Preface

My aim in writing this book is to offer a comprehensive synthesis of the low temperature (sedimentary) realm of evaporite evolution. It's now more fifteen years since the last comprehensive book on evaporite sedimentology was published; an excellent piece, edited by Judy Melvin (1991). There are also the earlier efforts of yours truly in 1989 and the volume edited by Charlotte Schreiber back in 1988. The present volume follows on from my previous book on evaporites (Warren, 1999). That book attempted to address the diversity of evaporites from deposition into the igneous and metamorphic realms. To achieve this in a single volume without destroying large areas of rainforest meant I had to brush over substantial parts of our wealth of knowledge in evaporite sedimentology, especially in terms of modern depositional studies. In this volume I have attempted to redress this, while also attempting to publish for the first time a comprehensive discussion of the role of evaporites in hydrocarbon generation and trapping. The pulling together of diverse sources of knowledge on exploitable salts, along with a summary of evaporite karst hazards as well as a summary of exploitation methods and pitfalls in dealing with evaporites in conventional and solution mining has not, to my knowledge, been done before.

After an introduction to evaporite textures and depositional brine chemistries (Chapters 1 and 2) this book goes on to present detailed discussions of; Quaternary environments (Chapters 3, 4), ancient salts (Chapter 5), salt tectonics (Chapter 6), evaporite karst and its indicators (Chapter 7), burial hydrology (Chapter 8), life in evaporitic settings and their potential for sourcing hydrocarbons (Chapter 9), the role of evaporites and seals as instigators of hydrocarbon reservoirs and traps in many sedimentary settings (Chapter 10). The last two chapters deal with the characteristics of exploitable salts (Chapter 11) and the methods for their exploitation and utilisation as waste storage receptacles via solution mining (Chapter 12). Chapter 12 also discusses some of the environmental problems that overzealous exploitation or ignorance has created. Parts of this book are updated and expanded versions of some of the chapters in my 1999 book (Chapters 1, 2, 5, 6, 7 and 11), the other chapters are completely new.

I would like to thank the following individuals and companies who allow me to work at the things I enjoy most; geological research and training. First and foremost my thanks to his Majesty, Sultan Haji Hassanal Bolkiah Mu'izzaddin Waddaulah Sultan Yang Di-Pertuan of Brunei Darussalam for allowing me to live and work in Brunei. Thanks to the Universiti Brunei Darussalam, which has generously allowed me the time to write this book and also through the UBD research facility funded some of the trips to various libraries to facilitate the gathering of the reference material so necessary in compiling a comprehensive text. Thanks to Brunei Shell (BSP) and to Total Brunei for their foresight in funding the Department of Petroleum Geoscience at UBD and so allow a centre of excellence to grow in this part of the world. My thanks to my fellow faculty and staff in Petroleum Geosciences at Universiti Brunei - Chris, Joe, Angus, Martin, Iqbal, Farrah and Lim. Thanks also to Schlumberger, Earth Sciences at Flinders University, King Fahd University of Petroleum and Minerals, to Ian Cartwright's Group at Monash University in Melbourne and to the former National Centre of Petroleum Geology at Adelaide University for allowing the use of their library facilities in compiling this book. Thanks to Chess at the DMR in Thailand and to Mahbub at King Fahd University, Saudi Arabia, and to all the other groups and individuals who over the years have challenged and changed my ideas on evaporites.

Most importantly and most completely, my thanks to my wife Jennifer, who even after more than 30 years of marriage still manages to live with her at times abstracted other half.

Lastly, I would like to acknowledge NASA. The numerous Landsat images used throughout this book to illustrate modern depositional patterns were cut from larger scenes downloaded from the GeoCover Orthorectified Landsat Thematic Mapper Mosaics site (<https://zulu.ssc.nasa.gov/mrsid/>). The data set was produced by the Earth Satellite Corporation for NASA and came from satellite imagery acquired by Landsat 5 & 7, circa 1990 & 2000. It is an excellent scientific resource published on the internet for free use by the world community but now perhaps superseded by Google Earth.

Galileo Galilei after recanting Copernican beliefs

Contents

Chapter 1: Interpreting evaporite texture.....	1
Evaporites defined?.....	2
Primary evaporites	5
Evaporitic carbonates.....	5
Carbonate laminites (subaqueous sediment?).....	5
Strandzone associations: Microbialites, pisolites and tepees	6
Stromatolites and microbialites	6
Vadose pisolites, ooids and other coated grains.....	16
Tepees	18
Carbonates - present and past	20
Primary evaporite salts.....	22
Gypsum beds	23
Halite beds (chevrons and crusts)	26
Halite cumulates, rafts and coated grains	27
Pedogenic and wind reworked salts.....	28
Laminites from settling of pelagic salts.....	33
Can growth-aligned evaporite crystals, interlayered with laminites, be deep?	35
Salt reefs, are they real?.....	36
Secondary (diagenetic) evaporites	38
Intrasediment salts ...	38
Sabkha nodules and crystals	40
Syn depositional karst in crusts	40
Nearsurface crystal and crust dissolution	41
Coming and going of salt crusts	41
Lenticular mudcracks.....	42
Haloturbated and chaotic halite	43
Shallow mineralogic re-equilibration	43
Porosity loss.....	44
Deeper burial - mosaic halite?	45
Limpid dolomite in mosaic halite	46
Burial of sulphate evaporites	47
Nodular anhydrite and water loss	47
Burial Salts: Nodules and stylolites	50
Evaporites as uplift indicators.....	51
Fibrous gypsum and halite (satinspar)	52
Saline clay authigenesis	54
Textural Synthesis	56
Chapter 2: Depositional chemistry and hydrology	59
Quaternary climatic hydrology	59
Chemical evolution of surface and nearsurface brines	67
Marine brines	67
Chemical composition and phase chemistry.....	67
Brine mixing drives precipitation or dissolution	74
Nonmarine brines.....	76
Trona- nahcolite chemistry (Path I brine).....	78
Are most continental salt lakes hydrologically closed?.....	79
Separating marine from nonmarine	83
Back reactions.....	83
Marine aerosols supply continental lakes	86

Acid groundwater in continental saline systems.....	88
Contributions from evaporite bedrock	91
Indicators of brine parenthood.....	92
Bromine profiles - brine genesis or stability?	92
Sulphur and oxygen isotopes	94
Boron Isotopes	96
Chlorine isotopes	98
Fluid Inclusions and brine temperatures	100
Seawater evolution.....	101
A Phanerozoic dilemma: marine versus nonmarine potash?	101
Precambrian oceanic chemistry	105
Hydrology is depositional style	112
Active phreatic/vadose regime.....	113
Hydrologies in saline basins	113
Mudflat aggradation mirrors water table changes	117
Indicators of fluctuating water tables.....	118
Stokes surfaces.....	119
Stokes surfaces and palaeohydrology	121
Degrading hydrology and playa capture.....	124
Salinity stratification and textures.....	126
Brine stability and evaporite textures	129
Brine reflux drives substrate alteration	130
Can reflux really work?.....	136

Chapter 3: Sabkhas, saline mudflats and pans 139

Introduction.....	139
What is a Sabkha?	139
Marine coastal sabkhas	141
Carbonate-hosted coastal sabkhas in the southern Arabian Gulf.....	143
Abu Dhabi facies associations	145
Island shoal and bank facies	145
Subtidal Facies.....	145
Intertidal facies (strandline sands)	148
Intertidal Facies (Lagoon-edge muds)	149
Supratidal Facies	151
Sabkha hydrology and hydrogeochemistry.....	152
Siliciclastic-hosted coastal sabkhas, western and northern Arabian Gulf	159
Coastal sabkhas of eastern Saudi Arabia	160
Sabkhas of coastal Kuwait.....	161
Sabkhas of Kadmah Bay.....	161
Al-Khiran Sabkha	164
Other coastal sabkhas.....	166
Gulf of Suez.....	167
Beach-dune and fluvial sabkhat on deltas.....	168
Western Nile delta coast, Mediterranean Egypt.....	168
Eastern Mediterranean Coast of the Nile Delta and Northern Sinai.....	170
Shatt el Arab estuarine sabkha, Iraq	172
Interpretive limitations of models based on Holocene sabkhas	173
Lacustrine sabkhas and pans.....	176
Depositional characteristics	176
The saline mudflat.....	178
Groundwater transport and fractionation in saline mudflats.....	178
Saline pan.....	179
Styles of continental sabkhas.....	181

Alluvial fan–ephemeral saline lake.....	181
Sabkha Yotvata, Israel.....	181
Basin and Range playas, USA.....	182
Salars of South America.....	187
Ephemeral stream floodplain - dune field–ephemeral saline lake.....	201
Lake Eyre, Australia.....	202
Lake Frome, Australia.....	208
Lake Callabonna, Australia.....	210
Perennial stream floodplain–perennial saline lake.....	210
Eolian sabkhas.....	211
Sea-margins with elongate eolian sabkhat.....	212
Sheets of eolian sabkhat.....	215
Salt pans (marshes) and diapirs.....	219

Chapter 4: Subaqueous salts: salinas and perennial lakes 221

Introduction.....	221
Sea-margin subaqueous salts.....	222
Coastal salinas of Australia.....	222
Carbonate salinas.....	223
Gypsum salinas.....	227
Halite salinas.....	230
Coastal salinas of the Middle East.....	231
Solar Lake, Gulf of Elat.....	231
Ras Muhammad Pool, Southern Sinai.....	232
Late Pleistocene salinas on the Egyptian Red Sea Coast.....	234
South American coastal salinas.....	236
Continental subaqueous basins.....	238
Perennial saline lakes.....	238
Great Salt Lake, Utah.....	239
Mono Lake, California.....	243
Lake levels and conditions.....	244
Tufa mound and pinnacles.....	244
Hydrological and hydrogeochemical evolution.....	246
Saline lakes of Turkey.....	247
Lake Van, Turkey.....	247
Salda Lake, Turkey.....	250
Lake Tuz, Turkey (Tuz Gölü).....	252
Lake Aci, Turkey.....	253
Lake Urmia, NW Iran.....	254
Lake Natron and Lake Magadi, East Africa.....	255
Brine chemistry.....	257
Holocene sediments.....	258
Late Pleistocene sediments.....	260
Diagenesis - magadiite and evaporitic chert.....	262
Dead Sea, Middle East.....	264
Geological Setting.....	265
Water level changes.....	266
Density stratification: Holomixis versus meromixis.....	268
Deep water Halite.....	270
Deep water laminites.....	273
Basin margin sediments.....	275
Lake Lisan, Jordan Valley.....	277
Lake Asal, Republic of Djibouti.....	280
Are all modern saline lakes shallow?.....	282

Chapter 5: Ancient basins and stratigraphic evolution..... 287

Linking present to past aridity	288
Varying extent of ancient evaporites.....	293
Building blocks of ancient salt beds	296
Evaporites: broad scale models.....	300
Lacustrine evaporites	301
Eocene Lake Gosuite, USA	304
Oligo-Miocene lake, Calatayud Basin, Spain	306
Permian lacustrine redbeds , Kansas	308
Other Lacustrine Red Bed Associations	310
Platform evaporites on epeiric shelves	310
Evaporitic epeiric ramps	312
Evaporites atop rimmed epeiric shelves	318
Marine versus nonmarine stages in epeiric seaways	323
Basinwide evaporites	324
Depositional styles.....	327
Tectonic styles.....	329
Importance of hydrographic isolation.....	332
Problems in correlation <i>sans</i> hydrology	335
Dolomite aprons in a drawdown basin	337
Sequence stratigraphy in evaporite basins?	340
Does sealevel control salt sequences?	342
Icehouse and greenhouse eustacy	343
Marine-margin platform evaporites	345
Platform evaporites in a greenhouse earth?	346
Basinwide evaporites	347
Basinwide sequence stratigraphy?.....	348
Basinwide examples	351
Messinian evaporites of the Mediterranean	351
Sequence stratigraphy in the Zechstein	362
Sequence stratigraphy in the Silurian Salina Group of the Michigan Basin	368
Summary	372

Chapter 6: Salt tectonics 375

Introduction	375
Physics of salt systems—	376
Density, viscosity, strength & buoyancy.....	376
Pressure effects	382
Thermal effects	384
Flow textures and rates	384
Triggers, drivers and outcomes of salt flow	389
Diapirs and extension.....	389
Diapirism and differential loading	391
Sedimentation rate controls diapir shape	394
Extension, falling diapirs and turtles	396
Falling diapirs and raft tectonics.....	396
Salt allochthons (salt breakout).....	398
Sheets, welds and basal (subsalt) shear zones	401
Near-diapir suprasalt shear (drag zones).....	404
Welds, loading detachments and growth faults	406
Minibasins floors become welds.....	408
Fault families in allochthons.....	410
Linking allochthons at the basin scale	413

Compressional salt tectonics.....	414
Shortening with gravity gliding	414
Thin-skinned fold and thrust belts	419
Inverted basins	422
Mild shortening in tectonically confined basins	423
Can extrusion indicate extreme shortening?.....	425
Distinguishing downbuilt and reactivated (mildly squeezed) diapirs.....	428
Sediments and flowing salt	430
Sediments and evolving salt structures	432
Siliciclastic patterns	435
Carbonate patterns	436
Sediments tied to salt basin evolution.....	440
Suprasalt clastic sedimentation.....	440
Suprasalt carbonate sedimentation.....	441
Subsalt sections.....	446
Caprock Formation (diagenesis).....	447
Complications of shale diapirism	450
Summary	452

Chapter 7: Karst, breccia, nodules and cement: Pointers to vanished evaporites 455

Introduction.....	455
Evaporite landforms....	458
Local scale karst.....	458
Dolines or sinkholes	458
Suffosion dolines	459
Collapse dolines.....	459
Solution Dolines	459
Breccia Chimneys and Pipes.....	460
Landscape residuals; karst domes and castiles	460
Expansion morphotypes at outcrop.....	462
Regional scale karst	463
Subsidence basins or troughs.....	463
Hutchison Salt, Kansas	464
Delaware Basin, west Texas	466
Holbrook Anticline, Arizona.....	468
Black Hills, South Dakota	469
Subsidence and landscape in diapiric regions.....	469
Five Islands, Gulf of Mexico	470
Zagros/Hormuz region, Arabian (Persian) Gulf	471
Salt Dissolution: Solution breccias and residues	472
Defining evaporite dissolution breccia	472
Bedded solution collapse breccias	474
Breccia extent	478
Stratiform breccias	478
Hydrology and texture	479
Diapiric solution breccias	481
Diapiric breccia versus salt ablation (retreat) breccia.....	485
Salt-cored thrust breccias, rauhwacke and orogeny.....	486
Partial salt dissolution: residues of less-soluble salts	493
Focused rapid dissolution - Evaporite clasts.....	493
Diffuse dissolution- Markers and residue beds.....	495
Gentle dissolution at the top	495

Maha Sarakham salt, Thailand.....	495
Palo Duro Basin, west Texas	497
Dissolution at the bottom	498
Basal anhydrite, Thailand	498
Caves in salt karst	500
Gypsum caves.....	501
Phreatic gypsum caves.....	502
Vadose gypsum caves	504
Miocene karst in the Madrid Basin, Spain.....	504
Modern karst in Cretaceous gypsum, Texas	506
Modern gypsum karst in Saudi Arabia	508
Halite Caves.....	509
Modern halite karst in the Dead Sea depression.....	510
Modern halite karst in crests of diapiric Hormuz salt (Precambrian) in the Arabian Gulf.....	512
Evaporite speleothems in carbonate karst.....	514
Karst hazards in evaporites	515
Problems in the Ripon area, UK	517
Problems with Miocene gypsum, Spain	519
Gypsum karst beneath Mosul, Iraq.....	520
Solving the problem?.....	521
Sulphuric acid speleogenesis	521
Mineralised breccias	528
Filled vugs and nodules	531
Silicified evaporites	532
Calcitisation and dedolomitisation.....	539
Calcitisation of evaporites	539
Dedolomitisation of matrix	545
Celestite as an indicator?	548
Fluorite as an indicator?.....	553
Baryte as an indicator?.....	555
Authigenic anhydrite as a burial salt.....	559
Enigmatic outlines in pseudomorphs.....	564
Summary	565

Chapter 8: Burial hydrology and chemistry..... 567

Burial hydrology	567
Fluids in subsiding sedimentary basins	569
Compactional fluids	570
Therobaric fluids.....	571
Deep flow in pull-apart basins	573
Flow in and adjacent to Collision Belts.....	574
Flow in post-orogenic hydrologically-mature basins	575
Alteration, pressure cells and salinity-driven convection.....	581
Haloes, convection and saltout	581
Evaporites as pressure seals	583
Salt-maintained overpressure.....	585
Pressure changes and drilling	591
Salt-generated Underpressure.....	592
Temperature anomalies and brine flow	593
Fluid flow in halokinetic basins	596
Suprasalt fluid flow and alteration	596
Burial dewatering of hydrated salts	601
Brine-rock burial evolution.....	604
Brine chemistry at depth.....	604

Effects and indications of water-salt interactions	610
Crustal cycling of brines?	612

Chapter 9: Halotolerant life in feast or famine (a source of hydrocarbons and a fixer of metals)..... 617

Introduction.....	617
Evaporitic Source rocks	619
Halobiota: adaptations and bio-markers	628
Metabolic pathways in producers and consumers	629
Salinity tolerance in the halobiota	635
Primary producers	636

Chapter 1: Interpreting evaporite texture

Salts such as halite, gypsum and trona, have long been significant in the affairs of man, both as a preservative and as an industrial feedstock. Gypsum and halite are listed, along with several other salts, in the Sumero-Assyrian dictionaries written during the rule of the Assyrian king Assurbanipal (668-626 BC). By then the ancient Egyptians had been using *natrum*, an impure mixture of trona and other sodium salts, for several thousand years, both as an important part of the mummification process and for salting food. Today halite is a major feedstock to the chemical manufacturing industries, as are several other varieties of salt. Salts are also important in the trapping, sealing and perhaps generation of hydrocarbons and various metal deposits. Manufactured salt cavities are used as long term waste repositories, as receptacles for the safe storage and cycling of liquids and gases and even for the manufacture of peak load electricity. This book is all about where, how and why this is so in the sedimentary realm.

What are the basic requirements to form and preserve a bed of salt? We need; 1) a surface and nearsurface brine body that is saline enough to precipitate and preserve salt, this typically means an arid to semi-arid climatic setting with a drawdown hydrology capable of maintaining substantial volumes of brine at or near the landsurface, 2) accommodation space in a sedimentary depression that is not filled by other sediment, and 3) a burial environment that does not allow sufficient undersaturated throughflow to completely dissolve the buried salts (Figure 1.1).

Figure 1.1. Classification of evaporite formation in the depositional-diagenetic realms emphasizing ongoing postdepositional evolution of mineralogy and texture.

Evaporites defined?

I define an evaporite as a salt rock that was originally precipitated from a saturated surface or nearsurface brine by hydrologies driven by solar evaporation (Figure 1.1). This simple definition encompasses a wide range of chemically precipitated salts and includes alkali earth carbonates (Table 1.1). Some workers restrict the term evaporite to those salts formed directly via solar evaporation of hypersaline waters at the earth's surface. In order to emphasise the highly reactive nature of evaporites in the sedimentary realm I think of such evaporites as primary, that is, precipitated from a standing body of surface brine and retaining crystallographic evidence of the depositional process (e.g. bottom-nucleated or current-derived textures). Outside of a few Neogene examples, there are few ancient evaporite beds with textures that are wholly and completely “primary” (Figure 1.1).

Almost every subsurface evaporite texture is secondary; it is diagenetically altered, frequently with fabrics indicating pervasive early recrystallisation and perhaps some later crossflow of basinal waters. Under this definition of a primary versus secondary salt, even the nodules in Holocene mudflats, including those in the type area for sabkhas the Arabian (Persian) Gulf, are secondary textures. They are a porewater overprint superimposed on a primary matrix of mud and sand. Ancient bedded evaporites are typically dominated by secondary textures, although beds may still retain “ghosts” or partial relicts of primary textures such as laminae, aligned anhydrite nodules after growth-aligned gypsum, or patches of aligned halite chevrons floating in a matrix of mosaic halite spar. Even when evaporite beds are extensively recrystallised, most retain laminae made up of impurities that define primary depositional laminae.

In the subsurface it is the ability of evaporites to flow easily, even as they backreact or dissolve, that distinguishes them from other types of sediment. Earliest secondary evaporites are syndepositional precipitates, forming cements and replacements even as the primary matrix accumulates around them. Early replacement sometimes preserves remnants of the original depositional texture, such as gypsum ghosts in nodular anhydrite or aligned halite chevrons. Nodular anhydrite ghosting lenticular gypsum was recognised in Permian mudflats in the early 1960s by Kerr and Thomson (1963), they interpreted it as a subaqueous saline pan indicator. Unfortunately, for the next two decades their results were overlooked by workers in the Permian Basin who incorrectly applied supratidal capillary models based on the Arabian Gulf sabkha anhydrite (Warren and Kendall, 1985).

Early diagenetic overprints and effects of later compaction-driven flow and pressure solution destroy much of the depositional evidence in any ancient evaporite bed. This means retention of primary crystal textures is at best patchy in both halite and anhydrite beds. Many ancient bedded halites are dominated by coarsely crystalline halite spar. Much of it was deposited in multiple episodes of early diagenetic (syndepositional) cementation, leaving less than 10-15% of the bed as primary growth-aligned chevrons. This syndepositional coarse sparry halite formed in multiple dissolution-precipitation events in microkarst pits and was precipitated between successive depositional episodes of chevron halite crust formation (Chapter 3). Other coarsely crystalline halite spar, especially in halokinetic beds, shows pervasive and multiple flow-aligned textures created by pressure-solution. Textures are driven by numerous salt creep and recrystallisation episodes, which occur millennia to millions of years postdeposition, and after hundred to thousands of metres of burial (Chapter 6).

Secondary evaporites form in subsurface settings equivalent to the eogenetic and mesogenetic porosity realms as defined for carbonates by Choquette and Pray (1970). Tertiary evaporite textures tend to form in the telogenetic realm (Figure 1.1) And, as in carbonate diagenesis, the most pervasive alteration of evaporites is either early in the burial history (eodiagenesis) or it occurs much later during uplift (telodiagenesis). Both the eogenetic and telogenetic settings are characterised by relatively permeable evaporites and hydrologies capable of high volumes of pore fluid crossflow. Alteration of a salt mass in the mesogenetic realm consists largely of recrystallisation overprints within a flowing salt mass, but with substantial alteration and dissolution possible about the edge of a bed or a flowing salt mass. In carbonates the mesogenetic overprint tends to be pervasive throughout the bed (Choquette and Pray, 1970). In evaporites the pervasive early loss of porosity and permeability in the shallow diagenetic/eogenetic realm means that deep burial (mesogenetic) alteration tends to be concentrated about the edges of a buried salt body (see discussion of dissolving salt “block of ice” model in Chapters 7 and 8). Unlike carbonates and siliciclastics, the core of the subsurface salt unit is largely unaffected by processes of burial alteration, although they are ongoing in the encasing nonevaporitic sediments and will only cease when the adjacent nonevaporite beds lose their effective porosity. Preservation of the unaltered core of the salt unit is why viable Permian halobacteria can be cultured from brine inclusions in remnant chevrons in Permian salt from west Texas (Vreeland et al., 2000).

Mineral	Formula	Mineral	Formula
Anhydrite	CaSO ₄	Leonhardtite	MgSO ₄ ·4H ₂ O

Table 1.1. Major evaporite minerals: less saline alkaline earth carbonates or evaporitic carbonates are indicated by **, the remainder are the more saline evaporite salts. Documented dolomite composition ranges from Ca_{1.16}Mg_{0.84}(CO₃)₂ to Ca_{0.96}Mg_{1.04}(CO₃)₂. Less common evaporite minerals, such as borates, iodates, nitrates and zeolites are not listed here, but are discussed in detail in Chapter 11.

Unlike quartzose and aluminosilicate sediments, buried evaporite beds can flow as ductile masses from the surface down to 8-10 km of burial and even into the metamorphic realm. At the same time their dissolving edges supply ions to adjacent nonevaporitic sediments. Salt flow can be: a) early diagenetic, coinciding with syndepositional fractionation, reflux or dissolution; b) later diagenetic, associated with complex

burial-stage bed dissolution or reprecipitation and driven by subsurface fluid flow in the zone of free convection below the zone of overpressure; c) widespread and pervasive, as occurs during halokinesis (salt tectonics); and d) postdiagenetic and extending well into the metamorphic realm where daughter minerals, such as scapolite and tourmaline, can act as a source of volatiles and lubricants long after the precursor salts have gone (Warren 1999; Chapter 6).

	Siliciclastic: (continental, fluvio-deltaic, shelf, submarine)	Carbonate: Humid-Oceanic/marine Tropical/subtropical	Carbonate-evaporite: Arid, land-locked Subtropical/Temperate
Early marine cementation	Rare	Local occurrence	Pervasive (especially in mesohaline platform)
Dolomitisation	Rare	Locally in mixing zones (?)	Pervasive (brine reflux and burial)
Leaching	Uncommon, mostly related to freshwater leaching, rare in burial diagenesis	Common, related to subaerial exposure and karstification	Intensive, related to hypersaline brines
Calcite cementation	Uncommon, locally common (mostly related to burial)	Common	Rare to local occurrence (mostly burial)
Anhydrite-halite	Uncommon	Rare to absent	Common to pervasive
Porosity types	Intergranular	1) Mouldic, vuggy and chalky microporosity (common) 2) Fracture and intercrystalline porosity (local occurrence)	1) Intergranular, mouldic, vuggy, and intercrystalline (dolomitic) porosity (very common) 2) Fracture and chalky microporosity (locally common)
Controls on reservoir quality	1) Stratigraphic position 2) Depositional facies	1) Stratigraphic position 2) Depositional facies 3) Karst in zones on meteoric influx	1) Depositional facies 2) Accessibility of sulphate- and chloride-bearing and later corrosive fluids (karstic or deep)
Geometry	Layered	Layered	1) Carbonate-basinwide evaporite: Massive irregular 2) Carbonate-salttern-mudflat evaporite: layered

Table 1.2. Characteristics of siliciclastic and carbonate depositional systems (in part after Sun and Esteban, 1994).

Exhumed or uplifted evaporite beds also undergo pervasive alteration, dissolution and replacement as they re-enter the zone of active phreatic flow (telogenesis) and regain permeability. Once again, alteration tends to occur from the edges inward. Soluble components from the altering and dissolving bed can be reprecipitated in adjacent shales as alabastrine and satinspar gypsum or fibrous halite. Exhumed evaporite textures are termed tertiary (Figure 1.1) and are varying combinations of competitive crystal alignment and geopetal void fills. The resulting fabrics can duplicate “primary” crystal alignments, especially when parts of a cavern fill can only be studied at a limited scale, as in core or a mine face. Not recognising a telogenetic overprint typically misidentifies tertiary evaporite textures as primary and so creates interpretive confusion (Chapter 7).

Adjacent nonevaporitic sandstones, shales and limestones also undergo diagenetic reactions when flushed by evolving pore fluids, but the diagenetic rock/fluid framework is slower to respond and requires years to millennia to overprint an original depositional texture. But, given enough time the textures of many other sediments, like evaporites, evolve during burial (Table 1.2).

Evaporite mineralogy and texture will change with time, but all ancient secondary and tertiary evaporites occur within the volume of rock that was originally precipitated as the primary or syndepositional salts. Outside of these evaporite sediments

there are two other classes of salts that are not “true evaporites” in that they did not form via hydrologies first driven by solar evaporation and are precipitates that do not necessarily occupy the same position in earth space as the precursor evaporites. I term the two classes, burial salts and hydrothermal salts (Figure 1.1). Burial salts are made up of minerals, such as anhydrite or halite, which do not necessarily occupy the same rock volume as the original sediment. Their occurrence is related to subsurface fluid flow, hydrofracturing, brine mixing and brine cooling. Burial salts typify the commonplace authigenic cements and replacement salts that precipitate in a nonevaporite matrix from subsurface brines derived by dissolution of an adjacent evaporitic salt bed. Because of the proximity to a “true” evaporite bed, most authors would consider burial salts a form of “true” secondary evaporite.

In contrast, hydrothermal salts do not require a nearby dissolving evaporite to form. Hydrothermal anhydrite forms by heating of seawater or by the subsurface mixing of CaSO_4 -saturated hydrothermal waters, either during ejection of hot hydrothermal water into a standing body of seawater, or during convective magmatic circulation. Hydrothermal salts are poorly studied, but often intimately intermixed with sulphides in areas of base-metal accumulations, such as the Kuroko ores in Japan or the exhalative brine deeps in the Red Sea. Hydrothermal anhydrite is a commonplace salt in many such active volcanogenic-hosted massive sulphide deposits (see Warren, 1999; Chapter 9).

Primary evaporites

The simplest subdivision of evaporite minerals is into evaporitic alkaline earth carbonates – aragonite, dolomite, low-Mg calcite and high-Mg calcite – and evaporite salts – gypsum, anhydrite, halite, trona, carnallite, etc. (Table 1.1). Primary evaporitic carbonates tend to form in the initial stages of brine concentration, whereas the other primary evaporite salts are precipitated in the more saline stages of concentration (Chapter 2). Evaporitic carbonates can contain and preserve elevated levels of organic matter that subsequently generate hydrocarbons or act as reductants for base metal sulphides (Chapter 9).

Evaporitic carbonates

Evaporitic alkaline earth carbonates are the first evaporite minerals to precipitate from a concentrating hypersaline surface water and are usually composed of aragonite, high- and low-Mg-calcite, magnesite or even primary dolomite. The essential hydrology of any evaporite depositional setting is that evaporative outflow exceeds inflow. This results in two characteristics of the carbonate depositional system, which hold also for the more saline evaporite salts. First, rapid changes in water level are possible, especially in the more marginward facies, leading to interlayering of strandzone and subaqueous units. Under such a regime any subaqueously precipitated carbonate is liable to subaerial exposure and syndepositional subaerial diagenesis. Second, the solute content, especially the Mg/Ca ratio, of shallow hypersaline water fluctuates as the salinity fluctuates. For example, the Ca content of any brine is depleted by the early precipitation of calcite or low-Mg calcite. Subsequent carbonate precipitates drop out of an increasingly saline water and so will have a higher Mg/Ca ratio and tend to be dominated by high-Mg calcite, aragonite, magnesite, or even dolomite.

Carbonate laminites (subaqueous sediment?) Mm-scale lamination is volumetrically the dominant

sedimentary structure in modern and ancient evaporitic carbonates as well as in higher salinity salts, but its origins are varied and complex (Figure 1.2). Sometimes it is an inorganic cumulate, other times it is biologically structured (biolaminite - see next section). Beds dominated by finely laminated, regular alterations of two or more sediment types are called laminites or rhythmites. Many evaporitic carbonate laminites form couplets or even triplets by the regular superposition of micrite with siliciclastic clay, organic matter or evaporite salts. Such couplets and triplets are frequently referred to as varves, yet are not necessarily “true” varves in that the layers do not define annual couplets.

As an example of a contemporary carbonate laminite, consider deep bottom sediments deposited prior to 1979 in the Northern Basin in the Dead Sea, Israel (Figure 4.48). They are made up of alternating light and dark mm laminae that accumulated beneath a density-stratified brine column more than 350 m deep. The whitish laminae are composed of stellate clusters of aragonite needles (5-10 μm diameter), which precipitated each summer at the air-brine interface and then sank. The darker laminae consist of clay minerals, quartz grains, detrital calcite and dolomite that washed in as suspended sediment from the surrounding highlands during occasional storm floods (Garber

Figure 1.2. Depositional significance of evaporitic carbonate textures. Note the distinction between subaqueous and strandline (ephemeral water) indicators.

et al., 1987). Thus laminites in the Dead Sea are not annual layers, but indicate flood events that occur every 3-5 years.

Permanent water column stratification, with periodic algal blooms at the surface, characterises the waters of Lake Tanganyika. Deep bottom laminites (seasonal varves) containing between 7% and 11% total organic carbon (TOC) accumulate as modern lake bottom sediments where waters are anoxic and more than 250m deep (Cohen, 1989). Or consider the shallow lacustrine laminites of the more saline Holocene Coorong Lakes, Australia (Warren, 1988, 1990). Coorong laminites make up more than 80% of the Holocene sediment volume in the Coorong Lakes and are composed of alternating dark-grey organic-rich and light-grey organic-poor laminae. Matrix mineralogies range from hydromagnesite to aragonite to Mg-calcite to dolomite and organic levels can be as high as 16% TOC. As in the Dead Sea, the Coorong laminites formed subaqueously on the floor of a chemically stratified lake. Unlike the 250+ metres depths of the Dead Sea and Lake Tanganyika, Coorong laminites accumulated as microbially entrained pelletal wackestone/mudstones beneath seasonally stratified perennial lake waters, less than 1-5 metres deep (Figure 4.4b). Once on the bottom these pellets are easily eroded and redeposited as wave-driven bedload, the resulting laminite layering is not a varve.

Laminites can also be preserved under conditions of ephemeral subaerial exposure. Algal-bound laminites (algal mats or biolaminites) crosscut by mudcracks characterise the algal channel and strandzone facies in many modern and ancient evaporitic carbonates such as the sabkhas of the Arabian Gulf (Figure 3.4e). Modern and ancient laterally extensive carbonate laminites, without evidence of subaerial exposure, indicate subaqueous deposition under fluctuating surface water chemistries. They indicate water depths that may have ranged from a few decimetres to hundreds of metres and are not necessarily associated with deepwater conditions (Warren, 1985; Kendall, 1992). They do indicate a lack of burrowing metazoans in saline carbonate sediments deposited across this wide range of water depths.

