elimination from the lung's FRC and a slow phase, with a half-time of 108 seconds, representing elimination from the pulmonary capillary blood and from peripheral tissues.[177] Therefore, a single, early sampling will fail to depict the transitory nature of the rise in $PvCO_2$. Increases in $PvCO_2$ were more pronounced when no epinephrine was used,[26,50–52,54,162] but not when epinephrine was used to improve tissue perfusion pressures.[17,54,73,148]

Most important, in none of these studies did pH values decrease after SB administration. Even when $PvCO_2$ transiently increased – arterial,[17,27,51–53,56,107,148,159,162–164,176] central venous,[17,25,51–54,56,73,107,161,162,164] cardiac venous,[50–52] or cerebral venous[26,148] pH significantly increased following SB administration. Thus, SB was never shown to exacerbate venous acidemia.

The notion that SB "paradoxically contribute to intracellular acidosis" is consistently traced back to the study by Berenyi *et al.*[178] After 4 minutes of VF, still with no metabolic acidosis, dogs received during 20 minutes of CPR approximately 10 meq/kg of SB (!). Epinephrine was not used and ventilation was unchanged. At 20 minutes, arterial PCO_2 was 64 torr, pH 7.81, and $[HCO_3^-]$ 120 meq/l! Cerebrospinal fluid, supposedly reflecting intracellular acid–base status, had a PCO_2 of 81 torr and a pH of 7.24, which was not significantly different from that of the control group. This "SB loading" model – with no relevance to clinical buffer therapy during CPR – is repeatedly cited as the evidence for "worsening of intracellular acidosis."

No other study that used a cardiac arrest/CPR model supported this hypothesis: intracellular pH either increased[68,146–148] (Fig. 37.7) or did not change,[48,89,91,96] following SB administration.

In a hypoxic lactic acidosis model, Sessler *et al.* showed that a very large SB dose did not produce paradoxical intracellular acidosis in the brain.[179] Multiple other *in vivo* "non-CPR" and *in vitro* models investigated this issue, with models of hypercarbic acidosis, cell suspensions, isolated heart preparations, and more.[180–186] Results are equivocal and depend on experimental design, model, initial intracellular pH, amount and mode of SB administration, and timing of intracellular pH measurements.[185,187]
Fig. 37.7. Cerebral intracellular pH and sagittal sinus blood pH during prolonged cardiopulmonary resuscitation. Dogs were placed in a control group or received sodium bicarbonate or lactate at 14 minutes of CPR. *$P < 0.05$ vs. prearrest $P < 0.05$ vs. values at 10 minutes of CPR; ‡ $p < 0.05$ vs. control group at the same time point. (From ref. 146. Copyright American Heart Association).

Timing of buffer administration

ALS Guidelines repeatedly stated that "after protracted arrest or long resuscitative efforts, SB possibly benefits the patient. However, SB therapy should be considered only after the confirmed interventions, such as defibrillation, cardiac compression, intubation, ventilation, and vasopressor therapy, have been ineffective."[3,8–10] It was estimated that these interventions are accomplished within the first 10 minutes of CPR.[3]

What is the actual timing of buffer administration in CPR? In a systematic analysis of SB usage in a large clinical trial, Bar-Joseph *et al.*[61] found that in the out-of-hospital setting, the time from collapse to ACLS was 11.4 minutes and to the first epinephrine 20.4 minutes. SB was administered 11.4 minutes after the first epinephrine, i.e., over 31 minutes after the patients' collapse.[61,62] A similar timeline for the first epinephrine dose was found in other large clinical trials.[188,189]

The long time intervals to administration of buffers should be related to the development rate of metabolic

acidosis, as discussed above. If buffers are thought to be effective in promoting return of spontaneous circulation, there is no "physiologic" sense in delaying their administration by 11 minutes beyond the first epinephrine.[62]

Comparison of different buffers during CPR

The controversy surrounding the use of the "CO_2-producing" SB, has led to the development and testing of other "CO_2-consuming" buffers. As of today, three buffers were considered as alternatives to SB during CPR: Tromethamine (THAM), Carbicarb®, and Tribonate®.

Tromethamine (THAM, Tris buffer)

Tromethamine is an organic H^+ ion acceptor, which crosses cell membranes and acts both as an extracellular and intracellular buffer.[190,191] With a pK = 7.84 it is a stronger buffer compared to SB (pK = 6.10), binding H^+ ions according to the formula

$$(CH_2OH)_3\,C-NH_2 + HA \leftrightarrow (CH_2OH)_3\,C-NH_3^+ + A^-$$
which leads to a right shift of the reaction

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$
and thereby decreases CO_2 and increases HCO_3^- concentrations.[192,193] THAM markedly reduced CO_2 in arterial, mixed venous, and great cardiac vein blood.[17,50] Interestingly, THAM was previously thought to bind CO_2 directly,[194] but this was disputed later.[193] In animal experiments, THAM was less effective than SB in promoting ROSC.[17,50] This may be related to its vasodilating effect, resulting in lower CPPs.[17,50] Therefore, THAM cannot be recommended for routine use as a buffer during CPR.

Carbicarb

Carbicarb® is an equimolar mixture of sodium carbonate (Na_2CO_3) and sodium SB ($NaHCO_3$), devised to capitalize on the "CO_2-consuming" effects of sodium carbonate without the hazards of its very alkaline pH of 11.[195] Carbicarb® was originally reported as capable of buffering H^+ ions with no net production of CO_2.[195,196] In the setting of hypoxic lactic acidosis, Carbicarb® provided greater hemodynamic stability compared to normal saline or SB, increased arterial pH without increasing $PaCO_2$, increased tissue oxygen utilization, and prevented further increases of lactate.[196,197] In cardiac arrest/CPR models, results depend on experimental details: Carbicarb® decreased while SB increased both $PaCO_2$ and $PvCO_2$ 2 minutes after the administration of large doses (2–2.5 meq/kg) of buffer.[51,52] When clinically rel-

evant doses (1 meq/kg) were given, Carbicarb® administration resulted in slightly (though not significantly) higher $PvCO_2$ compared to SB administration.[17] Blecic *et al.*[56] found no difference between Carbicarb® and SB (1 meq/kg) in either $PaCO_2$ or $PvCO_2$ at 5 minutes post ROSC. In all of the studies, both buffers corrected blood pH effectively. In fact, arterial pH values of 7.90 and 8.21 were measured after the administration of the large Carbicarb® doses.[51,52] Intramyocardial pH did not increase and was not different 2 minutes after either Carbicarb® or SB administration.[51] No significant differences in resuscitability, or arterial or coronary perfusion pressures were found between these buffers during CPR.[17,51,52,163] Carbicarb® and SB were equally effective in ameliorating postresuscitation myocardial dysfunction following prolonged VF.[107]

Overall, despite a theoretical advantage, Carbicarb® was not shown to be superior to SB during CPR in any of the clinically relevant parameters.

Tribonat®

This is a mixture of SB, THAM, phosphate, and acetate, that was introduced in 1985 by Wiklund *et al.*[166,198,199] and is used clinically mainly in Scandinavia. Tribonat® was designed to overcome previously reported disadvantages of both sodium SB and THAM: compared to SB it has a lower sodium content, a significant intracellular buffering capacity, and it was hypothesized that it causes less metabolic alkalosis.[166,198,199]

In two cardiac arrest models, Tribonat® resulted in better ROSC rates than did SB.[73,148]

In a cardiac arrest model, neither arterial nor CSF pH and PCO_2 differed between Tribonat®- and SB-treated piglets.[68] A recent, large and well-designed animal study compared Tribonat®, SB, and saline in piglets undergoing CPR.[148] No differences were found between Tribonat® and SB effects on arterial, mixed venous, and internal jugular pH and PCO_2 – although both buffers improved these variables compared to saline. No differences were found between the effects of these buffers on cerebral cortical blood flow, cerebral oxygen extraction ratio, and cerebral tissue pH both during CPR and following ROSC.

The hemodynamic responses to epinephrine during CPR were compared:[112] while SB-treated animals had higher systemic blood pressures before epinephrine administration, Tribonat® (as well as THAM and saline) resulted in larger systemic pressure increases following epinephrine, so that there were no differences between the groups at this point. No differences were found between the effects of Tribonat® and SB on myocardial energy metabolism during CPR.[26,73]

Thus, in cardiac arrest models, Tribonat® was more effective than SB in restoring early resuscitability, but despite theoretical expectations, no other differences between the two buffers were found. Tribonat® seems to be an acceptable alternative to SB.

Buffer therapy postresuscitation

Guidelines[8,10] recommended the use of sodium SB after ROSC, especially following prolonged CPR. Lacking any specific published evidence, however, this may be supported only by rational conjunctures or common practices.

Sun *et al.* reached contradictory conclusions regarding the effects of buffers on postresuscitation myocardial dysfunction in two studies using the same rat CPR model.[107,168] The first study[107] concluded that buffers administered during CPR may ameliorate postresuscitation myocardial dysfunction and thereby improve postresuscitation survival. Their later study,[168] which added epinephrine and esmolol (to block the beta1 effect of epinephrine) to buffers, concluded that buffers caused greater impairment of postresuscitation myocardial function and decreased postresuscitation survival. Unfortunately, the authors provided no hypothesis to explain these differences. Both of these studies compared multiple small ($n = 5$ each) groups, limiting their statistical power.

Buffer therapy for cardiac arrest and CPR under special circumstances

Cardiac arrest associated with pre-existing metabolic acidosis

ACLS Guidelines[2,3,10] recommended SB for patients with "preexisting metabolic acidosis" (Level IIa recommendation). Neither the Guidelines nor the background text[169] specify to which type of "preexisting metabolic acidosis" it relates, and at what degree of acidosis is buffer indicated. Obviously, the basic presumption of this downright indication is that metabolic acidosis is detrimental, yet the same Guidelines are very reserved regarding buffer therapy for metabolic acidosis developing during arrest and CPR. Are these lactic acidoses really different?

There is practically no literature to support this longstanding recommendation, which may be supported by inference from other situations and rational conjecture. Since buffer therapy – including SB – is not detrimental,

however, there seems to be no clinical logic in changing this recommendation.

This indication for buffer treatment may be especially important in pediatric advanced life support (PALS), as pediatric cardiac arrest is usually secondary to on-going respiratory or circulatory failure resulting from whole-body hypoxia and lactate production.[22] In adults, pulseless electrical activity is also secondary to deteriorating primary conditions with metabolic (lactic) acidosis developing before the final cardiac arrest.[92,214]

Cardiac arrest associated with hyperkalemia

The use of SB for "cardiac arrest associated with hyperkalemia" is another longstanding, seemingly undisputed recommendation (Level I or Level IIa)[2,3,8–10] The origins of this recommendation date back to a 1959 paper by Bellet[200] and to a dramatic case report by Stewart *et al.*[201] Nevertheless, literature search for hyperkalemia, CPR and SB found only nine case reports, which do not allow drawing any unequivocal conclusions, as patients were treated with various means, including SB, to reduce serum potassium levels.[202–210] No animal studies on hyperkalemia in cardiac arrest models were reported. Evidence suggests that SB is not very effective in the initial management of hyperkalemia in patients who are stable, not acidotic and not in cardiac arrest.[211,212] One small case series[213] reported on a significant reduction of elevated serum potassium (associated with ECG changes) following SB therapy in four profoundly acidotic patients. Since the potassium-lowering effect of sodium SB is not large and not immediate, it cannot be relied upon as a sole therapy to treat hyperkalemia during CPR. SB should be combined with other measures such as calcium, insulin/glucose, or hemodialysis.[211,212]

Cardiac arrest associated with tricyclic antidepressant toxicity

SB has been indicated as a Class IIa recommendation in cardiac arrest associated with tricyclic antidepressant toxicity.[8–10,214] Surprisingly, only a single case report involving the use of SB in the treatment of cardiac arrest following tricyclic antidepressant intoxication was published.[215] Nevertheless, vast literature exists on the efficacy of SB in treating the cardiovascular toxicity of tricyclics and other sodium channel blockers such as type 1a antiarrhythmics and cocaine. No randomized clinical trials are available, but observational studies,[216] case reports,[217–219] and animal studies[220–228] demonstrated rapid improvement in

hypotension and cardiac arrhythmias following SB administration. It remains controversial whether it is the alkalinization or the administration of extra sodium that causes these beneficial effects.[225,227–232] As SB is readily available, however, its toxicity is low and its benefit is high, it can be safely recommended for tricyclic antidepressant toxicity. No clear-cut recommendations concerning dosing and the duration of therapy can be provided from the published literature.[233]

Conclusions

1. Both CO_2 accumulation and lactate production contribute to the rapidly developing acidosis during cardiac arrest and CPR.
2. As a result of the low tissue perfusion generated by external cardiac massage, CO_2 and H^+ accumulate at the tissue level. This phenomenon is responsible for the large veno-arterial differences in PCO_2 and pH consistently found during CPR.
3. The hypothesis derived from this finding, suggesting that SB – a typical "CO_2-producing" buffer – paradoxically aggravates intracellular acidosis was not substantiated.
4. Acidosis, especially when coupled with hypoxia, decreases cardiac contractility and reduces the chances for successful defibrillation. Profound cerebral acidosis develops within minutes of cardiac arrest, further impairing brain energy metabolism, enhancing brain edema, and worsening histopathologic and neurological damage.
5. Hyperventilation cannot effectively compensate for metabolic acidosis, and, at least theoretically, may have detrimental effects.
6. No large, prospective RCT of buffer therapy in CPR was performed. One relatively small prospective RCT found no outcome benefit of buffer therapy. A recent retrospective analysis found that EMS systems with frequent and earlier use of SB had better CPR outcome than did EMS systems with infrequent and late use of SB.
7. At least eight animal studies found a beneficial outcome effect of buffers (mainly SB), whereas 10 other studies did not find such an effect.
8. Careful review of the literature does not confirm any of the claims previously raised against SB when it is used in a clinically appropriate manner during CPR:
   - When used in combination with vasopressors and in clinically relevant dosages, SB does not compromise coronary perfusion pressure.
   - Buffer therapy does not worsen, but rather improves tissue oxygenation.
   - SB only rarely increases serum Na^+ and osmolarity during CPR and the clinical importance of these changes is rather minimal in light of the extremely grave prognosis of prolonged CPR.
   - SB does not exacerbate central venous acidosis. Early after administration of large SB doses, $PvCO_2$ may transiently increase, but arterial, central venous, and cardiac venous pH always increase significantly.
   - No "paradoxical intracellular acidosis" was proven in cardiac arrest/CPR models, even when very large SB doses were used. Most data suggest that intracellular pH increases following SB administration.
   - SB does not inactivate simultaneously administered epinephrine.
9. Clinical data show that SB administration is often delayed and administered at a stage when little or no benefit can be expected.
10. Although logical, there is no evidence for a beneficial effect of SB for "pre-existing metabolic acidosis." Similarly, there is very little, rather contradictory evidence, on the effects of buffers "upon return of spontaneous circulation."
11. None of the other buffers tested as an alternative to SB have proven to be superior or to have less clinically important side effects.
12. There is only weak evidence for a beneficial effect of SB in cardiac arrest associated with hyperkalemia. SB cannot be relied upon as a sole therapy to treat hyperkalemia and should be combined with other measures such as calcium, insulin/glucose, or hemodialysis.
13. SB can be safely recommended for cardiovascular emergencies associated with tricyclic antidepressant toxicity.
14. What are our current knowledge gaps?
    - There is an urgent need for a proper prospective randomized clinical trial of SB in ACLS. Until this is accomplished, it seems unjustified to discard a potentially useful, and rather harmless, drug from use in a clinical emergency that has an extremely unfavorable outcome and no other viable alternatives are available.
    - There are no published clinical data on pediatric use of buffers.
    - Recommendations for dosage and timing of repeated buffer doses are not supported by sufficient factual data.
    - There is a need to clarify the cause–effect relationship between correction of acidosis and CPR outcome.

Addendum

The new Guidelines for Cardiopulmonary and Cerebral Resuscitation (CPR) 2005[236] were published after completion of this chapter. The paragraph relating to Buffers is very succinct, and is copied here in its entirety (reference numbers relate to this text):

Consensus on science

There were no published LOE 1, 2, or 3 studies on the use of sodium bicarbonate during CPR. One LOE 2 study[97] showed no advantage of Tribonate over placebo (neutral), and 5 retrospective analyses of uncontrolled clinical use of sodium bicarbonate were inconclusive (LOE 4).[4,60,94,96,154] One LOE 4 study[62] suggested that emergency medical services (EMS) systems using sodium bicarbonate earlier and more frequently had significantly higher rates of ROSC and hospital discharge and better long-term neurologic outcome.

Results of animal studies are conflicting and inconclusive. Sodium bicarbonate was effective for treating the cardiovascular toxicity (hypotension, cardiac arrhythmias) caused by tricyclic antidepressants and other fast sodium channel blockers (see "Drug overdose and poisoning," below). Only 1 LOE 5 publication[215] reported the successful treatment of VF cardiac arrest caused by tricyclic poisoning using sodium bicarbonate.

Treatment recommendation

Giving sodium bicarbonate routinely during cardiac arrest and CPR (especially in out-of-hospital cardiac arrest) or after ROSC is not recommended. Sodium bicarbonate may be considered for life-threatening hyperkalemia or cardiac arrest associated with hyperkalemia, pre-existing metabolic acidosis, or tricyclic antidepressant overdose.

Cardiac arrest resuscitation monitoring

Kevin R. Ward and Joseph Bisera

Department of Emergency Medicine, Virginia Commonwealth University and Virginia Commonwealth University Reanimation Engineering Shock Center
The Weil Institute of Critical Care Medicine, Rancho Mirage, California

Introduction

Shock is a complex entity traditionally defined as a state in which the oxygen utilization or consumption needs of tissues are not matched by sufficient delivery of oxygen. This mismatch commonly results from states of altered tissue perfusion. From this perspective, cardiopulmonary arrest represents the most extreme of shock states.

Figure 38.1 represents the basic relationship between oxygen consumption (VO_2) and oxygen delivery (DO_2) that is pertinent to individual organs as well as to the whole body.[1–3] VO_2 can remain constant over a wide range of DO_2, because most tissue beds are capable of efficiently increasing the extraction of oxygen. This will be reflected by decreasing venous oxygen saturation from each organ. When DO_2 reaches a critical threshold, however, tissue extraction of oxygen cannot be further increased to meet tissue demands. At this point VO_2 becomes directly dependent on DO_2 (DO_2crit) and cells begin to convert to anaerobic metabolism, as manifested by increases in certain metabolic products such as lactate, NADH, and reduced cytochrome oxidase. The point of DO_2crit is the point of dysoxia or ischemia at which tissue DO_2 cannot meet tissue oxygen demand.[2] Oxygen debt can be defined as the amount of cumulative difference of VO_2 between baseline and that spent below DO_2crit. As discussed later, the level of accumulated oxygen debt in shock states is critically linked with survival.[4,5]

Several unique physiologic aspects and principles of cardiac arrest and CPR exist that limit the usefulness of many monitoring modalities, some of which will be more useful in the postresuscitation period.[6] These include the following.

1. Cardiac arrest produces a global state of ischemia wherein all organ systems, especially those most metabolically active (heart and brain), experience severe ischemia within minutes. DO_2crit is immediately surpassed. As opposed to other shock states, such as those produced by hemorrhage or sepsis, there is no compensatory state prior to sudden death cardiac arrest. Thus every minute of cardiac arrest results in a greater temporal based oxygen debt than other etiologies of shock. This state of profound whole body ischemia is further complicated because the brain and heart, which are usually globally spared from dysoxia until the late stages of other forms of shock, reach dysoxia almost immediately (within minutes) in cardiac arrest. Additionally, depending on the cause of the arrest, individual organ regions may have undergone significant ischemia (such as occurs in acute myocardial infarction) before arrest, or globally (such as occurs in asphyxial arrest) and thus accumulated a significant degree of regional or whole body oxygen debt before the actual arrest.

2. Traditional CPR is incapable of restoring DO_2 to a point of VO_2 independence. This is especially true of the brain, in which high-energy phosphate depletion occurs within minutes and cannot be restored with CPR. Only ROSC or alternative methods of CPR such as open chest cardiac massage or cardiopulmonary bypass can produce this.

3. Optimal outcomes from cardiac arrest are, for the most part, directly linked to pre-arrest events and the duration of arrest. Thus the goal of CPR is to achieve hemodynamic changes capable of producing ROSC within seconds to minutes, as opposed to the minutes to hours
Fig. 38.1. Biphasic relationship between oxygen delivery (DO_2) and oxygen consumption (VO_2). Oxygen extraction ratio (OER) increases and mixed venous oxygen saturation (SvO_2) decreases in response to decreased DO_2. Below a critical DO_2 (DO_2crit), VO_2 becomes delivery-dependent. DO_2 below DO_2crit results in the beginning of anaerobic metabolism as noted by an increase in a variety of cellular products including lactate, NADH, and reduced cytochrome oxidase (CtOx). The DO_2crit of various organ systems can occur at points either above or below whole body DO_2crit, depending on the metabolic and blood flow regulatory characteristics of the organ system and the rapidity of the reductions in DO_2. $DO_2 = CO \times CaO_2$ (normal range: 460-650 ml/min/m²); $VO_2 = CO \times (CaO_2 - CvO_2)$ (normal range: 96-170 ml/min/m²); CaO_2 (arterial oxygen content) $= (Hb \times 1.39 \times SaO_2) + (0.003 \times PaO_2)$; $CvO_2 = (Hb \times 1.39 \times SvO_2) + (0.0003 \times PvO_2)$. CO, Cardiac output; PaO_2, arterial oxygen tension; Hb, hemoglobin; SvO_2 normal range 70%–80%.

time frame that can be used to effect favorable hemodynamic changes during the postresuscitation period. To date, the major hemodynamic factor determining the ability to produce ROSC is coronary perfusion pressure (CPP).

Therefore, it is apparent that the most immediate goal of CPR is to restart the heart as soon as possible so as to limit the total time of ischemia especially to the brain, and the heart itself. Because of this compressed time frame, selected monitoring end-points must have the ability to detect targeted processes or parameters that are linked with ROSC and are capable of changing within seconds of interventions (i.e., coronary perfusion pressure). Consequently, monitors must have corresponding response times and be capable of being applied to the patient and reporting data within seconds.

Monitoring during CPR

Traditional monitoring

Monitoring during CPR has traditionally consisted of carotid or femoral pulse palpation along with ECG evaluation in one or more leads. Although the lack of a palpable pulse during CPR may indicate inadequate forward flow, quantification of forward flow cannot be estimated in the presence of a palpable CPR-generated pulse since pressures generated by chest compressions may be transmitted equally to both the major arterial and venous vessels.[7] In addition, inability to palpate a pulse has not been demonstrated conclusively to rule out spontaneous forward flow in certain rhythms such as pulseless electrical activity.[8] Myocardial blood flow is not dependent on palpated

arterial systolic pressure, but depends instead on CPP, which is defined as the difference between aortic diastolic and coronary sinus (or right atrial) diastolic pressure.[9] ECG monitoring during CPR will indicate the electrical status of the heart, but not mechanical activity. Although perhaps the best attainable in certain circumstances, these two monitoring modalities do not provide reliable information about the effectiveness of CPR (both mechanical and pharmacologic interventions) or prognosis given current treatment recommendations.

In the absence of immediate defibrillation it is now clear that the essential menu of CPR interventions, including chest compression, management of the airway, and breathing for the victim take priority. In the out-of-hospital setting, only a small minority of witnessed cardiac arrests receive successful defibrillation with an AED within 3 minutes after collapse. Thus, in the lay setting, monitoring challenges exist that may affect outcome.

The first challenge encountered by the bystander/lay rescuer is the limited capability to *detect* cardiac arrest promptly. The detection, and indeed, the definition of cardiac arrest that then prompts CPR is now based solely on the observer's capability to observe or sense breathing and/or detect a pulse in an unresponsive individual. Yet, the very specificity of the pulse check, including the carotid pulse, by lay persons under stress, even after completion of the Basic Life Support Course (BLS), is no better than random. Since 1968 the pulse check has been the "gold standard" for determining whether the heart is beating. Evidence indicated that the pulse check by lay rescuers failed to identify a pulse as present or absent 50% of the time and it was therefore random.[10,11] Since 1992, however, the validity of the pulse check has been called into question and in the American Heart Association Guidelines the pulse check was deleted as a basis for establishing that the victim has cardiac arrest triggering CPR, including immediate defibrillation.[12,13]

Prompt distinction between the presence of heartbeat and the absence of breathing would allow the A, B, C, and D (airway, breathing, chest compression, and defibrillation) to be optimally prioritized, and even quality-controlled, contingent on real-time measurements.[14–17] Failure to restore breathing and circulation with chest compression compromises survival in some patients.

In a recent study, CPR before delivery of the initial shock increased survival (to hospital discharge) from 24% to 30%.[18] Significantly better outcomes followed chest compression when it preceded electrical defibrillation, although delaying defibrillation can compromise successful defibrillation.[18–20] Under experimental conditions, successful resuscitation by defibrillation is reduced to 40% if

the delay is 15 seconds and < 5% if defibrillation is delayed by as much as 20 seconds.[21]

Current versions of AEDs, which analyze rhythm, do provide the intelligence and prompting for electrical defibrillation during ventricular fibrillation. As yet, however, they do not provide real-time measurements of the mechanical heartbeat, breathing, blood circulation, or the intelligence for optimizing and sequencing of CPR in real-time, especially for the nonprofessional and occasional professional rescuer. These new insights add incentive to providing real-time diagnosis during cardiac arrest for optimal guidance for sequencing of the essential airway, breathing, and chest compression intervention as well as electrical defibrillation.

An example of how this might be done is with the use of simple transthoracic impedance. Measurement of transthoracic impedance has evolved over more than a century with impedance plethysmography described as early as 1897 for physiological measurements.[22] Circulation and respiration were both quantified by impedance measurements.[23–26] Impedance monitoring as a clinical application for management of the critically ill and injured for estimating cardiac output followed the demonstration of Kubicek that changes in transthoracic impedance were indicative of changes in intrathoracic blood volume.[27] More recently, these techniques have been incorporated into commercial devices for estimation of stroke volumes and therefore cardiac output in the critically ill and injured.[28] The applicability of impedance methods during CPR has been shown to be a useful alternative for detection of breathing, or heart beat, or both.[29] The same electrodes that sense the electrocardiogram for diagnosis of the ECG rhythm and for delivery of a defibrillating shock were employed for the impedance measurements. Indeed, the impressive correlation between the arterial pulse pressure and impedance (Fig. 38.2) indicates that the impedance signal serves as a surrogate not only for "pulse check" but also to quantify arterial pressure produced by cardiac injection. Concurrent measurement of ECG and impedance would enable prompt detection and interpretation of cardiac or respiratory arrest, and therefore, guide more appropriate priority interventions for either (1) artificial breathing or (2) chest compressions, or both, preceded or followed by automated defibrillation.

Central hemodynamic or global monitoring

Coronary perfusion pressure

Laboratory data have clearly demonstrated the relationship between CPP and myocardial blood during CPR and the need to reach a certain threshold of CPP in order to
Fig. 38.2. The relationship between pulse pressure and thoracic impedance demonstrates the potential for AEDs to detect spontaneous circulation and thus provide first responders better direction in the initial care of the collapsed victim. (From ref. 29.).

achieve ROSC.[9,30,31] Clinical studies have confirmed the link between CPP and ROSC and have established that using current resuscitative treatment modalities as recommended by the American Heart Association, a minimum CPP of 15 mmHg is necessary to achieve ROSC if initial defibrillation attempts fail.[32,33] This is necessary, although not always sufficient, to achieve ROSC, and factors such as significant coronary artery lesions, downtime, and others have shown that despite reaching a CPP of 15 mmHg, ROSC is not possible. For example, not only are myocardial oxygen requirements of ventricular fibrillation higher than for example the asystolic heart, fibrillation has been demonstrated to cause mechanical compression of subendocardial vessels.[34,35] Higher opening pressures and flow may be required to achieve ROSC in these circumstances.[36,37] In addition, vasopressors such as epinephrine have been shown in some instances to increase further the imbalance between myocardial oxygen demand and delivery despite increasing myocardial blood flow.[30]

Clinical studies have demonstrated that CPP can be positive or negative during CPR and are indistinguishable by palpation of a pulse alone (Fig. 38.3).[38] Although monitoring of CPP is the most directly reliable indicator of adequacy of chest compression and pharmacological interventions, its major drawbacks are that it requires time and resources (both equipment and human), because access to both the arterial and central venous vasculature is needed to determine arterial diastolic and central venous diastolic pressure. In addition, pressure transduction supplies and equipment are necessary to verify pressure tracings and calculate CPP since most pressure monitors, while capable of reporting systolic and diastolic arterial pressure, report central venous pressure as a mean value.

Animal data indicate that the ability to achieve a diastolic arterial pressure of at least 40 mmHg is predictive of ROSC and is likely to be related to achieving a threshold CPP; however, clinical CPP data to substantiate this are lacking and critical CPPs can be achieved in humans without a diastolic arterial blood pressure of 40 mmHg.[39] Furthermore, it may be impossible to achieve a diastolic arterial pressure of 40 mmHg in some individuals by traditional closed chest compressions.

Measurement of CPP in the manner described above is possible in the hospital, especially in intensive care units where patients may already be instrumented. Unfortunately, this important variable is often ignored. Measurement is also possible in most emergency departments with proper staffing and preparation, and should be utilized, especially in circumstances in which central vascular access is obtained for drug administration. Nonetheless, it does not appear that simply monitoring diastolic CVP alone can predict CPP. In reality, since it is becoming increasingly popular to carry out cardiac arrest resuscitations in their entirety in the prehospital setting, it is unlikely that real-time direct CPP monitoring will ever become standard in emergency departments or other settings. Its application in the prehospital setting is simply not feasible from a technical and time standpoint.

Arterial blood pressure monitoring
Use of the oscillometer or other non-invasive blood pressure monitoring techniques are unreliable in their ability to measure true arterial blood pressure during CPR. These
Fig. 38.3. Aortic (Ao), right atrial (RA), and coronary perfusion (Ao-RA) pressure tracings during human CPR. (a) Positive coronary perfusion pressure (CPP) generated during both compression and relaxation phases of chest compressions. (b) Positive CPP generated only during relaxation phase of chest compressions. (c) Negative CPP throughout compression cycle. The degree of CPP cannot be predicted by palpation of CPR-produced peripheral pulses. (From ref. 38.).

methods require detection of pulsations in the cuff or other detector transmitted by the artery. Although these techniques provide acceptable levels of variance from intra-arterial measures in stable patients, levels of variance are greatly increased in states of critical illness. Motion produced during CPR as well as the low pressure produced will require sensitivity not required of standard applications of the technology.[40] If knowledge of systolic

pressure is desired, use of a manually inflated pressure cuff along with a Doppler device is recommended, with the caveat that diastolic pressure cannot be determined in this manner. It must be emphasized, however, that achieving a target systolic pressure alone during CPR has never been associated with ROSC; thus, use of non-invasive blood pressure monitoring will be of little value during CPR. Because of the physiology of cardiac arrest and

CPR-induced perfusion pressures, significant changes in systolic blood pressure may occur without favorable changes in CPP. Direct arterial blood pressure monitoring will be useful in distinguishing true electromechanical dissociation (EMD) from pseudo-EMD in which patient body habitus or significantly low pulse pressure prevents detection of pulsatile flow by pulse detection or end-tidal CO_2 monitoring (discussed later).[8]

During the postresuscitation phase, invasive arterial blood pressure monitoring is recommended because of the noted unreliability of non-invasive measures during labile states.[40] Since to stay in the autoregulatory range of the brain and to maintain coronary perfusion pressure a minimal perfusion pressure of 70 mmHg is recommended, invasive arterial pressure will be helpful in ensuring this. Invasive monitoring will also make acquisition of arterial blood gases easier.

Laboratory testing

Intermittent venous and arterial blood sampling for gas or chemistry analysis is of limited utility during CPR and basically has no application in the out-of-hospital setting. Use of whole blood gas and electrolyte measurements (now available at many institutions and in point of care testing kits) can provide both hemoglobin and potassium levels within minutes. These may be helpful in excluding hyperkalemia and severe anemia as a cause of arrest or of inhibiting attempts at resuscitation. Co-oximetry measurement of hemoglobin for evidence of carbon monoxide poisoning would be helpful in certain circumstances. Severely elevated carboxyhemoglobin levels are likely to preclude successful resuscitation by standard resuscitation techniques since a state of functional anemia will exist in combination with the poor perfusion produced by CPR, thus further reducing DO_2.

Typical blood gas findings during CPR include severe venous respiratory acidosis and arterial respiratory alkalosis, which reflect the large dead space created in the lungs by cardiac arrest and the poor forward blood flow produced by chest compressions as compared to the normal circulation (Fig. 38.4).[41–44] SaO_2 is usually 99% with PO_2 levels well above 100 mmHg.

Lactate monitoring during CPR itself has been examined as a means to determine the duration of cardiac arrest, the so-called "down time" and to titrate therapy.[45–47] Normal lactate levels (in the absence of liver failure) are less than 2–3 mmol/L. Lactic acidosis existing during CPR and the initial postresuscitation period is due to inadequate DO_2 (Type A lactic acidosis). However, single measurements have limited value. Changes in lactate will not occur rapidly enough during CPR to allow changes in therapy.

Indeed, it can be argued that better CPR may result in increasing lactate levels because of washout phenomena (removal of lactate sequestered in tissue beds into the central circulation) and/or because of enhanced delivery of substrate to cells that are still below the point of DO_2crit, thus resulting in additional lactate production. Moreover, lactate levels at the beginning of CPR may differ among individuals, depending on the etiology of arrest. For example, an asthmatic who experienced significant hypoxemia before arrest will have higher levels of lactate and a higher oxygen debt than will the victim of sudden death. Lactate levels during CPR have not been demonstrated in humans to correlate with neurologic outcome.[48]

The major utility of lactate monitoring is in the postresuscitation setting as a useful endpoint to guide hemodynamic management. Lactate levels are universally elevated immediately after ROSC; therefore, use of lactate as a postresuscitation endpoint to assess adequacy of DO_2 will require serial measurements. It is thus not the absolute level of lactate that is prognostic in shock, but the ability to halt dysoxic lactate production and clear it.[49–52] Lactate clearance of at least 5%–10% an hour should be a goal. Rising lactate levels or the inability to clear lactate indicates continuing accumulation of oxygen debt and thus DO_2 levels below DO_2crit or significant regional dysoxia.[3,50] Therapies aimed at increasing DO_2 or reducing VO_2 should be instituted.

It is not uncommon to observe elevated or rising lactate levels in the postresuscitation period despite normal or elevated systemic blood pressures. This should be interpreted as an indication of severe microcirculatory shunting, which may be secondary to excessive circulating levels of catecholamines or other vasoactive mediators.[53] In this setting, the presence of elevated lactate levels concomitant with elevated central or mixed venous hemoglobin oxygen saturation again indicates severe microcirculatory injury and portends a poor outcome.[53,54] Non-intuitive therapies such as vasodilator therapy may be required to reverse this state.

Although lactic acid and base deficit are highly correlated, hyperlactemia (levels 2–5 mmol/L) may be observed in the latter phases of postresuscitation care in the absence of metabolic acidosis as a consequence of processes that increase the glycolytic flux of glucose to lactate, such as catecholamine administration.[55] Nevertheless, clinicians should aggressively rule out occult hypoperfusion as a cause of elevated lactate levels.

Postresuscitation laboratory testing of other markers or compounds as indicators of myocardial function, neuronal injury, immune and inflammatory function, and others will inevitably be developed as our ability to treat cardiac arrest and the postresuscitation syndrome

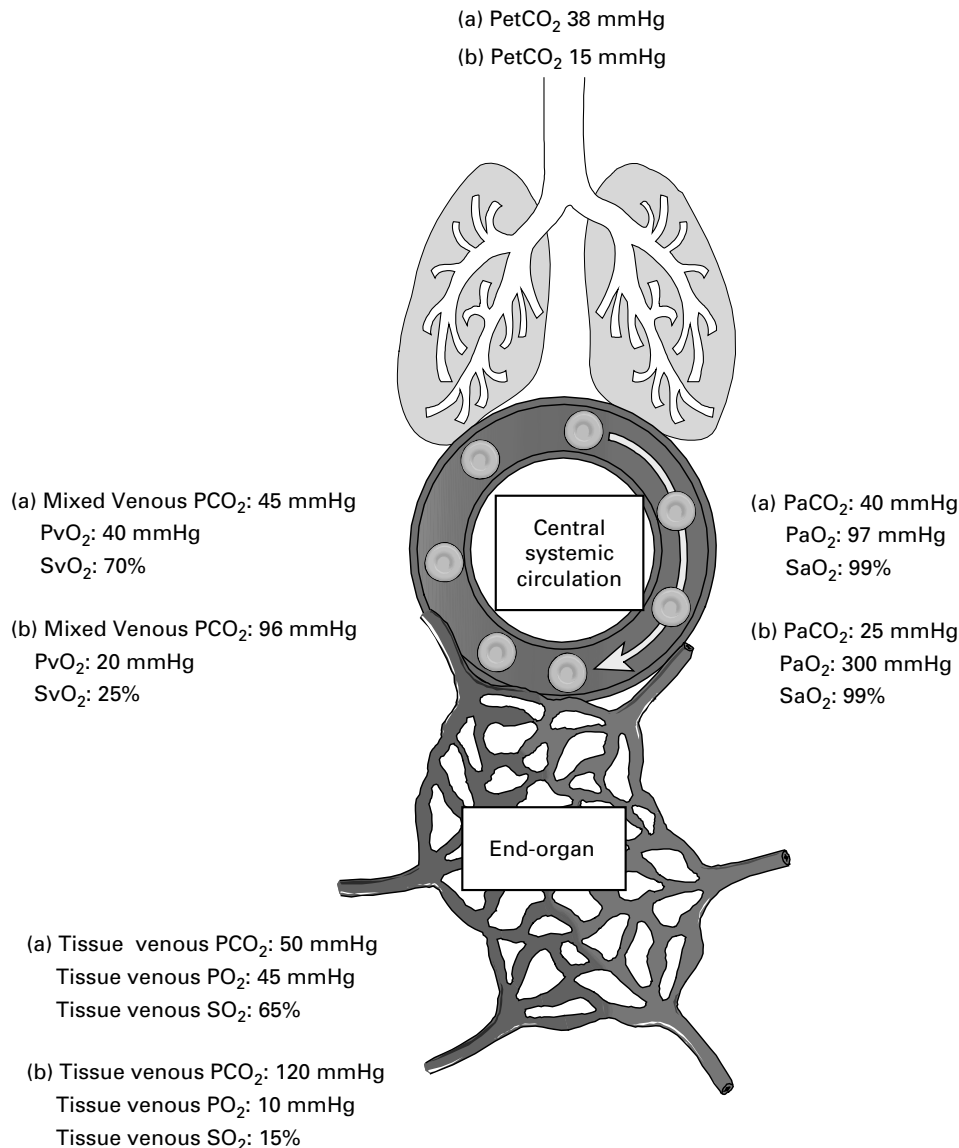

Fig. 38.4. Representative blood and tissue gas levels of the normal circulation (a) and during cardiac arrest and CPR (b). Mixed venous values represent aggregate values from all organ systems. Thus tissue venous values are not necessarily identical to mixed venous values but can be higher or lower depending on the individual organ system's level of metabolic activity. The majority of blood volume at the level of the tissue is contained in the venous compartment. Because of the tremendous reductions in blood flow produced by CPR, a deadspace in the lungs is created thus producing gaps between mixed venous PCO$_2$, PetCO$_2$, and PaCO$_2$. The severe reductions in DO$_2$ to each organ system result in very high oxygen extraction at the level of the tissue, which produces very low tissue venous PO$_2$ and thus SO$_2$ levels. The very high venous PCO$_2$ levels are due to decreased removal of both aerobically and anaerobically produced CO$_2$ (see Fig. 38.5).

evolves. Much of this will be as a result of advances in our understanding of the molecular basis and complex interplay between systems in the pathology and treatment of the disease. It is possible to envision performing bedside genomic and proteomic profiling in the postresuscitation period to obtain better understanding of prognosis or to develop individual pharmacogenomic approaches to therapy for the patient.

Pulse oximetry

The technique of pulse oximetry utilizes two wavelengths of light (red and infrared) to determine the percentages of oxy- and deoxyhemoglobin. This is determined by isolating the small increase in blood volume occurring at the site of measurements in response to systole and comparing it to background absorption, which includes blood, bone, skin, and other tissue components. The technique thus requires pulsatile flow. There has been confusion with respect to the role of pulse oximetry during CPR. Because of the physiology of CPR, which produces low systemic blood flow and significant increases in physiologic deadspace, along with ventilation that uses high flow oxygen, arterial blood gases reveal hemoglobin oxygen saturations of 99%, as PaO_2 levels are uniformly above 100 mmHg.[41,56] Thus, in the absence of significant anemia, obtaining maximum arterial oxygen content during CPR is rarely a problem. For monitoring the effectiveness of chest compressions, use of SpO_2 to observe the produced plethysmograph is unreliable because of various factors, including presence of nail polish, temperature-induced vasoconstriction of digits, shunting due to reductions in CPR blood flow, and others. In addition, studies have demonstrated that very low pulsatile blood flow is capable of producing a plethysmograph.[57,58] Various manufacturers have developed very bright light-emitting diodes and sensitive detectors that can pick up very weak signals. They have even developed sensitive motion artifact rejection software. Most manufacturers "auto scale" the detected plethysmograph for the user so that information on signal intensity is not available. Thus, the ability to detect a peripheral SpO_2-produced plethysmograph is not indicative of adequate CPR.

The characteristics of the plethysmograph determined by pulse oximetry have not been examined for its ability to correlate with central hemodynamics produced by closed chest compressions and pharmacologic interventions, although it may warrant study. It is likely, however, that interpatient variations produced by arterial vascular disease and other factors will preclude its use as a sensitive guide to resuscitation.

End-tidal CO_2 monitoring

Capnometry is the measurement of the concentration of CO_2 in the airway during inspiration and expiration. Capnography refers to the graphic display of this measurement over time. Measurement of CO_2 concentrations at the very end of expiration is termed end-tidal CO_2 ($PetCO_2$). CO_2 in respiratory gases can be measured by several methods, with infrared spectroscopy being the most common. $PetCO_2$ can also be measured qualitatively and semiquanti-

tatively by using pH-sensitive filter papers containing metacresol purple, which changes color in response to varying concentrations of CO_2 owing to the formation of hydrogen ions.[59,60]

Beginning with the work of Kalenda and Smallhout, the value of $PetCO_2$ monitoring for resuscitation of victims of cardiac arrest has been demonstrated repeatedly.[61] The value of $PetCO_2$ monitoring lies in its ability to reflect closely alveolar CO_2. Alveolar CO_2 is determined by the combination of CO_2 production (VCO_2), pulmonary capillary blood flow (i.e., cardiac output), and alveolar ventilation. As such, alveolar CO_2 and $PetCO_2$ are linearly related to VCO_2. VCO_2 depends on two different factors: pulmonary excretion and metabolic production of CO_2. In low flow states with steady-state ventilation, VCO_2 declines secondary to decreased delivery of CO_2 to the lungs and to ventilation/perfusion mismatches in the lung resulting in an enormous increase in deadspace (up to 0.7 in the setting of CPR).[62] This results in a widening of the arterial PCO_2 to $PetCO_2$ gradient and is further reflected by mixed venous hypercarbia. Although difficult to measure, VCO_2 also declines secondary to reductions in actual CO_2 production from decreases in DO_2.[42,63,64] Although sometimes described as logarithmic, VCO_2 and thus $PetCO_2$ basically have almost the same biphasic relationship with DO_2 as does VO_2 (Fig. 38.5). Thus, DO_2crit determined by following changes in VCO_2 and $PetCO_2$ does not significantly differ from determinations using changes in VO_2 or lactate production.[63,65] Concomitant with reductions in DO_2 will be increases in tissue CO_2, as decreases in blood flow will reduce the amount of aerobically produced CO_2 removed from tissue, creating a tissue respiratory acidosis.[66–68] Additional tissue CO_2 will be produced after DO_2crit is reached, as metabolic acids such as lactic acid are buffered by tissue bicarbonate, although tissue CO_2 production as a whole will be decreased in accordance with decreases in VO_2.[69]

VCO_2 and thus $PetCO_2$ are linearly related to DO_2 during metabolic states dependent on oxygen supply. Since during CPR, oxygen content does not change significantly, then the major component of DO_2 tracked by VCO_2 or $PetCO_2$ is cardiac output. This is advantageous during CPR since, as discussed earlier, CPR is a state where VO_2 is directly dependent upon DO_2.

Again, in order for this to be valid, both alveolar ventilation (minute ventilation) and VCO_2 must be assumed to be relatively constant. If this is assumed, changes in $PetCO_2$ will reflect changes in pulmonary capillary blood flow or cardiac output. Of note, in this setting, although $PetCO_2$ correlates with cardiac output, it does not correlate with actual $PaCO_2$ during CPR in humans,
Fig. 38.5. Biphasic relationship between DO_2 and VCO_2. Note the similarities between the relationships as compared to Fig. 38.1. When minute ventilation is held constant, DO_2crit can be determined by reductions in VCO_2 and thus $PetCO_2$. This corresponds to the point of delivery-dependent VO_2. *CO_2 represents CO_2 that accumulates as a result of decreased removal of aerobically produced CO_2 secondary to decreases in flow (respiratory acidosis). #CO_2 represents additional tissue CO_2 production and accumulation due to buffering of metabolic acids produced by anaerobic metabolism after DO_2crit is reached, and would correspond to the production of lactate at the point of DO_2crit (see Fig. 38.1). $+ CO_2$ represents the combination of aerobically and an aerobically derived CO_2. Overall VCO_2 is decreased due to declines in VO_2. Quantities of CO_2 as depicted on the Y axis are not drawn to scale, but instead are depicted to demonstrate their temporal relationship to each other in reference to changes in DO_2.

because of the large increase in pulmonary deadspace produced.

Although VCO_2 production during CPR is difficult to measure, there are not likely to be wide swings. In addition, the extremely high concentrations of CO_2 in the mixed venous blood pool (> 60 mmHg) and large pulmonary deadspace ensure that small changes in VCO_2 do not cause appreciable changes in $PetCO_2$.[42] Only ROSC or improved artificial circulation (e.g., with open chest massage) will result in a dramatic and sustained increase in $PetCO_2$. Minute ventilation should be held relatively constant if $PetCO_2$ is to be used as an indicator of cardiac output.

Both animal and human data have demonstrated that $PetCO_2$ correlates with CPP and cerebral perfusion pressure (CePP) during CPR.[70–72] The correlation between $PetCO_2$, CPP, and CePP is due to its relationship with cardiac output in the low-flow setting of CPR. This can be predicted on the basis of the known relationship between mean arterial pressure and cardiac output when peripheral vascular resistance (PVR) is constant. Thus when PVR is not significantly changing, increases in cardiac output will result in increases in organ blood flow; the increased cardiac output will result in an increase in $PetCO_2$ if minute ventilation and VCO_2 are held constant.

These correlations between $PetCO_2$, CPP, CePP, and cardiac output may be uncoupled by epinephrine and other vasopressors administered during CPR. Animal and human studies have shown that $PetCO_2$ decreases when large doses of epinephrine are used during cardiac arrest, despite significant increases in CPP and myocardial and cerebral blood flow.[31,73] Initially thought to be due to increases in shunt fraction, it has been found that this effect is due to actual decreases in CPR-produced cardiac output as a result of increases in afterload.[31] Thus, although cardiac output is decreased, DO_2 to the myocardium and cerebrum are increased because of the redistribution of blood volume, much of which lies in the aorta. Although consistently shown in animals, the effect of epinephrine administration during CPR on reducing $PetCO_2$ in humans has been variable.[74,75] When decreases in $PetCO_2$ occur after epinephrine administration, they correlate with the timing of increases in central arterial levels of epinephrine and the concomitant vasopressor effect. The duration of these changes, if they occur clinically, has not been well quantified. Interestingly, such changes in $PetCO_2$ may be potentially useful for timing subsequent epinephrine or other vasopressor dosing or in understanding if CPR is producing enough forward flow to distribute intravenously administered vasopressors to the systemic circulation.

Because sodium bicarbonate contains and produces CO_2, its bolus administration during CPR will cause a variable but significant transient rise in $PetCO_2$. The timing of this increase is within 1 minute of administration, and it usually lasts for <2 minutes depending on whether minute ventilation changes.[76]

End-tidal CO_2 can be used as a feedback to optimize chest compressions during CPR. Monitoring $PetCO_2$ during cardiac arrest may detect unrecognized fatigue in the CPR provider.[61,77] Since an effective threshold for chest compressions has been demonstrated, $PetCO_2$ may be of value in detecting compression thresholds, with either manual or mechanical chest compressions.[78,79] Changes in pulse pressure as detected by palpation of CPR-produced peripheral pulses do not necessarily correlate with flow.[7] $PetCO_2$ on the other hand provides evidence of improvements or deterioration in real-time forward flow, given that the possible effects of bicarbonate and vasopressor agents on $PetCO_2$ are recognized. One effective strategy might be to perform CPR at a rate and compression depth to produce maximum $PetCO_2$ values. Chest compressions need not be halted during CPR to palpate pulses if $PetCO_2$ monitoring is performed.

In cases of mechanical causes of PEA, $PetCO_2$ monitoring should be valuable in indicating the immediate success of such therapeutic maneuvers as needle decompression of tension pneumothorax, pericardiocentesis for relief of cardiac tamponade, or fluid resuscitation for hypovolemia. $PetCO_2$ monitoring might also be (deemed to be) helpful in determining which patients with PEA have true electromechanical dissociation versus those with significant cardiac contractions, but in whom a pulse cannot be palpated due to obesity, vasoconstriction, or hypothermia. Paradis *et al.* found that a significant number of patients with PEA had arterial pulse pressures when monitored invasively, with several patients having systolic blood pressures of 90 mmHg.[8] $PetCO_2$ monitoring would have demonstrated values significantly greater than 0 mmHg in these patients when no chest compressions were performed.

Several investigators have reported $PetCO_2$ values during CPR that may offer prognostic information concerning chances of obtaining ROSC. These include averaging $PetCO_2$ values over 20 minutes of resuscitation, taking initial and maximal $PetCO_2$ values, measuring $PetCO_2$ changes after epinephrine administration, and measuring $PetCO_2$ values during resuscitation of various presenting rhythms such as asystole or PEA.[80–85] Levine and colleagues have demonstrated that a $PetCO_2$ value of <10 mmHg after 20 minutes of resuscitation in out-of-hospital cardiac arrest with PEA has a 100% predictive value of no ROSC.[84] Similar results have been observed in other out-of-hospital studies, as well as in the in-hospital setting.[74,75,81,82] Others have demonstrated that an initial $PetCO_2$ value of <15 mmHg has a 91% predictive value for no ROSC. The use of high-dose epinephrine (>10 mg) changes, but does not eliminate, the ability of $PetCO_2$ to predict ROSC. Two studies have demonstrated that reductions in $PetCO_2$ after epinephrine administration result in positive predictive values for ROSC ranging from 29% to 53% and negative predictive value ranging from 92% to 100%.[74,75] Nonetheless, it should be remembered that epinephrine doses of ≥ 1 mg may decrease or have no effect on $PetCO_2$.[75]

Although no formal guidelines or recommendations have been made by any organization concerning the use of $PetCO_2$ to guide CPR efforts, the following is suggested. For $PetCO_2 < 10$ mmHg, the clinician should modify the ongoing resuscitation. Standard CPR should be enhanced (e.g., by increased rate or depth of compression). If, despite optimal performance of CPR, $PetCO_2$ values remain <10 mmHg and the clinical scenario warrants aggressive intervention, the clinician should consider an alternative method of CPR, such as open chest cardiac massage. If, despite optimal resuscitative efforts, the $PetCO_2$ cannot be raised to ≥ 10 mmHg and the patient's dysrhythmia is not

amenable to electrical therapy, ceasing resuscitation efforts in a normothermic arrest patient should be considered.[76]

Because values are low during CPR and mixed venous PCO_2 is so high, ROSC should be immediately detected by significant increases in $PetCO_2$. Indeed, $PetCO_2$ values have been shown to be the first changes noted after ROSC.[76,86,87] Upon ROSC, there is a rapid rise in $PetCO_2$ that will generally overshoot values of 40 mmHg. This overshoot stems from the large tissue and venous respiratory acidosis that has existed since the onset of arrest. Elevated $PetCO_2$ may persist for some time as CO_2 is washed out of various tissue beds. $PetCO_2$ monitoring can be helpful at this time in adjusting minute ventilation as a guide to bringing $PaCO_2$ back to baseline, because ROSC will reduce deadspace back to levels where $PetCO_2$ can be used to estimate $PaCO_2$. This will assist in using ventilation to control systemic pH. Similarly, $PetCO_2$ monitoring can help detect deterioration in perfusion after resuscitation. Sudden reductions in $PetCO_2$ after ROSC when no changes in ventilation have been made can be interpreted as significant deterioration in cardiac output, consistent with returning to a state below DO_2crit.[63,65] In these instances, re-arrest is likely to be imminent if no action is taken.

In summary, $PetCO_2$ monitoring is an ideal tool for use during CPR and in the postresuscitation period because of its linear relationship with cardiac output in low flow states and the relationship between cardiac output and critical perfusion pressures such as CPP and CePP. Its link with these central hemodynamic events during CPR allows real-time changes to be detected within seconds of interventions, given current cardiac arrest treatment protocols. For diagnostic and treatment decisions, $PetCO_2$ monitoring during CPR should be carried out with devices that use infrared technology, so that quantitative values can be obtained and the capnogram can be inspected. Figure 38.6 provides several examples of $PetCO_2$ monitoring during cardiac arrest by use of time-compressed capnography.

Cardiac output and oxygen consumption monitoring
There are now numerous invasive and non-invasive means to monitor cardiac output, ranging from traditional thermodilution methods with the pulmonary artery catheter to less invasive methods that utilize impedance (impedance cardiography), esophageal Doppler technology, rebreathing of CO_2 (CO_2 Fick method), and others.[88–91] Although the use of non-invasive methods to measure cardiac output during CPR is tempting, the efficacy of such an approach is questionable, especially in light of the proven utility of $PetCO_2$ monitoring described above. If the goal of CPR is to produce the highest cardiac output and CPP to achieve ROSC in the shortest period of time, it would be difficult to

justify actual cardiac output monitoring during CPR. Furthermore, given the low cardiac outputs and motion that CPR produces, it is doubtful that any cardiac output readings obtained with these techniques would have the required accuracy and precision to be useful.

Cardiac output monitoring may be more useful in the postresuscitation setting as a means to recognize cardiac dysfunction and to optimize global DO_2. Use of cardiac output as an end-point *per se* is ill-advised since significant end-organ hypoperfusion can exist despite normal and even supernormal cardiac output.[92–98] Instead, cardiac output monitoring may be more appropriately used as a guide to volume resuscitation in determining optimal preload (volume challenges provided until no further increase in cardiac output is obtained). In addition, its use in conjunction with markers of end-organ perfusion (discussed below) may assist in identifying the points in which pharmacologic therapy to increase cardiac output have been maximized and, in turn, the need to institute additional circulatory adjuncts such as intra-aortic balloon pumping. The method of cardiac output monitoring used is less important than how and when it is used.

Measurement of VO_2 in states of critical illness is very underutilized. Although its use during CPR will be uninformative since a state of severe DO_2-dependent VO_2 is present, its use during the postresuscitation phase of care has shown promise in predicting survival. There are two major methods of measuring VO_2: 1; the use of the indirect or reverse Fick method which requires insertion of a pulmonary artery catheter for determination of cardiac output and the arterial to mixed venous difference in oxygen content; and 2, the use of indirect calorimetry. The latter is believed to be more accurate, because it eliminates the potential for mathematical coupling of VO_2 with cardiac output that is thought to occur.[1] In addition, it takes into account actual oxygen utilization of the lung itself, which can be substantial in some situations.[99]

Rivers *et al.* have reported the use of VO_2 monitoring after cardiac arrest and found that failure to achieve of VO_2 greater than 90 ml/min per m^2 within the first 6 hours of arrest was associated with 100% mortality at 24 hours after ROSC.[53] There appear to be two reasons for this. First there is as expected a component of cardiogenic shock in which DO_2 is impaired in relation to the amount of cardiac output. Importantly but under-recognized, however, is that the oxygen extraction ratio in these individuals is lower than expected and is accompanied by venous hyperoxia.[53,54] This indicates the likely presence of an impairment in microcirculatory DO_2 because of microcirculatory occlusion or shunting, which contributes to the accumulation of a fatal level of oxygen debt.
Fig. 38.6. Capnogram tracings of $PetCO_2$ during cardiac arrest and CPR. (1) Effect of rescuer fatigue is demonstrated at point A. Point B demonstrates the effect of changing to a new chest compression provider. (2) Patient with pseudo-EMD. At point A the patient is pulsless but has persistent $PetCO_2$ value of 20 mmHg without chest compressions; at point B, chest compression is restarted; at point C, a dopamine infusion is begun; and at point D, chest compressions are stopped and a pulse is palpated. (3) Sudden rise in $PetCO_2$ (A) heralds ROSC and pulses are palpated at point B. (4) Point A shows a transient rise in $PetCO_2$ just after an intravenous bolus of sodium bicarbonate.[60,76]

A very valuable surrogate of VO_2 monitoring is mixed venous (SvO_2) or central venous ($ScvO_2$) hemoglobin oxygen saturation monitoring. The use of mixed venous hemoglobin oxygen saturation (SvO_2) has long been advocated as a means to detect tissue hypoxia in the critically ill or injured patient since it is a reflection of oxygen extraction which, in turn, reflects the adequacy of DO_2.[93] Normal values average 75%. SvO_2 reflects the aggregate balance between tissue oxygen delivery and consumption or the extraction ratio of all tissues, and thus reflects global DO_2 (Fig. 39.1). It is not difficult to understand the potential value of such a measure as an early warning system in identifying reductions in DO_2 before DO_2crit, as well as the need for increasing DO_2 even after a state of VO_2-independent DO_2 is reached. Nevertheless, placement of a pulmonary artery catheter is difficult in the immediate postresuscitation period (and may not be needed) and impossible during CPR. Although not truly mixed, a suitable surrogate of SvO_2 may be $ScvO_2$ monitoring.[100–103] $ScvO_2$ has been advocated for use during CPR.[100] Similar to tissue CO_2 measurements, $ScvO_2$ values will be significantly below baseline, demonstrating maximum oxygen extraction. Rivers and colleagues have found that similar to CPP thresholds, there appears to be a $ScvO_2$ threshold below which patients undergoing CPR cannot be resuscitated. In their studies, no patient with an $ScvO_2$ of less than 30% could be resuscitated. All but one patient who achieved ROSC obtained an $ScvO_2$ during CPR of at least 40%. These findings should reflect the adequacy of DO_2 from a cardiac output produced during CPR. Unfortunately, the study by Rivers did not report simultaneous $PetCO_2$ levels and thus it is unclear if $ScvO_2$ monitoring would have any significant advantage over $PetCO_2$ monitoring during cardiac arrest that would justify its use.

Similar, however, to some of the tissue-specific methods of monitoring discussed below, the real value of $ScvO_2$ or SvO_2 monitoring will likely be in the postresuscitation setting as a means to exclude occult tissue hypoxia and to determine the adequacy of DO_2. Of special note is the ability of the technique to detect venous hyperoxia as a manifestation of severe microcirculatory injury, especially after high dose vasopressor use.[53] In this setting, $ScvO_2$ levels are noted to be significantly elevated in the presence of elevated lactate levels, indicating that significant shunting is likely.[53,104] In this setting, the body is not consuming oxygen (again likely to be due to problems with microcirculatory DO_2) and measures that increase microcirculatory DO_2 must be considered quickly before fatal levels of oxygen debt are reached. Such measures might include intra-aortic balloon pumping, use of vasodilators, or use of extracorpreal circulation tech-

niques. Although studies examining the use of both SvO_2 and tissue-specific indicators of oxygenation, for example, gastric tonometry in other shock states such as trauma and sepsis (discussed below), have demonstrated the superiority of tissue-specific measures over SvO_2, these studies have not applied the techniques very early. It is therefore unclear whether there would be cases in the immediate post-arrest period where $ScvO_2$ would be normal, but tissue-specific measures would be abnormal. The transition from perfusion-limited shock states (hemorrhage, cardiogenic) to those associated with significant inflammation (sepsis) make the interpretation of SvO_2, $ScvO_2$, and tissue-specific measures such as gastric tonometry more difficult.[92,93,105] Recent evidence suggests, however, that early use of $ScvO_2$ will be able to identify significant tissue hypoxia (much of it occult) and will be useful as an end-point to guide treatment, in addition to identifying states of venous hyperoxia after cardiac arrest.[53,103,106] The technique has the added advantage of allowing the user to monitor central venous pressure and thus assist in optimizing preload.

Ultrasound

Rapid access and use of ultrasound in the emergent setting is becoming more common, given advances in the quality and portability of devices. In the setting of cardiac arrest, ultrasound can rapidly assist the clinician in distinguishing between true electromechanical dissociation (EMD) and pseudo-EMD during treatment of PEA. It will also assist the clinician in diagnosing other causes of PEA or arrest, such as pericardial tamponade (in addition to guiding pericardiocentesis), and in diagnosing exsanguinating intra-abdominal or intrathoracic hemorrhage. Special ultrasound variations such as transesophageal echocardiography, which provide higher resolution visualization of the heart and mediastinal structures, may be useful in identifying other causes of cardiac arrest, such as pulmonary embolism or aortic dissection and in detecting severe valvular abnormalities.[107] Lastly, the use of ultrasound for echocardiography in the postresuscitation period could be extremely helpful in judging the degree of post-arrest myocardial dysfunction and in making decisions on how to assist the failing heart. Ultrasound may also assist in vascular cannulation of central vessels, when "blind" cannulation by use of anatomical landmarks, is unsuccessful.[108,109] The major limitations to the use of ultrasound in the settings above are the experience and skills of the operator. Making the diagnosis of pericardial tamponade or intraabdominal hemorrhage will require less skill than determining the degree of myocardial dysfunction in the postresuscitation setting.

Tissue-specific monitoring

Figures 38.1 and 38.5 demonstrate that the biphasic relationship between VO_2 and VCO_2 with DO_2 exists not only for the whole body, but also for individual organ systems, which may have DO_2 crit values that differ from whole body DO_2crit. Studies have demonstrated, for example in hemorrhagic shock, that the DO_2 crit of the splanchnic bed occurs at a higher global DO_2 than the DO_2crit of the whole body.[69,110,111] As noted earlier, however, cardiac arrest immediately results in a state of profound delivery-dependent VO_2, so that all organ systems are immediately past their DO_2crit values. Therefore, each would show evidence of profound tissue hypoxia and flow stagnation as represented by very low venous hemoglobin oxygen saturations and elevated venous or tissue CO_2 levels. The advantage of monitoring one tissue over another in this setting is difficult to defend. Nevertheless, tissue-specific monitoring in the postresuscitation setting may make sense based on the characteristics of the tissue and the goals to be achieved.

Tissue CO_2 monitoring

Several options that are available to monitor tissue CO_2 have been studied in various shock states. These include transcutaneous CO_2 ($PtcCO_2$) skin monitoring, interstitial fiberoptic PCO_2, gastric mucosal CO_2 via gastric tonometry ($PgCO_2$), and most recently sublingual tonometry ($PslCO_2$).[93,112–120] $PtcCO_2$, $PgCO_2$, and $PslCO_2$ are non-invasive, whereas interstitial PCO_2 monitoring requires insertion of a probe into tissue parenchyma. Details of how CO_2 is actually measured by these techniques have been well described.[93] All of these methods are based on the diffusion of CO_2 from tissue: each will reflect the balance among supply of CO_2 to the tissue, CO_2 production by the tissue, and CO_2 removal of the tissue. This balance does not mean all tissue compartments contribute equally. Values are a composite of vascular and interstitial levels in the immediate environment of the sensor. Since the majority of blood volume in tissues is venous (approximately 70%), the tissue CO_2 concentrations will mainly reflect venous PCO_2 concentrations.[121,122] The ability of these measures, however, to reflect the balance between DO_2 and VO_2 or to reflect perfusion pressures or other real-time hemodynamic changes during CPR has not been studied. The highest CO_2 concentrations that can be reached in each tissue after cardiac arrest in humans are not known, but in animal models, some tissue beds reach levels well over 100 mmHg.[123] The majority of CO_2 accumulation in each tissue will be secondary to the inability to remove CO_2 that was being produced aerobically prior to ischemia. As mentioned previously, additional CO_2 will be produced in response to

metabolic acids (mainly lactate) produced after the onset of ischemia by the cells as they are buffered by endogenous bicarbonate stores. Interpretation of real-time changes in tissue PCO_2 in response to interventions will be challenging compared to use in other shock settings in which there is significantly more flow and more time for trending. If improvements in forward flow are not accompanied by an increase in minute ventilation, arterial PCO_2 will be increased; thus, more CO_2 will be delivered to the tissue.[44] Use of vasopressors to improve CPP and CePP will most likely result in decreases in peripheral tissue flow, thus potentially further reducing removal of CO_2 during CPR. It is doubtful that tracking tissue CO_2 changes will be meaningful during the short duration of cardiac arrest, especially given the redistribution of blood flow that occurs during CPR and in response to vasopressor administration. Response times are unlikely to be rapid enough to guide the resuscitation effort. Although this seems counterintuitive on the basis of the previous discussion of $PetCO_2$ monitoring, it must be remembered that $PetCO_2$ reflects CO_2 at the end of its journey from the tissue beds. Its rapid breath-by-breath analysis makes its response time to interventions difficult to improve upon. The only thing that can be said with certainty is that, upon ROSC, tissue PCO_2 should decline rapidly as CO_2 is removed from previously stagnant tissue beds and aerobic metabolism is reestablished.