Strandzone associations: Microbialites, pisolites and tepees

The strandzone in many evaporitic carbonate systems is characterised by an association of stromatolites, mud-cracked cryptalgalaminites (biolaminites), pisolites, ooids, intraclasts, cemented crusts and tepees (Figure 1.2). Strandzones typify deposition associated with fluctuating shorelines about the

edge of a more permanent brine lake or seaway and form in areas of groundwater springs, mudflats and ponds. Rapid fluctuations of strandlines (wet and dry cycles) and associated high rates of capillary crossflow mean this facies association is syndepositionally cemented as it aggrades into stacked layers of intraclast breccia, biolaminites, pisolites and tepees, typically separated by salt beds or their dissolution breccias. Biofilms and mats, in otherwise muddy and granular matrices of any uncemented strandzone sediment, gives a leathery depositional strength to this sediment that encourages the preservation of rip-ups, tears and overfolds due to storm-induced erosion. Biostabilization also tends to encourage the preservation of fenestrae and gas-filled cyanobacterial domes in the surface crusts of many modern strandzones of saltflats and playas.

Stromatolites and microbialites

Microbialites are biogenic structures, the mineralised result of the metabolic activities of microphytic algae, cyanobacteria or archaeobacteria (Figure 1.3; Riding, 2000). Microbialitic structures are commonplace sediments in evaporitic strandzones, textures range from biolaminites (\approx cryptalgalaminites) and stromatolites (matrix-supported agglutinated microbial reefs) through tufa/travertine (cement-supported) reefs to thrombolites (agglutinated reef). Stromatolites and cyptalgalaminates are the most easily recognised microbialites in ancient evaporitic settings (Figure 1.3). Quaternary tufas and travertines tend to characterise the humid hydrological stages of saline lakes when water levels tend to be high and surface water less saline. Internally, microbial textures can be stromatolitic (fine planar-undulating to wavy-crenulated lamination), oncologic (concentrically laminated), thrombolitic (with mesoscale clotted textures, not to be confused with clotted or grumous microfabrics, which occur in both thrombolites or stromatolites) or cryptic (no obvious internal structure).

Biology of stromatolites and microbial layers

Stromatolites to some researchers are a specific layered type of microbialite, often defined as laminated organosedimentary structures with positive relief away from a point or limited surface of attachment (e.g. Burne and Moore, 1987). In this sense stromatolites are equivalent to agglutinated microbial reefs in the terminology of Riding, 2002. To others, stromatolites are not necessarily a biological construct. Microbes and biofilms may be present at the time chemical sediments accumulate, but they play a passive role in textural style during the deposition of this type of stromatolite. Researchers with this view of stromatolites like to add the phrase "it may or may not be of

biological origin” to any definition of an ancient stromatolite. This distinction becomes important as we shall see in a later discussion of pre-Mesozoic evaporitic stromatolites, but reliably defining the contribution of a biofilm to rock texture in ancient evaporitic carbonates is at times near impossible.

Stromatolite shapes range from columnar to domal to subspherical. Internal layers of most modern stromatolites define the successive positions of an agglutinating bioplexi (algal/bacterial community), with each accreting layer produced by trapping and binding of sand to mud-sized sediment. In some settings agglutination occurs in conjunction with direct carbonate precipitation onto or within cyanobacterial trichomes, a process driven by changes in ambient $p\text{CO}_2$ (Figure 1.4a). Modern lacustrine stromatolites tend to be precipitative biochemical structures, while modern marine-margin stromatolites tend to be largely agglutinated structures; both possess surface microbial communities that evolve as the stromatolites prograde (Duane and Al-Zamel, 1999). Many coarser-grained stromatolites in the modern marine and marine margin realms, as in Lee stocking Island and Shark Bay, are poorly layered agglutinated forms and are transitional into thrombolitic structures. Fine-grained mm-laminated stromatolites tend to form best in or near seepage zones in modern hypersaline lakes, such as Marion Lake in South Australia, Gotomeer in the Netherlands Antilles and the Dead Sea in the Middle East, rather than in the open marine realm (Warren, 1982a; Kobluk and Crawford, 1990; Druckman, 1981).

Dominant members of modern microbial plexi range from archaea to eubacteria to cyanobacteria to algae with the proportions and species changing with depth in the sediment and salinity of the water column (Figures 9.16, 9.17). The most common biotal constituents of well-preserved stromatolitic bioherms in Phanerozoic evaporitic settings are filamentous and coccoid cyanobacteria, with lesser halobacteria (Figure 1.4b, c). Species components not only change with water depth and brine salinity but have changed over the course of geological evolution (Figure 1.4b). Modern cyanobacteria typically extrude a mucilaginous sheath that protects the contributing biota from UV radiation. The gooey mucilage also captures sediment particles creating further UV screening, but too thick a sediment layer can cut the necessary exposure to light and so slow photosynthesis. Large amounts of water are held in the mucous sheath and so it also serves as a buffer against osmotic stress.

Modern mesohaline stromatolites exhibit regular occurrences of the halotolerant cyanobacterial species

Microcoleus chthonoplastes, *Lyngbya* sp., *Entophysalis* sp. and *Synechococcus* sp. (Gerdes et al., 2000a). *Microcoleus* is one of a number of cosmopolitan cyanobacteria that form ensheathed filamentous cellular bundles in most growing biolaminites. It grows best in the salinity range 80-160‰ but is present as living filaments in salinities as high as 300‰.

Figure 1.3. Modern agglutinated stromatolite reefs. A) Intertidal stromatolites in Hamelin Pool, Shark Bay Australia (image courtesy of DiscoverWest). B) Cross section of a Shark Bay intertidal stromatolite showing internal mm lamination with truncated edges. C) Lacustrine stromatolites from Cuatro Ciénegas Posas, Mexico. Most particles are captured by the mucilage are diatom frustules (Image courtesy of Alan Riggs).

Figure 1.4. Microbialites. A) Styles of mineral accretion about a trichome. B) Biological components that construct various microbialites and the changes over geological setting and time. C) Classification of microbialites according to dominant constituents (after Riding, 1991; 2000).

Fibrillar cyanobacteria are able to glide up and down through nearsurface sediment in order to position themselves in optimal light conditions. This is done by hormogonia, a part of a filament of a photosynthetic cyanobacterium that detaches and grows by cell division into a new filament. Hormogonia are motile and respond phototactically so that, if too much sediment accretes to the mat or if a deepening brine cover reduces the light reaching the filaments, they move upwards to where they accumulate on or just below the sediment surface. It is this periodic repositioning that creates the internal laminated structure and phototropic thickening seen in modern stromatolites and algal mats. Left behind in the sediment matrix are the abandoned sheaths, immotile filaments, cells and mucilage that after passing through the decomposer community becomes buried organic matter (Chapter 9).

Coccolids in modern biolaminites tend to create slime-sheathed pustules and individual cells grow by binary fission (Gerdes et al., 2000a). *Gloeotheca* and *Synechococcus* are two of a number of such coccoid cyanobacteria that make up the other major component of a cyanobacterial plexi. These organisms increase their slime content in order to deal with phototoxicity and tend to dominate exposed surfaces of algal mats and stromatolites, as in the algal mats of the Abu Dhabi and Saudi sabkhas. Coccolids tend to occur in zones about edges of water-covered biolaminites flourishing on the floors of tidal channels (Chapter 3).

Pleurocapsalian cyanobacteria are a cosmopolitan type of coccoid bacterial that dominate modern pustular and pinnacle mats. The typical internal structure in a pustule is colonial, with individual nodules showing discontinuous but more or less concentric layers. Slime production is stimulated by an increase in light intensity, salinity or temperature. This creates sediment with a yoghurt-like consistency made up of polysaccharides interwoven with sediment matrix. The slime coat not only protects the coccolids, but also insulates the other species of the mat community from the lethal effects of increasing light, salinity and temperature. Microbial metabolism facilitates or even drives the precipitation of primary dolomite in many evaporitic carbonates (van Lith et al., 2002).

It is the alternation between mm-scale layers dominated by the filamentous forms and layers enriched in the coccolids that creates the biolamination of modern marine and marine margin stromatolites (Reid et al., 2001). Aggradation in a modern marine-edge stromatolite represents a dynamic balance between sedimentation and intermittent lithification within the cyanobacterial mat. Periods of rapid sediment accretion, during which stromatolite surfaces are dominated by pioneer communities of gliding filamentous cyanobacteria, alternate with hiatus intervals. Microscale discontinuities in sedimentation are characterized by development of surface films of exopolymer and subsequent heterotrophic bacterial decomposition, which

forms thin crusts of microcrystalline carbonate. During prolonged hiatus, climax communities develop, which include endolithic coccoid cyanobacteria. These coccoids modify the sediment micro-environment to create thicker lithified laminae. Subsequence preservation of lithified layers at depth creates the millimetre-scale biolamination that characterises modern and ancient stromatolites.

At the broader scale, successive layers in modern biolaminites can indicate seasonal changes. *Microcoleus*-dominated layers (often associated with diatoms) accumulate in the winter, while coccoid-dominated layers typify the more saline summer growth layers. Alternations of coccoid and filamentous layers in a mat can create lamination even in the absence of agglutinated sediment, although the preservation potential of such organic-only layers is low unless deposited on the anoxic floor of a perennial stratified brine lake (Chapter 9).

Non-stromatolitic lacustrine microbialites

Stromatolites are one part of a much wider group of layered microbialites growing in a wide range of saline marine and nonmarine settings (Figure 1.4c; Riding, 1991, 2000). According to Riding, sediment trapping by filamentous plexi in a modern biolaminite results in an agglutinated stromatolite reef, which is characterised by a particulate microstructure that preserves few, if any, details of the original size, shape or orientation of the biotal plexi responsible for capturing sediment (Figure 1.4a).

On the other hand, biomineralized deposits, such as tufa/travertine cement reefs described by Riding 2002, retain considerable palaeontological detail about the constituent organisms preserved as skeletal microfossils. Mineralisation is especially important in nonmarine microbialites, as in lacustrine tufa cement reefs that define the water-covered margins of the less saline high-water stages of many Quaternary salt lakes. These tufa cement reefs are porous, unbedded or only poorly bedded, and created by cyanobacteria, algae, grasses, and reeds thriving in brackish to fresh lake and river waters and groundwater seeps along the landward side of the saline pan or lake edge. Rapid CaCO_3 precipitation veneers living plants, which would otherwise be masses of soft vegetation, with cement crusts (Riding, 2000; Pedley et al., 2003). Relief on a tufa buildup can be high, with commonplace steep to overhanging, locally cavernous, cemented masses. Tufas tend to occur where inorganic CaCO_3 precipitation is enhanced by CO_2 degassing of venting spring waters.

Likewise travertines, which tend to form layered deposits of CaCO_3 near the outflow points of groundwater and thermal springs, can preserve details of the contributing microbes. Travertine cement reefs are layered microbialites with “shrub” and crystalline fabrics associated with non-skeletal organisms (Figure 4.3; Riding 2002). Deposits tend to form steep-sided mounds, with elevated rimmed pools, normally developed atop and about the mounds. Smoothly banded crystalline crusts construct horizontal, sloping, vertical or overhanging sheets with pisoids typically developing at the bottom of water-filled pools and polygonal saucers. Chafetz and Folk (1984) and Folk (1993, 1999), along with many others working in travertines, document microtextures such as spheroidal dolomite, dumbbell-shaped crystals, fine diurnal-layered dendrites and bushes, all of which indicate a strong bacterial contribution to travertine precipitation. Reeds and grasses can be preserved as moulds within bacterial travertines, but most macro-organisms are excluded by the elevated temperatures and high levels of dissolved minerals (salinity) that typify travertine carbonates. Most travertines are only a few kilometers in lateral extent and, as in tufa cement reefs, subaerial surfaces are common, as are gradations into adjacent marsh and fluvial environments.

CO_2 degassing, in combination with evaporation and rapid microbial growth, can drive extreme carbon isotope enrichment in the organic matter and co-precipitates in many CO_2 -limited organic-enriched sediments, including evaporitic marls, tufas and travertines (Schouten et al., 2001). Enriched $\delta^{13}\text{C}$ values of up to +13‰ in calcite and -10‰ in organic matter were measured in calcite tufas accumulating in well-oxygenated carbonate saturated waters in El Peinado and San Francisco lakes, both high altitude saline lakes in the southern Andean Altiplano, northwestern Argentina (Figure 1.5). Valero-Garces et al. (1999) argue that the large enrichments of the heavier carbon isotopes in the algally bound sediments indicate non-equilibrium gas-transfer fractionation of the carbon isotopes during CO_2 degassing. Parent waters were derived from thermal springs and subject to subsequent evaporative concentration. In general most ions in lacustrine tufas in volcanic settings ultimately come from geothermal and volcanic CO_2 sources. Physical fractionation, rather than biological enrichment in these settings, may have a greater significance than credited in the commonly accepted biological metabolism arguments typically used to explain carbon isotope records in evaporitic carbonates (see Schouten et al., 2001 for opposing argument). Likewise, the dilution of the isotopic signature by C-14-free CO_2 from volcanogenic sources may hinder accurate C-14 chronologies of lake sedimentation when based on samples of lacustrine organic matter and other aquatic plants.

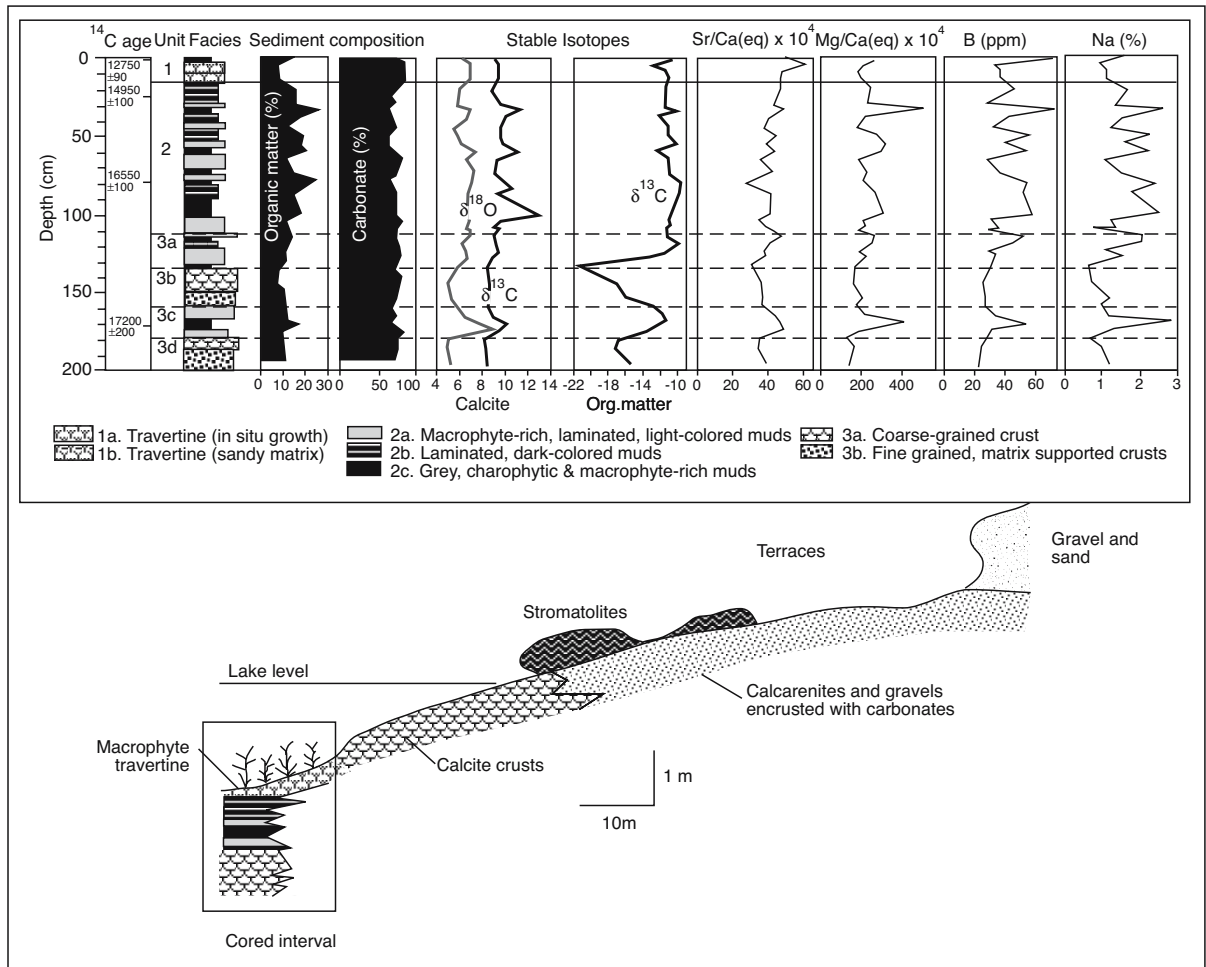

Figure 1.5. Sedimentary facies, sediment composition, stable isotopes and geochemistry of the Lake El Peinado core, Andean Altiplano. Core was collected in the perennially subaqueous carbonate margin of the lake (after Valero-Garcés et al, 1999, 2001). Macrophytes are the current active carbonate binders. Stromatolites today are not active, but grew at an earlier time of more saline water when conditions did not favour macrophytes. Dates are uncorrected AMS ¹⁴C ages (years BP). All isotopic measurements are reported as δ values vs. the PDB standard.

Microbialite sedimentology in saline lakes

Mineralisation associated with biofilm metabolism is much more important than simple agglutination in many Holocene lacustrine stromatolites. Niches occupied by stromatolites and tufa/travertine cement reefs in saline lacustrine settings circumscribe a much wider range of salinities and water conditions than evidenced by modern marine thrombolites and stromatolites. Isopachous biomineralized subaqueous stromatolite reefs, texturally identical to their ancient mm-laminated counterparts, still grow in the mesohaline carbonate-saturated seepage waters of some modern marine-fed gypsum lakes (von der Borch et al., 1977; Warren 1982a). The coarse-layered sandy agglutinated forms of Shark Bay and the mud-cracked supratidal algal mudstones of the Abu Dhabi sabkha have fewer ancient evaporitic counterparts.

Similarly, healthy carbonate-precipitating microbialites communities in the upper parts of less-saline carbonate-rich littoral and slope breaks about many prograding lacustrine margins in modern temperate and tropical carbonate lakes, can be used as analogues for microbial growth in the high water stages of some ancient saline basins (Dean and Fouch, 1983). For example, modern thrombolites, tufas and stromatolites occur in littoral waters (10-60m deep) about the edges of Lake Tanganyika (Cohen and Thouin, 1987) and Salda Gölü in Turkey (Braithwaite and Zeder, 1996). Near identical fresh to brackish water stromatolites, along with oncoids, travertines and tufas, occur in Plio-Pleistocene sediments of the East African Rift Valley lakes (Casanova, 1986). Similar marginward microbial tufa cement reefs (bioherms) reached thicknesses of 7 metres, with diameters of 15 metres, in the Oligocene Ries Basin (Rid-

ing, 1979; Arp, 1995). Freshwater to mesohaline stromatolites characterise Oligocene lake margins in France (Casanova and Nury, 1989) and the 1-10m deep freshwater-filled evaporite karst pond fills (posas) in a modern gypsiferous playa, Cuatro Ciénegas in Coahuila, Mexico (Figure 1.3c; Minckley, 1969; Winsborough et al., 1994). Other examples of ancient lacustrine counterparts include the Tertiary of southern France (Truc, 1978) and the Eocene Green River Formation of the USA (Surdam and Wolfbauer, 1975).

Widespread mm-laminated evaporitic stromatolites also accumulate in more saline lacustrine settings, settings where surface brines are waters supersaturated with respect to a carbonate phase, typically aragonite. In these settings the role of biology is less obvious in the laminates. Biofilms of archaea, eubacteria and algae may be passive rather than active participants during the formation of domal to massive laminar stromatolites. It is in this group of structures that the phrase “may or may not be of biological origin” comes into play. Modern examples of such enigmas include manganiferous aragonitic stromatolites that define the northwestern strandplain margin of the Northern Basin of the Dead Sea (see Druckman, 1981 vs. Garber and Friedman, 1983). Texturally identical evaporite-associated biomineralized stromatolites and biolaminites have characterised the mudflat and strandzone margins of saline and alkaline playa lakes and marine evaporite basins throughout much of the Phanerozoic, especially at times or in regions of transition into or out of episodes of basinwide evaporite precipitation (Figure 1.8a).

Mineralogy of most modern lacustrine stromatolites is dependent on what carbonate phase is precipitating in the ambient lake water. This is true even when biotal metabolism plays a significant role in driving carbonate precipitation. Stromatolites and microbial bioherms are aragonitic in many modern saline lakes (e.g. Great Salt Lake, Eardley, 1938; Marion lake, South Australia, von der Borch et al., 1977) and the precipitation process is often facilitated by the metabolic activities of bacteria (Pedone and Folk, 1996). Hydromagnesite-aragonite mm-laminated stromatolite domes and mats dominate in the schizohaline ephemeral waters of North and South Stromatolite Lakes in the Coorong region of South Australia (Figure 4.5a), while poorly preserved hydromagnesite-magnesite stromatolites characterise much of the present-day playa surfaces of the Caribou Plateau in Canada (Renaut, 1993a). Similar stromatolite domes characterise the highly alkaline

(pH>9) fresh to brackish waters of Salda Golu (Lake) in Turkey where lake margin subaqueous stromatolites are composed mostly of hydromagnesite, along with entrapped diatom tests (Figures 1.6, 4.29; Braithwaite and Zedef, 1994, 1996).

At the basin scale, Quaternary calcitic and aragonitic algal tufa and travertine reefs form atop spring vents in groundwater outflow zone where they can construct substantial spring mounds (Habermehl, 1988). Tufa growth rates can be impressive; Rosen et al. (2004) documented aggradation rates of 30 cm/year in the modern subaqueous tufas of Big Soda Lake in Nevada. Some impressive thinolitic tufa reef mounds in temperate and high-altitude saline lakes were originally constructed of an unusual but interesting variety of low temperature calcite called ikaite (Chapter 4). This hexahydrate form of calcite is found today forming ephemeral precipitates in near freezing brines around spring vents of CO₂-rich waters in Mono Lake and in Quaternary sediments of the Lohanton Basin (Pyramid Lake), Nevada. Similar spectacular tufa mounds occur in groundwater outflow zones on the subaqueous floor of Lake Van, Turkey. Once the water temperature about a spring mound rises above 3-4°C the ikaite dehydrates to calcite, but the calcite can preserve the characteristic lenticular and twinned outline of its precursor. But a lenticular to lozenge shape in a calcite pseudomorph is easily confused with other evaporite minerals, such as gypsum and gaylussite, which also are readily pseudomorphed by calcite (Chapter 7). Ikaite pseudomorphs can have little to do with an evaporite precursor, and occur in modern marine shelf sediments of the Antarctic and in modern and ancient glacial outwash fans from around the world (Shearman and Smith, 1985; Larsen, 1994; Riccioni et al., 1996).

Figure 1.6. Schematic cross section of Salda Gölü showing hydromagnesite stromatolite growing subaqueously in front of the carbonate tufa terrace (after Russell et al., 1999).

Microbialite sedimentology in marine settings

Unlike modern stromatolites and microbialites, which tend to construct significant rock masses in salinity or temperature stressed environments, Precambrian stromatolites were environmentally diverse and abundant across hypersaline, normal marine and nonmarine settings. They first appeared around 3.45 Ga and dominated biogenic sedimentation from 2800 to 1000 Ma (Riding, 2000). The beginning of their Proterozoic decline and environmental restriction, variously identified at 2000, 1000 and 675 Ma, has been attributed to reduced marine cementation or to eukaryote competition. The former was perhaps tied to higher calcium concentrations in Precambrian oceans compared to oceans of today (Laval et al., 2000), while the latter related to the evolution of the gastropod radula (Garrett, 1970). The previously enigmatic lack of calcified cyanobacteria filaments in stromatolite-bearing Precambrian sequences is now explained as a likely result of high concentrations of dissolved inorganic carbon in the Precambrian ocean (Arp et al., 2001) or by the postulate that many Archaean stromatolites were inorganic precipitates (Pope et al., 2000).

Precambrian stromatolites were not confined to the more arid peritidal marine or marginward lacustrine seep situations that characterise most Phanerozoic stromatolites. Such high stress environments (hypersalinity/exposure) tend to exclude many metazoan marine grazers that otherwise browse and destroy algal mats. Modern areas of thick extensive marine-margin stromatolites/cryptalgal laminites are located at the edge of the cropping range of marine grazers, examples of gastropod restriction include the seaward side of the algal facies of the Arabian Gulf (Figure 3.4d; Kendall and Skipwith, 1969) and the hypersaline intertidal flats of Shark Bay, Western Australia (Figure 1.3a; Logan, 1987).

Various thrombolites and dendrolites, mainly formed by calcified cyanobacteria, became important marine microbialites early in the Palaeozoic and reappeared in the Late Devonian, as marine stromatolite populations declined. Microbial marine carbonates retained their importance through much of the Mesozoic, they became scarcer in marine environments in the Cenozoic, but locally re-emerged as large agglutinated domes, possibly reflecting increased algal involvement in sediment binding and cementation.

There are still a few modern normal-marine settings where metre-scale stromatolites flourish. Holocene columnar stromatolites grow as part of a thrombolite-stromatolite association on the floor of modern tidal channels off Lee Stocking Island, Exuma Cays. These bio-columns show three

associations of internal sedimentary structures: (1) prokaryotic stromatolites comprised of alternating layers of coarse-grained ooids and peloids, and fine micrite that are formed exclusively by microbial activity; (2) eukaryotic stromatolites comprised of microbially-induced micritic layers alternating with detrital layers bound and cemented by eukaryotic algae; and (3) thrombolites displaying irregular, clotted fabrics and formed by communities of microbes, algae, and metazoans (Figure 1.7a; Feldmann and McKenzie, 1998).

Onshore in San Salvador in shallow turbid water, beneath the modern mesohaline waters of Storr's Lake, marine-influenced thrombolite layers alternate with stromatolite layers to create mushroom shaped mounds. This alternating layering perhaps reflects changes in salinity and light penetration (Figure 1.7b; Mann and Nelson, 1989). Formation of many modern marine thrombolites has been attributed to carbonate precipitation driven in large part by sciaphile (dark-loving) bacteria, which flourish under low sedimentation rates, low water energies and higher turbidity, hence the preservation of a clotted fabric and lack of lamination (Dupraz and Strasser, 1999; Riding, 1991). Phanerozoic marine thrombolites, in contrast, are mostly interpreted as non-laminated microbialites (not a stromatolites) constructed by cyanobacteria and are not usually interpreted as sciaphiles.

According to Feldmann and Mckenzie (op cit.) the contemporaneous formation of prokaryotic stromatolites, eukaryotic stromatolites, and thrombolites under identical conditions within the present marine environment is unlikely. They suggest that the prokaryotic stromatolites in the Lee Stocking bioherms represent microbial forms that began to develop in an environmentally-stressed intertidal setting during the early Holocene flooding of the Great Bahama Bank. In contrast, thrombolites began to form under the present, normal-marine subtidal conditions (Figure 1.7a). The eukaryotic stromatolites represent intermediate forms between prokaryotic stromatolites and thrombolites, with a gradual change from stromatolite to thrombolite reefs tied to rising sealevel. With the deepening, there would have been a decrease in salinity, an increase in energy, and possibly an increase in nutrient supply; all factors that favour thrombolite growth.

Unfortunately, most environmental and depositional models for Phanerozoic stromatolites tend to draw heavily on Holocene peritidal marine-margin analogues, such as Shark Bay, a hypersaline setting where sand grain trapping (agglutination), rather than micrite precipitation, is the dominant mode of sediment accretion. Accordingly, using modern analogues, many

Figure 1.7. Thymbolites in mesohaline to marine settings. A) Evolution of microbialites during a rise in sea level from time X to time Z in the formation of marine subtidal stromatolites in Lee Stocking Island in the Bahamas (after Feldmann and Mckenzie, 1998). B) Distribution of algal/thymbolitic structures in mesohaline aragonite muds of Storr's Lake, San Salvador (after Neumann et al., 1988; Mann and Nelson, 1989). C) Thymbolites (aragonitic) passing into gypsiferous mud mounds below the halocline at the southern end of the channel in Gotomeer, Bonaire (after Kobluk and Crawford, 1990).

sedimentologists assume that well-preserved Phanerozoic stromatolites must have formed in intertidal to supratidal marine settings. As we shall see in Chapter 5, a marine-connected basin is not the best way to model evaporitic carbonates associated with thick evaporites. Microbes living in ancient saline systems constructed a far more diverse and wide ranging biotal association in evaporitic settings than simplistic Shark Bay analogs imply (Chapter 9).

Microbialites typify marine to evaporite and evaporite to marine transitions

Throughout the rock record, Pope et al. (2000) noted that a transition between a carbonate platform or an isolated carbonate

buildup and the overlying evaporites is commonly defined by assemblages of stromatolites or interlaminated carbonates and evaporites. The stromatolites display lamination textures that vary from peloidal and discontinuous on a scale of a millimetre to a few centimetres, to isopachous and continuously laminated on a scale of a centimetre to a few metres. The isopachous lamination may be composed of either: (1) micrite or radial-fibrous calcite, or (2) dolomite. The isopachous laminae are remarkably uniform, varying little in thickness over a given lateral distance, whereas stromatolites formed of peloidal laminae, also show marked variations in thickness over an equivalent lateral distance (phototactic thickening). They observed that isopachous textures are uncommon on most open-marine carbonate platforms and apparently developed in transitional

Location	Units	Carbonate Fabrics	Composition
Great Slave Lake, Canada, Palaeoproterozoic (1.8-1.9 Ga)	Perthei Grp. (c) Stark Fm. *e)	Tufa, isopachously laminated stromatolite at contact in shallow water; Fibrous marine cements throughout platform	Basinwide evaporite Halite >> gypsum (no anhydrite)
Oman, Vendian (570-543 Ma)	Buah Fm. (c) Ara Fm. (e)	Fibrous marine cements throughout platform and isolated thrombolitic bioherms; Isopachously laminated stromatolites at contact; tufa-like crusts in carbonates within evaporites	Basinwide evaporite Halite >> gypsum
Michigan Basin, Silurian (≈ 400 Ma)	Guelph Fm. (c) Salina Fm. (e)	Fibrous marine cements within pinnacle reefs; Isopachously laminated stromatolites (travertine-like coatings) cap marine reefs; Calcite laminites in interpinnacle reef areas	Basinwide evaporite Halite >> anhydrite, potash salts
Western North America; Middle Devonian (≈385 Ma)	Winnepegosis (c)	Stromatolites cap marine reefs, fibrous marine cements in reefs and carbonate-evaporite laminites between reefs in deeper-water settings	Basinwide evaporite Halite >> anhydrite
Sverdrup Basin, Carboniferous, Arctic Canada	Nansen (c) Otto Fiord (e)	Carbonate-evaporite laminites in basinal setting, fibrous marine cements throughout shelf-margin reefs and buildups	Halite ≈ anhydrite
Zechstein Basin, England, Late Permian (≈ 260 Ma)	Middle Magnesian Limestone (c) Hartlepool Anhydrite (e)	Fibrous marine cements throughout reef complex; Isopachously laminated stromatolites (Crinkly Beds) in bioherm capping marine reef complex; Laminar coatings within bioherm, neptunian dikes and cavities; Laminites in basinal setting between buildups	Basinwide evaporite Halite >> anhydrite Locally on platform: Anhydrite >> halite
Mediterranean Messinian (Middle Miocene)	Terminal Carbonate Complex (c)	Thinly laminated stromatolites at transition from marine carbonate to evaporite; fibrous marine cements within reefs underlying stromatolites	Basinwide evaporite Halite >> gypsum
Abu Shaar Complex, Egypt; Messinian (Middle Miocene)	Ruidais Fm. (c) Kareem Fm. (e)	Fibrous marine cements throughout marine reef complex; Thinly laminated stromatolites with fibrous cements on toe of slope; Unique pisoids with distinctive fibrous fabric	Basinwide evaporite Anhydrite > gypsum > halite

Table 1.3. Selected examples of unique evaporitic carbonate fabrics in basinwide transition facies passing from carbonate through mesohaline to hypersaline deposition. Carbonate = (c), Evaporite = (e). (after Pope et al., 2000 and contained references).

carbonate-to-evaporite settings because of basin isolation and drawdown leading to increasing temperature, salinity, and anoxia related to water stratification (Table 1.3; Figure 1.8a). The resulting ecologic restriction created an opportunity for isopachous stromatolite growth.

Stromatolites with isopachous lamination are interpreted to form via in situ precipitation of sea-floor-encrusting calcite and possibly dolomite, whereas the stromatolites composed of peloidal, discontinuous lamination are inferred to have formed by trapping and binding of loose carbonate sediment in microbial mats and can be unrelated to the onset of basinwide evaporite restriction and drawdown. According to Pope et al. (2000), isopachous stromatolites may have accumulated by chemogenic precipitation in the absence of microbial mats, while peloidal stromatolites grew by agglutination in the presence of microbial mats and since the onset of the Phanerozoic have been largely restricted to environmentally stressed biogenic sediment. I would not exclude biofilms from isopachous stromatolites, it is just that high inorganic precipitation rates can swamp the phototactic effects used to interpret biofilms.

Pope et al. (2000) went on to note that when compared to pre-Mesozoic occurrences, stromatolites with thin, isopachous lamination and radial-fibrous textures, though present, are rare to absent in transition facies in Jurassic and younger evaporite basins, such as the Messinian of the Mediterranean region. Instead, the isopachous precipitative facies have been replaced by stromatolites with peloidal, clastic phototropic textures and by mesohaline mudstones with a low-diversity diatomaceous and coccolith biota. These stromatolites are sometimes interlayered with thrombolites (as in Storrs Lake, Caribbean). They interpret the shift away from chemogenic stromatolites to agglutinated stromatolites as a change in seawater chemistry tied to the evolution of the nannoplankton. Accumulation of the biogenic planktonic mudstones in deeper ocean waters since the Mesozoic has had two important effects: (1) Production of coccolith tests in the world's oceans (chalks) helped extract calcium carbonate from seawater, thus lowering the growth potential for inorganic precipitation of sea-floor-encrusting stromatolites. (2) Settling of both coccoliths and diatoms would have created a sediment flux to the sea floor, which would have served to impede growth of chemically precipitated stromatolites because of ongoing smothering of any growing seafloor crystals.

Post-Mesozoic peloidal stromatolites (bio-agglutinates) and thrombolites tend to characterise transitions into and out of episodes of basinwide evaporite deposition. One of the best-preserved transitions of this style of stromatolite/thrombolite occurrence comes from the Late Miocene of SE Spain in cyclic stromatolitic carbonates deposited during and at the termination of the Messinian salinity crisis (Figure 1.8b; Chapter 5). For example, large microbial carbonate domes (both stromatolites and thrombolites) defined the margins of the Sorbas and Alboran Basin during the uppermost Messinian. They occur in a unit overlying the Messinian evaporite succession and were deposited in a variety of environments, including fan deltas (Martín et al., 1993; Braga et al., 1995), beaches, and oolitic shoals (Riding et al., 1991).

Their abundance and continuity in the transitional marine setting is comparable in many respects to their omnipresence as transitional forms in the Precambrian. There is, however, an important difference in some parts of the Messinian sequences. Although major unconformities separate normal marine reefs

from the carbonates of the “terminal complex complex (TCC),” an impoverished and depauperate, normal-marine biota of Late Miocene corals (*Porites*), coralline algae, serpulids, bivalves, and encrusting foraminifers at times lived alongside the stromatolitic microbes as the TCC was accumulating (Martín et al., 1993; Braga et al., 1995). The intimate association of stromatolites with a stressed, but stenohaline, marine biota rules out the possibility of continually elevated salinities at the onset of TCC deposition, as suggested by several earlier authors to account for the occurrence and proliferation of widespread microbial structures in the Messinian strata (Esteban, 1980; Rouchy and Saint-Martin, 1992). The most plausible explanation for this transition into and out of hypersaline into normal marine waters is that microbes acted as opportunistic biota and, for a time, outcompeted other organisms, settling and growing successfully in most of the available and rapidly expanding marine niches (Pope et al., 2000; Feldmann and McKenzie, 1997). This happened during the initial stages of marine recolonization of the Mediterranean Sea, after drawdown and deposition of either the lower or upper evaporite sequences.

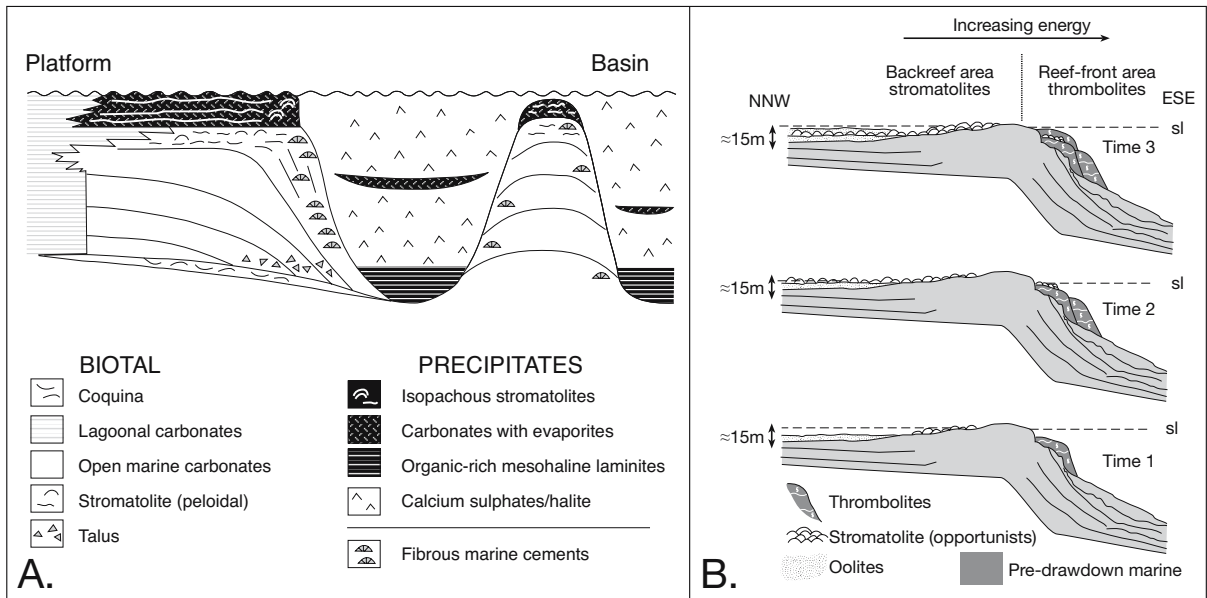

Figure 1.8. Schematics of marine carbonate to evaporite transitions. A) Typical transitions, showing relative positions in the basin stratigraphy of precipitated isopachous stromatolites and the precipitated carbonate fabrics that typify sediments accumulating mesohaline carbonates immediately prior to complete basin isolation and drawdown that defines the onset of basinwide calcium sulphate and/or halite evaporite deposition (after Pope et al., 2000). B) Platform edge distribution of stromatolites and thrombolites relative to cyclic sea-level changes during the Intra-Messinian flooding event in a marginal Mediterranean sub-basin. Time 1) Relative high sea-level stand with thrombolite growth in the subtidal zone at the front reef, oolite deposition in the deeper parts of the back-reef area, and stromatolite growth in the intertidal zone of the back-reef area. Time 2) Relative low sea-level stand promoting thrombolite growth in the basinward migrated subtidal zone at the front reef and opportunist stromatolite growth in the intertidal zone on both the previously deposited ooid sands and thrombolites. Time 3) Relative high sea-level stand with thrombolites growing over the preceding stromatolites in the subtidal zone at the front reef, opportunist stromatolite growth in the intertidal zone of the back-reef area, and sand deposition in the deeper water of the back-reef area (after Feldmann and Mackenzie, 1997).

Thus, the development of microbial structures during the Messinian seems to be related, although indirectly, to the end of each “salinity crisis” and the creation of unoccupied marine ecologic niches as seawater encroached on drawdown unconformities. Earlier but ecologically comparable vacant niche scenarios are found atop Phanerozoic platform carbonates at the onset of basinwide evaporite stages (Table 1.3); examples include the Silurian of Michigan Basin (Sears and Lucia, 1979) and the Permian of the Zechstein Basin (Paul, 1980). The abundance of stromatolites and thrombolites in normal marine environments in the aftermath of a mass extinction of the pre-existing marine benthic biota via drawdown can be explained by the stromatolite and thrombolite communities acting as opportunistic disaster forms taking advantage of vacant ecologic niches (Schubert and Bottjer, 1992).

Vadose pisolites, ooids and other coated grains

Fenestral carbonates, sometimes intercalated with grainstones, are frequently interpreted as peritidal sediments (Shinn, 1983).

Figure 1.9. Fabrics of pisoids created by in-place processes. Although all these features have been interpreted as requiring vadose pore conditions, only downward directional elongation (micro-stalactite) require such an interstitial condition (after Esteban and Pray, 1983).

Often the grainstones facies are dominated by coated grains, including oolites, and their wave-agitated mechanical genesis is indicated by well preserved crossbed sets. A marine conception is indicated by nuclei of marine shell fragments and intercalation with packstones and wackestones containing marine fossils. More typically in evaporitic settings these metre-thick beds of coated grains lack obvious crossbeds or marine fossils and are intercalated with biolaminites and sharp crosscutting truncation surfaces. Units tend to be inverse graded and coarsen upward into pisolitic rudstones, they are commonly interlayered with evaporite solution breccias (Figures 1.9, 1.10a). Pisolitic beds show many textural features, such as bridged coats and polygonal fitting of pisoids, that imply they formed “in situ” under conditions of little or no wave-induced agitation. Individual pisolites, now composed of calcite or dolomite, can show nonconcentric internal truncation surfaces and brick-like crystal terminations indicative of exposure and an aragonite parent (Figure 1.10b, c; Assereto and Folk, 1976).

Pisolite rudstones tend to be caught up in tepee structures and other strandzone layers and beds that also contain internal structures and cements indicative of alternating vadose and phreatic conditions. Such features include perched inclusions, inverse graded pisolite beds, and pendulous circumgranular cements (Figures 1.9; Dunham, 1972; Esteban and Pray, 1983; Handford et al., 1984). They indicate a depositional setting that was part of a strandzone, typified by the “to and fro” of the strandline edge of a brine lake or seaway in a zone of groundwater seepage. The associated water table rose and fell as, pore water conditions alternated between vadose and phreatic.

Pisolite crust cements formed in a strandzone retain infiltrated micrite and pendulous grain underhangs that indicate the sediment spent at least a part of its time above the water table. The term vadose pisolite is sometimes used to distinguish these evaporitic pisolites from permanently subaqueous isopachous “marine” pisolites or the pedogenically formed calcrete pisolites. The prefix marine is a little misleading when describing isopachous pisolite crusts. Modern examples of isopachous pisolites, along with fitted, pisolith crusts define CaCO_3 -saturated peripheral marine seepage areas on the strandplain of evaporite-filled coastal lakes in western and southern Australia (Warren 1982a, 1983a; Handford et al., 1984) and the thermal spring-fed margins of large halite-filled continental salars in the Andean Altiplano (Risacher and Eugster, 1979; Jones and Renaut, 1994). Both settings lack a surface connection to marine waters. The term seepage should perhaps replace the term marine when describing strandzone pisolites.

Figure 1.10. Pisolites from Permian of west Texas. A) Polished slab of pisolitic dolomite from the uppermost Yates Formation. Note reverse grading of grains, and “fitted fabric” in which grains have interlocked boundaries produced by compromise growth of outer coatings. Sample from roadside outcrop at “hairpin turn” on New Mexico Highway 7 in Carlsbad Caverns National Park, Eddy Co., NM. B) Thin-section photomicrograph (cross-polarized light) of a pisoid from the Yates Formation. Note irregular, lumpy, partially concentric coatings; fracturing (“autobrecciation”) of micritic-peloidal matrix; and evaporite plugging of remnant intergranular porosity. Sample is from 1708.1 ft depth in Gulf/Chevron PDB-04 well on Northwestern Shelf of Delaware basin, 30 km ENE of Carlsbad, Eddy Co., NM. Long axis of photo = 14.5 mm. C) Thin-section photomicrograph (plane-polarized light) of a marine-cemented pisolitic dolomite showing transition from pisoid to botryoidal cement crust. Note that the extremely elongate rays of cement which extend from upper surface of the pisoid show squared crystal terminations. This is used as evidence for an originally aragonitic composition for the cement. Sample from 1739.3 ft depth in Gulf/Chevron PDB-04 well on Northwestern Shelf of Delaware basin, 30 km ENE of Carlsbad, Eddy Co., NM. Long axis of photo = 16 mm. (Images and descriptions courtesy of P. Scholle, <http://geoinfo.nmt.edu/staff/scholle/guadalupe.html>; accessed 11 Dec, 2004).

Ancient pisolites may be marine-fed or continental; all accumulated in CaCO_3 saturated waters. Seepage pisolites are part of a sedimentological association where pisolite crusts are forming mainly as accretionary chemogenic particles in areas of cooling, degassing and concentrating resurgent groundwater. Many are coated with microbial communities, which through their photosynthetic activity help drive the process of carbonate supersaturation. Seepage pisolites occur within confined saline groundwater seepage areas that are located on, or adjacent to, extensive carbonate mudflats about saline waterways. Such systems are not restricted to marine seepage settings but also

form about the strandzone margins of continental saline lakes and salars.

Esteban and Pray (1983) argue vadose (seepage) pisolites characterise the Permian island shoal and sandflat facies of west Texas (Figure 1.10). There pisolitic crusts were thicker and most obvious within the central depressions of decametre-diameter saucers in what was an extensive tepee-overprinted megapolygonal terrain. Warren (1983a) argued the same pisolites were part of a marine seepage facies about the edge of a widespread saltern/mudflat depression that covered the platform interior behind a sandy island shoal.

Nominal “marine” pisolites are characterised by isopachous rim cements, little or no grain fitting and few vadose textures. They are commonplace in normal marine Proterozoic carbonates compared with the Phanerozoic marine (Swett and Knoll, 1989). Their greater abundance reflects a more carbonate-saturated marine chemistry in Precambrian seas (see below). But, throughout geological time, an isopachous pisolite texture has also been a boiler-plate feature of the hypersaline lacustrine realm.

Work by Gerdes et al. (1994) has shown that in addition to “seepage” pisolites other carbonate grains, such as ooids and peloids, typically thought of as indicators of marine conditions and mechanical agitation, can precipitate *in situ* in CaCO_3 -saturated evaporitic settings. They grow within modern microbial mats in hypersaline settings and require no wave-agitated or pelagic phase to precipitate concentric laminar grain coats. Laboratory experiments with unconsolidated muds, and comparisons with fenestral and grainstone textures in evaporitic Guadalupian backreef strata in west Texas by Mazzullo and Birdwell (1989), demonstrated that intense *in situ* alteration of fenestral mudstones can create peloidal grainstones. They go on to argue that such diagenetic grainstones may be the precursors of some forms of pisolitic rudstone.

Wave-agitated shore-parallel crossbedded ooid sand belts, very similar to their modern marine look-alikes, can accumulate in a lacustrine strandzone. For example, cross-stratified oolitic lacustrine grainstones and packstones typify wave-agitated strandzone or lake margin sediments of contemporary Great Salt

Lake, Utah (Eardley, 1938), the Upper Cretaceous to Eocene lacustrine strandzone of Green River Formation of the Uinta Basin, Utah, USA (Williamson and Picard, 1974) and the high energy, lake-shoreline carbonates of the Upper Triassic Mercia Mudstone Group of southern Britain (Milroy and Wright, 2000). Texturally these hypersaline ooids show a radial texture that contrasts with the more typical tangential structure of modern marine ooids. Eardley (1938) noted that ooid sand bodies in Great Salt Lake are concentrated along relatively narrow, wind-swept coasts, adjacent to steep basement promontories and in waters that are less than 2 metres deep (Figure 4.19b). In contrast, strandzone algal bioherms are typically, although not exclusively, associated with wider, less exposed and more gradually inclined shorelines distal to basement uplands. Work by Halley (1977) on ooids from the Great Salt Lake showed that in an agitated setting radial ooids are structurally weaker than comparable tangential marine ooids. He argued that a statistically significantly proportion (>1%) of syndepositionally broken ooids is a reliable indication of radial aragonite ooids associated with hypersaline shorelines (Chapter 4).

Tepees

Tepees are the buckled and broken margins of saucer-like megapolygons in limestone or dolomite crusts that appear as an inverted “V” in vertical two-dimensional exposures (Figures 1.11, 1.12a, b; Adams and Frenzel, 1950). Tepees are commonplace strandzone features in both modern and ancient settings (Assereto and Kendall, 1977; Warren, 1982a, b, 1983a; Esteban and Pray, 1983; Kendall and Warren, 1987;

Figure 1.11. Cross section of a field locality of the Permian Tansill Formation at Hairpin Curve in Guadalupe National Park, west Texas. Note the prominent development of pisolites in intertepee depressions within the upper tepee complex and the erosional surfaces that truncate the tepee complexes (after Esteban and Pray, 1983).

Figure 1.12. Tepee Structures, Permian Basin, west Texas. A) Tepee structure in Tansill Formation. Note that if the upturned margins of the structure were returned to a horizontal position, they could not be accommodated on a flat bedding plane; this shows that these are expansion polygons. Light yellow layers are dolomitized pisolitic and fenestral sediment; darker, gray layers are zones of sheet spar (aragonitic cement crusts). Interstitial growth of aragonite (in marine or coastal spring settings) was the most likely cause of sediment expansion and buckling. Outcrop at southwest end of parking lot at Carlsbad Caverns visitor's centre, Carlsbad Caverns National Park, Eddy Co., NM. B) Stacked sequence of tepees, associated with fenestral and pisolitic dolomites, in the basal part of the Tansill Formation. A 1.8 m thick sandstone at the base of the exposure (at level of man) has truncated tepee stacks in the underlying Yates Formation and possibly acted as an aquifer for the resurging brines that precipitated these tepees. The sandstone sheets, which thin to a feather edge toward the shelf margin, have been interpreted as sabkha sandflats formed by eolian processes during sealevel lowstands. Roadside outcrop on Dark Canyon road approximately 2 km west of the canyon mouth, Eddy Co., New Mexico. C) Peloidal and skeletal grainstones with fenestral fabric in the near-back-reef Tansill Formation. These strata were probably deposited on a relatively high-energy mudflat. Outcrop on south side of Dark Canyon, less than 1 km west of the canyon mouth, Eddy Co., NM. Coin is 2.4 cm in diameter. D) Close-up of sheet spar (aragonite cement) crust from within a tepee structure. Note growth of banded cements from top as well as bottom of cavity and incorporation of fragments of matrix sediment. Roadside outcrop at hairpin turn on New Mexico Highway 7 in Carlsbad Caverns National Park, Eddy Co, NM. (Images and descriptions courtesy of P. Scholle, see <http://geoinfo.nmt.edu/staff/scholle/guadalupe.html>; accessed 11 Dec, 2004 for more details on this region of New Mexico).

Logan, 1987; Kendall, 1989; Smoot and Lowenstein, 1991; Last, 1992; Jones and Renault, 1994; Mutti, 1994; Armstrong, 1995). Some authors have extended the use of the term tepee to pressure ridges in crusts of gypsum or halite. I prefer to restrict usage of the term tepee to overthrust ridges in carbonate crusts and to use the term pressure ridge for overthrust ridges in halite or gypsum crusts. That is, although I use the term tepee nongenetically, I restrict its usage to carbonate crusts and add a

prefix to describe its genesis, e.g. groundwater/seepage tepee, seafloortepee, sabkha tepee, caliche tepee (Kendall and Warren, 1987); some may even be seismic (Pratt, 2002) or microbial (Chow and George, 2004). Others workers restrict the use of the term tepee to inorganic overthrust structures (carbonate and salt hosts) and use the term petee to describe overfolded to overthrust ridges in what were originally biogenically-bound surface layers. Petees can occur in layers and crusts composed

of both evaporitic carbonates and more saline salts, the ridge crest need not be fractured, but can be a series of polygonally linked folds. See Gavish et al., 1985 for the original definition of petee and Noffke et al., 2003 for a comprehensive discussion of petees and other microbially induced sedimentary structures that are commonplace in evaporitic settings. Microbial petees typically have synoptic relief measured in centimetres, but range up to a metre high in the lagoonal strata of the Devonian Lennard Shelf in the Canning Basin of northwest Australia (Chow and George, 2004).

Tepees, along with vadose pisolites are characteristic features of cemented carbonate crusts in areas of a strandplain that experience wetting and drying cycles, CaCO_3 -saturated groundwater seepage, fluctuating salinity conditions, and marked diurnal changes in surface and nearsurface temperatures (Figure 1.12c). Successive episodes of tepee development often stack one bed atop another, with the tepee-overprinted units separated by erosion surfaces, breccias or carbonate-cemented quartz sands (Figures 1.11, 1.12d). Pisoids in the Permian strata of west Texas appear to accumulate best within intertepee depressions or saucers (Figure 1.11; Esteban and Pray, 1983). Subsequent expansion episodes, along with local buckling, may rework beds formed in these pisoid-rich depressions into new tepees. When the pace of resurgence was strengthened during times of increased groundwater outflow, tepee crests were capped by domal stromatolites (Figure 4.5c; Warren, 1982a; Kendall and Warren, 1987).

Many ancient tepee-influenced horizons are interbedded with evaporite solution collapse breccias. This characteristic intercalation reflects the to and fro of a brine sheet edge over the strandzone carbonate facies, typically at times when the platform was isolated from a surface connection to the ocean and brine levels were fluctuating in response to the vagaries of evaporitic drawdown (Chapter 5). Some evaporite solution collapse may postdate the depositional hydrology of the cycle that formed the tepee, but, based on modern analogues such as Marion Lake and Lake McLeod, the schizohaline brine hydrology that forms the marginward saline seeps where tepees flourish is dominated by pore waters that are undersaturated with respect to halite and gypsum. Resurging groundwaters dissolve nearby evaporite beds as they form the tepee/pisolite beds (Warren 1982a). The end result of this ongoing dissolution is the collapse of the overlying tepee-affected strata. Any subsequent prograding of the seepage margin into the evaporite basin means the tepee zone is cannibalised from below and along its landward margin by its own groundwaters. All that may be preserved as widespread evidence of a prograding tepee hydrology within an ancient platform cycle is a terra rosa

profile mixed with remnant breccias composed of fragments of tepee crusts, stromatolite breccias and other residues of the strandplain (Burri et al., 1973; Assereto and Kendall, 1977; Bogoch et al., 1994; Mutti, 1994).

At a broader scale, the occurrence of a substantial tepee-rich unit in a platform interior carbonate succession indicates an episode of exposure and water table drawdown. For example, in the Italian Alps the principal tepee-dominant unit is interpreted as a sequence boundary and forms a regional marker in the highly cyclic Latemar (Triassic) platform interior (Hardie et al., 1986). This 300m thick tepee facies separates the lower cyclic facies and the upper cyclic facies of the Schlern Formation in the Latemar platform (Egenhoff et al., 1999; Mutti, 1994). It is characterized by 79 tepee zones (0.2 to 13m thick) alternating with intervals of thinning-upward, caliche-capped mudstone to packstone cycles.

Some authors have suggested a Milankovitch cyclicity may be preserved in thickness variations within the platform interior sediments of the Latemar (Hinnov and Goldhammer, 1991). If so, the highly altered, overprinted and collapsed origin of at least some of the tepee intervals, probably means individual eustatic parasequences are no longer recognisable within the tepee facies. The predominance of tepees in the Latemar platform also suggests periodic evaporative drawdown in the platform interior. Seepage hydrology needed to form pisolites and tepees implies an exposed but somewhat elevated platform rim at the time the tepees of the interior were active. In contrast, the thicknesses of the transgressive systems tracts (subtidal successions) also preserved in the platform interior indicate flooding and are more likely to retain finer-scale eustatically/climatically distinctive thicknesses.

Carbonates - present and past

Phanerozoic evaporitic carbonates accumulate in CaCO_3 -saturated waters and the consequent aragonite/dolomite muds and cements are distinctive and quite easily separated from open marine shelly carbonate shelf textures. The separation between marine and hypersaline settings is much less distinctive in Proterozoic strata or older. In fact, the best modern textural analogues for many Precambrian marine carbonates are to be found in Holocene evaporitic carbonates and not in modern normal marine carbonates. The dichotomy reflects two major events in earth history: 1) the evolution of an increasingly bicarbonate-depleted and sulphate-enriched ocean by the Proterozoic, and 2) the rise of a shelly marine macrofauna at the Cambrian-Precambrian boundary.

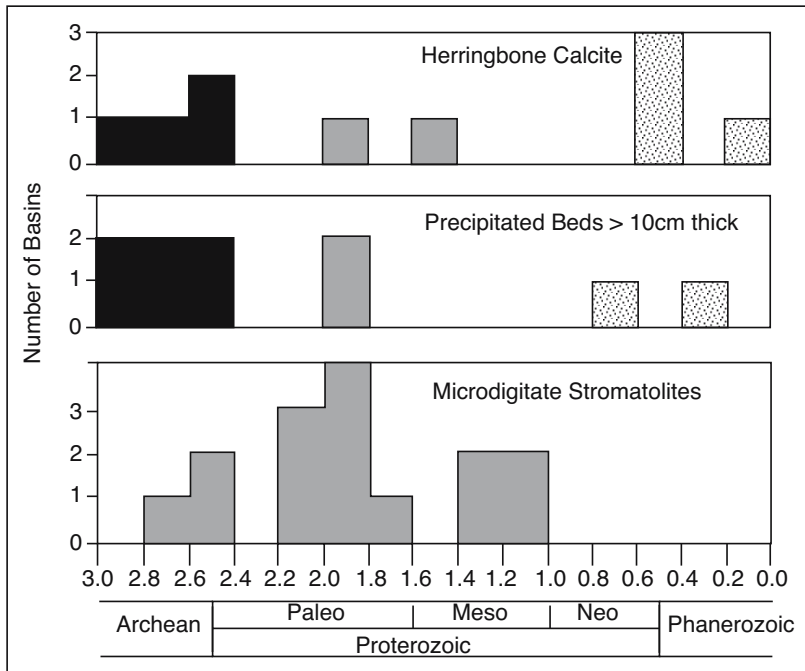

Figure 1.13. Carbonate precipitation from seawater through time. Black fill represents basins where the textures are abundant across a range depositional settings. Grey fill represents basins where the textures are present in a limited number of depositional settings. Stippled pattern indicates textures and minor components with limited extents (after Sumner and Grotzinger, 1996).

During much of the Precambrian, CaCO_3 was extracted from seawater by a combination of inorganic and microbial processes, the same two sets of processes that dominate in modern evaporitic carbonate settings. Archean carbonate sediments entrain numerous and prolific giant botryoids of aragonite that can be up to 1 metre in radius, as well as widespread Mg-calcite precipitates (Grotzinger and Read, 1983; Grotzinger and Kasting, 1993; Grotzinger and Knoll, 1995; Sumner and Grotzinger, 2004). These beds sometimes formed cementstone sheets several metres thick with strike lengths of more than 100 km, with no modern counterparts in normal marine carbonates (Figure 1.13).

By the Palaeoproterozoic, marine carbonates entrained less spectacular masses of aragonite and calcite, although cementstone crusts and microdigitate stromatolites in tidal flats remained a characteristic style of carbonate platform aggradation. In contrast, Meso- through Neoproterozoic carbonate sedimentation saw a progressive decline in the precipitation of massive widespread carbonate cements and an increase in widespread precipitation of micritic whittings. Throughout the Precambrian, periodic high-energy events ripped up and transported fragments of these cementstone crusts and whiting beds to redeposit them

as intercalated intraclast conglomerates and breccias. The secular decrease in the volume of seafloor precipitates reflects a change in the chemical state of the ocean. The much lower sulphate concentrations and much higher bicarbonate to calcium ratios reflect the elevated levels of CO_2 in the Archean atmosphere (Chapter 2; Grotzinger and Kasting, 1993).

The change in the earth's atmosphere and ocean chemistry is also reflected in the evolving nature of microbialites (Grotzinger and Knoll, 1999). During the Archean and early Proterozoic, when CO_2 levels were much higher than today, stromatolites formed by "in situ" precipitation of laminae and coniform stromatolites were commonplace. But younger Proterozoic marine stromatolites grew largely through the accretion of carbonate sediments, mostly through the physical process of microbial trapping and binding (agglutination) and coniform stromatolites had by then largely disappeared from

the world's oceans (Sumner and Grotzinger, 1996) and today are found only as tufas in hypersaline lakes (Warren, 1982a). The carbonate supersaturation of Archean seawater has led some to question the biogenicity of the 3.43 Ga stromatolites at North Pole, Australia - historically interpreted as the world's oldest biological fossils (Grotzinger and Rothman, 1996 vs Hoffman et al., 1998).

The dramatic rise of a skeleton-secreting and sediment ingesting macrofauna at the beginning of the Phanerozoic further changed the nature of marine shelf sedimentation. The proportion of chemically precipitated open-marine mud and cement decreased and new sedimentary particles, such as abundant shell fragments, faecal pellets and biologically derived muds, came to dominate the marine carbonate realm. The formation of widespread cementstone sheets on the seafloor had ceased several hundred million years before the rise of the shelly macrofauna. It was only in hypersaline environments that carbonate supersaturation persisted throughout the Phanerozoic. There isopachous stromatolites and other halotolerant microbialites continue to flourish in the absence of bioturbation and gastropod grazing.

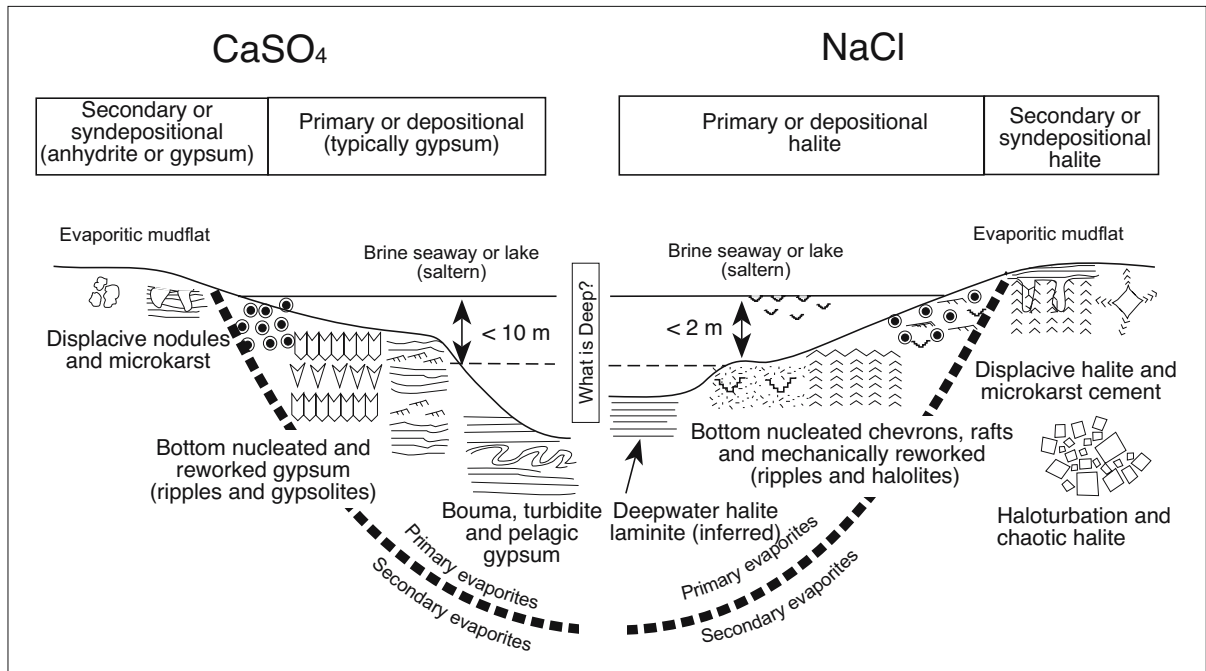

Figure 1.14. Depositional signature of primary evaporite textures and syndepositional secondary evaporites for CaSO_4 and NaCl salts. Secondary textures related to burial are discussed later in this chapter.

Primary evaporite salts

Evaporite salts are deposited in a brine pan or seaway after the brine has precipitated the alkaline earth carbonates. The salts, dominantly CaSO_4 or halite, show a range of crystal textures that indicate relative stability, depth and permanence of the precipitating brine (Figure 1.14).

Simple monomineralic carbonate, sulphate or halite layers and laminae, as well as beds composed of complex interlayered mixtures, dominate subaqueous deposits of many saline lakes and seaways. Laminae created by chemical settling are a typical subaqueous stratification style at the onset of primary salt accumulation. Some laminae outline underlying crystal morphologies, others are flat-planar and can be correlated for long distances across the basin. Biolaminae, including microbial bedding and accretionary tufa and travertine deposits described previously, are common intercalations and indicate less saline intervals in the same brine body. Mechanically reworked laminae (ripples, dunes and slumps) are less common in subaqueous evaporites than in their carbonate or siliciclastic counterparts. This is due to the predominance of chemical sedimentary processes operating in the brine bodies at the salt precipitating stage whereby early crystal precipitates interlock and cement as they evolve into growth-aligned crystals.

Widespread layers or crusts composed of cm-dm sized aligned bottom-nucleated crystals are one of the most widely recognised shoalwater textures. Depending on the salinity of the precipitating brine this bottom-nucleated unit is typically composed of halite chevrons or aligned gypsum crystals. Beneath deeper waters, crystals may accumulate on the bottom as a silt-sized “rain from heaven” pelagic deposit or as a mass of coarsely crystalline monomineralogic bottom meshworks. A range of slope deposits, dominated by reworked shoal water crystals, typifies the subaqueous region separating the shallow from the basinal (Chapter 5).

Over time, decimetre-to-metre thick salt beds can stack one atop the other to form evaporite units that can be hundreds of metres thick. When conditions are suitable, huge thicknesses of shoalwater evaporite can accumulate in very short time frames. For example, a more than one-km-thick sequence of interbedded halite and clay has accumulated in less than 10,000 years in the Danakil Depression of the Ethiopian rift (Figure 11.4). No other type of sediment, carbonate or siliciclastic, can aggrade as rapidly as a subaqueous evaporite bed (Warren, 1991).