The real value of tissue CO_2 monitoring will be in the postresuscitation phase of care, where it can assist in assuring resolution of end-organ perfusion abnormalities. $PgCO_2$ and perhaps $PslCO_2$ may be particularly helpful. It is known that the splanchnic bed is particularly sensitive to reductions in systemic blood flow, in part because the responsiveness of its vasculature to the myriad of vasoactive mediators associated with shock.[124,125] Of special concern in the victim of cardiac arrest are the mediators angiotelin II, vasopressin, endothelin, and epinephrine. Endogenous levels of these agents are significantly elevated during shock and will be even higher in the postresuscitation phase, if vasopressin and epinephrine are administered during the arrest to achieve ROSC or in the postresuscitation period to maintain blood pressure.[126,127] These and other vasopressor agents provided for blood pressure support in shock states have been shown to contribute to ischemia in intestinal mucosa.[124,128] This, in turn, has been hypothesized to lead to a breach of the intestinal mucosal barrier, allowing bacteria and other toxic mediators into the systemic circulation, which leads to sepsis and multisystem organ failure.[129–133] This paradigm, which is generally accepted in other shock states, has not been well studied in the setting of cardiac arrest.[125] The postresuscitation experience of patients who received vasopressin

during CPR has not been well described and no clinical studies regardless of vasopressin use have been reported that have examined the incidence of splanchnic hypoperfusion or ischemia as determined by $PgCO_2$ monitoring. Nonetheless, the need for vasopressor support in the postresuscitation phase is high and will be complicated by significant cardiogenic shock. Monitoring of splanchnic blood flow by either $PgCO_2$ or $PslCO_2$ as performed in other shock states makes sense, especially in the very early stages of postresuscitation care since, as with other shock states, there is clear evidence that occult splanchnic ischemia can exist in the presence of normal systemic variables, such as blood pressure, heart rate, cardiac output, and mixed venous hemoglobin oxygen saturation.[92,134,135]

$PgCO_2$ monitoring has been used successfully to guide resuscitation of trauma patients and those with septic and cardiogenic shock.[95,115,136] This technique essentially monitors intraluminal CO_2 that has diffused into the stomach from the stomach mucosa. A modified nasogastric tube containing a CO_2-permeable balloon is placed in the stomach. Air is intermittently circulated through the balloon. CO_2 diffuses from the mucosa into the balloon where it is circulated proximally and measured via an infrared detector in the same manner as $PetCO_2$. This CO_2 value has been used previously to estimate the intramucosal pH (pHi) by substituting it for arterial CO_2 in the Henderson-Hasselbalch equation. Use of this formula assumes that arterial HCO_3^- and mucosal HCO_3^- are equivalent. pHi values of less than 7.32 are considered abnormal. The technique also assumes constant minute ventilation. A more robust use of the technology involves $PgCO_2 - PaCO_2$ or $PgCO_2 - PetCO_2$ gap to detect abnormalities in perfusion since this does not require the previous assumptions regarding HCO_3^- and, in addition, does not require strict maintenance of normocapnia, because since hypo- or hyperventilation, although affecting $PgCO_2$, will not affect the gap. Given that the arterial to alveolar PCO_2 gap is approximately 4 mmHg, it is thought that a $PgCO_2 - PaCO_2$ or $PgCO_2 - PetCO_2$ gap of 11–14 mmHg is abnormal and reflects perfusion abnormalities.[116] Although the response time of current $PgCO_2$ methodologies will not permit their use during CPR, they should prove to be quite valuable during the postresuscitation period. As with other shock states, normalization of the $PgCO_2 - PaCO_2$ or $PgCO_2 - PetCO_2$ gap will help ensure that occult tissue hypoxia is not present, thus helping to avoid further accumulation of oxygen debt and its associated complications.

$PslCO_2$ monitoring as a substitute for $PgCO_2$ monitoring to detect shock and guide its treatment is a recent development. Several studies appear to support the premise that the sublingual surface of the tongue may be as sensitive to disturbances in perfusion as the rest of the GI tract, perhaps because it shares the same embryonic origin as the rest of the gut.[66,67,117,137–140] This technique uses fiberoptic determination of CO_2 within a disposable cover (similar to an oral electronic thermometer) which allows diffusion of CO_2 from the sublingual surface into the space between the cover and sensor. The advantage of this technique is that the response time is faster since the sensor is more or less in direct contact with the tissue surface as opposed to $PgCO_2$ balloon, which is in the middle of a large lumen (the stomach). The disadvantage is that it is currently still difficult to perform continuous monitoring. As with $PgCO_2$, or any other tissue CO_2 monitoring technique, the gap of the measure with either $PaCO_2$ or $PetCO_2$ should be utilized in order to avoid misinterpretation of $PslCO_2$ in the setting of hyper- or hypocarbia. Definitive values of this gap or of absolute $PslCO_2$ levels have not been determined, but it is likely that they will not differ from those of the $PgCO_2 - PaCO_2$ or $PgCO_2 - PetCO_2$ gap. Although use of the $PslCO_2 - PetCO_2$ gap may have potential value in monitoring during actual CPR, it is not likely that it will have an advantage over simple $PetCO_2$ monitoring. As suggested above, it is plausible that the use of vasopressors would actually increase $PslCO_2$, despite increasing CPP above a critical threshold for ROSC.

Similarly, $PtcCO_2$ monitoring of the skin and/or interstitial tissue PCO_2 monitoring of tissues such as skeletal muscle may be useful in assuring resolution of end-organ tissue perfusion abnormalities in the postresuscitation setting. Both should be used similarly to that described for $PgCO_2$ and $PslCO_2$. Continued elevations of CO_2 as measured by these methods in the presence of normocapnia have been associated with increased mortality.[112,119,120,141,142] Of note, the technology used to measure interstitial PCO_2 is the same as that used in the development of continuous arterial blood gas monitoring and is thus also capable of simultaneous measurement of PO_2 and pH. The disadvantage of the technique is that it is slightly invasive, and can only sense the environment several micrometers from the sensor. It also requires a considerable calibration time (about 30 minutes).

Tissue oxygen monitoring

Similar to tissue CO_2 monitoring, several options exist for monitoring tissue oxygenation, which provides information on the balance between DO_2 and VO_2 of the tissue. These include transcutaneous PO_2 ($PtcO_2$) monitoring from the skin, interstitial PO_2 monitoring from tissue parenchyma, and tissue hemoglobin oxygen saturation (StO_2) by using near infrared absorption spectroscopy (NIRS). The general principles making tissue oxygenation

monitoring potentially helpful are the same as those discussed above for tissue PCO_2.

Of special interest is the use of StO_2 monitoring by NIRS. Visible light (450–700 nm) penetrates tissue for only short distances, because it is usually strongly attenuated by various tissue components that absorb and scatter at these wavelengths. In the NIR spectrum (700–1100 nm), however, photons are capable of deeper penetration (several centimeters or more) even through bone. It is also within this spectral region that oxygen-dependent electronic transitions of the metalloproteins hemoglobin and cytochrome oxidase (the terminal electron acceptor in the mitochondrial electron transport chain) absorb light. These chromophores absorb NIR radiation differentially based on their concentration and interaction with oxygen. These changes in absorption can be measured by using NIRS technology. The Beer–Lambert law provides the physical and mathematical basis for NIRS, although it is modified to account for the inhomogeneous media that the NIR light traverses. The depth of penetration and volume of tissue being interrogated by NIRS depends on the distance between optodes. The technique of NIRS differs from that of pulse oximetry, because pulse oximetry targets only the arterial component of blood flow.

The basis for using NIRS to monitor the state of tissue oxygenation is similar to that of tissue PCO_2 monitoring in that it relies on the compartmentalization of blood volume, which in most systems is believed to be proportioned among the arteriolar, capillary, and venular compartments in a ratio of 10:20:70%, respectively.[121,122] Thus, the values obtained by NIRS closely parallel those of venous hemoglobin leaving the tissue. This essentially allows it to be used in the same manner as SvO_2 and $ScvO_2$, except that instead of representing an aggregate reflection of the balance between DO_2 and VO_2 for the entire body, it reflects the balance in an individual organ (skeletal muscle, brain, and others). In addition to being non-invasive, the use of StO_2 monitoring may prove more sensitive than $ScvO_2$ or SvO_2 if the organ being interrogated is sensitive to changes in DO_2. Figure 38.7 depicts the use of NIRS for monitoring StO_2 of a skeletal muscle bed.

The vast majority of NIRS technology has been used to monitor the oxygenation status of the brain in neonates and in adults undergoing operative procedures that may affect the brain, such as carotid endarterectomy or cardiopulmonary bypass.[143] It is also being aggressively studied in the setting of trauma by using skeletal muscle or GI tract as the end-organ of interest.[144–148] Normal NIRS-derived StO_2 values for brain and skeletal muscle range from 60% to 80%. Use of NIRS during both cardiac arrest and in the postresuscitation phase has only been reported
Fig. 38.7. Schematic representing NIRS in the reflectance mode overlying skin and skeletal muscle. NIRS is capable of providing information about the balance between oxygen delivery and consumption of an organ(s) by assessing the state of hemoglobin oxygen saturation in the microvasculature, as well as intracellular oxygen utilization via the redox state of cytochrome oxidase. The value and measure of StO_2 lies in the distribution of blood in the organ of interest with approximately 70% of blood volume being in the venous compartment under normal conditions. When NIRS is used to assess skeletal muscle perfusion, the contribution of myoglobin must be taken into account. Note that the technology diagrammed here might allow differentiation of the NIRS radiation returning from the subcutaneous tissue versus deeper underlying tissues such as skeletal muscle. Light follows an elliptical pathway, thus spacing of detectors at various distances from the light source assist in determining the origin of the returning signal.[148]

for the brain,[149–152] where special bilateral probes are placed on the forehead. This is necessary because it reduces the amount of skeletal muscle that the NIR light must traverse. The NIRS spectra between hemoglobin and myoglobin cannot be distinguished from each other. This is important since myoglobin and hemoglobin are present in almost equal proportions in skeletal muscle, with the p50 for myoglobin being only 5 mmHg.[153,154] There is some evidence that, when used as an indicator of skeletal muscle oxygenation, the NIRS signal is derived mainly from myoglobin and not from hemoglobin within the tissue.[155] This would limit its use during CPR and potentially the postresuscitation period, if skeletal muscle were chosen as the end-organ to guide resuscitation efforts. On the basis of these issues, when used for brain oxygenation monitoring, the NIRS signal is reported to derive from the frontal lobes. The bilateral probes were developed to allow comparison between the cerebral circulations of both hemispheres during surgical procedures in which the circulation to one hemisphere may be compromised. As expected, in many instances, StO_2 values are so low they cannot be registered. There is some evidence, however, that during CPR, higher cerebral StO_2 values are associated with ROSC.[149] This is not surprising given the redistribution of blood flow during cardiac arrest and the relationship between myocardial and cerebral blood flow with CPR-produced cardiac output described earlier. Similar to $PetCO_2$ monitoring, StO_2 values should immediately increase upon ROSC. Additional studies will be needed to include a larger number of patients to determine whether, as with $PetCO_2$ monitoring, there is a threshold cerebral StO_2 value below which victims cannot achieve ROSC. Unfortunately, no studies to date have measured cerebral StO_2 values concomitantly with $PetCO_2$ monitoring to assess whether StO_2 values are simply a reflection of cardiac output and therefore CPP and CePP, similar to $PetCO_2$. If this is the case, it may be hard to justify StO_2 monitoring during CPR over the technology of $PetCO_2$ monitoring, which can also provide information about proper airway management and sudden hemodynamic collapse after ROSC.

It is tempting to suggest the use of cerebral StO_2 monitoring in the postresuscitation phase to guide therapy. Whereas it may be a valid assumption that the circulation to the frontal lobes during cardiac arrest is indicative of blood flow to the rest of the brain (since the cerebral circulation is maximally dilated), use of cerebral StO_2 monitoring during the postresuscitation phase may be more complicated. It is well known that the brain undergoes a complicated pattern of heterogeneous blood flow and oxygen extraction in the postresuscitation period along with the potential for decreased global cerebral DO_2.[156–160] Although there is

potential for use of cerebral oximetry in this setting, it gave mixed results.[149,152] When compared to jugular venous bulb oximetry (a measure of global cerebral oxygen utilization), NIR cerebral oximetry values are higher, indicating that they may not reflect global cerebral blood flow and oxygenation, especially given that the majority of blood flow heterogeneity and damage will occur in the regions of the hippocampus and basal ganglia, which are supplied by circulation different from that of the frontal lobes. Because of blood flow heterogeneity and differences in regional cerebral metabolic activity, it may be difficult to conclude that changes in cerebral StO_2 values are secondary to changes in blood flow vs. extraction due to increased metabolism. Infarction of a region of brain tissue being interrogated may result in increases in StO_2.[150] It is unclear how the use of therapeutic hypothermia will affect the potential for NIRS use in the brain in the postresuscitation period.

As mentioned earlier, NIR StO_2 monitoring of skeletal muscle as an end-organ during CPR or in the postresuscitation period will require further study. Use of NIR StO_2 monitoring of the GI tract is still in the experimental stages of development.

Although the potential exists to use NIRS to determine the redox status of the cytochrome oxidase (the terminal electron acceptor in the mitochondrial transport chain) and thus the point of DO_2crit for the organ being monitored, this has proven to be extraordinarily challenging, in part because the reduced form of cytochrome oxidase does not have an absorption spectrum, and because the amount of cytochrome oxidase is so much smaller compared to hemoglobin. Thus, in order to use NIRS to monitor the redox state of the mitochondria, monitoring must take place before changes in the redox state. This obviously limits its value for monitoring during cardiac arrest or postresuscitation.

Direct visualization of the microcirculation
The ability to visualize microcirculatory blood flow directly and non-invasively has recently been introduced to clinical practice through the technique of orthogonal polarization spectral imaging (OPSI).[161] Linearly polarized light is used to illuminate the tissue. Because of the wavelength used, the light is reflected by the background, and is absorbed by hemoglobin.[161–164] Optical filtration allows elimination of the light reflected at the surface of the tissue to produce high-contrast-reflected light images of the microcirculation. Red cells appear dark (due to absorption of light by hemoglobin), but vessels are not visible unless they contain red cells. The technique works best on mucosal surfaces. With experience, semiquantitative information on microcirculatory hemodynamics is possible by assessing the density of functional (perfused) vessels

within the field of view, as well as the flow of red cells. Unfortunately, automated software is not yet available for real-time quantitative analysis. OPSI of the sublingual area has been used in the evaluation of the microcirculation in patients with sepsis, cardiogenic shock, and during transfusions.[164–166] The technique establishes that the sublingual mucosal surface is very sensitive to changes in blood flow and that these changes reflect what may be occurring at a more global level. Manipulation of hemodynamic variables has been shown to improve microcirculatory flow. These have included both transfusion and vasodilation, indicating that rapid feedback can be obtained at a local tissue level in response to acute interventions.[167,168]

Its study and use in cardiac arrest is only beginning. Whether or not it will have clinical utility during arrest and CPR is unclear. Nevertheless, similar to its use in sepsis and cardiogenic shock, it may have a significant role as a monitoring endpoint in the postresuscitation care of the patient. This may be particularly helpful in understanding and optimizing the effects of postresuscitation hypothermia. Figure 38.8 demonstrates the sublingual circulation of a pig in ventricular fibrillation and during CPR.

Ventricular waveform analysis

It has long been held that ventricular fibrillation (VF) represented a simple chaotic dysrhythmia with little structure. It had been observed that the initial VF rhythm appeared "coarse" and later became "fine" in appearance as the arrest continued and that coarse VF seemed to be more amenable to treatment than fine VF. Often defibrillation of fine VF resulted in postcountershock asystole or PEA, which was difficult to resuscitate. Several studies seem to clearly indicate that deterioration of the VF waveform occurs in response to depletion of intramyocardial high energy phosphates, which may make it more prone to injury from the countershock itself. Indeed, several studies have demonstrated that treatment of VF with chest compressions and epinephrine before countershock appears to increase the chances of successful defibrillation into a perfusing rhythm.[18,19,169,170] Before the last decade, little had been done to objectively analyze the rhythm for patterns, which could predict response to treatment.

Currently endorsed guidelines for applying a defibrillation shock, namely those proposed by the American Heart Association and European Resuscitation Council, propose a three-shock sequence at the earliest practical moment when there is no detectable sign of consciousness after
Fig. 38.8. OPSI of the sublingual mucosa of a pig during cardiac arrest (A) and during CPR (B). An increase in functional capillary density can be seen as produced by CPR. The vessel population in the field of view represents a combination of arterioles, capillaries, and venules.

management of airway and breathing. Thus the very nature of these guidelines promotes delivery of defibrillation countershock without consideration of its potential harm. Such a defibrillation procedure may ultimately result in excessive application of electrical energy with low likelihood of successful ROSC and increase in myocardial injury.[14,16,17,171,172]

Optimally, only a single electric shock should be effective. Implementing this approach would require methods by which the success of defibrillation may be predicted before delivery of the shock. This would allow delivery of the least total energy at the earliest time with high probability of success.

Electrocardiographic rhythm analysis for estimating success of defibrillation has been under investigation for several decades as a method to minimize the risk of defibrillation injury and as a potential method to prioritize interventions for early terminations of VF. The rationale for the analysis of the VF waveform is that if VF is likely to be terminated by defibrillation shock; it would be of benefit to shock immediately. In contrast, an indicator of poor success of defibrillation would guide rescue intervention toward alternate therapies, such as precordial compression, that may improve resuscitation outcomes.

Studies linking properties of VF to defibrillation success were demonstrated by Weaver as early as 1985.[173] Weaver's study found an inversely proportional relationship between the duration of VF and the amplitude and further correlation of the survival rates of victims of cardiac arrest to the amplitude. Weaver's study also pointed out potential pitfalls in associating VF properties to defibrillation success. For example, electrode size, location, and chest dimension may affect the signal amplitude, which will adversely affect the amplitude as a reliable, single parameter measure.

Other investigators adopted alternative approaches characterizing VF frequency properties, which alleviated many of the problems associated with reliance on amplitude alone.[174–179] These "frequency domain" approaches share a common background in decomposing the electrocardiogram into a spectrum by orthogonal transformation, such as Fourier or Wavelet. Still other investigators implemented methods that deviated from quantification by transform or pure amplitude. Menegazzi and Callaway recently developed a fractal technique of "scaling exponents" to predict defibrillation success. A VF signal is analyzed for its relatedness to minute changes in VF. The more random and unrelated an incoming VF signal is in relation to its present position in "time," the higher the score will be and less likely the success of defibrillation.[180,181] This is consistent with anecdotal observations that coarse VF, a more easily convertible rhythm, is somewhat less random and more predictable than is fine VF.

Eftestol demonstrated a method of incorporating multivariate information to a *single variable* ((P_{ROSC} (v)), the probability of successful defibrillation).[176,182] This method selects a combination of features such as centroid frequency, peak power frequency, spectral flatness and energy that would produce the highest prediction of sensitivity and specificity. The usefulness of P_{ROSC} may be improved by adding new features to existing sets and searching for the combination that provides the best predictable performance.

Similarly, amplitude spectrum area (AMSA) combines amplitude and frequency in the frequency domain according to the following equation:

$$AMSA = \sum AiFi$$

Ai is defined as the magnitude of the complex Fourier coefficient of the transformed VF waveform. Fi is defined as the frequency of the complex Fourier coefficient.[177, 178]

In a retrospective study by Eftestol, positive changes in P_{ROSC} were observed in patients who were successfully defibrillated to ROSC while there were no increases in P_{ROSC} in patients who were defibrillated but were not resuscitated.[183] AMSA derived by Marn-Pernat on experimental animals without interrupting precordial compression was confirmed by Povoas, who utilized real-time monitoring with sensitivity and specificity of 0.90.[177,178] During CPR, a progressive increase in the AMSA was observed and correlated well with coronary perfusion pressure (Fig. 38.9).[178]

Both P_{ROSC} and AMSA therefore support the notion that VF waveform analyses and especially the trend of sequential values can identify thresholds for predicting the success of electrical defibrillation. These indicators can also serve as quality control for cardiopulmonary resuscitation during uninterrupted chest compression, with the anticipation of achieving more successful defibrillation. These objective measurements integrated in existing AEDs would then eliminate the current empiricism of delivering repetitive electrical shocks that cause myocardial injury. If the likelihood of successful defibrillation is remote, the rescuer can be guided accordingly and especially emphasize the importance of precordial compression to improve myocardial blood flow and myocardial oxygen delivery before the next attempt at defibrillation.

The attractiveness of using spectral analysis of the VF waveform is its apparent direct link to myocardial blood flow (demonstrated in animal models).[184] This will be particularly important in humans where significant coronary artery occlusions may exist that impede myocardial blood flow, despite what appears to be good CPR-produced cardiac output and CPP based on $PetCO_2$ analysis.
Fig. 38.9. The amplitude spectrum area (AMSA) depicted during cardiac arrest and CPR is shown to correlate well with coronary perfusion pressure (CPP) without interrupting CPR. The AMSA predicted successful ROSC with a sensitivity and specificity of 0.9.[177]

Use of VF analysis tools is limited to VF and will thus not be helpful in gauging the response of asystole, PEA, or pulseless ventricular tachycardia to treatment, nor will it predict outcome. An important aspect of VF waveform analysis technology that requires study is its performance in settings where VF is not the initial rhythm encountered, or in which patients have repetitive episodes of VF with intervening rhythms, including ROSC followed by refibrillation. Despite this, incorporation of this type of technology in defibrillators including AEDs holds great potential to improve outcomes from VF. Although the data are compelling, this technology awaits a definitive prospective trial. The major impediment to use of such technology will be the mammoth re-education of health care providers who have been taught for decades to defibrillate first and then provide adjunctive treatments.

Postresuscitation monitoring

Resuscitation of the cardiac arrest victim does not end with ROSC. The immediate post-ROSC period represents a complex shock state with components of both traditional cardiogenic shock from ischemia, and microvascular shunting due to vasopressor use and occurrence of microthrombi. It is during this time that rapid institution of both global and tissue-specific goal-directed measures

of oxygen transport should take place to optimize the potential for both satisfactory cardiovascular and neurologic outcomes. The reader is again referred to Figs. 38.1, 38.4, and 38.5. The time of ROSC does not ensure that a state of VO_2-independent DO_2 exists. Thus, the clinician must institute such monitoring techniques that can assist in assuring that both overt and occult tissue hypoxia is being resolved. The importance of this cannot be overemphasized. Both animal and clinical studies have demonstrated the effect of cumulative oxygen debt on mortality or in developing significant morbidity including multisystem organ failure. Studies in critically ill surgery patients demonstrate little or no mortality when oxygen debt is less than $4100\,ml/m^2$. Mortality increases to 50% and 95% when cumulative oxygen debt is $4900\,ml/m^2$ and $5800\,ml/m^2$, respectively.[4,5] In contrast, for a 70-kg individual with a baseline VO_2 of $120\,ml/min/m^2$, a 30-minute cardiac arrest would create an oxygen debt of only $3600\,ml/m^2$. Rivers has shown that significant additional oxygen debt that cannot be quantified by blood pressure and other conventional means can accumulate after ROSC.[53,54] It is thus apparent that significant ongoing accumulation of oxygen debt is possible during the postresuscitation period. Deferring aggressive postresuscitation care until, for example, the patient is moved from the emergency department into the intensive care unit is ill-conceived and could allow patients to develop cumu-

Table 38.1. Monitoring goals during CPR and postresuscitation

Monitoring end points during CPR	
CPP:	≥ 15 mmHg
$PetCO_2$	> 10 mmHg (prior to vasopressor administration)
$ScvO_2$	$> 40\%$
Postresuscitation monitoring goals	
Global end points	
Mean arterial pressure	70–90 mmHg
CVP/PCWP	10–15/15–18 mmHg (or pressure which results in no further improvement in CO_2)
Hemoglobin	≥ 10 g/dL
Lactate	< 2.0 mM
SaO_2	94–99%
$ScvO_2/SvO_2$	70–80%
VO_2	> 90 mL/min per m^2
Tissue-specific end points	
pHi	> 7.32
$PgCO_2$–$PaCO_2$ gap	< 15 mmHg
$PgCO_2$ – $PetCO_2$ gap	<15 mmHg
$PslCO_2$–$PaCO_2$ gap	<15 mmHg
$PslCO_2$–$PetCO_2$ gap	<15 mmHg
StO_2	$> 65\%$ (skeletal muscle, brain, or GI tract)

lative oxygen debts, which are not consistent with prolonged survival.

Although there are many end-points to choose from, those that can be instituted rapidly within the first minutes of ROSC are preferred, and may be able to guide the clinical team as to whether additional monitoring and therapy are warranted. Our preference is to use a combination of global and tissue-specific techniques in a goal-directed fashion. The techniques and principles discussed are applicable to all forms of initial resuscitation including trauma. Table 38.1 lists those end-points that should be considered during CPR to gauge the effectiveness of the resuscitation, as well as end-points that might be considered to optimize the postresuscitation effort. Although many may consider these experimental, they are far more objective and sensitive than the use of traditional heart rate and blood pressure monitoring. The effect of therapeutic hypothermia on these variables has not been well studied. Reduced global oxygen demand should be one favorable aspect, thus making it potentially easier to reach a state of VO_2-independent DO_2, especially in the face of reduced myocardial function.

Special considerations in the therapy of non-fibrillatory cardiac arrest

Tom P. Aufderheide, Todd M. Larabee, Norman A. Paradis

Medical College of Wisconsin Milwaukee, WI, USA and
University of Colorado Health Science Center, Denver, CO, USA

Non-fibrillatory cardiac arrest is a term used to encompass the defined cardiac arrest rhythms, pulseless electrical activity (PEA) and asystole, arrest rhythms that are distinct from ventricular fibrillation or pulseless ventricular tachycardia. Until recently, the term electromechanical dissociation (EMD) was used in place of PEA. EMD was defined as the presence of electrical complexes without accompanying mechanical contractions of the heart. Several studies have demonstrated that often during EMD arrest there actually is mechanical cardiac activity associated with the electrical complexes seen on a cardiac monitor.[1,2] PEA, defined as organized electrical activity with the absence of clinically detectable pulses, is thus a physiologically more appropriate terminology. Patients in asystole, by definition, have no discernible ventricular activity by electrocardiography or ultrasonography, and no associated perfusion. This chapter will focus on the diagnosis and treatment of PEA subsets.

The incidence of PEA during cardiac arrest appears to be changing. Prior to 1990, PEA was reported to be the initial presenting rhythm in approximately 20% of hospitalized patients who are monitored at the onset of cardiac arrest and 16.5% of patients who present to a prehospital system in cardiac arrest.[3,4] Several recent studies have reported the incidence of PEA to be 35%–40% of all in-hospital resuscitation events.[5–7] Data from the Ontario province advanced life support (OPALS) study found over a 4-year study period an increasing PEA incidence of 19.9% to 24.5%, with a coexisting shortened EMS system response time.[8] The OPALS group further demonstrated a 50.1% incidence of PEA arrests in the subgroup of patients that arrested after the arrival of EMS.[9] A Swedish longitudinal study demonstrated that the incidence of PEA increased from 6 to 26% over a 17-year study period (1980–1996) with an associated shorter EMS response time and an increased rate of bystander cardiopulmonary resuscitation.[10] Approximately 20% of PEA patients are successfully resuscitated, and 2–4.4% are discharged from the hospital alive.[11,12]

The reasons for the changes in incidence of PEA are unclear, but may be related to our improved diagnostic capabilities for detecting coronary artery disease.[13] Ventricular fibrillation (VF) is the most common presenting rhythm in patients with sudden cardiac death due to CAD. As our abilities to detect previously undiagnosed CAD improve, the incidence of sudden death related to this disease decreases. One theory, then, is that the decline in the rate of VF may be leading to a relative increase in the incidence of alternative cardiac arrest rhythms such as PEA.

Patients in PEA present with a spectrum of perfusion states that range from hypotension to complete absence of perfusion.[1] Approximately 80% of patients have visible echocardiographic myocardial wall motion correlated with electrocardiographic (ECG) complexes.[2] Between 40 and 50% of patients may have demonstrable aortic pressure if invasive central monitoring is accomplished.[1]

Pseudo- and true pulseless electrical activity

One of the most significant advances in understanding the spectrum of perfusion states in PEA is the recognition of pseudo- and true PEA.[1] Pseudo-PEA patients tend to be younger, have a shorter time from onset of cardiac arrest, and a higher frequency of witnessed arrests.[1,11] Patients

in pseudo-PEA receiving cardiopulmonary resuscitation also have a higher measured coronary perfusion-pressure when compared with patients in true PEA.[1] This information supports the contention that patients in pseudo-PEA have a less deranged pathophysiologic state and may be more amenable to resuscitation. Patients with pseudo-PEA are more likely to have a return of spontaneous circulation with standard doses of epinephrine than are patients in true PEA[4]. In one study, 14 (77%) of 18 patients with pseudo-PEA who received high-dose epinephrine had return of spontaneous circulation.[1]

For these reasons, rapid differentiation of pseudo- and true PEA may assist the clinician in the choice, duration, and intensity of therapeutic intervention, possibly improving patient outcome. Consideration of electrocardiographic characteristics may assist differentiation. PEA patients who are resuscitated successfully have average QRS widths less than or equal to 0.09 + /− 0.04 second and frequently have normal initial Q-R deflection (Fig. 39.1, Tables 39.1–39.3 from past chapter).[1,11] Furthermore, no patient in pseudo-PEA had a QRS interval or initial deflection in the QRS of greater than 0.2 second.[1] Despite the strong correlation between normal duration of the QRS and pseudo-PEA, there is significant overlap.[1] Immediate emergency department echocardiography, placing a Doppler probe over the femoral artery, or rapid placement of a peripheral arterial line or central monitoring arterial catheter, can differentiate true from pseudo-PEA.

Causes of pulseless electrical activity

PEA frequently results from a primary condition that profoundly decreases preload or afterload, or causes severe inflow or outflow obstruction. The primary disorder results in hypoxia, acidosis, and increased vagal tone, which, if not rapidly reversed, affect the strength of myocardial contraction, resulting in PEA. The most common cause of PEA is severe respiratory insufficiency or respiratory arrest, reported in as many as 53% of PEA cases.[4] Mechanical causes of PEA are so classified because their etiology is related to anatomical structure and their resolution requires mechanical intervention. Tension pneumothorax causes a reduction in venous return to the heart and may be resolved with needle or tube thoracostomy. Cardiac tamponade may critically reduce left ventricular filling and may resolve with pericardiocentesis. Auto-positive end-expiratory pressure (PEEP) results in increased alveolar pressure and air trapping in ventilated patients with bronchospastic pulmonary disease. Under these circumstances, decreasing inspiratory volumes and respiratory rates decreases excessively high intrathoracic pressure (which impedes venous blood return to the heart) and may circumvent cardiovascular collapse.

Hypovolemia is the primary cause of PEA in 4%–5% of patients.[4] Massive pulmonary embolism is responsible in 1%–5%.[4,14] Numerous causes of direct myocardial dysfunction result in PEA. Acute myocardial ischemia can cause ventricular "stunning," or acute myocardial infarction may result in a critical loss of myocardial contraction. This has
Fig. 39.1. Simultaneous aortic arch pressure (expressed in millimeters of mercury) and lead II ECG from patient in pseudo-PEA. Total QRS duration of 0.12 msec or less and especially a normal duration of initial QR deflection are more frequently seen in patients with pseudo-PEA. (From ref. 1.)

Table 39.1. Unsuccessful vs. successful resuscitations

Group [a]	Rate	Presence of P waves (%)	QT interval (s)	QRS interval (s)
Group I ($n = 405$)	55 ± 27 }[b]	21.0 }[b]	0.56 ± 0.2 }[b]	0.12 ± 0.06 }[b]
Group II initial ($n = 98$)	75 ± 45 {	42.9 {	0.46 ± 0.21 {	0.09 ± 0.04 }
Group II final ($n = 98$)	114 ± 36 }[b]	60.0 }[c]	0.40 ± 0.11 }[c]	0.09 ± 0.03

[a] Group I, unsuccessful resuscitations; group II, successful resuscitations.

[b] $P \leq 0.01$.

[c] $P \leq 0.04$.

Table 39.2. Duration of ECG components in patients with true PEA and pseudo-PEA[a]

	True PEA	Pseudo-PEA	P
QR	0.19 ± 0.13 (0.04–0.56)	0.07 ± 0.05 (0.02–0.20)	0.0004
RS	0.12 ± 0.08 (0.05–0.24)	0.09 ± 0.05 (0.04–0.24)	0.5
QRS	0.24 ± 0.12 (0.11–0.56)	0.12 ± 0.06 (0.04–0.26)	0.006

[a] Values are durations expressed in seconds, with range in parentheses.

Table 39.3. Characteristics of patients with true PEA and pseudo-PEA

Characteristic	True PEA	Pseudo-PEA	P
Age (yr)	71 ± 15	65 ± 15	0.7
Total arrest time (min)	25 ± 11	21 ± 13	0.44
Witnessed arrests	22/55	26/39	0.01
PO_2 (mm Hg)	237 ± 168	310 ± 134	0.03
PCO_2 (mm Hg)	34 ± 23	24 ± 16	0.04
pH	7.23 ± 0.25	7.23 ± 0.25	0.7
Coronary perfusion pressure (mm Hg)	9.9 ± 11.5	19.2 ± 9.5	<0.0001

been variably reported in 13% to 60% of non-fibrillatory arrest patients.[4,15,16] Decreased left ventricular contraction from severe congestive heart failure may produce hypotension, causing decreased coronary perfusion that further impairs myocardial function, resulting in greater hypotension and onset of PEA. Ingestion of drugs such as tricyclic antidepressants, β-blockers, calcium channel blockers, and digitalis, all of which have direct cardiotoxic effects, may result in PEA. Hyperkalemia reduces cardiac conduction and decreases inotropic activity of the heart. Hypothermia has similar effects.

Postdefibrillation pulseless electrical activity and asystole

Patients who experience immediate PEA after countershock from ventricular fibrillation were thought to have a better prognosis than patients in whom defibrillation fails to produce any organized rhythm.[17] The development of postdefibrillation PEA was thought to represent a transient recovery rhythm that in many cases improved spontaneously, leading to the appearance of pulses, supraventricular activity, stabilization of hemodynamic status, and possible long-term survival.[17] More recent data, however, suggest that the outcome of these patients is actually worse than in those found in primary PEA or asystole. In a 5-year retrospective study, Niemann *et al.* compared the outcome of a group of patients found in VF and defibrillated into PEA

or asystole to a group of patients found in PEA or asystole prior to EMS interventions.[18] Return of spontaneous circulation and survival to hospital admission was more likely in those found in primary PEA and asystole. Survival to hospital discharge was not significantly different between the groups.

Initial diagnostic maneuvers

Rapid identification of PEA subsets and reversible causes of non-fibrillatory cardiac arrest

A rapid search for reversible causes of PEA should be undertaken while resuscitative efforts are being initiated. Potentially reversible causes include: severe respiratory insufficiency, tension pneumothorax, cardiac tamponade, auto-PEEP, hypovolemia, pulmonary embolus, acute myocardial infarction, congestive heart failure, drug ingestions such as tricyclic antidepressants, β-blockers, calcium channel blockers, and digitalis, hyperkalemia, and hypothermia.

Hints to the etiology of the arrest may be obtained through the history and physical examination, and should be acted upon aggressively in order to restore coronary perfusion pressure and spontaneous circulation.

Clinical approach

History

Prehospital providers, the patient's family, medical records if immediately available, and the patient's family physician are all potential sources of information for the emergency physician caring for a patient with PEA. An estimate of time from onset of cardiac arrest and whether it was witnessed or unwitnessed may assist clinical decision-making. Witnesses or family may be able to relate the patient's symptoms before onset of arrest, such as an extended period of shortness of breath that would indicate a pulmonary cause or chest pain that would indicate a cardiac cause.

The patient's past medical history may be helpful in uncovering a possible cause for PEA. A prior history of coronary artery disease may indicate myocardial ischemia or possible myocardial infarction. Renal dialysis patients are at risk to develop severe hyperkalemia. Patients who have undergone prolonged immobilization, such as those placed in casts following an orthopedic procedure, are at risk for developing pulmonary embolus. Patients with a prior history of peptic ulcer disease or esophageal varices may have depletion of intravascular volume secondary to gastrointestinal bleeding. A history of chronic obstructive pulmonary disease (COPD) or smoking may lead the clinician to consider tension pneumothorax. A prior history of psychiatric illness or depression may lead to the consideration of a drug overdose. Documentation of severe peripheral arterial vascular disease may indicate the possibility of a false-positive diagnosis of PEA. Current medications, including tricyclic antidepressants, β-blockers, calcium channel blockers, and digitalis, should be determined and assessed for potential cardiac toxicity.

Physical examination

Airway, breathing, and circulation (ABC) should be assessed or reassessed immediately on the patient's arrival to the Emergency Department. The airway should be evalu-ated for obstruction, equal and bilateral breath sounds, and the presence of a midline trachea. The airway should be secured or prior endotracheal placement confirmed by auscultation and capnography. Initially, the patient should be ventilated with 100% oxygen to restore maximal systemic oxygenation, although excessive ventilation (resulting in increased intrathoracic pressure and impeding venous blood return to the heart) should be strictly avoided. The possibility of auto-PEEP PEA should be considered in patients with COPD or bronchospastic pulmonary disease, and the frequency and duration of ventilation further decreased accordingly.

Bilateral femoral and carotid pulses should be rapidly and carefully assessed, with and without CPR, particularly if the patient has no clinically detectable pulse. Femoral or carotid pulses should be present with adequate CPR. Immediate use of Doppler ultrasound, while briefly interrupting CPR, may reveal blood flow that was not detected by simple arterial palpation. Rapid placement of a peripheral arterial line may also be helpful. Auscultation for heart tones may also assist the clinician in determining the presence of underlying myocardial contractility.

If the patient continues in PEA, the American Heart Association advanced cardiac life support (ACLS) protocol for PEA should be initiated or continued (Fig. 39.2). While resuscitative efforts progress, further physical examination should be undertaken to identify causes that may be reversible. Evidence of deep venous thrombosis in the lower extremities may indicate a pulmonary embolus, whereas evidence of an arteriovenous fistula may indicate a renal dialysis patient who is at risk for hyperkalemia. A rectal examination should be performed, a nasogastric tube placed, and a gastric aspirate acquired to uncover signs of gastrointestinal bleeding. A core temperature should also be obtained, if appropriate, before discontinuing resuscitation efforts.

Ancillary evaluation

Ancillary data should be gathered in an expeditious and directed fashion. As soon as the patient is placed on a cardiac monitor, a rhythm strip or 12-lead electrocardiogram should be acquired to determine Q-R and QRS duration. A Q-R or QRS duration of less than or equal to 0.2 second is highly correlated with pseudo-PEA.[1] If not already accomplished, Doppler ultrasound should be performed in all patients with PEA to detect blood flow not revealed by arterial palpation. Immediate emergency department echocardiography, where available, may greatly assist in identifying the PEA subtype. Normal echocardiographic wall motion indicates PEA possibly due to a readily reversible cause, such as hypovolemia or tension pneumothorax. Wall motion that is present but decreased may indicate pseudo-PEA, whereas absent wall motion represents true PEA. Immediate echocardiography also may identify acute cardiac tamponade, pulmonary embolus, ruptured intraventricular septum or ventricle, or pericardial effusion and tamponade. Rapid placement of central arterial monitoring catheters may also help to identify subsets of PEA patients, differentiating pseudo- and true PEA. Chest radiography is useful for diagnosis of pneumothorax, congestive heart failure, or, in the presence of an enlarged cardiac silhouette, possible cardiac tamponade.

Specific therapies for reversible etiologies

Figures 39.2 and 39.3 summarize the therapeutic interventions in PEA.

As previously stated, an aggressive initial evaluation should be undertaken in a patient who presents with PEA arrest to discern any immediately reversible etiologies for the arrest. This section will focus on the therapeutic interventions for these reversible causes.

Hypovolemia

Hypovolemia is the primary cause of PEA in 4 to 5% of patients.[4] Reports of bloody stools, fevers or possible sepsis, or signs of recent trauma can all direct the provider to consider hypovolemia as a potential cause of the PEA arrest. Physical examination may show guaiac-positive stools in support of the history. Aggressive intravenous fluid resuscitation is warranted in all patients presenting with PEA arrest to ensure adequate preload.

Hypoxia

There are many etiologies for hypoxemic states, all of which can result in PEA cardiac arrest. Obvious causes such as asphyxiation and strangulation will be apparent by history and physical examination. Patients with a history of COPD or asthma are at risk for hypoxemia and hypercarbia as well as associated complications, such as tension pneumothorax. Severe hypoxemia may also be related to infection or to coagulation disorders resulting in pulmonary embolism. Information obtained from available history and medical records may help discern the underlying etiology for hypoxemic states. Physical examination should focus on symmetry of breath sounds and adventitious sounds, as well as jugular venous pulsations and distention. Skin crepitus may be helpful in diagnosing pneumothorax. Chest radiography is useful early during resuscitation for cases of tension pneumothorax that are not clinically apparent or other pulmonary causes. Pulse oximetry is rarely useful because of low or absent peripheral perfusion and arterial vasoconstriction. Depending on the primary cause, patient management in all hypoxemic situations should be directed at securing a permanent airway through endotracheal intubation and appropriate ventilatory management. For example, patients with COPD may have a high degree of auto-PEEP due to increased air trapping that results in elevated intrathoracic pressures, decreased venous blood return to the heart, and decreased forward blood flow.[19,20] Management of ventilation for any patient with PEA should focus on maximizing

coronary perfusion pressure (forward blood flow) during CPR. Following establishment of an advanced airway, ventilation rates should not exceed 8–10 breaths per minute and each breath should be limited to 1 second. Even lower ventilation rates for patients with auto-PEEP may be required to achieve adequately reduced intrathoracic pressure at the necessary expense of permissive hypercapnia.

Cardiac tamponade

Cardiac tamponade is an uncommon etiology in the presentation of non-fibrillatory arrest. A patient with a history of cancer, recent cardiothoracic surgery, renal failure and dialysis, coagulopathy, platelet disorder, or chest trauma may suggest this diagnosis. Physical findings such as distended neck veins, muffled heart tones, and pulsus paradoxus are helpful if they can be reliably determined, but are difficult to establish during the initial phases of resuscitation and may be absent. Cardiac tamponade is best diagnosed with early bedside ultrasonography on patient arrival in the emergency department.[21,22] Electrical alternans may be apparent on the electrocardiogram in cases of pseudo-PEA owing to the "swinging of the heart while beating," usually associated with effusions of 300–600 ml.[23,24] Specific therapy for cardiac tamponade includes fluid administration, pericardiocentesis, thoracostomy, and, if required, resuscitative thoracotomy.

Volume expansion with crystalloid infusion may be used as a temporizing maneuver while the clinician is preparing for pericardiocentesis or thoracotomy. Gascho *et al.* studied the effects of volume expansion and vasodilation in a canine non-arrest model of acute pericardial tamponade.[25] They found that volume expansion alone, and in conjunction with vasodilation with nitroprusside, improved tissue blood flow. Vasodilation should not be used during cardiac arrest secondary to pericardial tamponade; drainage of the tamponade is the therapy of choice. The subxiphoid technique is best used for pericardiocentesis since it avoids injury to the coronary arteries. The subxiphoid region should be quickly prepared with a povidine-iodine solution and a 16- to 18-gauge catheter over needle introduced between the xiphoid process and the left subcostal angle at a 30 to 45 degree angle to the skin. The tip of the needle should be directed at the inferior tip of the left scapula. This procedure may be difficult and dangerous while CPR is in progress and the clinician should discontinue CPR for 30 seconds while attempts at drainage are made. If unsuccessful, CPR should resume for several minutes and another attempt at drainage should be made. When fluid is aspirated, the catheter is advanced into the pericardial space and the needle

removed. A three-way stopcock should be attached to permit repeated aspirations if necessary.[26]

If this technique is unsuccessful and cardiac tamponade is still highly suspected, a resuscitative thoracotomy can be performed. The benefit of this approach is unclear because there have been no outcome studies of thoracotomy in non-traumatic PEA cardiac arrest. The clinician must weigh the benefits of direct pericardial drainage and open cardiac massage with the possible long-term morbidity from instituting this invasive technique in the presence of prolonged, low flow cardiac arrest. Conversely, thoracotomy may be both diagnostic and therapeutic in PEA arrest: the clinician can directly observe the myocardium for signs of mechanical activity (allowing differentiation of pseudo- and true PEA) and, with internal massage, amplify the ineffectual contractions in pseudo-PEA.

When performing thoracotomy, a left anterolateral incision over the fourth interspace provides the best access to the heart. Once the chest is entered, the pericardium should be inspected for evidence of pericardial tamponade. If tamponade is present, the pericardium should be opened via an incision anterior and parallel to the phrenic nerve.[27] Once the pericardial fluid is drained, and if return of spontaneous circulation occurs, the thoracotomy must be closed in the operating room.

Tension pneumothorax

Pirolo *et al*. reviewed the autopsy files of 50 patients who had died after documented episodes of PEA and found a 4% (2 of 50) incidence of pneumothorax.[3] This condition is suggested by unilateral decreased breath sounds after endotracheal intubation, jugular venous distention, devi-ation of the trachea away from the side of pneumothorax, and hyperresonance to percussion over the affected hemithorax. The clinician should first determine appropriate placement of the endotracheal tube by auscultating the epigastrium to rule out esophageal intubation. Bilateral breath sounds should also be assessed, and, if unilaterally reduced, the endotracheal tube should be withdrawn slightly to rule out endobronchial intubation. Proper placement of the endotracheal tube can also be confirmed by end-tidal CO_2 capnography. Since the esophagus can have low levels of CO_2 present, the end-tidal CO_2 should be monitored over several breaths. Continued presence of CO_2 confirms proper endotracheal tube placement.[28] If decreased breath sounds persist after these maneuvers, needle thoracostomy should be performed, followed by tube thoracostomy. Needle thoracostomy may be performed with a large catheter over needle system (14 to 18 gauge). The system should be attached to a syringe and the insertion site

quickly prepared with povidine-iodine (1 to 2 seconds). The needle should be introduced in the second intercostal interspace in the midclavicular line. Once the pleural space is entered, the catheter should be advanced over the needle and air aspirated through the syringe. A three-way stopcock should be attached to the catheter to permit repeated aspirations as necessary.[29] Once time permits (usually after return of spontaneous circulation), tube thoracostomy should be performed. If the clinician still suspects pneumothorax following unsuccessful needle thoracostomy, however, definitive tube thoracostomy should be performed immediately. Of note, needle thoracostomy should only be performed when pneumothorax is suspected by history or physical examination. The cavalier performance of bilateral needle thoracostomy in all patients in PEA is not warranted and may increase postresuscitation morbidity.

Hypothermia

There are numerous documented cases of accidental hypothermia and prolonged cardiac arrest that have been successfully resuscitated after instituting re-warming protocols. The lowest recorded temperature in a patient who suffered from accidental hypothermia with successful resuscitation is 13.7 °C (56.7 °F) in an adult[30] and 14.4 °C (57.9 °F) in a child.[31] It may be difficult to determine by history and physical if the initial event leading to cardiac arrest was due to hypothermia or to another etiology with resulting hypothermia. History and physical should be undertaken to determine primary from secondary accidental hypothermia. Cold-reading thermometers are needed to record core body temperatures accurately in this population. The characteristic Osborn waves on the electrocardiogram in patients with a cardiac rhythm appears as a deflection at the J-point in the direction of the QRS complex.

Passive rewarming techniques (warm packs, warming blankets) are not indicated in hypothermic patients in cardiac arrest. Treatment of severely hypothermic patients (core temperature <30 °C (86 °F)) in arrest should be directed at active core rewarming techniques, including warm humidified air via endotracheal tube, warm peritoneal lavage, warm intravenous fluids, and extracorporeal cardiopulmonary bypass. Forced air rewarming techniques have been described[32,33] as well as intrathoracic lavage.[34] Walpoth *et al*. examined the long-term outcomes of 32 patients who underwent extracorporeal cardiopulmonary bypass for severe accidental hypothermia.[35] Of the 15 long-term survivors, no adverse neurologic sequelae were documented, and the group had an average time from discovery to extracorporeal warming of 141 +/−50 minutes. Owing to the need for prolonged periods of CPR in these patients, a

mechanical compression device is advocated to ensure consistent delivery of compressions.[36] Resuscitation efforts may be withheld for patients with associated lethal body injuries, those found with an ice mask, and those who are so frozen as to hinder chest compressions.[37] Rewarming efforts in the remainder of the population should continue until body temperature approaches normal and there is no response to ACLS protocols. In patients who are refractory to rewarming, efforts should also be discontinued.

Pulmonary embolism

Pulmonary embolism is a less common cause of cardiac arrest. The overall incidence of disease is debatable, but estimates of 1%–5% are reported in the literature.[2,104,123] For those patients who present primarily as PEA arrest, however, the incidence may be >50%.[37,38] Sudden cardiac arrest in a young, otherwise healthy patient should raise suspicion for this cause. History should probe for causes of hypercoagulability including use of oral contraceptives, prolonged immobility, recent orthopedic surgeries, and cancer, among others. Physical examination should focus on pulmonary auscultation and examination of the lower extremities for signs of deep venous thrombosis, such as unilateral edema or palpable posterior cords. These physical findings, however, are unreliable and may be absent. For those patients with a presenting rhythm, the 12-lead electrocardiogram may show evidence of right ventricular strain or right atrial enlargement (P-pulmonale in lead II). The classically described S1, Q3, T3 pattern is related to the axis shift associated with right ventricular strain, but is present in less than 5% of patients with pulmonary embolus. Tachycardia and non-specific ST-T changes are the most common presenting finding on the electrocardiogram, but 25% of patients will have no change in their EKG from baseline.[39] Bedside echocardiography may show evidence of a dilated right ventricle, indicating elevated pulmonary arterial pressures. In patients without evidence of an alternative diagnosis following history, physical examination, ECG and chest radiography, and in those for whom the clinician has a high suspicion for embolism without contraindications, thrombolytic therapy should be initiated empirically. It should be started as soon as possible while high quality CPR continues. CPR should continue for a time sufficient for the thrombolytic therapy to dislodge the clot (at least 45 minutes to 1 hour).

Hyperkalemia

Hyperkalemia as the etiology of non-fibrillatory arrest should be suspected in patients with renal dysfunction.

Any patient with a history of end stage renal disease or dialysis who presents in arrest should be immediately treated for presumed hyperkalemia. Other etiologies for hyperkalemia include excessive use of salt substitute, rhabdomyolysis, tumor lysis syndrome, adrenal insufficiency, and multiple recent transfusions. Hyperkalemia is also extensively described associated with the use of succinylcholine and related rhabdomyolysis.[40,41] In patients with a presenting cardiac rhythm, the electrocardiogram is the most useful diagnostic tool. The earliest electrocardiographic sign of hyperkalemia is tall symmetric T waves in the anterior leads.[42] There is a progression of further EKG changes that correlate poorly with serum potassium levels.[43] These include prolongation of the PR interval or QRS interval, P-wave flattening with eventual disappearance, a sinusoidal wave pattern, and eventually ventricular fibrillation. Since hyperkalemic patients die as a resut of an arrhythmia, immediate cardiac membrane stabilization should be undertaken by intravenous administration of calcium chloride (8–16 mg/kg) (unless a contraindication exists such as coexisting use of digoxin). This should be followed by intravenous sodium bicarbonate (1 mEq/kg bolus), often with repeated doses until electrocardiographic changes are evident. This should then be followed by 10 units of regular intravenous insulin and one ampule of intravenous D50. Onset of therapeutic action of insulin is about 30 minutes. Emergency dialysis should be considered once the patient has been resuscitated.

Metabolic acidosis

Severe metabolic acidosis exerts a negative inotropic effect on the heart. In particular, severe acidosis can impair cardiac contractility, increase pulmonary vascular resistance, sensitize the myocardium to arrhythmia, and lower the threshold for ventricular fibrillation. These changes in myocardial function occur in conjunction with an associated hyperkalemia that can accompany severe acidosis because of action of the potassium-hydrogen ion exchange pump at the cellular level. The causes of metabolic acidosis are categorized into non-anion gap and high-anion gap. Acute severe metabolic acidosis leading to cardiac dysfunction and arrest is more commonly due to the high-anion gap etiology, including diabetic ketoacidosis, uremia, lactic acidosis, and multiple toxic ingestions including salicylates, methanol, paraldehyde, and isopropranol. Multiple medications have been associated with the development of a severe metabolic acidosis, including metformin, colchicine, arginine, and herbicides.[44–47] Starvation and physical restraint have also been documented as etiologies of severe metabolic acidosis and arrest.[48,49] Attempting to determine

whether metabolic acidosis is the etiology of cardiac arrest can be difficult, as prolonged arrest can lead to a lactic acidosis. Laboratory evaluation should include a basic chemistry panel, a serum lactate level, and an arterial blood gas. Treatment should be directed at the underlying etiology of the acidosis. Bicarbonate therapy for acidosis is controversial because of acid-base shifts in the cerebral spinal fluid, but is generally recommended for a serum pH less than 6.9 and should be considered if the serum pH is less than 7.1.

Myocardial infarction/ischemia

Although the largest contributing disease among all causes of sudden cardiac death, the incidence of myocardial infarction as a primary cause of non-fibrillatory arrest appears lower, with reported ranges from 13% to 60% of all causes.[4,15,16] The diagnosis should be considered in all patients with a past medical history of coronary artery disease or those who have the known risk factors for the disease. A history from EMS workers, family, or other witnesses of patient symptoms preceding arrest is also helpful. An early 12-lead electrocardiogram should be obtained in all patients with a presenting cardiac rhythm, as acute ischemic changes may be evident and will direct further therapy. If the diagnosis of acute myocardial infarction is made, therapy must be directed at thrombus disruption or removal. Depending upon the institution, the patient can be transported to the cardiac catheterization laboratory for emergent intervention while resuscitative efforts are continued, or thrombolytic therapy can be initiated in the emergency department. The use of thrombolytic therapy during resuscitation from cardiac arrest remains controversial. An initial study of thrombolytics in patients presenting with cardiac arrest showed significantly increased rates of return of spontaneous circulation and ICU admission,[50] while a second study in patients with PEA cardiac arrest demonstrated no benefit,[51] but was possibly confounded by patient selection criteria and timing of thrombolytic therapy during the study.[52,53] The use of thrombolytics for patients with non-fibrillatory cardiac arrest, in whom resuscitative efforts are initially unsuccessful, is an appropriate area for ongoing research.[54]

Non-specific therapy for non-fibrillatory cardiac arrest

In many cases of non-fibrillatory cardiac arrest, the clinical presentation does not clearly indicate any immediately reversible etiology. Although the overall goal during a resuscitation is to treat any reversible etiology, non-specific pharmacologic therapies should be initiated quickly in an effort to improve coronary perfusion pressure, cardiac output, and perfusion of other vital organs. This section will address the role of various pharmacologic agents in accomplishing this task.

Adrenergic agents

Adrenergic agents have long been known to improve resuscitation because of their vasoactive properties, specifically α-adrenergic stimulation. The specific physiologic response to adrenergic stimulation is improved coronary perfusion pressure (coronary diastolic arteriovenous perfusion gradient). Increased coronary perfusion pressure has been shown experimentally and clinically to predict return of spontaneous circulation.[55,56] Adrenaline has been the adrenergic agent of choice in cardiac arrest, but appropriate dosing has been questioned. Higher doses of epinephrine have been shown to improve regional myocardial blood flow, coronary perfusion pressure, and defibrillation rates in animal models of ventricular fibrillation arrest,[57–60] but clinical studies have not confirmed this benefit.

Some studies have been undertaken which address the use on high-dose epinephrine in non-fibrillatory cardiac arrest. As previously noted, a subgroup of patients present in pseudo-PEA cardiac arrest, with aortic pressure fluctuations detectable by aortic catheter. This subgroup of patients possibly would benefit from high-dose epinephrine. Paradis *et al*. studied the administration of standard or high-dose epinephrine to patients with pseudo- and true PEA and found the best response to resuscitative efforts (e.g., return of spontaneous circulation) in patients with pseudo-PEA who received high-dose epinephrine (14 of 18 [78%]). Nevertheless, no patient in this study survived to hospital discharge.[1] Lindner *et al*. performed a clinical study comparing high-dose epinephrine (5 mg) to standard dose epinephrine (1 mg) in PEA and asystolic cardiac arrest.[61] Return of spontaneous circulation was achieved in 56% (5 of 9) patients with high-dose epinephrine and 7% (1 of 14) standard dose epinephrine patients ($P<0.05$). Hospital discharge rates were 22% (2 of 9) in the high-dose epinephrine group and 7% (1 of 14) in the standard dose epinephrine group. This difference in hospital discharge rates was not statistically significant.[61] In a multicenter study of high-dose epinephrine (0.2 mg/kg) in prehospital cardiac arrest, Brown *et al*. found that patients presenting with PEA had higher rates of return of spontaneous circulation compared to patients receiving standard dose epinephrine (0.02 mg/kg) (47% versus 33%, respectively; $P<0.05$).[62] The hospital discharge rates and neurologic

outcomes for this subgroup of patients were not reported.[62] In another multicenter study of high-dose epinephrine, Stiell *et al.* found no difference in resuscitation and discharge rates in patients receiving high-dose epinephrine (7 mg) or standard dose epinephrine (1 mg).[63] Since this study included in-hospital cardiac arrests, the results are difficult to compare with those in other studies. Furthermore, prehospital arrest patients did not receive epinephrine in the prehospital setting; instead, they received their epinephrine after hospital arrival, approximately 21 minutes after arrest.

Adverse effects associated with use of adrenaline, including increased myocardial oxygen consumption and ventricular dysrryhthmia, have been a stimulus to find the best vasoactive agent for use during cardiac arrest. Various adrenergic agents have been compared, with equivocal results.[57,60,64–68] Most previous work with adrenergic agent dose response and comparisons of various adrenergic agents has been performed in ventricular fibrillation models of cardiac arrest,[57,60,64–67] whereas the dose and type of adrenergic agents used in PEA cardiac arrest have not been extensively studied. Ralston *et al.* studied a postcountershock model of PEA and found the median effective dose (ED 50) of epinephrine to be 14 μg/kg intravenously and 130 μg/kg endotracheally.[69] Lindner and Ahnefeld compared epinephrine and norepinephrine (45 mg/kg) in an asphyxiation PEA model and found a resuscitation rate of 100% with both drugs.[70] Epinephrine resulted in resuscitation earlier than did norepinephrine, but no hemodynamic differences were noted between the drugs. DeBehnke *et al.* compared standard dose epinephrine (0.02 mg/kg) and high-dose epinephrine (0.2 mg/kg) in a postcountershock model of PEA and found no difference in return of spontaneous circulation rates between groups; however, coronary perfusion pressure was higher in the high-dose epinephrine group.[71]

Methoxamine is a pure α-adrenergic agonist and therefore lacks β-adrenergic activity, which may be detrimental during cardiac resuscitation.[72] In an asphyxial model of PEA, Redding *et al.* found a 100% resuscitation rate with use of methoxamine (20 mg).[73] In a clinical study of PEA arrest, methoxamine (10 mg) and epinephrine (1 mg) were compared in 80 cases of prehospital and in-hospital PEA arrest. A resuscitation rate of 55% (22 of 40) was found in each group, with only one patient who received epinephrine being discharged from the hospital.[74] Notably, the dose of methoxamine in this clinical study (10 mg or approximately 0.14 mg/kg in a 70-kg patient) was substantially lower than the dose used in the animal experiment (20 mg or approximately 1 mg/kg in a 20-kg dog). Patrick *et al.* performed a clinical study with higher doses of methoxamine.[75] Sixty-

eight PEA patients received 20 mg of methoxamine followed by 40 mg 4 minutes later and were compared to 77 patients who received 2 mg of epinephrine followed by 2 mg every 4 minutes during resuscitation. They found no differences in return of spontaneous circulation, survival to hospital discharge, or neurologic status of those patients discharged between the two groups. Similarly, Olson *et al.* performed a prospective, randomized, double-blind out-of-hospital clinical trial administering equipressor doses of epinephrine (0.5 mg) and methoxamine (5 mg) to 102 patients in ventricular fibrillation refractory to initial defibrillations. The rates of return of spontaneous circulation and admission to the emergency department with a pulse did not differ between the two groups. There was an insignificant trend toward improved survival to hospital discharge in the epinephrine group (19.6% vs. 7.8%, $P = 0.07$).[76]

Phenylephrine, another pure α-adrenergic agonist, has been investigated for use in cardiac arrest. When 1 mg of epinephrine was compared to 10 mg of phenylephrine in 13-kg dogs, there were no differences in hemodynamics, resuscitation rates, and neurologic deficit scores.[77] There also was no difference in resuscitation on 24-hour survival between epinephrine and phenylephrine in a canine ventricular fibrillation cardiac arrest model.[78] Brown *et al.* compared 0.2 mg/kg epinephrine, with 0.1 mg/kg and 1 mg/kg phenylephrine in a swine ventricular fibrillation model and found improved defibrillation rates, myocardial blood flow, and oxygen extraction ratios in animals receiving epinephrine.[60] In a similar study, some of these investigators showed that 10 mg/kg of phenylephrine was no different from 0.2 mg/kg of epinephrine in improving regional cerebral blood flow in a swine model.[64] One clinical study of out-of-hospital cardiac arrest compared 1 mg of phenylephrine to 0.5 mg of epinephrine and found no difference in the return of spontaneous circulation rates.[67] In total, these studies investigated the use of phenylephrine in cardiac arrest and found equivocal results.

β_1-Stimulation with agents such as isoproterenol produce improved chronotropy. β-Stimulation also causes vasodilation, however, which will decrease cerebral and myocardial blood flow. Until further research on the use of β-agonists in PEA arrest is performed, this potentially detrimental physiologic effect precludes its use for this condition.[79]

The literature on the use of adrenergic agents in non-fibrillatory arrest is mixed. Problems with previous experimental models include the diversity of models chosen (postcountershock versus asphyxial), variability of adrenergic doses used, and lack of a neurologic outcome model. From the available data, it is reasonable to recommend standard dose epinephrine (1 mg) as an initial dose in non-

fibrillatory arrest. In a patient with pseudo-PEA, either documented through invasive monitoring or suspected by ECG analysis or echocardiography, a trial of high-dose epinephrine appears reasonable. Further studies evaluating long-term survival and neurologic recovery in pseudo-PEA arrest are required before a stronger recommendation for high-dose epinephrine can be made.

Vasopressin

Vasopressin is a peptide hormone naturally produced in the pituitary gland whose main physiologic function is related to free water balance (antidiuretic hormone) with actions at the level of the kidney. At concentrations above normal physiologic levels, it has been found to have direct effects at the level of the arterioles as a potent vasoconstrictor. In this regard, some authors have advocated its use during resuscitation in conjunction with, or in place of, epinephrine.[80–85] Several studies have been undertaken to address these issues. Wenzel, *et al*.[68] in a randomized comparison of vasopressin and epinephrine for out-of-hospital cardiac resuscitation, analyzed 1186 patients, of whom 589 received vasopressin and 597 received epinephrine. They found no significant differences between the groups related to return of spontaneous circulation, hospital admission, or hospital discharge. The authors performed a subset analysis of 104 PEA patients in the vasopressin group as compared to 82 patients in the epinephrine group. Again, no significant differences were found in the rates of return of spontaneous circulation, hospital admission, or hospital discharge between the groups. In a meta-analysis of 1519 cardiac arrest patients from five randomized controlled trials comparing vasopressin and epinephrine, Aung and Htay[86] found no significant differences between the vasopressin and epinephrine groups related to return of spontaneous circulation, death before hospital admission, death within 24 hours, death before hospital discharge, or combination of number of deaths and neurologically impaired survivors. In the PEA subset analysis (145 patients in the vasopressin group and 133 patients in the epinephrine group), no significant difference was found between groups with respect to the rate of death before hospital discharge.

Although the data are limited, there appears to be no specific beneficial effect of vasopressin on outcomes of patients in PEA arrest as compared to those treated with epinephrine. No studies have been implemented to examine this drug's effect on outcomes from patients found in PEA cardiac arrest, nor have studies examined the effect of vasopressin on the outcomes of patients who have pseudo-PEA.

Atropine

Atropine has been recommended in cases of bradycardic PEA owing to its cardioaccelerary properties. The effects of atropine in PEA have been less than convincing. Redding *et al*. studied atropine (0.5 mg), comparing it to methoxamine (20 mg) and calcium chloride (5 ml of a 10% solution), and found that methoxamine significantly improved resuscitation compared to atropine and calcium chloride.[73] Atropine was found to be no different from calcium chloride in this model of PEA arrest.[73] The only clinical study of atropine in PEA compared 2 mg of atropine with placebo in patients with slow, pulseless idioventricular rhythms and found no difference in resuscitation rates.[87] Currently, ACLS guidelines recommend a total atropine dose of 0.04 mg/kg as a vagolytic dose in bradycardic PEA (<60 beats/ minute) and asystole.[88] This dose of atropine is based on several studies of patients undergoing spinal anesthesia or healthy volunteers.[89,90] None of the patients in these studies were in cardiac arrest or a low cardiac output state. DeBehnke has questioned the dose of atropine in PEA arrest.[91] He studied the effects of surgical vagolysis in asphyxial PEA arrest and found improved return of spontaneous circulation rates in animals that received vagotomy. This study supports the contention that vagolysis is important in resuscitation from PEA arrest. In a second animal study, Debehnke *et al*. compared standard and high dose atropine in a canine model of PEA arrest.[92] No differences in resuscitation rates were observed between the groups, and the rates tended to decrease in the higher dose groups. Currently, administration of 0.04 mg/kg of atropine in bradycardic PEA and asystolic arrest is recommended.