Gypsum beds

A few thousand years ago subaqueous crystals of gypsum, up to 1 metre tall, grew in stable bottom waters of shallow (<10m deep) Holocene brine pans of southern Yorke Peninsula, South Australia (Chapter 4; Warren, 1982b). The crystals coalesced into crusts and beds dominated by swallowtail and palmate gypsum crystals. Similar giant growth-aligned subaqueous gypsum with single crystals up to 10 metres tall have been documented in the Lower Miocene evaporites of Poland (Babel, 1990) and the various Late Miocene Messinian sub-basins of the Mediterranean (Rouchy and Saint-Martin, 1992). Growth cycles in these subaqueous gypsum deposits range from mm couplets to decametre beds to brining cycles that are tens of metres thick (Figure 1.15a,b).

Large aligned gypsum crystals that make up the bottom-grown beds typically entrain curved growth faces interspersed among parallel-sided prisms. Very few natural gypsum beds are made up of growth-aligned crystals that first formed as aggregates of upward-oriented simple twins. That is, natural crusts and bed of growth oriented gypsums are not conjoins of the simple prisms shown in Figure 1.16a. In fact, the crystal forms illustrated in Figure 1.16a, and given in many mineralogy texts as typical gypsum morphologies, are the least common forms of gypsum in natural subaqueous systems.

Where a curved face encapsulates a crystal, a single lensoidal crystal forms (Figure 1.16b). The term “bird-beak” gypsum is sometimes used to describe its distinctive lenticular shape. The characteristic hooked termination can be used

with pseudomorphs to help separate gypsum from the truncated lenticular “axe-head and keg barrel” forms of diagenetic anhydrite. Individual lenticular gypsum crystals range from sand-size to boulder-size. Lenticular sand-sized forms make up the uppermost lake sediments and the gypsum lunettes about the saltflat edges of many coastal and continental salt lakes in Australia (Chapter 4; Warren, 1982b). Holocene lenticular gypsum crystals are intimately associated with algal sediments in marine-seepage-fed Ras el Shetan mudflats in the Gulf of Aqaba, Egypt (Aref, 1998a).

Bedded gypsum growing on the shallow bottom of a perennially subaqueous lake or seaway typically precipitates as masses of large parallel-sided megacrystals that show varying levels of expression of the curved faced (Figure 1.16c). Individual growth-aligned crystals are decimetres to metres long in gypsum beds in marine seepage fed Holocene salina such as Marion Lake and Lake Asal, while ancient counterparts in the Middle Miocene of Poland are more than 10 metres long (Babel, 1990). Varying degrees of curvature lead to the growth of distinctive gypsum twins with acute (narrow) to obtuse (wide) angles along the twin plane. Doug Shearman described this form of overlapping curvature along the twin plane as “arms of Siva” gypsum. Strong vertical development of the upper half of some twins creates beds of upward aligned gypsum crystals showing strong curvature of the intercrystalline faces. Such forms are sometimes called palmate gypsum. Some purists would argue that most of these natural forms of growth aligned gypsum are not true twins (Babel, 1990). The varying degrees of curvature entrained in the crystal generate changes

Figure 1.15. Subaqueous gypsum from the late Miocene of Sicily. A) Stacks of layers of aligned cm-scale gypsum crystals, each layer indicates growth competition from a marly gypsarenite base (lens cap for scale). B) Metre-scale layers showing a larger subaqueous growth cycle from a finely laminated marly base through coarsely-bedded aligned gypsum to a series of domal mounds capping the cycle (people for scale).

Figure 1.16. Gypsum. A) Prismatic forms of gypsum parallel to (010) with arrow head twins along (100) or (101) and extreme acicular forms of prism and twin on the right. B) Lenticular form of gypsum. Note how the lenticular form (on right) is dominated by the curved faces that are much less important on a typical prism as seen in the side and top views of a crystal (on left). C) Various forms of typical subaqueous "zig-zag" gypsum growth as described in text (after Shearman, 1978; Orti-Cabo and Shearman, 1977; Rouchy et al., 1994).

in the apparent twin angle, even in a single crystal. This breaks the rule of constancy of twin angle, leading some to refer to them as pseudo-twins (e.g. Schreiber, 1988a). Whatever the crystallographic semantics, these large aligned crystals only grow on the gypsum-saturated bottoms of shallow subaqueous brine lakes and seaways.

The reason why the curved face comes to dominate some gypsum crystals (e.g. lenticular crystals and displacive rosettes) is not well

understood. On the basis of a number of laboratory-based growth experiments using brine columns separated by gel growth media, Cody and Cody (1988) argued the lenticular shape of displacive gypsum (intrasediment sediment growth) reflects influence of temperature and the presence of humic compounds in the parent brine (Figure 1.17). Two temperature dependant trends were obvious in the precipitates. At low temperatures the hemipyramidal habit, dominated by the $1\{111\}$ faces dominate. At higher temperatures the lenticular $3\{103\}$ is obvious in all crystals. They concluded that elongate prisms grow best at low temperatures and in the absence of habit-modifying organics.

They found that the modifying influence of temperature on morphology was swamped by the presence of low levels of organics in all the growth experiments. With increasing polytannate concentrations (analog for terrestrial humics), crystals become less elongate and penetration twinning along the $a\{100\}$ develops. This is followed by secondary complex nucleation near twin faces as rosette and rosette-like aggregates form (aka desert roses). The changes in morphology are interpreted as the result of a high degree of adsorption of organic compounds on the $\bar{1}03$ and $\bar{1}11$ faces that inhibits their growth and consequently minimizing growth parallel to the crystallographic c-axis (Cody, 1976). This adsorption is thought to reflect the peculiar surface structure of the face, which unlike the other faces of gypsum is almost entirely composed of Ca^{++} ions and these Ca^{++} ions bond readily with organics (Aref et al., 1998a).

Warren (1982b) found that masses of sand-sized lenticular gypsum crystals make up near surface beds deposited in seasonally vadose settings in the numerous coastal salinas of southern Australia. He argued the lenticular shape tends to form

best in the upper seasonally vadose parts of the brine pan fill subject to periodic short-term dissolution and regeneration. The pristine parallel-sided gypsarenite prisms that constitute the underlying thick bed of gypsarenite or growth-aligned laminar selenite were not present at this level in the lake stratigraphy. However, the vadose gypsum in these salinas grows in surface and near-surface pore waters that are more influenced by surface runoff from nearby vegetation-covered calcareous dunes and so entrain higher tannic acid levels.

Growth-aligned coarse-grained gypsum beds form in Holocene coastal lakes of Southern Australia beneath the waters of perennial subaqueous brine pans that are density stratified for more than 6-8 months of the annual depositional cycle. In the early stages of infill of the salina, the perennial bottom brine was always saturated with respect to gypsum. Salinity conditions were stable and allowed the upper euhedral surface of the aggrading crystal bed to preserve the upper outlines of crystals in each growth stage. If the gypsum precipitating today in Lake Inneston, South Australia, is indicative of the subaqueous growth style, then throughout much of their growth, any large upward facing gypsum crystals are covered by a microbial mat or film that captures aragonite pellets and can be considered a type of gypsum stromatolite (Figure 4.5d). Similar subaqueous gypsum mounds, coated with cyanobacteria, line the southern end of the brine channel leading into Gotomeer in the Netherlands and pass into laminated aragonitic microbialites in the shallower waters along the channel edge (Figure 1.7c; Kobluk and Crawford, 1990)

Rapid bottom growth of gypsum probably only takes place when stratification of the brine column is lost via seasonal concentration of the fresher surface water body to the same salinity as the dense gypsum-saturated bottom waters. Once this happens the whole water column is supersaturated with respect to gypsum and gypsum growth

begins anew on a metres-deep brine pool floor. As the aggrading euhedral gypsum bed surface encloses CaCO_3 impurities, it encapsulates and preserves zig-zag laminae within the bed.

Aragonite pellets that mantle the re-entrant laminae in the salina gypsum are a combination of a pelagic “rain from heaven” and faecal pellets excreted by a grazing biota grazing the biofilm that covers the gypsum. Metazoan life flourishes during the freshened salina stage when a less saline surface water body ($\approx 50\text{cm}$ thick) floats atop the lower brine mass from spring to early summer). Pellets in Lake Inneston and Deep Lake salinas signify the feeding activities of ubiquitous ostracodes and the Southern Hemisphere brine shrimp (*Parartemia zietziana*). When salinities in the surface waters are suitable, this

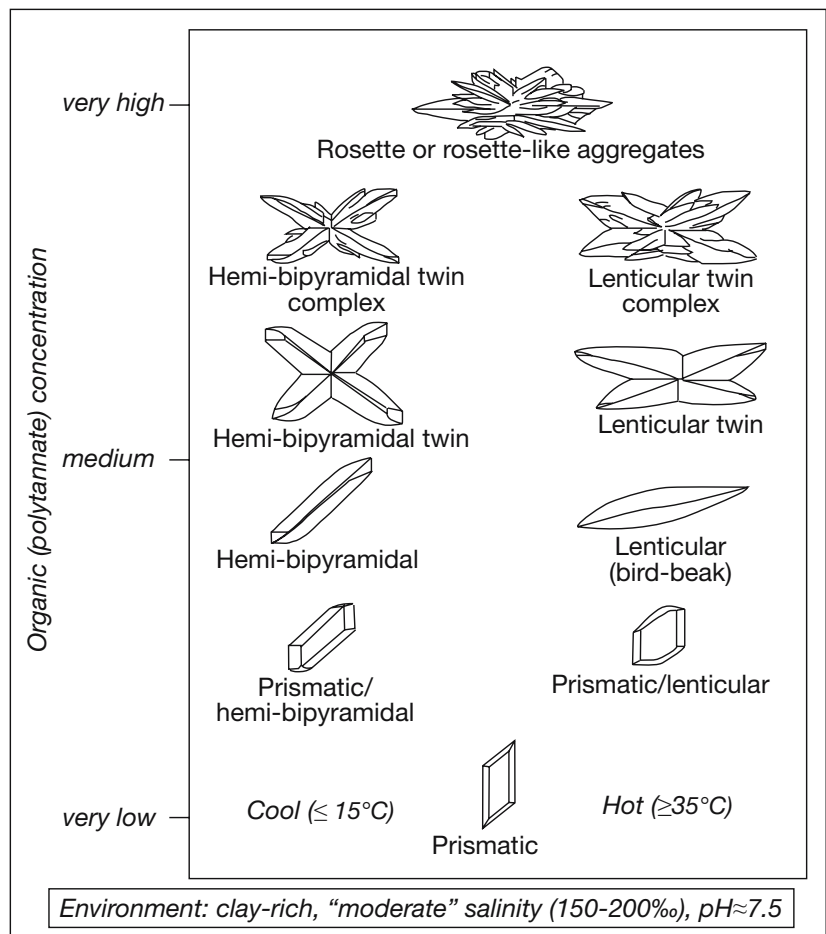

Figure 1.17. Laboratory based changes in gypsum growing in a muddy (bentonite) sediment matrix at moderate salinity and neutral pH in environments characterized by increasing temperatures and dissolved polytannate concentrations. Polytannate is considered to be an analog for terrestrial humic material. c-axis vertical in all examples (after Cody and Cody, 1988).

Figure 1.18. Halite. A) Growth aligned forms of subaqueous halite and typical chevron growth fabric outlined by inclusions in the crystals. Those crystallite cubes with upward-aligned edges, rather than faces, come to dominate the growth fabric as a series of merged chevron crystals. Other bottom growth forms include upward-growing halite teeth and aggregates of hoppers on the bottom that were created by overgrowths on sunken rafts. B) Halite raft growth, where crystals hang from the air-brine interface. C) Various forms of skeletal or intrasediment halite hoppers. Notice how the outline of the halite shape or its pseudomorph can vary from rectangular to triangular depending on the plane of intersection of the viewing horizon with the crystal hopper (in part after Shearman 1970; Rouchy et al., 1994).

halotolerant biota spreads through surface waters over the whole brine lake (Chapter 9). When surface salinities later increase to levels that can no longer support a metazoan population, mass mortality occurs. Soon after, the upper and lower brine masses equilibrate/mix and lakewide gypsum precipitation begins again. Even so, small populations of brine shrimp and ostracodes flourish about seawater-fed seeps in the tepee and mound-spring dominated salina strandzone.

Over millennia, the depositional surface of the salina aggraded as successive gypsum layers infilled the centre of the brine lake depression (Warren, 1982b). As the top of the salina gypsum bed aggraded, it reached a level where even the dense bottom water mass was seasonally freshened. Then the perennial bottom waters, as well as surface waters, were undersaturated with respect to gypsum for a number of months each year. At that time the upper gypsum surface dissolved each winter to form a flat planation surface. Now the seasonal growth of the aggrading bed surface enclosed CaCO_3 pellets laying atop this dissolution surface to form a flat mm-laminated gypsum bed (Figures 2.49, 4.5f).

Halite beds (chevrons and crusts)

Crystals in halite crusts first precipitated on the floors of shallow hypersaline brine pools as upward-growing chevrons, cubes and cornet-shaped crystals (Figure 1.18a, 1.19a,b). Chevron structures preserve the outlines of successive crystal growth edges and are defined by enclosed brine inclusions. Remnants of aligned chevrons are the most commonplace primary texture preserved in ancient halites. Abundant inclusions impart a cloudy or milky appearance to the chevron crystals, a feature that is often used in ancient counterparts to distinguish primary halite from clear or spar-like crystals of secondary or diagenetic halite. Crystals can accumulate as successive layers of growth-aligned prisms or can form as syntaxial overgrowths on floundered rafts and other cumulate crystals that have settled to the pan floor. As for all isotropic crystals growing in crowded conditions, the crystal edges of halite cubes that point upward into the brine grow more rapidly than crystals with upward-pointing crystal faces. The upward pointing “V’s” of the edges quickly dominate and so creates an aligned chevron texture that characterises many subaqueous halite crusts (Figure 1.18a). Less common are thin crusts and beds composed of upward-facing cornets and plates. There the

crystals grew by the upward aggradation of the horizontally aligned faces, and perhaps indicate less crowded conditions of bottom growth (Handford, 1990, 1991).

Such crystals accumulations form halite beds up to 5 metres thick in Lake McLeod, Western Australia where the beds are composed of stacked decametre-thick crusts dominated by bottom-nucleated aligned chevrons. Brine sheets that precipitated the halite were always less than two metres deep and usually less than 0.5 m deep (Logan, 1987). Similar units of stacked crusts, but with obvious truncation surfaces and capillary overprints, characterise saline pans in Salar Uyuni and other pans worldwide (Figure 3.30). Patchy remnants of chevron halite crusts, deposited in shallow to ephemeral brines, are also preserved in ancient thick halite beds such as the Ordovician-Silurian Mallowa Salt of the Canning Basin (Cathro et al., 1992) and the Permian San Andres Formation of west Texas (Hovorka, 1987).

Elevated cell densities of halobacteria in extremely hypersaline brines can change the precipitation behaviour of halite (Gerdes et al., 2000a, b). Proteinaceous compounds coating the surface of the growing halites encourage the growth of dendritic crystals rather than chevrons. Crystals forming in organic-enriched brines contain more and larger brine inclusions than crystals growing at the same salinities from sterile brines. Cells are smaller and much more numerous in the organic-enriched brines and the cells are thought to create templates for halite nucleites.

Halite cumulates, rafts and coated grains

Crystallites grow in the uppermost part of a standing body of water where water is rapidly lost by evaporation and salinities are at their highest. Silt and sand-sized crystals settling to the bottom of the brine pool then form layers and beds of cumulate crystals (e.g. “salt and pepper” halite and massive gypsinites). Periodic influxes of freshened surface waters, followed by evaporative concentration, can produce laminites composed of bottom cumulates, which contain increasing fractions of the more saline minerals. Such “rain-from-heaven” laminites are composed of alternate carbonate-sulphate and sulphate-halite couplets and triplets.

When surface water salinities are suitable and surface waters are undisturbed by wind and waves, crystals can continue to grow as rafts held by surface tension at the air-brine interface (Figure 1.19b). Rafts float and grow until the crystal mass becomes so heavy that it exceeds the holding ability of the interfacial surface tension and sinks to the bottom. Halite rafts in quiescent waters can be centimetres to decimetres across before they sink to the bottom. Eventually, increasing wind and wave action breaks up the rafts while they are out in the brine lake and still well away from the strandzone. These remnants then sink to mix with the smaller crystals and so make up part of the texture of the cumulate beds of the brine lake floor. Later, when the lake shallows and further desiccates, these cumulate beds are covered by crusts and beds of bottom-nucleated chevron halite or swallowtail gypsum. This upward transition from cumulates to crusts is commonplace in modern crusts.

Figure 1.19. Subaqueous halite A) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 8.1 m. Halite chevrons with dense fluid inclusion banding (dark) and vertical, competitive growth fabrics. Horizontal field of view is 4 mm. B) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 15.8 m. Bottom-grown halite crystals with vertical growth fabric. Note that halite crystals widen upward and contain faint fluid inclusion banding. Some mud (dark patches) is trapped within or between crystals. Horizontal field of view is 4 mm. C) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 8.6 m. Halite pisoids, 2-5 mm in diameter and with faint radial fabric, from the upper shallow saline lake interval. Note mud drape (black) and fine-grained halite cumulates above the largest pisoid. Horizontal field of view is 10 mm. (images and descriptions courtesy of Tim Lowenstein; see <http://www.geol.binghamton.edu/faculty/lowenstein/dv/deathvalley.html> - accessed Dec 7, 2004).

Rafts and other cumulate crystals in very shallow to ephemeral brine pans may be blown or carried by bottom currents to the strandzone to accumulate as subaerially exposed masses of strandzone crystals. Such deposits characterise surface carnallite/halite shores about the brine pan edge of Lake Qaidam in China and trona cumulates about the edges of Lake Natron and Lake Magadi. Whenever the adjacent lake water body freshens and expands, the dissolution of the strandzone salts generates dense brine plumes that cement underlying sediment (Casas et al., 1992; Hovorka, 1992; Schubel and Lowenstein, 1997).

Ancient cumulate crystal beds, not covered by bottom-nucleated crusts, were sometimes mechanically reworked by storm and wave-induced bottom currents into crossbeds and ripples. This tended to happen on the bottoms of ancient perennial brine seaways and lakes that were above wavebase and covered by brines that were less than 5-10 m deep. In even shallower nearshore positions that were subject to higher wave-energies, fine-grained cumulate crystals formed the nuclei to concentric ooids composed of gypsum and halite (gypsolite and halolite respectively). Today, such coated grain textures are precipitating immediately basinward of the strandzone of Lake Asal in the African Rift Valley and along the southern end in the Dead Sea (Castanier et al., 1992, 1999), they are also preserved in perennial brine halites in Death Valley California (Figure 1.18c). In a recent paper, Perthuisot and Castanier (2000) have argued that the process of halolite formation is bacterially mediated. The significance of bacterial activity in precipitating evaporitic oolites is widely debated. It is much like the unresolved debate on the importance of bacteria in marine ooid formation that has gone on for decades amongst carbonate sedimentologists.

Pedogenic and wind reworked salts

Many arid to semi-arid desert soils are gypsiferous in areas surrounding the perennial saline lakes, the brine pan depressions and their dune margins. Where gypsum dominates the pedogenic profiles, the soils are typically described as gypcretes, gypsites, gypsicretes, *croûte de nappe* or *croûte gypseuse zonée*. Currently, something like 2×10^6 km² of gypsum-entraining soils cover the world landscape (Nettleton, 1991). Gypsum crusts have been reported from all the continents, including Antarctica (El-Sayed, 1993). They typify soils in arid areas where mean monthly evaporation exceeds mean monthly precipitation, Watson (1985) notes a close association of gypsum soils with areas receiving less than 250 mm annual rainfall.

Use of the term gypcrete often has a connotation of gypsum being the dominant hardpan cement, while the term gypsite im-

plies a fine-grained (silt-sized) powdery soil. According to Aref (2003) gypsum crusts and soils are surficial and penesurficial accumulations that have the following specifications: 1) a minimum thickness of 0.1 metre; 2) a minimum gypsum content of about 15% by weight; and (3) a gypsum content at least 5% greater than the underlying rocks. If the soil contains less than 15% gypsum it is classified as a gypsiferous soil. Watson (1985) also grouped the consolidated gypsum, together with weakly cemented and powdery gypsum accumulations under the term gypsum crust.

Four mechanisms or processes precipitate most gypsum soils and crusts worldwide: 1) in-situ pedogenic weathering of existing gypsiferous or volcanogenic (ash) parent material; 2) eolian or fluvial input of gypsum or SO₄-rich sediment; (3) an oceanic aerosol source, creating in sulphate-enriched rainfall that evaporatively concentrates within the regolith (4) in-situ oxidation of sulphide minerals. The first two sources are direct evaporite associations, while the third is typically associated with salt lakes, sabkhas and playas in semi-arid or desert settings within 500-1000 km of the coast. Many gypsic soil horizons are combinations of both pedogenically precipitated and detrital wind- reworked gypsum.

Soils with gypsic horizons form in various parent materials such as alluvium, eolian sediments and weathered geologic formations, many in regions of pre-existing gypsiferous sediments (Taimeh, 1992). For example, differentiated gypsum soils 0.5 to 1.5 metres thick, largely formed by capillary evaporation, cover much of the area east of the Fayum depression (chott) in the north central part of Egypt (Figure 1.20; Aref, 2003). These pedogenic gypsum crusts only cap Middle Eocene carbonate rocks that are interbedded with thick gypsiferous shale beds and the soils are mostly a result of the hydrological reworking of this Eocene source. The soils show a three-part layering from top to bottom of: (1) massive powdery gypcrete, (2) massive indurated gypcrete, and (3) massive mottled gypcrete. All layers are composed of variable amounts of microcrystalline gypsite, fine to coarse lenticular gypsum, as well as porphyroblastic, prismatic and fibrous gypsum. Precipitation of the various types of gypsum is driven by capillary evaporation of CaSO₄-enriched meteoric waters, so most of the gypsum occurs as vadose surficial crust dominated by displacive gypsum growth. In the lower vadose zone, gypsum accumulates by illuviation, interspersed with hydromorphic (sparry) accretion when water table levels are higher (Aref, 2003). The resulting gypsum carapace, although susceptible to dissolution, tends to preserve the residual landforms from severe erosion or weathering and so form gypsum-capped mesas.

Figure 1.20. Formation of pedogenic gypsum crusts at the eastern side of the Fayum depression Egypt (after Aref, 2003). During dry periods, the gypsum-rich meteoric waters are drawn to the surface by capillarity (per ascensum), which leads to gypsum crystallization and crust accretion on the lower slope. During a subsequent wetter period, the surface gypsum crust is partially dissolved by meteoric water that moves downward and is mixed with laterally moving gypsum-rich meteoric water from the gypsiferous beds, which leads to deposition of subsurface gypsic crust. During subsequent weathering of the landscape the gypsum crusts can preserve residual landforms from subsequent erosion and weathering.

Elsewhere, marine aerosols are focused into playa sinks and then reworked by eolian processes, as in much of the Namibian Desert and in soils about the arid salt lakes areas of southwestern and southeastern Australia. Other evaporite salts, with their inherently higher solubilities, tend to dissolve too rapidly in most vadose situations to form soil crusts and so do not form thick preservable accumulations in most of the world's deserts. Impressive exceptions to this generalisation can be found in the hyperarid Atacama Desert of South America. There pedogenic accumulations of nitrates and iodates, along with halite and gypsum, are accumulating in the desert regolith; and have been doing so since the mid Miocene, when uplift of the Andes first created desert conditions (Figure 11.42). For the same reason, namely hyperaridity, small parabolic dunes of halite (0.7-1.3 m in width and length) are today blowing across the saline pan floor of Salar de Uyuni (Svendsen, 2003).

Pedogenic gypsum horizons can sometimes stack to substantial thicknesses. This is especially so in arid subsiding groundwater basins where ancient evaporite beds exposed by diapirism or uplift about the basin edge are being recycled by karstification. For example, there is a 25 metre thick gypcrete hosted in Miocene alluvial fan sediments in the Calama Basin of northern Chile. The gypcrete is a single horizon in the alluvial bajada and it surrounds an ancient endorheic basin. It formed via stacking of gypsum-cemented soil horizons (Hartley and May, 1998). It was probably preserved, despite its high susceptibility to meteoric recycling, by its 9.5 Ma carapace of ignimbrite. This relatively impervious volcanoclastic ashfall isolated it from downward-percolating meteoric waters.

Locality	Style	Reference
Bonneville Salt Flats, Utah	Gypsum dunes along the edges of an active continental sabkha formed atop a now deflated perennial saline lake	Jones, 1953
White Sands, New Mexico	Gypsum dunes created by active deflation of gypsiferous sediments of Pleistocene Lake Otero	Langford, 2003
Salt Flat Playa, New Mexico	Gypsum dunes along the edges of an active continental sabkha forming atop a former perennial saline lake	Hussain and Warren, 1988
Laguna Ojo de Liebre area of Baja California	Gypsum dunes along the mudflat edges of coastal lagoons	Kinsman, 1969
Continental playas or salt lakes of inland Australia	Gypsum lunettes in most salt lakes in zones of continental seepage outflow in the interior of Australia including; Lake Eyre, Lake Frome, Lake Fowler, Lake Malata-Greenly, Lake Amadeus, Prungle Lakes, Lake Lefroy and Lake Cowan. Other less saline pans are lined by lunettes of pelleted clay or sand	Bowler, 1983 Chen et al., 1990 Dutkiewicz et al., 2002 Magee, 1991 Zheng et al., 2003
Salinas of coastal western and Southern Australia	Gypsum dunes formed by late Holocene deflation of lacustrine gypsarenites in a marine seepage lake that is currently filled to within a few cm of sea level (e.g. Lake Macdonnell, Marion Lake, Streaky Bay Lakes, Hutt Lagoon)	Arakel, 1980 Warren, 1982b
Dunes in chotts in South-central Tunisia	Gypsum dunes derived by the subaerial break-up and deflation of gypsum crusts that cover much of the seepage areas in the chott	White and Drake, 1993

Table 1.4. Some regions where gypsum dunes (lunettes) are associated with the deflation of saline lake (playa) sediment.

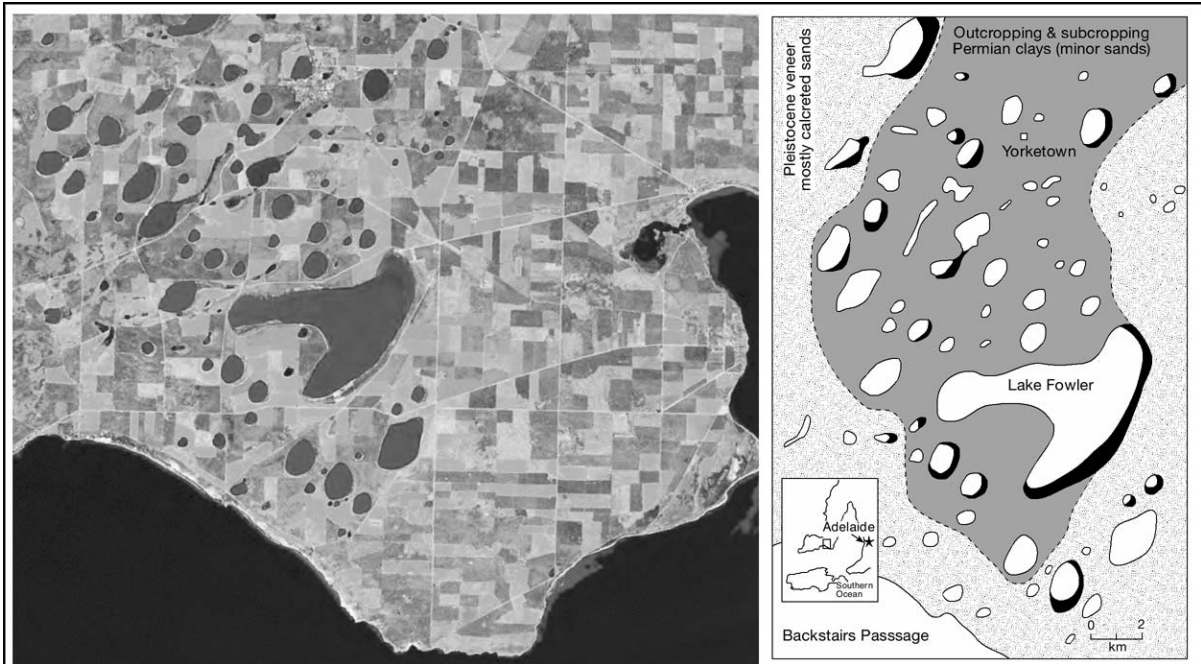

Figure 1.21. Late Pleistocene lunettes in saline pans (salt lakes) in semi-arid southern Australia near the town of Yorketown showing gypsum lunettes at the edges of some of the wind-oriented lakes at the southeastern end of Yorke Peninsula. The largest is a gypsum lunette some 2 km long 100 metres wide and 30 metres thick at the southeastern strandline of Lake Fowler, the large T-shaped lake with a long axis ≈ 6 km (see Warren 1982b for description of gypsum in the lunette). It was extensively quarried in the early part of last century. Larger gypsum dunes (lunettes) are shaded black in the geological map (Landsat image courtesy of NASA).

Gypsum dunes, stabilised by gypsite-soil caps, form wind-reworked vadose deposits around the margins of many Holocene and Quaternary brine lakes throughout the world (Table 1.4). For example, gypsum dunes line the salt pan edges of undisturbed continental salt lakes and coastal salinas in southern and western Australia. Today all lakes are in the penultimate stages of their Holocene brine pan fill; hydrologies are characterised by ephemeral surface waters interspersed with long periods of deflation. In the coastal zone these are the same pans that precipitated large bottom-aligned gypsum crystals in the earlier perennial brine stages of their Holocene infill. But now, with the aggradation of the gypsum fill to near sealevel elevations, the lake surface is at hydrological equilibrium with current sealevel and can aggrade no further (Warren, 1982b). Surface brine sheets come to saturation quickly and dry up by late spring. Rapid multiple nucleation of gypsum crystallites takes place across the floor of the brine pool. Beds of sand-sized gypsum (gypsarenite) now accumulate on the floor of ephemeral brine lakes, only to be subject to later desiccation and deflation.

Each summer, as undisturbed salinas exsiccate, the water table falls and the upper part of any newly formed gypsarenite layer leaves the capillary zone and is blown into dunes that line the margins of the lake (lunettes). Capillary zone deflation forms the characteristic truncation or Stokes surfaces in regions sourcing eolian sediments worldwide (Table 2.11). When dune growth ceases, a stabilised and vegetated gypsum dune is subject to the set of pedogenic processes that form gypsite and gypcrete. Gypsum rhizoliths and bioturbation structures, as well as bioturbated gypsum soils (gypsites) form atop eolian crossbeds (Figure 4.5g).

Gypsum and pelleted clay dunes (lunettes) line the edges of many salt lakes and playas in southeastern, southern and southwestern Australia; Prungle Lakes and Lake Fowler (gypsum lunettes) Lake Tyrell (clay lunette) and Lake Mungo (quartz sand lunette; Figure 1.21; Table 1.4). These lunettes are relicts of a Late Pleistocene deflationary period, when the lacustrine hydrology changed from perennial water-filled lakes to desiccated mudflats. Likewise, there are gypsum dunes in deflationary depressions in Salt Flat Playa and the Bonneville/Great Salt Lake region of Utah (Table 1.4). Internal sedimentary structures in many of these lake gypsum dunes or lunettes show tabular cross beds with consistent bedform orientation. Many lack abundant trough or festoon cross beds, suggesting consistent wind directions (Figure 1.22a; Jones 1953; Bowler, 1973, 1983). Grain constituents clearly indicate deflation of former lake sediments, which were vadose prior to deflation and passage into the dunes (Figure 1.22b).