Sodium bicarbonate

Past data indicated that bicarbonate administration in cardiac arrest was detrimental because of paradoxical cerebrospinal fluid acidosis, inability to reverse myocardial acidosis, and potential decreases in coronary perfusion pressure.[93–95] Further study of this issue remained controversial, as some experimental and clinical studies of the use of bicarbonate in cardiac arrest had not shown any benefit,[96] and other investigators demonstrated benefit during cardiac arrest.[97–99] Most recent data support the use of sodium bicarbonate or a buffering solution during cardiac arrest.[100–103] No study has specifically addressed the issue of bicarbonate use in non-fibrillatory cardiac arrest. Vanags *et al*. retrospectively studied various interventions in out-of-hospital PEA cardiac arrest and found that administration of bicarbonate was as effective as epinephrine and

atropine in generating pulses.[104] Since this study was retrospective, only a temporal relationship to drug administration could be observed. Patients whose last drug administered was bicarbonate had similar return of spontaneous circulation and save rates compared to those whose last drug administered was epinephrine or atropine. A prospective randomized clinical trial of bicarbonate use in cardiac arrest and in non-fibrillatory arrest is necessary to determine definitively the optimal role for bicarbonate during cardiac arrest. The use of bicarbonate has been shown to be beneficial in patients with shock secondary to tricyclic antidepressant, aspirin, and phenobarbital overdose and in cases of hyperkalemia.[105–107] Hence, bicarbonate therapy might also be useful in cases of PEA arrest secondary to these causes.[105–107] In these situ-ations, the initial dose of bicarbonate should be 1 mEq/kg intravenously, followed by 0.5 mEq/kg 10 minutes later. If arterial blood gas values are available, the bicarbonate dosing should be titrated based on the calculated base deficit.[107]

Other agents

Calcium

Older ACLS guidelines have included calcium in the PEA resuscitation protocol.[108] This was based on the hypothesis that calcium ions would enhance myocardial contraction and aid in resuscitation. In the early 1980s, the effectiveness of calcium use during cardiac arrest was questioned. Animal and clinical studies demonstrate that calcium does not improve resuscitation in PEA arrest.[109–112] There may be a subgroup of patients in PEA, however, who would benefit from calcium administration. Stueven et al. retrospectively divided PEA patients by QRS morphology and found that patients with wide QRS complexes (<0.12 second) or peaked T waves and ST-segment elevation were more easily resuscitated when calcium was administered (8 of 39 vs. 1 of 31; $P < 0.028$).[112]

When hyperkalemia, hypocalcemia (such as seen following massive blood transfusion), or calcium-channel blocker overdose is the cause of PEA cardiac arrest, calcium administration may be life-saving. A 10% solution of calcium chloride provides 27.3 mg of elemental calcium/ml. The recommended dose of calcium chloride is 2 to 4 mg of elemental calcium/kg, which equals approximately 10 ml of the calcium chloride solution. A 10% solution of calcium gluconate provides 18 mg of elemental calcium/ml, so that 10 to 15 ml of the solution will be needed to provide 2 to 4 mg of elemental calcium/kg. These doses can be repeated every 10 minutes as needed.[107]

Glucagon

Glucagon has been shown to have chronotropic and inotropic properties because of its non-adrenergically mediated stimulation of myocardial adenyl cyclase.[113,119] Niemann et al. studied the effects of 1 mg of glucagon on resuscitation from postdefibrillation PEA and found a significant improvement in return of spontaneous circulation rates in animals receiving glucagon.[115] No clinical study of glucagon use in PEA arrest has been performed, and its use cannot be recommended. Glucagon has been shown to be beneficial in cases of β-blocker overdose, however, and should be considered in cases of PEA arrest secondary to overdose with these agents.[106] The dose is 3 to 10 mg intravenously and an infusion of 2 to 5 mg/hour after return of spontaneous circulation is achieved.[106]

Naloxone

There is speculation that naloxone may increase arterial pressure in various shock states. Rothstein et al. administered naloxone (5 mg/kg) after postcountershock PEA and showed return of spontaneous circulation in 100% of animals (4 of 4).[116] There has been no clinical study of naloxone use in PEA arrest. Nevertheless, naloxone should be used in dosages of 2 to 10 mg intravenously in patients with narcotic-induced PEA arrest.[106] A case report documents the use of naloxone in asystolic out-of-hospital arrest due to opioid ingestion with return of spontaneous circulation.[117]

Aminophylline

Aminophylline is a competitive antagonist of adenosine and has been used to treat conduction disturbances and bradycardia in stable patients.[118–120] Viskin et al. administered 250 mg of aminophylline in patients with bradyasystolic arrest refractory to atropine and epinephrine and achieved return of spontaneous circulation in 73% (11 of 15) of patients, but only one patient was discharged from the hospital alive.[121] A recent review of 16 previous articles describing the use of aminophylline in PEA and asystole suggests that the drug may be useful in some cases of non-fibrillatory arrest refractory to epinephrine and atropine.[122] Mader et al. have reported the most recent article related to the use of aminophylline in non-fibrillatory arrest.[123] In a randomized controlled trial of aminophylline vs. placebo as an adjunct to atropine-resistant prehospital asystolic cardiac arrest, they reported a trend towards improvement in ROSC and reversal of asystole in the aminophylline group. Fewer

patients in the aminophylline group survived to hospital admission, and none were alive at 24 hours. The benefits for use of this drug during non-fibrillatory cardiac arrest require further investigation.

Improved hemodynamics during CPR in non-fibrillatory cardiac arrest

One of the most promising interventions in patients with PEA and asystole is improved hemodynamics during CPR. There is an inversely proportional relationship between mean intrathoracic pressure, coronary perfusion pressure, and survival from cardiac arrest.[124,126] Increased ventilation rates and increased ventilation duration impede venous blood return to the heart, decreasing forward blood flow to the heart and brain during CPR.[124–127] Conversely, generation of negative intrathoracic pressure on the upstroke of CPR augments venous blood return to the heart, significantly improving hemodynamics and outcome.[128–130] This hemodynamic principle of intrathoracic pressure is a fundamental physiologic concept applying to states of profound shock[124,126–128,131–136] and defines cardiopulmonary interactions during CPR.

The impedance threshold device (ITD)

The impedance threshold device (ITD) is a CPR hemodynamic adjunct based on the principle of intrathoracic pressure changes.[128] Placed on any airway (facemask, ET tube, combitube, LMA, and others), it impedes entry of air into the lungs during the upstroke of CPR without impeding normal positive pressure ventilations. This creates relatively negative intrathoracic pressure on the upstroke of CPR, thereby augmenting venous blood return to the heart and increasing hemodynamics during CPR.[128] Aufderheide *et al*. performed a prospective, double-blind trial in adult patients with cardiac arrest randomized to receive standard CPR with a sham ITD or standard CPR with a functional ITD.[129] In a substudy of 20 patients, systolic blood pressure was recorded at the scene of cardiac arrest by using invasive femoral arterial monitoring.[131] The hemodynamic substudy demonstrated an average systolic blood pressure of about 85 mmHg during CPR with the active device and a systolic blood pressure of about 40 mmHg during CPR with the sham device, thus more than doubling the hemodynamics and effectiveness of CPR.[131] In this initial feasibility study of only 230 patients, proximal outcome in all patients was insignificantly improved. Nevertheless, nearly half the patients had PEA as an initial cardiac arrest rhythm or had PEA at some time

during cardiac arrest. In these patients, return of spontaneous circulation, ICU admission, and 24-hour survival was significantly increased compared to control.[129] Reviewing invasive hemodynamic monitoring demonstrated that 68% of episodes of PEA were pseudo-PEA with an average invasive systolic blood pressure of 28.6 ± 11.6 mmHg.[175] These data indicate that the majority of patients with PEA have some myocardial contraction and that improved hemodynamics during CPR is an effective intervention for patients with PEA.

Use of the ITD during CPR in patients with out-of-hospital cardiac arrest in Staffordshire, England demonstrates similar benefits for patients with asystole.[130] Thayne *et al*. implemented ITD use in the Staffordshire Ambulance System comparing survival (defined in this study as admitted to the emergency department with a sustained pulse) with historical controls. Survival in all patients receiving an ITD (61/181 [34%]) improved by 50% compared to historical controls (180/808 [22%]) ($P < 0.01$). Survival in patients presenting with asystole tripled in the group receiving an ITD (26/76 [34%]) compared with controls (39/351 [11%]) ($P = 0.001$). In this study, presumed improvement in CPR hemodynamics resulted in markedly improved short-term survival for all patients, especially patients with asystole.[130]

There have been no interventions studied (pharmacological or mechanical) in non-fibrillatory cardiac arrest that hold as much promise for improved outcome as augmenting hemodynamics during CPR. As a result, early administration of basic life support with the impedance threshold device is strongly recommended by the National American Heart Association (IIa Recommendation). Other methods for improving hemodynamics during CPR exist, but have not demonstrated significant benefit in prospective, randomized clinical trials or are limited by the technical logistics of their application.

Interposed abdominal compression cardiopulmonary resuscitation (IAC-CPR)

IAC-CPR has been shown to improve coronary perfusion pressures and blood flow compared to standard CPR.[137–141] Two clinical studies from 1992 showed improved return of spontaneous circulation and long-term survival rates when IAC-CPR is used during in-hospital PEA arrest.[141,143] Conversely, a prospective, randomized trial of standard CPR versus IAC-CPR in the out-of-hospital setting failed to demonstrate improved cardiac resuscitation rates.[144] Given the mixed results from multiple trials, a meta-analysis of all IAC-CPR animal, preclinical and clinical trials advocates for early implementation of this technique during resuscitative efforts.[145]

Active compression–decompression cardiopulmonary resuscitation (ACD-CPR)

The ResQPUMP®, a device designed to apply active compression–decompression CPR, was developed after an ordinary bathroom plunger was applied to the chest of a patient during cardiopulmonary arrest. With active decompression as well as compression, spontaneous circulation was restored and the patient was discharged from the hospital neurologically intact.[144] Studies in both a dog model of ventricular fibrillation and in a small number of humans in cardiopulmonary arrest, active compression–decompression (ACD)-CPR resuscitation with a hand-held suction device improved cardiopulmonary circulation in comparison to standard CPR.[147,148] Lindner et al. found that ACD-CPR significantly increased myocardial and cerebral blood flow during cardiac arrest in a swine model in the absence of vasopressor therapy as compared with standard CPR.[149] The largest human study to date was reported by Plaisance et al. in 1999.[126] They found that both the rate of hospital discharge without neurologic impairment and the 1-year survival rate were significantly higher among patients who received active compression–decompression CPR as compared to patients who received standard CPR. The majority of these patients presented in asystole.

Pneumatic vest CPR and other mechanical adjuncts

Pneumatic vest CPR is based on the thoracic pump theory: increases in intrathoracic pressure produce forward blood flow during cardiac arrest and higher vascular pressures can be achieved with circumferential compression of the thorax compared with manual CPR. Halperin et al. demonstrated significantly improved myocardial and cerebral blood flow with vest CPR compared with manual CPR in a ventricular fibrillation dog model.[150] This study also demonstrated improved survival after ventricular fibrillation cardiac arrest in animals receiving vest CPR compared with those receiving manual CPR.[150] In a preliminary study in humans, Halperin and colleagues have also demonstrated increased aortic pressure and coronary perfusion pressure with vest CPR compared with standard CPR and an insignificant trend toward a greater likelihood of return of spontaneous circulation.[151]

A retrospective review comparing prehospital adult cardiac arrest patients assigned to receive either manual CPR or CPR using an Autopulse device (Revivant Corporation) was undertaken by Casner et al. with the primary endpoint of arrival to the ED with measurable spontaneous pulses.[152] This study demonstrated a significant difference in the primary outcome with use of the Autopulse device. When subgroup analysis was undertaken to compare the outcomes for the different presenting rhythms, only those patients with an initial arrest rhythm of asystole were found to benefit from the use of the Autopulse device. In those whose initial arrest rhythm was PEA, the difference approached, but did not achieve, significance. A larger, prospective randomized multicenter clinical trial (the ASPIRE Trial) found no significant difference in outcome with the device compared to standard CPR. Further studies are required to characterize the benefits of this approach.

LUCAS is a new device for mechanical compression and decompression of the chest during CPR.[153–155] Hemodynamic studies in a porcine model of ventricular fibrillation demonstrate significantly higher cardiac output, carotid artery blood flow, end-tidal CO_2, and coronary perfusion pressure compared with standard CPR.[153] Ongoing clinical trials will characterize the benefits of this new hemodynamic adjunct.

Open chest CPR

Improved blood flow has been reported when open-chest cardiac massage is used for resuscitation from cardiac arrest.[156] Before recommending open-chest CPR for resuscitation in PEA arrest, definitive prospective, randomized clinical trials should be performed that establish safety and efficacy of this technique.

Cardiopulmonary bypass

Cardiopulmonary bypass is an excellent reperfusion technique that has been shown to improve resuscitation rates in ventricular fibrillation cardiac arrest.[157–162] Only one study has investigated the use of cardiopulmonary bypass in PEA arrest (postdefibrillation animal model) and found improved return of spontaneous circulation rates when cardiopulmonary bypass was compared to standard CPR with standard dose epinephrine and high-dose epinephrine.[71] DeBehnke investigated the use of cardiopulmonary bypass after increasing intervals of prolonged asphyxial PEA arrest and found cardiopulmonary bypass significantly increased 1-hour survival when applied early (<15 minutes after PEA arrest).[163] The largest human study in out-of-hospital cardiac arrest patients was published by Nagao et al. in 2000.[164] The majority of these 36 patients presented with ventricular fibrillation due to acute coronary syndrome, with no data available regarding the PEA subset. Of the 23 survivors to hospital discharge, only 12 patients had good cerebral performance scores, and 10 patients were reported with

significant neurological deficits. Interpretation of the study results is challenged by uncontrolled use of post-resuscitation hypothermia. Thus, cardiopulmonary bypass appears to be a reperfusion technique in its infancy. Appropriate application to patients who suffer out-of-hospital cardiac arrest, and in particular, to those found in PEA or pseudo-PEA remains to be defined.

Aortic balloon counterpulsation

Aortic balloon counterpulsation during CPR may enhance coronary perfusion pressure and coronary and cerebral blood flow. Inflation of an intraaortic balloon (IAB) during CPR may raise aortic diastolic blood pressure (AODP), increasing coronary perfusion pressure. In an early animal study comparing the use of IAB vs. epinephrine-only during VF arrest, 10 of 10 animals were resuscitated in the IAB groups, while 1 of 5 was resuscitated in the epinephrine-only group.[165] Although other animal studies have shown benefits with IAB use,[166,167] no human clinical trials have been performed. A case report of 2 patients who suffered cardiac arrest while being maintained on an intraaortic balloon pump (IABP) documents augmented coronary perfusion pressure measurements with the IAB use during CPR.[168]

Transvenous and transthoracic cardiac pacing

In the middle 1980s, transcutaneous and transvenous cardiac pacing were studied as an adjunctive therapy for patients during non-fibrillatory cardiac arrest unresponsive to pharmacologic interventions. Although found to be somewhat successful in patients with symptomatic bradycardia not in arrest, no survival benefit was demonstrated in patients with PEA or asystolic cardiac arrest unless the technique was used early in resuscitative treatment.[169–174] Current ACLS guidelines continue to allow consideration of cardiac pacing early during resuscitative efforts from non-fibrillatory arrest.

Postresuscitation issues

Following return of spontaneous circulation in non-fibrillatory cardiac arrest, attention should be directed at continued treatment of the underlying etiology of arrest, and assurance of adequate tissue perfusion and oxygenation. Excessive ventilation rates, prolonged duration of ventilation, and high tidal volumes should be avoided. The resulting increase in intrathoracic pressure will impede venous blood return to the heart and compromise hemo-

dynamics. Despite normalization of blood pressure, central venous pressure, and heart rate postresuscitation, some patients may have continued myocardial dysfunction and poor tissue oxygenation or perfusion. Central venous oximetry, lactate levels, and calculation of the shock index (heart rate/systolic arterial pressure) can be utilized to assess the adequacy of tissue oxygenation and cardiac dysfunction.[175] If the underlying etiology was mechanical, therapy should be specifically directed at that cause. Patients with pneumothorax relieved by needle thoracostomy should have tube thoracostomy performed for definitive treatment. Patients with pericardial tamponade should have definitive drainage of their tamponade or closure of the emergency thoracotomy if performed. All patients should have adequate oxygenation and tissue perfusion assured, with use of volume expansion and pressor therapy as needed. Right heart catheterization, central venous oximetry, and lactate levels should guide therapy in these cases. In patients whose PEA arrest was caused by pump failure secondary to acute myocardial infarction, emergent cardiac catheterization with angioplasty has been shown to improve patient outcomes. These patients may develop profound myocardial dysfunction and require circulatory assist with balloon counterpulsation. In situations where cardiac catheterization or angioplasty is not available, thrombolytic therapy should be administered if the CPR time was less than 10 minutes and no other contraindications exist.[176] The acid–base status should be optimized through increased alveolar ventilation for primary respiratory acidosis and judicious bicarbonate use for metabolic acidosis. Electrolyte abnormalities should be identified and corrected during this postresuscitation period.

Future of directions in the therapy of non-fibrillatory arrest

Patients with pseudo-PEA and reversible causes of PEA should be rapidly identified, as they are most likely to benefit from aggressive therapeutic intervention. Q-R and QRS duration along with immediate use of Doppler ultrasound applied in all PEA patients hold the potential for quick and non-invasive identification of the pseudo-PEA subgroup. Spreng *et al*. described an audible esophageal Doppler probe that non-invasively detects pseudo-PEA.[177] The availability of emergency echocardiography may rapidly and accurately distinguish pseudo-PEA from true PEA. Enhancing hemodynamics by delivering high quality CPR (e.g., compression rate of 100 compressions/minute, depth of 1½ to 2 inches per

compression, minimal interruption of chest compressions, allowing the chest to completely recoil after each compression, avoiding excessive ventilation rates) and use of the impedance threshold device (ITD) (IIa Recommendation by the American Heart Association) remains one of the most promising interventions for this patient population. The use of thrombolytic therapy in cardiac arrest and PEA remains controversial.[50,51–53] The identification of PEA patient subgroups by non-invasive and immediately available methods, combined with delivering significantly improved hemodynamics during CPR, may substantially improve patient outcomes.

Cardiocerebral resuscitation: a new approach to out-of-hospital cardiac arrest

Gordon A. Ewy and Michael J. Kellum

University of the Arizona Sarver Heart Center, University of Arizona College of Medicine, Tucson, AZ, USA
Emergency Department, Mercy Walworth Medical Center, Lake Geneva, WI, USA

Introduction

Prehospital treatment of cardiac arrest became practical in 1960 when the technique of closed chest cardiac massage was demonstrated effectively to prolong the time for successful defibrillation following cessation of circulation due to cardiac arrest.[1] Closed chest massage was merged with externally applied defibrillation and mouth-to-mouth ventilation to form what is today known as cardiopulmonary resuscitation or CPR.[2–5] By 1966 standardized training and performance criteria had been developed and published.[5] A few years later the American Heart Association (AHA) adopted CPR and spearheaded the campaign to disseminate it to both professionals and the public. The AHA periodically reviews the science, practice and implementation of CPR and publishes updated "guidelines."[6–10]

As an organizational model, CPR can be considered an outstanding public health achievement; but its success in this realm is marred by its failure as a treatment modality for patients who sustain an out-of-hospital cardiac arrest (OOH-CA). When the currently recommended guideline-driven CPR is used to treat patients with an OOH-CA, survival rates have been and continue to be dismal. These poor and unchanged survival rates, in spite of periodic updates, may in part be explained because CPR was conceived as and is currently promulgated as an appropriate intervention for what turns out to be two pathophysiologically entirely different disorders: respiratory arrest and cardiac arrest.

A new approach to the resuscitation of individuals with out-of-hospital cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia was developed by the University of Arizona Sarver Heart Center CPR Research Group in Tucson, Arizona.[11–13] Many of the changes were based on animal experimentation. This new approach, now called Cardiocerebral Resuscitation (CCR), was implemented in Tucson in late 2003 and a modified version was instituted in 2004 in Rock and Walworth Counties of Wisconsin.[14] At the time of its implementation, it was a dramatic departure from the existing technique of cardiopulmonary resuscitation (CPR) endorsed by the American Heart Association and the international community in "Guidelines 2000."[10]

Data from the Emergency Medical Services (EMS) quality control observational study in Rock and Walworth counties of Wisconsin showed that this new approach is clinically sound, for when the principles of Cardiocerebral Resuscitation were utilized in the prehospital care of adults with a witnessed arrest and an initially shockable rhythm, a 300% improvement in survival was observed.[14]

The purpose of this chapter is to describe cardiocerebral resuscitation (CCR) and its implementation, to review its scientific rationale and to promote its acceptance by emergency care providers worldwide.

Survival

The definition of "survival" is relevant for both statistical and clinical reasons. Both the return of spontaneous circulation and being alive at hospital admission were initially used as "survival" endpoints. But because many such "survivors" ultimately died before being discharged from the hospital, a more clinically relevant definition of "survival" has been introduced: neurologically intact survival at hospital discharge.[15,16]

Comparisons of survival rates are often difficult to interpret because of differences in the definition of survival and the inclusion/exclusion criteria that exist in any given report. But when survival rates for OOH-CA are examined, it is clear that they are very low and, with few exceptions, that they have remained stagnant over the last few decades.[17,18] Overall survival rates from non-traumatic OOH-CA in Tucson, Arizona have been unchanged at about 6% over the past decade.[19] Overall survival in larger cities such as Chicago, Los Angeles, and New York is closer to 1%.[17] Most survivors are found in the subset of patients with a witnessed arrest and an initially shockable rhythm. In this group, survival in Tucson, Arizona has been $10 \pm 2\%$ for the past decade,[19] while survival in Los Angeles in 2002 was 6%,[17] and in Rock and Walworth counties in Wisconsin during 2000–2003 it was 20%.[14]

Three phases of ventricular fibrillation

The three-phase time-sensitive model of cardiac arrest due to ventricular fibrillation, articulated by Weisfeldt and Becker, is helpful in understanding some of the problems with CPR that are overcome with cardiocerebral resuscitation.[20]

The first or electrical phase lasts for about 4 or 5 minutes from the onset of collapse. During this period the most important intervention is prompt defibrillation. Although the heart is fibrillating, the myocardium has not yet used up its energy stores nor has it undergone serious cellular damage and is therefore not only responsive to the defibrillation shock but, if defibrillated, is also able to generate a perfusing rhythm. This is why automated external defibrillators (AEDs) have been utilized so successfully in a wide variety of settings, including airplanes, airports, casinos, and in the community where prompt defibrillation could be accomplished.[21–24]

The second or circulatory phase lasts for a variable period of time, but probably from minute 4 or 5 to minute10 after the onset of a VF arrest. Within this time, the lack of myocardial perfusion during active myocyte contractions results in waning cardiac energy stores and the accumulation of toxic metabolites. Immediate defibrillation is inappropriate in this phase because the dysfunctional ventricles seldom generate a perfusing rhythm. The shock usually results in ventricular asystole or pulseless electrical activity (PEA). Therefore, the most crucial intervention during this phase is to restore myocardial blood flow by the generation of adequate coronary perfusion pressure with chest compressions prior to defibrillation. Although not proven, myocardial perfusion is assumed to

help replenish energy stores and to remove toxic metabolites to the point that the heart can respond adequately to the defibrillation shock. These changes are assumed to occur as chest compressions during the circulatory phase have been shown to increase the amplitude of the electrocardiographically recorded fibrillation wave forms and improve the chances of successful defibrillation with a perfusing rhythm.[25–27] It is very probable that restoring perfusion to the brain during this time period is also of critical importance for neurologically intact survival.

The third or "metabolic" phase follows the "circulatory" phase. Defibrillation first during this phase is almost universally unsuccessful and survival rates for individuals first treated at this stage are uniformly very poor. In theory, both the provision of adequate cerebral and coronary perfusion, as well as adequate oxygenation and ventilation would be a necessary prerequisite to survival. Multiple interacting detrimental factors are operant during this phase. Innovative therapies are needed. As noted above, an appreciation of these three phases helps put into context some of the recent findings in resuscitation research.

Cardiocerebral resuscitation

Cardiocerebral resuscitation, as its name implies, was developed to improve neurologically normal survival of patients with cardiac arrest by advocating continuous cerebral and cardiac perfusion by early and near continuous chest compressions.[12,13] Its recommendations for defibrillation are also guided by the three-phase time-dependent model of ventricular fibrillation.[20] Its primary focus is amelioration of the global effects of the lack of perfusion that follow the cessation of effective cardiac activity. It is this lack of perfusion that initiates, perpetuates, and intensifies the pathophysiological derangements that thwart the effectiveness of interventions such as defibrillation and ultimately leads to disability or death. The perfusion pressures generated by chest compressions are typically quite marginal relative to those developed by the beating heart; any interruption of chest compressions has a marked effect on perfusion and therefore the chance of neurologically intact survival. The performance of near continuous appropriately delivered chest compressions is therefore a fundamental tenet of cardiocerebral resuscitation (CCR).

The emphasis on limiting interruptions of chest compressions is based on the findings that the major determinant of neurologically normal survival from prolonged cardiac arrest is not the blood gas composition, the acid–base balance, or the frequency or strength of

defibrillation shocks, but rather the cardiac and cerebral perfusion pressures generated during chest compressions.[13,33–37] Adequate perfusion must be generated relatively early in the arrest, because delays in its establishment results in few, if any, favorable outcomes.[38]

Chest compressions generate perfusion; and when they are stopped, blood flow is immediately curtailed. This in itself is detrimental; but equally important is that such interruptions also transiently diminish the effectiveness of subsequent chest compressions. It takes several compressions to regenerate the perfusion pressures that existed before the interruption.[39] This effect is magnified by repeated interruptions for activities such as rescue breathing or assisted ventilations. But it is also relevant to interruptions for any reason, including those for pulse checks, rhythm analysis, stacked shocks, intubation, patient reassessment, intravenous line placements, and pacing without perfusion. This is a major reason why cardiocerebral resuscitation advocates near continuous uninterrupted chest compressions and recommends that they only be interrupted for rhythm analysis and defibrillation.

It should be emphasized once more that cardiocerebral resuscitation was not developed for use in patients whose arrest is non-cardiac in origin (even though many of its principles might well be applicable in the management of patients with respiratory arrest as well).

Cardiocerebral resuscitation summary

Cardiocerebral resuscitation is recommended for adults with witnessed unexpected collapse without normal breathing – a condition that is almost always due to cardiac and not respiratory arrest or for patients with witnessed collapse and a ventricular arrhythmia that might respond to defibrillation or cardioversion.

There are three components of cardiocerebral resuscitation or CCR. The first is directed toward the public to emphasize the importance of activating the EMS system (calling 911 in the United States), chest-compression-only bystander CPR, and using an AED early in witnessed arrest if a unit is readily available. Notably, the major difference between CCR and CPR for this component is that CCR discourages rescue breathing. This lay component has been called "Be a Lifesaver" in Tucson and "Call and Pump" in Rock and Walworth counties of Wisconsin.[12–14] The most appropriate name is probably, "Be a lifesaver – call and pump." The second component of cardiocerebral resuscitation consists of new recommendations for EMS systems and personnel (Fig. 40.1.).[12–14] This component will be discussed in detail in the following sections. The third

component of cardiocerebral resuscitation is similar to the second, but is for in-hospital personnel and encourages the use of mild hypothermia and other therapies that improve survival in comatose patients following a cardiac arrest.[28–32]

Cardiocerebral resuscitation guidelines

Laypersons are taught to "Be a lifesaver – call and pump." They are to call 911 as soon as possible and then begin continuous chest compressions (CCC) – that is pump on the chest. Rescue breathing is not recommended. The technique of CCC is ideally taught with emphasis on a metronome-guided rate of 100 per minute. Additionally, full chest recoil after each compression is specifically emphasized. Dispatchers answering 911 calls give CCC-only instructions to callers and it is recommended that they also provide metronome guidance.

Law officers and other EMS rescuers who are equipped with AEDs are to defibrillate immediately *only* if they personally witness the collapse or if good continuous-chest compressions are being provided by a bystander. Otherwise, they are to perform CCC for 2 minutes (200 compressions so they do not have to be concerned about the time) before defibrillation. To assure prompt defibrillation after the chest compressions, if only one rescuer is on scene, AED pads are attached before continuous chest compressions are initiated. If two rescuers are available, one initiates chest compressions while the other attaches the defibrillator pads. If a shockable rhythm is present, a single shock is delivered, by using maximum joules and biphasic waveforms if possible, and chest compressions are immediately resumed for another 200 compressions. Therefore, most of the voice instructions on the AEDs available at the time of this writing are to be ignored. During training, emphasis is placed on minimizing the hands-off period between cessation of CCC and delivery of the shock and between the shock and resumption of CCC. Pulse checks are not to be done following the shock, but rather are performed after the 200 postshock chest compressions during the rhythm analysis period. Establishment of intravenous access is encouraged as soon as possible, but again without interruption of CCC.

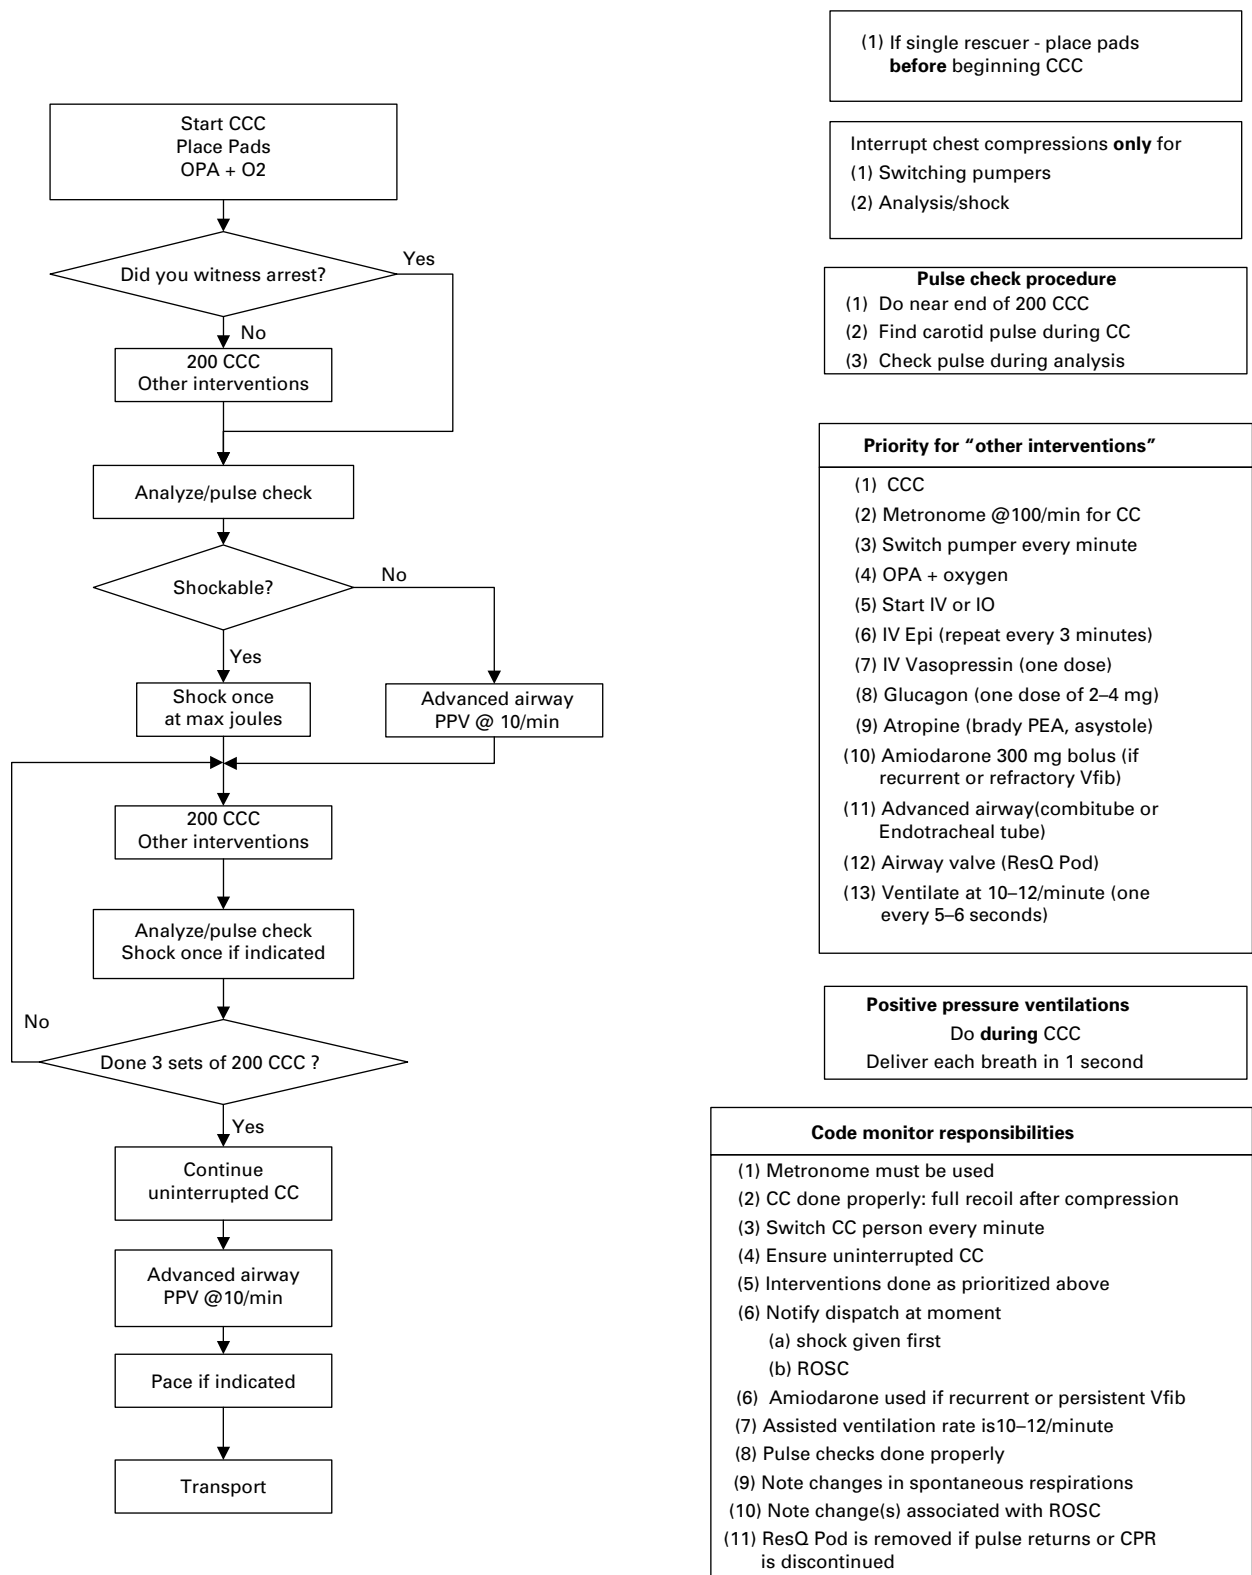
Initial airway management consists of insertion of an oropharyngeal airway and provision of high flow oxygen by non-rebreather mask. Rescue breaths and assisted ventilations (positive pressure ventilations that increase intrathoracic pressure and decrease venous return to the heart) are not encouraged until either the return of spontaneous circulation or until after three cycles of "200 CCC/rhythm analysis/ ± shock" are completed.


Fig. 40.1. Adult cardiac arrest.

If the first analysis after 200 CCC reveals a non-shockable rhythm, chest compressions are resumed and ventilation and advanced airway interventions are initiated with emphasis upon minimal, if any, interruptions of CCC. Hyperventilation is to be avoided. Individual ventilations are to be performed at a rate of no more than 10 per minute. Each breath is to be delivered over a 2-second interval.

Of note, recommendations for ventilation after prolonged periods of chest-compression-only are not well established and are the subject of ongoing investigations.

This protocol is only applicable to individuals with a presumed cardiac arrest, i.e., an adult with unexpected sudden collapse without normal breathing.

Defibrillation

Immediate defibrillation is the treatment of choice during the first or "electrical" phase of a VF arrest; that is during the first 4 minutes or so. Unfortunately, rescuers equipped with defibrillators seldom arrive during this phase. As mentioned above, immediate defibrillation during the "circulatory" phase is counterproductive, producing either asystole or PEA. Two human studies and animal studies have demonstrated that this detrimental effect of defibrillation can be avoided if the heart is perfused before delivering the shock.[25–27] During this phase, adequate coronary perfusion is a prerequisite to successful defibrillation and currently this can only be achieved by chest compressions.

Therefore, CCR advocates 2 minutes of CCC prior to defibrillation in all cases except those where the AED-equipped rescuer actually witnesses the collapse. This recommendation simplifies the EMS decision-making process for a rescuer. It was developed for two reasons. First, it is very often difficult to ascertain an accurate down-time in real-life circumstances and thereafter to calculate the minute interval. Second, the studies cited above did not demonstrate a detrimental effect of performing compressions (actually CPR) during the first or electrical phase of VF arrest.[26,27]

Single shocks

Stacked shocks and their associated preshock analysis and postshock pulse check activities interrupt chest compressions for significant periods of time. Stacked shocks are therefore not advocated in CCR. Instead, single shocks immediately followed by resumption of chest compression without a pulse check are recommended. In a recent study from Seattle, a median interruption of 29 seconds was observed when stacked shocks were utilized.[40] This interruption of perfusion to the heart and brain is significant, because studies have shown that interruptions as brief as 10–15 seconds significantly reduce the efficacy of a shock and increase the incidence of postresuscitation myocardial dysfunction.[41,42] In man, the group in Seattle found that rhythm reanalysis and subsequent shocks generated a pulse in only 1 of 50 individuals studied. This meager benefit came at a cost of no perfusion for median periods of 45 and 55 seconds, respectively, for 2nd and 3rd shocks.[40] These authors concluded, "Because the activities of rhythm reanalyzes, stacked shock, and initial postshock pulse checks had low yield with regard to the balance between achieving or detecting a pulse and initiating CPR, one consideration would be to eliminate these activities from the resuscitation algorithm."[40] It is reasonable to conclude, especially with the increasing percentage of defibrillators having biphasic design, that the cardiocerebral resuscitation approach of delivering single instead of stacked shocks is credible.[12,13]

Postshock activities

A pulse is rarely present immediately after a shock that is delivered during the circulatory phase of VF arrest. A recent study reported that a pulse was detected during the initial postshock interval in only 2.5% of cardiac arrest victims.[40] Pulse checks immediately after a shock are therefore not advocated. They seldom provide useful information and they routinely interrupt chest compressions. Instead, CCR recommends that pulse checks be performed during the rhythm analysis period, when cessation of compression is mandatory. The pulse site is ascertained during the last few seconds of the 200 compression cycle.

The Sarver Heart Center CPR Research Group of the University of Arizona noted in their experimental laboratory that following prolonged VF arrest, that is, in the circulatory phase of VF arrest, the shock almost always defibrillated the subject into a non-perfusing rhythm. Because researchers had immediate access to the hemodynamics of the instrumented swine, they would immediately restart chest compressions to restore coronary perfusion pressures. With this approach, pulseless electrical activity was likely to revert to a perfusing rhythm.[12,13] This is why a second set of 200 chest compressions is recommended immediately after the defibrillator shock.

Chest compression technique

Cardiocerebral Resuscitation recommends a chest compression rate of 100 per minute, the upper rate of that currently recommended by Guidelines for CPR.[9] Metronome guidance is advocated, because in the out-of-hospital setting chest compression rates are very commonly above 120 per minute and not infrequently approach 150 per minute (Kellum *et al.* personal communication). The impact of rapid rates on perfusion has not been well studied in man. In experimental animals, compression rates of 120 were found to be more effective than chest compression rates of 60 per minute.[43] These findings were instrumental in the AHA Guidelines change from compression rates of 60 per minute to 80 to 100 compressions a minute in 1992.[9] Compression rates of 150 in experimental studies are associated with diminished cardiac output.[44]

Recently, the importance of full chest recoil during the release phase of each compression has been highlighted.[45] Incomplete chest recoil compromises perfusion, because it interferes with the generation of a negative pressure in the chest cavity and therefore is associated with decreased venous blood returning to the heart. As a consequence, cardiac output is reduced. These authors noted incomplete chest recoil to occur in 46% of simulated resuscitations performed by paramedics. In a companion study, they found significant decreases in both coronary perfusion pressure and cerebral blood flow when incomplete chest recoil occurred.[45] Accordingly, lifting the hands from the chest after each chest compression is essential to assure complete chest recoil.

Furthermore, when incomplete chest recoil was combined with excessive ventilations, perfusion was severely compromised.[45] Excessive ventilation rates (see below) are extremely common features reported by both in-hospital staff and out-of-hospital paramedics.

Airway ventilations

The three recommendations that CCR makes concerning airway management and ventilations in OOH-CA are summarized as follows. (1) Bystander and first responder CPR is simplified to continuous-chest compression-only CPR. (2) Initial EMS airway management is limited to assuring an open airway and administration of high flow supplemental oxygen. (3) Advanced airway management and assisted ventilations should be initiated only when appropriate and performed in a manner that minimizes their negative impact on perfusion pressures.

Although each of these three recommendations represents a deviation from the CPR guidelines 2000, and each is counterintuitive to the "ABCs" that have been taught for decades, the reasoning for each is presented below. Cardiocerebral Resuscitation does not advocate the elimination of ventilations; instead, it emphasizes the beneficial effects of negative intrathoracic pressure, e.g., normal breathing, chest recoil, gasping or agonal breathing, and deemphasizes the use of positive intrathoracic pressure ventilation from "rescue breathing," bag-mouth ventilation, and endotracheal intubation with positive pressure ventilation.[46]

Bystander "CPR"

Bystander and most first EMS responder should provide continuous-chest-compression only, without rescue breathing. At the onset of primary ventricular fibrillation, the pulmonary veins, left side of the heart, and entire arterial system are filled with oxygenated blood. Hence, the traditional CPR-recommended initial step of positive pressure "rescue" breathing with oxygen-poor exhaled breaths never seemed reasonable. What is critical is that the existing oxygenated blood be delivered to the tissues. Because of this logic, years ago, the Dutch recommended replacing the ABCs of CPR with CBA.[47]

It is well documented that bystander CPR saves lives when coupled with advanced cardiac life support.[48–51] A significant problem contributing to the less than optimal survival rates in OOH-CA, however, is the failure of citizens to initiate bystander CPR, predominantly because they do not want to do mouth-to-mouth rescue breathing on a stranger.[52–56] In some cultures the reluctance is even greater.[57] In Japan, only 2% of students and 3% of nurses said they were willing to perform mouth-to-mouth rescue breathing on a stranger.[57] Other reasons include fear of harming the victim or the complicated psychomotor skills necessary. The requirement for "rescue breathing" is a major problem. The AHA "Guidelines 2000" state that, "If a person is unwilling or unable to perform mouth-to-mouth ventilation for an adult victim, chest-compression-only CPR should be provided rather than no attempt at CPR being made."[58] Nonetheless, in our areas, before the institution of cardiocerebral resuscitation, this approach was seldom if ever mentioned or taught.

But the major reason for recommending continuous-chest-compression CPR for single bystander is that rescue breathing, when performed the way it has been taught for the past few decades, e.g., two breaths before each 15 chest compressions, is actually harmful.[59] Each recommended breath is taught to be delivered over at least 2 seconds. This

recommendation assumes a short time to deliver the two recommended breaths before each 15 chest compressions. But, by the time the would-be rescuer stops chest compressions, lifts the victim's chin, pinches their nose, takes a deep breath, makes a seal with their mouth over the victim's mouth, blows, watches the chest rise and fall, repeats this sequence a second time, and then finds the location to reposition their hands and resume chest compressions, the recommended "two quick breaths" interrupts chest compression an average of 16 seconds.[60] By using a simulated single rescuer protocol, continuous-chest-compression BLS was compared with "standard" BLS in the experimental laboratory where the two breaths were given over 16 seconds before each of the15 compressions.[59] In this study, Kern and associates found that the survival rate was 13%.[59] The survival rate of 13% was of intense interest, for in Tucson, Arizona the average survival of individuals with OOH-CA due to ventricular fibrillation over the past decade was similar.[19]

Abella and associates reported that in-hospital suboptimal compression rates correlated with poor return of spontaneous circulation and thus initial survival.[61] Initial survival rates were significantly higher for patients receiving more than 87 compressions per minute than were those receiving fewer than 72 compressions per minute.[61] Obviously, if every set of 15 compressions is interrupted for 14 to 16 seconds to deliver the recommended two ventilations, the individual will not receive enough chest compressions to survive.

Unfortunately, any changes in the guidelines that alter the 2:15 rescue breathing to chest compression ratio might improve survival, but only in those who receive prompt bystander-initiated resuscitation. "Further, any change in the ratio will not change the reluctance of bystanders to perform bystander-initiated CPR."[62] One can only conclude that the recommendation of chest-compression-only CPR for bystanders of cardiac arrest as recommended by cardiocerebral resuscitation is logical.

What is the role of gasping or agonal respirations?

Another observation is that, if a subject collapses with ventricular fibrillation, gasping lasts for a variable period of time. Gasping is both fortunate and unfortunate. It is fortunate because, when chest compressions are promptly initiated, the subject is likely to continue to gasp and provide self-ventilation. Indeed, Kouwenhoven, Jude, and Knickerbocker in one of their early programs indicated that ventilation was not necessary during chest compression because the subject gasped.[1] (Demonstration of the

technique of CPR for New York Society of Anesthesiologist 1960s. Copy of demonstration provided on CD by J.R. Jude). Nevertheless, gasping may be unfortunate, as most lay individuals interpret this as an indication that the individual is still breathing, and do not initiate bystander CPR or activate the EMS as soon as they should. Education will be essential to improving prompt initiation of bystander chest compressions in patients with cardiac arrest.

Ventilations by emergency medical systems personnel can be deadly!

The two major problems with assisted ventilations by the Emergency Medical Services are the deleterious effects of early intubation and hyperventilation.

As noted above, any interruption of chest compressions during the circulatory phase of VF arrest markedly decreases the chances of survival. In addition to the excessive delays caused by AEDs, when the delay time for the average intubation is added, the victim has little chance of survival. Even in children, where respiratory arrest is more common, it has been shown that the use of bag-mask ventilation is better than intubation.[63]

As also noted above, however, all positive pressure ventilations increase intrathoracic pressures and thereby reduce venous return. In the setting of cardiac arrest, this can result in a significant reduction of cardiac output that, in turn, compromises both cardiac and cerebral perfusion.[64] This is more than a theoretical issue; studies in trained and retrained paramedics showed that once assisted ventilations are initiated, they are almost always performed at rates that severely compromise perfusion. Indeed, a recent publication by Aufderheide and Lurie entitled "Death by hyperventilation" highlighted this real problem.[65] In-hospital as well as field observations documented that these personnel delivered an average of 37 breaths per minute rather than the 12–15 minutes recommended by the guidelines.[66]

Even when one is on the scene, it is difficult to get the excited individual to "slow down" when it comes to delivering ventilations. Cardiocerebral resuscitation protocols minimize the chances for excessive ventilations. Cardiocerebral resuscitation advocates placement of an oropharyngeal device and oxygenation by non-rebreather mask in the initial phases of treatment and deliberately delay positive pressure ventilations in patients with an initially shockable rhythm. Assisted ventilations are not started until ROSC or three series of 200 chest compressions and shock (if necessary) are completed.[14] While the first person with a duty to respond applies the defibrillator pads and begins chest compressions, the second emergency-trained

and equipped EMS person places an oropharyngeal airway and a non-rebreather mask with high flow oxygen.

The optimal type of ventilation by EMS personnel for patients who have only had bystander-chest-compressions prior to their arrival is unknown, and is the subject of intense investigation.

Conclusions

This chapter describes cardiocerebral resuscitation, a new approach to out-of-hospital witnessed arrest due to ventricular fibrillation or pulseless ventricular tachycardia in adults. We reviewed the studies that led the University of Arizona Sarver Heart Center CPR Research Group and the Tucson Fire Department and the EMS systems of Rock and Walworth counties in Wisconsin to advocate and to help institute this new methodology for witnessed unexpected sudden cardiac arrest in adults. It is dramatically different from Guidelines 2000 and is significantly different from Guidelines 2005. Compared to historical controls, where Guidelines 2000 CPR was used, cardiocerebral resuscitation resulted in significant improvement in neurologically normal survival in patients with out-of-hospital cardiac arrest and shockable arrhythmias.[14] In patients with witnessed cardiac arrest and a shockable rhythm on arrival of EMS system, survival was increased 300%.[14] Although these findings were in an observational study, they were so dramatic and in accordance with our animal research studies that we recommend this approach for all out-of-hospital cardiac arrests with a shockable rhythm until a different protocol is proven to be better.

Note added in proof

Since this chapter was initially submitted, preliminary data on the effect of initiating Cardiocerebral Resuscitation in a large metropolitan area has become available. Survival of adults with cardiac arrest was compared for 6 months before and after training of medics in two EMS agencies to perform Cardiocerebral Resuscitation. The primary endpoint was survival of patients with VF to hospital discharge. Survival to hospital discharge was 3.5% (3/85) prior to initiation of Cardiocerebral Resuscitation and 21% (21 of 97) after (<0.001).[67]

Thrombolysis during resuscitation from cardiac arrest

Fabian Spöhr and Bernd W. Böttiger

Department of Anaesthesiology, University of Heidelberg, Heidelberg, Germany

Cardiac arrest has been associated with a very poor prognosis. It has been estimated that 15%–37% of patients suffering in-hospital cardiac arrest, and only 5%–14% of patients suffering out-of-hospital cardiac arrest are expected to be discharged from hospital.[1–3] Unfortunately, the prognosis of these patients has hardly changed during the last 20 years,[4] which may be explained in part by the lack of specific therapeutic strategies for cardiac arrest. Several promising drug therapies have failed to improve long-term survival.[5,6] For example, administration of amiodarone in patients with shock-refractory ventricular fibrillation has been demonstrated to increase the number of patients admitted to hospital,[7] but no drug therapy has shown a positive impact on long-term survival.

Coronary artery disease resulting in acute myocardial infarction (MI) or ischemia-related arrhythmia and massive pulmonary embolism (PE) are the causes of sudden cardiac arrest in more than 70% of patients.[8–10] Systemic thrombolysis is an established and effective therapy for acute MI or PE occurring with hemodynamic instability.[11] The fear of causing life-threatening bleeding complications, however, has been a major drawback for using thrombolytic drugs during CPR. Consequently, thrombolytic agents have historically been withheld in the setting of cardiac arrest. According to the international guidelines for the therapy of acute MI, prolonged or traumatic CPR has been regarded as a relative contraindication for thrombolytic treatment.[12,13] In the recent international guidelines for cardiopulmonary resuscitation, however, CPR is no longer a general contraindication to thrombolysis.[14,15] A high incidence of fatal bleeding complications, however, may outweigh the potential therapeutic benefit of thrombolysis during CPR.

In the first part of this chapter, we will outline the pathophysiological background for the use of thrombolytic drugs during CPR. In the second part, data from clinical studies will be presented and discussed. In the third part, safety concerns will be highlighted.

Pathophysiological considerations and mechanisms of action

Thrombolytic therapy initiated during resuscitation after acute MI or massive PE aims to treat the cause of cardiac arrest while the patient is still being stabilized. Direct thrombolysis at the site of coronary or pulmonary occlusion may resolve the underlying cause of cardiac arrest in a majority of patients and may increase the chance for restoration of spontaneous circulation (ROSC) and the maintenance of spontaneous circulation substantially.[16] This is the most intuitive mechanism of thrombolytic agents administered during cardiopulmonary resuscitation (CPR). All thrombolytic agents, except for streptokinase which is rarely used nowadays, directly activate plasmin by stimulating the conversion of plasminogen to plasmin. Plasmin has proteolytic activity on prothrombin and thrombin, thereby resolving the vascular obstruction (Fig. 41.1).

In addition, thrombolytic drugs may have an important effect on the microcirculation, especially cerebral reperfusion, after ROSC. Microcirculatory reperfusion disorders are known to be one of the major reasons for cerebral dysfunction after cardiac arrest.[17–19] It has been demonstrated that 30 minutes after cardiac arrest lasting 15 minutes, 30% of the cerebral microcirculation was not adequate.[18]
Fig. 41.1. Simplified diagram demonstrating the action of thrombolytic drugs. Thrombolytic drugs activate the enzymatic conversion of plasminogen to plasmin. Plasmin has a proteolytic activity on fibrinogen and fibrin which are the final substances resulting from the activation of coagulation.

Although the pathophysiology of cerebral reperfusion disorders is not completely understood, increased blood viscosity, endothelial cell swelling, leukocyte–endothelial interactions, and capillary fibrin deposition caused by activation of coagulation, may play an important role for the impaired cerebral reperfusion, also referred to as "no-reflow" phenomenon, after cardiac arrest.[20,21] The degree of the "no-reflow" phenomenon probably translates into neurological outcome after cerebral reperfusion. After cardiac arrest, a marked imbalance between activation of coagulation and fibrinolysis has been demonstrated. In out-of-hospital cardiac arrest, blood coagulation was significantly activated in all patients and was demonstrated until 8 to 48 hours after ROSC. In contrast, in most patients, the plasma levels of d-dimer, an indicator of endogenous fibrinolytic activity, were not increased during CPR.[22] These data suggested that in patients after cardiac arrest, a marked activation of blood coagulation was not counterbalanced by an appropriate activation of endogenous fibrinolysis. An impairment of fibrinolysis during and after CPR caused by massive generation of fibrin in patients who suffered out-of-hospital cardiac arrest was reported in another study.[23] Activation of coagulation during reperfusion after cardiac arrest may be caused by hypoxia, stasis of the blood, endothelial cell damage, and high levels of catecholamines in the blood.[16] In addition, significant activation of thrombocytes was reported during and after CPR in humans.[24,25] Therefore, thrombolytic treatment during CPR aims at adjusting the balance of coagulation and fibrinolysis in order to reduce microcirculatory reperfusion deficits after the arrest.

In an early observation, Crowell *et al.* found beneficial dose-dependent effects on survival and neurological

outcome when heparin or streptokinase were administered *before* cardiac arrest in dogs.[26] Consistently, a combination of heparin, dextran, and hypertensive perfusion 12 minutes *after* cardiac arrest, resulted in an improved neurological outcome in dogs.[27] Whereas activation of coagulation may be prevented by heparin, an intravascular deposition of fibrin is not likely to be resolved by heparin alone. Thrombolytic treatment started *during* CPR and continued for 5 hours improved the recovery of cerebral perfusion and neurological performance in dogs compared to untreated controls.[28] The effect of thrombolytic therapy administered during CPR on cerebral "no-reflow" was investigated by fluorescent microscopy in cats.[20] In that trial, animals that received a bolus of alteplase and heparin after 15 minutes of cardiac arrest showed a significant reduction in the cerebral "no-reflow" in the entire forebrain compared to animals that had received no thrombolytic treatment. These experimental data suggested that the poor prognosis of patients suffering cardiac arrest after fulminant PE or acute MI is caused by pathophysiological changes that are not influenced by conventional resuscitation efforts. Thrombolytic treatment may have two beneficial effects in these patients: while the direct actions of thrombolytics are aimed at treating the cause of cardiac arrest, the effect of thrombolytics on microcirculatory reperfusion after cardiac arrest may contribute to a good neurological performance of patients even after prolonged resuscitation.[16]

Clinical studies

The first report on thrombolysis during CPR in a patient with fulminant PE was published more than 30 years ago.[29] In the years following, many other case reports have been published, most of them demonstrating an exceptionally high rate of ROSC after unsuccessful conventional treatment and a high rate of neurologically intact survivors even after prolonged CPR.[30] The promising results of case reports and case studies have led to a number of clinical studies in the in-hospital and out-of-hospital setting.

In-hospital studies

Several small in-hospital studies on thrombolytic therapy during CPR have been performed (Table 41.1). In an early study, 20 cardiac arrest patients with fulminant PE diagnosed by pulmonary angiography received streptokinase via the pulmonary artery catheter. ROSC was achieved in 11 patients (55%).[31] In a retrospective analysis,[32] seven of nine patients with acute angiographically proven PE showed hemodynamic stabilization after administration of a

33	retrospective	21	PE	rt-PA	2 liver ruptures, mediastinal bleeding	2
35	prospective	30	n.r.	TNK	–	2
36	randomized, placebo-controlled	19	n.r.	TNK	–	1
Total		**133**			**9 (6.7%)**	**27 (20.3)**

AMI = myocardial infarction, CPR = cardiopulmonary resuscitation, n.r. = not reported, PE = pulmonary embolism, rt-PA = recombinant tissue plasminogen activator (alteplase), SK = streptokinase, TNK = tenecteplase, UK = urokinase.

thrombolytic drug during CPR (streptokinase, urokinase, or alteplase), and five patients survived. Some of these patients received CPR for up to 90 minutes to achieve ROSC. Another retrospective study found ROSC to be achieved significantly more frequently in 21 patients presenting with cardiac arrest after massive PE who were treated with a bolus dose of recombinant tissue plasminogen activator (alteplase) during CPR compared to a control group of 21 patients receiving standard treatment. Survival rates, however, were not significantly different in the two groups.[33] In patients suffering cardiac arrest after acute MI, Gramann and colleagues prospectively treated 28 patients with thrombolytics during CPR after conventional resuscitation had been unsuccessful. Nine patients were stabilized initially (32%), but only three patients (11%) survived.[34] In a prospective observational study,[35] 30 patients with out-of-hospital (83%) and in-hospital (17%) cardiac arrest of unknown origin received in-hospital treatment with tenecteplase after failure of conventional resuscitation efforts. ROSC was achieved in 30% of these patients, 17% were admitted to, and 7% were discharged from hospital. A recent prospective, double-blind, placebo-controlled pilot study[36] randomized 35 patients who were transferred to hospital after out-of-hospital cardiac arrest to either treatment with tenecteplase or standard treatment. Patients treated with tenecteplase achieved ROSC more frequently compared to standard treatment, but there was no difference in survival at hospital discharge. Unfortunately,

that study was not powered to show a significant difference in long-term outcome between the standard and thrombolytic treatment. In summary, clinical studies on thrombolysis during CPR have shown a significantly improved rate of ROSC compared to standard treatment in patients with cardiac arrest after massive PE or acute MI. In addition, most survivors who recovered were neurologically intact after CPR even after prolonged resuscitation (> 90 minutes). The recent guidelines on CPR recommend considering thrombolytic therapy in patients with proven or suspected PE and performing CPR up to 60–90 minutes when thrombolytic agents have been given.[14,15] More studies, however, are necessary to determine if an improved short-term survival can translate into an improved long-term survival in these patients.

Out-of-hospital studies

As already stated, out-of-hospital cardiac arrest is known to be associated with an extremely poor prognosis, and only 5%–14% of patients suffering out-of-hospital cardiac arrest are expected to be discharged from hospital.[1–3] Four studies on out-of-hospital thrombolysis have been performed (Table 41.2). An inclusion criterion in all studies was a suspected cardiac cause of cardiac arrest, i.e., acute MI or massive PE, which account for more than 70% of causes for sudden cardiac arrest.[8–10] In 34 out-of-hospital cardiac arrest patients refractory to conventional advanced cardiac

life support, "rescue" thrombolytic treatment was administered.[37] Five patients survived longer than 3 weeks, and three of them were neurologically intact. In the first controlled prospective study on thrombolysis in out-of-hospital cardiac arrest,[38] 40 patients received thrombolytic treatment (alteplase) and heparin during CPR after resuscitation had been unsuccessful for more than 15 minutes. Compared to conventionally treated patients, significantly more patients were hemodynamically stabilized in the thrombolysis group (ROSC, 68% vs. 44%), and admitted to an intensive care unit (58% vs. 30%); 15% of the patients treated with alteplase were discharged from the hospital alive, whereas only 8% of patients from the control group were discharged. These results were confirmed by a retrospective chart review[39] comparing 108 patients who received alteplase during CPR with 216 control patients. ROSC was achieved significantly more frequently after thrombolytic treatment (70.4% vs. 51.0%). Survival after 24 hours (48.1% vs. 32.9%) and survival to discharge (25.0% vs. 15.3%) were significantly improved in the thrombolysis group. In contrast to these studies, the first randomized, double-blind, placebo-controlled trial in patients presenting with pulseless electrical activity of the heart did not show improved survival of patients who were treated with alteplase during CPR.[40] The results of that trial have been difficult to interpret, however, since a population with an extremely poor prognosis (no survivor among 116 patients in the control group) was studied. Therefore, the study was not powered to show any difference in a group of patients with such a poor prognosis.[41] In summary, early thrombolytic therapy may improve the outcome of patients suffering out-of-hospital cardiac arrest of cardiac origin, but more data from a large multicentre trial, which is currently under way in Europe (see below), are required. The success of any measure in these patients appears to depend on the initial EKG rhythm; in patients presenting with asystole or pulseless electrical activity, only studies with an extraordinary high number of patients can be powered to show a possible difference.

Safety of thrombolysis during CPR

The major safety concern associated with the use of thrombolytics is the risk of severe intracranial or systemic hemorrhagic complications. It is well known that thrombolysis is associated with the risk of bleeding. The risk for major bleeding, defined as bleeding that required transfusion or was life-threatening within the first 35 days after thrombolysis for treatment of acute myocardial infarction, is estimated to be about 1.1%, compared to 0.4% in the control group, as shown in a large meta-analysis.[42] The incidence of intracranial bleeding after thrombolysis for acute myocardial infarction is estimated to be 0.8% compared to 0.1% in the control group without thrombolysis.[42] In patients receiving thrombolysis for massive PE, the incidence of episodes of intracranial bleeding, one-third of which are fatal, has been reported to be up to 1.9%.[43] In summary, the risk for severe bleeding in patients with acute MI or PE who received thrombolytics is thought to range between 1.9% and 3.0% as compared to 0.5% in patients not receiving thrombolytics.[44] In addition, conventional resuscitation efforts are frequently associated with relevant bleeding complications,[45] among which hemorrhages of the heart and the great vessels, the lung, and abdominal bleeding are most common.[46,47] An overall

incidence for hemorrhagic complications in patients after CPR of more than 15% has been suggested by autopsy studies.[44]

Although the incidence of severe CPR-related bleeding complications associated with thrombolysis after CPR is similar to the incidence of severe hemorrhage reported in the large studies on thrombolysis for acute myocardial infarction or PE,[44,48] the risk of severe bleeding caused by thrombolysis *during* CPR may be higher. As shown in Table 41.1, the incidence of CPR-related bleeding complications reported by several in-hospital studies on thrombolysis *during* CPR appears to be about 6.7%. Although these hemorrhages were severe, all of them were treated successfully by blood transfusion or urgent surgical intervention.

Out-of-hospital thrombolytic treatment during CPR may be expected to be associated with a significantly higher incidence of bleeding, as history-taking and physical examination of the patient are often limited. The overall incidence of severe bleeding complications related to CPR reported in out-of-hospital studies on thrombolysis during CPR, however, was 2.0% (Table 41.2) and therefore, similar to the overall incidence of bleeding following thrombolytic therapy without CPR. In the retrospective study by Lederer *et al.*,[39] autopsy was performed in a subgroup of non-surviving patients which revealed 6 severe bleeding incidents in 45 patients who had received thrombolytic treatment, 3 of them directly related to CPR. Interestingly, 7 cases of severe bleeding were identified in the corresponding control group of 46 patients. Therefore, thrombolytic treatment did not appear to have influenced the incidence of severe hemorrhagic events. Consequently, the recent CPR guidelines do not regard ongoing CPR as a contraindication to thrombolytic therapy.[14,15] In summary, recent data do not suggest that thrombolysis during out-of-hospital resuscitation is associated with a critically increased bleeding risk. Nevertheless, more data are necessary to assess the exact risk and the benefit/risk ratio of thrombolysis during CPR.

Outlook

A large randomized, double-blind, placebo-controlled multicenter trial on thrombolysis during CPR after out-of-hospital cardiac arrest has been recently performed in Europe. The Thrombolysis in Cardiac Arrest (TROICA) trial was designed to enroll more than 1000 patients in 10 European countries who suffer witnessed cardiac arrest of presumed cardiac origin. The primary endpoint was survival at 24 hours and 30 days; additional endpoints include

neurological performance of surviving patients and the incidence of bleeding complications. The study showed an increase in survival at the primary endpoints by addition of tenecteplase to standard therapy. Interestingly, thermolytic therapy also did not increase symptomatic intracranial hemorrhage and major bleeding rates. A detailed presentation of these results that were presented at the World Congress of Cardiology 2006 is expected for 2007.

Conclusions

The poor prognosis of patients suffering cardiac arrest has not changed. No drug therapy has been found to improve the long-term survival of patients undergoing CPR. Thrombolytic therapy administered during CPR has been shown not only to eliminate the coronary thrombosis or pulmonary vascular obstruction, but also to improve microcirculatory reperfusion after ROSC. Clinical studies on thrombolytic treatment of patients suffering cardiac arrest of presumed cardiac origin have shown improved short-term outcome and a trend towards improved long-term outcome. The risk of causing critical bleeding complications does not appear to outweigh the potential benefit in patients with suspected massive PE. In addition, thrombolytic therapy may also be considered in patients with acute MI in whom conventional CPR has been unsuccessful. A large, randomized, placebo-controlled study which has recently been performed in Europe is expected to yield more detailed evidence for or against a generalized use of thrombolytic drugs in patients suffering cardiac arrest of presumed cardiac origin.

Percutaneous coronary intervention (PCI) after successful reestablishment of spontaneous circulation and during cardiopulmonary resuscitation

Marko Noc[1], Bjørn Bendz[2] and Karl B. Kern[3]

[1] University Medical Center, Ljubljana, Slovenia
[2] Rikshospitalet University Hospital, Oslo, Norway
[3] University of Arizona Sarver Heart Center, Tucson, Arizona, USA

Introduction

Coronary artery disease represents the most important cause of out-of-hospital cardiac arrest. Immediate coronary angiography in patients after reestablishment of spontaneous circulation demonstrated angiographic evidence of coronary artery disease in 80% of patients, with the majority (90%) having significant obstructive stenoses of one or more coronary arteries.[1] Experimental animal models have shown that coronary obstructions have a profound effect on the utility of cardiopulmonary resuscitation to perfuse the myocardium during cardiac arrest.[2] We found that coronary diameter stenoses as little as 33% decreased distal perfusion by more than half (see Chapter 18 for more details).[2] Postmortem examinations of sudden cardiac death victims indicate that unstable plaque with associated coronary thrombosis may be documented in more than 80% of the cases.[3] Accordingly, acute coronary thrombotic events leading to critical narrowing or complete coronary obstruction and possibly distal microembolization may be a main trigger of sudden arrhythmic cardiac arrest.

Current strategy for management of acute coronary syndromes

Acute coronary syndrome (ACS), based on 12-lead electrocardiogram, is traditionally divided into evolving ST segment elevation acute myocardial infarction (STEMI) and unstable angina/non-ST elevation myocardial infarction (UA/NSTEMI) (Fig. 42.1). More than 90% of the patients with STEMI have a complete thrombotic occlusion of the epicardial part of one of the coronary arteries without adequate collateral flow to the distal part of the affected artery. The mechanisms of coronary obstruction in patients with UA/NSTEMI are more heterogeneous. Pre-existing chronic coronary narrowing, plaque inflammation, thrombosis and spasm, alone or in combination, lead to critical stenosis rather than complete occlusion of the culprit artery.

Immediate, complete, and sustained recanalization of the culprit coronary artery, preferably by primary percutaneous coronary intervention (PCI), is crucial for survival of patients with evolving STEMI. This is also true for a small subgroup of patients presenting with an isolated posterior wall acute myocardial infarction. In these patients the ECG often shows both ST depression and a tall R wave in the second and third (V2–V3) precordial leads in this subgroup.

Patients with UA/NSTEMI, on the other hand, undergo early risk stratification and those with high risk features (positive troponin, ST depression, recurrent ischemia/heart failure/malignant arrhythmia despite adequate medical therapy) qualify for an early invasive approach including coronary angiography and revascularization within 24 to 48 hours after admission.[4]

Immediate coronary angiography and PCI after resuscitated cardiac arrest

Since acute coronary syndrome is the underlying event in the majority of the patients with sudden arrhythmic

cardiac arrest, immediate coronary angiography, followed by PCI, after reestablishment of spontaneous circulation is ideally suited to define and treat the culprit coronary event. By adequate percutaneous treatment of the coronary culprit, greater electrical stability and myocardial salvage leading to reduction in recurrent arrhythmias, hemodynamic stabilization and reduction in infarct size may be expected. The American College of Cardiology and American Heart Association in their guidelines for Coronary Angiography[5] suggest that adult patients successfully resuscitated from sudden cardiac arrest are at high risk for recurrence and should undergo coronary angiography to identify coronary artery disease for potential revascularization therapy (Class I recommendation). Although they recognize that immediate coronary angiography in survivors of out-of-hospital cardiac arrest can reveal acute coronary occlusion in nearly 50% of patients, and that successful emergency PCI of an acute occlusion is an independent predictor of survival,[1] no specific recommendation concerning timing of such angiography is provided. The most common approach has been to perform coronary angiography on cardiac arrest survivors before implantation of an ICD before hospital discharge. If the patient is deemed not a candidate for the ICD (usually secondary to central nervous system injury), coronary angiography is likewise not usually performed. An AHA statement from 1997 further addresses this issue.[6]

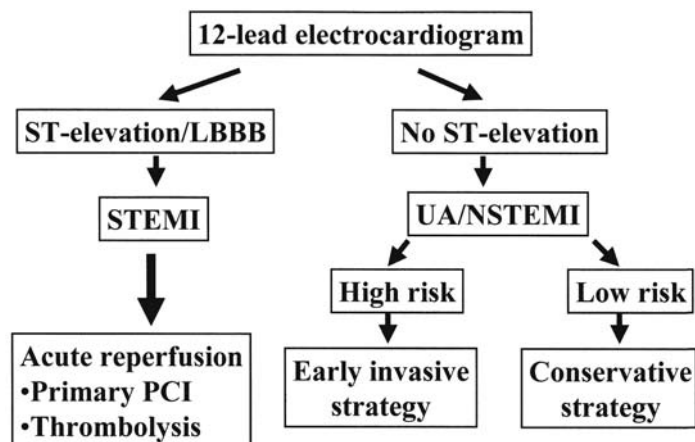
An alternative approach is to submit all resuscitated victims of cardiac arrest to coronary angiography upon presentation at the hospital. Most will not have regained consciousness by that time, making assessment of their long-term neurological prognosis uncertain. Some European centers have championed this approach,[1] but at the present time the data supporting such treatment are limited.[7,8] There are no current recommendations from either American Heart Association/American College of Cardiology[7,9] or the European Society of Cardiology[4] with respect to such an immediate invasive approach. Accordingly, immediate coronary angiography and PCI for all resuscitated cardiac arrest victims is routinely performed in only a few PCI centers. It is becoming more common to perform early postresuscitation angiography and PCI in patients showing evidence of a STEMI (showing persistent ST elevation after resuscitation). In contrast, for patients with UA/NSTEMI, coronary angiography and percutaneous or surgical revascularization is usually delayed for several days until more accurate information regarding their neurological outcome can be obtained.[10] It is, important to notice, however, that acute chest pain and ST-segment elevation may be less predictive for acute coronary occlusion after resuscitated cardiac arrest. Even


Fig. 42.1. Classification of acute coronary syndrome and principles of treatment based on 12-lead electrocardiogram. STEMI = ST-segment elevation acute myocardial infarction; LBBB = new left bundle branch block; UA = unstable angina pectoris; NSTEMI-acute myocardial infarction without ST-segment elevation; PCI = percutaneous coronary intervention.

though the positive predictive value for coronary occlusion in the presence of both signs is 87%, the negative predictive value is only 61%.[1] The absence of localizing electrocardiogram changes may indicate that the occlusion may be old and is not necessarily causally related to the fatal arrhythmia. Moreover, interpretation of the 12-lead electrocardiogram is further complicated because transient broad QRS complexes often appear immediately after reestablishment of spontaneous circulation and may resolve spontaneously by the time the next 12-lead electrocardiogram is obtained. Several 12-lead electrocardiograms are warranted after resuscitation to ensure that such transient changes are not mistaken for a STEMI.

An immediate invasive approach with coronary angiography and PCI would make sense if improvements not only in survival but also in survival with acceptable neurological outcome (Cerebral Performance Scale 1 and 2) could be expected. Except for patients with short intervals of cardiac arrest who have already regained consciousness on reaching the emergency department (Figs. 42.2 and 42.3), neurological outcome is impossible to predict accurately in unconscious patients at the time when decision for immediate coronary angiography and PCI has to be made. Since patients with unwitnessed cardiac arrest, no basic life support, long delay between call and arrival of the ambulance, and non-shockable rhythms on first electrocardiogram are unlikely to regain consciousness despite initially successful cardiac resuscitation,[11] they generally have not been treated with an immediate invasive
Fig. 42.2. Electrocardiogram of 41-year-old patient who had emergency personnel-witnessed ventricular fibrillation and regained consciousness after short period of chest compression and successful defibrillation on the field.

approach. The decision for such an approach is therefore largely made on an individual basis and may vary significantly according to interventional and acute cardiac care hospital facilities and practice.

Primary PCI in STEMI after resuscitated cardiac arrest

During primary percutaneous coronary intervention, the thrombotic occlusion in the infarct-related artery is first-passed by a guidewire introduced via the guiding catheter (Figs. 42.4 and 42.5). A PCI balloon is then advanced over the wire and filled with the contrast medium under high pressure to compress and fragment the thrombus and restore coronary patency and flow. Alternatively, a dedicated suction device can be used to aspirate the

thrombotic burden. In a great majority of the current patients (≥80%), a coronary stent is deployed to secure a good and stable angiographic result with epicardial patency and normal epicardial coronary blood flow in excess of 90%.

Even though primary PCI is considered both a better and safer reperfusion strategy than thrombolysis in evolving STEMI,[12] data on the use of such mechanical reperfusion in the subgroup of patients with resuscitated cardiac arrest are very limited. Kahn and coworkers were the first to report 11 selected patients with out-of-hospital ventricular fibrillation and STEMI after reestablishment of spontaneous circulation.[7] Four of their patients had regained consciousness before arrival in the emergency department. The infarct-related arteries were the left anterior descending artery (LAD) in 9 patients and the right coronary artery (RCA) in 2 patients. PCI was successful in 7 out of

(d)
Fig. 42.3. Immediate angiography revealed subtotal "hazy" stenosis of the midshaft of the left main coronary artery (a). Direct stenting with a drug-eluting stent was successfully performed under hemodynamic support of intraaortic balloon counterpulsation (b). Finally angiography revealed widely patent left main coronary artery in both angiographic views (c) and (d).

11 patients; 6 patients survived to hospital discharge. Complete neurological recovery was documented in 4 patients and mild disability in 2 patients.

Recently, Bendz and coworkers reported long-term survival in 40 STEMI patients with less than 10 minutes of untreated ventricular fibrillation before reestablishment of spontaneous circulation in the field.[8] A great majority of the patients (90%) were unconscious at the time of coronary angiography. The infarct-related arteries were LAD in 50%, left circumflex (LCX) in 5%, RCA in 30% and an unprotected left main coronary artery (LMCA) in 15%. Contemporary techniques of primary PCI, including coronary stenting and glycoprotein llb/llla inhibitor, resulted in much better angiographic results than were reported by Kahn and coworkers.[7] Optimal angiographic results in the culprit artery were obtained in 95% of the patients. In-hospital and 2-year mortality of this very high risk STEMI subgroup of patients was only 28%. Accordingly, with contemporary technology, primary PCI is both feasible and highly successful in selected STEMI patients after resuscitation from cardiac arrest.

The recent advances in preserving central nervous system function after resuscitation by using mild therapeutic hypothermia in comatose survivors of cardiac arrest[13,14] makes an interesting theoretical basis for more aggressive use of primary PCI in resuscitated victims of cardiac arrest with persistent ST elevation. Thus, a combination of primary PCI preceded or followed by induction of hypothermia (32° to 34° Celsius) may be an important future approach. At the moment, however, there are no specific data in the literature showing improved outcome with this combined approach.
Fig. 42.4. 12-lead electrocardiogram of 56-year-old still unconscious patient after resuscitated out-of-hospital ventricular fibrillation on arrival to emergency department. ST-segment elevation in precordial leads together with multiple ventricular ectopic beats is seen.

PCI during cardiopulmonary resuscitation

Cardiac arrest can occur during coronary angiography or PCI or both procedures. This complication, although rare, must be dealt with expeditiously if the patient is to be resuscitated and survive long-term with intact neurological function. An important part of therapy is to deal with the underlying cause of cardiac arrest during angiography or PCI.[15]

In the majority of the cases, interventions such as cardioversion/defibrillation, intravenous pacing, pharmacological agents such as epinephrine and amiodarone, as well as mechanical support by intraaortic balloon counterpulsation at least temporarily restore spontaneous circulation, which allows a lifesaving PCI attempt. If these stabilizing measures fail, PCI may be attempted *during* ongoing cardiopulmonary resuscitation (CPR). Such a combined PCI/CPR procedure requires not only extraordinary skills, but close cooperation and coordination between the interventional cardiologist and the CPR team. Intermittent pauses in chest compressions during different phases of PCI (placement of guiding catheter, passage of a guidewire, balloon inflation, stent deployment) may be

required, but the more chest compressions and hence circulatory support to the central nervous system, the less likely will irreversible neurological damage result. Continuous monitoring of aortic pressure is very valuable for assessing the adequacy of chest compression because it provides an invasive and fair estimate of coronary perfusion. If at all possible an aortic diastolic pressure of at least 25–30 mmHg should be maintained during CPR.[16] If an intraaortic balloon counterpulsation is in place, continuous balloon inflation during chest compression may further increase vital perfusion pressures by centralizing the flow generated by chest compression to the heart and head.[17] Fast and successful PCI of the culprit lesion may, in addition to the previously described measures, result in reestablishment of spontaneous circulation.

A review of Anglo-Saxon literature revealed reports of 11 patients who underwent a combined PCI/CPR procedure either in the setting of ongoing acute coronary syndrome or due to complications during elective coronary angiography or PCI.[18–22] In 10 patients, the culprit event was a severe stenosis or occlusion of unprotected LMCA. One patient presented with ongoing STEMI due to ostial occlusion of LAD. Since an ostial spasm with complete occlusion

(a)

(b)

(c)

(d)
Fig. 42.5. Immediate coronary angiography revealed complete thrombotic occlusion of left anterior descending artery (a). Guidewire was easily advanced across the occlusion. The PCI balloon was positioned at the site of thrombus and filled by contrast medium under thigh pressure (b). Following balloon deflation, antegrade flow was re-established (c). Because of dissection and residual thrombosis at the culprit lesion, a bare metal stent was successfully implanted with optimal angiographic result (d). The patient was then transferred to the intensive care unit for temporary mechanical ventilation and hemodynamic support, regained consciousness 3 days later, and was discharged in normal neurological condition.

of LCX occurred during the LAD stenting, this patient may be regarded as having the equivalent of an unprotected LMCA occlusion as well. Accordingly, there was an extremely large amount of ischemic myocardium in each of these 11 patients who developed cardiac arrest on the angiography table. PCI with balloon predilatation or direct stenting during interruptions of chest compression was successful in every patient, and 9 out of 11 patients survived at least to hospital discharge.

It is, however, very important to emphasize that only successful cases are likely to be reported in the medical literature and actual survival of such patients is probably much worse. Nevertheless, these case reports underscore

the notion that combined PCI/CPR intervention should be attempted, because the patient may survive long term with complete neurological recovery if the catastrophic coronary problem can be resolved quickly and adequate cerebral perfusion is maintained during PCI.

But what if cardiac arrest preceded the patient's entry into the cardiac catheterization suite? What if ongoing resuscitation efforts have been underway without success for a while? Is PCI possible and efficacious in such dire circumstances? This is perhaps the most difficult situation since long-term central nervous system outcomes depend on both the quality of resuscitation effort and its duration. Each individual case must be carefully and

quickly evaluated before preceding with an attempt at PCI.

Observations of the coronary anatomy at the onset of cardiac arrest may also explain, at least in part, why even timely CPR may not be effective in a considerable number of patients in the field. A major coronary event such as severe stenosis or occlusion of an unprotected LMCA, unless resolving spontaneously, most likely precludes adequate myocardial perfusion during CPR and hence failure to reestablish spontaneous circulation. In such patients, use of thrombolytics *during* CPR for refractory cardiac arrest may be a preferred approach. Thrombolytics given during CPR in an attempt to use chemical reperfusion means and reestablish spontaneous circulation in the field, may at least theoretically represent the only option of achieving reperfusion of such a culprit sentinel artery[23–25] before the coronary anatomy can be defined and PCI performed.

Summary

Percutaneous coronary intervention after successful resuscitation is becoming more common, particularly for those cardiac arrest victims manifesting evidence of a STEMI post resuscitation. The greatest challenge is determining the most appropriate candidates, because the majority of such patients are comatose and their long-term neurological function is not easily determined before the time such intervention is contemplated and performed. Percutaneous coronary intervention can be attempted during resuscitation, but great care in needed to ensure that adequate chest compressions are performed throughout the effort to avoid damage to the central nervous system even if the myocardium is reperfused.

Introduction

Emergency Medical Services (EMS) constitute a unique component of health care in the prehospital setting. Prehospital EMS systems are commonly understood as the resources used for planning and providing medical care for patients who experience an unpredicted need for emergency or urgent medical care outside a hospital. The EMS system's primary role is to provide care for patients whose lives are at immediate or imminent risk. In the beginning of organized prehospital care, most emergencies were of traumatic origin but in the last decades this has changed to include medical problems. In 2002 at the conference of the European Resuscitation Council in Florence the *First Hour Quintet* (FHQ) was defined, a set of five major medical problems of prehospital care on which EMS can have a significant impact on the outcome; these are:

- out-of-hospital cardiac arrest (OHCA)
- severe respiratory difficulties
- severe trauma
- chest pain, including acute coronary syndrome
- stroke.

Together these conditions are among the four leading causes of death in the European Union (EU). Cardiovascular problems, cancer, external causes, and respiratory diseases represent the top four leading causes of death and morbidity: 80% of all deaths are attributable to these common causes. Cardiovascular disease (CVD) is the number one cause of death in all EU countries, resulting in 4 million deaths per year in Europe or 1.5 million in the EU, respectively. CVD also accounts for the largest amount of years of life lost by early death in Europe and in the European Union, contributing significantly to the escalating costs of health care. Coronary Heart Disease (CHD) is the most important cause of death in the adult population, comprising 55% of all CVD deaths. Acute coronary syndromes (ACS) include acute myocardial infarction (AMI), unstable angina, and sudden cardiac death. This diagnostic group represents the most severe forms of CHD. With this group, rapid access to the health system and prompt definitive care are vital. Mortality from ACS is extremely common outside the hospital, with 52% of deaths occurring before the patient reaches the hospital (World Health Organization (2004): The World Health Report 2004. Changing History. Geneva). Out-of-hospital cardiac arrest with prehospital cardiopulmonary resuscitation is the most time-critical emergency. Chance of survival from this event decreases every minute by 5%–10% that passes without treatment.[1–3] The design of EMS systems significantly influences survival rates.[4,5] On the basis of data from different EMS systems across the world, the annual incidence of resuscitation for out-of-hospital cardiopulmonary arrest of cardiac aetiology is 5–119 per 100 000 population[5–7] with an average incidence of 38 CPR attempts per 100 000 per year.[7]

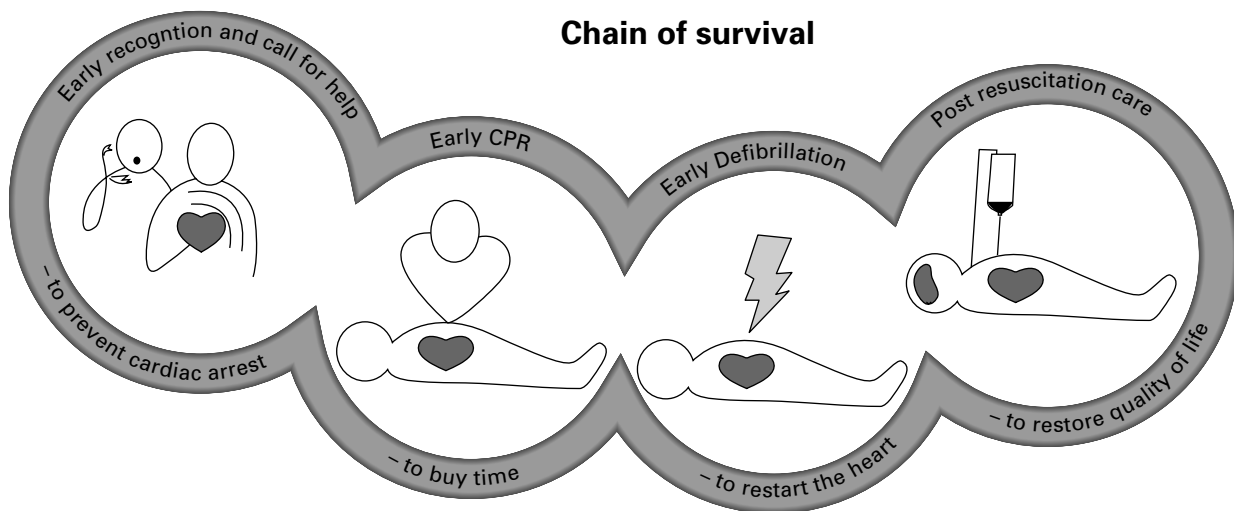
In cases of OHCA therefore, EMS systems are the only organised providers bringing professional care to patients. Success of resuscitation measures is closely linked to minimizing the time without treatment and delivering definitive care as fast as possible. To reach these targets, each


Fig. 43.1. ERC chain of survival.

link of the Chain of Survival (Fig. 43.1) must be analyzed and optimized by the provider of EMS. This includes early recognition of the emergency and activation of the EMS, early CPR, early defibrillation, and early advanced life support.

First link: Early recognition and call for help

Early recognition and call for help is the first link in the chain of survival. This step is a complex task for EMS and dispatch providers, however, because it encompasses multiple requirements.[8,9]

1. Recognition of sudden cardiac arrest by lay persons, which will be improved by training programs[10–12]
2. Call for help, knowledge of the "common" emergency number, comprehensive transfer of essential information to the dispatch center
3. Early receipt of the call in the dispatch center
4. Ability to differentiate calls into categories, including immediately life-threatening, urgent, and non-life-threatening (prioritization)[13–17]
5. Recognition of sudden cardiac arrest as an emergency of highest priority (criteria-based dispatch)[8,18,19]
6. Localization of emergency (calling line identity)
7. Localization of nearest ambulance and dispatching the appropriate response (Global Positioning System (GPS), computer-aided dispatch of Emergency Life Support (ELS), Basic Life Support (BLS), Advanced Life Support Units (ALS))[20]
8. Telephone-guided CPR[8,21–25]
9. Fastest possible drive to the place of emergency (GPS-guided)[26]

EMS providers are involved in all of these requirements. For example, to improve the ability of lay persons to recognize sudden cardiac arrest, public training programs have to be organized. These programs should start at primary school, but they must be continued during secondary school, high school, and university, and other job training.[12,27–31] Lay rescuers should be taught how to call for help, as well as basic life support skills and the use of automated external defibrillators (AED).[32,33] By using geographic information systems (GIS) it is possible to identify clusters of OHCAs in which the patients did not receive bystander CPR and where direct educational programs should be started.[34]

The provision of organized prioritization and dispatching systems is the crucial first step in the delivery of any emergency medical support, especially in sudden cardiac arrest.[9,35] Dispatch procedures have an important gate-keeper role in sorting, streaming, and directing resources. While dispatch centers may take a wide range of calls, it is vitally important that they are able to differentiate calls into categories, including *Immediately Life-Threatening*: like sudden cardiac arrest, or *Urgent* and *Non-Life-Threatening*. They must have the alternative to respond immediately to emergencies of CPR with ALS-units and to pass non-urgent minor illness calls to alternative resources, such as General Practice or ELS/BLS units.[14] This allows them to avoid down-grading the responsiveness of the resource-limited system. The best strategy for prioritization of the calls is still under discussion. A distinction is drawn between computer-aided criteria-based dispatch.[36–40] and having highly qualified personnel at the dispatch centers, like physicians

in France[41,42] or paramedics and highly trained dispatchers in other parts of Europe.[43–47] Independent of the employed personnel at the dispatch centers, it is commonly accepted that improvement of dispatch techniques needs a supervisory quality assurance program.[35,48–51]

After identification of OHCA, dispatch personnel must localize the place of emergency and send out the nearest ambulance unit. These tasks will be supported best by computer-aided dispatch, including caller line identification and GPS.[26,52,53]

Second link: Early CPR, to buy time

After ischemia, the recovery of the brain is related to the duration of no-flow. In the clinical situation it is widely accepted that after more than 5 minutes of ischemia, full recovery of brain function is almost impossible. Experimental studies, however, clearly demonstrated that after 11 minutes[54] or even 60 minutes[55,56] of cerebral ischemia under normothermic conditions, neurological recovery to nearly normal function is possible. These studies, therefore, emphasize the hypothesis that there is still a chance for survival after sudden cardiac arrest beyond the 5-minute limit. But with increasing time of no-flow, the chance of survival after OHCA dramatically decreases:[57–59] this is a clear request for optimized EMS design. Many clinical studies consistently show that the early initiation of BLS measures – cardiac massage and ventilation – will improve neurological recovery and increase survival rates two- or threefold.[2,60–62]

To buy time, basic life support should be started when the first contact to EMS is made. Telephone-guided CPR[8,63–65] organized by the dispatch center therefore should be considered, because early bystander CPR can double or triple survival from OHCA.[2,60,61] The new guidelines of CPR recommend–especially for telephone-guided CPR – that laypeople should be encouraged to perform compression-only CPR if they are unable or unwilling to provide rescue breaths, although combined chest compression and ventilation is the better method of CPR.[33,65] To minimize duration of layperson CPR, the ambulance units bringing professional help to the OHCA victim should arrive in the shortest time. This could be attained by training the EMS drivers[66,67] and the implementation of GPS and GIS assisted dispatch.[26]

The providers of EMS therefore are challenged to reduce the time interval without professional treatment to a minimum.[68,69] However, this medical need is limited by financial resources and legal requirements. The response time interval, which is one of the main determinants of EMS costs, is often defined by law, but the definition across Europe differs widely. The European Emergency Data Project (EED).[9] (www.eed-project.de) defined the response time interval uniformly as time interval from receiving the call at the dispatch center to arrival of the ambulance on scene. For comparing and benchmarking EMS systems a uniform format must be used. The response time interval should be expressed as a percentage of highest priority calls that were reached within 8 minutes. By using this format the ability of the EMS system to meet the widely accepted 8-minute response-time standard will be measured. The data must be provided as percentiles. Average response times are not only misleading, they are also clinically inappropriate. The EED-group found the response time to be a valuable indicator of EMS system performance across Europe. In 2004, 22 out of 31 UK Ambulance trusts reached the nation-wide key target defined by getting a first EMS response in 75% of category A calls within 8 minutes (http://ratings 2004.health carecommission. org. uk/). In some European and US high performance EMS systems, up to 85%–90% of all highest priority calls were read within 8 minutes (www.eed-project.de).

To reduce the time interval of no-flow and to optimize the response time interval, EMS providers should review and implement the following measures.

1. Training of laypersons in BLS skills beginning in primary schools[27,28,30,70–72]
2. Telephone-guided CPR[8,21–25]
3. First responder unit organized by professional care providers (fire fighters, police, patient transport ambulance)[69,73–79]
4. First responder units initialized by volunteer aid organizations[73,80]
5. Strategy of the nearest ambulance unit[81]
6. Computer-aided dispatch, caller line identification, GPS localization and guidance of ambulance units[18,26,52,82]
7. Ambulance base paging[83,84]
8. Improved deployment of ambulances by using Geographic Information Systems and the Global Positioning System[85,86]
9. Predictive analysis for localization of highest priority calls

Third link: early defibrillation, to restart the heart

Public access defibrillation, first responder units with AEDs

Early defibrillation is a key link in the Chain of Survival. In ventricular fibrillation after cardiac arrest it is a class 1 recommendation of the 2005 guidelines of CPR,[87,88]

because it has been shown that early defibrillation improved outcome from VF/VT cardiac arrest.[73,89–92] EMS providers therefore are responsible for implementing early defibrillation programs. They have to equip BLS- as well as ALS-units with manual or automated defibrillators; they have to consider public access defibrillation[93–95] or first responder AED programs. The latter could be organized with the fire department, police, transporting ambulances, or volunteers. Depending on local or national standards or within the regulations by law EMS providers are responsible for the medical education of first responder units, their connection to the professional EMS, and debriefing and quality improvement programs. Medical direction of the EMS systems, therefore, should be an integrated part of quality assurance.[96] The logistic problem that occurs if first responders did not arrive before the professional EMS-teams at the scene must be overcome by intelligent deployment of all resources including BLS-, ALS- and first responder units. Geographic Information Systems and the Global Positioning System are modern tools for solving these multivariate problems of deployment.[34,85] Mobile EMS-units, on the other hand, should be controlled by a computer-based dispatch technology, including calling line identity, GPS-aided automatic vehicle location, digital mapping, predictive analysis, real-time system status management, and digital data transmission.

In introducing public access defibrillation programs to their communities,[95] EMS providers should manage the whole process, including positioning of PADs, training of anticipated lay rescuers, linking PAD initiative to the professional EMS, and programs of continuous audit. PAD programs will increase survival from OHCA most effectively if defibrillators are located where witnessed cardiac arrest occurs most frequently, but because 80% of OHCA occur in private or residential settings, PAD programs have only limited impact on survival rates. Currently, no studies have documented effectiveness of home AED deployment. Therefore some studies conclude that it might be better to establish an increased number of mobile first responder units than to start a PAD program.[97,98]

Fourth link: advanced life support and postresuscitation care to restore quality of life

Immediately after arrival at the scene, professional EMS teams will adopt and continue BLS-skills from lay- or volunteer-rescuers and continue cardiopulmonary resuscitation by starting ALS measures. Basic life support – compression and ventilation with a ratio of 30:2 – is the fundamental measure for successful CPR, because nutritive blood flow to the heart and brain depends crucially on effective heart massage.[33] The most effective performance of compression and ventilation, however, is only achieved with periodic drill and training, which cannot be expected from lay rescuers. Professional rescuers therefore take over BLS skill immediately, and reduce hand-off time to a minimum during CPR. EMS providers have to decide whether to implement mechanical devices to increase myocardial blood flow during CPR such as "active compression–decompression CPR" in combination with "impedance threshold device" (ACD+ITD),[99] load-distributing band CPR (AutoPulse™[100,101]) or mechanical piston device/Lund University Cardiac Arrest System (LUCAS[102]).[88,103]

The new guidelines for adult advanced cardiac life support were published in 2005 in the journals Circulation and Resuscitation.[88,103] These guidelines were developed by clinical experts around the world who followed precisely defined procedures for searching and evaluating medical evidence. The recommendations were grouped as follows: (1) causes and prevention, (2) airway and ventilation, (3) drugs and fluids given during cardiac arrest, (4) techniques and devices to monitor and assist the circulation, (5) periarrest arrhythmias, (6) cardiac arrest in special circumstances, (7) postresuscitation care, and (8) prognostication.

The advanced life support skills discussed and recommended in previous chapters are listed as follows.

1. Defibrillation
2. Endotracheal intubation and confirmation of tube placement
3. Monitoring of CPR efficiency by end-tidal CO_2
4. Intravenous access and alternatives (intraosseous route, via tracheal tube)
5. Application of drugs (adrenaline, vasopressin, amiodarone, atropine, thrombolytics and others see below)
6. Electrical stimulation of the heart (pacemaker)
7. Treatment of periarrest arrhythmias (vagal maneuvers, magnesium, ß-blockers, diltiazem, amiodarone, propafenone, digoxin, clonidine, sotalol, isoproterenol, atropine, dopamine, adrenaline, ventricular pacing, electrical therapy, defibrillation)
8. Search for and treat possible contributing factors
   - Hypovolemia   → adequate volume replacement
   - Hypoxia   → reoxygenation, tracheal intubation
   - Hydrogen ion   → buffers (acidosis)
   - Hypokalemia   → potassium
   - Hyperkalemia   → Ca and buffers, glucose, and insulin

- Hypoglycemia → glucose
- Hypothermia → appropriate rewarming
- Toxins → specific antidotes
- Tamponade, cardiac → drainage of pericardium
- Tension pneumothorax → thoracic drainage
- Thrombosis (coronary or pulmonary) → thrombolytics (after 12-lead ECG)
- Trauma → diagnosis, sedation, analgesia, intubation, infusion therapy (colloids, crystalloids), immobilization, transportation – advanced trauma life support (ATLS)

9. Induction of therapeutic hypothermia after ROSC in comatose patients
10. Cardiac arrest in special circumstances (hypothermia, drowning, electrocution, pregnancy, asthma)
11. Documentation of findings, diagnosis and CPR measures according to the "Utstein Style"

All these recommended ALS skills must be performed during resuscitation from out-of-hospital cardiac arrest under enormous pressure of time. To increase and optimize survival after OHCA, EMS providers and their BLS/ALS teams should follow the recently published CPR guidelines in detail. From the medical point of view, it cannot be accepted to withhold from a patient BLS, defibrillation, or ALS measures if sudden cardiac arrest occurred outside the hospital. Best results can only be achieved if the chain of survival is implemented in all links. Because CPR is a complex and demanding medical treatment, which requires detailed knowledge about the pathophysiology and pharmacology of sudden cardiac arrest and the underlying diseases, it is common sense that CPR has to be performed by the best trained ALS-teams. In hospitals around the world Medical Emergency Teams and Cardiac Arrest Teams have been established or are under consideration in order to avoid or to treat cardiac arrest. These teams consist of physicians and nurses with critical care training. In many European countries, this concept was rolled out years ago to the preclinical situation and the emergency physician on scene is an integrated participant in those high quality EMS systems. Therefore, many European citizens today expect to have a specialized emergency physician performing the whole ALS-treatments outside the hospitals (www.eed-project.de)[37,43,104–109] Recently published clinical studies comparing and benchmarking resuscitation success after OHCA clearly established that survival rates of greater than 7 patients discharged alive per 100 000 inhabitants annually were found only in EMS-systems with emergency physicians operating in the field.[7,43] It was demonstrated that compared to a paramedic EMS system, the preclinical treatment by an emergency physician increased vital scores and the probability of survival after CPR.[43]

Conclusions

EMS system design has to address these medical needs and the public expectation on the provision of best medical response to life-threatening emergencies. Each component of the EMS process depicted in the "EMS Patient Journey Template" (Fig. 43.2) developed by the European Emergency Data Project has to be carefully designed according to its crucial role within the chain of survival described above.[9,110] The advances in communication and information technologies (including GPS and GIS) have opened up new opportunities to minimize call to scene time systematically, while simultaneously maximizing the effective use of the available resources, both clinical and fiscal. Nonetheless, there is an urgent need to harmonize and standardize the emergency dispatch process. Utstein-like standards of reporting the EMS dispatch process and guidelines for rapid assessments and decision-making in the dispatch center could lead the way for further improvements.

Throughout the world, it would be reasonable to suggest that all citizens should have access to organized EMS with basic life support (BLS) provided to their community as a minimum standard. BLS, as defined by the European Resuscitation Council in 2005, is the ability to deliver cardiopulmonary resuscitation (CPR) and to provide a defibrillator to treat ventricular fibrillation in cardiac emergencies. BLS needs to be supported by the knowledge and the ability of first responders to carry out Emergency Life Support (ELS) on the citizens of the community to bridge the time gap until a BLS provider arrives on scene. The ideal standard for any EMS system is to aim towards the capability of providing early advanced life support (ALS) and advanced trauma life support. The first hour Quintet conditions – as defined by the European Resuscitation Council – require early delivery of full ALS skills.

Introduction

In-hospital resuscitation practices have changed very little despite significant advances in resuscitation science. Unlike pre-hospital providers, hospital personnel have been slow to focus on resuscitation practices and even slower to adopt evolving science and technology to improve outcomes. Consequently, there has been no improvement in survival over time for hospitalized patients suffering a cardiorespiratory arrest, where overall survival remains approximately 18%.[1]

Hospitalized patients have different comorbidities from persons who arrest outside of the hospital. In a large series of cardiorespiratory arrests occurring in hospitalized patients in the United States, many arrest patients had electrocardiographic or oximetry monitoring, an invasive airway, or were receiving an intravenous vasoactive drug prior to their arrest, suggesting that this population has varying degrees of underlying instability.[1] Nevertheless, to stop here and suggest that survival will always be poor because the patients are "sick" and cannot be expected to do well leads to a self-fulfilling prophecy. Although the hospitalized patient population may inherently be more acutely ill, the hospital also has potential resources that far outweigh those in the pre-hospital setting.

Different strategies may be necessary to improve survival in the hospital environment. One of the most significant changes that must occur is within the hospital culture. Attention needs to be focused on the science of resuscitation, and on the process of care delivery. The importance of administrative and organizational support is paramount to achieving success. Traditionally, hospitals focus only on the arrest event itself when planning their resuscitation practices. Little attention is given to prevention or the specific care the patient receives after return of spontaneous circulation (ROSC).

There is an emerging concept of a "bow-tie" strategy to encompass the entire spectrum of hospital-based resuscitation practices (Fig. 44.1). In this schematic, the arrest event represents only a small part of the time and resources that a hospital needs to commit to the resuscitation program. It illustrates that there is a substantial period of time prior to the majority of arrests when easily identifiable physiological triggers can be identified and intervention implemented to decrease the likelihood of cardiorespiratory arrest. This shifts the hospital response from a "reactive" one that merely responds to patients once they have had an arrest, to a "pro-active" one where prevention of the arrest is the primary goal. There is no better way to improve survival from cardiorespiratory arrest than to prevent it from occurring in the first place. For those patients who do suffer an arrest, the schematic also demonstrates that the resuscitation process does not end with ROSC, but suggests that targeted care of the recently resuscitated patient is needed.

The purpose of this chapter is to present a comprehensive strategy, beginning with early intervention and prevention, and ending with targeted postresuscitation therapies.

Prearrest rapid response systems

In-hospital cardiac arrests,[2–7] intensive care unit (ICU) admissions,[8–10] and unexpected deaths[11] are often preceded by warning signs for clinically significant periods of time prior to the event. Evidence of deterioration is

LOSC = loss of spontaneous circulation
ROSC = Return of spontaneous circulation.

typically present for up to 6–8 hours, but in some studies up to 72 hours prior to the event. Nearly 80% of patients suffering an in-hospital cardiac arrest have a heart rate, respiratory rate, or oxygen saturation out of the normal range within the 8 hours prior to the event. This suggests that many of these events are predictable and therefore potentially preventable.

A better understanding of the organizational factors that provide the conditions in which adverse events occur is required. The identification of both active errors (errors of omission and commission) and latent errors caused by inadequate systems has led to an appreciation that serious events are commonly preceded by multiple failures within the hospital system.[12–17] Examples of such failures include evidence that the majority of potentially avoidable arrests or unplanned ICU admissions had a delay in diagnosis or errors in diagnosis, and most patients had inadequate treatment prior to their event.[13] There is evidence that junior physicians are insufficiently trained or experienced to respond appropriately to patients with critical illness, but are commonly the only doctors who review patients with potentially preventable arrests in the hours prior to their event. Some cardiac arrests classified as potentially preventable occur in patients nursed in an area inappropriate for their primary illness, even though it is known that mortality is higher where patients are admitted to an inappropriate level of care for their illness.[13] Once a cardiac arrest has occurred, most patients will still die despite the intensive level of care and resources provided after the event, with approximately 18% surviving to discharge. Compare this to a 60% survival in non-arrest patients admitted urgently to the ICU from the floor. Outcomes are clearly better when the arrest is prevented and aggressive care occurs early.

These findings have directed attention towards prevention of these serious events by using a systems approach. Critical care medicine has been using systems to improve patient care for decades, with trauma systems now well developed in most health services, and the chain of survival for out-of-hospital cardiac arrests providing a system-type response similar to those now advocated for in-hospital critical events.

The most effective approach to identifying and responding to in-hospital clinical deterioration is the Medical Emergency Team (MET).[18–20] This is a team-based system response to patients identified as being at risk of clinical deterioration. The MET system is designed to recognize and respond rapidly and appropriately to any patient within the hospital displaying signs of instability. The MET system comprises the Medical Emergency Team itself, ongoing education and awareness campaigns, and monitoring and feedback processes.[21,22] The ICU or Emergency Department of the hospital generally provide the Medical Emergency Team members. The team is composed of at least two people, a physician and a nurse with advanced diagnosis and resuscitation skills. The team may be called by any member of the clinical staff to any of the units in the hospital to obtain immediate assistance in caring for an unstable patient. The team is available at all times, and is activated by calling an emergency number. The response is immediate. The team will attend a call with equipment required for advanced resuscitation, including drugs, fluids, intravenous access, intubation and ventilation equipment, and a cardiac monitor and defibrillator. The aim is to be able to evaluate and treat the patient immediately, with the goal of preventing cardiac or respiratory arrest or transfer to the ICU.

The MET calling criteria are specified clearly and based on abnormal clinical observations in addition to a subjective "seriously worried" criterion. These criteria are used as a screening tool, to help clinical staff recognize and respond to patients at risk of acute decompensation. "Calling criteria" posters are typically displayed throughout the hospital, and all members of staff are educated on the specific calling criteria used in their hospital.

The functions of the team include diagnosis, critical intervention, and resuscitation, as well as decision making. Decisions include not only the treatment decisions, but also decisions about the need for transfer to a higher level of care or even another institution, notification and consultation with the responsible consultant and team, and institution of "do not attempt resuscitation" (DNAR) orders where appropriate. Although the MET is capable of a range of responses, it is often required to perform only relatively simple interventions, such as the administration of oxygen

and nasopharyngeal suctioning, obtaining IV access and administering fluids or basic medications.[22,23] The MET also provides support to clinical staff on the wards, and may also provide training on the appropriate management of patients at risk for clinical deterioration.

The MET system has been associated with many beneficial outcomes. These include a 17%–65% reduction in the rates of cardiac arrest in three single-center "before and after" studies, although one other smaller before-and-after study did not show any effect.[2,24–26] The MERIT trial is the only randomized controlled clinical trial evaluating the effects of MET vs. no-MET within the same hospital.[27] This was a neutral trial; however, the event rate was underpowered to detect a difference between the two groups. The MET has also been associated with reductions in unplanned ICU admissions, reductions in morbidity and mortality postsurgery, reductions in length of ICU admissions and reductions in length of stay, as well as reductions in total in-hospital mortality.[23–25,28] In addition, the MET may facilitate increased rates of appropriate DNAR documentation, as well as an improvement in the process and planning of critical care admissions.[22]

The effectiveness of the MET not only depends on the activities of the team, but on the cohesive activities of the entire system. The MET system includes initial and ongoing education of physician and nursing staff to raise awareness, and improve identification, of patients at risk and to increase appreciation of the urgency of response required for such patients. This process includes regular MET education sessions on the ward, department meetings and active support of the system by both administration and clinicians, calling card ID badges, posters of the calling criteria, an overhead address system or paging system for calling the MET, formal MET reviews, and other informal feedback processes. Hospitals that have implemented the MET usually require a dedicated coordinator to ensure these activities are organized and occurring continuously. This coordinator may also be responsible for the MET databases, the incorporation of the MET outcomes into the quality system as outcome indicators, and to provide feedback to all involved in a MET response.

The implementation of the MET requires attention to cultural and structural factors within the hospital that may prevent the system from being used effectively. These may include concerns about the resources required to run the system and about loss of control over patient care, and fears of retribution for bypassing the hierarchy or crossing the boundaries of the hospital organization in calling the MET, as well as fear of negative comments from the MET members when a call is attended. Implementation should take account of the time needed for the necessary change in culture required for the MET system to become fully functional, and the ongoing training and support required for the system's optimal function.

The success of the MET system also depends on the frequent and complete documentation of clinical observations and vital signs in all patients admitted to the hospital. Clearly, if the observations are not measured, the MET will not be called even though the signs of deterioration are present. Many studies have provided evidence that observations are often missing or incomplete, in particular for the respiratory rate.[5,22]

When appropriately implemented, MET systems can decrease the incidence of in-hospital cardiac arrests, improve survival from arrests, and lower the number of urgent transfers to the ICU. The development of a MET system has been identified as a patient safety issue in the United States by both the Joint Commission for the Accreditation of Hospitals and the Institute for Healthcare Improvement, and is endorsed by organizations such as the American Heart Association and the Society of Critical Care Medicine.

Cardiac arrest event

Process issues: administrative structure

Despite the most meticulous attention to patient safety and attempts to prevent catastrophic events in hospitals, cardiorespiratory arrests will occur. Most hospitals have a committee or some sort of oversight mechanism responsible for governing resuscitation practices. With rapidly accruing new science, new defibrillator technology, and devices for improving hemodynamics during CPR, hospitals are now faced with potentially needing more frequent equipment updates. Because most resuscitation programs have no independent budget, many resuscitation committees are finding it increasingly more difficult to maintain the quality of their programs. Political and financial support is often quite variable. Committees must have the authority to act on their findings and recommendations. Resuscitation committees are often caught between having all of the responsibility and none of the authority to do what is best for patient care. This culture of "delegation to the powerless" must change for hospitals to be able to adopt evolving technologies more readily.

The members of the resuscitation committee can vary widely among hospitals. It is important to have representation from groups that are related to the local resuscitation practices. With the advent of the MET system, hospitals will need to decide if the MET committee will be

part of the overall resuscitation committee or will be politically and financially separate. Committees will also need to expand their focus to assure optimal postresuscitation management.

Organized response to cardiac arrest

First responder

The most critical period of a cardiac arrest is the first few minutes after collapse, regardless of whether the arrest occurs inside or outside of the hospital. Therefore, improvement in very early treatment (mostly prior to admission of the rescue team) has the potential to have the most marked influence on the chance of survival after in-hospital cardiac arrest. Thus, the single most important issue is to secure optimal preparedness for a cardiac arrest, regardless of place within the hospital. This preparedness involves all health care providers within the hospital and includes various aspects of training (see below).

The consequences of increased preparedness for a cardiac arrest within the hospital has recently been highlighted. Thus, it has been shown that a program including widespread education of use of defibrillators with AED-function all over the hospital was associated with an improved survival to discharge after in-hospital cardiac arrest.[29] Furthermore, in agreement with findings in out-of-hospital cardiac arrest,[30] it has been suggested that among patients found in ventricular fibrillation, those who were defibrillated within 3 minutes after collapse have a very high survival (maybe as high as 70%), regardless of where the arrest took place.[31] Thus, the goal for every hospital should be to defibrillate all patients who suffer from ventricular fibrillation within 3 minutes after collapse. This goal can only be achieved by having defibrillators on each ward that are easy to handle and therefore can be used by a large proportion of health care providers.

Technical personnel training includes education and skills development in the recognition of a cardiac arrest, chest compression and ventilation, the use of simple devices such as mouth to mask ventilation and the use of suction devices, how to call for the rescue team, the use of medication and intubation, and the use of automated external defibrillators as well as manual defibrillators.

The appointment of a resuscitation training officer has enhanced the survival rate after in-hospital cardiac arrest.[32] This indicates that organized training of the hospital staff in CPR might improve survival after in-hospital cardiac arrest. In the UK, all public hospitals are obliged to have an appointed Resuscitation Training Officer supervising and organizing CPR-related activities.

In 2003, 60% of hospitals in Sweden had a service assigned to CPR education and other CPR-related activities; the corresponding figure for Finland was 75%.[33] Data from Finland indicate that nurses seem to receive more training than physicians.[33] In the United States, physician training in CPR is not mandatory. Some hospitals in the UK documented an increase in the survival rate of patients resuscitated from VF/VT that was linked to improvements in resuscitation training.

Because rapid defibrillation is of major importance, it would be helpful to have defibrillation performed by first responders.[34,35] With appropriate training, nurses can use an automated external defibrillator (AED) appropriately and can retain the actual skill. Nurses trained in basic life support can often use AED in a simulated cardiac arrest situation, even without prior training.[36] Nonetheless, when not under supervision, they are often reluctant to use the AED and fail to deliver defibrillation prior to arrival of more advanced care providers.[37] There are no specific recommendations for either manual or automated defibrillation in the hospital. What is important is that the shock gets delivered by the fastest mechanism in a given environment.

Skills retention

Skills retention has been shown to be limited.[38] Thus, repetition courses are required. The optimal interval between courses are not known, but an interval of 1 year has been considered to be appropriate. Nonetheless, with respect to defibrillation, skill retention has been reported to be good.[39]

Rescue team

There is no clear definition of how a rescue team should deal with in-hospital cardiac arrest. The three major aspects are quantity (number of persons), quality (competence), and proximity (how soon the rescue team will appear on scene). Local factors will influence the structure of the rescue team. In large university hospitals outside the United States, for example, it is common to have a rescue team consisting of multiple senior physicians. An anesthesiologist, a cardiologist, and an internist may all respond to resuscitation calls. In large training hospitals in the United States it is more common to have the resuscitation care delivered by junior physicians in training. In small hospitals there may be no resuscitation teams. In these instances, there is often an anesthesiologist who, in collaboration with the ward or emergency physician, performs resuscitation.[33] In many hospitals one rescue team may cover the whole hospital, whereas in other hospitals multiple teams may exist. Whereas there is no one correct way to structure the emergency response to in-hospital cardiac arrest, the

program must assure that enough trained and experienced people respond in a timely fashion.

Before the arrival of the advanced rescue team, there must be an organized response on the ward where the event occurs. Policies and procedures should be in place to ensure a rapid local response with quality CPR and early defibrillation prior to arrival of the team.

Despite the presence of a dedicated team working under appropriate protocols, the cardiac arrest response is often chaotic, loud, and inefficient. While most hospitals focus on assuring adequate technical skills of the responders, there is typically little focus on non-technical issues such as communication and overall team performance. Crisis Resource Management (CRM) training is used in other medical settings, such as trauma team response and subspecialty practices, particularly anesthesia.[40–42] CRM focuses on improving interpersonal skills and team building to make medical responses more efficient. Instead of a disorganized response with all team members trying to do the same thing, there is a clear team leader who directs all clinical activities. Every responder has a specific job to perform, knows what that job is, uses checklists to assure accuracy, repeats and confirms all activities with the team leader, and effectively communicates with other team members. Focus on non-technical training of resuscitation teams may be an important way to improve patient care and decrease medical errors.

Ethical issues and outcomes reporting

Multiple comorbidities are linked with poor survival, including cancer,[43] septicemia,[44,45] renal failure,[46,47] and neurological disease.[48,49] The question of whether old age alone predicts mortality is not clear, with some studies supporting this assumption[50,51] and others not doing so.[52,53] Several prediction models for poor survival exist; however, using them on an individual patient to make decisions on withholding care is not widely practiced, since it is difficult to predict individual outcome from aggregate data.

Prearrest DNAR practices differ widely among hospitals. Aggressive resuscitation efforts indicate that CPR is initiated on a high proportion of patients suffering from cardiac arrest. When this occurs, the risk of starting CPR on a patient with a very low chance of survival is higher. A non-aggressive approach assigns DNAR status to more patients and indicates that CPR is started on a relatively low proportion of patients suffering from cardiac arrest, resulting in a greater chance of survival when resuscitation attempts are made. Percent survival of patients suffering from in-hospital cardiac arrest will depend on whether an aggressive or non-aggressive approach is used, and can influence reported quality improvement data as well as research outcomes.

Science

The American Heart Association's National Registry of Cardiopulmonary Resuscitation (NRCPR) is an international quality improvement database of over 75 000 in-hospital cardiac arrests.[1] Persons who experienced an arrest in the NRCPR dataset are typically male (57%) in their mid to late 60s. Over one-third of arrest events occur on medical-cardiac services. Several pre-existing conditions are associated with cardiac arrest. Myocardial infarction, congestive heart failure, respiratory insufficiency, diabetes mellitus, and infection are the most prominent comorbidities. Cardiac arrhythmia, acute respiratory insufficiency, and hypotension are the most common precipitating factors. Nearly half of all arrests occur in the ICU. Only 25% of in-hospital arrest victims had ventricular fibrillation (VF) as the initial pulseless rhythm, despite 86% of patients being either monitored or witnessed at the time of the arrest. This suggests that a delay in rhythm recognition alone may not completely explain the infrequent presence of VF. Forty-four percent of all patients had ROSC, while only 17% survived to hospital discharge. Survival was higher with VF as the presenting rhythm (34%) compared to asystole (10%) and pulseless electrical activity (PEA) (10%). Use of the term "overall survival" to describe outcome may be misleading. The 34% survival rate from VF that occurs in only 25% of arrests is diluted by the 10% survival rate for asystole and PEA that occurs in 66% of arrests. Future descriptions of cardiac arrest outcomes should be based on the initial arrest rhythms, not overall survival from all rhythms combined. Of those patients who died prior to discharge, 63% were made DNAR after ROSC. The average length of stay after an arrest is nearly 2 weeks for survivors and less than 2 days for those who die in the hospital, suggesting that care is being withdrawn very early after an event. Of those who survived to discharge, 86% of patients with a cerebral performance category (CPC) scale of 1 on admission had a CPC scale of 1 at the time of discharge, suggesting that survivors have relatively well-preserved neurological function.

Correct performance of chest compressions and ventilations is associated with a significant survival benefit in both animal and human studies. Abella and colleagues performed quantitative recordings of actual CPR during in-hospital cardiac arrest and found that the quality of CPR was deficient, according to guideline recommendations.[54] Chest compression rates and depth were lower than recommended, ventilation was significantly faster than recommended, and there were prolonged periods of no chest

compression activity at all, resulting in long "no-flow" states. Experience from a single hospital in Sweden indicates that when CPR is started within 1 minute after collapse there is a marked improvement in survival compared to later initiation of CPR.[55] These findings suggest the need for rescuer feedback and more intensive monitoring of the quality of CPR during in-hospital resuscitation.

Postresuscitation care

All patients surviving a cardiac arrest ultimately receive the rest of their care in the hospital. It is the final common denominator for patients who arrest both in and outside the hospital setting. Care delivered and decisions made after ROSC will have a significant impact on outcome. In an era in which scientific, clinical, and regulatory communities demand improved long-term outcomes before recommending and adopting changes in practice, optimization and standardization of postresuscitation care is necessary to ensure that survival is more likely to reflect the intervention being studied rather than the quality and type of care delivered after ROSC. The science defining optimal postresuscitation care is in its infancy, yet is growing rapidly. Therapies such as therapeutic hypothermia and tight blood glucose control have been identified as providing benefit. The challenge faced by hospitals to implement new diagnostic and therapeutic initiatives in these patients is multifaceted. Hospitals must have a person who is responsible for the identification of new science and who is empowered to implement clinical change. Disseminating new scientific information to the end-user at individual hospitals is a formidable task, only to be surpassed by changing behavior. A survey performed in the United States by Abella *et al.* documented that nearly 90% of physician responders had never induced hypothermia in a comatose cardiac arrest survivor 18 months after the publication of two large randomized controlled clinical trials documenting benefit.[56] Literature documenting that change in practice does not parallel change in knowledge is abundant. It is often not until algorithms, standardized protocols, and flow-sheets are developed to help physicians and nurses operationalize the science that extensive changes in behavior occur. This is especially true of low volume clinical occurrences such as survival from cardiac arrest, and where care is often performed by clinicians unfamiliar with evolving postresuscitation science. In many teaching hospitals, cardiac arrest events and postresuscitation therapies are often delivered primarily by physicians at various levels of training, without direct or immediate supervision by a senior physician. Hospitals must begin to move away from delegating the decisions to junior inexperienced doctors in training.

Therapeutic hypothermia

The 2005 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science states that "Unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°C–34°C for 12–24 hours when the initial rhythm was VF. Cooling to 32°C–34°C for 12–24 hours may be considered for unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest from any other rhythm or cardiac arrest in the hospital. The supporting science for therapeutic hypothermia in these populations is discussed in detail elsewhere in this book. This section focuses on issues pertinent to program development and implementation.

A systematic, comprehensive approach to the delivery of therapeutic hypothermia to comatose survivors of cardiac arrest must be implemented to assure optimal support, development, and utilization. It is imperative to gather individual "thought leaders" in resuscitation and have representation from physicians, nurses, administrators, and whatever ancillary services will be needed to provide the therapy. Decisions must be made regarding which units in the hospital will provide the hypothermia. Optimally, all units receiving post-non-traumatic arrest patients should be capable of delivering hypothermia. Decisions to centralize the location of these patients within an intensive care area, however, may decrease the resources needed to initiate and maintain the program. Resuscitation committees need to be armed with as much information as possible to educate those less familiar with evolving postresuscitation practices. Once a hospital-wide decision has been made to provide therapeutic hypothermia, appropriate policies and procedures require development. Inclusion and exclusion criteria can be somewhat subjective and decisions need to be made as to whether or not the therapy will be provided to in-hospital patients as well as those that arrest out of the hospital. Because hypothermia is a relatively new therapy, hospitals are required to develop their own criteria for its implementation and monitoring; however, decisions can be assisted by criteria used in the randomized clinical trials of hypothermia in comatose survivors of cardiac arrest.

Two types of educational programs are helpful before program implementation. Widespread education of all clinical providers is crucial to more rapid acceptance and application of the process. All physician and nursing staff, including doctors in training or house officers who may

be caring for or covering these patients while in the ICU, must be educated. More detailed education on the physiological effects and potential complications of therapeutic hypothermia, as well as instruction on how to deliver the therapy is required for the specific groups of nurses and physicians primarily responsible for care delivery. An understanding of the physiology, and knowing how to expect a typical patient to behave, is helpful in alleviating the stress and uncertainty of providing a new therapy.

There are several mechanisms by which therapeutic hypothermia can be delivered. Cooling can be done externally or internally. Readily available ice packs, iced saline and gastric lavage, and conventional cooling blankets found in most hospitals can be used. Specific equipment is also available for temperature regulation that uses both endovascular and external methods. There is no current recommendation of one type of delivery mechanism over another. Hospitals should consider personnel requirements, ease and accuracy of induction, maintenance and reversal, and patient accessibility when deciding the technique by which hypothermia will be provided.

As with all new therapies, there is much to be learned about the optimal approach to providing care and minimizing complications. There are many specific clinical details that remain suboptimally understood in patients treated with therapeutic hypothermia. This should not deter a hospital from implementing a therapy shown to be of benefit, but should encourage meticulous observation and evaluation of these patients to assure that new clinical information is identified and shared.

Much practical information has been gathered since the implementation of this therapy. Program coordinators need to consider several details in order to develop a successful program. Attempting to reach the target temperature within the shortest amount of time possible is a common goal. Decrease in temperature may be slowed by the presence of overhead lights shining down on the patient, heated air in the ventilator, an elevated ambient room temperature, and by several pieces of electronic equipment in the room each giving off heat. Temperature should be monitored frequently and overshoot of the target temperature should be avoided, since temperatures less than 30°C may cause complications. Local protocols should be developed with specific sets of routine laboratory tests to evaluate for possible complications, such as renal insufficiency, infection, coagulopathy, or pancreatitis. Neurological examination should be documented before the initiation of hypothermia. Modified Rankin and CPC data are needed to document the patient's baseline. The Glasgow Coma Scale and brainstem reflexes should be documented before, during, and after therapy.

Many patients treated with hypothermia are therapeutically paralyzed to decrease shivering and may remain paralyzed throughout the duration of the hypothermia. It is impossible to detect focal or generalized seizure activity in these patients since they cannot move. Since seizure activity is common in postarrest patients who have suffered a global ischemic insult, there is an increasing concern that seizures may be undetected until paralytic agents are discontinued. This has prompted some centers to perform routine electroencephalographic monitoring during the hypothermia or only to use paralytic agents until the target temperature is reached.

Metabolic management

Tight control of blood glucose with insulin lowers hospital mortality in critically ill adults. Although this has not been studied specifically in the cardiac arrest population, there is a strong association between postarrest hyperglycemia and poor neurological outcome. The optimal blood glucose level in these patients has not been determined, but frequent monitoring of glucose, treatment with insulin, and avoidance of hypoglycemia should be part of a comprehensive postresuscitation protocol.

Postresuscitation decision making

The decision to stop resuscitation efforts or to withdraw care after ROSC from cardiac arrest is one that is often made very early after the event and is commonly based more on emotion than on physiology. Data from the NRCPR show that 63% of patients who initially survive an in-hospital cardiac arrest are declared DNAR.[1] With an average hospital length of stay for those who die of 2 days, this documents that the decision to withdraw care is frequently being made very early. Good clinical indicators exist for predicting poor outcome in patients who remain in persistent coma after arrest. They include a lack of papillary reflex at day 3, extensor posturing or worse at day 3, absence of certain-wave in cortical evoked response within 72 hours to 1 week, and the occurrence of status myoclonic seizures (not to be confused with simple myoclonus). The neurological literature supports waiting for a 3-day period to be able more accurately predict neurological outcome on postarrest patients who are not treated with therapeutic hypothermia. Making decisions to withdraw or not provide care prior to this time may be premature. The optimal timeframe for decision making on DNAR status in patients treated with hypothermia is unknown. It remains unclear how quickly the brain is expected to gain near maximal benefit from the hypothermia, and when is it reasonable to assume that no significant

improvement will occur. Although no recommendations are available based on data, it may be reasonable to wait an additional few days beyond the 3-day recommendation when evaluating neurological status in comatose patients treated with mild hypothermia.

The aggressiveness with which an individual hospital withdraws care and withholds future resuscitation attempts has significant bearing on individual and aggregate survival data and can have a tremendous impact on clinical trial data, where survival to discharge after cardiac arrest is an end point.

Summary

The hospital provides a unique setting for pre-, intra-, and postresuscitation care. The burden of prevention and optimal postresuscitation management, in addition to acute resuscitation, poses unique opportunities not recognized in the past. With a focus on patient safety and implementation of medical emergency teams/rapid response systems, prevention of cardiopulmonary arrest and improved outcomes is a reality. For patients who ultimately suffer an arrest, opportunities for improved care delivery come from crisis management training, skilled responders, and optimal performance of both CPR and advanced care delivery. The sequence of events that begins with the ischemic insult from the arrest and the global reperfusion that accompanies return of circulation create a cascade of metabolic activity that can be treated with such therapies as therapeutic mild hypothermia. Hospitals must develop programs that focus specifically on postresuscitation care, and more effort is needed to remain abreast of this rapidly evolving area, so that new advances can be rapidly incorporated into clinical practice. The in-hospital chain of survival needs to be expanded by an additional two links from both a systems and clinical perspective. The first link begins with rapid response systems that prevent clinical deterioration in a significant number of patients, followed by the traditional links of early access in summoning the appropriate clinical team and equipment, early and good quality CPR, early defibrillation by whatever mechanism gets the shock delivered as quickly as possible within individual hospital settings, early advanced life support delivered in a consistent manner by healthcare providers experienced in resuscitation practices, and ending with the final link of optimal postresuscitation care. The clasp that holds this enhanced in-hospital chain of survival together is a comprehensive quality review program that includes mechanisms for the rapid adoption of new science as well as appropriate process and outcomes

review. Perhaps this broader focus will be the key to improving survival for in-hospital cardiac arrest.

Introduction

Cardiopulmonary resuscitation is an invasive medical treatment. Its measures can cause more or less severe complications, which often remain unrevealed unless autopsy is performed.

Performing sufficient chest compressions needs regular thumps with force up to 392 N (40 kp). The human thorax, the ribs, and especially the sternum are not built for such force and will frequently suffer iatrogenic injuries. If the patient's biological age is unknown, the occurrence of some of these injuries cannot be avoided. In the last decades, a number of chest compression devices have been developed to increase cardiac output and to replace the rescuer's hands and his/her manpower. Although some of these devices are already commercially available, there is a general lack of information on their adverse effects in comparison to manual chest compression.

Defibrillation constitutes one of the most invasive resuscitative measures. Complications of defibrillation may affect the patient, the rescuers, and the immediate environment. Although systematic investigations have rarely been conducted, the available evidence will be discussed in the corresponding paragraph.

Time is critical in CPR, and medical personnel as well as lay rescuers generally work under emotional pressure. Moreover, CPR is frequently performed under challenging conditions, such as at night, in uncomfortable weather conditions, environmental dangers, inadequate manpower, noise, in a confined space, and other adverse circumstances, which in particular, are found in the prehospital setting. Therefore, it is understandable that, for example, endotracheal intubation has to be performed under conditions that are considerably worse than in the OR and therefore cause harm more frequently. Meticulous autopsy can find macro- and micro-lesions caused by intubation maneuvers.

This chapter will provide detailed information on typical complications of chest compression (including use of new CPR devices), defibrillation, and airway management.

Complications of chest compressions

Chest compression is a blunt thoracic trauma with defined localization and force. It is reasonable to assume that these complications can be reduced by proper hand position and technique. The following complications are described in the literature, but are too numerous to all be discussed in this chapter: rib and sternal fractures, fractures of clavicles, scapulae, and vertebral column, flail chest, skin trauma, subcutaneous emphysema, pulmonary edema, pulmonary hematoma, pneumothorax, hemothorax, embolization, lung laceration, pneumomediastinum, mediastinitis, cardiac contusion/rupture, pericarditis, liver laceration, and bowel injury.

Precordial thump

A solitary precordial thump is sometimes used in the pulseless victim.[1] The potential to convert the patient from ventricular tachycardia to fibrillation, however, has led most authorities to consider one immediate precordial thump manoever after a monitored cardiac arrest if an electrical defibrillator is not immediately available.

Transient complete atrioventricular block,[2] pleomorphic ventricular tachycardia,[3] induction of re-entrant ventricular tachycardia after supraventricular tachycardia,[4] and a faster ventricular tachycardia rate[5] are conditions that have been described during the treatment of ventricular tachycardia with a chest thump. Thus, monitoring the patient during the chest thump maneuver is recommended.

Manual chest compression

Skeletal injuries

The incidence reported for rib fractures after conventional closed-chest compression in the treatment of cardiac arrest ranges from 13% to 97%; the incidence of sternal fractures ranges from 1% to 43%.[6] In a retrospective review of forensic records of 499 deaths (343 males, 156 females) in patients who had received CPR before death, rib fractures were described in 29% and sternal fractures in 14%.[7] The best method to detect fractures of the thorax is by autopsy that prospectively reveals such fractures. However, only five studies are available that have employed this method.[8–12] These studies report rib fractures in 32% to 60% and sternal fractures in 19% to 43%.