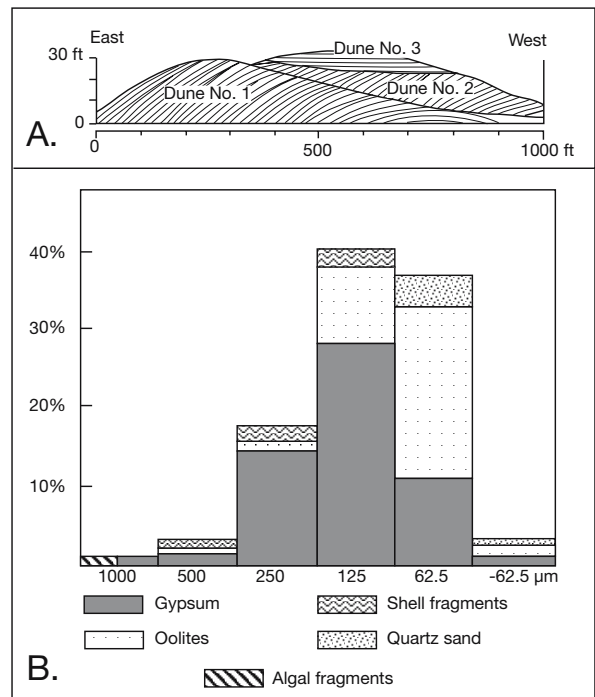

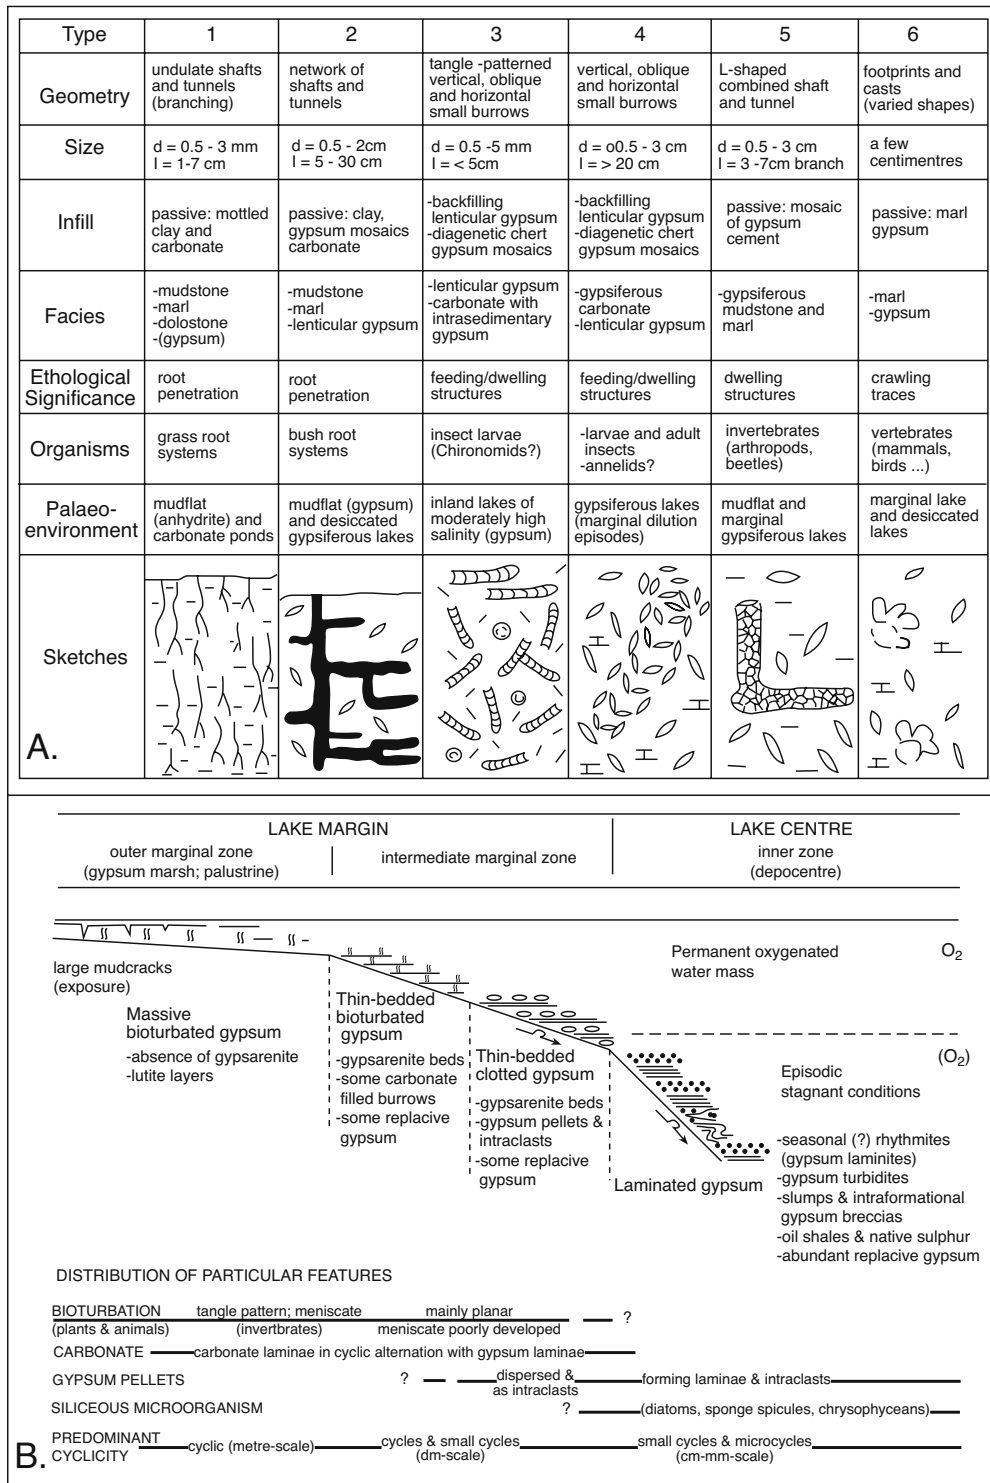

Figure 1.22. Eolian gypsum in the Bonneville saltflats, Utah. A) Cross section through the dune complex near Knolls, Utah. B) Grain size distribution and mineralogy of the sands showing it is the result of deflation of sediments laid down in highstand conditions in the Bonneville/Great Salt Lake Basin (after Jones, 1953). See Chapter 4 for a discussion of Great Salt Lake.

Gypsum dunes are part of a much broader lake-edge eolian sandflat association with the lakes often supplying large volumes of eolian sediment into adjacent sand seas or ergs (Chapter 2). Dunes described as ‘lunettes’ have a characteristic crescentic shape, other lake edge dunes may show more linear or longitudinal outlines (Figure 1.21; Bowler 1973, 1986). Lunette sediments range in composition from quartz-rich, sandy clay, through gypseous clay to nearly pure gypsum. Pure quartz dunes formed under lake-full conditions and are distinct from that of the clay and gypsum-rich varieties, which formed by flocculation and deflation from adjacent subaerially exposed lake floors. In arid to semi-arid zones throughout the Quaternary the interplay between salinity of lake waters and groundwater levels is critical in lunette growth and the mineralogy of the lunette (Bowler, *op cit*).

Although body fossils are rare in most evaporite beds, many subaerial and subaqueous gypsum soils preserve abundant trace fossils that, in addition to track and trails, also include rhizoliths and other pedotubules. Rhizoliths in a gypsiferous lacustrine system form at times of freshening of lake waters, they indicate periodic subaerial exposure and colonisation by terrestrial plants.

Rodriguezaranda and Calvo (1998) identified six associations of trace fossils in subaerially exposed evaporitic sediments of the continental Tertiary basins of Spain: (1) networks of small rhizoliths; (2) large rhizoliths; (3) tangle-patterned small burrows; (4) isolated large burrows; (5) L-shaped traces; and (6) vertebrate tracks (Figure 1.23a). The rhizoliths occur both in the marginal areas of hypersaline lakes and across lakes characterised by ephemeral but moderately high salinity waters (Figure 1.23 b). In either setting, pedoturbation indicates colonization by grasses and bushes and so indicates vadose conditions at the sediment surface that were tied to a drying of the lake and a lowering of the water table.

According to Rodriguezaranda and Calvo (1998) burrowing invertebrates were especially active in

those Spanish evaporite lakes where gypsum was the main mineral phase, not the more saline salts. They define a separate, sometimes pedogenic, facies in these lakes they called a “bioturbated gypsum deposit.” It is typified by tangle-patterned small burrows and minor isolated large burrows; they are interpreted as burrows of insect larvae, probably chironomids, coleopterans and annelids. Similar organisms typify modern lake environments with water concentrations averaging 100–150 g/l, they flourish in lake areas subject to frequent drying and terrestrial encroachment (Chapter 9).

What is interesting about the bioturbation of these Miocene gypsum lakes in Spain is that the mm-scale layers rich in faecal pellets and associated with this bioturbation can be composed of gypsum and not the aragonite typically seen in Holocene coastal salinas (Figure 1.23b). For example, the gypsum-pellet-rich Libros Gypsum was deposited in the southern Teruel Basin (NE Spain) during the Miocene (Orti et al., 2003). It accumulated in a deep saline lake in which the water stratification became unstable with progressive shoaling. In the basin depocentre, a continuum of lacustrine evaporite lithofacies was influenced by the activity of organisms. Rhythmites, composed of laminae of pelletal gypsum and laminae of very fine lenticular gypsum crystals mixed with siliceous microorganisms, formed in addition to gypsum turbidites, intraformational gypsum breccias and slump structures.

The pelletal laminae originated from the faecal activity of animals (crustaceans?) ingesting gypsum crystallites in the lake water during episodes of maximum evaporation, whereas the laminae of very fine lenticular gypsum mixed with microorganisms accumulated during episodes of relative dilution. In the wide marginal zones of the basin, the Libros Gypsum unit consists of massive to thin-bedded bioturbated gypsum and thin-bedded clotted gypsum, which formed in intermediate to very shallow (palustrine) water depths. The bioturbated gypsum lithofacies were produced by the action of diverse organisms, presumably worms and coleopterans, and chironomid larvae to a lesser extent; the massive lithofacies precipitated in very shallow water; and the thin-bedded lithofacies formed in shallow to deeper settings. The thin-bedded clotted gypsum is a relatively deep facies that may have diverse origins (e.g. bioturbation, compaction, disruption of soft sediments and early diagenesis). There is a well-developed metre-scale cyclicity in the marginal lake sequences, which is not observed in the inner lake deposits. This suggests a depth change in the various lacustrine subenvironments is needed to record cyclic evaporitic processes. The isotopic composition of the pelletal gypsum indicates early sulphate-reducing bacterial activity in the bottom of the lake (Orti et al., 2003).

Biological metabolism drives substantial fluctuations in pedogenic pore pressures and salinity in gypsiferous and magnesitic soils in many lake margins and vegetated areas of coastal sabkhas. This is especially so in the immediate vicinity of plant roots, and it can precipitate CaSO_4 nodules around the plant roots. Anhydrite and gypsum nodules are growing about halophyte roots in the modern gypsiferous supratidal sabkha succession of the Al-Khiran sabkha of Kuwait (Gunatilaka et al., 1980). Anhydrite nodules in pedogenic horizons in the bedded Miocene magnesites of the lacustrine Calatayud Basin in Spain evolved into vertically aligned textures that today resemble gypsum ghosts (Sanz-Rubio et al., 1999). Early stages of this nodule growth were associated with typical pedogenic features such as rhizoliths and clotted to peloidal textures. The consequent anhydrite nodules, which replaced dissolving gypsum during very shallow burial, developed a strong vertical orientation as nodules precipitated along what were mostly vertical soil fissures. It is this nodular texture, mimicking a ped structure, that still dominates most clayey soils in the region. Much of the soil fissuring reflects expansion and contraction driven by root metabolism and a changing soil moisture profile.

Laminites from settling of pelagic salts

At the other end of the mechanically-reworked evaporite spectrum from lunettes and soils are the continuously subaqueous basin-centre “rain-from-heaven” accumulations composed of laminar couplets of sand- and silt-sized evaporite crystals. Crystals originally precipitated at the air-brine interface or within the upper metre or two of the perennial brine body. This uppermost part of a deep brine body is most subject to freshening or concentration (Figure 2.37b). The resulting finely layered and laminated bottom cumulates are thought to typify many ancient “deepwater” evaporite-laminites. Such deposits are often found in basinal positions located well away from the evaporite platform margin.

In some ancient basinal settings, such as in the Castile Formation – a widespread Permian laminite in west Texas, water depths on the drawdown seaway bottom were mostly sub-wavebase and the sediment-brine interface lay beneath anoxic gypsum-saturated bottom waters. Repetitive layering in laminites is resolvable at two scales, 1) at the scale of individual 1.5–2.0 mm laminar couplets of calcite and anhydrite with calcite making up about 6% of a typical couplet, and 2) at the coarser scale of millennial brining upward parasequences ≈ 4 m thick (Figure 1.24a). The mm-couplets are remarkably regular in thickness, and are commonly repeated thousands of times without interruption (Kirkland et al., 2000). The evaporitic sediments that formed the anhydrite-calcite couplets were cumulates.

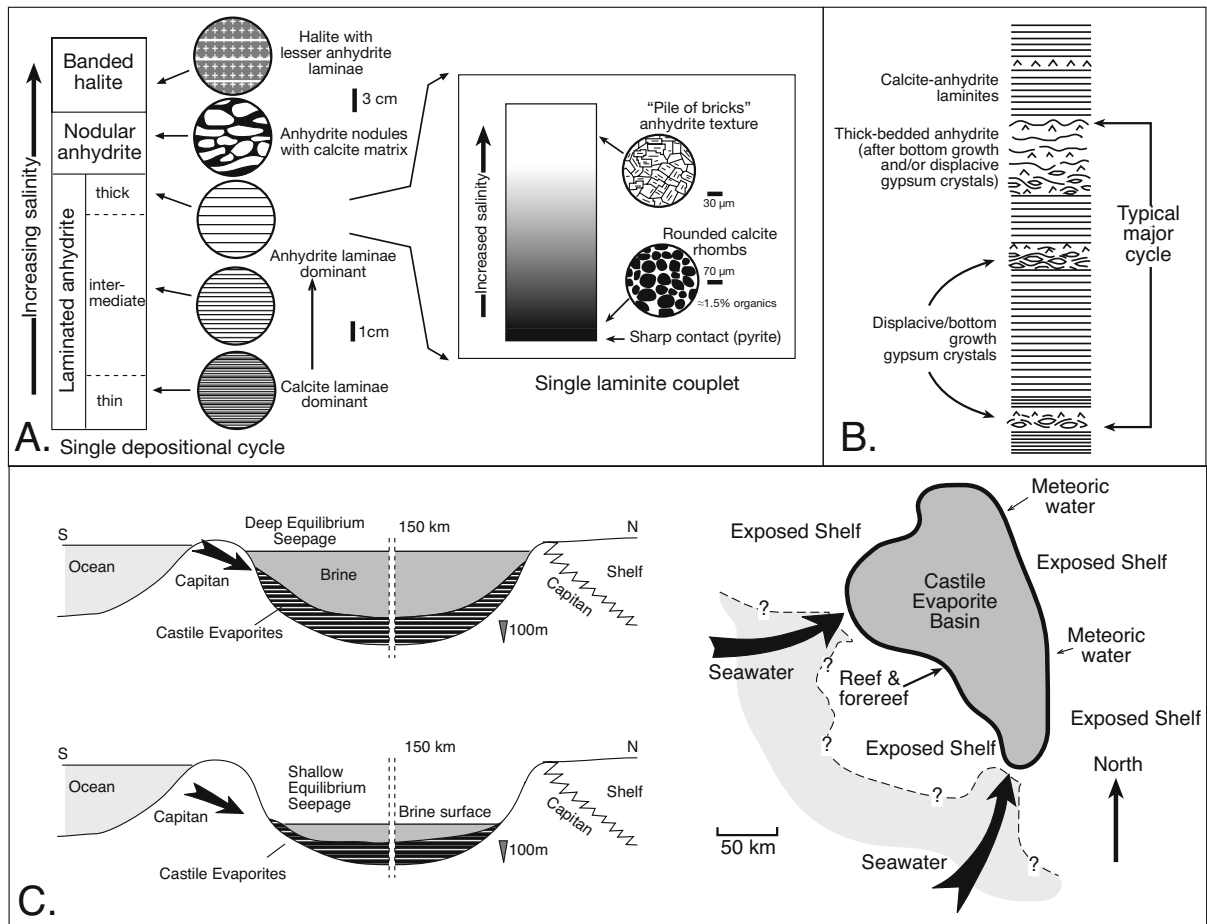

Figure 1.24. Castile Formation, Delaware Basin, west Texas. A) Representative section of a millennial cycle in the Permian Castile Formation of west Texas with a typical thickness of 1.4 metres. Inset shows a typical calcite-anhydrite couplet with typical thickness of 1.5 - 2.0 mm. (after Kirkland et al., 2000). B) Typical sedimentary cycle within the Anhydrite 1 Member, it is capped by thick-bedded anhydrite after displacive and bottom-growth gypsum. Laminae at the base of most cycles are thinner with less anhydrite and more calcite. This cycle is overlain by a layer of laminated anhydrite with less calcite. The top of the Anhydrite 1 Member (which is made up of 5 cycles) is overlain by the Halite 1 Member (after Leslie et al., 1997). C) Alternate models for Castile deposition, both based on a closed-basin, deep-marine-brine model. Brine drawdown either came to drawdown-seepage equilibrium when the brine depth was hundreds of metres or when the brine depth was tens of metres. Seawater seeped into the isolated basin along one or more segments of the reef front. These seepage areas were possibly most active near location of the what were former open marine surface channels through which seawater had entered the Delaware Basin during Guadalupian time (in part after Kirkland et al., 2000).

Crystallites formed at the brine surface or in the upper part of the brine column and "rained" onto the basin floor. Thickness variations of anhydrite laminae in parts of cores dominated by alternating laminae of calcite and anhydrite have been correlated from well to well over distances of up to 113 km (Anderson et al., 1972; Dean and Anderson 1982). Many laminar groupings can be correlated throughout the entire basin to within a fraction of a millimetre (Kirkland et al., 2000).

Spacing variations indicate cyclicity due to Milankovitch fluctuations in solar intensity and so are often interpreted as true

varves (Dean and Anderson, 1982). If so, it means the broader scale brining upward cycles were deposited in something like 1800 - 3000 years per cycle, with an average of 2700 years and something like 175,000 years to deposit the Castile Formation (Kirkland et al., 2000). A cycle generally begins with couplets of calcite-anhydrite in which the anhydrite lamina are thin, and calcite may form as much as 80-99 wt % of the couplet. Above the basal carbonate-rich portion, anhydrite laminae increase in thickness, forming the calcite-banded anhydrite typical of the bulk of the Castile where calcite constitutes 10-15 wt % (Figure 1.24a). Upward within a cycle, anhydrite laminae

become thicker, with calcite laminae constituting about 5 wt %. Farther upward within these thick anhydrite laminae are nodules of anhydrite.

Some beds, typically about 1 m thick, are made up of nodular anhydrite mosaics and, like the laminae, can be correlated across the basin (Leslie et al., 1997). Sporadically associated with these beds of nodular mosaic anhydrite are centimetre-size, anhydrite pseudomorphs after upward-growing gypsum crystals (Figure 1.24b; Hovorka, 1989). These textures suggest that at times the basin was not as “deep” as many have postulated from the laterally extensive laminites. Rather, they represent time intervals when the basin brines became sufficiently shallow (<50 m) to allow supersaturated surface brines to come into contact with the basin floor (Kendall and Harwood, 1989). These supersaturated brines caused precipitation of bottom-growth gypsum on the basin floor and precipitation of displacive gypsum in the upper few decimetres of the sediment column. In about one in ten cycles, nodular mosaic anhydrite is overlain by anhydrite-banded halite where the halite is coarsely crystalline and recrystallised. Although the contact with the halite is abrupt, deposition was regular and uninterrupted and perhaps tied to basinwide evaporitic drawdown (Chapter 5).

Rather than indicating shoalwater drawdown, Leslie et al. (1996) interpreted abundant, structureless interbeds of coarse nodular mosaic anhydrite up to 10 m thick in Castile Formation cores from the Union 4 University 37 borehole to be re-sedimented beds and not aligned nodules after bottom-growth gypsum (Figure 1.24b). Whatever their origin, these intervals do not exhibit the mm-scale laminae that typify most of the Castile anhydrite. Leslie et al. (op. cit.) interpreted these beds as the product of turbidity currents that originated in sulphate shoals along the eastern margin of the Delaware Basin. Thick turbiditic units are less common nearer the centre of the basin, as seen in cores from the PDB-03 research well, where laminites dominate. Differences in the interpretation of brine depth during deposition of the Castile remain unresolved (Figure 1.24c).

Slumped and current-reworked deepwater anhydrite laminites and turbidites have been recognised in slope and rise areas near platform margins in many other ancient evaporites, e.g. Zechstein basinal evaporites in NW Europe (Schlager and Bolz, 1977), the Triassic lacustrine slope deposits of Northern Chile (Bell, 1997) and the Middle Miocene (Belayim Formation) evaporites of the Red Sea Rift (Rouchy et al., 1995). These deepwater reworked sequences are defined by entrained turbidite textures and Bouma cycles sandwiched in anhydritic mm-laminites. The source for this reworked anhydrite was

either clastic CaSO_4 crystals eroded from the adjacent, but much shallower, platform or gravitationally unstable “pelagic” salts. These deepwater sequences are discussed in “depth” in Chapter 5.

Deepwater ancient halites are rarely documented, perhaps because cumulate halite is more liable to recrystallisation and flowage. By analogy to ancient anhydrite laminites “deep” water halite has been thought to be thin bedded and intercalated with anhydritic laminites, but documented examples are not forthcoming. Primary textures patchily preserved in most ancient bedded halite are aligned chevrons. The formation of possible analogs to “deep water” halite on the bottom of the modern Dead Sea suggests the deepwater halite texture is a massive meshwork of poorly aligned clear coarsely crystalline halite prisms, far different from the commonly accepted notion of a “deep water laminite” (Chapter 4).

One of the few documented examples of an ancient “deep water” halite mass flow comes from the lower Miocene Vorotyshcha Suite in the Ukrainian part of the Carpathian foreland basin (Peryt and Kovalevich, 1997). These halite breccias have traditionally been interpreted as tectonically deformed units related to the overthrust nappes of the Carpathians. Most clasts in the breccia consist of intrabasinal sandstone, marlstone, halite, and anhydrite, but exotic clasts consisting of rocks that are characteristic of the Carpathian flysch rocks are also present. Breccia beds are intercalated with salt layers containing chevron crystals and cubic hopper crystals, and some layers are composed of detrital salt. These salt layers rarely display graded bedding or cross-lamination, and continue over great distances. There are also slump structures associated with the bedded salts., where “deep water” halite breccias are interlayered with beds of potash. Deposition versus deformation is an ongoing debate in the interpretation of these sediments.

Can growth-aligned evaporite crystals, interlayered with laminites, be deep?

Textural interlayering of beds of aligned cm-scale nodules with beds of laminites, like those of the Permian Delaware Basin fill, underline a broader interpretation problem in our current notions of what constitutes a deepwater evaporite signature. Can layers of growth-aligned coarse bottom crystals, intercalated with laminites, ever have accumulated on the bottom of a deepwater brine lake or seaway? The high degree of supersaturation required for primary growth-aligned crystal growth means that brine depths are generally shallow during crust growth in all modern examples. Maximum brine depths

are measured in metres atop gypsum laminites in modern coastal salinas and decimetres to centimetres for halite crusts in saline pans. Halite chevrons and aligned laminated gypsum prisms retain intracrystal evidence of successive growth pulses as either thin layers of less saline salts or varying densities of entrained brine inclusions. This style of microlaminated intracrystal layering reflects changes in crystal precipitation rates induced by short-term changes (daily to monthly) in salinity on the subaqueous floor of the shallow to ephemeral brine pan (Warren 1982b; Handford, 1991).

One inference made from modern evaporite textures is that laminated beds separating “in situ” bottom-growth aligned crystals do not necessarily form in deep (>2 m) water in the salinas of Australia, the Red Sea and Sicily (Figure 2.49 and Chapter 4). This has had significant implications in water depth interpretations of the Castile and other “deep water” laminite formations. Bottom brines in deep stratified brine columns are probably too dense and too stable to change with the rapidity required to form the mm-scale intracrystal discontinuities or layers seen in modern coarsely crystalline beds. Hence, laminated bottom-nucleated coarsely-crystalline growth-aligned textures do not form widespread bottom precipitates in modern deeper water settings (Chapter 4).

Rather, the bottom waters of a deep stratified brine system reach saturation and accumulate coarse salts only if the total brine column is at saturation all the way up to the air brine interface. This deposits monomineralic deep bottom beds made up of meshworks of poorly oriented fine to coarse crystals like those forming halite beds on the deep bottom of the Dead Sea and the mirabilite beds on the bottoms of decametre deep saline lakes in western Canada (Figure 5.6).

Thus, a modern analogy doesn't exclude a notion of deepwater halite or gypsum laminates interlayered with coarsely crystalline beds. But it does exclude the notion of this coarsely crystalline beds (be they halite or gypsum) entraining regular discontinuities or finely intrabed layers. Otherwise one must ask, what mechanism could act over the floor of an ancient brine seaway, which was up to hundreds of metres deep and hundreds of kilometres across, to rapidly displace or cool dense halite- or gypsum-saturated bottom waters with short-lived pulses of less-dense freshened or cooler water, which would then pulse the rate of bottom crystal growth? Freshened water will always float atop a dense brine. The volume of less dense water required to displace and dilute a brine column hundreds of metres deep, or the time required for complete mixing to the bottom, excludes a deepwater “in situ” origin for fine layering

in coarsely crystalline bottom-nucleated fabrics. But it does not prevent “rain from heaven” carbonate laminates accumulating in deep brines, as happened in the Dead Sea when it was a stratified water mass prior to 1979 (Figure 4.43).

As more studies are completed on modern deepwater evaporites it is increasingly obvious that laminated beds alternating with growth aligned beds are not the typical signature of a deep subwave-base evaporite in a meromictic brine column. It suggests that if the elongate nodules in the Castile and other deepwater evaporites are after coarse gypsum then they were deep bottom crystal meshworks that indicate times of holomictic brines in a hydrographically isolated seaway. Then when the brine column returned to more typical meromictic conditions it became a seaway where laminites accumulated on the deep sea floor. This explains the correlatable lamina spacings over distances of more than 100 km in laminite beds. As in many evaporite interpretation quandaries, part of the problem lies in the pervasive diagenetic overprinting of primary gypsum texture by a mosaic of overprints that were driven by ongoing compaction and flow. The other part of the interpretation quandary lies in the observation that the present icehouse climate mode limits the range of modern marine-fed evaporite basins available for study (Chapter 5).

If a crystal crust is growing near a deepwater hydrothermal spring, there is also the possibility of pulsing crystal growth in the bottom waters due to temperature fluctuations or changes in the rate and saturation of the spring outflow. This last scenario is not volumetrically important in terms of widespread beds of ancient growth-aligned evaporite textures.

Salt reefs, are they real?

Halite in modern pans and salinas typically constructs beds made up of stacked subaqueous crusts, which may locally entrain recrystallised cumulates and have been periodically subaerial. Beds tend to be dominated by flat layers with synoptic relief of no more than decimetres related to the formation of pressure ridges. However, mushroom-shaped halite buildups or reefs, with steep near vertical sides and a relief measured in metres, are currently forming in artificial solar ponds on the southern margin of the Dead Sea (Chapter 11). Halite reefs began to form in the 1970s and 1980s, after dykes were built to enclose most of the southern basin of the Dead Sea (>200 km²) and so create two sets of solar evaporation ponds on either side of the Truce Line Channel (Figure 11.9; Talbot et al., 1996). At that time the reefs were attributed to salting-out via common-ion mixing between natural Dead Sea brines and end-brines from

Figure 1.25. Subdivision of the mushroom-shaped salt reefs of the southern Dead Sea is related to the permanency and salinity of stratification in the perennial pond brines in the inter-reef areas (after Talbot et al., 1996).

the first potash plant (Chapter 2). However, tens of thousands of new salt reefs continued to grow in the enclosed salt ponds long after the pans were re-engineered and end-brines from both plants were channelled directly back to the depths of the northern Dead Sea basin (Charrach, 1986; Ram et al., 1988).

The reefs grow in metres-deep perennial halite saturated brine pans as large isolated vegetable-like shapes that merge to form networks of polygonal salt walls (Figure 1.25; Talbot et al., 1996). The walls subdivide large salt concentrator ponds into thousands of small compartments that resist brine throughflow. This is contrary to the engineer’s plan of large subaqueous pans filled with brines that were easily homogenized by wind. Instead of following a designed flow path of homogenisation and downstream fractionation, brines in the compartments between the halite reef walls stratify, ultimately allowing unrecoverable carnallite precipitation in depressions between the walls.

In the inter-reef polygons is an evaporatively-maintained supersaturated 10-cm-thick surficial layer floating atop brines that are halite saturated all the way down to a cumulate covered

floor (Figure 1.25). Epitaxial halite overgrowths expand along the supersaturated uppermost brine layer and the salt reefs develop botryoidal overhangs. Salt projections can merge into a hollow platform roofing over a cell of encased brine. Reefs and their overhangs prolong the crystallization season in the halite-saturated pans by breaking up the continuity of brine throughflow to the carnallite pans. Depositionally, they replace the planned cumulates with brine compartments walled by expanding overhangs. Salt-crustured shallows on bridged-over reef platforms and around the pan strandlines are typically made up of thin flat salt beds with vertical palisade and chevron textures that characterise ephemeral brine pans everywhere (Figure 1.25).

In the 1980s, in order to destabilise the problematic salt reefs, brine levels in the compartments were allowed to draw down by lowering the rate of supply of pumped brine. But, rather than diminishing the evaporation area available for reef growth, the damp emergent salt reefs seemed to act as giant transpirative pumps. This further accelerated salt crystallization rates in the remaining brine compartments, which continued to reconfigure

the evaporation ponds into smaller and smaller areas. Even today the problem is not solved and once an inter-reef area is isolated from brine throughflow, waters caught up in reef-walled depressions concentrate to bitter saturation. Bottom-nucleated carnallite drops out before reaching the target crystallizer pans. Thus, pervasive salt reefs lessen the volume of suitable brine product reaching the final fractionation pans. The solution to this problem is not subtle, reefs in both the Israeli and Jordanian saltworks are periodically removed by a combination of dredging and blasting.

The densest halite reef complex occurs in a broad band that crosses both the Israeli and the Jordanian salt ponds (and their pre-enclosure depth contours), despite each suite of ponds being different distances from the northern basin (Figure 11.9). The most vigorous salt reefs within this band nucleated on an old road incorporated into the Jordanian ponds. The natural end of salt reef formation is probably when shallow brines on hollow reef platforms become ephemeral on solid salt flats. But if pans in the saltworks are allowed to evolve and fill to this stage, they are no longer suitable brine concentrators for the continuous feed bitter crystallisers further down the fractionation string.

Reefs seem to evolve from cracks along pressure-ridged salt crusts, and once supersaturated surface brine layers form, grow rapidly outward and upward via epitaxis. Compared to natural saline pans, brine depths in the pans of the Dead Sea saltworks are maintained at artificially deep levels by pumping Dead Sea brine into the pans. Zones of new salt reefs grow alongside recently flooded pan shores and quickly become unrecognizable as former pressure ridges once the brines deepen. Salt reefs are not seen in modern natural brine pans and salars as the water depths where stacked salt crusts accumulate are always too shallow or ephemeral for pervasive reef growth. Talbot et al. (1996) argued epitaxis in supersaturated surface brine layers helps account for the rapid deposition of modern thick beds in the Dead Sea prior to the building of the salt works. He argues that similar structures probably formed in marine-fed regions of pure salt accumulation on the floors of ancient rifts that periodically opened to the ocean.

Domal gypsum reefs occur in modern salinas and in the Messinian of the Sorbas Basin, Spain (Figures 4.5d, 1.15b), but as yet no ancient halite reefs have been documented. They should be distinguishable as botryoidal layers of nonvertically-aligned chevron crystals, which would follow a megapolygonal pattern between saucers of recrystallised cumulates. Part of the problem of recognition lies in the scale of outcrop exposure needed to

recognise such a salt reef. Bedded gypsum outcrops entraining reefs and domes are commonplace, but nonhalokinetic ancient halite never makes it to the surface. Halite reef textures would be next to impossible to document in cores, but should be visible in mine walls in the same way that ancient halite megapolygon and pressure ridges are, but would easily be misinterpreted as mesoscale syndeositional karst features. Another part of the problem is a lack of expectation of halite reef structures, which are not a commonly listed texture in sedimentology textbooks. And yet another problem is that rapid infill means metres-deep perennial halite-saturated brine bodies are not found in modern salt lakes, only in anthropogenic ponds as in Israel and in quarried coastal pans in Saudi Arabia (Figure 3.15). But, as will be seen in Chapter 5, there are many ancient saline seaways where salt reefs were possible in halite-saturated brine bodies with depths measured in metres to tens of metres.

Secondary (diagenetic) evaporites

Most ancient evaporites show strong evidence of secondary or diagenetic textural overprints. Providing brine is saturated with respect to a particular evaporite mineral it has the potential to precipitate that mineral. This potential exists both at the surface and in the subsurface. So far, we have discussed the primary processes of evaporite precipitation in the context of single-phase primary evaporite crystals deposited on the floor, or about the margins, of brine pans, lakes, salterns or saline seaways. However, evaporites also precipitate as intrasediment crystal growths and replacements, or as cements in preexisting evaporite and nonevaporite hosts.

Processes of secondary evaporite formation are reflected in crystals and textures that indicate displacive growth, recrystallisation, back reactions and replacement. Such events indicate a superimposed brine chemistry that differs in terms of chemical composition, or salinity, or temperature from the brine chemistry that formed the primary or preexisting evaporitic sediments (see Chapter 2).