For the very rare situation of CPR with the patient in the prone position, e.g., in the operating room for a vertebral operation, no complications or injuries are described in the literature.[13]

Other complications

Chest wall bruising is among the most common adverse effects of CPR – it is reported for up to 59% of all resuscitated patients.[10] Pulmonary fat emboli can be detected in almost all cardiopulmonary resuscitated patients when special attempts are made to detect this complication.[14,15] Bone marrow emboli are found in 11% to 27%.[8,16–20] The clinical relevance of these findings is undetermined.

Critical internal organ damage can also result from chest compressions. Table 45.1 provides an overview of all those soft-tissue injuries that may worsen outcome and that, according to research, have an apparent incidence of at least 1%. Further, tracheal, esophageal, gastric, renal, and diaphragmatic ruptures, and various internal hemorrhages have been described in case reports.

Chest compressions with chest compression devices

All chest compression assist devices, reported in the literature, have only been studied in adults; moreover, the complication rates have not been studied in a standardized manner. Sternal and/or rib fractures are sometimes reported or excluded by external examination of the

Table 45.1. Incidence of internal organ damage seen after CPR.

Complication	Incidence reported	References
Left ventricular hemorrhage	0 to 8%	11, 16, 17
Pneumothorax	1 to 3.0%	9, 15, 45
Hemothorax	1 to 9%	15, 16, 45
Hepatic laceration/rupture	1 to 4.3%	9, 10, 15
Hemopericarditis	1 to 8%	7, 9, 15, 17, 18
Aortic laceration	0.5 to 1.6%	15, 46
Splenic laceration/rupture	0.3 to 2.6%	9, 15, 16, 28

Modified from ref. 6.
Fig. 45.1. Sternal fragments after ACD-CPR preceded by standard CPR.

thorax, by X-ray, rarely by autopsy, very rarely by special autopsy focusing on skeletal injuries, and never by computed tomography or magnetic resonance imaging.

Active compression–decompression (ACD) CPR

Only one randomized ACD-CPR trial included assessment of skeletal injuries in fatal cases by thorough autopsy.[9] This trial was halted by the local ethics committee because of an unexpectedly high rate of rib and sternal fractures (13/15, 87%, and 14/15, 93%). Earlier studies had suggested that ACD-CPR is associated with rib fractures in 4% to 87% and sternal fractures in 0% to 93%.[21–25]

Another study that specifically addressed skeletal injuries after ACD-CPR alone, as well as after standard CPR followed by ACD-CPR revealed rib fractures in 11/16 and 14/15 patients, respectively, and sternal fractures in 11/16 and 9/15 patients, respectively.[26] This study included cases in which multiple rib and comminuted sternal fractures (Fig. 45.1) were associated with aortic laceration or atrial or ventricular rupture. The authors concluded that sternal fractures with its saw-like fragments might pose a particular threat to intrathoracic organs. The same authors investigated biomechanical aspects of ACD-CPR complications.[27] The shape of the patient's chest seems to have a considerable influence on the way in which forces are transmitted to the thorax.

Accordingly, to date, the frequency of skeletal chest injuries after ACD-CPR cannot be specified with certainty. A Cochrane review from 2002[28] and a combined analysis[29] from eight trials stated that ACD-CPR is as safe as standard CPR.

LUCAS-CPR

LUCAS, Lund University Cardiopulmonary Assist System, is a device for standardized, gas-driven automatic chest compression and decompression up to the physiological level.[30] The first report on 100 consecutive cases of out-of-hospital cardiac arrest treated with LUCAS failed to assess the occurrence of traumatic sequelae.[31]

AutoPulse

Revivant AutoPulse is an automatic, battery-driven, circumferential chest compression device. A study of AutoPulse application in 31 in-hospital cardiac arrests did not disclose adverse effects associated with this device.[32] In an autopsy report of three patients who had been treated with Revivant AutoPulse, the following complications were reported: unusual cutaneous abrasions in all three cases, bilateral confluent paravertebral hemorrhages of the midthoracic spine in one patient with preceding manual CPR, abrasions on one breast in a female patient, non-

displaced bilateral parasternal rib fractures, and upper arm contusions.[33] According to the authors of this study, all of these findings appear to be associated with the CPR device.

Minimal invasive direct cardiac massage (mid-cm)

Only one study exists where the minimal invasive direct cardiac massage device[34] was used in humans;[35] in one out of 25 patients a heart rupture was caused by the device.

Open-chest CPR

Open-chest CPR is a heroic procedure that may improve vital organ perfusion and the outcome of selected patients. Because it is invasive, open-chest CPR places both the patient and the clinician at a significantly greater risk than does external chest compression.

Injury to the chest wall is inevitable during performance of this procedure, and should not be considered a complication. Lacerations of the intercostal or internal mammary arteries are avoidable and, as such, are complications. Hemodynamic control of an injured intercostal artery can be obtained by placing a suture through the next intercostal space lateral to the incision and looping it around the artery and rib. Gaining control of a torn internal mammary artery is often difficult and requires at least initial placement of a hemostat.

Because entry into the chest must be made expeditiously under emergency conditions, pulmonary lacerations are common. Care must be taken not to enter the chest with the knife, but to use scissors that are placed superficially to a protecting finger.

Fracture of the ribs is an avoidable but common complication of open-chest CPR. In cases of non-traumatic cardiac arrest, the operator needs an opening large enough to permit cross-clamping of the aorta and to provide cardiac compression. In older patients, fractures may occur despite minimal opening of the rib space. Care must be taken by the operator not to lacerate the hand or wrist on a jagged bone fragment.[36]

Except in patients who have penetrating trauma to the chest, it is not necessary to incise the pericardium. Some authorities believe that more effective compressions of the myocardium can be performed with an intact pericardium, and the myocardium is protected. Properly performed internal cardiac massage has a pattern of injury similar to that in external cardiac compression.

Blind attempts to place an aortic cross-clamp may result in injury to the mediastinum. It is not necessary to include the whole aorta within the clamp to occlude flow to distal structures significantly. If the aortic cross-clamp is placed too tightly, aortic injury may occur. If the clamp is left in

place for too long, abdominal or retroperitoneal structures may be injured. During spontaneous circulation, cross-clamps should not be left in place for more than 20 minutes in normothermic patients. It is not known whether this also applies to patients in cardiac arrest. The state of emergency of this procedure does not allow adequate time to disinfect the skin before the incision is made. Despite this, the incidence of infection among survivors is low.[36]

Once the chest has been opened, there is significant risk of exposure to aerosolized blood. This occurs more frequently when there is a pulmonary laceration. All personnel should use universal precautions.

Methodology of detecting skeletal injuries

As discussed by Hoke *et al.*, most of the studies reporting on skeletal injuries after CPR cannot be compared to one another,[6] because of essential differences in inclusion and exclusion criteria, protocols, methods of data collection and presentation. Further, evaluation of clinical records, clinical examination, and chest radiographs must be considered inadequate for assessing the incidence of chest fractures. Plain chest radiographs have frequently been used to assess thoracic fractures, especially in studies of active compression–decompression CPR.[23,24,37] Nevertheless, the sensitivity of plain chest radiographs is poor. In a prospective study comparing postmortem findings of X-ray and forensic results in 19 patients after attempted cardiopulmonary resuscitation, no correlation was found between the X-ray and the autopsy findings and it was shown that postmortem autopsy is more accurate in detecting rib and sternum fractures as compared to X-ray.[38] It is possible that computed tomography or magnetic resonance imaging can play a future role in unravelling skeletal injuries and could replace autopsy in this regard.

Differences in gender, age, and location

In a forensic autopsy records report of 499 records of patients who had received CPR before death, rib fractures were found in 29% and sternal fracture in 14%.[7] More females than males sustained rib fractures (37% vs. 26%; $P < 0.05$). There was no significant gender difference for sternal fractures. In addition, the incidence of rib fractures increased with age ($P < 0.001$). While the positive correlation between age and rib fracture incidence is in accordance with another large autopsy study,[9] the latter found no difference in relation to gender.

A study on 27 human corpses showed a significant correlation between sternal fractures and gender ($P=0.008$) and between rib fractures and age ($P=0.008$) after ACD-

CPR was performed on the corpses for 60 seconds.[39] Female corpses were found to have a higher risk for sternal fractures, whereas corpses of older patients had a higher risk for rib fractures. Maximal compression force (measured by a built-in force transducer in the ACD device) was another factor associated with a higher risk for rib and sternal fractures ($P= 0.48$). In 20 of the 27 corpses either the sternum fractured or the ribs fractured parasternally or medioclavicularly. Sternum fractures do not seem to protect against rib fractures and vice versa. The sternum fragments tilted inwards at the time of the fracture, and only moved inwards thereafter.

Chest injuries in children

According to the literature available, rib fractures occurred in 0% to 2.1% of all children in whom CPR was attempted.[40–44] In contrast, sternal fractures have never been reported. All in all, 770 pediatric CPR cases were included in the five aforementioned studies, only three of which exhibited skeletal injuries attributable to CPR. In addition, a few case reports have been published. In a retrospective review of autopsy records for deceased children under 12 years of age who had been given CPR without historical or physical evidence of preceding trauma, 211 children (mean age 19.0 months) met the inclusion criteria.[42] The mean duration of CPR was 45 minutes. Fifteen children (7%) showed at least one injury as a result of CPR, including retroperitoneal hemorrhage ($n=2$), pneumothorax ($n=1$), pulmonary hemorrhage ($n=1$), epicardial hematoma ($n=1$), and gastric perforation ($n=1$). Only one patient was noted to have rib fractures.

Thus, although significant iatrogenic injuries are rare in children who receive CPR, recognizing the possibility of a complication may be critical in the management of children who survive cardiac arrest. Regardless of resuscitation history, physical abuse should be considered whenever traumatic injuries are encountered.

Conclusions

In conclusion, organ injuries after CPR maneuvres must be seen as serious complications. Rib fractures are common adverse effects especially in elderly patients. Sternal fractures are more dangerous than rib fractures as these may cause direct organ injuries in the thorax; sternal fractures may occur more frequently in females. Correct CPR technique is likely to reduce the risk of skeletal injuries.

New CPR methods with CPR assist devices should be evaluated for their pressure pattern and compared with

standard manual chest compressions in regard to skeletal and organ injuries. Chest X-ray is inadequate as a method for investigating the incidence of rib or sternal fractures. Only autopsy with detailed focus on CPR-related injuries provides adequate evidence.

Complications of external defibrillation

Electric defibrillation and cardioversion are irreplaceable as first-line interventions to terminate ventricular fibrillation (VF) and hemodynamically unstable ventricular tachycardias. They are vigorous procedures, however. Currents up to 70 amperes at voltages above 1000 volts are applied to the chest, depending on energy selected, waveform technology, and transthoracic impedance. Such electric shocks would, under different circumstances, be considered a high-tension electrical accident. There are dangers for the person being defibrillated as well as for the person carrying out the procedure and in the immediate environment. The main issues, including burns, skeletal muscle damage, myocardial injury, pacemakers and implantable cardioverter-defibrillators, and hazards for responders are discussed in the following paragraphs.

Complications for the patient

Burns

Skin burns at the site of electrode attachment to the chest are frequent adverse effects of defibrillation and probably the best recognized among health care professionals. Their severity ranges from transient faint erythema to deep serious lesions. Affections of the skin are typically more intense at the edge of the electrode mark, referred to as the "perimeter effect" (Fig. 45.2). It is not established whether manual paddles and self-adhesive pads differ with respect to skin burns. It is known, however, that commercially available self-adhesive pads vary significantly both in their own intrinsic impedance and thermal affection of the skin.[47] In cardioversion sequences, higher cumulative shock energies cause more damage.[48] Evidence suggests that prophylactic use of topical 5 % ibuprofen, but not 0.1% betamethasone, cream reduces pain and inflammation after external cardioversion.[49]

Superficial burns are most probably due to thermal effects at the electrode-skin interface, although electroporation of dermal cells with subsequent local inflammatory reaction may contribute. Basically, heating of the skin results from conversion of electrical to thermal energy. The
Fig. 45.2. Current density distribution under a defibrillation electrode modeled by a finite-element method. This so-called perimeter effect accounts for greater skin affection at the edges of electrodes. (Courtesy of Vessela Krasteva, Sofia, Bulgaria.).

energy converted to heat is linearly related to the resistance of the electrode-skin interface, which comprises the electrode surface, the conduction gel, and the skin itself. Three factors contribute to this resistance and hence influence heating of the skin: electrode contact, paddle force, and hairiness.

The importance of complete paddle contact to the chest is emphasized by both international resuscitation guidelines and defibrillator manufacturers. Indeed, when using hand-held paddles operators should ensure that the paddles are in full contact with the skin. Use of a sufficient amount of an approved conductive gel or paste and gel-pads, respectively, is obligatory. Ultrasound gel or other clinical lubricants are inappropriate, as their conductivity is usually too low. During attachment of self-adhesive pads it must be ensured that no air bubbles are trapped underneath the electrode pads. Such disposable pads must be checked further for their expiration date and for leaks in the hermetic packaging.

Paddle force is another important determinant of resistance of the paddle-skin interface. In adults, increasing paddle force decreases transthoracic impedance (TTI) exponentially. This is largely due to a decrease of the resistance at the paddle-skin interface.[50] Although difficult to control for the operator, an optimal paddle force of 78 N (8 kg) has been suggested for adult patients on the basis of a clinical study.[51]

A hairy chest is another important source of high resistance at the electrode-skin interface. Transthoracic impedance (TTI) is significantly higher in hirsute subjects compared to non-hirsute subjects, both with manual defibrillation paddles and self-adhesive electrode pads.[52,53] This most probably reflects a higher resistance between the electrodes and the skin. In one study, shaving of hirsute patients resulted in a remarkable mean TTI decrease of 35%.[52] Interestingly, even shaving of non-hirsute skin is associated with a significant TTI reduction as well.[53] If the reason was creation of numerous tiny epidermal lesions functioning as low-impedance pathways, these lesions would pose a particular risk for further injury to the skin, because low-impedance pathways are transited by high currents. Therefore, it has been proposed that – if circumstances permit – it may be better to clip hair close to the chest with scissors.

In summary, skin burns are frequent and seem to be unavoidable after multiple defibrillations. The major determinant of heat production is high resistance at the electrode–skin interface. Following common rules for defibrillation as well as manufacturer advice will help to minimize local resistance. No direct evidence exists, however, that these measures actually reduce the extent or intensity of defibrillatory skin burns. Postprocedural anti-inflammatory and analgesic treatment may be necessary.

Skeletal muscle damage

Substantial pectoral muscle necrosis as a result of multiple defibrillations has been demonstrated pathologically.[54,55] Also, elevated serum levels of creatine kinase (CK) are common findings after CPR both in patients with and without electrocardiographic evidence of myocardial infarction. This could reflect skeletal or cardiac cell damage, or both. Although after CPR, cardiac-specific enzymes often increase as well, upper-normal CK levels are seen with and without concurrent elevations of myocardial cell markers, thus indicating skeletal muscle damage. Whereas about 90% of cardiac arrest survivors exhibit serum CK levels > 80 U/l, serum CK-MB concentrations > 10 U/l have been reported in 78%, and elevations of troponin T above $0.1\,\mu g/l$ in 90%.[56,57] Concerns about myocardial injury secondary to defibrillations are discussed later in this chapter.

Three possible causes may account for muscle damage demonstrated: (1) mechanical injury as the result of chest compressions; (2) electroporation or thermal injury caused by defibrillation; and (3) ischemia and accompanying metabolic consequences arising from circulatory arrest. Indeed, increases in serum CK levels correlate positively with both cumulative defibrillation energy administered and the duration of chest compressions during the course of CPR.[56–58] The independent contribution of these interdependent factors to CK release, however, is unknown. Several studies investigated whether electric shocks alone are capable of producing a significant CK release. In summary, total creatine kinase levels above the upper normal limit are seen after approximately 50% of elective direct current transthoracic cardioversions of arrhythmia, whereas troponin levels are largely unaffected. Further, similar to the effect of CPR, the maximum CK rise correlates with the cumulated energy dose administered during therapeutic cardioversion.

In conclusion, evidence of damage to skeletal muscles is common after CPR. Multiple electric countershocks are likely to play a major causative role for this finding and chest compressions may contribute. Patients undergoing prolonged or recurrent resuscitation attempts, including repeated defibrillations, may even be at risk for complications of rhabdomyolysis.

Myocardial injury

Defibrillation and cardioversion are achieved by means of a current flow through the myocardium, which alters the transmembrane potential. Concerns have been expressed

that this life-saving current may at the same time cause an electric injury to the heart. Damage to myocardial cells has been assessed by microscopic and macroscopic examination, and determination of serum levels of myocardial enzymes.

Early histologic studies demonstrated that repetitive defibrillation with high energy doses can cause myocardial damage. In a dog model of VF, defibrillated with a damped sine waveform, an energy dose of 30 J/kg (which corresponded to a peak current of 5.8 A/kg) caused pathologically detectable damage in 50% of cases.[59] Also in a dog model of VF, conduction abnormalities were induced by voltage gradients greater than 64 V/cm for monophasic and 71 V/cm for biphasic shocks ($P<0.005$).[60] In contrast, the intracardiac voltage gradients produced by common commercial monophasic and biphasic defibrillators are substantially lower; in a recent study they did not exceed 33 V/cm, even with 360 J shock energy at very low impedances of $35 \pm 3\ \Omega$.[61] Likewise, the peak current delivered by common defibrillators is substantially lower than current levels previously described as being harmful.[62] These findings are in accordance with earlier reports that had established that the ratio of the voltage/current necessary to cause myocardial damage or dysfunction to the voltage/current that defibrillates the heart (referred to as the safety factor) is about 4 to 10 for monophasic and even greater for biphasic waveforms.[59,60,63]

Another approach for studying myocardial damage is determination of serum levels of cardiac troponins I (cTnI) or T (cTnT). Their release into the bloodstream is specific for cardiac cell death and, since 2000, constitutes the biochemical basis for the diagnosis of myocardial infarction. In approximately 90% of all out-of-hospital cardiac arrest (OOHCA) survivors, cTnT will be elevated.[56] This may reflect: (1) implication of a causal myocardial infarction (MI); (2) ischemic damage due to lack of perfusion during cardiac arrest; (3) mechanical injury of the heart as a result of chest compressions; and (4) electrical injury caused by defibrillation attempts. When measured after elective cardioversion for atrial fibrillation, cTnT levels are not or only minimally elevated above the detection threshold of 0.01 μg/l, indicating no or only minimal myocardial injury.[64] In cardiac arrests, however, the interrelations are far more complex. While it has been established that cTnT is elevated in 80% to 85% of all survivors of OOHCA without evidence of acute MI, the extent to which hypoxia, chest compression, and defibrillation contribute to troponin release from cardiac cells is largely unknown.

Another approach to estimating the impact of defibrillation on myocardial integrity is the study of postshock functional parameters, such as arterial pressure, indices of systolic and diastolic function, or electrocardiographic indices of ischemia. When delivered during sinus rhythm or after short periods of VF in animal models, transthoracic shocks cause only modest and transient myocardial dysfunction and normal function is usually restored within seconds or a few minutes. Experimental data suggest, however, that ischemic hearts, as in cardiac arrests, are more susceptible to detrimental effects of defibrillatory countershocks. In animal models of resuscitation after 7 min of untreated pediatric VF, certain defibrillation protocols resulted in systolic dysfunction that lasted longer than 4 hours and a reduced 24-hour survival with good neurologic outcome.[65,66] In contrast, another animal study of prolonged pediatric VF did not find impaired postresuscitation cardiac function or reduced survival with different defibrillation schemes.[67] In a rat model that simulated cumulative shock energy by delivering one defibrillation with excess energy, a strict relationship between shock energy and both cardio-circulatory impairment and survival time was demonstrated.[68]

In summary, excessive defibrillation energies can cause structural damage to and functional impairment of the heart. In adult resuscitation, however, clinically relevant defibrillation energies are unlikely to result in myocardial injury in addition to that caused by the underlying condition. In infants, transthoracic defibrillation may precipitate cardiac dysfunction under specific circumstances, the extent and impact of which has yet to be demonstrated. With respect to adverse effects, biphasic defibrillation waveforms seem to be safer compared to monophasic impulses.

Pacemakers (PM) and implantable cardioverter-defibrillators (ICD)

Nowadays, an increasing number of patients at high-risk for cardiac arrest are implanted with an ICD or a pacemaker. The safety concerns with regard to these devices are twofold. First, myocardial damage may occur at the site of endocardial insertion of the PM/ICD lead. Second, externally applied electric countershocks may interfere with such a device.

Two mechanisms have been suggested that may result in tissue modifications at the electrode-endocardium interface.[69] First, ICD and PM leads are excellent conductors. Consequently, a considerable proportion of the transthoracic current may travel along the lead producing a detrimentally high current density when entering the heart at the electrode-endocardium interface. Second, a process called capacitive coupling may occur, i.e., the transthoracic current induces an additional current in the intrathoracic lead capable of causing micro-cauterizations to the heart.

Even with the defibrillation paddles attached as far as possible from the pectoral implantation pocket, transient loss of PM capture, sensing failure, and lead dislocation can occur. Postcardioversion ventricular stimulation thresholds in patients with a unipolar PM implanted have been demonstrated to be more than six times the baseline value – associated with a transient loss of capture in 50% of patients.[69] In this study, duration of capture failure ranged from 5 s to 30 minutes (mean approx. 1.5 min). Therefore, immediate external pacing should be attempted in all those PM carriers who exhibit asystole after defibrillation or show electrocardiographic evidence of an exit block of the internal PM.

Finally, the possibility of electromagnetic interference of defibrillation with implanted devices is generally acknowledged. The spectrum of interference ranges from reprogramming and malfunction to total breakdown of the device. After every resuscitation, a functional check of PMs and ICDs by a specialist is mandatory. During and after resuscitation, alterations in the mode of functioning of the PM and the ICD should be considered in interpretation of ECG readings. Furthermore, paddles or pads, for external defibrillation must not be placed on the skin directly over the device. Concrete recommendations for the distance between the hard lump beneath the skin (where the device can be expected) and the external electrodes differ considerably, ranging between > 1 inch (> 2.5 cm) and 6 inches (15 cm).

Hazards for responders

Current advanced life support courses attach great importance to a safe defibrillation procedure.[70] In spite of very few critical incidents reported, the possibility of harm to any of the rescuers involved is evidently taken very seriously. The following paragraph discusses the evidence regarding electric shock to the rescuer and the danger of fire as well as explosions in conjunction with transdermal medication patches.

Electric shock to the rescuer
Considering that a defibrillator discharge delivers several thousand volts to the patient it is not surprising that there are concerns that deleterious electrical injuries may be inflicted on responding medical personnel who are in close contact with the patient or adjacent material while defibrillation is carried out. In fact, numerous minor incidents are documented in the literature. These incidents can be divided in two groups: (1) intentional shocks to subjects without therapeutic indication, thus based on carelessness, ignorance, or intention to harm; and (2) accidental

shocks as complications of regular medical or maintenance procedures.

Intentional shocks
Reports on intentional shocks in the medical literature include suicide attempts, confusion with training devices, a few cases of people who had "fooled around", and finally, one case of a child who played with a defibrillator. One report included a 23-year-old man who self-administered a 200-J defibrillation to his chest.[71] The first postshock ECG recorded showed polymorphic ventricular tachycardia which, after defibrillation, degenerated to VF. The patient eventually died. Two other incidents comprised deliberate transthoracic defibrillator discharges, neither of which resulted in arrhythmia or in long-term disability.[71]

As described, a full-capacity transthoracic discharge may prove fatal. It has long been known that electric shocks applied for cardioversion of tachyarrhythmias can result in VF. A vulnerable phase exists within the cardiac cycle, during which VF can be induced by external electric stimuli. Occasionally, appropriately R-wave-triggered cardioversion shocks also cause VF. Morbid circumstances, such as a structural heart disease, drug abuse, and ischemia, facilitate degeneration of arrhythmias into VF.

Defibrillatory countershocks applied to the head have also been reported. They cause tonic-clonic seizures, altered vigilance, amnesia, confusion, dissociative symptoms, changes in affect, paresthesias, local burns, and pain. This is in accordance with observations made after electroconvulsive therapy (ECT), a therapeutic option in severe psychiatric disorders that deliberately exposes the patient's head to electric shocks. But ECT impulses and defibrillation can only be compared in a limited manner, because of substantial differences in electrical shock parameters. Nevertheless, in the three cases of "cranial defibrillation" cited above, no long-term complications have been noted apart from memory loss for the event itself. Restriction of accessibility of defibrillators for suicidal patients, persons who behave irrationally, and, obviously, children is indicated.

Accidental shocks
Accidental electric shocks to medical personnel may occur during standard procedures, such as resuscitation attempts or device maintenance. They are either due to neglect of safety precautions by the operator or failure of or damage to the defibrillator. Gibbs *et al.* reported 8 incidents observed in King County, WA, USA, between 1979 and 1988 along with 13 incidents that were reported to the Food and Drug Administration in the USA within a 45-month period between 1984 and 1987.[72] Of these 21 episodes, 3 were

caused by equipment failure while 17 were caused by improper handling and neglected safety precautions, respectively; the reason for the remaining episode could not be determined. Based on the records of the Emergency Medical Services in King County, where paramedics had treated more than 3000 cardiac arrest patients at that time, the authors estimated the incidence of electrical shocks to ambulance personnel at approximately 1 injury per 1700 shocks. In most cases, the physical consequences of such accidental shocks are minor. Short-term discomfort and local tingling have been described. More serious sequelae included burns and one case of hospital admission for frequent premature ventricular contractions. To the best of our knowledge, there are no case reports of death or long-term impairment in personnel after suffering an electric shock during defibrillation or cardioversion of a patient. Likewise, we are not aware that such an accidental shock to bystanders has ever resulted in a critical medical condition or even cardiac arrest. It is a popular but erroneous belief that a current always travels the path of least resistance. Unless there is arcing of electricity from the electrodes, the majority of the total current produced by the defibrillator will travel through the chest. The current to which a bystander may be exposed can only be a fraction of the total current, being indirectly proportional to the resistance of the bodies, the bystander's shoes, the floor and the bed. It has yet to be investigated whether such shunt currents are at all capable of reaching the fibrillation threshold and thus inducing VF. The safety precautions advocated by the medical authorities and manufacturers to prevent electrical accidents include standard device maintenance procedures, avoidance of excessive amounts of conduction gel during resuscitation (and preferential use of gel pads), giving announcements aloud, checking that everybody stands clear before defibrillator discharge, and ensuring that manual paddles are placed only on either the patient's chest or in the defibrillator pockets. Although the actual risk of being harmed by shunt currents during defibrillation is very low it seems reasonable to follow these rules.

Danger of fire

Defibrillation may set the patient, rescuers, the bed, and medical equipment on fire. Severe burns, considerable material damage, and the exigency of ward evacuation have been described repeatedly. Such fires are no mysteries of resuscitation; circumstances that may culminate in this hazardous complication are well known and precautions for its prevention are available. Three prerequisites must be fulfilled to ignite a fire by defibrillation: (1) an oxygen-enriched atmosphere must exist in the vicinity of the defibrillator electrodes; (2) an electric spark is needed

for ignition; and (3) an agent that is combustible must be present. If any of these three "ingredients" is absent, a fire is very unlikely.

1. An oxygen-enriched atmosphere (OEA) appears to be the basis for ignition. Ventilation bags with an oxygen-flow of $\geq 10\,l/min$ put next to the patient's head increase the oxygen concentration of the ambient air at several points around the head and chest of the patient.[73] The same finding applies to mechanical ventilator tubes when they are disconnected from the tracheal tube, left close to the patient, and continue to deliver oxygen. Also, oxygen masks left on the patient's face during defibrillation are sufficient to establish an OEA – probably by leakage of oxygen under the edges of the mask.[74] Evidence suggests that keeping the ventilation devices 1 m off the patient's head is safe. Clearly, a mechanical ventilator that is left connected to a tracheal tube poses no threat. It is a matter of controversy, however, whether a manual ventilation bag that remains connected to a tracheal airway with oxygen leaking from the overflow valve is safe or not. Since increased ambient oxygen concentrations have been demonstrated in a corresponding manikin model, it appears prudent to consider this condition as dangerous as well.[75] The highest oxygen concentration on the body surface is usually measured in the axilla. Indeed, oxygen, being slightly denser than room air, may accumulate in swales and cavities as, for instance, those provided by crumpled sheets or clothing.

2. An electric arc or spark is essential to set combustible material on fire by defibrillation. Sparks are more likely if resistance of the electrode–skin junction is high. This condition occurs when electrode paddles or pads are not in proper contact with the chest across their entire surface, when inadequate conductive gel is used, or when adhesive electrode pads are dried out. Case reports have also suggested that too much gel (smeared across the chest) and ECG electrodes next to the defibrillator electrodes may have contributed to fire incidents in the past.

3. Oxygen itself is not flammable. To feed a fire it needs an agent that is combustible. Some agents present during resuscitation are particularly prone to be ignited by a spark in an oxygen-enriched atmosphere. These include fine body hair, surface nap fibres found on most fabrics, dust, and others. Once one of these easily flammable materials has been ignited, other adjacent matter may catch fire. Often, the flame flashes instantaneously over the surface of the bed or patient in a phenomenon referred to as "surface-fibre flame propagation."[76] Spreading of the fire front towards the oxygen source is common, and damage of devices such as the mechanical ventilator have been described.

Table 45.2. Safeguards to minimize the risk of fire during defibrillation

1. *Prevention of an oxygen-enriched atmosphere*
   Always connect an airway adjunct to oxygen supplies properly.
   Before defibrillation, leave a mechanical ventilator tube properly connected to the tracheal airway, but remove manual ventilation bags and oxygen masks as far away from the patient as practical (at least 1 m).
   During resuscitation never leave an open oxygen source next to the patient.

2. *Prevention of sparks*
   Avoid electrode placement over an irregular chest surface. If contact gaps, e.g., caused by depressed intercostal spaces, are inevitable, consider anterior-posterior electrode position.
   Do not place paddles or pads over or close to ECG wires or ECG electrodes.
   Shave or, if time permits, clip excessive chest hair under the area of electrode contact.
   (a) Use of manual paddles:
       Use an appropriate amount of conductive gel. Make sure the gel is approved for defibrillation. Consider gel-pads as a substitute for jelly.
       Apply firm and even paddle force according to the guidelines. Make sure the whole paddle surface is in contact with the skin.
   (b) Use of self-adhesive pads:
       Check date of expiration and integrity of the pad packaging before application.
       When attaching the pads to the chest wall, make sure that they are not folded, air bubbles are not trapped underneath, and adherence to the skin is complete.
       Remember to change dried-out pads during long-term or repetitive resuscitation according to manufacturer's advice.

3. *Removal of flammable material*
   If feasible, move gowns, patient's clothing, bedding, drapes, curtains, etc. from the resuscitation area.

In conclusion, fires ignited by defibrillation are not rare, but adherence to a few simple rules can prevent this potentially devastating complication (Table 45.2).

Danger of explosions

In the past, attempted defibrillation through nitroglycerin (glyceryl trinitrate) patches has occasionally resulted in "explosions" including arcing, a loud noise, and smoke. This was first interpreted as an actual explosion of the pharmacologic agent. In contrast, further investigations concluded that this phenomenon only occurred in medication patches containing metal foil or mesh, and that it appeared to be due to a voltage breakdown resulting from the high resistance of such patches.[77–79] This voltage-breakdown follows the same principles as were discussed above in conjunction with burns and may be accompanied by an arc between the defibrillator electrode and the metal foil in the patch. As a consequence, perforation of the patch is common. Modern transdermal medication patches no longer contain a metal foil. Nonetheless, as such patches may increase the resistance at the electrode–skin interface, with the subsequent risk of sparks, burns, and dissipation of defibrillation energy as discussed above, it is reasonable to advise defibrillating personnel not to place defibrillator paddles or pads over any kind of medication patches. Patches should be removed.

Conclusions

Most patients who undergo multiple defibrillation attempts will develop at least first-degree burns at the site of electrode attachment. Higher cumulative energy will cause more severe burns. Repetitive countershocks may be accompanied by a considerable degree of skeletal muscle decomposition, including the risk of rhabdomyolysis. At least in adults, clinically relevant postresuscitative impairment of myocardial function so far has not conclusively been shown to be attributable to defibrillation. In pacemaker or ICD carriers, medical personnel must be aware that defibrillation can result in temporary or permanent malfunction or breakdown of the device. Minor electric shocks may be inflicted to rescue personnel during defibrillation of a patient. No case of long-term impairment or lethal outcome of such accidental shocks has been reported in the medical literature, however. In contrast, non-therapeutic full capacity transthoracic shocks can be fatal. Defibrillation can ignite a fire at the bedside if an oxygen-enriched atmosphere is present; preventive measures are available. Safety precautions for defibrillation are discussed above.

Complications of artificial respiration

Universal complications of artificial respiration

Injuries associated with reclination of the cervical spine
To keep the airway patent and protected is one of the first steps in resuscitation of collapsed patients.

The patency of the airway can be maintained by chin lift (performed with one hand at the side of the patient) and jaw thrust (Esmarch maneuver performed with both hands above the patient) and additional head tilt, with or without the assistance of airway device, for example, oropharyngeal or nasopharyngeal airway devices.

Airway management can be particularly complex when there are facial bone fractures, head injuries, and cervical spine instability.[80]

Whereas results of some authors indicate that the chin lift technique provides the most consistently adequate airway,[81,82] other authors stated that the jaw thrust maneuver is more effective in improving airway patency and ventilation, especially in children.[83]

During head tilt and the assistance for intubation, the patient's neck is put in an extreme reclination and maximal straightening, which leads to a high tension load on the cervical column. Typical complications are intimal lesions in the vessels[84] and retropharyngeal hemorrhage.

When the maneuvres are conducted with high force and velocity, the risk is high for injury to the cervical spine itself. Elderly people have a higher risk for such osseous lesions, because of degenerative and osteoporotic alterations. Spinal cord injury and dislocation of the cervical spine may occur, especially in patients with preexisting trauma.

Pneumoperitoneum

Mechanical ventilation and cardiopulmonary resuscitation can be specific causes of non-surgical pneumoperitoneum. Pneumothorax has also been associated with pneumoperitoneum. A direct passage through pleural and diaphragmatic defects and a passage via the mediastinum along perivascular connective tissue or major diaphragmatic portals to the retroperitoneum and finally to the peritoneum are considered as mechanisms. The management of pneumoperitoneum of suspected thoracic etiology can be conservative when there are no peritoneal signs or a suspicious ruptured viscus.[85]

Regurgitation and aspiration

The risk of gastric regurgitation and subsequent pulmonary aspiration is a recognized complication of cardiac arrest – a risk, that may be further increased by the resuscitative procedure itself. A study comparing bag valve mask (BVM) and laryngeal mask airway (LMA) confirmed that when an LMA is used as a first line airway device, regurgitation is relatively uncommon.[86]

Despite orotracheal intubation, aspiration around the tracheal tube may be a complication provoked by frequent swallowing movements.[87]

Artificial respiration without devices: gastric distension and rupture

Air insufflation in the stomach is a frequent complication of mouth-to-mouth ventilation promoted in the case of airway obstruction. The gastric distension interferes with ventilation by elevating the diaphragm, resulting in a decreased lung volume. Constant cricoid pressure – the Sellick maneuver – during artificial breathing could prevent gastric distension in these instances and should be recommended.[88] Rupture of the stomach is a rare complication of cardiopulmonary resuscitation. An incidence of 0.1% has been reported in the literature.[69] Between 1970 and 2000 the number of cases referred in the literature did not exceed 30.[90]

The majority of reported cases have been associated with difficulty in airway management or esophageal intubation (Fig. 45.3).[91]

In an experimental study design, the mean rupture pressure of the human stomach was 73 +/− 13 mmHg (9.7 +/− 1.7 kPa) and the mean rupture volume was 2670 +/− 410 ml. A viscoelastic model can be used for representing the relations between pressure and volume as well as pressure and time. The site of main ruptures coincides with mesenteric insertion at the lesser gastric curvature. The effusion of gastric contents into the lesser omentum and the mediastinum may be responsible for an occasional lack of abdominal symptoms.[92]

Artificial respiration with devices

Tracheal intubation
Securing the airway with an endotracheal tube is the gold standard, but excellent success in emergency airway management depends on initial training, retraining, and actual frequency of a given procedure in routine.[93]

Intubation may result in further injury of oral and/or cervical soft tissue by mechanical damage during the manipulations, especially in a sequence of multiple attempts.[94]

Undesirable incidents or complications are seen in about 20% of prehospital emergency airway management procedures. The most common complications ($n=201$)

are: more than one attempt of intubation (14.4%), vomiting and/or aspiration (6.8%), esophageal intubation (3.2%), and mucosal injuries (1.7%).[95]

Multiple endotracheal intubation attempts are associated with significant complications, offer limited advantage over bag valve mask, and may possibly affect outcome. Indications for field intubations may require review, especially in rural pediatric trauma. In the field, more attempts of intubation were necessary compared to planned intubation in operation rooms. Airway complications and multiple intubations were associated with transport delay, lower GCS, longer hospital stay, and lower discharge GCS, but were independent of injury severity score, sex, age, and survival.[96]

In elective intubation, the teeth most likely to be injured are the upper incisors. In most cases dental injury is not associated with a pre-event prediction of difficult intubation.[97] Compared to metal laryngoscopes plastic blades do not fracture any dental model materials; therefore, plastic laryngoscope blades are less likely to cause dental fracture compared with metal blades.[98]

Chewing on an endotracheal tube may be another cause of tooth damage.[99] Such factors must be taken into account in cases of claiming iatrogenic damage.

Tapia's syndrome (paralysis of the hypoglossal and recurrent laryngeal nerves) is due to extracranial involvement of the hypoglossal nerve and the recurrent laryngeal branch of the vagal nerve and may be a complication of intubation.[100] Use of more than one tube, a narrow laryngeal space, and accidental flexion of the neck contribute to a bilateral recurrent paralysis of the laryngeal nerve.[101]

Although tracheal rupture is a rare complication of endotracheal intubation,[102] if it does occur, the mortality is 75%[103]. Tracheal rupture leads to pneumothorax and emphysema of subcutaneous tissue and infections. Lesions from intubation are always located in the membraneous part and follow the longitudinal axis of the trachea.[104] Even the hypopharyngeal tissue can be perforated during intubation.[105]

Esophageal intubation

Cardiac arrest during emergency tracheal intubation is a relatively common problem. Airway-related complications play a prominent role in these cases. Out of 3035 critically ill patients suffering from cardiopulmonary, traumatic, septic, metabolic, or neurological-based deterioration and requiring emergency airway management, 60 suffered from cardiac arrest. Esophageal intubation was a frequent complication ($n = 38$; 63%), often leading to hypoxemia (97%) and regurgitation (67%). Immediate access to advanced airway devices and endotracheal tube-verifying

Fig. 45.3. Intestinal insufflation after esophageal intubation.

devices appears to have a significant impact on the incidence of hypoxemia-driven cardiac arrest.[106]

Nasotracheal and nasopharyngeal airway

Complications such as hemorrhage occur more frequently with the nasotracheal than with the orotracheal route.[107] On the other hand, the orotracheal intubation route was significantly associated with a higher frequency of aspiration compared with nasotracheal intubation in children. These results suggest that the nasotracheal intubation route is recommended as the first choice for reducing this potential clinical complication.[87]

Blind nasopharyngeal airway insertion may result in lethal iatrogenic injury when used in a head-injured patient. Even an intracranial insertion of a nasopharyngeal airway during resuscitation after trauma has been reported. Oropharyngeal airways may be used to assist with ventilation.[108]

In patients with lesions of the cervical spine, direct laryngoscopy for endotracheal intubation entails the risk of injuring the spinal cord. In an attempt to avoid this complication, flexible fiberoptic nasal intubation can be used.[109]

Alternative airway devices

Alternative airway devices have been developed, especially for emergency care systems when the use of endotracheal intubation by prehospital care personnel is restricted by policy or statute, or as a second line airway device. These alternative airway devices include Laryngeal Mask Airway (LMA), the Esophageal Obturator Airway (EOA) and Esophageal Gastric Tube Airway (EGTA), the

Pharyngeotracheal Lumen Airway (PTL), and the Esophageal-Tracheal Combitube (ETC). The EGTA adds a Levine tube to the EOA to relieve gastric pressure.

Ventilation and oxygenation can, in some circumstances, be achieved equally well with the EOA/EGTA device or with endotracheal intubation. Alternative airway devices can be inadequate and the complication rate is relatively high. The PTL and the ETC seem to provide adequate ventilation and oxygenation with few complications.[110]

Laboratory and clinical evidence supports the important role of alternative airway devices to mask ventilation and endotracheal intubation in the chain of survival. In particular, the laryngeal mask airway (LMA) and ETC proved to be effective alternatives in providing oxygenation and ventilation to the patient in cardiac arrest.[111]

In a comparative study of patients in cardiopulmonary arrest with ventricular fibrillation, endotracheal tube airway and EGTA were compared. Complication rates and success of intubation were similar in the two groups, although only training time was longer for endotracheal intubation.[112]

The esophageal–tracheal Combitube (ETC) is a ventilatory device consisting of a twin lumen tube with proximal and distal inflatable cuffs. The major benefit of the Combitube is that its design and function allow for ventilation through non-laryngoscope-assisted insertion into either the trachea or esophagus.[113]

Although visualized endotracheal intubation remains the preferred method of airway control, the ETC may be an effective prehospital airway device as both a backup to the endotracheal tube and a primary airway. Although the ETC does not require visualization with a laryngoscope, comprehensive training and continuing education are key factors in maintaining skill retention.[114]

Complications of ETC include subcutaneous emphysema, pneumomediastinum, and pneumoperitoneum. In a cadaver study, a protrusion of the anterior wall of the esophagus and distension resulting from inflation of the distal cuff was found, which could lead to esophageal injuries.[115,116]

In another study[118], the serious or potentially lethal complication rate was 3.3 times more common with the use of the EOA/EGTA than with the tracheal tube.

In a direct comparison of LMA, ETC, and the tracheal tube, the use of the tracheal tube by medical students was difficult and the skills acquired deteriorated significantly over time. The LMA, the LT and the ETC seemed to have an advantage over the tracheal tube insofar as the techniques were more easily learned and the skills better retained. For the LMA and the ETC, the authors recommended that

these alternative devices be included in the medical school curriculum for airway management.[118]

Insufflation of the stomach with air can be a complication of face mask ventilation in the case of airway obstruction. Although the laryngeal mask airway (LMA) has proven of value in airway resuscitation, it has two major failings: a relatively low seal pressure, and lack of access to the alimentary tract. These problems led to the development of the LMA-ProSeal, which permits ventilation with higher airway pressures.[119] The placement of the ProSeal laryngeal mask airway is said to be significantly easier than for the laryngeal mask airway.[120]

Cricothyrotomy and tracheotomy

Percutaneous transtracheal ventilation has proven useful in emergency airway management. Its speed and ease of performance are offset by the need for specialized equipment to accomplish it.[121] There is a tendency toward carbon dioxide retention and poor alveolar washout. The most common complication is subcutaneous emphysema caused by incorrect placement of the catheter.[122]

Infections are a rare complication of percutaneous transtracheal ventilation. In a reported case, the contamination of the deep neck spaces facilitated by pressure dissection of the fascial planes led to cervical osteomyelitis.[123]

Tracheotomy and coniotomy are procedures that cause frequent early and later complications; therefore, there must be a rigorous indication that they are necessary. If emergency airway access is needed and translaryngeal intubation is not possible, a cricothyroidotomy should be considered.[124] Careful management and expert nursing support can prevent many later complications.

"Minimally invasive" cricothyroidotomy devices are now available for the professional health care provider who is not proficient or comfortable with performing an emergency surgical tracheotomy or cricothyroidotomy.[111]

The main indication for cricothyroidotomy is the inability to establish an airway by intubation, usually in a situation of possible neck injury or severe facial trauma. The use of emergency cricothyroidotomy is supported in situations in which intubation is not successful or thought not to be safe. Tracheostomy subsequent to emergency cricothyroidotomy does not necessarily reduce airway-related morbidity in these patients.[125]

Conclusions

Ventilation with the objective of oxygenating the blood is a decisive step in resuscitation. For this purpose the airway must be kept patent and protected. First, the indication for

artificial airway management must be examined carefully. Depending on preexisting conditions like head and cervical spine injuries, airway management can be particularly complex.

Any action taken – even mouth-to-mouth resuscitation – is subject to more or fewer complications, some of them life-threatening. The rescuer should be aware of these hazards and minimize their frequency by continuing education and comprehensive training. Concomitantly, refraining from indicated airway management and artificial ventilation leads to a lethal outcome in every patient.

New advanced airway devices can be helpful and are increasingly included in the medical staff training for airway management. Professional skills have to be achieved and sustained: practice makes perfect.

Bringing it all together: state-of-the-art therapy for cardiac arrest

Max Harry Weil and Wanchun Tang

Weil Institute of Critical Care Medicine, Rancho Mirage, CA, USA

Introduction

The history of CPR is in part documented in the Old Testament,[1] but the science of CPR is but a half century old and is still emerging from its infancy.[2] Accordingly, it is not unexpected and certainly not shameful that as the science of resuscitation goes forward, we must sometimes retreat as often as we advance. Yet, that is indeed progress and inevitably the path that is characteristic of meaningful achievements in science and medicine.

Airway techniques and devices

One size does not fit all[3]

The vast majority of sudden deaths in children and, indeed, in victims under the age of 40 years are attributable to failure of ventilation. Accordingly, either mechanical obstruction by foreign body, laryngospasm, or laryngeal edema, or bronchoconstriction, constrains air exchange. Neuromuscular or skeletal injury, including intrathoracic crises such as pneumothorax, may account for death, though typically *not* sudden death. It is in these settings that the priority is establishment and maintenance of a patent airway and external ventilation. Since a majority of the foreign bodies that are swallowed by children and adults lodge in the posterior pharynx, the rescuer is the person best prepared to remove these promptly. Hence, the traditional (A) of the ABC survives, especially for children and young adults and in settings of witnessed cardiac arrest when respiratory distress with paradoxical chest and abdominal movements and especially stridor precedes loss of consciousness.

There has been an appropriate re-examination of the role of routine endotracheal intubation during CPR, whether in the field or in the hospital. For practical purposes, endotracheal intubation interrupts chest compression. The predominance of evidence now favors clearance of the airway, but coincident with starting chest compression. Even among professional rescuers, there is an unduly high incidence of initially failed intubation and potentially fatal esophageal intubation. There is trauma to the airway with bleeding after emergency intubations out-of-hospital in as many as 30% of attempted intubations. Routine endotracheal intubation during CPR is therefore now disadvised. The alternative is that of a more reliable and less traumatic method of airway control, namely the use of a laryngeal mask airway (LMA). The LMA may be inserted rapidly and securely by a minimally trained professional rescuer with initial benefits comparable to those of endotracheal tubes.[4]

Drug administration

The routine of establishing a route by which resuscitative drugs may be delivered into the central circulation was prompted, in part, by the priority and essentially universal use of epinephrine, atropine, sodium bicarbonate, calcium gluconate or chloride, and lidocaine beginning in the 1960s. Intracardiac injection lost favor because it had questionable effectiveness and a risk of serious injury. Endotracheal administration survived as an alternative. Yet none of these drugs nor any routine pharmaceutical intervention can now be regarded as of proven benefit, even treatment with epinephrine. This is more directly

addressed below. Accordingly, the assumption that there is a high priority for establishment of a route for drug administration routinely *during* CPR is now not sustained. Nevertheless, there are major exceptions. Intravenous access is required for volume repletion after volume depletion and especially exsanguinations, for administration of specific antidotes to drug intoxication, and for emergency management of major electrolyte or endocrine abnormalities, especially hyperkalemia.

Ready access to the central circulation may be gained through the internal jugular or subclavian veins. Although the supraclavicular approach to the jugular or the subclavian vein has been utilized during CPR, this is inevitably a challenging procedure during chest compression. Femoral vein cannulation may be accomplished without interruption of CPR, but the site is less predictable. Evidence favoring endobronchial administration of drugs is quite controversial. As stated above, the evidence favoring its use is not persuasive. Absorption is erratic and drugs accumulate such that effects are of unpredictable onset and duration. This route would best be viewed as a last resort in instances in which venous access for specific indications becomes a priority.

A new development has been intraosseous access to the central circulation. Employed initially with high success, in children, the technique has been expanded for use in adults. Commercial kits are now available. Ease of insertion by trained operators, usually into the tibia, and confirmation of appropriate placement provides a highly effective option for reliable and minimally invasive access to the central circulation.[5]

Ventilation

Methods by which pulmonary gas exchange is restored by artificial ventilation represent the very foundation of resuscitation medicine. Yet objective evidence of its life-saving value during routine CPR after sudden death has greatly diminished. Most important, delays in instituting or maintaining chest compression for external ventilation have been shown to have adverse effects on outcomes. There is persuasive physiological rationale and experimental confirmation that in settings of cardiac arrest due to sudden death and therefore in the absence of asphyxia, chest compressions without ventilation do not compromise outcomes. To the contrary, positive pressure breathing, whether by mouth-to-mouth, mouth-to-nose, valved bag and mask, or mechanical ventilators increases intrathoracic pressure and thereby impedes cardiac filling

in close relationship to the tidal volumes and the rates at which breaths are delivered. Accordingly, the greater the tidal volumes and the higher the frequency, the less is the cardiac output generated by chest compression. Hyperventilation resulting in extremes of hypocapnia also may compromise the success of resuscitation.[6] There is some optimism that these adversities may be mitigated by use of the impedance threshold valve. Greatly reduced pulmonary blood flow requires greatly reduced minute volumes for adequate alveolar ventilation. Hence, as little as 300 mL of tidal volume may be adequate for the average adult patient when cardiac output is likely to be less than 20% of normal during CPR. Whether hyperventilation-induced hypocapnia and specifically the marked reduction in arterial PCO_2 is itself detrimental has not as yet been secured.

The demotion of ventilations as a priority intervention, however, does not apply to asphyxial cardiac arrest due to drowning or airway obstruction or to pediatric and neonatal resuscitation. Whereas there is no secure proof that increasing the inspired oxygen concentrations delivered into or near the airway improves outcomes, there is sufficient rationale and no adverse effects have been identified.

Public access defibrillation

The enthusiasm for early use of automated external defibrillators (AEDs) was understandably ignited by remarkably successful experiences in Rochester, Minnesota, especially by police first responders; in the Las Vegas casinos; in the Chicago airports, in part by untrained rescuers; and by Basic Life Support/AED trained cabin attendants in flight.[7] The ultimate life-saving benefits have been less impressive, however, for at least three reasons. First, there is persuasive evidence of benefit in public settings, but the preponderance of cardiac arrests occur in the home. Second, there is a remarkable decrease in the incidence of sudden death presenting as ventricular fibrillation (VF) both in- and out-of-hospital. The overall incidence has decreased below 50%. Third, it is now apparent that the non-professional rescuer's initial resuscitation effort may have been distracted by prioritizing defibrillation therefore engendering delays in initiating and maintaining uninterrupted chest compression.

Accordingly, chest compression has once again become the primary and initial intervention for both lay and professional rescuers during out-of-hospital CPR, except perhaps for witnessed sudden death during the initial 3 to 5 minutes and asphyxial cardiac arrest.

Sequencing CPR

There is much merit in the proposal by Weisfeldt and Becker[8] to identify three time-sensitive phases of resuscitation after cardiac arrest. Nonetheless, these apply primarily to sudden death of cardiac cause, in contrast to either cardiac arrest in settings of asphyxia or exsanguination. The first is the electrical phase which the authors estimate to be 4 minutes. It is the phase during which electrical conversion takes precedence. The second phase extends from 4 to 10 minutes and this is the time window for restoring blood flow that currently is performed almost entirely with precordial compression or, in uncommon instances of chest surgery or trauma to the thorax, open chest direct cardiac compression. The third and final phase is the metabolic phase in which there is myocardial (and cerebral) ischemic injury with progression to cell death. The heart itself loses compliance and there is evidence of progression to a stone heart. As highlighted by Cobb,[9] chest compression with effort to restore circulation promptly continues to take the lead as the *initial* intervention in all instances of sudden death, except for opening of the airway and restoring breathing in settings of asphyxial cardiac arrest, in addition to precordial compression.

Prevention

Sudden cardiac death is epidemic, and the predominant cause of cardiac arrest in industrialized nations is cardiovascular disease, specifically atherosclerosis. A remarkable 70% of all deaths in the United States are now attributed to coronary or cerebral vascular diseases which terminate in myocardial infarction or stroke.

Prevention of sudden death therefore appropriately focuses on prevention of identifiable risk factors. Though family history may in part account for as many as 50% of fatal atherosclerotic vascular events, evidence favors lifestyle interventions and, when that alone is of limited effectiveness, appropriate pharmacological interventions.

It is likely that understanding of a "metabolic syndrome"[10] has been both a conceptual and a pragmatic advance. The hallmarks include a combination of abdominal obesity, hypertension, hypertriglyceridemia, fasting hyperglycemia, and a disproportionately higher LDL cholesterol and a lower HDL cholesterol. Lifestyle interventions include diet, exercise, and cessation of smoking. Pharmacological interventions include control of hypertension, hyperglycemia, and hyperlipidemia and, in some instances, the administration of antiplatelet agents.

Relatively rare causes of sudden death, especially in children and younger adults, are genetic causes of heart disease. These are now better identified by genotyping[11] and include hypertrophic (subaortic, septal) cardiomyopathies, long QT syndromes, Brugada syndrome, so-called catecholaminogenic polymorphic ventricular tachycardia and arrhythmogenic right ventricular dysplasia. Syncope is an important warning sign.

Perhaps the largest cause of cardiac death is that of end-stage heart failure when ejection fractions decline to less than 30%. Both survivors of cardiac arrest and individuals who are identifiably at high risk of sudden death are candidates for internally implanted defibrillators and this has proven to be a major advance for prolonging survival in such patients.

Vasopressor agents and sodium bicarbonate

Perhaps no two subjects bearing on CPR have been debated more vigorously and, from our vantage point, with greater emotional fervor than the use of vasopressor agents and sodium bicarbonate. Epinephrine has been the singularly most prominent resuscitative drug for more than a century and for good reason. It improves the success of initial resuscitation with the likelihood of restoring spontaneous circulation. In experimental animals, it has been shown to increase survival, but there is no secure evidence of survival benefit in human patients. Unfortunately, the same applies to vasopressins. Theoretically, vasopressin has advantages over epinephrine in that it may diminish the severity of postresuscitation myocardial dysfunction, especially in patients with ischemic heart disease, in whom beta adrenergic blockade has reduced the risk of fatal ischemic episodes. There is experimental evidence of protection by the administration of a beta adrenergic blocking agent during CPR. Hence, there has been interest in alternative non-adrenergic vasoconstrictor drugs, including angiotensin II, endothelin for which no secure data of benefit exist, and arginine vasopressin. At the time of this writing, vasopressin has advantages over epinephrine, but there is no secure proof that any vasopressor drug improves long-term outcomes.

With respect to bicarbonate or other buffer agents, there is no persuasive evidence of improved outcomes but instead the potential of serious adverse effects.

Drug management of arrhythmias

Two dicta emerge. The first is that the routine administration of any antiarrhythmic drug during CPR has not been

proven to increase long-term survival. The second is that almost all antiarrhythmic drugs are also proarrhythmic. Of all agents currently available, amiodarone remains the best option for drug management of recurrent ventricular tachycardia and ventricular fibrillation other than those due to electrolyte abnormalities. Admittedly, no survival benefit beyond hospital discharge has been demonstrated. There is now no secure evidence favoring the administration of lidocaine, bretylium, and procainamide. Administration of atropine, though still widely practiced for management of bradyarrhythmias or agonal rhythms, also has no proven survival benefit. Accordingly, present data prompt us to conclude that antiarrhythmic agents, like other routine pharmacological interventions, have so far failed to improve outcomes of sudden death. Moreover, these drugs unfortunately have the potential for serious adverse effects.

Postresuscitation care

Hypothermia was widely used in conjunction with cardiac surgery in the 1950s and later in conjunction with cardiopulmonary bypass. The recent demonstration that modest hypothermia in the range of 32ºC to 35ºC produces impressive improvement in neurological outcomes has prompted widespread enthusiasm for its routine use. The rationale for its use, and especially the pioneering of the late Peter Safar, have established both the rationale and benefits of its routine use. As yet, however, there is need for agreement on preferred methods of cooling, methods of monitoring core temperature, and the rationale for and interpreting measurements such as blood gases during hypothermia. Prevention of adverse effects of hypothermia, including thrombocytopenia and platelet dysfunction, which compromises blood clotting, is being actively explored.

Complications include cold diuresis, hypernatremia with hyperosmolal states, probable pancreatic dysfunction with increases in serum amylase and hyperglycemia, and decreased insulin effectiveness. The risks of infection, especially pneumonia and wound infections, are increased. Better understanding of these complications is sought as a basis for patient selection. The technique is promising and important. The goal is to mitigate the devastation that follows irreversible ischemic injury to the brain and major neurological deficits after successful initial resuscitation.

Monitoring and measurements

It is clear that the detection of cardiac arrest cannot be achieved reliably by palpation of the carotid or femoral pulses, especially by non-professional providers. Accordingly, the pulse check is appropriately deleted from the armamentariam of the BLS provider. Even for the professional provider, it is unlikely that palpation is reliable, especially during uninterrupted chest compression. Most important, however, is the consensus that chest compression should not be delayed for a pulse check. The possibility that the presence or absence of the heart beat may be detected by measurements of transthoracic impedance is attractive.

The most consistent guide for predicting the likelihood of defibrillation and restoration of spontaneous circulation is the coronary perfusion pressure (CPP). Except for patients who are invasively monitored in the hospital prior to cardiac arrest in the operating suite, cardiac catheterization laboratory, or intensive care unit, this is not applicable in other settings and especially out-of-hospital. End-tidal PCO_2 (EtPCO_2), however, is an excellent surrogate of both coronary perfusion pressure and cardiac output generated by chest compression.[12] EtPCO_2 is also useful for guiding effective chest compression and for the decision to discontinue CPR. Chest compression should consistently increase and maintain EtPCO_2 at levels exceeding 15 mm Hg. Although there are only observational clinical data to secure the proposed rule that CPR efforts may be abandoned absent EtPCO_2 values exceeding 10 mm Hg for more than 10 minutes in normothermic patients, this deserves consideration.

Pulse oximetry fails during cardiac arrest when peripheral blood flow is critically reduced or ceases. Measurements of cardiac output and oxygen consumption during CPR are both impractical and of no proven value. Blood gases, oximetry, serum electrolytes, and arterial blood lactate are potentially useful measurements including detection of carbon monoxide intoxication, life-threatening hypoglycemia, some drug intoxications, and electrolyte abnormalities. Sublingual tissue CO_2 is also of unproven value for guiding cardiac resuscitation. Nevertheless, each of these measurements is of substantial value primarily for postresuscitation management rather than during CPR.

There are important advances in the search for a predictor to guide the timing and predict the success of a defibrillating shock.[12] These include electrocardiographic measurements based on voltage (amplitude), frequency, and an algorithm that represents a combination of amplitude and frequency (AMSA).

Thrombolysis

The therapeutic value of anticoagulants and thrombolysis in settings of acute myocardial ischemia and following

pulmonary embolization is undisputed. There is also evidence of impaired microvascular blood flow with stasis during and following resuscitation from cardiac arrest. The potential value of anticoagulants and of thrombolytic agents that have proteolytic activity acting on prothrombin and thrombin in settings of CPR have been based on experimental data, but as yet have gained no clear clinical support. Observational studies project a five-fold greater likelihood of bleeding including intracranial hemorrhage. The incidence of serious bleeding is only 3%, however, which is best viewed in relation to the current national estimate of greater than 95% overall mortality after out-of-hospital cardiac arrest. Though the rationale for anticoagulants and thrombolysis is conceptually attractive, clinical data are insufficient to support its use as adjunctive therapy during CPR at this time.

In-hospital resuscitation

The overall survival is largely contingent on co-morbidities. Better outcomes are likely if preventive measures are instituted by which the incidence of cardiac arrest is reduced. Proactive Medical Emergency Teams (METs) have been organized to identify patients at risk, arrange prompt transfer of such patients to more intensive observation and management in monitored beds, or transfer into intensive care units. The success of the MET, the organized early response team, which typically includes a Critical Care or Emergency Medicine specialist and a Critical Care/Emergency Medicine RN specialist, is likely to be contingent on the local hospital setting. There is lesser need in teaching hospitals and greater benefit in non-teaching hospitals in the absence of in-house physicians. Hospitalists increasingly provide in-house services, including MET equivalents. The effectiveness of a MET is also contingent on the geographic location of patients and availability of monitored beds. Finally, much is determined by the culture of the institution and the extent to which physicians and other health providers share responsibility without undue fear of intrusion or perceived liabilities.

A special issue relates to the perceived obsolescence of manual defibrillators that do not deliver biphasic waveform, lower energy shocks, and escalating energies up to 360 joules. The likelihood that such compromise outcomes is now of lesser concern, however. The new and now more appropriate routine is delivery of only one shock with brief interruption of chest compressions. A single shock will therefore be at the lowest power setting, typically 200 joules.

Complications

As yet unsettled are the possible benefits and the adverse effects of the "precordial thump" delivered after witnessed cardiac arrest. There is persuasive evidence that a mechanically induced chest wall impact so timed that it immediately precedes the peak of the T wave may induce ectopic ventricular arrhythmias including ventricular fibrillation, so-called COMMOTIO CORDIS. Defibrillation produces skin burns, the so-called perimeter effect.[13]

Electrical shocks produce increases in both total creatine phosphokinase (CPK) principally from striated muscle and in the cardiac CPK-MB fraction together with Troponin T of myocardial source. If the rescuer is shocked, it is an unpleasant experience but quite remarkably, there has never been documentation of serious injury.

In a majority of victims, manual precordial compression fractures ribs. This applies also to mechanical chest compression, including the LUCAS® and the Autopulse®, together with a minority incidence of sternal fractures.

In contrast to primary cardiac causes of cardiac arrest in older adults, the predominant causes of cardiac arrest in pediatric patients are not cardiac. They are associated with asphyxia and especially foreign body aspiration and drowning or traumatic blood loss with exsanguination. More recent experimental studies nevertheless provide persuasive evidence that opening the airway and starting ventilation do not alone result in optimal outcomes. After onset of cardiac arrest, conventional precordial compression would best be part of initial management.

Ventricular fibrillation occurs in fewer than 10% of pediatric patients. If VF evolves during resuscitation from pulseless rhythms or asystole, the likelihood of a favorable outcome is diminished. The empirical decision to "dose" the energy delivered at 2 joules/kg proves 90% effective. Newer versions of AEDs that deliver biphasic waveform shocks provide pediatric cables and electrodes that attenuate the delivered shock to between 50 and 80 joules, an appropriate dose for children.

The routine of airway intubation for pediatric patients with cardiac arrest in out-of-hospital settings has been largely abandoned because of the dual detriments of delayed ventilation and precordial compression and the high incidence of both airway trauma and esophageal intubation.

As in adults, substantially lower tidal volumes are now delivered to avoid hyperventilation. Also as in adults, there is currently no proof that routine administration of drugs is of proven value. Calcium gluconate or chloride is administered on specific indication, including calcium channel blockade overdose, hyperkalemia, and hypocalcemia.

Sodium bicarbonate is administered for management of hyperkalemia and tricyclic antidepressant overdose.

Vascular access is now most predictably obtained by the intraosseous route. Neurological recovery is compromised by fever. We anticipated major benefits of hypothermia, but for pediatric patients additional objective clinical confirmation is awaited.

In pediatric patients who sustain cardiac arrest after cardiac surgery, early implementation of extracorporeal oxygenation (ECMO) has survival value.

Concluding comments

Though a preponderance of controlled clinical studies have failed to establish survival benefits, especially for drugs, the absence of proven benefit is not to be interpreted that there is no potential for benefits. There are extraordinary ethical and legal limitations that typically impose serious restraints on the enrollment of patients during cardiac arrest, and equally formidable challenges in the implementation of such human experiments. Accordingly, we must not despair of what may appear to be a see-saw of progress, but maintain appreciation and optimism for the progress that is being achieved.

Postresuscitation disease and its care

Postresuscitation syndrome

Erga L. Cerchiari

Department of Anaesthesia and Critical Care,
Ospedale Maggiore, and Area of Anaesthesia and Critical Care,
Surgical Department, Provincial Health Care Structure, Bologna, Italy

The postresuscitation syndrome (PRS) has been defined as a condition of an organism resuscitated following prolonged cardiac arrest, caused by a combination of whole body ischemia and reperfusion, and characterized by multiple organ dysfunction, including neurologic impairment.[1]

Background

Following resuscitation from cardiac arrest, patients either recover consciousness or remain unconscious, depending on the duration of cardiac arrest and the effectiveness of any CPR, but also on prearrest conditions such as age and comorbidities.[2]

Shortening no-flow times by timely interventions that can maintain some perfusion and promote the restoration of spontaneous circulation (e.g., bystander CPR, early defibrillation, and other means) improves the possibility of a successful outcome with the patient recovering consciousness.[3]

The wider availability of resuscitation techniques to reverse clinical death, however, has led to increasingly frequent observations of a pathological condition occurring in patients who remain unconscious, involving multiple organ injury or failure following reperfusion after prolonged cardiac arrest.