Intrasediment salts

The well-studied nodular anhydrites and gypsums of the Abu Dhabi sabkha in the Arabian Gulf are probably the most widely recognised examples of syndeositional intrasediment evaporites (Figure 3.4g). The nodules form displacively and replacively from concentrated pore fluids in the capillary and upper phreatic zones beneath the sabkha surface (Figure 1.26a). In the type area these intrasediment crystal growths precipitate

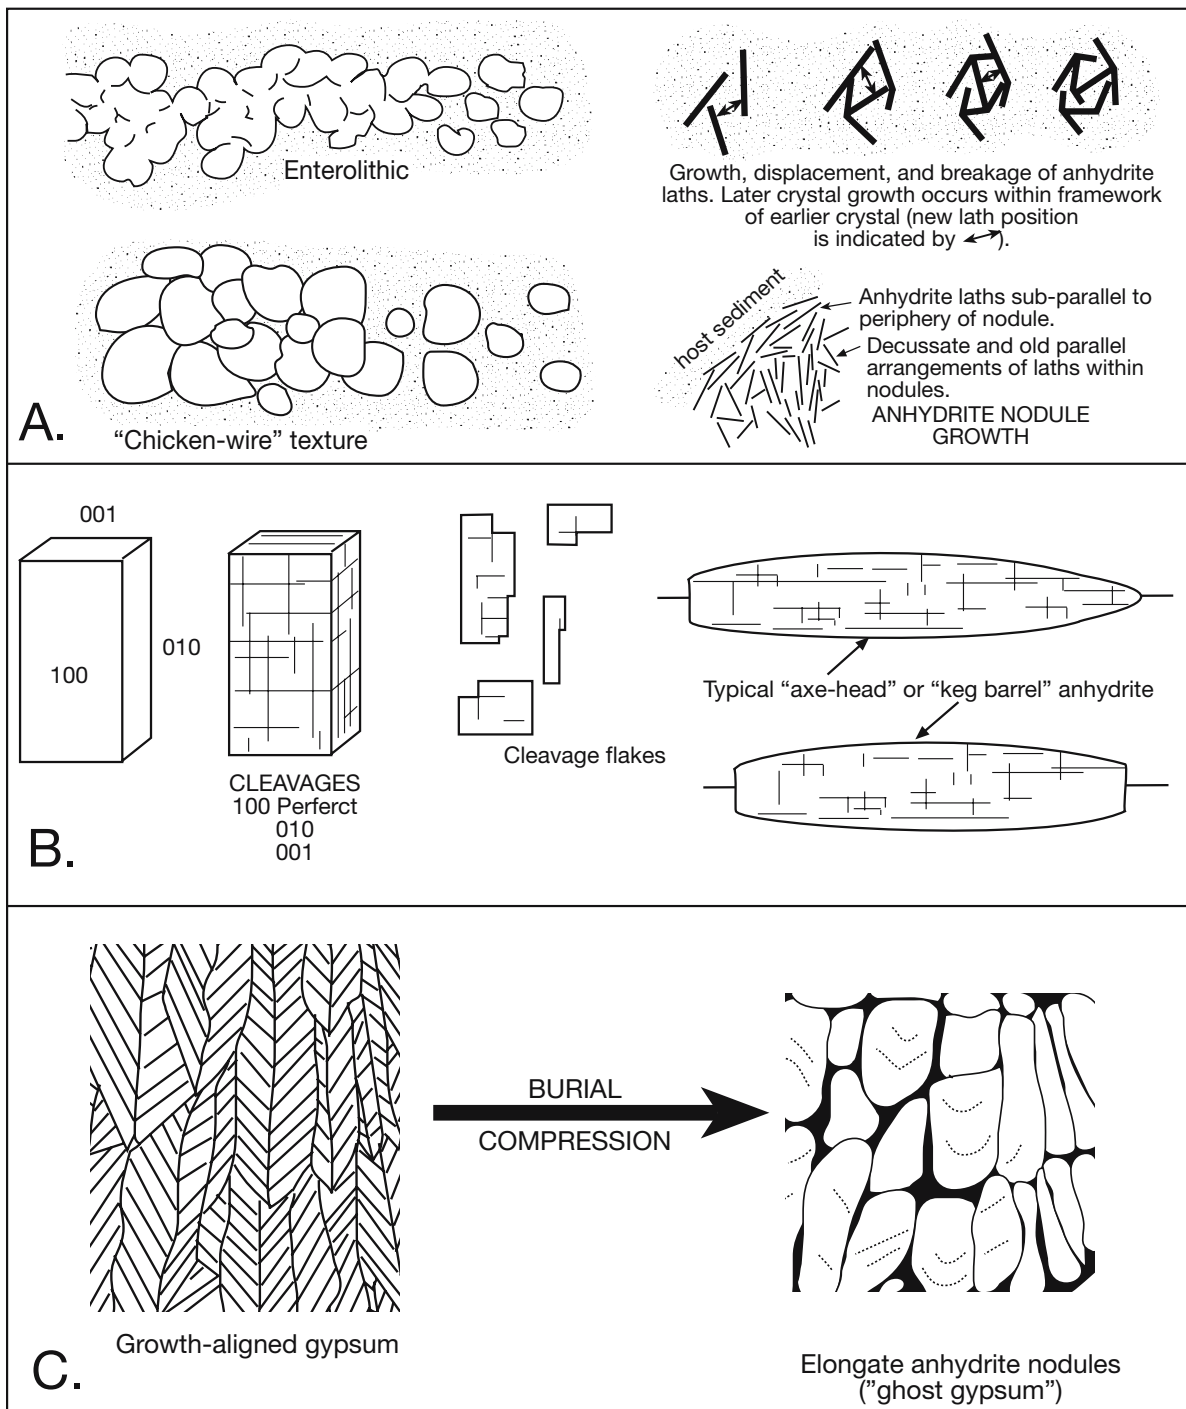

Figure 1.26. Anhydrite characteristics. A) Anhydrite nodule growth into chicken wire and enterolithic anhydrite. Also shows how successive new anhydrite laths break and rotate earlier formed laths. The end result is a nodule with a margin composed of laths aligned subparallel to the its edge. Many nodule interiors preserve clusters of subparallel laths showing large nodules grow by accretion of smaller nodules. B) Crystallographic characteristics of anhydrite laths showing well developed orthorhombic cleavage. Large isolated anhydrite spar crystals in mudstones sometimes have a lenticular form. It or its pseudomorphs can be distinguished from lenticular gypsum by a typical "axe-head" and "beer-keg morphology" with well developed cleavages at one or both ends of the lens. C) Preservation of gypsum ghosts as elongate anhydrite nodules created during burial. (after Shearman and Fuller, 1969; Warren and Kendall, 1985).

in a matrix of upper intertidal and supratidal sediments. But in addition to anhydrite capillary salts, gypsum and halite also precipitate displacively in numerous continental and pedogenic settings. Salts and their crusts may come and go, driven by the vagaries of groundwater resurgence, surface flooding and reconcentration, so that all that may be left as indicators of their former presence are highly disturbed sediments with a few halite or gypsum pseudomorphs.

The amount and variety of intrasediment salt is highly variable. Some mudstones contain scattered crystals and nodules that make up less than 1% of the rock volume. Others are made up of approximately equal volumes of host matrix and evaporite salts, while yet others are characterised by layers composed almost entirely of intrasediment salts. The thickness of the layer over which intrasediment salts can precipitate is controlled by the style of brine supply. If the salts are precipitating by capillary evaporation beneath a subaerially exposed mudflat then the thickness is controlled by the pore throat size of the host sediment. Capillary zones can be metres thick in fine clays, while they are only centimetres thick in sands. If the intrasediment salts are precipitating by the downward percolation of dense cooling brines from a subaqueous water body then the thickness is dependent on the rate of diffusion or reflux into the underlying clay. Handford (1991) estimates intrasediment halite can precipitate in brine-saturated soft muds down to depths of 1-2 metres below the sediment-brine interface.

Sabkha nodules and crystals

As gypsum and anhydrite nodules grow and coalesce in highly saturated pore waters of the capillary zone, they form enterolithic, contorted fold (ptygmatic) and chickenwire textures, which typify the supratidal portion of a coastal sabkha sequence. New laths of anhydrite form between older laths as such anhydrite nodules grow “from the inside out” (Shearman and Fuller, 1969). Successive laths crystallise, displace, rotate and perhaps break the older laths, while the expanding nodule pushes aside the adjacent host matrix. Figure 1.26a illustrates this process and the position of each successive new lath is indicated by a double-ended arrow in the figure. The end result of this “inside-out” growth is a near pure anhydrite nodule, with laths about the edge of the nodule rotated into a subparallel alignment to the nodule margin. Many nodules are constructed of a number of subsets of this subparallel arrangement, implying large nodules grow by accretion of smaller nodules.

Capillary halite crystals typically show an incomplete development of the cube face, and in soft muds with supersaturated

pore brines there is intense development of the cube edges at the expense of the cube faces to create dendritic or pagoda-like morphologies. Rapid crystal growth often entrains some of the mud matrix within the halite, usually parallel to the cube faces. Such rapid growth is thought to indicate a rapidly attained and high degree of supersaturation with respect to halite (Arthurton, 1973; Southgate, 1982) or perhaps growth in organic-rich brines (Gerdes et al., 2000a, b).

Displacive halite grows by capillary evaporation of supersaturated pore waters in soft brine-soaked mudflat or sabkha sediments (Figures 1.18c). Such hoppers are found growing in carbonate muds along the western shore of the Dead Sea (Gornitz and Schreiber, 1981). Similar halite crystals are found actively growing as much as metres below the surface of present day mudflats in Bristol Dry Lake in California (Handford, 1991). Growing about the edges of the same lake are unusual capillary pavements of growth-aligned seepage gypsum (Rosen and Warren, 1990). Dendritic or pagoda forms of halite cannot easily grow in deeper burial environments where rates of salinity fluctuation and kinetics of reactions are much slower. The surrounding matrix is more likely to be indurated, so secondary crystals formed at depth tend to be fracture or mould fills.

Syn depositional karst in crusts

Crusts and beds dominated by primary subaqueous textures (chevrons and palmate/zig-zag structures) can be partially dissolved by more dilute surface brines or by subaerial exposure. Freshening can be via a rise in the brine-pool level associated with rainfall and sheetflooding, by seawater flooding, or by morning dew dissolution associated with the complete drying of the brine pan. The resultant dilution creates a truncating dissolution surface that crosscuts crystal faces in both subaerial and freshened subaqueous settings (Figure 1.27). In a subaerially exposed halite crust numerous cm-dm-scale vertical to subhorizontal karst cavities typically form beneath an upper crystal-truncating exposure surface. Cavities subsequently fill with clear evaporite cement sometimes atop a cavity-lining rind of detrital mud and clay (Figure 3.30). In chevron halite beds these cavities are often filled with a clear inclusion-poor halite spar cement. Void infill is often related to the depositional event that precipitated an immediately overlying chevron halite or swallowtail gypsum layer (Handford, 1991; Warren, 1982a). Using bromine signatures, Cathro et al. (1992) found the Silurian brines that precipitated the cloudy primary halite in the Mallowa Salt of the Canning Basin were indistinguishable from the signatures in the secondary spar-like halite that

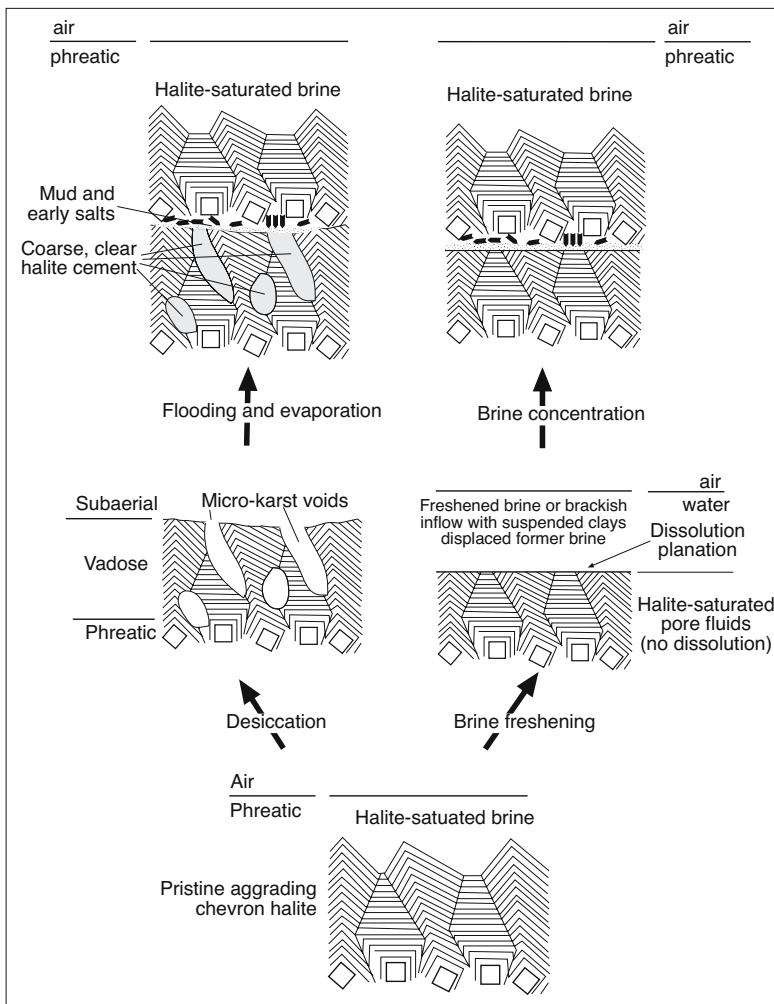

Figure 1.27. Syndepositional overprints on chevron halite. The textural evolution illustrated on the left shows the formation of vadose microkarst, while that on the right illustrates the effect of bottom freshening on the floor of a perennial brine pool and the formation of a planation surface with no vadose karst development.

filled voids in the primary halite, implying an early origin from the same depositional/syndepositional brine. This is a depositional signature still preserved in these beds more than 400 million years later.

Intensity and frequency of dissolution overprints in salt crusts are largely determined by brine depth, frequency of dilute water floods and the permanency of the brine body. Most modern and ancient halite salt pan crusts preserve evidence of syndepositional dissolution in the form of dissolution surfaces and halite-spar-filled cavities. Lowenstein and Hardie (1985) emphasised that the presence of such features in a halite bed is the unequivocal signature of ephemeral surface waters.

The texture reflects dissolution events that accompany subaerial exposure of any salt crust and the periodic flooding of the halite pan by fresh to brackish meteoric water (Figure 3.30). Dissolution cavities are less likely to occur in bottom-nucleated beds deposited in evaporite basins covered by deeper perennial brine bodies. Freshened inflow waters tend to float atop the denser halite-saturated brine body at least until its density equalises that of the underlying brine. If brine freshening does occur in a perennial brine situation then a planation surface without vadose cavities is the likely result (Figure 1.27, 2.49).

Nearsurface crystal and crust dissolution

The following section focuses on small-scale syndepositional features indicative of the groundwater cycling of salt crystals and crusts, Chapter 7 looks broader and deeper in a discussion of dissolution mechanisms creating “the salt that was.”

Coming and going of salt crusts

Salt crusts and isolated crystals on many modern saline mudflats are ephemeral; they are not preserved in the final sediment matrix, yet their growth and subsequent dissolution on or within nearsurface sediments can alter sedimentary structures and textures to such an extent that it is difficult to identify the original texture. Areas

dominated by this set of processes occupy large schizohaline areas of modern salt flats in SE Arabia such as Sabkhat Rumadan in Saudi Arabia, Sabkhat Matti and the At Taf coastal region, both in the Emirate of Abu Dhabi, and the Umm as Samim region in Oman (Figure 3.15; Goodall et al., 2000).

These salt flats are affected by varying combinations of tidal-marine, alluvial and eolian depositional processes and the resulting sediments include both clastic- and carbonate-dominated successions. The efflorescent and precipitated salt crusts in these areas can be grouped into two main types: 1) thick crusts, with high relief (> 10 cm) and 2) a polygonal or blocky morphology; or thin crusts, with low relief (< 10 cm)

and a polygonal or blister-like appearance. The thin crusts may assume the surface morphology of underlying features, such as ripples or biogenic mats (petees).

A variety of small-scale textures resulting from the interaction of detrital sediments with the salt crusts were observed by Goodall et al. (2000), they include: pustular growths, hair-like spikes and irregular wrinkles. Evolution of crusts over time creates a variety of distinctive sedimentary fabrics by salt-growth sediment deformation, salt-solution sediment collapse, sediment aggradation and compound mixtures of these processes. Preservation ranges from completely preserved crust to highly disturbed siliciclastics where only suggestions of former salt crusts remain (haloturbation).

When a subaerial sabkha surface is marked by a salt crust with pressure ridges, the lee side of a ridge acts as a trap to cross-drifting sands that become enmeshed and cemented by further salt growth. Eolian-dominated sabkhas accrete via a set of processes that begin with a sandstorm, followed by a

new salt ridge episode, followed by another sandstorm (Figure 1.28a). The resulting sediment is an irregularly layered sandy mud, disturbed by ongoing intrasediment salt and carbonate growth and solution (Fryberger et al., 1984; Goodall et al., 2000). In other words haloturbation, rather than obvious crust preservation, is the dominant texture in many eolian sabkhas (Figure 3.60).

Salt-crust processes can produce features that may be confused with eolian adhesion structures. For example, distinctive wavy-laminated facies in the Lower Triassic Ormskirk Sandstone Formation in the Morecambe Field of the Irish Sea Basin had previously been interpreted as the product of fluvial sheetfloods modified by soft-sediment deformation and bioturbation. Close inspection of laminations in core revealed many of the same sedimentary fabrics seen in Sabkha Matti (Goodall et al., 2000). This facies is the product of salt growth on eolian sediment and is not of fluvial origin.

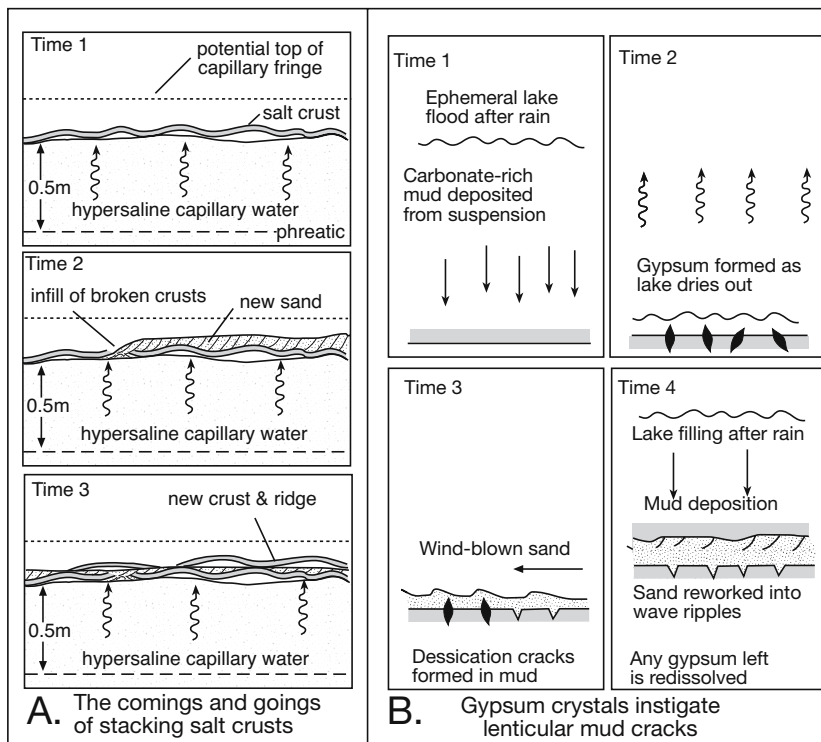

Figure 1.28. Residual evaporite textures indicating syndepositional precipitation and dissolution. A) Salt crust accretion mechanism. Time 1) Development of salt crust at top of capillary zone. Time 2) Covering of crust by windblown sand. Time 3) Incorporation of crust and salt cover by capillary wicking, portions of the old crust may dissolve and collapse (after Fryberger et al., 1984). B) Instigation of lenticular mud cracks (syneresis mimics) by early gypsum growth and dissolution in an ephemeral mudflat/saline pan (after Astin and Rogers, 1991).

Lenticular mudcracks

Evaporites growing in association with drying muddy sediments and eolian sands can also produce mudcracks that may be confused with syneresis cracks. There are numerous mud cracks in irregular arrays and often showing lenticular outlines in the Orcadian (Devonian) laminites of Scotland. They are considered one of the type examples of syneresis cracking and were used as evidence that these sediments were deposited in a shallow (<30 m) lacustrine environment. Yet, lenticular shaped features seem to initiate many of the mudcracks. Rather than a subaqueous origin, these mudcracks are equally characteristic of the incipient stages of subaerial shrinkage with what appear to be gypsum pseudomorphs in some of the straight cracks (Astin and Rogers, 1991).

Cracks are abundant and irregularly clustered because early gypsum crystals acted as nuclei for cracking and controlled crack morphology (Figure 1.28b). The majority of the lenticular

cracked surfaces formed as the ephemeral lakes waters dried up and deposited lenticular or bird-beak gypsum. The crystals were modified to varying degrees before being covered by wind blown sand laminae and buried. Subsequently the gypsum, along with minor halite, dissolved to leave the characteristic cracks in the lake sediments. In a review of other documented examples of subaqueous syneresis cracks, Astin and Rogers (op. cit.) argue that many can be reinterpreted as the result of gypsum instigation, followed by desiccating cracks centred on the crystals and then burial. They go on to conclude that syneresis cracks, although well documented in the laboratory, are rare and insignificant in nature and that evaporites growing in mudcracks are commonplace. King had noted carnallite-filled mudcracks in the salt clays of the Permian Salado Fm., west Texas, as early as 1946.

Haloturbated and chaotic halite

Percolation of capillary waters periodically saturated and undersaturated with a particular evaporite salt can also create textural havoc in a nonsalt matrix. For example, displacement halite grows via capillary evaporation during the supersaturated phase of pore flushing of the saline mudflat facies surrounding many brine pans. The growth of this halite disturbs and rotates primary mechanical structures in the original sediment matrix (laminae, ripples, mudcracks, etc.). But with each flooding of the brine pan there is a freshening of surface waters and nearsurface pore fluids, driven by sheet flood runoff followed by seepage down to a depressed water table. Near surface pore waters become undersaturated with respect to halite and the displacement halite dissolves. Sediment matrix then collapses into the voids so formed, further disrupting any primary structures in the sediment matrix. As the pore fluids are again concentrated by capillary evaporation, intrasediment halite and gypsum begin to grow once more, further displacing and disrupting existing textures. This process of alternate wetting and drying with the associated destruction of primary stratification in the matrix is known as haloturbation (Smith, 1971). If the sediment is preserved with halite still present, it is termed chaotic halite. If the halite is completely dissolved, all that may be left is a haloturbated massive mudstone.

Because it is largely a syndepositional process that occurs prior to induration of the clayey matrix, one of the effects of

Figure 1.29. Evolution of smeared intraclasts by collapse of lacustrine mudstone into void space created by dissolution of halite crystals during the freshened stage of a wet-dry cycle in an evaporitic mudflat. LM = lacustrine mudstone; CHM = chaotic halite mudstone; SIC = smeared intraclast; DH = displacive halite (after Powers and Holt, 2000).

haloturbation is to create highly deformed intraclasts within the haloturbated or chaotic-halite bed. Powers and Holt (2000) use the term “smeared intraclasts” to describe this form of salt-related mudflat texture. It can be used to recognise a hypersaline capillary mudflat unit, even if the original displacive salt is leached. Smeared intraclasts are typically 2-5 cm across, are made up of the same lithology as the surround matrix and show distorted or smeared internal thin beds or laminae (Figure 1.29). The facies transition layered and undisturbed mudflat to haloturbated mudflat to chaotic halite indicates increasing proximity to a perennial saltpan (Chapter 3).

Shallow mineralogic re-equilibration

Dense saturated bottom brines percolating down through a shallowly buried primary evaporite unit can create diagenetic havoc within the original texture. For example, saturated bottom brines percolating through a buried cumulate halite deposit can convert it into a tightly cemented coarsely crystalline halite mosaic retaining little evidence of the primary texture (Smoot and Lowenstein, 1991; Cathro et al., 1992). Dense halite-saturated brines flushing down through shallowly buried subaqueous gypsum beds that are dominated by bottom-nucleated gypsum crystals can set up diagenetic conditions where the gypsum is replaced by halite/anhydrite pseudomorphs of the original aligned gypsum. In Permian evaporites of west Texas the replacement mimics the crystal shapes in beds composed of bottom-nucleated gypsum precursor, as well replacing internal layering within crystals. This tends to happen early and be driven by reflux of halite-saturated brines into gypsum beds. Ambient high temperatures and salinities mean much of the finer grained gypsum matrix has already converted to nodular

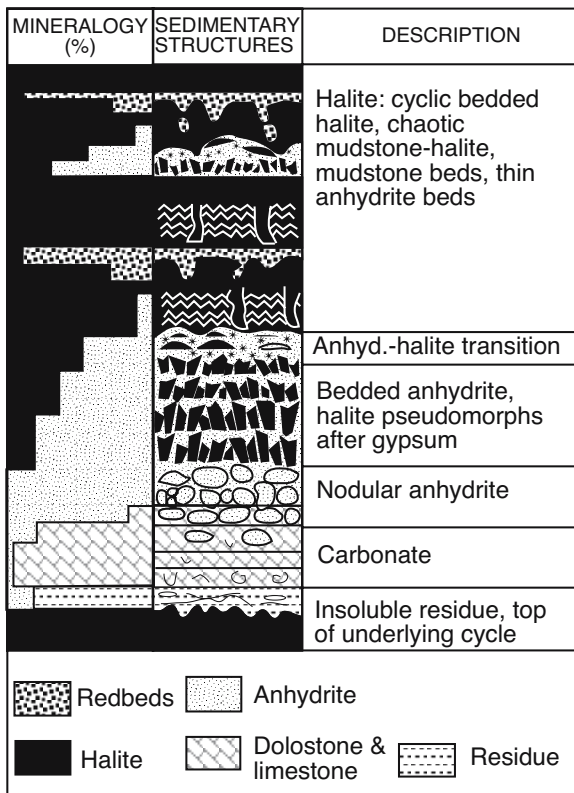

Figure 1.30. Typical depositional cycle in the Permian evaporites of the Texas Panhandle where gypsum (rather than anhydrite) was the dominant sulphate precipitated, even at salinities near halite saturation. Large gypsum crystals grew vertically on floors of brine pools, surrounded by a matrix of autochthonous transported gypsum sand and silt. Most or all of the primary gypsum was altered to anhydrite or leached and replaced by halite in the very shallow (<2m) burial environment under the influence of halite-saturated diagenetic brines (after Hovorka, 1992).

anhydrite. Reflux in ancient brine platforms drove a process of gypsum dissolution and halite replacement a few metres beneath the brine-covered sediment surface in ancient brine seaways (Figures 1.30, 2.54; Hovorka, 1992).

In a similar fashion, changes in the near surface hydrology within the modern saline mudflats of Salt Flat playa in west Texas, have “sabkha-ized” a subaqueous laminated lacustrine gypsum bed (Hussain and Warren, 1989). The process was driven by the superposition of a Holocene capillary hydrology onto subaqueous gypsiferous laminites originally laid down in a Pleistocene salt lake. This capillary zone overprint precipitated nodular displacive gypsum within a matrix of laminated gypsum/dolomite. The change in hydrology indicates a change in climate from more humid Late Pleistocene to more arid Holocene

conditions. It also set up shallow subsurface pore chemistries, whereby lenticular gypsum crystals were pseudomorphed and replaced by halite spar.

Owing to the mixing of waters of two salinities, reflux dolomitization beneath a platform evaporite can take place concomitantly with CaCO_3 dissolution (Sun, 1992). Relative rate of limestone solution compared to dolomite growth is a likely control on porosity levels during the later stages of the reflux dolomitization process (Sun, 1995). If the rate of dolomite growth keeps pace with the rate of CaCO_3 dissolution, then the mimetic replacement of micrite matrix and micritised grains occurs with little change in porosity levels, as in many ancient evaporitic peritidal dolomites. If the rate of reflux dissolution exceeds the rate of dolomite replacement, as in open marine platform carbonates beneath the seaward edge of a platform evaporite, then there is large scale skeletal aragonite dissolution, along with an increase in effective porosity in the dolomitized interval compared to precursor limestone. During shallow subsurface brine reflux in the Permian in the Palo Duro Basin, Texas, the flow of such refluxing waters dissolved marine carbonate to form anhydrite-filled moulds (Bein and Land, 1983), while in the Levelland-Slaughter interval it enhanced reservoir porosity (Figure 10.24; Elliott and Warren, 1989).

Porosity loss

Syndeositional alteration, cementation and porosity loss, in a halite bed continues into the shallow subsurface until the bed can no longer support fluid flushing. This occurs once all effective porosity is occluded by compaction and secondary evaporite cementation. In halite-dominated continental sequences this loss of effective porosity is typically early and shallow (Figure 1.31). Casas and Lowenstein (1989) showed that Quaternary halite layers only 10 m below the land surface have typical porosities of <10% and that layers at depths below 45m are tightly cemented without visible porosity. By 100m of burial, almost all the halite units were tight and impervious. Diagenetic porosity occlusion by surface-driven hydrology in these halite beds was essentially over. No further porosity change can occur until beds start to dissolve deep in the mesogenetic realm or even in the metamorphic realm as the dihedral intercrystalline angle of halite begins to change as the beds approach greenschist conditions (Lewis and Holness, 1996).

From a few hundred metres burial until it reaches the zone of metamorphism, a halite unit maintains permeabilities that are measured in no more than microdarcies or nanodarcies. Thus halite beds and allochthonous sheets provide a highly effec-

tive seal to sediments beneath. To move closer to the surface, trapped basal fluids must either flow laterally around such a salt barrier or dissolve it. If the trapped pore fluids are hydrocarbons then no dissolution can occur as halite is virtually insoluble in gas and oil. Retention of pore fluids below a salt barrier means porosity in the host sediment is maintained to a much greater depth and that sediments below a salt barrier in an actively subsiding basin are typically overpressured.

The pervasive early loss of porosity from more than 50% near the surface to zero by 100m burial also has important implications for textural and geochemical studies of ancient bedded halite. Casas and Lowenstein (1989) showed that this porosity loss was entirely due to early post depositional diagenetic cementation by clear halite. Other mechanisms of porosity loss by chemical or mechanical compaction were dismissed for lack of evidence. There were no strained or broken crystals, pressure solution boundaries nor stylolites, and patches of chevrons preserved in among the mosaic halite spar were all undeformed.

Many Phanerozoic halite beds that have not undergone halokinetic deformation also contain patches of relict depositional and early diagenetic textures, which have remained unchanged for hundreds of millions of years. For example, the Ordovician-Silurian Mallowa Salt (formerly Carribuddy Forma-

tion) in the Canning Basin, West Australia, retains aligned halite chevrons crosscut by syndepositional karst and an overprint of coarse mosaic recrystallised halite (Figure 1.32a; Cathro et al., 1992). Such textures are thought to be syndepositional, yet are not dominated by large volumes of pristine chevron halite. Rather, they preserve evidence of early porosity loss brought on by numerous syndepositional cycles of dissolution and recementation. Lowenstein and Hardie (1985) showed that patchy remnants of chevrons and cornets in a dominantly coarse-grained mosaic of halite spar are not necessarily a burial fabric. All “mature” saltpan halites have this fabric within tens of metres of the depositional surface.

The mechanisms that allow a shallow brine to become supersaturated with respect to halite and to precipitate intercrystalline cements/replacements are still not well understood. One possible mechanism is brine mixing. When compositionally distinct brines mix in the subsurface a new halite-saturated brine may result. This is the case when MgCl₂ brines are mixed with CaCl₂-rich brines (Raup, 1970). Casas and Lowenstein (1989) have questioned whether this is the dominant mechanism that forms pervasive halite cements in most shallowly buried playa sediments. Rather, they suggest a simple temperature drop is the dominant control. Surface brines in halite-forming surface waters can be heated to temperatures in excess of 60 - 70°C, while groundwater brines typically have temperatures of 15 - 30°C. They suggest that the cooling associated with the downward reflux of a surface water is all that is required to saturate a brine and so precipitate widespread halite cements.

Deeper burial - mosaic halite?

Formation of pervasive mosaic halite spar early in the burial history of a salt bed creates a problem in recognising those parts of a halite unit that have been subjected to later burial recrystallisation as a deeper burial environment is also thought to form mosaic halite spar. Diagenetic textures in most ancient bedded halite units are dominated by sutured mosaic textures, where grain boundaries suture in the same fashion as neomorphic pseudosparite in calcite (Spencer and Lowenstein, 1990). Individual crystals display curved boundaries that tend to meet at triple junctions with angles approaching 120°, and interstitial impurities concentrate along the crystal boundaries (Figure 1.32b).

Mosaic texture is comparable to the polygonal equigranular mosaic texture that forms in annealing metals, where cooling grains tend to optimise their size, shape and orientation in order

Figure 1.31. Porosity in Quaternary halite beds versus depth (after Casas and Lowenstein, 1989). All effective porosity is lost by 70 m burial.

Figure 1.32. Halite textures in the Silurian Mallowa Salt, Canning Basin. A) preserved halite chevron in growth position with erosionally truncated crest implying periodic bottom freshening and hence fairly shallow brine. B) Recrystallised mosaic halite, an enigmatic texture that dominated most of the crust textures in the unit (after Cathro et al., 1992).

to minimise energy. The same mosaic texture can also be found in a soap foam as bubble boundaries with 120° triple junctions. The exact mechanism that controls the formation of mosaic textures in halite is still not well understood. It forms either early during brine reflux cementation or later during burial driven compaction and pressure-solution recrystallisation. During burial it can form a pervasive overprint in flowing

halite. Flowing salt sometimes tends to flatten in the direction of maximum stress and this flattening can be used to distinguish it from other forms of mosaic halite (Figure 6.10a).

Limpid dolomite in mosaic halite

Late, ordered, stoichiometric, euhedral to subhedral limpid dolomite along the contact between bedded halites and interbedded mudstones in the platform evaporites of the San Andres Formation of the Palo Duro Basin, Texas is the outcome of focused burial diagenesis in halite-mudstone successions (Gao et al, 1990). In the Permian example documented by these authors, the limpid dolomite is characterised by a low Sr content and depleted $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ signatures (Figure 1.33). This they interpret as indicating meteoric or structural waters held in adjacent deeply buried mudstones are a source of ions for the dolomite. This limpid dolomite is not the product of reflux brines, which created the pervasive dolomite in the interlayered San Andres platform carbonates. Limpid dolomite crystallises locally under favourable sulphate-reduction conditions during burial compaction and salt dissolution. Compaction mixed the waters, released from the dewatering mudstones, with brines derived by the dissolution or recrystallisation of adjacent impervious halite beds. Limpid dolomite spar precipitates along halite-shale contacts where escaping shale waters caused the halite to dissolve and recrystallise as mosaic spar. This mode of dolomite formation is part of a larger set of fluid flow processes that precipitate sparry burial dolomite at the contact between a dissolving salt bed and crossflowing basinal waters

Figure 1.33. Limpid dolomite in halite of San Andres Fm. Palo Duro Basin. Limpid dolomites are depleted in carbon-13 and oxygen-18, compared to typical isotopic signatures in the massive (reflux) dolomite of the San Andres Fm (after Gao et al., 1990).

Figure 1.34. Evaporite diagenesis showing evolution of burial-related secondary evaporite textures (includes burial salts).

(e.g. dolomite formation in the basal anhydrite NE Thailand, Figure 7.34a).

Burial of sulphate evaporites

Due to water release, gypsum and other bedded evaporite units made up of hydrated salts with entrained structural water show an inherently more complicated textural response to burial than the simple mosaic overprint of halite beds (Figure 1.34; Warren, 1991). Gypsum releases structural water as it converts with burial to nodular mosaic anhydrite (Figure 1.35). Carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$) releases Mg and water as it converts to sylvite (KCl) by incongruent dissolution associated with burial diagenesis or phreatic flushing by meteoric waters. Loss of structural water during burial dehydration means syndepositional textures in the converting bed are modified by this flush of escaping water.

Nodular anhydrite and water loss

Gypsum rather than anhydrite is the most common form of sedimentary $CaSO_4$ at earth surface temperatures. Intense

solar heating in very arid regions can dehydrate gypsum to form bassanite/anhydrite at the surface. Gypsum also converts to anhydrite in the capillary zones of sabkhas and evaporitic mudflats where the gypsum is bathed in highly saline NaCl brines. But thick anhydrite beds deposited in ancient saline giants were laid down on the subaqueous floors of perennial brine lakes and seaways not mudflats. Prior to anhydritisation, beds of primary saltern gypsum extended across tens of thousands of square kilometres. Such beds compacted and converted by burial dehydration to nodular anhydrite during early burial, so releasing large volumes of water (Warren, 1991).

As gypsum is buried and ambient temperature rises above 50-60°C, it converts to nodular anhydrite. The depth of transformation is between a few metres to more than a kilometre. The exact depth in any region will depend on lithostatic pressure, local geothermal gradient and pore brine salinity (Figure 8.25). For example, in Miocene Lower Fars evaporites of the United Arab Emirates, with its relatively saline pore brines, the conversion depth ranges from 60 to 245 m across a zone some 10 metres thick (Billo, 1986). In the Salton Sea region with

Figure 1.35. Gypsum converted to anhydrite by burial in Bristol Dry Lake, California. A) Lenticular gypsum meshwork from a lake floor sediment sample a metre below the lake surface. B) nodular anhydrite still retaining the outline of the gypsum precursor. Sample from a lake core some 140 metres below the lake surface.

its high geothermal gradients, the conversion from gypsum to anhydrite occurs at 80-105°C and at depths of less than 200-250m (Osborn, 1989). Similar anhydrite conversion was noted at 150-200m depth in cores from the Pleistocene evaporites in nearby Bristol Dry Lake, California; but here the isotopic evidence suggests sulphate-reducing bacteria also play a role in the conversion (Figure 1.35; Rosen and Warren, 1990).

If the nearsurface pore-fluid salinity approaches halite saturation, the conversion from gypsum to anhydrite can occur at shallower depths and much lower temperatures $\approx 35 - 45^\circ\text{C}$. Such temperatures occur as shallow as 1-2 metres below the depositional surface of a halite-saturated brine pool where sediments reside in the zone of active phreatic flow or brine reflux (Figure 2.54). At such depths the buried gypsum bed retains well-developed intercrystalline porosity and inherently high permeabilities. This facilitates the leaching of the gypsum crystals and their infill by clear halite spar, which pseudomorphs the various forms of the precursor gypsum (e.g. Figure 1.30).

With less saline brines in the pores of a buried CaSO_4 bed, the conversion of gypsum to anhydrite may not occur until burial depths of hundreds of metres. By such depths, natural compaction has greatly depleted intercrystalline porosity in the gypsum bed. Release of water from already compressed and cemented gypsum will create 40% water-filled porosity in an otherwise impervious anhydrite unit. Over the long term this water is not retained but escapes into the subjacent sediments. A likely effect within the converting CaSO_4 bed is a decrease in its inherent strength; and in compressive situations, an increased ability to act as a lubricating horizon or décollement, even if no halite is present (Figure 8.26). If the water cannot drain freely

from the dewatering gypsum, the bed may convert to a quicksand-like consistency. This explains some of the intense deformation and enterolithic textures with flow orientations that are commonplace even in flat-lying and otherwise undeformed ancient bedded anhydrites.

As it converts, the more deeply buried and compressed CaSO_4 unit loses almost all of its original texture. Rare indistinct elongate, and partially flow-aligned, nodular “ghosts” may be all that remain of the primary bottom-nucleated textures in many ancient anhydrite beds (Figure 1.26c). Loss of water of crystallisation also affects units subjacent to the dehydrating

gypsum/anhydrite. The escaping water is saturated with respect to CaSO_4 , but undersaturated with respect to other evaporite minerals, including any nearby carbonates, as well as halite and the bittern salts. The onset of anhydritisation will be effected by the salinity and temperature of pore waters and the volume of pore water throughflow (Table 7.12).

Such a complex anhydritisation history is well documented in the varying onset of anhydritisation in calcium sulphate sediments of the Middle Miocene Badenian evaporite basin in the Polish Carpathians. Three distinct, now anhydritised, facies associations record a range of depositional environments from nearshore to deeper basinal settings (Figure 1.36; Kasprzyk, 2003). Coarsely crystalline platform sulphates were deposited in subaerial and shallow-marine environments (shoreline and inner platform-lagoon system) mainly as autochthonous selenitic gypsum. These were reworked and redistributed into deeper waters (outer platform-lagoon, slope and the proximal basin floor system) to form resedimented facies composed mostly of allochthonous clastic gypsum and minor anhydrite. In contrast small gypsum prisms tend to accumulate in water characterised by rapidly fluctuating bottom brine conditions. The prisms were often mechanically reworked into rippled and ooid-like accumulations or captured in algal mats. These laminites were deposited in brine depths ranging down to hundreds of metres, but most accumulate in shallow brines less than a metre or two deep or as pelagites in the deeper part of the basin. It is the rapid salinity fluctuations associated with very shallow waters that favour rapid crystallite formation and multiple nucleation.

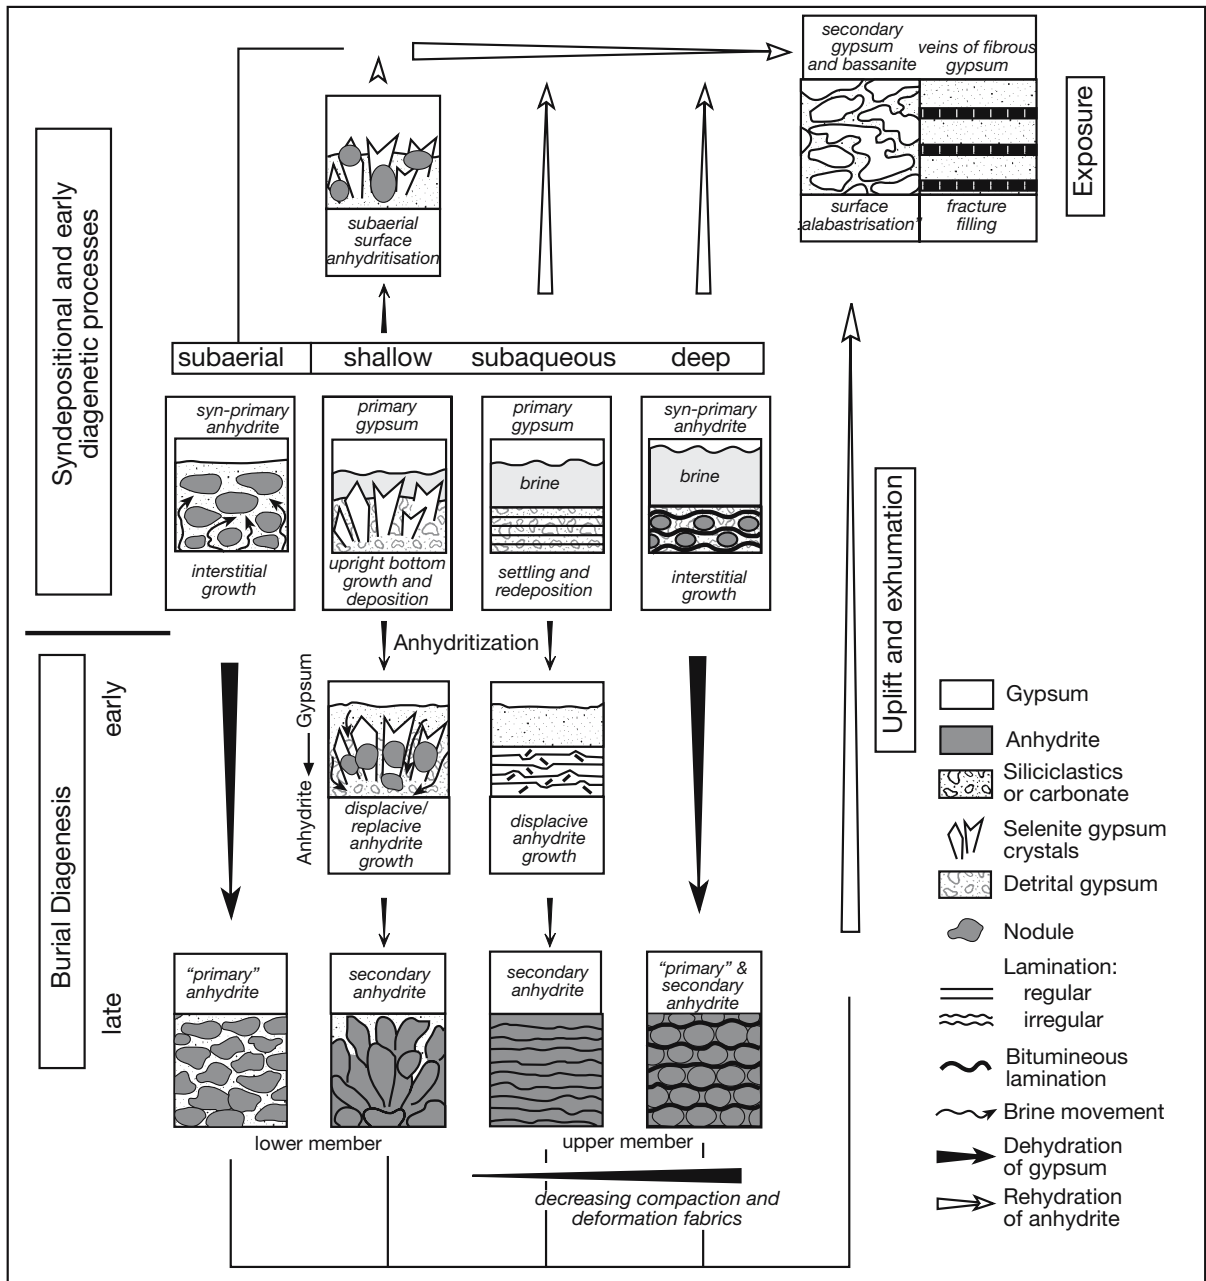

Figure 1.36. Sulphate textural evolution is clearly seen in Middle Miocene sulphates in the Carpathians (after Kasprzyk, 2003). Platform sulphates were deposited in subaerial (sabkha) and shallow-marine environments (shoreline and inner platform-lagoon), mainly as autochthonous coarse-grained aligned (selenitic) gypsum. This platform sediment was reworked and redistributed into deeper waters (outer platform-lagoon, slope and the proximal basin floor system) to form resedimented facies composed mostly of allochthonous clastic gypsum and minor anhydrite. Burial and the conversion to anhydrite subjected these sulphates (mostly gypsum) to two different hydrological styles: (1) syndepositional anhydritisation of gypsum deposits by highly concentrated brines or elevated temperatures in surficial to shallow-burial environments (mostly in the lower member of these Badenian sulphates), and (2) successive phases of anhydrite formation (syndepositional de novo growth, early diagenetic to late diagenetic replacement of former gypsum), which occurred during progressive burial (mostly in the upper member). Finally, the succession was uplifted and re-entered the active meteoric realm where various fibrous and alabastrine textures formed.

Subsequent anhydritization was superimposed on depositional gypsum facies. It was the result of interactions between concentrated seawater, meteoric runoff and highly saline, residual pore fluids. And so two different anhydrite styles overprinted the original Badenian sulphates (Kasprzyk, 2003): (1) syndepositional anhydritisation of gypsum deposits driven by highly concentrated brines and elevated temperatures (mostly in the lower member), (2) successive phases of anhydrite formation (syndepositional de novo growth, early diagenetic to late diagenetic replacement of former gypsum) during progressive burial (mostly took place in the upper member). In the basin the anhydrite started to grow in a fine-grained bottom host under very early, probably syndepositional conditions and formed a displacive micronodular laminated lithofacies. Likewise the onset of anhydritisation was very early in clastic gypsum of the strandline. It formed abundant displacive anhydrite with intense syndepositional deformation structures related to nodule growth. This environment was subject to early exposure, high temperatures and high salinities. Later, a deeper burial anhydrite phase spread through the coarsely crystalline gypsum of the shelf. This created replacive nodular anhydrite in sediment hosts so that primary crystal textures are well preserved.

Porosity loss in these units is essentially complete by burial depths of 500m. After this, these anhydrous units, like halite at even shallower depths, are essentially impervious and act as aquitards and pressure seals to any crossflow of pore water, hydrocarbons or metals. Evaporite salt beds below 500-1000 metres typically respond to further burial by flowage and edge-focused dissolution.

Burial Salts: Nodules and stylolites

Subsurface sulphate-rich waters derived from deeply buried dissolving evaporites can precipitate anhydrite nodules in adjacent nonevaporitic strata. Such nodules are a form of burial salt fed by saline compactional and thermobaric waters. Superficially these nodules can resemble those of a sabkha anhydrite, but there are a number of distinguishing features (Machel, 1993; Machel and Burton, 1991; Warren, 1991). Most obvious is that the burial nodules precipitate in porosity zones that are not depositionally defined. They can occur within or adjacent to faults, or within open marine shelf carbonates, which are not intertidal/supratidal units. They often occur within, or juxtaposed to, dark, bituminous argillaceous seams and pockets, or within zones of anastomose bituminous veinlets and carbonaceous

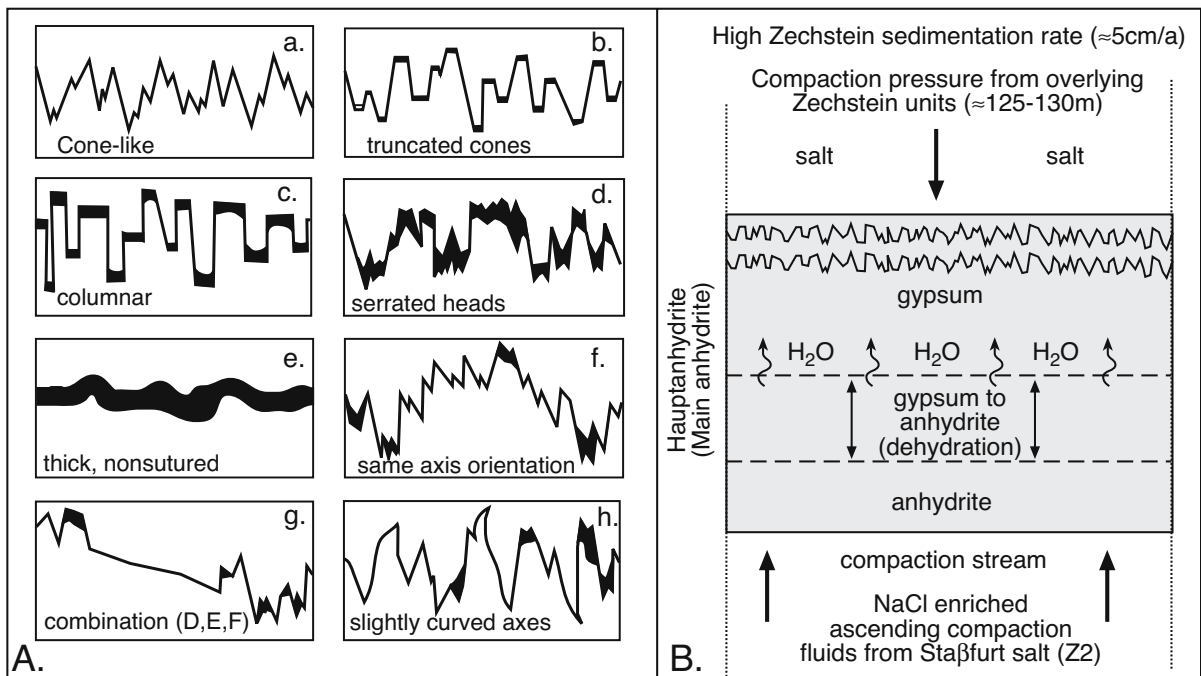

Figure 1.37. Stylolites in anhydrite beds. A) Types of stylolite seams or sutures hosted in the Hauptanhydrit (Zechstein) of the Gorleben salt dome, Germany. B) model for the development of stylolites in the upper part of the Hauptanhydrit during deposition of the younger Zechstein beds. Stylolitisation is restricted to a gypsum matrix (pre-anhydritisation) and occurred less than 150 m below the sedimentation surface (after Bäurele et al., 2000).

haloes, all of which are the result of pressure solution and stylolitisation. They typically replace the host rock and crosscut stylolite boundaries in the carbonate matrix. Thus, they enclose material generated during burial diagenesis, such as authigenic pyrite and saddle dolomite, and show little evidence of mechanical compaction. They are often associated with coarsely crystalline, late-stage poikilotopic and pore-filling anhydrite spar cements.

Stylolites hosted in a limestone or dolomite matrix are widely recognised pressure solution features though to indicate burial depths in excess of 0.5-1.0 km (Bathurst, 1980). Stylolites in evaporite beds are not common and may not necessarily form by such deep burial. Some have argued that anhydrite and halite can not exist at the pressure necessary to form stylolites without pervasive recrystallisation. But stylolite horizons do occur in the Gorleben Zechstein salt dome in the Bänderanhydrit located near the top of the Zechstein Hauptanhydrit (Bäurele et al, 2000). Stylolites were also noted by Peryt et al. (1993) in the Werra Anhydrit (Zechstein 1) of western Poland and by El Tabakh et al. (1998a) in the Basal Anhydrite of the Cretaceous Maha Sarakham of Thailand. The latter can be related to differential salt solution during burial flushing (Figure 7.33).

Bäurele et al. (2000) tied the pressure-solution seams in the Hauptanhydrit to the presence of thin magnesite-clay interlayers and distinguished five principal stylolite morphologies (Figure 1.37a). The orientation of the sutured seams is generally bedding-parallel with the stylolite axes vertical to the bedding surface. Some seams have been deformed by salt flow and the anhydrite beds with bedding parallel stylolites are now steeply inclined to the horizontal. There is no relation between stylolite formation and pressures created by the modern salt dome crest. Solution rates of up to 26% were calculated by measuring maximum stylolite amplitudes in core.

The bedding-parallel occurrence of the Hauptanhydrit stylolites, in combination with the observation that the stylolite seams are crosscut by anhydrite pseudomorphs after gypsum, argues that the stylolites formed before the dehydration of gypsum to

Figure 1.38. Rehydration fabrics in calcium sulphate from uplift, meteoric flushing and dissolution. These are the tertiary evaporites of Figure 1.1.

anhydrite was complete. The lower parts of the Hauptanhydrit were excluded from the stylolitisation process as they had already been converted to anhydrite by ascending compaction fluids of the underlying Zechstein 2 Salt (Figure 1.37b; Bäurele et al., 2000). Porosity and permeability loss that is an integral part of the conversion process prevents the formation of stylolites once any interval had converted to anhydrite. The transition depth in the Zechstein was around 125 m. Pervasive dehydration of gypsum to anhydrite in the Hauptanhydrit was probably complete before the end of Zechstein sedimentation. The arguments of Bäurele et al. (2000) imply that the formation of stylolites occurs in gypsum, not anhydrite, and is a relatively shallow burial process ($\approx 100-150\text{m}$).

Evaporites as uplift indicators

At the other extreme of the burial cycle is the conversion of exhumed and uplifted evaporite beds entering the telogenetic realm. Most common is the conversion of anhydrite into diagenetically regenerated gypsum (Figure 1.38). Uplifted halite beds first undergo differential dissolution to leave behind layers of residual nodular anhydrite, which are then dissolved by ongoing meteoric flushing (Figure 7.29). Two commonplace gypsum fabrics are the result of exhumation: coarse

porphyroblastic gypsum and fine-grained alabastrine gypsum (Holliday, 1970; Warren et al., 1990). Porphyroblastic gypsum often retains dispersed relics of the precursor anhydrite. Crystal forms are coarse, up to two cm across, and can be euhedral or anhedral, thin and acicular or thick and stubby. Porphyroblasts often aggregate into cm-scale rosettes or blebs with acicular gypsum rinds. This creates a texture that is sometimes described as “daisywheel gypsum.”

Daisy wheel gypsum is a response to rehydration under the relatively homogenous conditions of uplift hydrology in a massive nodular anhydrite unit entering the lowermost parts of the telogenetic zone. Rates of fluid crossflow are low, so chemical dissolution is slow and dissolution fronts tend to be focused about the bed contacts between aquifers and the anhydrite (gypsum is not stable at such depths). As an anhydrite bed is uplifted into the telogenetic zone it once again comes into contact with low salinity, low temperature waters. In many uplift situations there is also an artesian flow system established so that both karstification and rehydration to gypsum tends to at first be focused on the edge of the bed where satinspar gypsum tends to dominate. As rehydration to gypsum becomes more pervasive within a bed, it tends to penetrate first along the impurity-rich more permeable edges of anhydrite nodules. Sparry aligned gypsum crystals grow toward the centre of the nodules to form daisywheel gypsum (Warren et al., 1990). As the rehydration proceeds through the bed, some of the gypsum then dissolves to give greater access to undersaturated waters to the gypsum bed to create caverns. Because of the destructive nature of porphyroblastic overprinting, interpreting original

depositional environment is next to impossible in nearsurface and outcropping CaSO_4 units, they are composed almost entirely of diagenetically regenerated gypsum.

Alabaster is the other form of telogenetic gypsum and is created where anhydrite pervasively rewaters to gypsum in the zone of active phreatic flow. Individual gypsum grains are typically less than $50\ \mu\text{m}$, with grain boundaries that range from poorly defined to equidimensional granuloblastic. The change from porphyroblastic to alabastrine may be depth-related (Warren et al., 1990). Porphyroblastic gypsum defines the re-emergence of nodular anhydrite from the stagnant phreatic into the deep portion of the zone of active phreatic flow. Alabastrine gypsum forms in the zone of more diffuse active phreatic flow. This re-emergence is also associated with the formation of gypsum karst and the formation of evaporite-dissolution breccias (Chapter 7).

Excess amounts of trace elements, especially strontium and boron, are released from some bedded anhydrites as they reconvert to gypsum. The released elements may precipitate in the regenerating alabastrine gypsum as celestite or boron-bearing minerals, such as proberite, ulexite, tyreskite and priceite.

Fibrous gypsum and halite (satinspar)

Veins and fractures filled with fibrous satinspar CaSO_4 (typically gypsum) or halite are widespread in the mudstones and shales adjacent to bedded evaporite units undergoing dissolution. Fractures may be subhorizontal and lie roughly parallel to the contact with the bedded evaporite unit or may form as conjugates. The fractures form and fill with fibrous cements in response to stresses set up in the bed by the formation of nearby stratiform cavities (Figure 1.39). The fracture filling is usually zoned and made up of two or more parallel layers of either fibrous CaSO_4 or fibrous halite. Fracture-fill crystals are oriented with their long axes perpendicular to the fracture walls. Coarse calcite crystals can occasionally fill the centre of the fracture. Most fracture fills are monomineralic and gypsum is the dominant mineral in most nearsurface fracture systems. Internal fracture zonation is pronounced and reflects episodic and ongoing opening and

Figure 1.39. Meshwork of satinspar gypsum veins created by dissolution of an adjacent anhydrite bed in the Permian of eastern Saudi Arabia (car key for scale).

filling of the fractures. Some fibrous fills are sigmoidally deformed showing fracture fill was ongoing as adjacent blocks slid and rotated in response to changes in nearby dissolution cavities (El Tabakh et al., 1998b).

Fibrous halite and satinspar formation are linked to fracture and cavity formation in active hydrological systems. Fractures filled with satinspar are linked to uplift and either the generation of open fractures induced by subsidence associated with salt dissolution and uplift (Figure 1.40; Gustavson et al., 1994) or to hydraulic fracturing associated with the conversion of anhydrite to gypsum (Cosgrove, 2001). Thus fracture-filling satin-spar may be a passive process in open fractures or a more active process with fractures forced open by overpressured CaSO_4 -saturated artesian waters.

Superimposed on these processes may be the force of crystallisation of gypsum. Shearman et al. (1972) suggested that displacive satinspar veining is a feature of anhydrite hydration, which may have been due to hydrofracturing by overpressured confined groundwater as exhumed anhydrite reconverted to gypsum. Shearman et al. (1972) pointed out that if all the calcium sulphate is retained within the system, the hydration of anhydrite to gypsum should result in an increase in volume of 63%. They noted that in many secondary gypsum rocks, former anhydrite is replaced on a volume-for-volume basis, and the additional volume of gypsum appears as fibrous or satinspar veins that cut the associated rock. Gypsum grew in the water-filled fractures, whenever the overburden was supported by pressurised water.

Progressive sediment fracturing (hydrofracturing?) is thought to be a response to unroofing. Unloading and release of overburden weight drives the formation of near surface fractures parallel to the earth's surface. Fibrous halite and satinspar

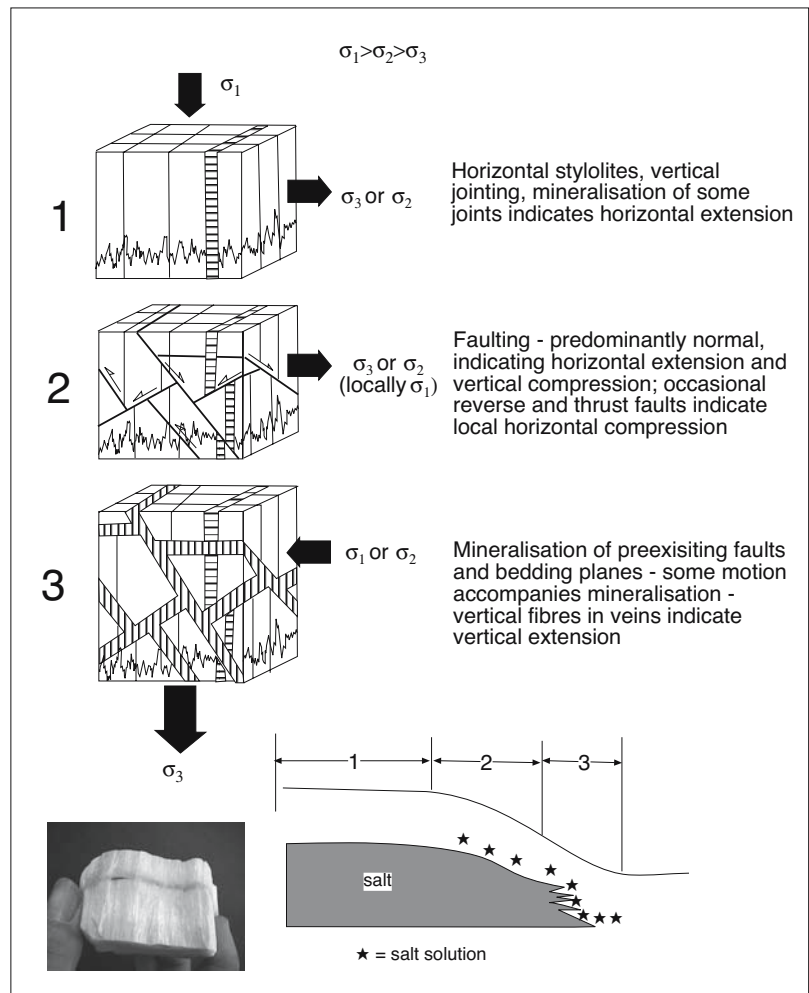

Figure 1.40. Conceptual model of deformation above salt dissolution zone showing structural sequence and proposed location relative to dissolution front. Stage 1 occurs prior to salt dissolution and is characterised by jointing resulting from normal burial. Late stage 1 and stage 2 occur as salt dissolution begins. Early stage 2 is characterised by a few vertical gypsum veins with horizontal fibres. Later stage 2 is characterised by normal faults and uncommon reverse faults. In stage 2 layer parallel extension results from the onset of dissolution and subsidence. Stage 3 is characterised by gypsum veining of bedding planes and faults. In stage 3 vertical extension results from widespread dissolution and collapse of underlying evaporites (after Gustavson et al., 1994).

CaSO_4 are commonly associated with, but not exclusive to, zones of exhuming evaporites (Figure 1.38). It is not known if satinspar filled fractures can also form at greater depths (1000s of metres) in mesogenetic realms associated with overpressuring and compactional or thermobaric waters.

Cosgrove (2001) describes networks of satinspar filled hydraulic fractures preserved only in the exhumed evaporite horizons of the Mercia Mudstones of the Bristol Channel Basin of south-

west England. Like Shearman et al. (op. cit.), he concludes its preservation relates to the volume changes associated with the hydration of anhydrite to gypsum, which occurred as the rock mass was exhumed and the relatively low temperature and pressure conditions necessary for the formation of gypsum were encountered (e.g., Jowett et al., 1993). Hydration in the Mercia Mudstones occurred during the tectonic inversion of the basin as basin sediments experienced tectonic compression during exhumation. This caused an increase in fluid pressure and facilitated the formation of hydraulic fractures that then fill with satinspar. Cosgrove goes on to argue that hydraulic fractures also formed in the muddy evaporite-free horizons. But the fractures reclosed and healed as soon as the fluids had passed through them and pressure had dropped as the appropriate brine required for their preservation as satinspar veins was not present within the nonevaporite sections.

The mechanism of creating satinspar filled fractures as documented by Gustavson et al. (1994) is a much more passive process. They note that most satinspar veins occur in highly fractured or brecciated strata that overlie or are associated with exhumed bedded halite, anhydrite and gypsum. There are often saline springs in the vicinity of a satinspar occurrence indicating active halite dissolution. In this scenario satinspar is a response to several hydrologically driven processes (Figure 1.40). Cavernous porosity is created as halite is dissolved by crossflows of low salinity active-phreatic waters down to depths of 200-750 metres. Extensional fractures form in the strata above these dissolution zones and anhydrite is rehydrated to gypsum either via a dissolution-precipitation interface or through a bassanite intermediary (Holliday, 1970). The deeply circulated groundwater is now saturated with respect to gypsum and any further anhydrite hydration results in supersaturation. Excess CaSO_4 now carried in solution by groundwaters flowing out of the dissolution zones precipitates gypsum in open high permeability fractures created during overburden collapse.

It may well be that the satinspar and the associated fracturing are a response to both active and passive modes of formation. Perhaps active hydrofracturing, as envisaged by Shearman et al. (1972), is more significant in driving satinspar fracture fill at greater depths where the dissolving evaporites and adjacent beds are still relatively tight and are first entering the telogenetic realm (via the zone of stagnant phreatic circulation. As exhumation and dissolution continues the fracture and fill process evolves into a more passive set of collapse induced features. This occurs once beds are shallower and have become more permeable. They have moved into the zone of active phreatic circulation and are closer to the landsurface (see Chapter 7 for more hydrological detail on the effects of telogenetic alteration).

Saline clay authigenesis

So far we have focused on the formation and alteration of the various evaporite salts, but the same evolving saline hydrologies can also drive the formation and alteration of clays (Table 1.5). Many authigenic clay minerals formed in hypersaline settings are enriched in magnesium (Fisher, 1988), but authigenic clays do not make up the greater volumes of clay in modern or ancient salt lakes. Most of the clays in salt lakes and playas are detrital and reflect compositions of older argillaceous formations in the palaeodrainage areas. Illite, kaolinite, chlorite, dioctahedral smectite and a number of mixed-layers clays are commonplace detrital clay minerals in saline formations (Calvo et al., 1999). Widespread flocculation of clays is an effective sedimenter of suspended clay wherever freshwater runoff and streams flood an area of standing saline water. Thus the composition of initial clay sediments in a playa largely reflects that of the minerals carried as suspended load into the lacustrine depression.

The magnitude of detrital clastic input is thought to be a significant factor in the relative volume of authigenic clay. Regions with rapid deposition of clays, tied to high detrital inputs, tend to be areas where the authigenic clay component is swamped by the high detrital input. Clay authigenesis in evaporitic basins is favoured in marginal playa areas where rates of detrital clay input are low (Figure 1.41). This encompasses interdunal depressions, peripheral sandflats

	Structural Formula	Mg/Si	Al/Si
Saponite	$(\text{Ca}, \text{Na})_{0.3}(\text{Mg}, \text{Fe})_3(\text{Si}, \text{Al})_4\text{O}_{10}(\text{OH})_2(\text{OH})_2 \cdot 4\text{H}_2\text{O}$	0.76-0.87	0.07-0.18

Table 1.5. Main authigenic clay minerals occurring in continental evaporitic environments (after Calvo et al, 1999).