The concept of postresuscitation disease as a unique and new nosological entity was introduced by Negovsky in 1972;[4,5] the most interesting aspect of this innovative concept was the recognition that the etiology depended on a combination of severe circulatory hypoxia with the unintended sequelae of measures used for resuscitation.

On the basis of the wide variety of ischemic/hypoxic mechanisms that can trigger its development, the disease was redefined by Safar as a syndrome in which pathogenetic processes triggered by cardiac arrest were exacerbated by reperfusion, causing damage to the brain and other organs, the complex interactions of which combine to determine overall outcome (see early experimental findings summary).[6,7]

The evidence of features common to the postresuscitation syndrome and multiple organ dysfunction syndrome led to the hypothesis that a systemic inflammatory response of the entire organism was triggered by ischemia and reperfusion, adding to the damage directly induced by ischemia during cardiac arrest.[8]

Two landmark studies, showing that mild therapeutic hypothermia started after reperfusion can improve recovery after cardiac arrest, confirm that outcome is determined not only by events occurring during arrest and CPR but also by pathogenetic processes continuing after reperfusion.[9,10]

Recent reports confirm the occurrence of a "sepsis-like syndrome" after resuscitation from cardiac arrest,[11,12] although the mechanistic relationship to the direct damage induced by ischemia during cardiac arrest has yet to be clarified.

Early Experimental Findings

Negovsky[4,5] and his group of Russian investigators pioneered the concept of postresuscitation disease as a unique nosological entity, caused by the combination of severe hypoxia and resuscitation, on the basis of hundreds of experimental observations that fall into three groups:

1.   Phasic Pattern of Postresuscitation Recovery

Independent of the type of insult, alterations in cerebral and extracerebral organs occur starting with reperfusion and developing over time.

From insult to 6 to 9 hours postinsult: rapid changes in cerebral and systemic hemodynamics, metabolism, and rheology (clotting disturbances, increased viscosity), increase levels of biologically active substances and prostaglandin derivatives; alterations of the immune system (increased bactericidal activity, depressed reticuloendothelial system, and hyperreactivity of B- and T-lymphocytes), and toxic factors in the blood (peptide fraction 800 to 2000 Daltons and endotoxin secondary to gram-negative bacteremia).

From 10 to 24 hours postinsult: normalization of cardiovascular variables and progression of metabolic derangements ensue. During this time, 50% of deaths occur as a result of recurrent cardiac arrest.

From 1 to 3 days postinsult: stable cardiovascular variables and improvement in cerebral function associated with increased intestinal permeability leading to bacteremia.

The stabilization phase (more than 3 days postinsult): characterized by the prevalence of localized or generalized infection that represents the major cause of delayed deaths. The degree of cerebral and extracerebral organ derangements is reported to be more severe and prolonged the longer the duration of the hypoxic–ischemic insult.

2.   Interactions between Cerebral and Extracerebral Postischemic Damage on Outcome

The severity of systemic and hemodynamic derangements after 20 minutes of isolated brain ischemia is comparable to that recorded after only 12–15 minutes of total circulatory arrest with ventricular fibrillation, suggesting that cerebral postischemic damage plays a role in development of extracerebral dysfunction, probably by inducing changes in neurohumoral regulation.

Cerebral function recovers better after bloodless global brain ischemia than after the same duration of circulatory arrest from ventricular fibrillation, leading to the conclusion that extracerebral factors account for about half of the pathological findings in the brain induced by cardiac arrest.

3.   Benefcal Effect of Trials with Detoxification Techniques

A series of trials aimed at removing toxins and normalizing homeostasis by various detoxification techniques showed that all the techniques can improve neurological recovery and survival compared with concurrent controls; cross-circulation was the most effective, in which circulation in the body of the resuscitated dog was maintained for 30 minutes post-ROSC by the heart of a healthy donor dog, aided by an extracorporeal circulation system.

Safar and his group in Pittsburgh, in parallel with – but subsequent to – the Russian experimental work, confirmed that extracerebral organ dysfunction may hamper cerebral recovery following resuscitation from cardiac arrest, based on the observations that (a) cerebral function after isolated global brain ischemia recovers better than after comparable durations of total body ischemia[13,14] and (b) the use of cardiopulmonary bypass for resuscitation and for short-term postresuscitation assistance improves myocardial performance after weaning, and significantly increases neurological outcome and survival.[15] Extracerebral organ dysfunction following resuscitation from cardiac arrest of increasing durations was studied in animal experimental models:[1,6,7,14–19]

- cardiac output and arterial oxygen transport, after a transient increase, showed a prolonged and profound decrease associated with increased peripheral resistance; this starts sooner and is more severe and prolonged after longer durations of VF, resolving by 12 to 24 hours postresuscitation
- pulmonary gas exchange, with assisted ventilation for 6 to 24 hours postresuscitation, is well maintained even after extubation (normoxia, normocarbia, and rapid pH normalization)
- coagulation disturbances with hypocoagulability start during resuscitation, with prolonged clotting times and decreased platelets and fibrinogen, and normalize at 24 hours after resuscitation; elevated fibrin-degradation products and decreased platelet counts were observed to 72 hours postresuscitation.

- erythrocyte count decreases significantly
- renal function (blood urea nitrogen, serum creatinine, osmolarity, sodium, potassium, and calcium) remain normal after a transient reduction in urine output with positive fluid balance, normalizing at 3 to 6 hours
- hepatic function is altered transiently; plasma ammonia and branched chain and aromatic amino acids increase, with higher levels in the animals with poor outcome, suggesting an alteration of liver-detoxifying function
- bacteremia is a constant feature after cardiac arrest, with transient leukocytosis but without hyperthermia (90% were constituents of the intestinal flora, suggesting postischemic bacterial translocation).

In summary, following resuscitation from cardiac arrest, multiorgan dysfunction occurs, but the abnormalities have different time patterns (Fig. 47.1).
Fig. 47.1. Time pattern of organ dysfunction after resuscitation from cardiac arrest from the early experimental work.[1,4–7]

Incidence and prevalence

The incidence of out-of-hospital cardiac arrest is estimated to be 49.5–66 per 100 000 cases per year:[2] in these, return of spontaneous circulation can be achieved in 17% to 33%, depending on the efficiency of the emergency response system.[20]

The incidence of in-hospital cardiac arrest has been estimated as 1.4/100 admissions/year:[21] in these cases, restoration of spontaneous circulation occurs in 40%–44%.[22]

Of the patients resuscitated from cardiac arrest, a small proportion (variable as a function of timeliness and effectiveness of response) achieve early recovery, with restoration of spontaneous respiration and consciousness. Identification and treatment of the cause of arrest is the main or only therapeutic challenge for this group of subjects.

But most survivors of cardiac arrest (80%) are comatose postresuscitation, and are admitted to the ICU where they represent the population of patients with postresuscita-

tion syndrome (PRS), amounting to about 15%–20% of all cardiac arrest victims (Fig. 47.2).

Among the PRS patients, mortality has been reported to be very high, reaching 80% by 6 months postresuscitation:[23–25] approximately one-third of the deaths are due to cardiac causes (early deaths usually < 24 hours), one-third to malfunction of extracerebral organs, and one-third to neurologic causes (late deaths).

The prevalence of the postresuscitation syndrome can only be inferred, because of the bias of data resulting from decisions to limit treatment, including instructions for "do not attempt resuscitation," in cases of recurrent cardiac arrest.[22–26]

Etiology

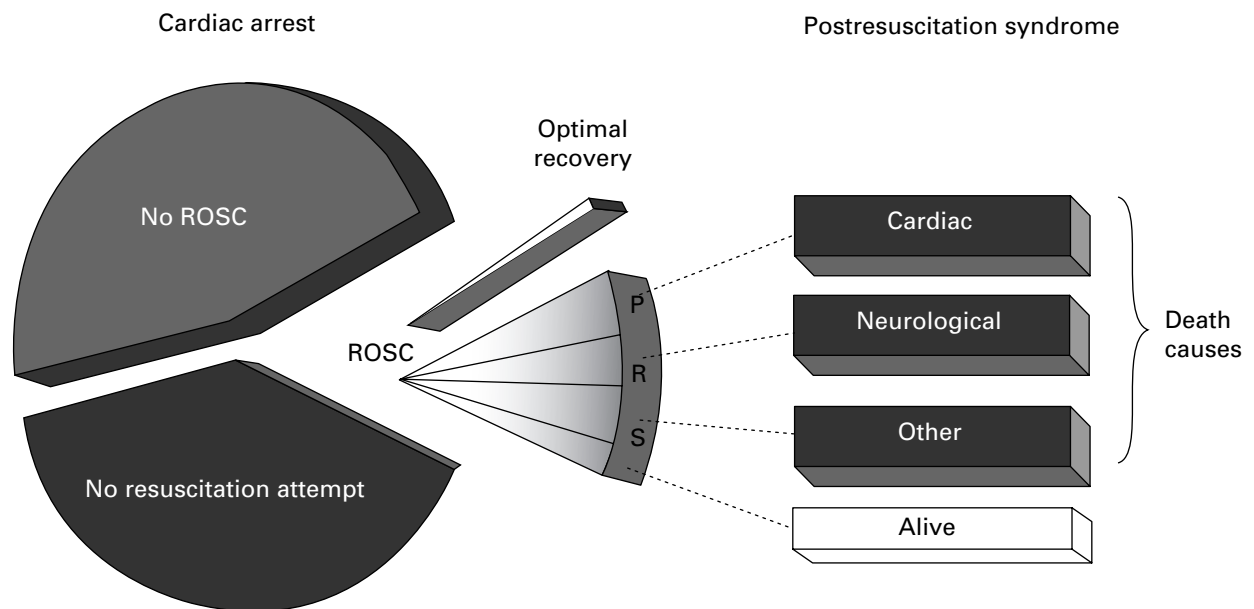
Following resuscitation from cardiac arrest of less than 5 minutes, recovery is rapid and complete. After prolonged arrest, ROSC is impossible or only transient.


Fig. 47.2. Estimated fate for cardiac arrest patients.

Therefore, the postresuscitation syndrome only develops following resuscitation given during an intermediate duration of ischemia (the limits of which are affected by prearrest conditions) and depending on the circumstances of resuscitation, leading to the "*reperfusion paradox.*"

The insult induced by cardiac arrest and CPR is multifaceted, encompassing several contributing factors occurring during cardiac arrest, during CPR, and following restoration of spontaneous circulation:[1,6,7]

- *ischemia – anoxia* occurring during the cardiac arrest with no-flow
- *hypoperfusion – hypoxia* during the low-flow of external cardiac compressions (inducing at best a cardiac output of 25% baseline)
- *reperfusion*, which, although potentially permitting survival, adds to the ischemic-hypoxic–hypoperfusion insult, inducing a variety of mechanisms that continue to evolve subsequently, including reperfusion failure and injury, altered coagulation, and activation of a systemic inflammatory response.

Pathogenesis

Two major pathways have been identified

1. a direct insult to the brain, which is particularly sensitive to ischemia; and to the heart, which may suffer postresuscitation myocardial stunning leading in turn to a secondary insult from postreperfusion impairment of cardiac output and hypoperfusion.
2. postreperfusion activation of the systemic inflammatory response syndrome, with hypoperfusion and/or altered perfusion as one pathological mechanism;[12] in this pathway, the PRS shares many features with severe sepsis, including elevation of plasma cytokines with dysregulated cytokine production, endothelial injury, complement activation, coagulation and fibrinolysis abnormalities, endotoxemia, disturbed modulation of the immune response, and adrenal dysfunction.

Organ function postresuscitation

The postresuscitation syndrome occurs in patients resuscitated after cardiac arrest of more than 5 minutes' duration and is characterized by different components: neurologic functional impairment, cardiovascular functional impairment – both well characterized – and the extracerebral extracardiac functional impairment comprising a complex picture of determinants and interactions.

The three major components variously contribute to the complex clinical picture of the patient resuscitated from cardiac arrest and admitted to ICU. Rapidly occurring early post-resuscitation changes create an acute phase of instability during which specific and aggressive treatments may favorably affect outcome. After the first

24 hours the clinical picture stabilizes and treatment becomes less specific, and is not different from that of a comatose ICU patient.

For purposes of clarity, the three components are described separately, with analysis of the relative contribution of the two pathogenetic pathways, functional derangement interactions, and contributions to outcome and specific early treatments.

Neurologic function postresuscitation

The best defined component of the postresuscitation syndrome is neurologic functional impairment.

With the increased application of resuscitation interventions, postcardiac arrest unconsciousness has become the third most common cause of coma. Almost 80% of patients who initially survive cardiac arrest remain comatose for variable lengths of time, approximately 40% enter a persistent vegetative state, while 10% to 30% of survivors achieve a meaningful recovery.[27]

Cardiac arrest causes a global ischemic insult to the brain. The extent of cerebral damage is a function of the duration of interrrupted blood flow. Accordingly, minimizing both the arrest (no-flow) time and the cardiopulmonary resuscitation (low-flow) time, is critical.

Even in selected patients with a witnessed cardiac arrest after ventricular fibrillation and an estimated arrest to ALS intervention interval no longer than 15 minutes, mortality at 6 months was 55% and of the survivors, 61% had an unfavorable neurological outcome.[9] With reperfusion, extracerebral factors may hamper neurological recovery, requiring interventions aimed at mitigating secondary postischemic anoxic encephalopathy.[7]

Pathophysiology

The mechanisms of cerebral damage following ischemia and reperfusion have been studied in detail (for detailed reviews see refs. 7,27).

Changes induced by ischemia set the stage for reoxygenation-induced, free radical-triggered injury cascades, exacerbated by reduced cardiac output and local circulatory impairment that starts during cardiac arrest with altered blood–brain barrier permeability and systemic changes such as activation of complement, coagulation, platelet aggregation, and adhesion of white blood cells.[28]

The pattern of prolonged global and multifocal cerebral hypoperfusion is associated with variations of regional cerebral blood flow both in the cortex and in the basal ganglia[29] with regional anoxic cerebral anaerobic metabolism.

Posthypoxic encephalopathy has been shown to be associated with a marked decrease of cerebral metabolic activity and of glucose uptake, even 24 hours after resuscitation.[30]

A significant activation of inflammatory mediators (Interleukin 8, soluble elastin, and polymorphonuclear elastase) immediately postinsult and lasting about 12 hours has recently been reported following both cardiac arrest and isolated brain trauma, suggesting an inflammatory response as a common pathogenetic pathway activated by cerebral damage.[31]

Clinical features and prognostic evaluation

A variety of methods have been proposed to monitor the evolution of the depth of coma and its prognosis, including neurological examination, electrophysiologic techniques, and biochemical tests.

A recent meta-analysis, including nearly 2000 patients, assessed the reliability of neurological examination, including Glasgow Coma Scale (GCS) and brainstem reflexes, reviewed at different time intervals after resuscitation; it concluded that patients who lack pupillary and corneal reflexes at 24 hours and have no motor response to pain at 72 hours have an extremely small chance of meaningful recovery.

The most reliable signs of prognosis occur at 24 hours after cardiac arrest: earlier assessment should not be based on clinical evidence alone.[32]

A systematic review of 18 studies analyzed the predictive ability of somatosensory evoked potentials (SSEP) acquired early after the onset of coma (1–3 days) in 1136 adult patients with hypoxic-ischemic encephalopathy: the results showed that patients with absent cortical SSEP responses have a less than 1% chance of regaining consciousness.[33]

A recent study tested the value of serial measurement of serum neuron-specific enolase (NSE) at admission and daily postinsult, in combination with GCS and SSEP measurements, to predict neurological prognosis in unconscious patients admitted to the ICU after resuscitation from cardiac arrest. High serum NSE levels at 24 and 48 hours after resuscitation predict a poor neurological outcome. Addition of NSE to GCS and SSEP increases predictability.[34]

By 48–72 hours postresuscitation, predictability of unfavorable long-term neurologic outcome may guide decisions to curtail treatment, because only patients with lighter levels of coma or who have regained consciousness by this time have any realistic prospect of long-term survival.[32]

Treatment

Research into cardiopulmonary cerebral resuscitation has attempted to mitigate the postischemic–anoxic encephalopathy but, until recently, experimental results had never been replicated in patients.[7]

Mild therapeutic hypothermia induced following reperfusion in patients who have been successfully resuscitated from ventricular fibrillation cardiac arrest is the only postresuscitation intervention that has proved effective in increasing the rate of favorable neurologic outcome in two different randomized studies conducted in Europe and Australia[9,10] and in reducing mortality in one of them.[9] Clinical and experimental results show a multifactorial neuroprotective effect of hypothermia during and after ischemic situations by influencing several damaging pathways.[27]

Thrombolytics, administered during arrest or early after reperfusion, have been shown in animal experiments to improve the microcirculation in the brain and may, by this mechanism, contribute to the favorable neurological outcome of patients as described in many case reports and small case series with predominantly positive results.[35] The first properly designed, large, randomized, double-blind multicenter study of thrombolytics was stopped before completion of recruitment because the data safety monitoring board judged it unlikely that, in the population in study, tenecteplase would demonstrate superiority over placebo. These results, presented at a 2006 conference, should be considered preliminary until a detailed analysis is performed and published.[36]

Cardiovascular function postresuscitation

Following successful resuscitation from prolonged cardiac arrest, a typical component of the postresuscitation syndrome is prolonged myocardial contractile failure, associated with life-threatening ventricular arrhythmias and hemodynamic instability.[37,38]

Cardiac complications are stated to occur in 50% of resuscitated patients, ranging from transient – but sometimes severe – impairment of myocardial function (occurring early and normalizing several days later) to permanent malfunction and fatal rearrest. The severe impairment of myocardial function in the early hours following resuscitation accounts for 25% to 45% of early postresuscitation deaths.[23–25]

The global nature of ischemic myocardial dysfunction[38] and also its occurrence following resuscitation from respiratory arrest[39] or electroconvulsive treatment[40] strongly support its role during cardiac arrest and cardiopulmonary resuscitation as the primary etiological determinant, as opposed to the role of the primary cause of arrest which is cardiac in 55%–65% of cases.[41]

The severity and duration of postresuscitation myocardial impairment is a function of both duration of cardiac arrest and subsequent resuscitation efforts,[16–42] with a contribution from adrenaline (epinephrine) used during CPR,[43,44] and the energy and waveform required for defibrillation.[45,46] In humans, the dose of adrenaline used during CPR has been reported to be the only variable independently associated with postresuscitation myocardial dysfunction.[44]

Pathophysiology

The mechanisms responsible for myocardial stunning after global myocardial ischemia remain unclear, but several hypothesis have been proposed. Among these are the postreperfusion long-lasting depletion of the total adenine nucleotide pool, the generation of oxygen-derived free radicals, calcium overload, and uncoupling of excitation-contraction due to sarcoplasmic reticulum dysfunction.[37,38]

Recently, a correlation has been established between levels of proinflammatory cytokines, synthesized and released in response to the stress of global ischemia, and the depression of myocardial function in the early postresuscitation period.[47]

Clinical features

In animal studies, postresuscitation myocardial dysfunction is characterized by increased filling pressures, impaired contractile function, decreased cardiac index, decrease in both systolic and diastolic right ventricular function,[16,38] starting at 2–6 hours and returning to normal at 24 hours postresuscitation.

These findings were confirmed initially by anedoctal observations of prolonged reversible myocardial dysfunction in human cardiac arrest survivors[50,51] and, later, were better defined in systematic studies in patients.[44,52]

The global nature of postresuscitation dysfunction has been demonstrated with echocardiography and ventriculography, which show a decrease in ejection fraction and in fractional shortening.

Myocardial dysfunction in patients may improve at 24–48 hours postresuscitation with return to normal values; persistently low cardiac index at 24 hours postresuscitation is associated with early death by multiple organ failure.[44] In the same study, despite the significant improvement of cardiac index at 24 hours, persisting vasodilatation was described, delaying the discontinuation of vasoactive drugs.

In parallel with the failure of the heart to sustain normal circulation, a condition of altered peripheral oxygen utilization has been described.[44] These two mechanisms together account for the persistent anaerobic metabolism characteristic of the early postresuscitation phase.

Relationship to neurological recovery and outcome

The cardiovascular impairment in the early postresuscitation hours has been reported to correlate with impaired

cerebral recovery from the ischemic insult of cardiac arrest.[16]

Indirect evidence of the role of impaired perfusion on cerebral recovery comes from the beneficial effect of cardiopulmonary bypass in augmenting flow after cardiac arrest.[15]

In cardiac arrest survivors, good functional neurological recovery has been independently and positively associated with arterial blood pressure during the first 2 hours postresuscitation, whereas hypotensive episodes correlate with poor cerebral outcome.[52] The latter finding could be explained by the loss or impairment of cerebral autoregulation in comatose patients resuscitated from cardiac arrest, causing a reduction in cerebral blood flow if blood pressure is low.[54,55]

The finding of a correlation between low cardiac index and neurologic outcome, however, has not been confirmed in a recent study in humans.[44]

Treatment

Successful treatment of myocardial dysfunction could reduce or prevent the cardiac causes of death that are the major determinants of early postresuscitation deaths.

Treatment with dobutamine has proved effective in supporting output and pressure during the postresuscitation phase prior to return to baseline function.[56] A dobutamine dose of 5 mcg/kg min has been shown to be better than a dose of 2 or 7.5 mcg/kg min, and better than placebo or aortic counterpulsation in sustaining cardiovascular performance for 6 hours postresuscitation.[56–58]

The similarities in cardiovascular status between septic and postresuscitation patients have suggested that in addition to the inotropic support with dobutamine the 'early goal-directed therapy' that has proved effective in severe sepsis should be included[59] – namely normalization of intravascular volume, of blood pressure by vasoactive drugs, and of oxygen transport by red cell transfusion during the first 6 hours postresuscitation.[11,12] Data on its effectiveness in cardiac arrest patients are not yet available.

Extracerebral extracardiac function postresuscitation

The extracerebral extracardiac function derangements, accounting for one-third of deaths,[23–25] represent the less specific component of the postresuscitation syndrome.[11,12]

In patients surviving the early postresuscitation phase, cardiovascular function improves, neurologic function may show gradual improvement or remain severely compromised, but conditions facilitating the development of sepsis are created, leading ultimately to multiorgan dysfunction.

Systemic findings and pathogenesis

The direct effect of cardiac arrest, besides its role in neuronal injury and myocardial dysfunction, is also involved in the genesis of coagulation disturbances,[60] endothelial injury,[60,61] and in triggering the cascades of inflammatory responses.[7,63]

A variety of changes and findings, which still need to be clearly classified and systematized, have been described following resuscitation from cardiac arrest:

- a considerable increase in various acute phase response proteins[64]
- a sharp rise in plasma cytokines and soluble receptors within the blood compartment as early as 3 hours postarrest[31,46,65–69]
- endothelial injury and release of intracellular adhesion molecules
- marked activation of complement, polymorphonuclear (PMN) leukocytes, and an increased PMN-endothelial interaction[61–64]
- marked activation of blood coagulation and fibrinolysis[60]
- leukocyte dysregulation[11,12]
- evidence of the presence of endotoxin in plasma

The complex interaction of endothelial injury, inflammatory and procoagulant host responses, intravascular fibrin formation, and microvascular thrombosis contribute to reperfusion defects,[7,60,64] which augment systemic hypoperfusion induced by cardiovascular dysfunction to trigger a secondary insult of persisting anerobic metabolism.

The altered systemic oxygen utilization, together with circulating endotoxin and immune hyporeactivity, may facilitate development of infection.[11,12]

Extracerebral and extracardiac organs, however, can tolerate periods of ischemia much longer than those generally occurring in cardiac arrest and resuscitation: thus, the impairment of function in these organs appears to be the combined result of the mechanisms triggered by ischemia but compounded by reperfusion.

Derangements of organ function

Clotting and fibrinolytic function

Starting during cardiopulmonary resuscitation, marked activation of coagulation has been demonstrated, without adequate concomitant activation of endogenous fibrinolysis,[60,70] suggesting that intravascular fibrin formation and microvascular thrombosis after cardiac arrest may contribute to organ dysfunction, including neurological impairment. With restoration of spontaneous circulation and reperfusion, coagulation activity (thrombin-antithrombin complex) increases, anticoagulation (antithrombin, protein C, and protein S) decreases, and

fibrinolysis (plasmin–antiplasmin complex) is activated or in some cases inhibited (increased plasminogen activator inhibitor-1 with a peak on day 1). These abnormalities are more severe in patients dying within 2 days and most severe in patients dying from early refractory shock. Protein C and S levels are low compared with those in healthy volunteers and discriminated OHCA survivors from non-survivors.[66]

Marked activation of complement, polymorphonuclear leukocytes, and an increased PMN-endothelieal interaction have been clearly demonstrated during cardiopulmonary resuscitation and early reperfusion after cardiac arrest in humans.[62]

Adrenal function

Serum cortisol levels have been reported consistently to be high in all patients resuscitated from cardiac arrest for up to 36 hours postresuscitation,[74–76] with lower levels in non-survivors,[74] particularly in those who died of early refractory shock.[76]

Relative adrenal insufficiency as assessed by corticotropin tests was observed in 42% of patients but showed no association with arrest duration variables or with outcome.[76]

Renal function

Renal dysfunction,[77] was recently confirmed in patients presenting with hemodynamic instability and was characterized by significant increases in plasma creatinine and by a decrease in the International Normalized Ratio.[44]

Intestinal function

Following cardiac arrest and reperfusion, severe intestinal ischemia occurs, showing a pattern of metabolic extracellular changes similar to those recorded in the brain.[78] It is associated with early intestinal dysfunction and/or endoscopic lesions identified in 60% of patients.[79]

A role for ischemia-reperfusion-mediated increase in intestinal permeability has been proposed as predisposing the patient to the sepsis syndrome.

Endotoxin and infection

The finding of plasma endotoxin detected in 46% of patients 1–2 days after resuscitation (although with no relation to outcome), and of endotoxin-dependent hyporeactivity of patients' leukocytes, with high levels of circulating cytokines and dysregulated production of plasma cytokines, delineates an immunological pattern similar to the profile characterizing patients with sepsis. Half of endotoxin-positive patients have been found to develop secondarily acquired bacterial infection

3–4 days postresuscitation (mostly pulmonary, occasionally bacteremia).[11,12]

The finding of bacteremia, generally associated with pathogens of intestinal origin, occurring in 39% of patients within the first 24 hours of admission postresuscitation associated with increased mortality,[80] was not confirmed in a subsequent study in which bacteremia was encountered only sporadically.[12]

The incidence of pneumonia in patients admitted to the ICU following cardiac arrest has been reported to vary from 24% to 45% of patients.[9,81]

In a systematic study,[82] newly acquired infection developed in 46% of patients resuscitated from cardiac arrest and admitted to the ICU, the most common being pneumonia (65% of infections). Compared with cardiac arrest survivors without infection, patients with infection had longer mechanical ventilation and ICU length of stay, but mortality was similar.

A possible role for procalcitonin has been proposed for the early identification of post-resuscitation patients with an acute phase response and bacterial complications: it was the only marker higher in patients with ventilator-acquired pneumonia.[83]

Hyperthermia not associated with positive blood cultures has been reported frequently during the first 24 hours following CPR, suggesting that mechanisms other than infection may contribute to the development of fever in cardiac arrest survivors.[82,84]

Correlation with outcome

The peak level and the time of occurrence of many of the above-mentioned mediators of the inflammatory response have been reported to correlate with outcome (differently defined as: early death, early death from cardiac causes, death at 1 month, and others) in different case series from single centers and without precise standardization of resuscitation procedures and postresuscitation treatments.[61–72]

The data now available suggest the opportunity for a reassessment and systematic analysis of the interactions involving various cascades and of their role in determining outcome in a well-designed multicenter study adopting a standardized treatment and evaluation protocol.

The better characterization of PRS in its early phase is confirmed by the high predictive value of cerebral impairment, the severity of which can be quantified, allowing a reliable prognostication of outcome.[47,52]

In the later phase of PRS, when secondary multiple organ derangement syndrome (MODS) becomes apparent, the existing limitations of prognostic evaluation based on severity scoring systems[85] inherent to MODS are further

complicated by the persisting postischemic impairment of cerebral function.

Treatment

Similar to the treatment of patients with impaired cardiovascular function, in PRS patients showing extracerebral and extracadiac impairment, the standard treatment encompasses mild hypothermia induced after reperfusion from cardiac arrest to improve neurological outcome[9,10] and dobutamine to sustain transient myocardial dysfunction.[56–58] Mild hypothermia has been hypothesized to interfere with the inflammatory cascades of cardiac arrest in its effect on survival.

One interesting trial studied the effect of isovolumic high-volume hemofiltration (HF) (200 ml/kg/h over 8 hours) with and without hypothermia, in an attempt to remove circulating molecules believed to be responsible for ischemia-reperfusion injury.[86] Compared with controls, the high-volume hemofiltration with and without hypothermia decreased the relative risk of death from intractable shock and improved survival. Nonetheless, definite conclusions must await larger randomized clinical trials testing the combination of HF with hypothermia in a larger cohort of cardiac arrest survivors.

The relevance of the quality of in-hospital treatment and its impact on overall outcome after resuscitation from cardiac arrest has been confirmed in two studies showing that factors associated with better outcome encompassed: the condition of patients prearrest (age under median 71 years old and better overall performance category prearrest); prehospital care (shorter time from emergency call to CPR initiation and no use of adrenaline); and in-hospital care (no seizure activity, temperature under 37.8 °C (median), S-glucose under 10.6 mmol/l 24 hours after admission (median), and BE over >3.5 mmol/l 12 hours (median) after admission).[87,88]

Summary

Widespread implementation of adequate system responses and application of resuscitation techniques to reverse clinical death increase both the rate of optimal recovery and, by raising the number of patients with restored spontaneous circulation, the occurrence of PRS.

Reduction of the duration of ischemia is the most obvious intervention to prevent development of PRS; nevertheless, strengthening the "chain of survival," may also restore spontaneous circulation in patients who otherwise would not have been revived and are at high risk for the development of this complex condition.

During the first 24 hours postresuscitation, the PRS is well characterized and requires aggressive treatment, aimed at reducing the progression of cerebral injury and the effects of the secondary insult determined by impaired cardiovascular performance. Besides standard intensive care support of impaired function, the gold standard includes mild hypothermia maintained for at least 12 hours and optimization of perfusion and oxygen delivery.

After the first 24 hours postresuscitation, the clinical picture is not different from that of a comatose intensive care patient. The role of the quality of treatment administered in this phase has been shown and includes brain-oriented care (prevention of hyperthermia and seizures, optimization of perfusion, glucose and metabolic control), and standard intensive care oriented to prevention of infection and support of impaired organ function.

It is of paramount importance to optimize postresuscitation treatment in the first 2–3 days after the arrest, until reliable prognostic instruments permit the prediction of an unfavorable neurologic outcome, in order to exclude self-fulfilling prophecies and provide sound information to families, but also to plan the continuation of appropriate treatment strategies.

Promising prognostic markers of the acute phase response and treatment strategies, aimed at improving disturbances in microcirculation and reducing the impact of the specific inflammatory response, deserve further evaluation in systematic, well-controlled studies.

Introduction

It is estimated that between 400 000 and 460 000 individuals suffer an episode of sudden cardiac arrest every year in the United States.[1] Yet, the percentage of individuals who are successfully resuscitated and leave the hospital alive with intact neurological function averages less than 10% nationwide.[2–4] Efforts to restore life successfully are formidably challenging. They require not only that cardiac activity be initially restored but that injury to vital organs be prevented or minimized. A closer examination of resuscitation statistics reveals that efficient Emergency Medical Services systems are able to re-establish cardiac activity in 30% to 40% of sudden cardiac arrest victims at the scene.[5–7] Yet, close to 40% die before admission to a hospital presumably from recurrent cardiac arrest or complications during transport.[8] Of those admitted to the hospital nearly 60% succumb before discharge, such that only one in four initially resuscitated victims leaves the hospital alive.

Although the causes of postresuscitation deaths have not been systematically investigated, the available information suggests that postresuscitation myocardial dysfunction, hypoxic brain damage, systemic inflammatory responses, intercurrent illnesses, or a combination thereof are the main culprits.[8–10] The core pathogenic process driving such poor outcome is the intense ischemia of variable duration that organs suffer after cessation of blood flow and the subsequent reperfusion injury that accompanies the resuscitation effort. In addition, the precipitating event of cardiac arrest may also play a role in the post-resuscitation phase.

This chapter focuses on the effects of cardiac arrest and resuscitation on the myocardium, mindful that many other organs are concomitantly affected by similar mechanisms of cell injury. The chapter is organized to describe: (1) the functional myocardial abnormalities that occur during and after resuscitation from cardiac arrest; (2) the underlying cellular mechanisms of such injury; (3) factors that may contribute to myocardial injury; (4) therapies that have been shown in the laboratory to prevent or ameliorate myocardial injury; and (5) the management of postresuscitation myocardial dysfunction. As the chapter develops the reader will learn that postresuscitation myocardial dysfunction is largely a reversible phenomenon such that support of the failing heart during the critical postresuscitation interval is fully justified.

Functional myocardial manifestations

The working heart is a highly metabolically active organ that consumes close to 10% of the total body oxygen consumption and extracts nearly 70% of the oxygen supplied by the coronary circuit. Nevertheless, it has minimal capability for extracting additional oxygen such that increased metabolic demands are met through coronary vasodilatation with augmentation of blood flow and oxygen delivery.[11,12] Consequently, a severe energy imbalance develops immediately after cardiac arrest supervenes and coronary blood flow ceases. The severity of the energy deficit is contingent on the metabolic requirements and is particularly high in the setting of ventricular fibrillation (VF) when the oxygen requirements are comparable to or exceed that of the normally beating heart.[13,14] A lesser energy deficit is anticipated when cardiac arrest occurs in a quiescent or minimally active heart (i.e., asystole or pulseless electrical

activity as a result of asphyxia or exsanguination).[15] Because most experimental studies have examined the myocardial manifestations of cardiac arrest and resuscitation in animal models of VF, caution should be exercised when extrapolating these findings to cardiac arrest settings precipitated by mechanisms other than VF.

With cessation of coronary blood flow and oxygen availability, the mitochondrial capability for regenerating ATP through oxidative phosphorylation stops, prompting anaerobic regeneration of limited amounts of ATP at the substrate level from breakdown of creatine phosphate and oxidation of pyruvate to lactate.[16–18] Hence, there is rapid depletion of creatine phosphate, marked elevation in lactate, and a relatively slow depletion of ATP.[17] In one recent study in a rat model of VF, 10 minutes of untreated VF were accompanied by decreases in myocardial creatine phosphate and ATP to levels 7% and 19% of baseline, respectively, whereas the lactate content increased by more than 50-fold.[19] Coincident with the energy deficit, accumulation of CO_2 and H^+ account for profound myocardial acidosis.[18,20]

When conventional closed-chest resuscitation is used, the coronary blood flow generated rarely exceeds 20% of the normal flow,[21] thus failing to reverse myocardial ischemia. In addition, reperfusion of ischemic myocardium activates multiple pathogenic mechanisms, leading to what is known as reperfusion injury. Accordingly, resuscitation typically proceeds during and in spite of severe myocardial ischemia and in the midst of reperfusion injury compounded by specific interventions, such as electrical shocks and adrenergic vasopressor agents, that can also contribute to myocardial injury. As a result, various functional myocardial abnormalities develop that may themselves compromise resuscitability and survival. These myocardial abnormalities represent a continuum along the injury process that can be grouped into those that manifest during the resuscitation effort and those that manifest after the return of spontaneous circulation. The former include ischemic contracture and increased resistance to electrical defibrillation; the latter include reperfusion arrhythmias and myocardial dysfunction.

Ischemic contracture

Ischemic contracture refers to progressive left ventricular wall thickening with parallel reductions in cavity size consequent to myocardial ischemia. Ischemic contracture was first reported in the early 1970s during open heart surgery when operations were conducted under normothermic conditions and in the fibrillating heart to render a bloodless surgical field.[22,23] The onset of ischemic

contracture in this setting was associated with reductions in myocardial ATP levels to < 10% of normal.[24] An extreme manifestation of ischemic contracture is the so-called "stony heart" and typically heralds irreversible ischemic injury.

More recent studies in animal models of VF and closed chest resuscitation have demonstrated a phenomenon akin to ischemic contracture, but of earlier onset and associated with less ATP depletion.[25,26] This form of ischemic contracture is likely to represent a manifestation of reperfusion injury[27] such that withholding chest compression (and hence coronary blood flow) markedly delays the onset of contracture.[28,29] The resulting left ventricular thickening with reductions in cavity size compromises ventricular preload and the amount of blood that can be ejected by chest compression.[14,27,30] Thus, ischemic contracture may partly explain the characteristic time-dependent reductions in the hemodynamic efficacy of chest compression.[31] Moreover, recent studies in a porcine model of VF demonstrate that the severity of ischemic contracture is proportional to the preceding interval of untreated VF.[26] In humans, ischemic contracture has been described as myocardial "firmness" during open-chest resuscitation after failure of closed-chest attempts and found also to compromise resuscitability.[32] Studies in the research laboratory have shown that ischemic contracture can be attenuated by pharmacologic interventions targeting reperfusion injury, resulting in hemodynamically more stable closed-chest resuscitation.[27,33] The possibility that ischemic contracture might increase coronary vascular resistance by extrinsic compression of the coronary circuit[14,34] has not been substantiated.[33,35]

Resistance to defibrillation

Electrical shocks delivered immediately after onset of VF are consistently effective in re-establishing cardiac activity. Even short delays (i.e., up to 3 minutes) may not be substantially detrimental and result in more than 50% likelihood of successful resuscitation.[36] Longer intervals of untreated VF – as usually occurs in out-of-hospital settings – predict decreased effectiveness of defibrillation attempts, however, in which electrical shocks may fail to reverse VF or may precipitate asystole or pulseless electrical activity.[37] Under these conditions, additional resuscitation interventions are required to restore myocardial conditions favorable for successful defibrillation. New approaches are being developed to optimize the effectiveness of electrical defibrillation by identifying the proper timing for shock delivery and by using safer and more effective defibrillation waveforms.[38,39]

Reperfusion arrhythmias

Electrical instability manifested by premature ventricular complexes and episodes of ventricular tachycardia and VF commonly occurs during the early minutes after return of cardiac activity. Episodes of VF have been reported to occur in up to 79% of patients, with the number of episodes inversely correlated with ultimate survival.[40] The mechanism responsible for postresuscitation arrhythmias is complex and probably involves prominent cytosolic Ca^{2+} overload with afterdepolarizations triggering ventricular ectopic activity.[41] In addition, there are repolarization abnormalities that include shortening of the action potential (AP) duration, decreased AP amplitude, and development of AP duration alternans creating conditions for re-entry.[42] Experimentally, these repolarization abnormalities are short-lived (5 to 10 minutes) and coincide with the interval of increased propensity for ventricular arrhythmias and recurrent VF.[27] They are in part related to opening of sarcolemmal K^+_{ATP} channels;[43] however, recent evidence suggests that activation of the sarcolemmal Na^+-H^+ exchanger isoform-1 (NHE-1) may also play a role.[44]

Postresuscitation myocardial dysfunction

Variable degrees of left ventricular systolic and diastolic dysfunction develop after resuscitation from cardiac arrest, despite full restoration of coronary blood flow. Left ventricular dysfunction is largely reversible, conforming to the definition of myocardial stunning.[45–48]

Systolic dysfunction has been documented by using load-independent indices of contractility, which demonstrates decreases in the slope of the end-systolic pressure-volume relationship (elastance) and increases in the volume intercept at a left ventricular pressure of 100 mm Hg (V_{100}).[46] Impaired contractility leads to reductions in indices of global ventricular performance, such as cardiac index, ejection fraction, and left ventricular stroke work,[8,47,49] and renders the heart susceptible to afterload increases during the postresuscitation phase. In a pig model of VF and closed chest resuscitation, the administration of vasopressin during cardiac resuscitation was associated with decreased left ventricular performance, with reversal by administration of a specific antagonist of the V_1 receptor.[50]

Diastolic dysfunction is characterized by left ventricular wall thickening with reductions in end-diastolic volume and impaired relaxation,[27] and appears to be maximal immediately after restoration of spontaneous circulation. The magnitude of diastolic dysfunction correlates closely with the magnitude of ischemic contracture,[51] suggesting a common pathogenic thread with diastolic dysfunction being a manifestation of resolving ischemic contracture. From a functional perspective, diastolic dysfunction may limit the compensatory ventricular dilatation required to overcome decreased contractility according to the Frank-Starling mechanism.

Postresuscitation myocardial dysfunction was first documented in humans by Deantonio and colleagues.[45] They reported on three female patients who were successfully resuscitated following transthoracic defibrillation after approximately 3, 10, and 30 minutes of cardiac arrest and who developed prominent left ventricular dilatation with reduction in fractional shortening within 3 days postresuscitation. None of these patients had coronary artery disease and ventricular function normalized within 2 weeks. Likewise, Ruiz-Bailen and coworkers reported severe postresuscitation myocardial dysfunction with reductions in left ventricular ejection fraction to 0.42 in 29 patients within the initial 24 hours postresuscitation.[52] In a subset of 20 patients who had left ventricular dysfunction, the ejection fraction decreased to 0.28 ($P < 0.05$). Patients who died had a significantly lower ejection fraction. Patients who survived gradually normalized their ejection fraction within an interval of approximately 4 weeks postresuscitation (Fig. 48.1).

Laurent and colleagues stratified 165 patients successfully resuscitated from out-of-hospital cardiac arrest based on whether hemodynamic instability was present within the initial 72 hours postresuscitation.[8] Hemodynamic instability was defined as hypotension requiring vasoactive drugs after fluid resuscitation. It occurred in 55% of the patients and was associated with longer resuscitation times, greater number of electrical shocks, larger amounts of adrenaline, and worse left ventricular function (Table 48.1). The incidence and severity of coronary artery disease was comparable between groups; however, a trend was noted towards a higher incidence of recent coronary occlusion in patients with hemodynamic instability. Myocardial dysfunction was initially accompanied by a low cardiac index (2.05 l/min per m^2) with elevated systemic vascular resistance (2908 dynes s/cm^5 per m^2). However, a hyperdynamic state developed during the ensuing 72 hours, characterized by increased cardiac index, decreased systemic vascular resistance, and the need for large amounts of fluids to maintain adequate filling pressures (Fig. 48.2).

The late hyperdynamic state reported by Laurent and coworkers is consistent with the development of a systemic inflammatory response akin to that observed during sepsis but precipitated by cardiac arrest and resuscitation.[53–55] Adrie and colleagues measured circulating cytokines in 61 victims of out-of-hospital cardiac arrest who were successfully resuscitated.[55] Measurements obtained at approximately 3 hours

Table 48.1. Factors associated with postresuscitation hemodynamic instability

	Hemodynamic stability (*n* = 75)	Hemodynamic instability (*n* = 73)	*P*
Resuscitation data			
Collapse to ROSC, min	15 (7–30)	25 (14–28)	< 0.01
Countershocks, *n*	2 (1–3)	3 (1–6)	< 0.01
Total epinephrine, mg	2 (0–10)	10 (3–15)	< 0.01
Angiography/ventriculography data			
Heart rate, beats/min	85 (48–118)	105 (75–143)	< 0.05
LVEF	0.43 (0.35–0.50)	0.32 (0.25–0.40)	< 0.01
LVEDP, mmHg	12 (5–25)	19 (10–32)	< 0.01
Recent coronary occlusion, %	37	51	0.06

ROSC = Return of spontaneous circulation; LVEF = Left ventricular ejection fraction; LVEDP = Left ventricular end diastolic pressure. Median (interquartile range). (Adapted from ref. 8.)
Fig. 48.1. Serial measurements of left ventricular ejection fraction by echocardiography in 29 patients successfully resuscitated from cardiac arrest (CA) without known cardiovascular disease – except for hypertension – and who survived a minimum of 72 hours. Patients had a median age of 65 years and 41% were females. Prearrest echocardiograms were available in 16 patients demonstrating a mean left ventricular ejection fraction of 0.60. Squares represent the entire cohort of 29 patients; circles represent a subset of 20 patients who had myocardial dysfunction. (Adapted from ref. 52.)

postresuscitation demonstrated prominent increases in plasma levels of tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-8, IL-10, soluble TNF receptor type II (sTNFII), IL-1 receptor antagonist (IL-1ra), and regulated on activation, normal T-cell expressed and secreted (RANTES). In a subset of 35 patients, increased endotoxin levels were detected in 46% within the initial 48 hours postresuscitation.

Underlying cell mechanisms: role of mitochondria

The underlying mechanism of cell injury is complex and probably time-sensitive. There are processes that develop shortly after onset ischemia and during reperfusion that lead to abnormalities in energy metabolism, acid base status, and intracellular ion homeostasis. Other processes

develop at a slower pace and encompass signaling mechanisms, leading to sustained disruption of energy production and contractile function with activation of apoptotic pathways. Discussion on the various cell mechanisms responsible for cell injury is beyond the scope of this chapter. Nonetheless, pertinent to our discussion is the growing evidence placing the mitochondria at the center of myocardial preservation, reperfusion injury, and postischemic dysfunction. Better understanding of mitochondrial injury may also serve to identify novel therapeutic strategies.[56–66]

Energy production

The mitochondria are organelles present in all eukaryotic cells that play an essential role in aerobic metabolism and generation of ATP. Mitochondria have an inner membrane that is highly impermeable and folds inwardly into the mitochondrial matrix, forming multiple cristae where proteins responsible for oxidative phosphorylation reside. The outer mitochondrial membrane is more porous and surrounds the inner mitochondrial membrane. Generation of energy in the form of ATP results from oxidation of NADH in the electron transport chain. This chain is composed of protein complexes assembled along the inner mitochondrial membrane where electrons are transferred down their redox potential while H^+ are pumped into the intermembrane space. The accumulation of H^+ establishes an electromotive force, which is used by F_oF_1 ATP synthase to form ATP from ADP and inorganic phosphate. ATP is then exported into the cytosol in exchange for ADP by the adenine nucleotide translocase (Fig. 48.3).

Disruption of the inner membrane permeability leads to reduction of the H^+ gradient, compromising the electromotive force required for ATP synthesis. Factors that may contribute to such injury during ischemia and reperfusion include mitochondrial Ca^{2+} overload and generation of reactive oxygen species (ROS) explaining decreased mitochondrial capability for regeneration of ATP.

Apoptotic signaling

In addition to the key role on energy production, mitochondria can also signal cell death by activation of the intrinsic apoptotic pathway through release of cytochrome *c*. Cytochrome *c* is a 14-kDa hemoprotein normally present in the intermembrane mitochondrial space that plays a key role by transferring electrons from complex III to complex IV (Fig. 48.3). Cytochrome *c* can be released to the cytosol, prompting the formation of an oligomeric complex with dATP and the apoptotic protease activating factor-1 (Apaf-1).[57] This complex recruits procaspase-9, forming the so-called apop-
Fig. 48.2. Serial measurements of cardiac index and systemic vascular resistance index (SVRI) in a subset of 73 patients who had hemodynamic instability after resuscitation from out-of-hospital cardiac arrest. A cumulative amount of 8,000 ml was required to maintain a pulmonary artery occlusive pressure > 12 mmHg. The mortality was 19 %. Median (interquartile range) *$P < 0.05$; † $P < 0.001$. (Adapted from ref. 8.)

tosome. In the apoptosome, procaspase-9 is activated and then released as caspase-9, which in turn, activates the executioner caspases 3, 6, and 7.[67,68] Active executioner caspases cleave several cytoplasmic proteins, including α-spectrin and actin, and nuclear proteins including poly (ADP-ribose) polymerase (PARP), lamin A, and the inhibitor of caspase-activated DNase (ICAD). Cleavage of ICAD leads to activation of caspase activated DNase (CAD), which in turn cleaves chromatin into 180 to 200 bp fragments. Other substrates activated during apoptosis include components of DNA repair machinery and a number of protein kinases,[67] ultimately culminating in cell death.

Various mechanisms have been proposed to explain cytochrome *c* release. One mechanism involves opening of a high-conductance mega channel formed by apposition of transmembrane proteins from the inner and the outer mitochondrial membrane known as the mitochondrial permeability transition pore (MPTP).[59] Opening of the pore allows molecules up to 1.5 kDa to enter the mitochondrial matrix along with water and solutes, leading to mitochondrial swelling with stretching and disruption of the outer mitochondrial membrane, ultimately causing
Fig. 48.3. Scheme depicting the structural organization of the electron transport chain, the mitochondrial permeability transition pore (MPTP), and the F_oF_1 ATP synthase in relation to the inner and outer mitochondrial membranes. PBR = peripheral benzodiazepine receptor; VDAC = voltage dependent anion channel; HK = hexokinase; CK = creatine kinase; ANT = adenine nucleotide translocase; CypD = cyclophilin-D; I, II, III, and IV = respiratory complexes; Q = coenzyme Q; C = cytochrome *c*; OMM = outer mitochondrial membrane; IMS = intermembrane space; IMM = inner mitochondrial membrane; ΔpH = pH gradient; ΨΔ = mitochondrial membrane potential. (Adapted from Gross A *et al. Genes Dev* 1999;13:1899 and Kim JS *et al. Biochem Biophys Res Commun* 2003;304:463.)

release of cytochrome *c*.[59] Pathophysiological conditions responsible for opening of the MPTP include Ca^{2+} overload, production of reactive oxygen species (ROS), depletion of ATP and ADP, increases in inorganic phosphate, and acidosis.[59] Cytochrome *c* can also be released without MPTP opening through formation of pores in the outer mitochondrial membrane. This is best explained by permeabilization of the outer membrane by pro-apoptotic proteins such as Bcl-2–associated X protein (Bax), Bcl-2 homologous antagonist killer (Bak), or truncated BH3 interacting domain death agonist (Bid).[69] Anti-apoptotic proteins such as Bcl-2, Bcl-x, and Bcl-w, however, may play important roles by counterbalancing the aforementioned pro-apoptotic effects.[70]

Mitochondrial Ca²⁺

Mitochondrial Ca^{2+} overload plays a critical role during ischemia and reperfusion. Ca^{2+} normally enters the mitochondria through a Ca^{2+} uniporter and leaves through a Na^+-Ca^{2+} exchanger located in the inner mitochondrial membrane. This transport mechanism enables changes in cytosolic Ca^{2+} to be relayed to the mitochondrial matrix and thus regulate the activity of various enzymes of the tricarboxylic acid cycle. Increases in cytosolic Ca^{2+} during ischemia prompt mitochondrial Ca^{2+} increases leading to production of reactive oxygen species (ROS). ROS cause peroxidation of cardiolipin, which is the principal lipid constituent of the inner mitochondrial membrane and to which a fraction of cytochrome *c* is bound. Peroxidation decreases the binding affinity of cardiolipin for cytochrome *c*,[71] facilitating its release out of the mitochondria. Modest increases in extramitochondrial Ca^{2+} (i.e., $2\,\mu M$) cause cytochrome *c* release without MPTP opening. At higher Ca^{2+} levels (i.e., $20\,\mu M$), ROS and Ca^{2+} acting together prompt MPTP opening, presumably through oxidative injury of the adenine nucleotide translocase. Both mechanisms of cytochrome *c* release can be prevented by blocking the mitochondrial Ca^{2+} uniporter with ruthenium red.[72]

Link to myocardial dysfunction

Mounting evidence suggests that acute modifications of regulatory proteins of the contractile apparatus occur through cleavage of specific components[73,74] following intracellular Ca^{2+} increase and activation of proteases such as calpain-1 and caspase-3.[75–78] Communal and colleagues reported that activated caspase-3 cleaves α-actin and α-actinin but not myosin heavy chain, myosin light chain 1/2, and tropomyosin.[77] Incubation of recombinant troponin (Tn) complex with caspase-3 selectively cleaved cardiac TnT, resulting in 25-kDa fragments. Functionally, activated caspase-3 decreases maximal Ca^{2+}-activated force and myofibrillar ATPase activity, suggesting that activation of apoptotic pathways may lead to contractile dysfunction. Radhakrishnan and coworkers recently demonstrated activation of caspase-3 in left ventricular homogenates of rat hearts harvested at 4 hours postresuscitation coincident with left ventricular dysfunction.[79] In models of VF and coronary occlusion, Ca^{2+} overload was associated with decreases in the Ca^{2+}-force relationship presumably following modifications in the interaction between proteins of the troponin complex.[80,81] Zaugg and coworkers specifically demonstrated, in a model of prolonged untreated VF, prominent cytosolic Ca^{2+} increases leading to reduced Ca^{2+} sensitivity of troponin, TnC and impaired contractility.[82] Similarly, Barta and coworkers demonstrated cleavage of TnI and TnT following activation of calpain-1.[78] In addition, these proteases have also been shown to cleave structural proteins such as titin, α-actinin, α-fodrin, and desmin.[83–85]

Various novel pharmacological interventions that have been investigated in the setting of cardiac arrest (and are discussed below) seem to protect the myocardium by limiting mitochondrial Ca^{2+} overload. Postresuscitation myocardial dysfunction, as pointed out earlier, is largely a reversible phenomenon. It is less clear, however, whether dysfunction and cell death represent part of a continuum manifesting varying degrees of severity. Much work remains before we can fully elucidate the process of ischemic injury and postischemic dysfunction. Meanwhile, understanding the mechanisms that affect mitochondrial function and its signaling of apoptosis may provide an opportunity for developing new resuscitation therapies.

Factors contributing to myocardial injury

Factors that contribute to myocardial injury during cardiac resuscitation include the duration of cardiac arrest, the delivery of electrical shocks, and the use of adrenergic vasopressor agents. Efforts to shorten the duration of the cardiac arrest by prompt recognition and rapid intervention are thus important to minimize injury. Likewise, delivery of quality cardiopulmonary resuscitation (CPR) may help reduce the duration of tissue ischemia by prompting earlier return of spontaneous circulation. Quality CPR may be attained by paying close attention to the rate, depth, and site of compression, minimizing the interruptions required to secure the airway, verify rhythm, and deliver shocks. In addition, adequate venous return is essential for hemodynamically effective chest compression, which can be secured by allowing full re-expansion of the chest cavity, avoiding hyperventilation, and creating an intrathoracic vacuum between compressions by using impedance threshold devices.[86] The following sections address the potential detrimental effects of electrical shocks and adrenergic vasopressor agents along with options to minimize such injury.

Electrical defibrillation

Delivery of electrical shocks during the resuscitation effort may contribute to myocardial injury and worsen postresuscitation electrical and mechanical dysfunction.[87–89] Manifestations of such injury include increased postresuscitation ectopic activity, atrioventricular block, and worsened postresuscitation myocardial dysfunction.[90] Key factors that determine injury include the energy level, number of shocks, and defibrillation waveforms.

Energy level

The presence and severity of myocardial injury is influenced by the amount of energy delivered to the myocardium. In an isolated perfused rabbit heart, Koning and coworkers reported minimal injury after epicardial shocks of 0.6 joule/cm^2. Nevertheless, as the energy was increased to up to 4.2 joule/cm^2 additional and more severe injury developed, including impaired systolic function, myocardial stiffness, release of creatine kinase, and cell necrosis.[91] Similarly, Doherty and coworkers found that significant myocardial injury, as evidenced by creatine kinase release, increased technetium-99m pyrophosphate uptake, and decreased thallium-201 and indium-113m uptake, developed only when the energy of shocks delivered directly to beating canine hearts (15- to 26-kg dogs) exceeded 20 joules.[92] The injury was characterized by dehiscence of intercalated disks between damaged myocytes. Kerber and coworkers, also in dogs, reported contractile abnormalities only when the energy of epicardial shocks was 40 Joules or more in 17- to 45-kg dogs.[93] In the cardiac arrest setting, Xie and coworkers using an intact

rat model of VF reported that postresuscitation myocardial dysfunction worsened in close relationship to stepwise increases in the energy used for external defibrillation from 2, to 10, and to 20 Joules.[89] It is important to realize, however, that the energy required to reverse VF is typically below the threshold at which significant myocardial cell injury occurs.[94]

The mechanisms of cell injury following electrical shocks relate in part to increased cytosolic Ca^{2+}. In single-isolated, cultured chick-embryo heart cells, exposure to defibrillator-type electrical shocks causes reversible depolarization followed by intensity-independent Ca^{2+} entry, attributed to opening of normal excitation channels, and intensity-dependent Ca^{2+} entry attributed to cell damage.[95] Further evidence that Ca^{2+} may play a role stems from observations in dogs in which prior administration of the Ca^{2+} channel blocker verapamil – but not the beta-blocker propranolol – attenuates the myocardial injury caused by transthoracic countershocks.[96]

Number of shocks

Multiple shocks are often required to terminate VF. Yet, repetitive electrical shocks may cause myocardial injury beyond that which is caused by individual shocks.[88,90,92,97] Injury may manifest by worsened diastolic dysfunction postresuscitation, despite no adverse effects on postresuscitation systolic function.[98] Thus, efforts to limit the number of electrical shocks are warranted. Until recently, delivery of electrical shocks immediately upon recognition of VF was regarded as an essential component of the chain of survival. Observations in a dog model of VF by Niemann and coworkers[99] and studies in victims of out-of-hospital sudden cardiac arrest by Cobb and coworkers[100] and by Wik and coworkers,[101] however, have challenged such an approach, suggesting that a period of chest compression before attempting defibrillation under conditions of prolonged untreated VF may improve the myocardial responsiveness to electrical shocks. The 2005 guidelines for cardiopulmonary resuscitation recommend that CPR be given for approximately 2 minutes before attempting electrical defibrillation when the ambulance response time is prolonged (i.e., > 4 minutes). Moreover, the same recommendation states that only a single shock be given and that CPR be resumed without a pulse check. These recommendations recognize that untimely delivery of electrical shocks may be detrimental to the resuscitation efforts, in part because of interruption in chest compression and because the ischemic myocardium seems to tolerate poorly the repetitive delivery of electrical shocks.

A more optimal approach would be to guide the timing of defibrillation based on real-time analysis of the VF waveform. Previous studies have recognized the value of measuring the amplitude and frequency characteristics of VF waveforms to estimate the duration of untreated VF,[102] assess myocardial energy metabolism,[103] and predict the response to defibrillation attempts.[104,105] Waveform analysis that incorporates amplitude and frequency in a single index has been demonstrated experimentally to have better positive and negative predictor power than VF amplitude and frequency alone.[106] Use of these indices in real-time could allow better targeting of individual shocks, thus avoiding the delivery of shocks when the probability of success is low.

Defibrillation waveforms

Until recently, delivery of electrical shocks by external (transthoracic) defibrillators used monophasic exponential waveforms, but the advent of implantable cardioverter-defibrillators introduced into clinical practice the use of biphasic truncated exponential waveforms. Biphasic waveforms have proven to be more effective for terminating VF and less damaging to the myocardium than monophasic waveforms. In a study of 40- to 45-kg pigs subjected to 10 minutes of VF, Tang and coworkers[107] reported comparable defibrillation efficacy by biphasic (fixed 150-joule) and monophasic (escalating 200-, 300-, and 360-joule) shocks. Biphasic waveform defibrillation was associated with significantly less postresuscitation myocardial dysfunction, as evidenced by lesser postresuscitation reductions in stroke volume, cardiac output, and ejection fraction. In contrast, Niemann and coworkers[37] using 26- to 36-kg pigs subjected to 5 minutes of untreated VF reported comparable defibrillation success using biphasic (fixed 150-joule) and monophasic (escalating 200-, 300-, and 360-joule) shocks without differences in postresuscitation myocardial or hemodynamic function. It is possible that the competitive advantage of biphasic waveform defibrillation occurs at lower energy levels than those that were used in this experimental setting.

In a recent clinical trial, fixed 150-joule impedance-compensating, biphasic truncated exponential defibrillation waveforms were compared with monophasic (truncated exponential or damped sine) defibrillation waveforms in 115 victims of out-of-hospital VF.[108] Biphasic waveform defibrillation was associated with significantly higher rates of successful defibrillation (100% vs. 84%, $P = 0.003$) and return of spontaneous circulation (76% vs. 54%, $P = 0.01$), but not hospital admission (61% vs. 51%, *NS*) or survival (28% vs. 31%, *NS*). Although a larger sample size would be required to assess effects on survival outcomes, hospital survivors who had received biphasic waveform defibrillation were noted to have better neurological out-

comes. This observation was attributed to possible earlier restoration of spontaneous circulation with biphasic waveform defibrillation. Larger clinical trials are awaited to assess impact on hospital survival.

Vasopressor agents

Although a prominent neuroendocrine vasoconstrictive response occurs during cardiac arrest that reduces distal aortic runoff, enabling preferential perfusion of the coronary and cerebral circuits, this response is limited, and exogenous vasopressor agents are typically required to secure increases in the coronary perfusion pressures above critical resuscitability thresholds. For this purpose, the American Heart Association recommends the use of either adrenaline or vasopressin. Studies have shown, however, that adrenaline under these low-flow conditions may not only fail to improve the myocardial energy deficit despite increases in coronary blood flow,[109] but may actually intensify ischemic injury and worsen postresuscitation myocardial dysfunction and survival.[110,111] These adverse effects of epinephrine are attributed to stimulation of β-receptors whereby the myocardial oxygen requirements are disproportionately increased during cardiac arrest[109] and can be minimized experimentally by using β-blocking agents.[112] In a rat model of VF and closed-chest resuscitation,[111] use of the β1-blocking agent esmolol in conjunction with epinephrine ameliorated the severity of postresuscitation myocardial dysfunction. Similar effects have been documented in larger animal models of cardiac arrest.[112,113] Even administration of the selective β1-blocker esmolol alone during chest compression has been shown to ameliorate postresuscitation myocardial dysfunction (Fig. 48.4).[114]

Notwithstanding the adverse effect of adrenergic agents under the low blood flow conditions of standard CPR, provocative studies by Angelos and coworkers suggest that epinephrine may be effective and devoid of its adverse effects when used in association with hemodynamically more effective resuscitation techniques.[115]

An alternative approach is the use of non-adrenergic vasopressor agents such as vasopressin. This agent appears to be more potent than epinephrine and to lack adverse effects on myocardial energy metabolism.[116] Nonetheless, vasopressin has a longer half-life and the vasopressor effects persist during the postresuscitation interval, leading to adverse effects on blood flow to various regional tissue beds. The vasopressor effect may also compromise myocardial performance by increasing afterload.[50]

More recently, activation of α2- receptors has emerged as a promising new experimental approach. These receptors are expressed in pre- and postsynaptic junctions of vascular smooth cells. Activation of presynaptic α2-receptors inhibits the release of norepinephrine. Activation of postsynaptic α2-receptors promotes peripheral vasoconstriction. Studies in rat and pig models of VF and closed-chest resuscitation have shown that administration of the α2-receptor agonist α-methyl-norepinephrine during chest compression is associated with less postresuscitation myocardial dysfunction when compared to epinephrine.[117,118] Activation of these receptors in Purkinje cells has been shown to reduce reperfusion arrhythmias in rats after left anterior descending coronary artery occlusion and reperfusion.[119] These effects have been linked to signaling via G-protein, causing attenuation in intracellular cyclic adenosine monophosphate levels.

Novel experimental therapies

The realization that ischemia and reperfusion activates a myriad of pathogenic pathways has persuaded researchers to investigate whether targeting such pathways may protect the myocardium and minimize postresuscitation myocardial dysfunction. Some of these studies are described below exposing the specific mechanisms of injury targeted.

Sarcolemmal Na$^+$–H$^+$ exchange

Increased sarcolemmal Na$^+$ influx with subsequent intracellular Na$^+$ overload due to the inability of the Na$^+$–K$^+$ pump to extrude Na$^+$ during myocardial ischemia has been recognized as an important pathogenic mechanism of cell injury during ischemia and reperfusion.[120–122] Na$^+$ becomes a "substrate" for reperfusion injury[123] and intensifies processes detrimental to cell function primarily by promoting sarcolemmal Ca^{2+} entry through the Na$^+$–Ca^{2+} exchanger (NCX) acting in its reverse mode.[124]

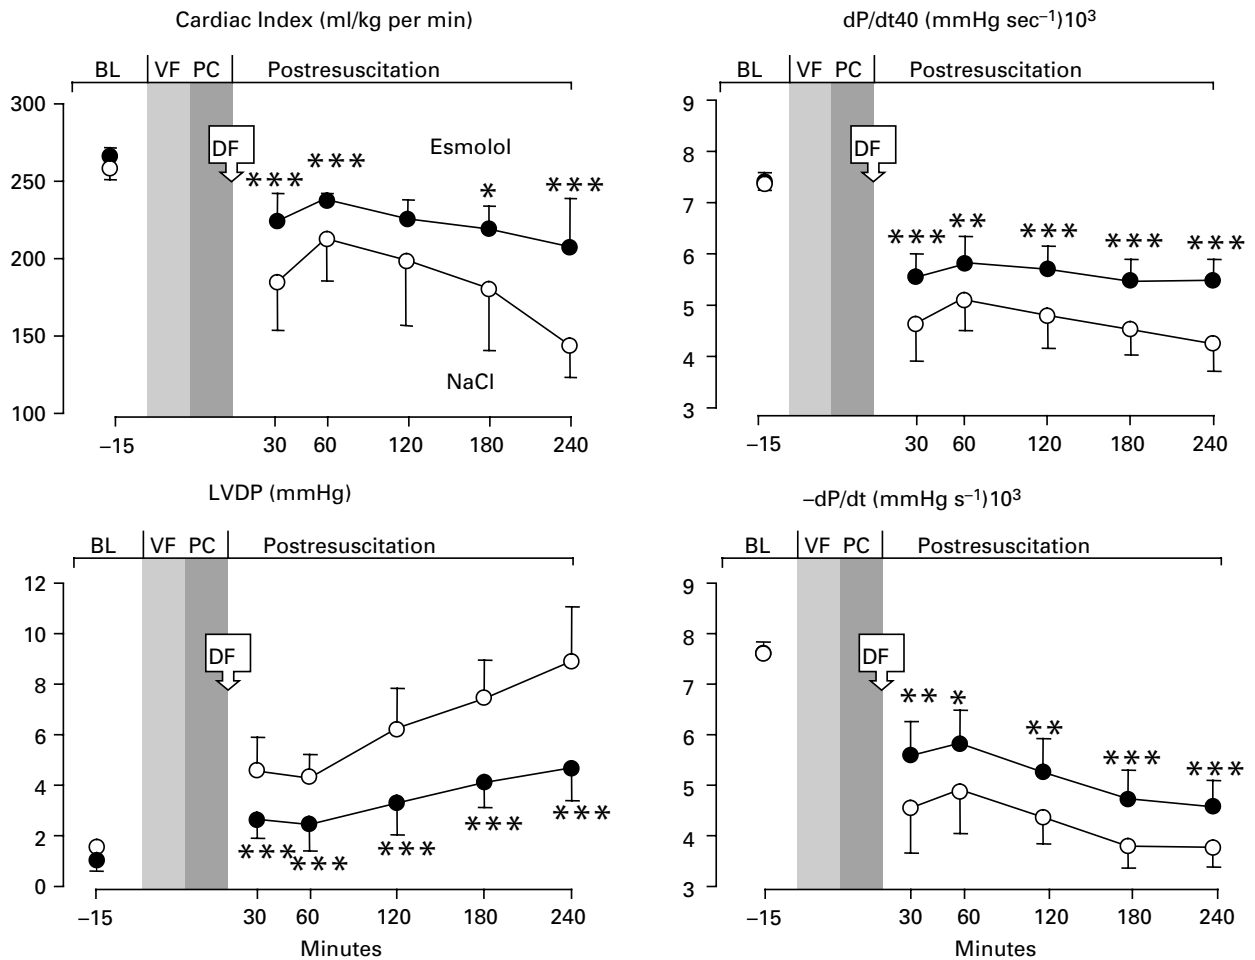
The conditions that develop during cardiac arrest are uniquely poised to trigger maximal and sustained NHE-1 activity. The intense intracellular acidosis that develops during ischemia is the initial trigger for NHE-1 activation. The subsequent resuscitation attempt, with closed-chest techniques, promotes reperfusion with coronary flows that rarely exceed 20% of normal. These low blood flow levels are not sufficient to reverse ischemia,[125] but are sufficient to supply the coronary circuit with normo-acidic blood, hence washing out the excess of extracellular protons favoring a trans-sarcolemmal proton gradient that maintains


Fig. 48.4. Myocardial effects of β_1-adrenergic blockade during closed-chest resuscitation in a rat model of VF. Esmolol (300 μg/kg, $n=9$) or NaCl 0.9% ($n=9$) was given into the right atrium at the second minute of precordial compression (PC) after a 6-minute interval of untreated VF. All esmolol-treated rats but only 5 controls were successfully resuscitated. Closed symbols represent esmolol ($n=9$); open symbols represent control ($n=5$). BL = Baseline; LVDP = Left ventricular diastolic pressure. dP/dt_{40} = rate of left ventricular pressure rise at left ventricular pressure of 40 mmHg; – dP/dt = rate of left ventricular pressure decline. Mean ± SD. *$P<0.05$; **$P\leq0.03$; *** $P<0.01$ vs. NaCl. (Adapted from Cammarata G *et al. Crit Care Med* 2004;32:S440.)

NHE-1 activity throughout the resuscitation effort and probably the initial postresuscitation phase.

Administration of selective NHE-1 inhibitors, such as cariporide, has been shown consistently to ameliorate myocardial injury during cardiac resuscitation.[25,27,33,126–129] In an intact pig model, cariporide reduced ischemic contracture during chest compression such that there was less ventricular wall thickening and better preservation of cavity size. This effect enabled chest compression to generate and maintain a coronary perfusion pressure above the threshold for resuscitability and to augment the hemodynamic efficacy of vasopressor agents.[27,128,129] Cariporide also ameliorated postresuscitation ventricular ectopic activity, prevented episodes of recurrent VF, and minimized

postresuscitation myocardial dysfunction (Fig. 48.5).[25,27] Although cariporide inhibits sarcolemmal NHE-1 and ameliorates cytosolic Na$^+$ and Ca^{2+} overload, recent evidence suggests that protection may also involve direct effects on the mitochondria by preserving the inner membrane H$^+$ gradient and delaying ATP depletion.[130]

The potential clinical applicability of NHE-1 inhibitors has been halted for the moment. A recent clinical trial in patients undergoing coronary artery bypass graft surgery demonstrated increased incidence of cerebrovascular occlusive events and higher overall mortality despite a significant reduction in non-fatal postoperative myocardial infarction.[131] Although information on the mechanism of this adverse effect of cariporide is not currently
Fig. 48.5. Postresuscitation hemodynamic and left ventricular function in pigs randomized to receive cariporide (3 mg/kg, open bars, $n = 4$) or NaCl 0.9% (closed bars, $n = 4$) immediately before starting chest compression after a 6-minute interval of untreated VF. Each animal was successfully defibrillated after 8 minutes of closed-chest resuscitation and observed for 60 minutes postresuscitation. Mean ± SEM. *$P < 0.05$ vs. baseline (BL) by repeated measures ANOVA; †$P < 0.05$ vs. cariporide by one-way ANOVA. (Adapted from ref. 27.)

available, it appears to be unrelated to the mode of action. Development of newer compounds is anticipated.

K$^+_{ATP}$ channel activation

Interventions aimed at activating known mechanisms of preconditioning during cardiac resuscitation may have favorable effects on postresuscitation myocardial dysfunction. One important mechanism of ischemic preconditioning that can be emulated pharmacologically involves opening of mitochondrial K$^+_{ATP}$ channels.[132–135] Opening of K$^+_{ATP}$ channels leads to increased K$^+$ conductivity of the inner mitochondrial membrane, an effect that is bioenergetically beneficial[136] and limits mitochondrial Ca^{2+} overload.[137] In a rat model of VF and closed chest resuscitation, administration of the K$^+_{ATP}$ channel opener cromakalim reduced postresuscitation myocardial function despite a significant reduction in coronary perfusion pressure during chest compression.[138] The favorable effect on postresuscitation myocardial function was comparable to

that of preconditioning and manifested by a higher postresuscitation +dP/dt$_{40}$, -dP/dt$_{max}$, cardiac index, and longer postresuscitation survival.

δ-Opioid receptor activation

Activation of δ-opioid receptors has been shown to play an important role in hibernation, leading to reductions in myocardial oxygen consumption. Activation of δ-opioid receptors, and more specifically δ$_1$- and δ$_2$- receptors, has been shown to ameliorate postischemic myocardial dysfunction and to preserve ultrastructural integrity in chick cardiomyocytes and isolated perfused rabbit hearts.[139,140] Sun and coworkers investigated, in a rat model of VF and closed-chest resuscitation, the effect of administering the δ-opioid receptor agonist pentazocine.[141] Administration of pentazocine was associated with significantly lower postresuscitation arterial lactate and less postresuscitation myocardial dysfunction, evidenced by a higher +dP/dt$_{40}$, -dP/dt$_{max}$, and cardiac

index. These effects were abrogated by pretreatment with naloxone.

Lazaroids

Lazaroids are 21-aminosteroid molecules that inhibit lipid peroxidation and scavenge oxygen free radicals.[142–144] Studies in a canine model of cardiac transplantation have shown that the lazaroid compound U-74389G given before reperfusion improves post-transplantation myocardial function.[145] Studies in a rat model of VF and closed chest resuscitation demonstrated that administration of U-74389G before chest compression ameliorates postresuscitation myocardial dysfunction as evidenced by a higher cardiac index and higher $+ dP/dt_{40}$ and a lower left ventricular end diastolic pressure with increased postresuscitation survival time.[146] Administration of the lazaroid was also associated with significantly fewer premature ventricular complexes. These studies suggest that antioxidants may play a role during cardiac resuscitation, further supporting the pivotal role of mitochondria for cardiac resuscitation.[72]

Erythropoietin

Erythropoietin is a 30.4-kDa glycoprotein best known for its action on erythroid progenitor cells and regulation of circulating red cell mass.[147] Within the past few years, however, investigators have reported that erythropoietin also signals survival responses during ischemia and reperfusion in a broad range of tissues including the heart.[148–157] Some of these protective actions are induced immediately upon administration and result in attenuating of ischemia and reperfusion injury even when given after the onset of ischemia and at the time of reperfusion,[154,156,158,159] suggesting that erythropoietin could be beneficial for cardiac resuscitation. Administration of human recombinant erythropoietin in a rat model of prolonged VF (5000 U/kg) at the start of closed-chest resuscitation enabled hemodynamically more effective chest compression and improved postresuscitation hemodynamic function.[160]

Management of postresuscitation myocardial dysfunction

The current approach to cardiac resuscitation emphasizes the prompt reversal of the precipitating cause of cardiac arrest (i.e., terminating VF or correcting hypoxemia) and the generation, by external means, of blood flow across the coronary circuit. This paradigm, however, does not include specific interventions aimed at myocardial protection and prevention of postresuscitation myocardial dysfunction. Yet, as pointed out earlier, opportunities exist to minimize myocardial injury by reducing the time interval for initiating CPR, and by providing quality CPR that can promote higher coronary blood flows. In addition, strategies aimed at more precise timing of shock delivery could minimize injury by avoiding repetitive defibrillation attempts. Regarding vasopressor agents, it is to be hoped that quality CPR might enable more judicious use of vasopressor agents by avoiding excessive dosing, and development of more effective and less toxic vasopressor agents is eagerly awaited. Of increasing interest is the possibility that β-adrenoceptor blocking agents administered during cardiac resuscitation may prevent injury stemming from endogenous and exogenous adrenergic stimulation; clinical studies are awaited to support this concept. The experimental agents shown above to be effective in various animal models of cardiac arrest support the concept that targeting pathways to ischemic injury may be effective. Yet, again, clinical data are awaited.

Recognition and assessment of myocardial dysfunction

Although critical care and emergency medicine physicians are well-trained to recognize and treat acute heart failure, it is not clear that myocardial dysfunction is commonly deemed a diagnostic possibility after an episode of cardiac arrest. Thus, it is important to consider postresuscitation myocardial dysfunction in every patient successfully resuscitated from cardiac arrest. Equally important is to recognize that such dysfunction is potentially reversible, thus justifying efforts to support the failing myocardium until competent pump function resumes. Assessment of postresuscitation myocardial dysfunction follows conventional practice and includes recognition of the classical symptoms and signs of pulmonary vascular congestion and reduced forward blood flow. Accordingly, the assessment should include, at the very least, a focused history and physical examination, a 12-lead electrocardiogram, a chest x-ray, and routine blood tests. Postresuscitation myocardial dysfunction should be suspected in the presence of increased heart rate, decreased arterial blood pressure and cardiac output, and arrhythmias, especially those of ventricular origin. Evaluation of cardiac function and morphology by echocardiography may be critical to establish the presence of and to quantify the severity of myocardial dysfunction. In addition, echocardiography may serve to identify associated conditions such as cardiac tamponade, myocardial infarction, papillary muscle rupture, pulmonary embolism, ruptured aorta, and aortic dissection.[161,162]

Further diagnostic work is dictated by the clinical course and may include the use of a pulmonary artery catheter to assess filling pressures and cardiac output more precisely. As previously discussed, a pattern of myocardial dysfunction found early after successful resuscitation may evolve into a hyperdynamic state as systemic inflammation unfolds (Fig. 48.2). Recognition of this transition is important, because the management is substantially different and large amounts of fluids may be required to ensure hemodynamic stability.

Inotropic interventions

The stunned myocardium is responsive to inotropic stimulation and therefore pump function may be improved by administration of traditional inotropic agents such as β-agonists (i.e., dobutamine) and phosphodiesterase inhibitors (i.e., milrinone). Dobutamine acts primarily on β_1-, β_2-, and α-receptors. Its hemodynamic effects include increases in stroke volume and cardiac output, with decreases in systemic and pulmonary vascular resistance. Studies in animal models of cardiac arrest have demonstrated substantial reversal of postresuscitation

systolic and diastolic dysfunction by using doses ranging between 5 and 10 μg/kg per minute (Fig. 48.6).[163–165] A dose of 5 μg/kg/minute was found in domestic pigs (24 ± 0.4 kg) to provide the best balance, by restoring postresuscitation systolic and diastolic function without adverse effects on myocardial oxygen consumption.[164] Phosphodiesterase inhibitors such as milrinone also exert inotropic and vasodilator effects and have been shown experimentally to improve postresuscitation myocardial dysfunction.[166] Nevertheless, the effectiveness of conventional inotropic agents may be limited by effects on heart rate and the possibility of worsening ischemic injury in settings of critically reduced coronary artery blood flow.

Conventional inotropic agents act by increasing cAMP after stimulation of β-adrenergic receptors or after inhibition of phosphodiesterases. Increased cAMP levels, in turn, signal phosphorylation of several Ca^{2+} regulatory proteins (i.e., L-type Ca^{2+} channels, phospholamban, the ryanodine receptor, TnI, and the myosin binding protein) leading to increased cytosolic Ca^{2+} cycling. Of note, Ca^{2+} cycling consumes energy and may predispose to ventricular arrhythmias. An alternative approach, therefore, is to
Fig. 48.6. Reversal of postresuscitation myocardial dysfunction by administration of dobutamine in a pig model of VF. VF was untreated for 15 minutes before attempting resuscitation by cardiopulmonary resuscitation including advanced life support and administration of epinephrine. Dobutamine was started at 15 minutes postresuscitation. Mean ± SEM. *$P < 0.05$ control. (Adapted from ref. 163.)

mediate inotropic responses by augmenting the sensitivity of the contractile apparatus to Ca^{2+} acting on TnC and downstream regulatory proteins,[167] so as to exert positive inotropic actions without increasing cAMP or cytosolic Ca^{2+}.

Agents that promote inotropy through these mechanisms are known as Ca^{2+} sensitizers. They are energetically more favorable[168] and are potentially devoid of Ca^{2+}-mediated arrythmogenic effects.[169] One compound, levosimendan, acts by binding to the N-terminal domain of TnC in a Ca^{2+}-dependent manner. Levosimedan was shown by Huang and colleagues in a pig model of VF and closed-chest resuscitation to improve postresuscitation myocardial function, resulting in greater increases in ejection fraction and greater reductions in pulmonary artery occlusive pressure when compared to dobutamine.[170] Further work, however, is required to define dose-response relationships, interactions with underlying coronary and myocardial disease, and the conditions under which inotropic stimulation may help manage postresuscitation myocardial dysfunction and improve outcome.

This book chapter is dedicated to Peter Safar, the father of modern resuscitation, and world leading pioneer in the field of therapeutic hypothermia.

Introduction

The history of induced hypothermia began in the 1950s with elective moderate hypothermia of the brain, introduced under anesthesia, for the protection–preservation during brain ischemia needed for surgery on heart or brain.[1,2] In the early 1960s, Peter Safar recommended the use of therapeutic resuscitative hypothermia for humans after cardiac arrest in his cardiopulmonary–cerebral resuscitation algorithm.[3] At this time, it was thought that moderate hypothermia (28–32 °C) was required for brain protection. Resuscitative hypothermia research was then given up for 25 years, as experimental and clinical trials had been complicated by the injurious systemic effects of total body cooling, such as shivering, vasospasm, increased plasma viscosity, increased hematocrit, hypocoagulation, arrhythmias, and ventricular fibrillation, when temperatures dropped below 30 °C, and lowered resistance to infection during prolonged moderate hypothermia.[4–7] Moderate hypothermia was too difficult to induce and to maintain.

Peter Safar deserves most of the credit that mild therapeutic hypothermia was re-discovered in the mid 1980s. When he considered the reasons for various outcomes with the same durations of cardiac arrest in his dog experiments, he observed that relatively small differences in brain temperature in the range of mild hypothermia (33–36 °C) at the start of the experiments had a major influence on neurologic outcome. He and his research group then confirmed these observations in systematic studies of mild hypothermia before, during, and after cardiac arrest in dogs.[8–12]

Fritz Sterz, who was research fellow in Safar's laboratory at this time, initiated after his return to Vienna the Hypothermia After Cardiac Arrest (HACA) European multicenter trial in the mid 1990s.[13] This landmark study, together with the Australian study by Bernard,[14] led to the recommendation to use mild hypothermia in patients resuscitated from cardiac arrest by the European Resuscitation Council[15] and the American Heart Association[16] in 2005, more than 40 years after the first recommendation by Peter Safar.

This chapter reviews the current status of therapeutic mild hypothermia in cardiac arrest. Laboratory and clinical studies are described, potential mechanisms and side effects of hypothermia, and cooling methods to induce mild hypothermia. The influence of mild hypothermia on the prediction of neurologic outcome after cardiac arrest is presented. In the conclusion, recommendations for the current use of hypothermia and recommendations for future laboratory and clinical research are given.

Therapeutic mild hypothermia

Animal outcome studies (Behringer)

This section documents the background of therapeutic hypothermia with regard to animal models with cardiac arrest or vessel occlusion that led to the recent trials of therapeutic hypothermia after cardiac arrest in humans.[13,14,17–21]

Protective hypothermia, induced before cardiac arrest, is differentiated from *preservative* hypothermia, induced during cardiac arrest, and from *resuscitative* hypothermia, induced after resuscitation from cardiac arrest. The first animal studies of *resuscitative* hypothermia after cardiac arrest were reported in the 1950s.[22,23]

Protective-preservative hypothermia

Therapeutic hypothermia was rediscovered in the mid-1980s, when Hossmann reported the beneficial effect of mild hypothermia, unintentionally induced before the experiment, on EEG recovery in cats subjected to 1 hour of global brain ischemia, followed by blood recirculation for 3 hours or longer.[24] At the same time, Safar analysed the outcome data of several cardiac arrest dog studies, and found that dogs that were mildly hypothermic at the beginning of the experiment showed better neurologic outcome than dogs that were normothermic at the beginning of the experiment.[25] These observations were followed by controlled randomized animal studies in various laboratories. In dogs, ventricular fibrillation cardiac arrest of 12.5-minute no-flow was accompanied by head immersion in ice water (which reduced brain temperature by only 1 °C) and followed by reperfusion cooling with brief cardiopulmonary bypass to 34 °C for 1 hour; functional and morphologic brain outcome variables were significantly improved in the hypothermic groups 4 days after the insult.[8] Busto and colleagues found in a 20-minute four-vessel occlusion rat model that small increments of intra-ischemic brain temperature (33°, 34°, 36°, or 39 °C) markedly accentuated histopathological changes following 3-day survival, despite severe depletion of brain energy metabolites during ischemia at all temperatures.[26] Siesjö and colleagues confirmed the beneficial effects of intra-ischemic hypothermia in a two-vessel occlusion rat model with various durations of ischemia by showing that intentional lowering of brain temperature from 37° to 35 °C markedly reduced and to 33 °C virtually prevented neuronal necrosis.[27]

Importantly, the benefit of intra-ischemic mild to moderate hypothermia on neuronal death is regarded as long-lasting. Green and colleagues found in a 12.5-minute four-vessel occlusion rat model that intra-ischemic hypothermia to 30 °C protected from behavioral deficits and neuronal injury for up to 2 months.[28] This longlasting effect of intra-ischemic hypothermia was confirmed by the same group in a 10-minute two-vessel occlusion rat model,[29] and by Corbett and colleagues in a 5-minute global ischemia gerbil model with brain temperature to 32 °C.[30]

Resuscitative hypothermia

The rediscovery of protective-preservative mild to moderate hypothermia in brain ischemia led to widespread research of *resuscitative* mild to moderate hypothermia in several animal models in the 1990s. Safar and colleagues conducted a systematic series of outcome studies in dogs of prolonged normothermic cardiac arrest followed by mild resuscitative cerebral hypothermia (34 °C), induced immediately after reperfusion and maintained for 2–3 hours[9,10,12] or 12 hours.[11] Controlled ventilation was maintained for 24 hours, and intensive care was provided for 3 to 4 days, with final evaluation of neurologic outcome and histologic damage in various brain regions. In one study,[9] ventricular fibrillation cardiac arrest after 10-minute no-flow was reversed by standard external cardiopulmonary resuscitation; cooling to 34 °C for 2 hours with a combination of head-neck-trunk surface cooling, plus cold fluid loads administered intravenously, intragastrically, and nasopharyngeally, was induced in one group at the beginning of resuscitation, and in another group after restoration of spontaneous circulation. In both groups, neurologic recovery in terms of histologic damage and functional outcome was improved compared to that in control animals. Next,[10] ventricular fibrillation cardiac arrest of 12.5-minutes no-flow was reversed by brief cardiopulmonary bypass; immediate mild (34 °C) or moderate (30 °C) hypothermia, induced with bypass, for 1 hour improved functional and morphologic brain outcome, but deep postarrest hypothermia (15 °C) did not improve function and worsened brain histology. In the next study,[12] ventricular fibrillation cardiac arrest of 12.5-minute no-flow was reversed by brief cardiopulmonary bypass; delaying cooling (to 34 °C for 1 hour) until 15 minutes after normothermic reperfusion did not improve functional outcome but histologic damage. Finally,[11] ventricular fibrillation cardiac arrest of 11-minute no-flow was reversed by brief cardiopulmonary bypass; a combination treatment of mild hypothermia by head-neck-surface cooling plus peritoneal instillation of cold Ringer's solution to keep brain temperature at 34 °C from reperfusion for 12 hours, plus cerebral blood flow promotion by induced moderate hypertension for 4 hours, plus colloid-induced hemodilution for 12 hours, led to the best outcome yet encountered in dogs, with lowest histologic damage ever achieved. Mild cooling in all dog studies caused no cardiovascular or other side effects.

At the same time, resuscitative hypothermia was also studied in rodent ischemia models. First, Busto and colleagues reduced hippocampal CA1 injury with 3 hours of immediate, but not 30-minute delayed postischemic hypothermia to 30 °C in a two-vessel occlusion rat model

with 10 minutes of ischemia and survival to 3 days.[26] Buchan and colleagues reduced hippocampal CA1 injury with 8 hours of immediate hypothermia to 34.5 °C in gerbils with 5 minutes of ischemia and survival to 5 days.[31] Coimbra and colleagues reduced hippocampal CA1 injury with 5 hours of immediate hypothermia to 29 °C in gerbils with 5 minutes of ischemia and survival to 7 days.[32] Chopp and colleagues reduced hippocampal CA1 injury with 2 hours of immediate hypothermia to 34 °C in a two-vessel occlusion rat model with 8 but not 12 minutes of ischemia, and survival to 7 days.[33] Carroll and colleagues progressively reduced hippocampal CA1 injury with immediate hypothermia to 28–32 °C for 1/2, 1, 2, 4, and 6 hours in gerbils after 5 minutes of ischemia, and survival to 4 days; 6 hours of hypothermia delayed for 1 hour after reperfusion also resulted in protection, but 6 hours of hypothermia delayed for 3 hours after reperfusion was not effective. In another study by Coimbra and colleagues hippocampal CA1 injury was reduced with 5 hours of hypothermia to 33 °C, delayed for 2 hours after reperfusion, in a two-vessel occlusion rat model with 10-minutes of ischemia, and survival to 7 days.[34] The same group reduced hippocampal CA1 injury with 5 hours of hypothermia to 33 °C, delayed for 2, 6, and 12 hours, but not for 24 and 36 hours, after reperfusion in a two-vessel occlusion rat model with 10-minutes of ischemia, and survival to 7 days; 3.5 hours of hypothermia delayed for 2 hours after reperfusion was less effective, and 30 minutes of hypothermia delayed for 2 hours after reperfusion was ineffective in the same model.[35]

Although the benefit of intra-ischemic hypothermia on neuronal death is regarded as longlasting,[28,30] results on longlasting effects of postischemic hypothermia are more controversial. Dietrich and colleagues found hippocampal CA1 protection in a two-vessel occlusion rat model with 10-minutes of ischemia and postarrest immediate hypothermia to 30 °C for 4 hours, when histologic evaluation was at 3 days after the insult; this protection significantly declined by 7 days, and was completely absent by 60 days after the insult.[29]

Colbourne and colleagues systematically explored factors affecting neuroprotection of hypothermia in gerbils.[36–38] In the first study,[36] Experiment 1 found that 12 hours of hypothermia (3 °C) delayed for 1 hour after reperfusion attenuated the early (<10-day) ischemia-induced open-field habituation impairments, and substantially reduced CA1 necrosis against 3 minutes of ischemia when assessed at 10 and 30 days, but was only partially effective against a 5-minute occlusion; in Experiment 2, prolonged hypothermia (32 °C) for 24 hours delayed for 1 hour after reperfusion resulted in near total preservation of CA1 neurons at 30 days even after 5 minutes of ischemia. In the

second study with ischemia of 5 minutes.[37] The observation period was extended to 6 months; hypothermia (32 °C) for 24 hours delayed for 1 hour after reperfusion provided substantial CA1 protection at 6 months, but there was less protection than at 1 month. Delaying hypothermia (32 °C, 24 hours) to 4 hours after reperfusion also provided significant protection at 6 months survival, but significantly less than delaying hypothermia for only 1 hour. In the third study with ischemia of 5 minutes,[38] increasing the duration of hypothermia to 48 hours resulted in longlasting protection of neurons at 1 month, even when hypothermia was delayed to 6 hours after reperfusion.

The longlasting effect of delayed (6 hours), prolonged (48 hours) hypothermia (32 °–34 °C) on functional and histologic outcome at 1 month was confirmed in rats with 10 minutes of severe four-vessel occlusion ischemia.[39]

The studies described above suggest that minimal delay and longer durations of hypothermia are of critical importance to extend the therapeutic window and to provide permanent protection of resuscitative hypothermia.

Clinical outcome studies (Holzer)

Historic use of therapeutic hypothermia after cardiac arrest

The first experiences of hypothermia after cardiac arrest were obtained in the 1950s by Benson *et al.*[40] who presented four cases of hypothermic therapy after cardiac arrest (temperature 30 ° to 34 °C) and Williams and Spencer[41] who compared treatment with hypothermia (31 °–32 °C) in 12 patients with 7 normothermic controls. In this controlled pioneer case study, patients treated with hypothermia had a favorable neurological recovery in 50% compared to 14% in the control group. Nonetheless, because of hemodynamic and respiratory problems in these early hypothermia protocols, hypothermia was not used clinically for this indication until the late 1990s.

Clinical pilot trials of hypothermia

In 1997 Bernard *et al.*[17] found improved neurologic outcome in survivors of out-of-hospital cardiac arrest with postarrest mild hypothermia (33 °C) by surface cooling with ice packs over 12 hours compared to a historic normothermic control group (11 of 22 vs. 3 of 22 patients).

Yanagawa *et al.*[19] used water-filled cooling blankets in combination with alcohol to cool cardiac arrest survivors to a core temperature between 33 °C and 34 °C over 48 hours. Three of 13 patients in the hypothermia group survived without disabilities as compared to 1 of 15 patients in the historical control group. The long duration of cooling

in this study led to a higher rate of pneumonia, but it was stated that in none of these cases the pulmonary infection was a direct cause of death.

In a different approach, Nagao et al.,[42] resuscitated patients in cardiac arrest on arrival at the emergency department with emergency cardiopulmonary bypass and intra-aortic balloon pumping. After successful resuscitation, hypothermia was attained by direct blood cooling to 34 °C via a dialysis coil for a minimum of 48 (71 ± 49) hours. Fifty-two percent of these patients survived with good neurologic recovery and no major side effects were reported.

The pilot study for the HACA trial[20] included 27 comatose patients after ventricular fibrillation cardiac arrest. Cooling blankets (Blanketrol II Hypothermia System, Cincinnati Sub-Zero Products, Inc) were placed within a special mattress consisting of air cushions (TheraKair, Kinetic Concepts, Inc), which allowed cold air to flow around the patient; head and body were cooled with a cooling blanket with constant cold air flow (Polar Bair, Augustin Medical, Inc). Patients were cooled to a target temperature of 33 ±1 °C, which was maintained for 24 hours, after which period the patients were passively rewarmed. After 6 months, good neurological recovery was achieved by 14 (52%) patients, 2 (7%) had poor neurological recovery and 11 (41%) died before discharge. Compared to historic controls this was a twofold improvement of outcome and no major complications were directly related to treatment with mild hypothermia.

For a safety and feasibility trial of therapeutic hypothermia after cardiac arrest, Felberg et al.[43] used external cooling blankets in nine patients with persistent coma and lack of acute myocardial infarction or unstable dysrhythmia. Hypothermia to 33 °C was maintained for 24 hours followed by passive rewarming. Three of the nine patients (33%) recovered completely, and one patient developed unstable cardiac dysrhythmia. Figure 49.1 summarizes outcome data of the pilot trials.

Randomized trials and meta-analysis of therapeutic hypothermia after cardiac arrest

The first randomized trial took place in one of the centers also participating in the European multicenter study.[18] In contrast to the multicenter trial the author included only patients with asystole and pulseless electrical activity and therefore no patient was included in more than one trial. A helmet device (Frigicap®) containing a solution of aqueous glycerol placed around the head and neck induced mild hypothermia in 30 patients. Once a bladder temperature of 34 °C was reached, or if cooling took longer than 4 hours, the patient was allowed to rewarm spontaneously over the next 8 hours. Two of 16 patients in the hypothermia group and none of 14 patients in the normothermia group had a favorable neurologic recovery (P = 0.49). Three patients in the hypothermia group survived vs. 1 patient in the normothermia group (P = 0.60). Oliguria occurred in 4 hypothermic and in five normothermic patients. There were no further complications reported.

In 2002 two randomized studies on hypothermia after cardiac arrest were published. In the Australian trial, 77 patients with return of spontaneous circulation after cardiac arrest of cardiac origin (ventricular fibrillation or pulseless ventricular tachycardia) were randomly treated with therapeutic hypothermia (33 °C, core temperature over 12 hours, cooled with ice packs) or normothermia.[14]
Fig. 49.1. Favorable neurologic recovery in clinical pilot trials of therapeutic hypothermia after cardiac arrest. Therapeutic hypothermia, shaded columns; historic control group, white columns.
Fig. 49.2. Favorable neurologic recovery in randomized clinical trials of therapeutic hypothermia after cardiac arrest. Therapeutic hypothermia, shaded columns; normothermic control group, white columns.

The primary outcome measure was survival to hospital discharge, with neurologic function appropriate for discharge to home or a rehabilitation facility. Twenty-one of the 43 patients treated with hypothermia (49%) survived with a good neurologic function at hospital discharge as compared with 9 of the 34 treated with normothermia (26%, $P=$ 0.046). After multivariate adjustment for baseline differences, the odds ratio for a good outcome with hypothermia therapy as compared with standard treatment was 5.25 (95% CI, 1.47 to 18.76; $P=0.011$). There was no difference in the frequency of adverse events, but hypothermia was associated with a lower cardiac index, higher systemic vascular resistance, and hyperglycemia.

In the European multicenter trial[13] patients resuscitated after ventricular fibrillation or pulseless ventricular tachycardia cardiac arrest were randomly treated with therapeutic hypothermia (32°–34°C bladder temperature, cooled with cold air) over 24 hours or with normothermia. All patients received standard intensive care according to a detailed protocol including the use of sedation (midazolam, initially 0.125 mg/kg per hour), analgesia (fentanyl, initially 0.002 mg/kg per hour), and relaxation (pancuronium, initially 1 mg/kg every 2 hours, then as needed to prevent shivering). Mechanical ventilation was mandatory for at least 32 hours. The primary end point was a favorable neurologic recovery within 6 months after cardiac arrest; secondary end points were mortality within 6 months and the rate of complications within 7 days. Seventy-five of the 136 patients in the hypothermia group (55%) had a favorable neurologic recovery (defined as cerebral performance

category 1 or 2). In the normothermia group 54 of 137 (39%) had favorable neurologic recovery (risk ratio, 1.40; 95% CI 1.08 to 1.81). Mortality at 6 months was 41% in the hypothermia group (56 of 137 patients died), as compared with 55% in the normothermia group (76 of 138 patients; risk ratio, 0.74; 95% CI 0.58 to 0.95). The proportion of patients with any complication was not significantly different between the two groups (93 of 132 patients in the normothermia group (70%) and 98 of 135 in the hypothermia group (73%), $P=0.70$). Sepsis was more likely to occur in the hypothermia group, however, this difference was not statistically significant. As inclusion and exclusion criteria were very strict only 8% of patients assessed for eligibility were included in this trial.

In all randomized trials only outcome assessment was blinded and therefore it was possible that some aspects of care differed between the groups. Figure 49.2 shows a summary of the neurologic outcome of the randomized trials.

In a meta-analysis,[44] which included individual patient data of all three randomized trials of therapeutic hypothermia after cardiac arrest it was shown that more patients in the hypothermia group were discharged with favorable neurologic recovery (risk ratio, 1.68; 95% CI 1.29–2.07). Furthermore, the 95% CI of the number-needed-to-treat to allow one additional patient to leave the hospital with favorable neurologic recovery was 4–13. Additionally, patients were more likely to be alive at 6 months with favorable functional neurologic recovery if they were treated with hypothermia (risk ratio, 1.44; 95% CI 1.11–1.76).

Neurologic outcome in recent clinical studies of different cooling methods

In a study of rapid infusion of large volume (30 ml/kg), ice-cold (4 °C) intravenous lactated Ringer's solution, Bernard *et al.*[45] included 22 patients who were comatose following resuscitation from out-of-hospital cardiac arrest. Eight of these patients had primary rhythms other than ventricular fibrillation. The rapid cold infusion resulted in a significant decrease in median core temperature from 35.5° to 33.8 °C and improvement of the hemodynamic situation. Of the 22 patients 10 (45%) survived to hospital discharge (2 of 8 patients with non-ventricular fibrillation rhythm).

A case series of three patients described the effect of therapeutic hypothermia after cardiac arrest from non-cardiac causes:[46] one patient had cardiac arrest from electrocution (rhythm ventricular fibrillation), one from drowning (rhythm asystole) and one from pulmonary embolism (rhythm pulseless electrical activity). All patients were treated with hypothermia (33 °C) over 24 hours and survived to hospital discharge with favorable neurologic recovery.

In a study evaluating the safety and feasibility of endovascular cooling in comatose patients who had been successfully resuscitated after cardiac arrest, Al-Senani *et al.*[47] cooled 13 patients to a target bladder temperature of 33 °C for 24 hours, followed by slow controlled rewarming over 18.3 ± 5.9 hours. Five patients (38%) had 30-day favorable neurologic recovery. No unanticipated or procedure-related adverse events occurred.

A pilot study was performed by Friberg *et al.*[48] using cold intravenous fluids and surface cooling with a cold helmet and a cold-water blanket (Thermowrap® and Allon® control unit, MTRE, Or Akiva, Israel) in five unconscious patients after cardiac arrest; three survived with good recovery to 6-month follow-up (60%). No adverse events were reported during treatment.

Virkkunen *et al.*[49] cooled 13 adult patients in the prehospital setting with ice-cold Ringer's solution after successful resuscitation from non-traumatic cardiac arrest. After hemodynamic stabilization, 30 ml/kg of Ringer's solution was infused at a rate of 100 ml/min into the antecubital vein. Four of these 13 patients (31%) survived to hospital discharge with favorable neurologic recovery.

Summary

Sufficient clinical evidence supports the use of therapeutic hypothermia after cardiac arrest in unconscious survivors of cardiac arrest, particularly if the primary rhythm was ventricular fibrillation and the arrest occurred outside the hospital; such hypothermia may also be beneficial in patients with other rhythms and in-hospital cardiac arrest.

Initial patient evaluation

The optimal timing and technique for induction of hypothermia after cardiac arrest are uncertain, and this is now the major focus of current research. The induction of hypothermia after cardiac arrest should be an integral component of the initial evaluation and stabilization of the patient. The steps are described below.

Airway/breathing

All patients who have been resuscitated from prolonged cardiac arrest remain comatose and will require endotracheal intubation for airway protection, oxygenation and control of ventilation. Mechanical ventilation with supplemental oxygen at a tidal volume of 10 ml/kg and a rate of 8–10 breaths per minute should ensure adequate oxygenation and normocapnea. Notably, production of CO_2 is decreased by 30% when core temperature is 33 °C, and therefore the minute ventilatory volume will need to be decreased to avoid hypocapnea, as guided by end-carbon dioxide readings and/or arterial blood gas analysis.

To facilitate both mechanical ventilation and assist in the rapid induction of hypothermia, a large dose of a non-depolarizing muscle relaxant should be administered immediately after initial neurological assessment, as well as an infusion of a sedative agent such as midazolam; these medications will abolish shivering.

Circulation

Evidence from laboratory studies indicates that hypertension after cardiac arrest is associated with improved neurological outcome.[11] One treatment that both induces mild hypothermia and improves blood pressure is rapid infusion of large volume (40 ml/kg), ice-cold (4 ºC) intravenous fluid (see later). If hypotension (MAP < 90 mmHg) persists despite this fluid therapy, then an inotropic drug may be infused. In our studies of induced hypothermia (IH),[45] adrenaline was the vasoactive drug of first choice as it has a low incidence of adverse cardiac effect. But if it does cause adverse side effects, noradrenaline would be a reasonable alternative.

If the patient is initially hypertensive, additional sedation may be administered (such as propofol) and consideration given to vasodilator therapy with glyceryl trinitrate considered.

Initial procedures

After initial "ABC" resuscitation measures described above, the following procedures and investigations should be undertaken. An orogastric tube should be inserted, since bystander expired air ventilation commonly results in air inflation of the stomach. Insertion of an intra-arterial line

facilitates continuous blood pressure monitoring and blood drawing for laboratory tests. A 12-lead electrocardiogram is required to diagnose acute coronary syndromes. A chest X-ray should be obtained during initial evaluation to exclude right main bronchus intubation and to evaluate any pulmonary complications of cardiac arrest such as aspiration pneumonitis and/ or pulmonary edema.

Central venous access may be required for central venous pressure monitoring and/or vasoactive drug infusion. A femoral venous line may be safer in this setting compared with subclavian or internal jugular puncture if thrombolysis is planned.[50]

Core temperature measurement

Core temperature must be monitored continuously and accurately when induction of hypothermia is planned. There is minimal temperature gradient among brain, bladder and rectal temperature[51,52] and it is usually most convenient to monitor bladder temperature after arrival at hospital. Tympanic temperature monitoring may be used pre-hospital, but is less accurate, particularly when the head is surrounded by ice-packs during surface cooling (see below).

Induction of hypothermia

Rapid lowering of core temperature in an adult patient after cardiac arrest requires that shivering be suppressed by administration of sedation and/or muscle relaxants, while heat is concurrently lowered. A range of techniques for rapid cooling may be applicable in this setting, depending on availability of resources and physician expertise (see Table 49.1).

Surface cooling

The simplest technique for cooling after cardiac arrest is extensive application of ice packs to the head, neck, and torso of the patient. In preliminary hypothermia studies,[45] this technique was effective but provided relatively slow core cooling (approximately 0.9 °C per hour). It was also very time-consuming and inconvenient for attending medical and nursing staff.

The European (HACA) study of hypothermia after cardiac arrest used surface cooling with a refrigerated air blanket to induce hypothermia.[13] This was also found to be very slow, however, with a decrease in core temperature of only 0.3 ºC/hour.

Increased conductive heat loss may be achieved using water blankets rather than cold-air blankets. These were compared by Theard *et al.* in surgical patients.[53] Both of these techniques (water and cold-air blankets) were relatively slow and there was no significant difference between

Table 49.1. Techniques for induction of hypothermia after cardiac arrest

- Body cavity lavage

the groups in the time taken for core temperature to drop from 35 °C to less than 34 °C (mean 178 minutes vs. 142 minutes). Nevertheless, cooling blankets are a feasible and safe for induction of mild hypothermia.[43]

More recently, developments in cooling technology have made surface cooling much more efficient. The most promising commercially available system uses large adhesive pads that are cooled by water at a controlled temperature applied around the trunk and limbs (Arctic Sun, Medivance, Colarado, USA). The water is circulated with a feedback control system, allowing very accurate control of patient core temperature. Although published data on patients after cardiac arrest are limited, this system has provided improved temperature control compared with traditional surface cooling blankets in febrile patients in a neurological intensive care unit.[54] Moreover, this system is non-invasive and can be readily applied by nursing staff.

Surface heat loss can also be attained with evaporative techniques by using fans and alcohol baths, but these are time consuming and impractical in most emergency and critical care units.

The fastest rate of surface cooling has been achieved with complete patient immersion in an ice-water bath.[55] This results in a rapid decrease in core temperature of 9.7 °C/hour, but is impractical for critically ill patients.

Since the skin of the torso and limbs may be poorly perfused in the early post-cardiac arrest period, while brain blood flow is preserved, it was proposed that cooling helmets may be more efficient than cooling blankets, and two studies have investigated this issue. First Wang *et al.* assigned 14 patients with neurological injury to either a cooling helmet or no cooling.[56] Brain temperature was measured directly (just below the surface of the brain) and compared with the patients' core temperatures. Brain surface temperature was reduced by 1.8 °C (range 0.9–2.4 °C) within 1 hour of helmet application, but a mean of 3.4 hours was required to achieve a brain temperature

lower than 34 °C and over 6 hours before systemic hypothermia (< 36 °C) occurred. Second, the tympanic temperatures of 16 patients who were cooled after cardiac arrest were compared to those of 14 normothermic controls.[18] The median tympanic temperature on admission to hospital in both groups was 35.5 °C. In the cooling helmet group, the core target temperature of 34 °C was reached after a median time of 180 minutes after resuscitation. The two studies indicate that cooling helmets are relatively slow to provide systemic hypothermia in adults and probably have no advantage over surface cooling with ice packs and/or cooling blankets.

Nevertheless, helmet cooling may be more efficient in neonatal patients, because of the relative size of the head compared with the torso and the presence of open cranial fontanelles. Animal studies have confirmed that moderate cerebral hypothermia can be induced while the body can be maintained at relative normothermia. In one study, Tooley et al. subjected piglets to 45 minutes of global hypoxic-ischaemic insult,[57] after which each piglet was cooled for 7 hours by using a cap wrapped around the head with circulating cold water (median 8.9 °C). Radiant overhead heating was used to warm the body during cerebral cooling. The mean deep brain temperature during the 7-hour cooling period was 31.1 ºC, while rectal temperature remained stable at 38.8 ºC.

This technique was then used in a clinical trial of hypothermia in neonates with hypoxic-ischemic encephalopathy[58] in which the cooling cap (Olympic Medical Cool Care System, Olympic Medical, Seattle, WA, USA) was placed around the head of the neonate for 72 hours. The system consists of a thermostatically controlled cooling unit and a pump that circulates water between 8 °C and 12 °C through the cap. The infants were also nursed under a radiant overhead heater, which was servo-controlled to the infant's abdominal skin temperature and adjusted to maintain the rectal temperature at 34 °–35 ºC. Improved outcomes in neonates with moderate, but not severe, hypoxic-ischemic encephalopathy were shown, and no cardiac arrest complications resulted from the cold cap.

Large-volume ice-cold intravenous fluid

A simple inexpensive technique for induction of mild hypothermia is rapid infusion of a large volume (40 ml/kg) of ice-cold (4 °C) intravenous fluid (LVICF). To date lactated Ringer's solution and normal saline have been used.

This technique was initially tested in volunteers and found to be safe and effective at lowering core temperature, particularly in older patients.[59,60] More recent studies have examined this technique in postcardiac arrest patients. In a study of 22 patients in an Emergency Department by

Bernard et al., 30 ml/kg of LVICF (lactated Ringer's solution) was rapidly infused intravenously, together with a large dose of a long acting neuromuscular blocker to prevent shivering.[45] This infusion decreased core temperature by 1.6 °C and blood pressure was increased and no patient developed pulmonary edema. In addition, there were improvements in acid–base and renal function. Fluid was infused into a peripheral i.v. cannula by using a pressure bag to ensure a high flow rate (100 ml/min) through a standard i.v. giving set.

In a study by Kliegel et al., cardiac arrest patients received 200 ml of LVICF via peripheral venous catheters to initiate IH prior to endovascular catheter insertion.[61] Following 24 ± 7 ml/kg cold fluid, the core temperature decreased from 35.6 °C ± 1.3 °C on admission to 33.8 ºC ± 1.1 ºC. The target temperature (<34 ºC) was reached a mean of 185 minutes after return of spontaneous circulation and 135 minutes after start of infusion. Two patients had radiographic signs of mild pulmonary edema, but no other complications that could be attributed to the LVICF infusion.

Although myocardial dysfunction is common after resuscitation from prolonged cardiac arrest,[62] there is evidence that rapid infusion of LVICF does not result in pulmonary edema in most patients. Kim et al. examined the cardiac effects of LVICF in cardiac arrest patients following hospital admission,[63] by using transthoracic echocardiography to assess cardiac function just before and 1 hour after infusion of LVICF. The infusion resulted in a mean core temperature drop of 1.4 ºC without significant changes in vital signs, electrolytes, arterial blood gases, or coagulation indices. The initial mean cardiac ejection fraction was 34%, and the fluid infusion did not effect ejection fraction, central venous pressure, pulmonary pressures, or left atrial filling pressures.

The LVICF has been used for the prehospital induction of hypothermia. In one study of 13 adult patients who were resuscitated from cardiac arrest, 30 ml/kg of lactated Ringer's solution was infused at a rate of 100 ml/minute into an antecubital vein.[49] The mean core temperature decreased from 35.8 ° ± 0.9 °C at the start of infusion to 34.0 ° ± 1.2 °C on arrival at hospital ($P < 0.0001$), with no serious adverse hemodynamic effects.

Although this study was supervised by physicians, it has also been shown that paramedics can administer LVICF after cardiac arrest. In a pre-hospital study, 20 adult patients with return of stable spontaneous circulation following out-of-hospital cardiac arrest were enrolled (Bernard SA, unpublished data). All patients were unconscious after return of spontaneous circulation and were intubated and ventilated. The patients received pancuronium followed

by 2000 ml of ice-cold lactated Ringer's solution IV over 20 minutes. Data on vital signs were collected before and after the fluid infusion, before arrival at the emergency department. Core temperature decreased by 1.8 °C. Transient oxygen desaturation in one patient was treated with furosemide without adverse effect.

Since there is evidence that hypothermia may be of maximal benefit when induced during CPR,[9,12] LVICF may be the most feasible technique for cooling during CPR in the field. Although human studies have not been published, this approach was tested in a laboratory study by Nordmark *et al*.[64] In this study, 20 piglets were subjected to 8 minutes of ventricular fibrillation, followed by CPR: they were then randomized into two groups, one given a 30 ml/kg infusion of 4 °C Ringer's solution at 1.33 ml/kg per minute, starting after 1 minute of CPR and the other received the same infusion volume at room temperature. After 9 minutes, cardioversion was used to achieve a return of spontaneous circulation. The mean temperatures in the LVICF animals were significantly reduced by a mean of 1.6 °C compared with 1.1 °C in the control group; there was no difference in cortical cerebral blood flow or hemodynamic variables and no adverse effects of the infusion.

On the other hand, there may be some concern that hypothermia induced during cardiac arrest decreases the effectiveness of defibrillation. This has been studied by Boddicker *et al*. in a swine model of cardiac arrest.[65] The animals were divided into four groups each with eight animals: normothermia; mild hypothermia (35 °C), moderate hypothermia (33 °C); and severe hypothermia (30 °C). Hypothermia was induced by surface cooling before the induction of ventricular fibrillation (VF). After 8 minutes of unsupported VF, without CPR, the animals were defibrillated with successive shocks as needed and then underwent CPR until either resumption of spontaneous circulation or no response at 10 minutes. First-shock defibrillation success was higher in the moderate hypothermia group (6 of 8 hypothermic animals vs. 1 of 8 normothermic animals; $P = 0.04$). Fewer shocks were needed for late defibrillation (≥ 1 minute after initial shock) in all three hypothermia groups compared with the normothermia group (all $P < 0.05$). None of the 8 animals in the normothermia group achieved return of spontaneous circulation, compared with 3 of 8 mild hypothermia ($P = $ NS), 7 of 8 moderate hypothermia ($P = 0.001$), and 5 of 8 severe hypothermia ($P = 0.03$) animals. These data suggest that mild hypothermia actually facilitated defibrillation.

Possible contraindications to LVICF include the presence of fulminating pulmonary edema and/or the patient with chronic renal failure (on dialysis) who may be unable to excrete a large fluid load. In these patients, intravenous

infusion of a small volume of a much colder liquid might be useful. Recently, an ice "slurry," comprising smoothed 100-micrometre ice particles at subzero temperature, has been developed. Vanden Hoek *et al*. studied the effects of a rapid infusion of this slurry in swine,[66] in which a central catheter infusion of ice slurry (50 ml/kg) was compared to an equal volume of chilled saline. The study included normothermic controls, and compared with these control animals, brain temperatures of the slurry and saline groups dropped by means of 5.3 °C and 3.4 °C ($P = .009$), respectively.

At this time, the use of LVICF appears to be the most feasible and effective approach to rapid core cooling, and it should be administered as soon as possible after resuscitation. On the basis of the promising animal data above, future clinical studies could test this therapy in the prehospital setting and during CPR.

To avoid a rebound increase in temperature as the cold fluid moves into the extra-vascular compartment at the end of the infusion, additional cooling techniques such as surface cooling (as above) or endovascular cooling (see below) may be required for the maintenance of IH.

Endovascular cooling

Several types of endovascular cooling catheters are currently available for induction and maintenance of hypothermia. Although there are minor differences in design, the principles of each catheter type are similar. The catheter is placed in the venous circulation (usually into the inferior vena cava via the femoral vein) and contains circulating saline at a controlled temperature. The fluid is pumped from a bedside heat exchanger that accurately controls fluid and therefore patient core temperature.

Preliminary clinical studies examined the use of this device in febrile neurological patients. Diringer *et al*. compared conventional treatment of fever (acetaminophen and cooling blankets) with this treatment plus an endovascular cooling catheter (Alsius, Irvine, CA) in patients with neurological injury and fever.[67] The "fever burden" (defined as the area under the temperature chart) was 7.92 °C-hours in the conventional group compared with 2.87 °C-hours in the catheter group, which represented a 64% reduction in fever ($P < 0.01$). Rates of infection and use of sedatives, narcotics, and antibiotics were similar in both groups.

The endovascular cooling catheter has also been used for core cooling patients undergoing interventional cardiac procedures. In the "Cool-MI" study, Dixon *et al*. studied the use of a cooling catheter during primary percutaneous coronary intervention (PCI) for acute myocardial infarction.[68] Patients were randomized to primary PCI with either normothermia or cooling by using an endovascular cooling

catheter, with a target core temperature of 33 °C. Sedation was administered for patient comfort and to prevent shivering. Cooling was then maintained for 3 hours after reperfusion, and was well tolerated, with no hemodynamic instability or increase in the incidence of arrhythmia. Although the median infarct size was not significantly smaller in patients who received cooling compared with that in the control group, the study established the safety and efficacy of the cooling technology.

The endovascular cooling device has also been used successfully for the induction of mild hypothermia in conscious patients with severe stroke[69] and in the operating room for patients undergoing elective craniotomy for repair of an unruptured cerebral aneurysm.[70]

Endovascular cooling has been used in patients with neurological injury after cardiac arrest by Al-Senani et al.[47] Core temperature was reduced to a target of 33 °C for 24 hours using a closed loop endovascular system placed in the inferior vena cava, followed by controlled rewarming. Thirteen patients (mean age, 60 years) were enrolled. The time from cardiac arrest to ROSC was 14.3 minutes (range 5–32.5). It took a mean of 3 hours and 39 minutes to reach 33 °C (average). The rate of cooling 0.8 °C/hour, range, 0.22 °–1.12 °C/hour). Temperature was tightly maintained for all patients averaging 32.7 ° ± 0.5 °C. Rewarming lasted 18.3 ± 5.9 hours. No procedure-related adverse events occurred.

However, the use of an endovascular cooling catheter is limited to the hospital setting. Moreover, the heat exchanger and catheters are expensive and catheters require insertion by a physician with additional training, which delays induction of hypothermia for some time after hospital arrival. Nevertheless, these devices appear to provide excellent temperature control during maintenance and rewarming from hypothermia.

Extracoporeal circuits
Extracorporeal circulation consists of large intravascular (usually intravenous) catheters, a blood pump, and an in-line heat exchanger. These circuits allow very accurate and rapid control of core temperature, but again this technology is very expensive, and requires specialized physician training for catheter insertion as well as time to prime. Also, the patient usually requires full anticoagulation. Therefore, this approach is unlikely to become commonly used in most emergency and critical care units.

The rapid rate of cooling has been demonstrated by Holzer et al.[71] In large swine, extracorporeal venovenous cooling reduced brain temperature from 38.0 ° to 33.0 °C in a mean of 41 minutes compared with endovascular cooling which took a mean of 126 minutes (P = 0.001). None of the swine developed significant hemolysis, arrhythmias, or bleeding.

Clinical experience with extracorporeal circuits to induce hypothermia has been limited to a few centers,[72] and only one report in patients with cardiac arrest. Nagas et al. treated 50 patients with out-of-hospital cardiac arrest with standard CPR and, if there was no response, with emergency cardiopulmonary bypass plus intra-aortic balloon pumping.[42] Subsequently, patients with systolic blood pressure above 90 mmHg and Glasgow coma cardiac arrest score of 3 to 5 received mild hypothermia (34 °C for 2 days), induced by extracorporeal coil cooling. Mild hypothermia was induced in 23 patients, and 12 (52%) of them showed good recovery.

Pharmacological techniques
In most patients, the induction of hypothermia requires some therapy assistance to suppress shivering. In conscious patients, sedation alone is used; however, the optimal combination of pharmacological agents is uncertain, but meperidine and buspiridone are widely used to suppress shivering. In general, comatose, ventilated patients are treated with a muscle-relaxant as well as sedative drugs.

Recently, use of magnesium bolus and infusion has been evoked to facilitate induction of hypothermia. In a study of patients with stroke in whom hypothermia (34.5 °C) was induced by surface cooling,[73] patients received meperidine alone, meperidine plus buspirone, meperidine plus ondansetron, or meperidine, ondansetron, and magnesium sulfate 4- to 6-g i.v. bolus of magnesium sulfate was followed by 1 to 3 g per hour infusion. Patients who received magnesium sulfate had a slightly decreased time to achieve a tympanic temperature of 35 °C and also had significantly higher mean comfort scores.

In a similar study, Wadhwa studied 9 healthy volunteers who were assigned to either placebo or magnesium (80 mg/kg) followed by infusion at 2 g/hour.[74] Lactated Ringer's solution (4 °C) was infused via a central venous catheter to decrease tympanic membrane temperature by about 1.5 °C/hour. Magnesium reduced the shivering threshold from a mean of 36.6° to 36.3 °C (P = 0.04). Although this change is statistically significant, this very small drop in the temperature of shivering threshold is unlikely to be clinically important.

Another pharmacological agent that may be useful in the future in induction of hypothermia is a neurotensin analogue. Specific receptors for neurotensin, an endogenous tridecapeptide, are found throughout the central nervous system of mammals, including rats and humans. Neurotensin is elevated in mammals during hibernation,

and is thought to induce hypothermia by activation of neurotensin receptors in the brain.

Recently, a neurotensin analog has been developed that can be administered intravenously, which may provide a practical method for rapidly inducing hypothermia within minutes without sedation or general anesthesia. In addition, when neurotensin degrades over 24 hours, the core temperature returns to normal without external application of heat. This has been studied in a rat model of asphyxial cardiac arrest by Katz *et al.*,[75] in which the animals were randomized to normothermia, brief external cooling (6 hours), prolonged external cooling (24 hours), or neurotensin administration 30 minutes after cardiac arrest. The animals with neurotensin-induced hypothermia had improved neurological outcome comparable to prolonged external cooling and improved outcome compared with the brief external cooling, but the feasibility and safety of this drug in humans is currently unknown.

Partial liquid ventilation with cold perflurocarbon

It has been known for many years that mammals can survive prolonged immersion in oxygenated perfluorocarbon (PFC) liquids. The principle of ventilation with oxygen-carrying fluids was subsequently developed to allow partial liquid ventilation in patients with respiratory failure, where it was proposed that the lung/fluid interface would be superior to the lung/gas interface. A clinical trial, however, did not demonstrate patient benefit by this approach.[76]

Nevertheless, instillation into the lungs of a large volume of ice-cold PFC would be expected to provide rapid core cooling, while still allowing adequate oxygenation and ventilation. This has only been studied in animal models at this time.[77]

Body cavity lavage

A number of studies have examined the effects of lavage of various body cavities with ice-cold fluid: these include gastric lavage with cold water, and bladder and peritoneal lavage with cold sterile saline.

Plattner *et al.* compared several of these cooling techniques with surface cooling in volunteers.[55] In addition to surface cooling techniques (ice water immersion) described previously, Plattner also studied gastric lavage (500 ml of ice water every 10 minutes) and bladder lavage (300 ml of iced Ringer's solution every 10 minutes). The first volunteer developed abdominal cramping and diarrhea after gastric lavage and this technique was not used again. Bladder lavage, however, decreased core temperature by 0.8 °C /hour, consequently this technique may be a useful adjunct to cooling, but it requires considerable additional nursing time to maintain the fluid exchanges.

Peritoneal lavage has been studied by Xiao *et al.* in a dog model:[78] 2 litres of Ringer's solution at 10 °C were instilled into the peritoneal cavity, left for 5 minutes, and then drained. Tympanic membrane temperature decreased by a mean of 0.3 °C/min. In addition, pulmonary artery temperature decreased by a mean of 0.8 °C/min. Although insertion of a peritoneal catheter and core rewarming in the Emergency Department has been described for patients with accidental hypothermia, peritoneal cooling has not been studied in postcardiac arrest patients.

Selective brain cooling

To avoid possible complications of systemic hypothermia, isolated brain cooling would be preferable, if this were technically possible. Cannulation of the carotid vessels and the infusion of cooled blood into the cerebral circulation was studied by Mori *et al.*[79] In a swine model of cardiac arrest, VF was induced and cardiac arrest (without CPR) was allowed for 20 minutes. Extracorporeal bypass was then instituted to restore coronary and cerebral perfusion, followed by restoration of cardiac rhythm. Some animals received selective brain hypothermia (32 °C) for 12 hours by use of femoral/carotid bypass. There was significant improvement in the neurohistology scores in the selective brain-cooled animals as compared with those of the normothermic cohort. Nevertheless, given the modest side effects of systemic hypothermia, and the potential complications of cannulating the carotid arteries under emergency conditions, this approach is unlikely to be used in the near future.

Maintenance of hypothermia

The optimal duration of IH after cardiac arrest resuscitation is uncertain. The Australian studies used 12 hours,[17] whereas the European study used 24 hours.[13] Whichever period is chosen, careful control of core temperature during this period is required.

Once a core temperature of 33 °C is reached by one of the techniques described above, adult patients usually become poikilothermic and shivering is largely abolished. The judicious use of sedation rather than pharmacological paralysis may be all that is required to maintain this core temperature. If the core temperature starts to rise (>33.5 °C), additional sedation and/or a muscle relaxant may be administered and ice packs applied to the head, neck, and torso of the patient. If available, a surface or core cooling technology (as described above) would be useful. If temperature decreases (<32.5 °C), ice-packs should be removed and paralyzing drugs withheld while a heated-air blanket is applied. The use of either surface cooling or endovascular cooling (as described above) with feedback

controls considerably simplifies the maintenance of IH in the critical care unit.

Rewarming from hypothermia

Active rewarming after a period of IH requires the use of either external heating or endovascular warming to increase core temperature. Some animal data suggests that rewarming from hypothermia should be undertaken slowly.[80] During this time, any shivering must be completely suppressed with sedation. In addition, rewarming may result in peripheral vasodilatation, and (warmed) i.v. fluid therapy may be needed to maintain blood pressure.

Summary

After resuscitation from prolonged out-of-hospital cardiac arrest, current evidence suggests that the comatose patient should be treated with mild hypothermia to improve neurological and overall outcome. Induction of hypothermia requires administration of a large dose of a long-acting muscle relaxant followed by the rapid infusion (>100 ml/min) of ice-cold i.v. crystalloid fluid (i.e., normal saline or lactated Ringer's solution) to a total volume of 40 ml/kg. Current evidence suggests that this is only rarely associated with development of pulmonary edema.

To prevent rewarming, surface cooling should be initiated and core temperature monitored using a bladder temperature probe. Hypothermia should then be maintained for 12–24 hours, and rewarming undertaken over 6–12 hours. Maintenance of hypothermia and later rewarming are most accurately achieved with endovascular or surface cooling devices that have feedback control.

At this time, the use of extracorporeal circuits and/or selective cerebral cooling is expensive and usually not feasible in most hospitals. It is unlikely that such advanced technologies will be shown to be superior to simpler techniques.

Mechanisms and potential side effects of therapeutic mild hypothermia (Poldermann)

Introduction

To apply hypothermia effectively in a clinical setting, it is important to be aware of the mechanisms underlying this treatment, as well as the potential side effects of the treatment. Insufficient understanding of these mechanisms and side effects can decrease their effectiveness, or at worst even lead to treatment failure, as illustrated by early experiences with induced hypothermia in treatment of cardiac

arrest, traumatic brain injury, and for other indications in the 1950s and 1960s.[81–83] At that time hypothermia was presumed to exert its effects exclusively through temperature-dependent reductions in metabolism, leading to a decreased demand for oxygen and glucose in the brain. It is now known that there are multiple effects on the body, as discussed in previous sections, and that the failure of treatment was largely due to the use of temperatures that were too low, lack of understanding of the underlying mechanisms, and failure to treat harmful side effects.

The most important breakthrough in treatment was the realization that neurological outcome could be improved by mild-to-moderate hypothermia (31°–35 ºC) rather than deep hypothermia (≤30 ºC), with far fewer and less severe side effects. This new insight stemmed from the observation that the protective effects of hypothermia were not exclusively due to a decrease in oxygen and glucose consumption in the brain. Rather the mechanisms involved were far more complicated.

Numerous destructive processes (collectively termed "postresuscitation disease") begin minutes to hours after an initial (ischemic or traumatic) injury, can continue for hours to several days after initial injury, and can be retriggered by new episodes of ischemia. Importantly, all of these processes are temperature dependent; thus, they are all stimulated by fever, and can all be mitigated or blocked by mild to moderate hypothermia. The wide-ranging effect of hypothermia on all of these mechanisms may explain why it has proved to be clinically effective, whereas studies with agents that affect just one of the destructive processes have been far less successful.[85,86]

The second important development was the advent of intensive care units to care for critically ill patients. The side effects of hypothermia are far more easily managed in this setting, and the methods for inducing and maintaining hypothermia at a specified level (discussed earlier) have improved significantly since the 1950s.

From studies on mechanisms underlying hypothermia's protective effects, it is clear that the key factors determining the success or failure of hypothermia treatment are speed of induction of hypothermia, duration of cooling, speed of rewarming, and prevention of side effects. Since relative contributions of different destructive mechanisms to the ongoing postresuscitation injury may differ, available "windows of opportunity" for therapeutic interventions such as hypothermia may vary, as well as the required duration of hypothermia. Better understanding of the underlying mechanisms may help us to target our treatments more specifically and help improve outcome.

With respect to side effects of hypothermia, some are intrinsically linked to the protective effects. For example,

hypothermia-associated immunosuppression which leads to the suppression of harmful inflammatory processes in the brain and heart, but also to increased risk of wound infections and pneumonia, as observed in various clinical studies.[84]

As discussed above, animal models can be roughly divided into global and focal injury models, to study global anoxia (cardiac arrest model) as well as traumatic brain injury, ischemic stroke, and subarachnoid hemorrhage. Hypothermia has been shown to improve neurological outcome in all of these models and in the overwhelming majority of animal experiments, provided that hypothermia was applied quickly enough. Nonetheless, reproducing these results in clinical trials has proved difficult, because the relative importance of different injury mechanisms may differ between humans and animals, and also among different animal species. Thus, a specific treatment that decreases histological brain damage in rats may also be effective in humans, but the effect may be too small to be clinically significant.[97,98] In addition, specific treatments may modify or inhibit a specific destructive mechanism that plays a central role in the development of injury in a particular animal model, but is far less important in humans.[87,88] The potentially positive effects of hypothermia may be overestimated on the basis of animal experiments; the brains of some animals, especially small animals such as rodents, appear to be more responsive to neuroprotection than is the human brain. But the protective effects may also be *under*estimated if only one mechanism and/or one animal model is examined. For example, many animal studies have focused on the influence of hypothermia on the so-called neuroexitotoxic cardiac arrest, which involves a severe disturbance of intracellular ion homeostasis following an ischemic event.[87–89] This destructive mechanism is a central feature of postischemic injury, and any potential neuroprotective effect depends on the ability of a treatment to influence this particular mechanism. Moreover, various studies in different animal models have shown that the time window to influence this neuroexcitatory cardiac arrest may be limited, ranging from an upper limit of about 120 minutes to as low as 10 minutes.[90] Thus if the benefits of hypothermia were linked to its influence on the neuroexitatory cardiac arrest alone, a "window of opportunity" of about 2 hours, would be expected. Clinical studies have shown improved neurological outcome in patients who remain comatose after cardiac arrest even when induction of hypothermia was delayed for up to 8 hours,[13] strongly suggesting that different mechanisms are probably affected simultaneously when hypothermia is induced.

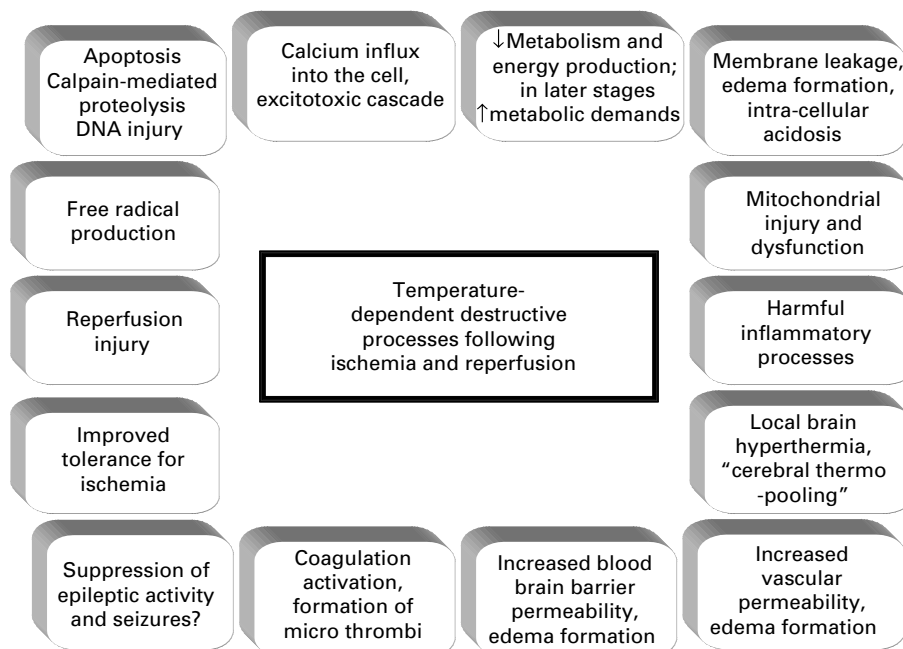
Potential mechanisms underlying the protective effects of hypothermia
The mechanisms described in more detail below are summarized in Fig. 49.3.


Fig. 49.3. Destructive mechanisms following ischemia and reperfusion.

Decrease in cerebral metabolism

When first applied in a clinical setting, hypothermia was presumed to exert protective effects due to a slowing of cerebral metabolism, leading to a decrease in glucose consumption and oxygen demand. Indeed, cerebral metabolism is reduced by between 5% and 8% for each ℃ reduction in body temperature during induction of hypothermia.[91] Therefore, these early trials attempted to decrease metabolic rates as much as possible, by lowering body temperature as far as possible. But it was found not only that protective effects could be achieved with mild hypothermia (31°–34℃); but that the protective effects of cooling appeared to be much greater than could be explained by changes in metabolism alone.[92] Thus, although a decrease in metabolism and oxygen demand is one of the mechanisms underlying hypothermia's protective effects, other mechanisms are equally or more important.

Apoptosis, calpain-mediated proteolysis, and mitochondrial dysfunction

After a period of ischemia and reperfusion, cells can become necrotic, fully or partially recover, or enter a path leading to apoptosis or programmed cell death. Whether a cell will become apoptotic is determined by a number of cellular processes, including mitochondrial dysfunction and disorders in cellular energy metabolism and the release of various enzymes, the caspases. Numerous studies have shown that hypothermia can interrupt the apoptotic pathway and prevent cell injury from leading to apoptosis.[93] Hypothermia probably acts at the early stages of the apoptotic process[94] by influencing mechanisms involved in apoptosis initiation, including inhibition of caspase enzyme activation,[93,94] prevention of mitochondrial dysfunction,[95] decreased overload of excitatory neurotransmitters, and modification of intracellular ion concentrations. Apoptosis is one of the destructive processes that begins relatively late in the postperfusion phase and continues for 48–72 hours or even longer.[96] Thus, prevention or mitigation of apoptosis can be influenced for some time after injury, which in theory provides a wide window of opportunity for therapeutic interventions such as hypothermia. Thus, influencing apoptotic pathways could play an important role in human neuroprotection and reducing postresuscitation injury.

Ion pumps and neuroexcitatory cardiac arrest

A large body of evidence suggests that hypothermia inhibits harmful excitatory processes occurring in brain cells during ischemia and reperfusion. Levels of high-energy metabolites such as adenosine triphosphate (ATP) and phosphocreatine in brain cells decrease within seconds when oxygen supply to the brain is interrupted.[91] The breakdown of ATP and the switch of intracellular metabolism to anaerobic glycolysis leads to an increase in intracellular levels of inorganic phosphate, lactate, and H^+, resulting in both intra- and extracellular acidosis and an influx of calcium (Ca^{2+}) into the cell. Loss of ATP and acidosis also inhibit mechanisms that normally deal with excessive intracellular Ca^{2+} by sequestration of Ca^{2+} from the cell, further aggravating intracellular Ca^{2+} overload. These problems are compounded by failure of ATP-dependent Na^+–K^+ pumps and K^+, Na^+, and Ca^{2+} channels, leading to an additional influx of Ca^{2+}.[89] Excess Ca^{2+} can induce mitochondrial dysfunction (increasing intracellular calcium influx further, in a vicious cycle) and activate numerous intracellular enzyme systems (kinases and proteases). In addition, immediate early genes are activated and depolarization of neuronal cell membranes occurs, with release of large amounts of the excitatory neurotransmitter glutamate into the extracellular space.[89] This leads to prolonged and excessive activation of membrane glutamate receptors, further stimulating Ca^{2+} influx through activation of Ca^{2+} channels again in a vicious cycle. Under normal circumstances, neurons are exposed to only very brief pulses of glutamate; when exposed to glutamate for prolonged periods of time, the neurons remain in a permanent state of hyperexcitability (the "excitotoxic cardiac arrest"), which can lead to additional injury and cell death. Moreover, high levels of glutamate can be neurotoxic, especially in energy-deprived cells. Activation of glutamate receptors can persist for some time after reperfusion, even when glutamate levels have returned to normal, which may also mediate brain cell death. Together, ischemia and reperfusion interrupt a delicate balance between calcium influx and sequestration at the cellular level.

Numerous animal experiments have clearly demonstrated that key destructive processes of the neuroexitatory cardiac arrest (such as calcium influx, accumulation of glutamate, and the release of its co-agonist glycine) can be prevented, interrupted, or mitigated by hypothermia.[26,89,97,98] Even a relatively small decrease in temperature can significantly improve ion homeostasis, whereas the occurrence of fever can trigger and/or stimulate these destructive processes.

The "window of opportunity" available to interrupt the problems described above remain unclear. Disruptions in Ca^{2+} homeostasis begin in the first minutes after injury, but continue in the hours or even days following ischemia, and can be retriggered by each new episode of ischemia. Although, in theory, this would again provide a significant time window for therapeutic interventions such as hypothermia, some animal experiments suggest that the

process can be blocked or reversed only if the treatment is initiated in the early phases of the neuroexitatory cardiac arrest.[12,29,87,90,91] Other studies have reported time frames possibly due to different types of injuries and ranging from 30 minutes to up to 6 hours in different species.[8–11,34,35,99–103] Some authors have suggested that the therapeutic window for hypothermia could be extended by combining it with other treatments, such as caspase use of inhibitors or other experimental compounds.[87,104,105]

Immune response and inflammation
In most types of brain injury a significant and protracted inflammatory response begins about 1 hour after a period of ischemia and reperfusion: pro-inflammatory mediators such as tumor necrosis factor-alpha (TNFα) and inter-leukin-1 (IL-1) are released in large quantities by astrocytes, microglia, and endothelial cells, and levels begin to rise ±1 hour after reperfusion and remain elevated for up to 5 days.[91,106] This stimulates the chemotaxis of activated leukocytes across the blood–brain barrier and leads to an accumulation of inflammatory cells in the injured brain, as well as the appearance of adhesion molecules on leuko-cytes and endothelial cells. Simultaneously, there is an activation of the complement system, beginning in the very early stages after brain injury further stimulating the passage of neutrophils and (in later stages) monocytes/macrophages.[106] These inflammatory and immunological responses occur predominantly during reperfusion and are accompanied by production of free radicals (see below). Such responses can cause significant (additional) injury through the phagocytic actions of macrophages, synthesis of toxic products, and further stimulation of immune reactions in a vicious cycle.

Notably, however, this inflammatory response is in part physiological, and may have a "dual role" in that some inflammatory mediators have neuroprotective properties, while others are neurotoxic.[106] Nevertheless, there is strong evidence indicating that a disproportionate and persistent production of cytokines and leukocyte infiltration can sig-nificantly increase the risk and extent of brain cell injury and infarction;[106] the interleukin-1 family appears to be particularly important in this regard.[107] Of note, this effect is partly time-dependent, with the destructive aspects of inflammation outweighing the potential benefits, espe-cially in the later stages of injury.[106]

Numerous animal experiments and also some clinical studies have shown that hypothermia suppresses ischemia-induced inflammatory reactions and release of pro-inflammatory cytokines in animal and clinical studies.[108,109] Apart from its effect on cytokine levels, hypothermia also prevents or reduces reperfusion-related

DNA injury, lipid peroxidation, and leukotriene produc-tion,[26,110,111] as well as decreasing production of nitric oxide, a key agent in development of postischemic brain injury.[89] In animal experiments the extent of brain injury and infarct size can be significantly reduced if *any* of these processes is mitigated or interrupted;[89] thus because hypothermia can affect *all* of these steps there is (at least in theory) a huge potential for improving neurological outcome. Moreover, as the inflammatory response begins relatively late (>1 hour) following ischemia and reperfu-sion, and as the destructive processes require time to develop fully and then continue for prolonged periods of time, they provide a clear therapeutic window for applica-tion of hypothermia to reduce the inflammatory response.

Free radical production
A destructive process that is closely linked to, but distinct from the mechanisms discussed above is the release of oxygen free radicals following ischemia and reperfusion. Mediators such as superoxide (O_2^-), peroxynitrite (NO_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals (OH^-) play important roles in determining whether injured cells will recover or die.[97,110] Free radicals can oxidize and impair numerous cellular components, and although brain cells have enzymatic and non-enzymatic antioxi-dant mechanisms to prevent this type of injury, the levels of free radical production following ischemia/reperfusion are so high that these defensive mechanisms are probably overwhelmed, resulting in peroxidation of lipids, proteins, and nucleic acids. Whereas hypothermia does not inhi-bit free radical production completely, it significantly decreases the amounts of free radicals that are pro-duced[97,110] allowing the endogenous protective (antioxi-dant) mechanisms to cope better with the free radicals that are released, and thereby preventing or significantly mitigating the peroxidation of lipids, proteins, and nucleic acids. If free radical production is sufficiently reduced, the cell can recover. The degree of inhibition of free radical production parallels the degree of hypothermia, i.e., the lower the temperature, the lower the amount of free radicals.

Vascular permeability, blood–brain barrier disruption, and edema formation
Ischemia/reperfusion leads to disruptions in the blood–brain barrier (BBB), which can significantly increase sub-sequent development of brain edema.[112–114] Therapeutic interventions such as mannitol administration in trau-matic brain injury or stroke can add to the BBB disrup-tion,[113] whereas mild hypothermia significantly reduces the disruptions in the BBB;[112–114] in addition, vascular

permeability after ischemia-reperfusion injury is also decreased, which further decreases edema formation.[115] Moreover, in support of this concept, induction of hypothermia decreases the extravasation of hemoglobin after traumatic brain injury.[116] Ischemia and reperfusion can also affect the integrity of the blood–brain barrier in other ways, including decrease in fluidity and integrity of cell membranes and increase in vascular permeability of microvascular endothelial cells in the brain mediated by vascular endothelial growth factor (VEGF) via the release of nitric oxide.[117] These processes of membrane disintegration and hypoxia-induced permeability changes can be relieved or reversed by hypothermia.[117]

In the clinical setting, the development of brain edema is usually assessed by measuring the intracranial pressure (ICP), which can be regarded as a "final common pathway" for all the destructive processes leading to brain edema.[118] Intracranial hypertension and brain edema can also cause development of additional neurological injuries in patients with TBI and stroke as well as causing additional injuries and critically determining outcome in encephalitis and meningitis. Some evidence suggests that brain edema can also affect posthypoxic injury after cardiac arrest.[119]

Since ICH appears to be both a marker for ongoing neurological injury and a cause of additional injury,[118] it seems reasonable that treatments that decrease ICP can also help improve neurological outcome. For example, in patients with traumatic brain injury, ICP is frequently used as a key index to guide treatments and to judge treatment effectiveness.[120]

Notably, although hypothermia has been shown to decrease ICP in many clinical studies, the results in improving survival and neurological outcome have been more mixed,[84,118] with some large trials failing to show any benefits of induced hypothermia.[121] These variable results may be related in part to the management of the side effects of hypothermia;[84,118] see next section below. Speed of induction and the depth and duration of hypothermia may also be important, as evidence suggests that whether or not a lasting protective effect is achieved is critically dependent on these factors.[36,84]

Intra- and extracellular acidosis and cerebral metabolism
The diminished integrity of cell membranes, the failure of various ion pumps, development of mitochondrial dysfunction, inappropriate activation of numerous enzyme systems with cellular hyperactivity, and the disruption of various other intracellular processes all contribute to the development of intracellular acidosis, a factor that powerfully stimulates many of the abovementioned destructive processes.[122,123] Ischemia/reperfusion also leads to significant rises in cerebral lactate levels, which can be effectively attenuated by hypothermia.[122,123] In addition, utilization of brain glucose is affected by ischemia/reperfusion, and some evidence suggests that hypothermia can improve brain glucose metabolism.[124] Both short- and long-term changes in cerebral metabolism may also develop following TBI, where various animal experiments and some clinical observations have reported initial increases in cerebral glucose metabolism (lasting for several hours) followed by a persistent decrease in metabolic rate, with depression of mitochondrial oxidative phosphorylation and glucose utilization lasting for several weeks.[125] Various studies have shown that hypothermia induced during and after reperfusion increases the speed of metabolic recovery, with better preservation of high-energy phosphates and reduced accumulation of toxic metabolites.[125]

Brain temperature and cerebral thermo-pooling
Even in healthy individuals the temperature of the brain may be somewhat higher than the measured core temperature. This difference can increase significantly in some patients after neurological injury, with differences ranging from 0.1 °C to more than 2 °C.[51,126,127] Moreover, even in healthy subjects there may be small differences in temperature between different areas of the brain, which can increase significantly when brain injury occurs, with injured areas becoming more hyperthermic than non-injured ones[128] because of the destructive "hyperactivity" of injured cells caused by the mechanisms outlined above.

Strong evidence from animal studies establishes that (external) induction of hyperthermia significantly increases the risk and extent of neurological injury,[129–131] because hyperthermia may promote necrosis and apoptosis in ischemic areas, even when fever develops (or is externally induced) some time after the initial injury. For example, Baena *et al.* demonstrated that moderate, transient whole-body warming to 39 °C–40 °C for 3 hours, induced 24 hours after a brief episode of forebrain ischemia in rats, induced a 2.6-fold increased neuronal injury in the hippocampus,[129] suggesting that fever even of short duration can be detrimental on the day after injury. Moreover, these effects become more pronounced when hyperthermia coincides with cerebral ischemia, suggesting that ischemic brain cells become even more susceptible to the harmful effects of hyperthermia than do reperfused ones.[132]

Numerous clinical studies have confirmed that fever is indeed an independent predictor of adverse neurological outcome and mortality in stroke, TBI and post-anoxic injury.[133–136] Azzimondi and associates prospectively observed stroke patients and noted that developing fever

was associated with a 3.4-fold increase in the risk for adverse outcome, with a 95% CI of 1.2 to 9.5.[134] Castillo and associates reported that fever developing within 24 hours after stroke onset was independently related to larger infarct volumes (OR 3.23, 95% CI 1.63 to 6.43) and higher neurological deficits (OR 3.06, 95% CI 1.70 to 5.53) at 3 months.[135] Kammersgaard *et al.* reported that each 1 °C increase of body temperature on admission independently predicted a 30% relative increase in long-term mortality risk, with a 95% CI of 4% to 57%.[136]

Although it has not yet been conclusively proven that fever itself increases neurological injury rather than just being a marker for it, the temporal relationship and the results from animal studies[129–131] strongly suggest that it is. This is in accord with observations from other animal studies that induction of mild hypothermia can prevent fever-related neurological injuries and improves tissue tolerance for ischemia.[84,137–139]

Coagulation activation and formation of micro-thrombi
Various studies have shown that cardiopulmonary arrest and resuscitation are accompanied by a marked activation of coagulation, which can lead to intravascular fibrin formation with blockage of the microcirculation in the brain and heart.[140,141] Administration of anticoagulants such as heparin and rt-PA has been shown to improve microcirculatory reperfusion and survival in various animal experiments;[141,142] in addition, thrombolysis can improve cerebral tolerance to ischemia.[143] Preliminary clinical observations suggest that administering thrombolytic agents to cardiac arrest patients during the very early stages of CPR can indeed improve neurological outcome and survival.[144]

Thus it appears that relatively mild ones, anticoagulants (e.g., low-dose heparin) or more powerful ones (e.g., rt-PA) can improve neurological and cardiac outcome in the early stages of ischemia/reperfusion, by enhancing the microcirculation and removing micro-thrombi. Hypothermia also induces a mild bleeding diathesis, through combined effects on platelet count, platelet function, and the coagulation cascade.[145–150] The anticoagulation effect of hypothermia could provide yet another mechanism for its neuroprotective and cardioprotective effects. But although this hypothesis seems plausible, as outlined above[140–144,151] the concept remains speculative, as there are no studies directly addressing this issue.

Vasoactive mediators
Some evidence suggests that hypothermia can influence the local secretion of vasoactive substances by the endothelium, such as endothelin, thromboxane A2 (TxA2) and prostaglandin I_2, in the brain and at other sites.

Endothelin and TxA2 are both powerful vasoconstrictive agents, while prostaglandin I_2 is a vasodilator; thromboxane can also induce platelet aggregation.[152] These two agents play an important role in regulating local cerebral blood flow, and a balance between the two is required to maintain homeostasis.[152] There is also some evidence suggesting that this local homeostasis may be disrupted after an ischemic and/or traumatic event, with a relative increase in the production of thromboxane.[153] Such disruptions in equilibrium could lead to vasoconstriction and therefore to hypoperfusion and/or thrombogenesis in injured areas of the brain.

This local imbalance in vasoactive mediator production with a relative predominance of vasoconstrictors can be corrected or modified by hypothermia.[111,154,155] Thus, Aibiki *et al.* reported that induction of moderate hypothermia (32 °–33 °C) led to a reduction in prostanoid production and attenuation of the imbalance between thromboxane A2 and prostaglandin I_2 in patients with traumatic brain injury.[154] Chen *et al.* observed decreased production of the vasoconstrictor endothelin-1 associated with hypothermia.[155] Although such preliminary evidence suggests that hypothermia may favorably affect secretion of vasoactive mediators, regulation of cerebral perfusion especially in the injured brain is highly complex, and the impact of hypothermia should be studied in greater detail. Apart from the temperature, local cerebral circulation can be influenced by numerous and highly diverse factors, including the presence or absence of normal cerebral autoregulation, ventilator settings and blood gas management, and concomitantly administered treatments such as mannitol and hypertonic saline, among others.

Improved tolerance for ischemia
Hypothermia has been shown to improve the tolerance for ischemia in various animal models.[156–158] For this reason, it is widely used in the perioperative setting, especially in major vascular surgery, cardiothoracic surgery and neurosurgical interventions. An ability to withstand periods of ischemia more effectively would be an important potential protective mechanism, because patients with different types of neurological injury may develop periods of ischemia for many days following their initial injury. In patients with subarachnoid hemorrhage the development of vasospasm every week after the initial bleeding episode can lead to significant additional ischemic injury. The risk of ischemia long after admission also applies to patients after CPR, where evidence suggests that cerebral ischemia may persist for several hours following successful resuscitation even when saturation and arterial oxygen levels are normal.[159] Thus an increased tolerance for ischemia could

be yet another mechanism for beneficial effects of hypothermia.

Role of epileptic activity and other mechanisms
Non-convulsive status epilepticus, i.e., epileptic activity without obvious clinical signs and symptoms, occurs frequently in patients with various types of brain injury (including subarachnoid hemorrhage, stroke, TBI and postanoxic encephalopathy).[160–164] Whether non-convulsive status epilepticus by itself causes permanent (additional) brain injury remains somewhat controversial; however, there is mounting evidence that brain injury can be significantly increased when non-convulsive status occurs in the acute phases of brain injury, i.e., while the destructive processes outlined above are ongoing.[160,161] Thus, although the role of non-convulsive status epilepticus by itself has not been fully clarified, when it occurs in combination with acute brain injury the two are synergistically detrimental, and can markedly increase brain injury.[160,161]

Evidence from various sources suggests that hypothermia can suppress epileptic activity. Various case reports and case series have reported successful use of hypothermia in the treatment of grand mal seizures.[165,166] Animal studies have shown that induction of hyperthermia increases the extent of epilepsy-induced brain injury, while prevention or prompt treatment of hyperthermia reduces these injuries,[167–169] and induction of hypothermia decreases epilepsy-induced brain injury.[169,170] Thus the anti-epileptic effect of hypothermia may also explain its neuroprotective effect.

In addition, an enhanced expression of various so-called *immediate early genes* which are a part of the cellular stress response to injury, and the induction of various *cold shock proteins* that can protect the cell from different types of injury including ischemia and trauma may also be added to protection by hypothermia.[171] There is evidence that hypothermia can suppress so-called *spreading depression-like depolarizations,* which can augment neuronal damage in various types of brain injury.[172] These mechanisms have been studied mainly in TBI and stroke; their role in the transient ischemic brain injury that characterizes cardiac arrest, and the precise influence of induced hypothermia on these processes, remain to be determined.

In summary, there are numerous mechanisms that may underlie the protective effects of hypothermia in various types of brain injury, and perhaps myocardial injury. That hypothermia can influence so many of the destructive mechanisms following ischemia and reperfusion may explain why it has proved effective in a clinical setting, at least in some situations, where other treatments have failed or proved far less successful.

Different destructive mechanism may play a more or less important role in different types of brain injury; in addition, their relative mechanisms may vary among patients, and even over time within the same patient. A more detailed understanding of these processes will help us to apply hypothermia treatment more effectively. The other key element of a successful use of this treatment will be avoiding side effects of hypothermia, as discussed below.

Side effects of induced hypothermia
Hypothermia induces physiological changes in virtually every tract and every organ in the body. The kinetic properties of most enzyme systems are temperature-dependent; thus the speed of various enzyme-mediated reactions (including drug metabolism) is significantly influenced by hypothermia, as well as circulatory, respiratory, and coagulation systems. The physiological changes induced by hypothermia, as well as the implications that this has for methods for inducing hypothermia, are discussed in a separate section above. Here we focus on the most important side effects, those that require detailed attention and management in a clinical setting. Of note that this some changes induced by hypothermia, although physiological, are nevertheless undesirable in critically ill, neurointensive care patients and therefore require preventive measures and/or treatment. In contrast, other consequences of hypothermia are side effects, but pose no great risk to the patient and thus usually do not require active treatment. For example, mild hypothermia frequently induces bradycardia and a decrease in cardiac output, which rarely requires treatment. In contrast, hypothermia induces insulin resistance and a decrease in insulin secretion in many patients, which can lead to hyperglycemia. This physiological consequence of hypothermia requires aggressive treatment because hyperglycemia has been shown to affect outcome adversely in critically ill patients,[173] and to have negative effects on neurological outcome, by increasing brain injury during episodes of ischemia.[87,170]

To discuss risks of side effects, hypothermic treatment is considered in three phases: the induction, maintenance, and rewarming. Each of these phases is associated with different problems and risks, and thus requires a different management approach.

In general, the induction phase of hypothermia, before the target temperature has been reached is where the risk of short-term side effects, (e.g., electrolyte disorders and severe disturbances of glucose metabolism), is greatest. Patients tend to be most "unstable" during this phase, and management is most difficult because many short-term changes occur. For example, ventilator settings and dosage

of vasoactive drugs usually require frequent changes, and various metabolic measures should be carefully monitored by frequent blood serum analysis. The risk of side effects of cooling can be minimized by cooling patients rapidly to reach the maintenance phase as quickly as possible. This can be accomplished by using combinations of different cooling methods, such as a combination of large-volume infusion of cold fluids and surface cooling.[174] Once the core temperature decreases below ± 33.5 °C, the patient tends to become more stable, with less risk for fluid loss or intracellular shifts, cessation or significant reduction of shivering, and no further major changes in hemodynamic parameters.[84,175,176]

Once the maintenance phase commences, the risk of acute side effects such as electrolyte disorders diminishes (although some risk still remains). In this phase attention should shift towards the prevention of longer-term side effects such as pneumonia, wound infections, and bed sores (see below).

The rewarming phase is also associated with electrolyte disorders caused by shifts from the intracellular to the extracellular compartment; this can be largely prevented by slow and controlled rewarming, to preserve the neuro-protective effects, rapid rewarming may reactivate the destructive processes outlined above.

The most important side effects of induced hypothermia are discussed below.

Arrhythmias, hemodynamic changes, and cardiovascular effects
Mild hypothermia (32 °–34 °C) induces significant changes in various hemodynamic parameters: cardiac output decreases by about 25% through decreased contractility and reduced heart rate. Central venous pressure usually rises, as well as an increase in arterial resistance. A slight rise in blood pressure, by ±10 mmHg, is caused by hypothermia-induced vasoconstriction of peripheral arteries and arterioles. This effect is absent or less pronounced in cerebral arteries, where the balance between cerebral blood flow and cerebral metabolism (as measured by oxygen and glucose utilization) is maintained or improved.[177,178] Under normal circumstances hypothermia also induces a small increase in central venous pressure. These observations have been confirmed in clinical trials in adults and in children.[5,179]

Hypothermia also induces electrocardiographic changes and alterations in the heart rhythm. When hypothermic treatment is first started and body temperature begins to decrease from normothermia, patients will develop sinus tachycardia, caused in part by a shift in circulatory volume from the peripheral compartment, especially the skin, to the core compartment. This leads to a relative increase in the venous return to the heart, which can induce a concomitant increase in heart rate. As temperature decreases further, below 35.5 °C sinus bradycardia ensues, with a progressive decrease in heart rate as temperature decreases further. Typically, at core temperatures of 32° the heart rate can decrease to around 40 beats per minute or even lower, although there is a wide inter- and intra-individual variability. This decrease is caused by a decrease in the rate of diastolic depolarization in the cells of the sinus node, and is accompanied by EKG changes, including prolonged PR-interval, widening of the QRS-complex, increased QT-interval, and sometimes so-called Osborne waves. Diastolic and systolic dysfunction may develop with decreased myocardial contractility. Lower heart rate combined with diminished myocardial contractility leads to a decrease in cardiac output of ± 25% at temperatures of 33 °–34 °C. In general, however, the decrease in metabolic rate is equal to or greater than the decrease in cardiac output caused by the bradycardia and decreased myocardial contractility. Mixed venous saturation, which can be measured to determine tissue oxygen extraction, usually remain unchanged or increase reflecting an unchanged or improved circulatory state. Thus hypothermia-associated bradycardia usually does not require treatment. If treatment is considered necessary, because of the mechanism underlying this form of bradycardia, atropine will not be effective. Therefore, stimulation of heart rate can be accomplished by administering isoprenaline, by rewarming the patient to slightly higher temperatures, or (in extreme cases) by inserting a pacing wire, although the last-mentioned is very rarely necessary.

The risk of developing clinically significant arrhythmias is very low as long as the patient's core temperature remains above 30 °C. The risk of severe arrhythmia increases significantly if core temperature drops below 28 °–30 °C, especially if electrolyte disorders have also developed. When arrhythmias do develop, they usually begin with atrial fibrillation (AF), which can be followed by more severe arrhythmias including ventricular tachycardia (VT) and ventricular fibrillation (VF) if temperature decreases further. Importantly, mechanical manipulations can trigger this transition from AF to VF, because the myocardium becomes highly sensitive to mechanical manipulations during hypothermia.[180] Thus, performing chest compressions because of extreme bradycardia this can easily lead to a conversion of sinus rhythm to VF, or AF to VF. A major problem is that once arrhythmias develop in hypothermic patients, they are much more difficult to treat than at normothermia, because the myocardium becomes less responsive to many cardiac and anti-arrhythmic drugs

during hypothermia. As these problems are extremely rare at temperatures above 28°–30°C, great care should be taken to keep core temperatures above this limit. In our center we routinely cool some patients to temperatures very close to this limit (between 30.5 and 32°C for refractory intracranial hypertension) without encountering severe arrhythmias, provided that electrolyte levels are carefully monitored and promptly corrected.

The relative increase in venous return induced by hypothermia can lead to an activation of atrial natriuretic peptide and a decrease in the levels of antidiuretic hormone (ADH). This (in combination with other mechanisms such as tubular dysfunction, see below) can lead to a marked increase in diuresis ("cold diuresis"), which if uncorrected can lead to hypovolemia, renal electrolyte loss, and hemoconcentration with increased blood viscosity.[181–183] The risk of hypovolemia is greater when the patient is also treated with agents that can increase diuresis, such as mannitol in patients with traumatic brain injury. The increased blood viscosity (of ± 2% per °C decrease in core temperature) can lead to problems in the microcirculation; the abovementioned mechanisms combined with tubular dysfunction can lead to severe electrolyte disorders (see below) and to a rise in serum sodium levels and osmolarity. Thus, careful attention should be paid to intravascular volume and fluid balance in patients treated with hypothermia, and hypovolemia should be avoided or promptly corrected.

Coronary perfusion and ischemia

From various studies in postoperative patients the presence of hypothermia is associated with increased risk of myocardial infarction, and it is widely believed that hypothermia can lead to coronary vasoconstriction and myocardial ischemia. In addition, various studies have shown that accidental hypothermia in the perioperative setting is associated with an increased risk for morbid cardiac events.[184,185] The actual situation is more complex, in particular because the result probably depends on the pre-existing condition of the patient's coronary arteries and on local factors: in healthy subjects, mild hypothermia (around 35°C) actually increases coronary perfusion,[186] whereas in patients with coronary artery disease hypothermia can induce vasoconstriction in severely atherosclerotic coronary arteries.[187]

Various animal experiments[188–195] and preliminary clinical studies have shown that hypothermia may actually decrease myocardial injury after cardiac arrest, provided it is initiated early enough.[68,196,197] Thus, the question whether hypothermia mitigates myocardial injury should be addressed in further larger studies, available evidence does not suggest that hypothermia *increases* this injury,

which might be the case if hypothermia caused vasoconstriction in these patients.

Electrolyte disorders

Patients treated with induced hypothermia are at high risk for developing electrolyte disorders, because of a combination of increased renal excretion of electrolytes and intracellular shift.[182] The mechanisms underlying the increased renal excretion are altered volume regulation and cardiac preload (see above) and tubular dysfunction.[182] This is important because electrolyte disorders, especially hypomagnesemia, may be associated with an increased risk for adverse neurological outcome. In experimental settings depletion of magnesium (Mg) leads to significantly worse neurological outcomes after traumatic injury, whereas administration of Mg during or some time after the event substantially mitigates secondary injury and reduces loss of cortical cells.[198–201] Magnesium may also play a role in prevention of reperfusion injury.[202,203] In addition, loss of Mg is associated with vasoconstriction of cerebral and coronary arteries.[204] Animal studies have shown that administration of magnesium following myocardial infarction is associated with reduced infarct size and improved preservation of myocardial function.[205] In clinical studies, hypomagnesemia has also been linked to atrial and ventricular arrhythmias, neuromuscular abnormalities with muscle weakness (including cardiac insufficiency), bronchospasm, seizures, and metabolic effects including decreased insulin sensitivity.[204] Hypomagnesemia can also induce other electrolyte disorders including hypokalemia, hypocalcemia, hyponatremia, and hypophosphatemia.

In clinical studies, hypomagnesemia is an independent predictor of adverse outcome both in critically ill ICU patients and in less severely ill patients in the general ward.[206,207] It is specifically associated with adverse outcome in patients with unstable angina or myocardial infarction,[208] and administering magnesium has been shown to reduce mortality and infarct size in these patients.[209]

With respect to other electrolyte disorders, hypokalemia and hypophosphatemia can also have highly undesirable effects, including arrhythmias, muscle weakness and neuromuscular abnormalities. Hypophosphatemia can induce weakness of the diaphragm and respiratory muscles leading to an increased risk of respiratory infections and failure to wean, in infants as well as impaired myocardial function and a decrease in cardiac output.[204,210,211]

The clinical consequences of hypokalemia (cardiac arrhythmias, muscle weakness, rhabdomyolysis, renal failure, and hyperglycemia) are usually well recognized, and in most ERs and ICUs, potassium levels are measured

promptly and frequently. The potential risks of disorders in sodium metabolism in neurological injury are also usually appreciated, as both hypo- and hypernatremia can significantly increase the severity of brain injury. Magnesium and phosphate usually receive far less attention from ER and ICU physicians, however. The list of potential complications of electrolyte disorders shows that preventing hypothermia-associated electrolyte disorders should be an important goal of therapy in patients treated with induced hypothermia.

Levels of Mg, P, and K should be maintained in the high or high-normal range in all patients with neurological injuries. Of note, serum Mg levels do not always accurately reflect true Mg status; intracellular Mg stores may be significantly depleted while serum Mg levels remain normal.[204] This also applies to levels of ionized Mg, although this better reflects the levels of "active" magnesium.

Hyperglycemia

As already discussed above, hypothermia can simultaneously decrease insulin sensitivity and reduce insulin secretion by pancreatic islet cells. Thus, patients treated with induced hypothermia will be at high risk for developing hyperglycemia, which is associated with increased morbidity and mortality in critically ill patients. Strict control of glucose levels with intensive insulin therapy can reduce morbidity and mortality.[173,212] Hyperglycemia is associated with increased rates of infection, critical illness neuropathy and renal failure.[173] This strongly suggests tight control of glucose levels when hypothermia is induced in critically ill patients.

Other metabolic effects and blood gas analysis

Hypothermia leads to an increase in the synthesis of glycerol, free fatty acids, ketonic acids, and lactate, this will cause a mild metabolic acidosis in most patients, which is a physiological consequence of hypothermia and does not require treatment. In contrast to the pH levels measured extracellularly, *intracellular* pH levels usually increase slightly during hypothermia.

The decrease in metabolic rate (5%–8% per °C drop in core temperature) also decreases oxygen requirements and the synthesis of carbon dioxide (CO_2). Thus the ventilator settings should be adjusted during induction of hypothermia, and blood gases should be monitored frequently especially during the induction phase of cooling.

Of note, the measurement of blood gases is influenced by the temperature of the blood. In blood gas analyzers, samples are warmed to 37 °C, so that when the actual temperature differs significantly from 37 °C, these measurements will not be correct. If blood samples from hypothermic patients are rewarmed under vacuum-sealed conditions, PO_2 and PCO_2 will be overestimated, and pH underestimated. For example, in a patient with an uncorrected core temperature of 30 °C and PCO_2 of 40 mmHg the actual (corrected) PCO_2 value would be 29 mmHg.[213] In the same patient with an uncorrected PO_2 of 100 mmHg, the value corrected for temperature will be 73 mmHg. True pH is also underestimated, with hypothermia leading to a more alkalotic status compared to normothermia (pH increase ± 0.011 pH unit/°C). In the example cited above, the measured pH would be 7.40, whereas the true pH would be 7.50. The concept of CO_2 management in which the PCO_2 obtained by measurement at 37 °C is kept constant (for example, at 40 mmHg) regardless of the actual body temperature is called *alpha-stat*. If the PCO_2 value is corrected for the actual body temperature, and is held constant at the same level as during normothermia, this implies that the "true" amount of CO_2 will increase during hypothermia. This concept of CO_2 management is called *pH-stat*. In other words, when alpha-stat CO_2 management is applied, pH that is not corrected for current body temperature remains constant, while true pH increases because the actual $PaCO_2$ has decreased. When pH-stat CO_2 management is used true pH remains constant, while pH that is not corrected for temperature decreases.

Which method is superior in managing hypothermic patients has not been settled. There is evidence to support both methods.[171,213] Supporters of the pH-stat method argue that it leads to hyperventilation, hypocapnia and hypocapnia-induced cerebral vasoconstriction, while pH-stat management induces a degree of hypercapnia leading to cerebral vasodilatation (provided cerebral autoregulation is intact). The latter would be a more attractive option. However, hypercapnia can impair or abolish cerebral autoregulation, presumably because CO_2-induced vasodilatation limits the vessels' capacity to dilate further.[171,214] This may mean that the body's capacity to divert blood to injured areas is impaired. In addition, some animal studies suggest that respiratory alkalosis is physiologically appropriate during hypothermia to preserve normal physiological conditions.[171]

Regardless of which method of blood gas management is chosen, physicians using mild hypothermia in their patients should be aware of the effects of temperature on blood gas analysis and on other laboratory measurements. In addition, the effect of temperature on PO_2 should be taken into account in all cases, and the measured PaO_2 should always be corrected for current body temperature in hypothermic patients to maintain true PaO_2 in the normal range, regardless of the pCO_2 management method chosen.[213]

Coagulation measures

Hypothermia induces a mild bleeding diathesis, with increased bleeding time due to effects on platelet count, platelet function, the kinetics of clotting enzymes and plasminogen activator inhibitors, and other steps in the coagulation cascade.[145,147–149] Standard coagulation tests will not show abnormalities unless they are performed at the patient's actual core temperature; similar to blood gas analyses, the samples are usually warmed to 37 °C before the clotting tests are performed. Even though the coagulation defects can be caused by hypothermia, the risk of clinically significant bleeding induced by hypothermia in patients who are not already actively bleeding is very low. None of the large clinical trials in patients with TBI, SAH, stroke, or postanoxic coma reported significantly increased risks of intracranial bleeding associated with hypothermia. In patients who are already actively bleeding, for example in multi-traumatized patients, the sites of bleeding should be controlled before hypothermic therapy is initiated.

Infections

Hypothermia impairs immune functions and inhibits various inflammatory responses. This side effect may be advantageous in that impairment of harmful inflammatory reactions in the brain may be one of the mechanisms through which hypothermia can be protective. Nevertheless, hypothermia inhibits secretion of proinflammatory cytokines and suppresses leukocyte migration and phagocytosis. Hypothermia-induced insulin resistance and hyperglycemia may further increase infection risks. Many of the clinical studies that induce hypothermia for various indications have reported a slightly, moderately or in some cases severely increased incidence of pneumonia when hypothermia was used for periods longer than 24 hours,[212,214–216] but if hypothermia is used for 24 hours or less no or only small increases in the rates of infection were reported. Various studies suggest that use of antibiotic prophylaxis in the form of selective decontamination of the digestive tract can decrease ICU mortality and colonization with resistant gram-negative bacteria,[217] and some evidence suggests that selective decontamination can prevent infections during prolonged use of hypothermia.[118,218] Thus antibiotic prophylaxis may be considered in patients treated with induced hypothermia.

An increased risk of wound infections associated with hypothermia has also been reported,[219,220] which may be related both to diminished leukocyte function and to hypothermia-induced vasoconstriction in the skin. Thus extra care should be taken in cooled patients to prevent bed sores, which are more likely to progress and/or show impaired healing. Extra attention should also be paid to catheter insertion sites and to any surgical wounds.

Shivering

When hypothermia is induced, the body will employ various mechanisms to generate heat and decrease heat loss. The latter is accomplished mainly through increasing sympathetic tone and through vasoconstriction in the skin, while heat generation may be accomplished by shivering. Shivering can increase oxygen consumption by between 40% and 100%,[221] an undesirable effect in patients with neurological and/or posthypoxic injury. This is less problematic in mechanically ventilated patients, as the work of breathing will not be increased by shivering. Nevertheless shivering can also present a technical problem by decreasing cooling rates; this problem is discussed more extensively elsewhere.

Shivering can be controlled by administration of sedatives, anesthetics, opiates and/or paralyzing drugs. In most patients shivering can be significantly attenuated by relatively small doses of opiates. When use of paralyzing agents and/or opiates is deemed undesirable, alternatives include administration of clonidine, neostigmine and ketanserine. Care should be taken to avoid adverse effects, however; for example, clonidine may worsen hypothermia-induced bradycardia.

Other side effects

As already stated, hypothermia can significantly influence drug metabolism and pharmacokinetics, because the enzymes that metabolize most drugs are highly temperature-sensitive. For many drugs commonly used in the ER and ICU, the effect of (lower) temperatures is unknown, because drug metabolism and clearance have not been studied at different temperatures. Nonetheless, it seems likely that the clearance of many drugs will be significantly decreased during hypothermia, as has been demonstrated in clinical studies for propofol, fentanyl, muscle paralysers and barbiturates.

Hypothermia can also lead to various changes in laboratory measurements. The most frequently occurring changes are shown in Table 49.2.

Finally, it is clear that most of the side effects of hypothermia can be prevented or well controlled in an appropriate intensive care setting. Patient management problems will vary according to the depth and the duration of hypothermia, and the underlying disease of the patient. In general the use of hypothermia in patients with TBI and stroke will present more problems than the use of hypothermia in patients following cardiac arrest and CPR.[84] It is important that the medical and nursing staff

Table 49.2. Most frequently occurring hypothermia-induced changes in laboratory measurements

Increase in serum amylase levels

Mild-to-moderate thrombocytopenia (platelet count 30×10^{12} -100×10^{12})

Increase in serum lactate levels (2.5–5 mmol/l)

Hyperglycemia

Electrolyte disorders (low Mg, K, P, Ca)

Increase in liver enzymes (SGOT and SGTP)

Mild metabolic acidosis

Mild coagulation disorders

Changes in blood gases

members using induced hypothermia be aware of the physiological and pathophysiological changes that can be expected, and that they can determine which changes require treatment and which do not (Fig. 49.3).

Prediction of neurologic outcome after cardiac arrest in patients treated with therapeutic mild hypothermia (Roine and Tiainen)

Global cerebral ischemia after cardiac arrest is a common cause of extensive brain damage by multiple pathophysiological mechanisms. The clinical syndrome related to global cerebral ischemia is called hypoxic-ischemic encephalopathy (HIE), the severity of which usually determines the outcome of cardiac arrest patients with restored spontaneous circulation. Most patients resuscitated from cardiac arrest are initially comatose. Early prediction of neurological outcome in patients resuscitated from cardiac arrest is a major ethical, medical and economical challenge. To avoid falsely pessimistic prognosis, the prognostic tests used in critical care are usually required to have high specificity and a narrow confidence interval for poor outcome, with less emphasis on sensitivity. When evaluating the prognosis of a comatose patient resuscitated from cardiac arrest, a false prognosis of poor outcome can lead to early withdrawal of care and thus carries a risk of a self-fulfilling prophecy. On the other hand, a falsely optimistic prediction may lead to unnecessary prolongation of intensive care therapy and might prevent admission of other patients who could benefit more.

Clinical status

The times from collapse to the start of basic and advanced life support and especially to defibrillation correlate with survival rate.[222,223] The prognosis declines with increasing duration of coma. No clinical findings on admission have been proven to reliably predict poor outcome and no attempt should be made to assess the neurologic prognosis on admission on clinical grounds. In a recent review article, Booth *et al.* examined all 11 studies between years 1979 and 2000 that addressed clinical signs in outcome prediction after cardiac arrest. They concluded that prognostic assessment of outcome on clinical grounds is not possible before 24 hours have elapsed, and motor signs are not meaningful before 72 hours.[224] This meta-analysis included 1914 comatose survivors of cardiac arrest. Patients sedated or anesthetized during the clinical examination were not included in the analysis. The most useful signs predicting poor outcome were absent corneal and pupillary reflexes, absent motor response at 24 hours, and absent withdrawal to pain at 72 hours after cardiac arrest.[224] Heavy sedation and opiate analgesia are, however, used much more frequently and in higher doses than they were a few decades ago. Old prediction rules based solely on clinical signs and the duration of coma are therefore often outdated or should be revalidated.

Generalized myoclonus status has been reported to be a terminal finding after cardiac arrest and to be incompatible with recovery.[225] Nevertheless, early myoclonic status is not necessarily an agonal event.[226] Therapeutic hypothermia usually requires muscle relaxation to prevent shivering, and this masks myoclonic jerking as well as seizures.

Assessment of clinical status is also masked to some extent by the use of therapeutic hypothermia. Induced hypothermia requires muscle relaxation, sedation and mechanical ventilation, which may complicate the clinical assessment. Hypothermia may also induce changes in drug metabolism and increase the duration of sedative drug effects.[220] The possible effect of individual medications to a patient's clinical status should always be carefully considered. Our own experience is that the sedative effect of both midazolam and propofol can be significantly prolonged in hypothermia-treated patients. Some of our patients did not recover consciousness until day five after cardiac arrest, but made a good recovery thereafter.

Serum markers

Neuron-specific enolase (NSE) is the neuronal form of the intracytoplasmic glycolytic enzyme enolase. NSE is located in neurons and in neuroectodermal cells. It is a dimeric enzyme composed of two γ subunits, with a molecular weight of 78 000 Dalton and biologic half-life of about 24 hours. Neuronal damage and impairment of blood–brain barrier integrity can be detected by release of

NSE into cerebrospinal fluid and eventually to the blood. Increased levels of NSE in cerebrospinal fluid and serum have been reported after ischemic stroke, intracerebral hemorrhage, brain injury, and cardiac arrest. Several studies have found high levels of serum NSE to be associated with poor outcome in patients resuscitated from cardiac arrest.[227–233]

The S-100B protein is an acidic Ca^{2+} binding protein with a molecular weight of approximately 21 000 Dalton and biologic half-life of 0.5 hour. The protein has two subtypes: αβ-heterodimer and ββ-homodimer; the αβ-form is found in astroglial cells; and the ββ-form is found predominantly in astroglial and Schwann cells, but it has also been demonstrated in tumors such as melanoma, schwannoma, and highly differentiated neuroblastoma. Increased serum levels of protein S-100B have been reported after traumatic brain injury, stroke, cardiac arrest, and cardiopulmonary surgery. High levels of serum S-100B after cardiac arrest have been reported to correlate with unfavorable neurologic outcome.[230,232,234–237]

We studied the time-course of serum NSE and S-100B in hypothermia-treated cardiac arrest patients. The levels of serum NSE were lower in hypothermia- than in normothermia-treated patients during the first 48 hours after cardiac arrest. NSE values decreased between 24 and 48 hours in 30 of 34 patients (88%) in the hypothermia group and in 16 of 32 patients (50%) in the normothermia group ($P<0.001$). Furthermore, the decrease in NSE values was associated with good outcome, and increase with poor outcome at 6 months after cardiac arrest. The results suggest that the time-course of serum NSE between 24 and 48 hours after cardiac arrest may aid in clinical decision-making. Decreasing levels of serum NSE over time may indicate selective attenuation of delayed neuronal death by therapeutic hypothermia.[238] In the same study the levels of serum S-100B did not differ between the two treatment arms. The serum S-100B levels decreased between 24 and 48 hours in 17 of 34 (50%) patients in the hypothermia group and in 15 of 33 (45%) patients in the normothermia group, but the decrease in the levels of serum S-100B during this time period was not related to the outcome. However, in another study by Hachimi-Idrissi et al., the serum S-100B levels decreased significantly between admission and 24 hours after cardiac arrest in the hypothermia-treated group.[239] In our study the ROC-analysis of serum NSE and S-100B at different time-points revealed that cut-off values predicting unfavorable outcome with a specificity of at least 95% were higher in the hypothermia group. Unfortunately, the sensitivity of these tests was remarkably poor in the hypothermia group.[238] The use of hypothermia seems to

reduce the prognostic value of both serum NSE and S-100B in outcome prediction, which may be explained by the neuroprotective effect of hypothermia, in preventing the continuing injury and release of these ischemia markers in the blood stream. Hypothermia is also known to maintain the integrity of blood–brain barrier after ischemic damage.[240,241]

Clinical neurophysiology

The short-latency median nerve somatosensory evoked potentials (SSEP) have been found to predict accurately permanent coma after cardiac arrest.[242,243] A bilaterally absent early cortical N20 response (first cortical response occurring approximately 20 ms after stimulation to median nerve at wrist) predicts permanent coma with a specificity of 100% (95% confidence interval 99–100%) and thus the median nerve SSEPs are the method of choice for predicting outcome after cardiac arrest. Significant improvement in SEP have been reported within 24 hours after ROSC,[244] and allowing at least 24 hours after cardiac arrest is recommended for obtaining a reliable prognosis based on SEP. Moreover, normal cortical SEP responses do not guarantee awakening from coma.

Short-latency SEP recording is a non-invasive, reproducible technique that can be easily performed at the bedside in the ICU. Short-latency SEPs are also quite resistant to anesthetic agents. Induced hypothermia requires muscle relaxation, which prevents the adjustment of SEP stimuli intensity based on thumb twitch. The intensity of the stimuli must be sufficient to evoke an ipsilateral supraclavicular response in patients with clinical muscle relaxation. Hypothermia of 33 °C reduces nerve conduction velocity and delays early cortical N20 response. In a study examining 30 still-hypothermic, comatose cardiac arrest survivors at 24–28 hours after resuscitation, the cortical N20 response appeared approximately 24 milliseconds after the stimulus. Bilateral absence of short-latency cortical potentials predicted permanent coma reliably also in these patients.[245]

Long-latency SEPs (N70 response) have been found useful in identifying patients with favourable outcome.[246] Madl et al. also reported that the N70 long-latency sensory evoked potential was more accurate in predicting individual outcome than a panel of three experienced emergency physicians review clinical data 24 hours after cardiac arrest.[247] Because of the slowing of neural transmission with hypothermia, the N70 cut-off values determined on normothermic patients cannot be applied to hypothermic patients. Recording of long-latency SEPs is more demanding than recording of short-latency SEPs, since long-latency SEPs are often less reproducible and more prone to

artifacts than short-latency SSEPs, this may be an issue, especially in the ICU environment. So far no studies examining long-latency SEPs in hypothermic cardiac arrest survivors have been published.

The prognostic ability of electroencephalography (EEG) has also been studied in cardiac arrest survivors. EEG is quite sensitive to drug effects and metabolic disturbances, which limits its prognostic usefulness. Only EEG with essentially complete generalized suppression after the first day of the arrest in the absence of sedative or anesthetizing drug effects is associated with invariably poor outcome. Suppression of EEG, periodic complexes, epileptiform activity, burst-suppression or alpha coma pattern does not preclude the possibility of neurologic recovery, although it usually indicates poor outcome.[248] Serial EEGs may offer supplemental information about the evolution of the patient's status. Mild hypothermia produces small changes in the EEG,[249] but no studies evaluating the prognostic value of EEG findings in cardiac arrest patients treated with hypothermia have been published.

Neuroradiological imaging

In the acute stage, conventional MRI or CT may be useful for differential diagnosis. In hypoxic–ischemic encephalopathy, later neuroradiological imaging may reveal bilateral watershed infarcts, laminar cortical necrosis, and cerebellar, white matter, and basal ganglia lesions. Neuroradiological imaging findings apparently have limited prognostic value, except for absent intracranial circulation or increased intracranial pressure. A normal conventional MRI or CT does not exclude the diagnosis of hypoxic-ischemic encephalopathy.[250] FLAIR (fluid-attenuated inversion recovery) and DW (diffusion weighted) imaging may help detect extensive ischemic damage in comatose survivors of cardiac arrest.[251,252] The difficulty of performing MR imaging in critically ill patients often limits the use of this examination.

Limitations of outcome prediction methods

Currently the methods used in assessing the neurologic prognosis are targeted to predict poor outcome (death or persisting coma). Despite all normal examination results some survivors of cardiac arrest never regain consciousness. So far, there are no methods to predict good outcome accurately in the early phase of treatment. Reliable prediction methods are required not just to direct intensive care for the patients benefiting from it, but also in order to alleviate the emotional distress of the patient's family suffering from prolonged uncertainty of their loved one's outcome.

The use of therapeutic hypothermia may complicate the evaluation of outcome. The prediction methods developed on normothermic patients cannot be applied directly to patients treated with hypothermia without validation studies. Therapeutic hypothermia also seems to postpone the first feasible prognostic evaluation, which should not be undertaken during hypothermia or shortly after rewarming the patient. As the amount of evidence and the number of studies concerning prediction of outcome in hypothermia-treated patients are still limited, caution and discretion should be exercised in assessing the neurological prognosis of victims of cardiac arrest and particularly regarding the end-of-life decisions.

Future of preservative hypothermia, suspended animation (Behringer)

Suspended animation

In sudden cardiac death, cooling can be started *before* ischemia (protection), *during* ischemia (preservation), and *after* ischemia (resuscitation). Cerebral protection has been used since the 1950s to protect the brain against global ischemia during cardiac surgery, but is logistically not feasible in sudden cardiac arrest patients. Cerebral resuscitation with mild therapeutic hypothermia after successfully restoring the circulation is described above. The following paragraphs will describe cerebral preservation, which might be feasible during no-flow and low-flow cardiac arrest. The concept of suspended animation, that is: "preservation of the organism during transport and surgical hemostasis, under prolonged controlled clinical death, followed by delayed resuscitation to survival without brain damage"[253] was introduced for trauma victims, who rapidly bleed to death. In these patients, conventional resuscitation attempts are futile, and currently mortality is near 100%. We believe that, if the concept of suspended animation is suitable for normovolemic cardiac arrest, it should be investigated.

Suspended animation in exsanguination cardiac arrest

Protective hypothermia for cardiac surgery is induced slowly and reversed with cardiopulmonary bypass. In the field, cardiopulmonary bypass is not yet available, and in trauma victims who exsanguinate to cardiac arrest, hypothermia must be induced before the brain loses its viability, i.e., within the first minutes of no-flow. Therefore, the use of an aortic cold flush was introduced to induce preservative hypothermia rapidly first in the most sensitive organs, the heart and brain, and cardiopulmonary bypass was used only for resuscitation and rewarm-

ing[254,255]. Dogs were exsanguinated over 5 minutes to cardiac arrest no-flow of 15 to 120 minutes.[256–259] At 2 minutes of cardiac arrest, the dogs received the aortic flush via a balloon-tipped catheter, advanced via the femoral artery. Cardiac arrest of 15–120 minutes was reversed with cardiopulmonary bypass, followed by restoration of spontaneous circulation, assisted circulation (with cardiopulmonary bypass) for 2 hours, mild hypothermia for 12 hours, controlled ventilation for 24 hours, and intensive care to 72 hours. Final outcome evaluation at 72 hours was evaluated in terms of overall performance category (OPC), neurologic deficit score (NDS), and total and regional histologic damage scores (HDS) in 19 different brain regions. Results depended on flush volume and flush temperature.

For cardiac arrest of 15 minutes[256] and 20 minutes,[257] aortic arch flush at the start of cardiac arrest with 25 ml/kg saline at 24 °C, decreased tympanic temperature to 36 °C, resulted in poor outcome, while the same flush at 2 °C, decreased tympanic temperature to 34 °C, resulted in good neurologic outcome and only mild histologic damage. For cardiac arrest of 30 minutes,[258] aortic flush at the start of the arrest with 25 ml/kg saline at 2 °C, decreased tympanic temperature to 34 °C resulted in all dogs in coma or brain death, while aortic flush with 100 ml/kg saline at 2 °C, decreased tympanic temperature to 28 °C, resulted in all dogs with good neurologic outcome and zero or only minimal brain HDS. For cardiac arrest of 60 minutes,[259] aortic flush at the start of the arrest with around 3 litres of saline at 2 °C to tympanic temperature 20 °C, resulted in good cerebral outcome, but some disabilities in the hindlegs; aortic flush with around 6 litres of saline at 2 °C to tympanic temperature 15 °C resulted in all dogs with normal outcome and only mild or zero histologic damage, as did flush with around 2 °C saline to tympanic temperature 10 °C. For cardiac arrest of 90 minutes,[259] aortic flush at the start of the arrest with around 10 litres of saline at 2 °C, decreased tympanic temperature to 10 °C, resulted in normal outcome and only zero or minimal brain HDS. For cardiac arrest of 120 minutes,[259] flush to tympanic temperature 10 °C resulted in mixed outcome, and had to include the abdominal viscera; achieving OPC 1 proved feasible but not consistently as observed after 90 minutes of cardiac arrest. With no-flow durations of 30 minutes or longer, the flush had to include the spinal cord to avoid paralysis of the hind legs.

Suspended animation was also explored in a clinically relevant pig model.[260,261] By using readily available equipment, profound hypothermia was induced via a thoracotomy and direct aortic cannulation. A total arrest time of up to 40 minutes at 10 °C core temperature, or a low-flow

perfusion of up to 60 minutes at 10 °C core temperature, was survived with normal neurologic recovery. Another group explored the effect of 3 hours of asanguinous low-flow perfusion in dogs with cardiopulmonary bypass with special solutions under ultraprofound hypothermia (< 5 °C), and survival with normal neurologic function to develop a method for protecting the brain during otherwise unfeasible neurosurgical procedures.[262]

Suspended animation in normovolemic cardiac arrest

Sudden normovolemic cardiac arrest accounts for far more deaths than exsanguination cardiac arrest. In Europe, the incidence of normovolemic cardiac arrest is 750 000 patients per year, and good neurologic outcome is achieved in only 6%–23% of them.[263] Therefore, we investigated whether the concept of suspended animation could be adopted for normovolemic cardiac arrest.

One possible approach to suspended animation was shown by Nozari et al. in dogs.[338] In this study, induction of hypothermia was with blood cooled by veno-venous shunt. After cardiac arrest no-flow of 3 minutes, and simulated unsuccessful advanced life support of 17 minutes, dogs were cooled via veno-venous extracorporeal shunt to tympanic temperature 27 °C or 34 °C with ongoing chest compressions for another 20 minutes. Two control groups were kept normothermic, with and without veno-venous blood flow. After 40 minutes of ventricular fibrillation, reperfusion was obtained by cardiopulmonary bypass for 4 hours, including defibrillation to achieve spontaneous circulation. All dogs were maintained at mild hypothermia to 12 hours, and intensive care to 96 hours. In the normothermic groups, all dogs achieved spontaneous circulation, but remained comatose and (except one) died within 58 hours with multiple organ failure. In hypothermia groups, all dogs survived to 96 hours without gross extracerebral organ damage.

Another approach to suspended animation tried in our laboratory was induction of hypothermia with cold aortic saline flush. In exsanguination cardiac arrest, the aortic flush balloon catheter could be inserted by the paramedic or ambulance physician in the field during bleeding, before arrest occurs, whereas in normovolemic cardiac arrest it is clinically unrealistic to think that the aortic flush catheter in place before at least 10 minutes of no-flow, because of the response time of the emergency system and the time required to place the aortic balloon catheter.

Studies in cell cultures and rodents support the concept of suspended animation for normovolemic cardiac arrest. It was shown in myocytes that injury to ischemic cells takes place after reperfusion by initiating several cascades

leading to cell death, but not during ischemia itself.[265–267] When ischemic myocytes were made hypothermic before reperfusion, there was less injury to the cells, even when the duration of ischemia was prolonged as compared to cells with normothermic reperfusion.[268] In a cardiac arrest mouse model, induction of moderate hypothermia to 30 °C just before attempted resuscitation resulted in better 72-hour survival compared to mice in which induction of hypothermia was delayed to 30 minutes after the start of resuscitation.[269]

The main challenge in bringing suspended animation to clinical practice consists of the rapid induction of cerebral hypothermia. In one study of exsanguination cardiac arrest in dogs, the aortic flush with 100 ml/kg of saline at 2 °C, decreased tympanic temperature to approximately 28 °C within 4 minutes[258] with a corresponding brain temperature of 18 °C (unpublished data). When the aortic flush as used in the exsanguination cardiac arrest model in dogs[258] was applied in 30-kg swine after 10 minutes of cardiac arrest no-flow, brain temperature remained above 35 °C (unpublished data). One explanation for the difference in brain temperature might be the difference in no-flow time between the two models. In the exsanguination cardiac arrest model, no-flow time before the flush was 2 minutes, whereas in normovolemic cardiac arrest model the no-flow time was prolonged to 10 minutes. Analyzing the pressure curves during the aortic flush with cold saline in normovolemic cardiac arrest, we found no pressure difference between arterial pressure in the descending aorta and venous pressure in the right atrium. Adding vasopressin to the aortic saline flush increased the arteriovenous pressure gradient, which resulted in a rapid decrease of brain temperature to 16 °C during the flush.[270]

After evaluating the feasibility of rapid induction of deep hypothermia after prolonged normovolemic cardiac arrest,[270] the concept of suspended animation was evaluated in a long-term outcome cardiac arrest model in swine.[271] After 15 minutes of ventricular fibrillation, deep hypothermia (about 17 °C) was induced with aortic flush, followed by 20 minutes of hypothermic stasis. At 35 minutes after cardiac arrest, cardiopulmonary bypass was initiated to facilitate restoration of spontaneous circulation and rewarming. Five out of six animals achieved restoration of spontaneous circulation and survived to 9 days, two animals with good neurologic outcome. In the control group, with conventional resuscitation attempts for 20 minutes and jump-start cardiopulmonary bypass, four animals achieved restoration of spontaneous circulation, but only one pig survived to 9 days, with poor neurologic outcome.

How could the results in cell cultures,[265–267] small animals,[269] and our studies[270,271] be translated into daily practice for resuscitating sudden cardiac arrest victims? A futuristic suspended animation scenario might be: when a patient is found in cardiac arrest, resuscitation should not be started by chest compressions, which would result in trickle flow, and thus induce reperfusion injury in a normothermic organism. Instead, once in the field, the emergency physician should insert the flush catheter, and rapidly cool the patient with aortic flush, and only after hypothermia is achieved, start with resuscitation efforts. Before applying suspended animation to humans, many questions must be answered in large animal outcome studies with long-term intensive care and evaluation of neurological outcome: first, it has to be proven that induction of hypothermia after prolonged cardiac arrest no-flow, preceding reperfusion, will improve neurological outcome; secondly, the limit of normothermic no-flow duration has to be determined, i.e., how long can no-flow duration be tolerated so that the animal has normal neurological recovery with induction of hypothermia before reperfusion; third, once cerebral hypothermia is achieved, hypothermic no-flow without chest compression has to be compared to hypothermic trickle-flow with chest compression to bridge the time until initiation of cardiopulmonary bypass for restarting the heart; fourth, the exact level of hypothermia that allows both mitigation of reperfusion injury and protection during hypothermic no-flow, has to be determined; fifth, it has to be proven that a sudden volume load of 100 ml/kg or more by the aortic flush is tolerated by the organism, once restoration of spontaneous circulation is achieved.

Conclusions and recommendations

Hypothermia research has developed enormously since the 1950s. We have learned that hypothermia does much more than simply reduce oxygen metabolism. It took more then 40 years for mild hypothermia after cardiac arrest to be recommended by the European Resuscitation Council and the American Heart Association. There it is stated: *"Unconscious adult patients with spontaneous circulation after out-of-hospital VF cardiac arrest should be cooled to 32 °–34 °C. Cooling should be started as soon as possible and continued for at least 12–24 h. Induced hypothermia might also benefit unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest from a non-shockable rhythm, or cardiac arrest in hospital"*.[15,16] At the time this chapter was finished in January 2006, the following inclusion criteria for the use of mild hypothermia after cardiac arrest are applied at the Emergency Department at the Medical University of Vienna.

- All patients receiving external chest compressions for any duration due to cardiac arrest, even under sedation.
- Patients not obeying any verbal command at any time after restoration of spontaneous circulation and prior to initiation of cooling.

And only few exclusion criteria are applied.

- Cardiac arrest due to trauma and/or severe bleeding.
- Terminal disease e.g., no further intensive care enhancement/intensification.
- Pregnancy
- Known coagulopathy (except: therapeutic induced)
- Time from sustained restoration of spontaneous circulation until initiation of cooling <240 minutes. An invasive procedure or transport (e.g., CT, PTCA, etc.) is no exclusion for cooling the patient, and cooling should be initiated as soon as possible.

Most of the side effects of hypothermia can be prevented or well controlled in an appropriate intensive care setting, by including sedation and paralysis. Patient management problems will vary according to the depth and the duration of hypothermia, and the underlying disease of the patient. It is important that the medical and nursing staff members using induced hypothermia be aware of the physiological and pathophysiological changes that can be expected, and that they are able to determine which changes require treatment and which do not. Most importantly, hypothermia should be regarded as a drug, and rigorous monitoring of the temperature is mandatory. If the temperature reaches 33 °C, all cooling efforts have to be stopped, and if the temperature drops below 32 °C, the patient has to be rewarmed with heating blankets or warm infusion to avoid further cooling below 32 °C, which might harm the patients. As faster cooling techniques are developed, esophageal temperature is preferred over bladder temperature for temperature monitoring, because bladder temperature lags behind esophageal temperature during fast cooling.

Clinicians should be aware that the use of therapeutic hypothermia might complicate the evaluation of neurologic outcome after cardiac arrest. The prediction methods developed on normothermic patients cannot be applied directly to patients treated with hypothermia without validation studies. The use of therapeutic hypothermia postpones the first feasible prognostic evaluation, to after hypothermia and shortly after rewarming the patient. As the evidence and the number of studies concerning outcome prediction in hypothermia-treated patients are still limited, caution and discretion should be exercised in assessing the neurological prognosis of victims of cardiac arrest and particularly regarding end-of-life decisions.

Despite all the knowledge about hypothermia acquired at this time, additional studies are needed for better definition of the optimal depth and duration of hypothermia, and the optimal rewarming rate after cooling, and to improve the techniques for inducing hypothermia. More laboratory studies in higher non-human primates are needed to investigate the role of hypothermia during cardiac arrest and even before start of resuscitation, e.g., suspended animation. In cardiac arrest, mild hypothermia is well established, but mild hypothermia might also benefit patients after stroke, traumatic brain injury, myocardial infarction, hemorrhagic shock, liver failure, pulmonary failure, or sepsis. These fields are all wide open for future research, and should be further pursued in laboratory and clinical studies.