Figure 1.41. Commonly observed distribution of authigenic clays in saline continental environments emphasising the differences between basins undergoing slow and rapid subsidence. Authigenic clays form mostly in saline lake-margin environments. Formation of authigenic clays in open-lake environments is dependent on the degree of schizohalinity. (after Calvo et al., 1999).

and muddy carbonate flats. In these low sedimentation areas the transformation of precursor clays is more effective, driven by episode surface inflow and groundwater discharge (Calvo et al., 1999). Highly reactive nearsurface and surface conditions are favoured by inherently large variations in pore water salinity, pH and pCO_2 levels.

Clay authigenesis in many saline depressions is driven by pedogenesis, especially in the marginal areas where sedimentation rates are low and subaerial exposure dominates at the sedimentation surface. Below the surface episodic wet-dry cycles means neoformed clays are the byproduct of complex reactions between Na and Mg-rich interstitial brines and detrital silicates. Pedogenic processes account for the formation of widespread lake margin palygorskite and sepiolite, typically in association with the creation of calcretes, dolocretes and silcretes. In cases where palygorskite dominates the soil profile, they are sometimes described as palycretes. Zeolites can also form from saline groundwaters in saline lake-margin pedogenic settings (Figure 11.61). Artesian and phreatic groundwater

discharge through springs into the lake margin areas also plays a significant role in the formation of other authigenic clays, as in saline lakes at the foot of Mt Kilimanjaro, in Tanzania and Kenya (Hay et al., 1995).

Once precipitated, authigenic clays can be retransported further out into the playa depression and in more humid climatic stages may even end up on the floor of freshwater lakes. This situation is seen in lacustrine sequences from the Miocene formations of the Madrid Basin (Bellanca et al., 1992) where significant amounts of palygorskite and sepiolite occur as either mud chips or clay aggregates in the basal part of a fresher water lacustrine unit. Eolian transport of saltating clay pellets or dust suspensions may also contribute to the transport of authigenic clays from marginal to more central areas. This sometimes leads to problems of interpretation of detrital versus authigenic in ancient lacustrine successions subject to oscillations in climate, especially when detrital clays are partially or fully inherited from arid soils.

Sepiolite, interstratified Mg-Smectite and palygorskite form authigenic phases in the Quaternary sediments of the Double Lakes Formation, Texas (Webster and Jones, 1994). The dominance of each of these minerals in separate horizons represents evaporative shifts in salinity at the time they precipitated. Sepiolite is thought to indicate a brackish lake, while Mg-smectite indicates more saline conditions. Palygorskite is interpreted as a saline pore water precipitate in the arid soils of the playa stage. Likewise Jones (1986) interpreted authigenic Mg-smectites (e.g. stevensite) as requiring higher salinity than sepiolite. Mg-silicates also define saline lake clays in Great Salt Lake (Spencer, 1983) and some Bolivian salars (Badaut and Risacher, 1983). In Bolivia, the authigenic Mg-smectite replaces the biogenic silica in diatom frustules and requires a pH in excess of 8.2. Authigenic stevensite occurs in unconsolidated muds underlying saline crusts in the interdunal depressions of northern Lake Chad and as small aragonite-associated oolites on the lake floor (Gac 1980, Darragi and Tardy, 1987). Similar stevensite oolites have been found in the Eocene Green River lacustrine basin. Authigenic sepiolite associated with calcite, gypsum and dolomite occurs about the margin of Saline Valley Playa, California and the edges of saline pans in the Kalahari of southern Africa (Hardie, 1968; Kautz and Porada, 1976). Palygorskite, sepiolite and authigenic smectite are commonplace precipitates in calcretes of groundwater discharge playas in inland Australia (Arakel et al., 1990).

Clearly, palygorskite and sepiolite (both two-chain structure fibrous clays) occur worldwide as authigenic phases in the soils and palaeosols of arid and semi-arid regions, but the mode of precipitation is still not well understood (Singer, 1979). Jones (1983) concluded sepiolite in the calcic soils of southwest Nevada required percolation of high salinity groundwaters. Magnesium and silica solutes were supplied by the weathering of nearby pyroclastics and carbonates. Sepiolite has replaced magnesite pebbles, from the edges in, during freshened highstand intervals in Miocene Lake Eskisehir in Turkey (Ece, 1998). Palygorskite in calcic soils is thought to be the result of incongruent dissolution of preexisting clays (Jones and Galán, 1988). Fibrous clays degrade when climate becomes more humid and alter to smectite. Paquet and Millot (1972) conclude that the transformation takes place when mean rainfall exceeds 300 mm and Calvo et al. (1999) suggested the transformation can be used as a palaeoclimatic indicator.

Alunite ($KAl_3(SO_4)_2(OH)_6$) is a common clay product in acid saline lacustrine settings (Figure 2.20), but can also form diagenetically in regions where sulphate reduction is occurring. It is thought to be derived by the reaction of clay minerals

with sulphuric acid created by oxidation of sulphides or H_2S at a redox boundary. It is a common product where clays are present in zones of sulphate reduction and examples have been documented in the Middle Miocene gypsums of the Gulf of Suez (Rouchy et al., 1995) and the Upper Miocene gypsums of the Lorca Basin in Spain (Rouchy et al., 1998).

Even the smectite to illite transformation, which is used as an indicator of diagenetic intensity and clay transformations occurring at higher temperatures may be influenced by salinity. This makes illite crystallinity a less reliable indicator of diagenetic stage in environments with saline pore fluids (Honty et al., 2004). Turner and Fishman (1991) found illite-smectite mixed layer clays having a range of expandabilities in altered tuff beds in a Jurassic lake in the Morrison Formation (Eastern Colorado Plateau, USA). The observed clays did not experience deep burial, and did not undergo hydrothermal alteration. The illite content generally increases from the lake margin (100–70% smectite) to the lake centre (30–0% smectite) and follows a lateral hydrogeochemical gradient, which was characterized by increasing salinity and alkalinity (Figure 11.62). It seems that in a saline depositional setting, solution chemistry is a principal factor controlling the smectite to illite proportion. Illite-smectite can form from smectite at low temperatures in several ways (see Honty et al., 2004), but forms best in saline environments subject to wetting and drying cycles, which is a hydrology exemplified in salt lakes and playas. In the presence of K^+ ions, alternating wetting and drying leads to irreversible fixation of K and the formation of illite layers. Illite-smectite clays forming at elevated pH may not even require wetting and drying cycles.

Textural Synthesis

Evaporitic settings can accumulate evaporitic carbonates as well as more saline salts dominated by gypsum and halite beds. Evaporitic carbonates accumulate across the whole range of brine depths from ephemeral to shallow perennial to deep. Carbonate laminites tend to dominate in the deeper brine areas, while a whole range of textures and features, including laminites, form in the shallow and strandzone settings. Strandzone regions are often characterised by pisolites and algal structures of various types, ranging from cryptalgalaminites to stromatolites and tufas. The ephemeral water and groundwater seepage systems that characterise strandzones facilitate the cementation and ongoing growth of carbonate crusts. Over time, these marginward carbonate crusts can grow and deform into overthrust V-shaped carbonate ridges called tepees.

The typical evaporite accumulating on the floor of a stable brine pool or a shallow shelf is composed of upward or growth-aligned crystals. Depending on the stability, salinity, and permanence of the overlying bottom brine, various mineralogical and dissolution surfaces can be superimposed on the upward growing prisms. When the overlying brine column is not subject to marked salinity fluctuations, then pristine crystal outlines are made up of stacked halite chevrons or zig-zag gypsums, with varying degrees of face curvature. When the overlying perennial brine body mixes and freshens, subaqueous crystal truncation surfaces can form. Similar surfaces can form where the brine body dries up. Desiccation-related dissolution surfaces are distinguished from subaqueous truncation surfaces by an inherent abundance of vadose, karst and geopetal features. These three are all features that form during complete drying and falling of the water table into the evaporite bed.

But evaporites do not just form on the bottom of a brine lake or seaway. They can also form where porewaters attain supersaturation in a preexisting nonevaporite matrix (secondary evaporites). Probably the best-documented textures of this type are sabkha nodules composed of anhydrite and gypsum in the supratidal sediments of the Arabian Gulf. Large crystals of displacive halite form in a similar fashion beneath the mudflats of the Arabian Gulf, where the capillary pore fluids are at halite supersaturation. Dense brines, created during the formation of primary and early secondary salts, can sink into the underlying sediments where they can facilitate backreaction and alteration processes in the now buried evaporite beds.

At greater depths of burial, evaporite salts can reprecipitate as pore-filling cements and burial salts. Many primary and early secondary textures are overprinted at this stage by dewatering and recrystallisation processes associated with compactional dewatering and thermobaric alteration. Brines created by the subsurface dissolution of evaporites may also reprecipitate as burial salts in nearby nonevaporite beds.

If evaporites beds survive the rigours of deeper burial, they can be uplifted and re-enter the active phreatic zone where they are once again subject to dissolution and recrystallisation. Satinspar fractures and alabastrine textures are common indicators of this style of alteration. Such evaporites can be classified as tertiary evaporites.

All of the textural and re-equilibration processes outlined in this chapter reflect the ongoing evolution of the brines that bathe the beds throughout their formation, burial and dissolution. Brine hydrology and its evolution is the fundamental control

on evaporites. In the next chapter we look at how brine evolution controls evaporites from the time they precipitate until the time they are completely dissolved.

Chapter 2: Depositional chemistry and hydrology

An evaporite is defined in Chapter 1 as a rock originally precipitated from a saturated surface or nearsurface brine by hydrologies driven by solar evaporation. There is no assumption as to the origin of the parent brine; it may be marine (thalassic), nonmarine (athalassic) or a hybrid. By definition, there is a need for aridity and for water loss to exceed inflow. This means deposition and diagenesis in evaporites is more climate dependant than in either siliciclastic or carbonate sediments. Reaction rates and reversibility are an order of magnitude faster. Suites of precipitated salts follow the geochemical make-up of the parent brine, while primary textures indicate hydrological stability and energy levels of the time of precipitation.

All evaporite salts are ionic salts, containing the major ions Na, Ca, Mg, K, Cl, SO_4 , CO_3 in varying proportions along with other less common ionic constituents, such as B, Ba, Sr, Br and I and varying amounts of structural water (Table 1.1). The mineralogy and order of precipitates in any brine pool is controlled by the ionic make up of the parent brine. This, in turn, reflects the chemical composition of lithologies contributing dissolved ions to the parent water on its way to the site of precipitation. Because of consistent ionic proportions in seawater worldwide, the modern marine evaporite series is predictable and tied to increasing salinity. With nonmarine brines, proportions vary according to source terrain and levels of hydrothermal input. Hence, the proportions of minerals and sequence of precipitation is more variable. But, we now know that the ionic proportions in seawater were not constant through time and that the modern evaporite series is not always a one-for-one analog for past marine-fed precipitates.

Quaternary climatic hydrology

Modern continental evaporites typically accumulate within ground-water discharge regions in semi-arid to hyperarid^{2.1} deserts (Figure 2.1a; Table 2.1). Coastal evaporites occur at the oceanic edge of the same deserts, typically in coastal depressions fed by marine seeps or by rising groundwaters along coast-parallel mudflats. Evaporites also form lake precipitates and efflorescences in cold polar deserts in Antarctica, but the volumes of salt in these cryogenic regions pale to insignificance compared to arid settings closer to the equator. Brine freezing

and mixing, rather than direct solar concentration, plays a much more important role in the crystallisation of most cold climate salts (Carlson et al., 1990; Marion et al., 1999).

Salt-accumulating continental depressions typically define the discharge areas of endorheic (internal drainage) basins; these are areas where more water is leaving the via evaporation than entering as rainfall, snowmelt, surface, or subsurface inflow (Table 2.1). They are found in: 1) tectonic basins, which include fault-defined intermontane basins and intracratonic structural sags, 2) interdune or inter-draa depressions about the edges of sand seas or ergs, 3) wind-deflation hollows, 4) abandoned fluvial valleys 5) bolide-impact or volcanic craters, or 6) interior drainage depressions created by a combination of the preceding. The greatest volumes of desert salts today accumulate within arid to hyperarid depressions in continental rifts, compressional sags and transforms.

Climate drives evaporite deposition at scales ranging from broad latitudinal belts (100s km) down to microclimates (cms; Table 2.2). At the broadest scale, evaporites in deserts are the result of large-scale atmospheric circulation. Modern deserts cover more than 30% of the world's landsurface, mostly within two belts lying 15° to 45° north and south of the equator (Figure 2.1b). Belts of aridity sit beneath cold dry descending air masses of the Hadley Cells, which define high-pressure belts known as the subtropical Trade-Wind Belts or Horse Latitudes. Global-scale atmospheric circulation is driven by varying intensities of solar irradiation, which is most intense directly above the equator and lessens toward the poles (Figure 2.1c). Hence, the equatorial belt experiences greater insolation than the adjacent temperate latitudes. Equatorial air warms as it rises, creating a tropical belt of low pressure. As it rises it cools, losing most of the water vapour as rainfall to the tropical jungles and rainforests below. This now moisture-depleted air moves up and away from the equator and further cools and compresses. Finally, it sinks back to the earth's surface at around 30° latitude north and south of the equator. The cool descending dry air is reheated as it returns to the lower atmosphere, garnering an enhanced potential to absorb moisture, and so the major desert belts of the world are created (Figure 2.1c).

Earth-scale distribution of Holocene climatic belts reflects current atmospheric dynamics. When the icecaps expand the circulation belts are pushed and compressed toward the equator and they have done so numerous times in glacial maxima of the current icehouse climate mode. This increases the intensity

^{2.1} Semi-arid deserts have a mean annual precipitation of between 250 and 500 mm. Arid deserts have less than 250 mm of annual rainfall. Extremely arid or hyperarid deserts have at least 12 consecutive months without rainfall.

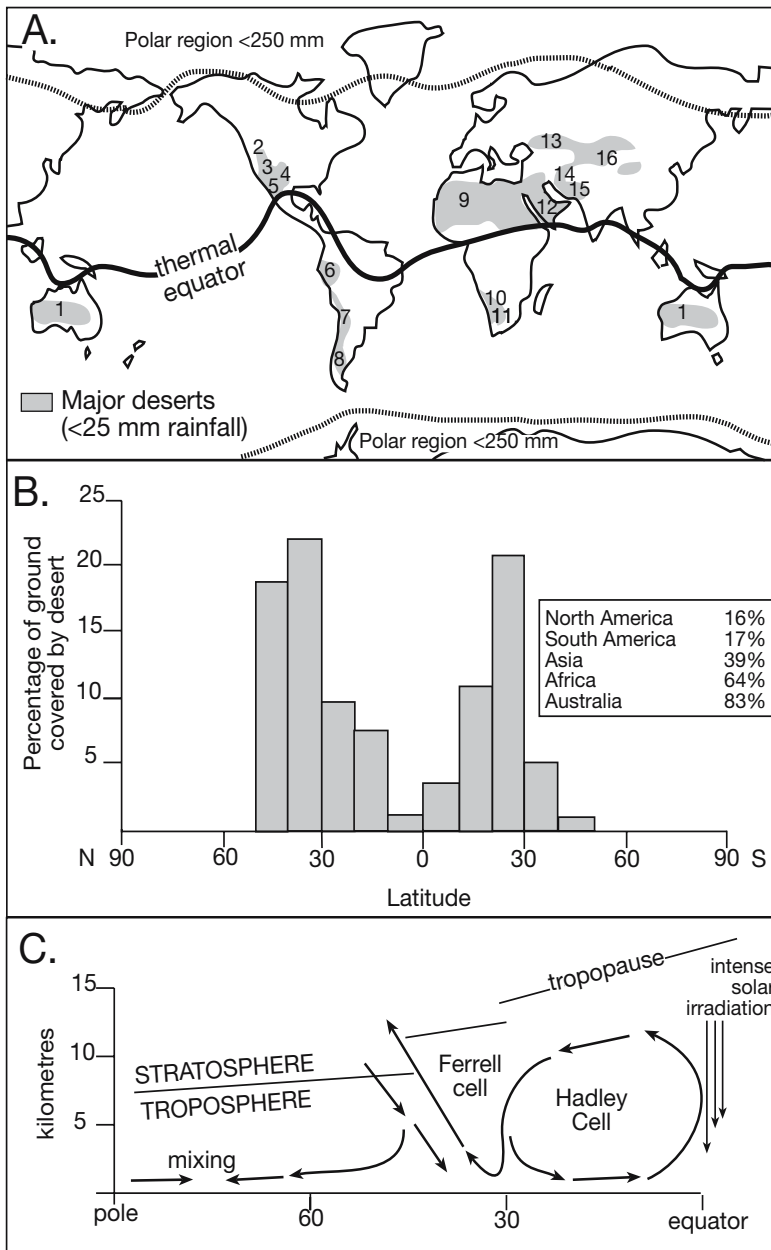

Figure 2.1. A) World distribution of modern deserts as determined by plotting areas with less than 250 mm annual precipitation. 1. Australian, 2. Great Basin, 3. Mojave (Sonoran), 4. Chihuahuan, 5. Baja California, 6. Peruvian, 7. Atacama (Chilean), 8. Patagonian, 9. Sahara, 10. Namibian, 11. Kalahari, 12. Arabian, 13. Turkestan, 14. Iranian, 15. Thar, 16. Gobi. Also shows polar regions with less than 25 cm precipitation. B) Latitudinal distribution of the world's modern deserts. Inset gives proportion of each continent that is arid or semiarid. C) Longitudinal cross section through the earth's atmosphere showing major circulation cells. Belts of cool dry descending air at 30° N and S of the equator create the main arid zones of the world (after Warren, 1989).

of circulation and alters the latitudinal distribution of climate belts. It has a marked effect on climate in Quaternary deserts, so that almost all modern continental playas in the Horse Latitudes have experienced numerous water-full versus dry stages in the last few hundred thousand years.

For example, the strontium-isotopic composition of preserved gypsum in Lake Frome, a large discharge playa in South Australia, records periods of high rainfall at 3-6, 12-15, and >17 Ka, and drier periods at ≈10 and ≈17 Ka (Ullman and Collerson, 1994). In the last interglacial (early in oxygen isotope stage 5) a nearby and much enlarged Lake Eyre maintained a perennial freshened water body upto 25 m deep (Magee et al., 1995). Subsequently, as climate deteriorated into glacial mode, there were a number of dry periods separating successively less effective wet phases, culminating in the deposition of a substantial halite salt crust around the time of the last glacial maximum. Lake Eyre only attained its present saline mudflat/ephemeral playa status some 3-4 Ka. The drying trend over the last hundred thousand years in Lake Eyre corresponds to a longterm lessening of monsoon intensity in the northern part of Australia, which is the main source area for waters flowing into the lake depression.

In Death Valley, USA, there were dry mudflats, characterised by abundant glauberite, gypsum and minor calcite from 0-10 Ka and 60-100 Ka (Li et al., 1997). In contrast, the wet period from 10-60 Ka was typified by halite and mud layers, with relatively abundant calcite. It encompasses sediments deposited 10-35 Ka, when Death Valley contained a perennial halite lake. This change matches a predominately Na-Ca spring-fed inflow during dry climatic periods and increased volumes of bicarbonate-rich river waters in the wetter periods.

Local topography induces variation in climate that can drive desert and playa formation. For example, the playas and midlatitude deserts of central Asia and central Australia are in part a product of their isolation from the nearest ocean. Continentality is the term that describes the geographic isolation of a desert by its large distance from the ocean. It explains why the highly continental Takla Makan Desert of central China is a hyperarid desert at 50°N latitude, well north of the world's subtropical high pressure belts. The other factor helping form this type of desert is the rain shadow effect.

Rain shadow deserts, also known as adiabatic deserts, form where air masses move up and over mountain ranges (Figure

2.2a). As air rises over a mountain range it cools, moisture develops into clouds and falls as rain on the side of the mountain range facing into the prevailing wind. Subsiding air on the other side of the range is dry and its moisture-bearing capacity increases further as it sinks and warms. For example, the deserts of Patagonia lie on the lee side of the Andes, while the deserts of Nevada and Utah are in the rain shadow of the Sierra Nevada. Adiabatic deserts can also be found behind the Himalayas, the Ethiopian uplands and Eastern Highlands of Australia. Extreme examples include the Dead Sea rift and the Afar depression, both areas are subsealevel depressions surrounded by high mountain ranges of the rift rim. Rain shadow effects increase where the region inland of the mountains lacks relief.

	Region	Location and setting	Notable evaporite features
Africa	East	Continental Danakil Depression, Lake Magadi, Lake Natron, Lake Kivu, Lake Tanganyika, Lake Turkana, Lake Urmia	Continental evaporites. In addition to large volumes of halite and CaSO_4 , potash salts and trona are important salts in particular lakes with mineral evolution dependent on inflow chemistry.
	North	Continental Saharan ergs, Lake Chad, chotts of northern Africa	Sodium carbonate is the dominant primary mineral in Lake Chad, while sodium sulphate and sodium chloride occur in subordinate amounts. Potassium and magnesium salts occur in near negligible amounts.
		Coastal Coastal sabkhas and salinas of Algeria, Tunisia, Libya, Morocco, the Nile delta and the Red Sea	Coastal sabkhas and salinas dominated by gypsum and anhydrite with small volumes of potash in modern chotts and sabkhas of Tunisia.
	Southern	Continental Pretoria, Otjiwalundo and other salt pans, interdunal sabkhas of Namibia	Thousands of small wind-aligned salt pans, often with downwind lunettes, dot the arid landsurface. They form preferentially on a clayey substrate that is made up of the Ecca and Dwyka Shales in South Africa, the Karoo in Namibia and the Kalahari Beds in Botswana.
	Middle East	Continental Rub al Khali ergs, Dead Sea evaporites	Dead Sea is accumulating pan halite in the shallow southern basin, along with carbonate laminites and massive halite in the deepwater northern basin.
Coastal Coastal sabkhas and salinas of the Arabian Gulf		Nodular calcium sulphate with minor halite in classic coastal sabkha successions of Abu Dhabi, Saudi Arabia and Kuwait.	
Antarctica	Continental Lake Bonney, Taylor Valley; Lake Vanda, Wright Valley, Organic Lake, Deep Lake and Ekho Lake in the Vestfold Hills.	Aragonite in the Taylor Valley and the Vestfold Hills. Sulphate minerals predominate in the Wright Valley. Halite and mirabilite are widespread (brine freezing). Trona and thermonatrite in the East Taylor Valley, and soda nitre, bloedite, and darapskite in the Wright Valley. Antarctite ($\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$) in Don Juan Pond.	
Asia	Central	Continental Qaidam Basin, Gulf of Kara Bogaz, Lake Inder	Potash salts (especially carnallite) are accumulating as karstic fills in bedded halite in perennial lakes and playas of the Qaidam Basin. Borates occur in Lake Inder.
	Southern	Continental Iranian playas; Van Golü, Salda Golü and Tuz Golü, Turkey; Didwana Lake and other playas of Thar desert	Iranian playas show complex facies interactions with rising salt diapirs. Turkish lakes are accumulating large volumes of magnesium carbonate and dolomite.
		Coastal Coastal sabkhas of Ranns of Kutch, India	Gypsum and halite sabkhas, widespread fluidization textures from earthquakes.

Table 2.1. Quaternary examples of evaporite accumulations in various deserts.

	Region	Location and setting	Notable evaporite features
Australia	Eastern	Continental Lake Tyrell, Lake George, Maar Lakes, Lake Victoria	Continental salt lakes (playas), some with gypsum/clay lunettes that rim brine pans; others, especially in volcanic maars, are characterised by Mg-rich carbonate sediments and crusts.
	Central	Continental Lake Amadeus (Karinga Creek lakes), Lake Eyre, Lake Frome, Lake Torrens Simpson and Victoria deserts	Continental salt lakes (playas), typically with gypsum lunettes that rim the deposit's brine pan. Many lunettes were more active in the Late Pleistocene. Salt crusts are now largely recycling through the lakes, with no massive accumulations. There is a fresher artesian aquifer beneath many continental lakes. Mostly halite and gypsum accumulate in the lakes, minor thermadite/mirabilite accumulating in the Karinga Creek area.
		Coastal Marion Lake complex, Lake Macdonnell, Streaky Bay Lakes, Fisherman Point sabkhas	Coastal lakes or salinas are classic Holocene areas for coarse-grained gypsum beds up to 10-15m thick, pisolite seepage pavements, modern tepees, mm-laminated domal stromatolites.
	Western	Continental Lake Lefroy, Lake Cowan, Lake Dundas, Lake Ballard, Lake Carey, Lake Raeside	Continental playa lakes within elongate and sinuous Tertiary palaeodrainages on the Yilgarn Craton. Evaporitic fill in the lakes is upto 10 m thick and mostly gypsum with lesser halite. Wind and wave-driven currents rework sediments that are then deflated by the wind to be redeposited in marginal gypsum dunes (lunettes).
Coastal Lake McLeod, Hutt Lagoon, Leeman Lagoon		Coastal lakes or salinas with gypsum and halite in beds up to 10-15m thick in Lake McLeod.	
Europe	Spain	Continental Playas of Los Monegros and Bajo Aragon, Laguna de Tirez in La Mancha	Glauberite and other sodium sulphates accumulating in modern playas.
Americas	Central Canada	Continental Ceylon Lake, Freefight Lake, Deadmoose Lake, Little Manitou Lake and many other saline lakes and playas on the Great Plain of central Canada	Salt pan and perennial subaqueous evaporites containing mirabilite, thenardite, and bloedite. Some lakes, such as Freefight and Deadmoose, are accumulating salts in perennial "deep" waters (10-30m).
	Northern USA	Continental Saline lakes and interdunal sabkhas, Nebraska and North Dakota. Draas of the southwest USA	Salt pans containing sodium sulphate salts, as in Central Canada.
	Southern USA	Continental Salt Flat playa, west Texas; playas in Rio Grande Rift	Pleistocene continental lacustrine accumulations of mostly gypsum±halite, now deflated and overprinted by Holocene sabkha signatures.
		Coastal Laguna Madre	Coastal mudflats with displacive gypsum.
	Western USA	Continental (Basin and Range) Death Valley, Saline Valley, Deep Springs lake, Searles Lake, Bristol Dry Lake, Great Salt Lake, Owens Lake, Salton Sea	Quaternary continental lakes with diverse range of salts including thick halites, lesser anhydrite, trona, glauberite and other salts depending on chemistry of inflow waters. Holocene is a time of saline mudflats, at other times in the Pleistocene the depressions were beneath the waters of a saline/brackish lake.
South Americas	Continental Salar de Atacama, Salar Uyuni, Salar Coipasa, Pastos Grandes, Laguna Salinas, Salar de Pintados	Large volumes of continental evaporites accumulated within the central Andes during Neogene uplift of the Altiplano-Puna plateau with associated development of the Andean volcanic arc. Halite and gypsum are dominant minerals, along with local and economically important borates, nitrates and potash salts.	
	Coastal Bocana de Virilá, Peru	Large volumes of marine-fed estuarine evaporites in a drowned river valley.	

Table 2.1 continued. Quaternary examples of evaporite accumulations in various deserts.

Rainshadow deserts and bedded evaporites are often part of a longer term tectonic association between sedimentation and climate in both extensional and compressional settings and are a climatic response independent of whether the earth is in

greenhouse or icehouse climate mode (Hay, 1996). Over millions of years, the rifting of continental blocks involves broad upwarping, followed by subsidence of a central valley and uplift of marginal shoulders. The result is an evolving regional climate-sediment association that is repeated many times in the Phanerozoic: first a vapour-trapping arch with centripetal fluvial drainage forms. This is followed by a rift valley, first with fresh-water lakes, culminating in an arid subsealevel evaporitic rift bordered by mountains intercepting incoming precipitation (adiabatic desert). Convergence tectonics also affects climate on a large scale. A rising mountain range is a barrier to atmospheric circulation, especially if perpendicular to the incoming circulation. The uplift of the Tibetan Plateau in the Late Tertiary created an easterly jet stream, which now flows from Tibet across the Arabian Peninsula toward Somalia. This stream of dry air accentuated the existing aridity and created an adiabatic desert that lies almost on the Equator. In the past both extensional sag and compressional tectonism have helped induce hyperaridity atop large subsealevel seepage depressions, which were capable of accumulating thick halite and gypsum successions (Figure 5.27).

Upwelling ocean waters off continental landmasses in the trade wind belts favour coastal deserts. Cold upwelling ocean water creates a belt of coast-parallel cool water. And, as evaporation is a function of heating, cold offshore oceans provide less moisture and less cloud to the adjacent land. The cool air above creates relatively dry onshore winds. As this colder air moves across the land it is heated, so developing an increased capacity to absorb rather than shed moisture (Figure 2.2b).

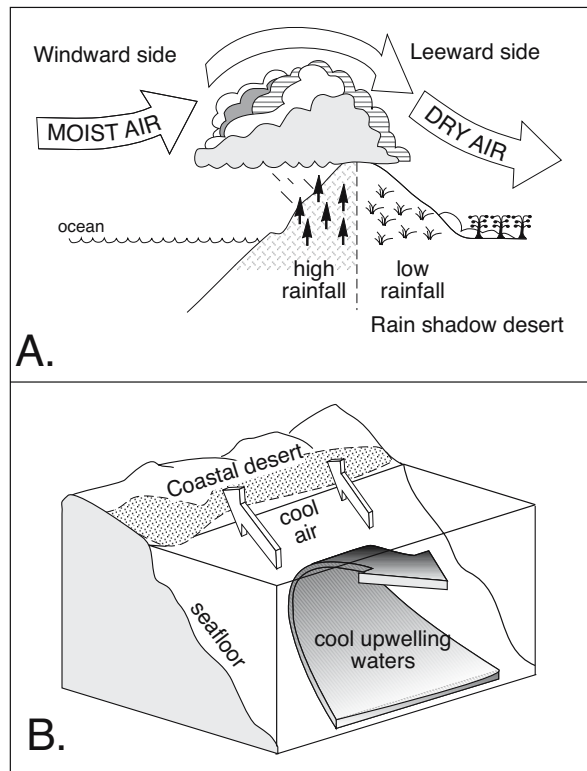

Figure 2.2 Local controls on deserts. A) Adiabatic or rain shadow desert where rain tends to fall on the seaward side of the mountains. B) Coastal deserts form in response to cool upwelling ocean waters and the cool dry onshore winds warming as they pass overland.

Cause	Locations	Examples
Descending or stagnant air mass	Subtropical regions. Regions beneath the descending limbs of Hadley cells (centred around 20-30° north and south of the Equator.	Sahara, Namibia, Kalahari (Africa) Chihuahuan and Sonoran (North America) Great Sandy and Simpson deserts (Australia) Arabian, Iranian, Thar deserts (Middle East and India)
Continentality	Regions within the continental interior. Locations isolated by distance from moisture sources, principally the oceans.	Saharan (Africa) Turkestan, Talimaklan, Gobi (Asia) Great Basin (North America)
Adiabatic or Rainshadow	Regions located in the lee of topographic barriers, such as mountains and plateaus. Cooling of rising airmass creates rainfall on the windward/ seaward side of a mountain range or barrier. As airmass subsides on the leeward side it warms and dries.	Turkestan, Talimaklan (Asia) Great Basin, Colorado Plateau (North America) Monte, Patagonian (South America)
Cool sea surface temperatures	Continental regions adjacent to cool (upwelling) seawater zones. The amount of moisture evaporated from the ocean surface is less under cooler conditions, so yielding drier air. Cooler sea surface temperatures also stabilize air masses, reducing convective rainfall.	Western Sahara, Namibia (Africa) Peruvian, Atacama, (South America) Rub'Al Khali (Saudi Arabia)

Table 2.2 Causes of modern deserts. (see Figure 2.1a for locations), typically more than one factor drives desertification.

Offshore, these cool strips of water are frequently engulfed in winter sea fogs, created by a blanket of warmer air atop cold seawater. Such cold upwelling ocean currents account for the deserts of Baja California and the Namib of southwest Africa (Benguela Current). The Peru Current, as it upwells along the west coast of South America, helps maintain hyperaridity in the Atacama Desert of Chile, which receives around 1 mm of rain every 5-20 years making it the driest desert in the world.

Fog, rather than rain, is the main supplier of moisture to coastal deserts in such areas and it also moderates the coastal air temperature. A range of unusual desert plants and animals have evolved behaviours and physical adaptations to make maximum use of this foggy water. For example, in the early morning some Namibian desert insects with water-capturing fluted carapaces stand on the coastal dunes with sails-high to collect condensation from foggy onshore morning breezes.

The present western edges of most tropical or Trade Wind deserts are washed by cool ocean currents driven by large scale ocean gyres, which rotate anticlockwise in the Southern Hemisphere and clockwise in the Northern Hemisphere. Throughout much of the Phanerozoic, coastal deserts in ancient trade wind belts, indicated by eolian dunes and evaporites, have characterised the western sides of continents (Hay, 1996).

At finer climatic scales, variations in effective evaporation rates influence salinity of any brine body or pore waters in nearby mudflats/sandflats. This in turn influences mineralogy and the preservation potential of precipitated salts. Water vapour pressure over a free-standing brine decreases with increasing salinity. Saturated water vapour pressure over any salt solution is always lower than the vapour pressure of pure water at a given temperature. This is due to the binding of water molecules into hydration sheaths about the various charged ions dissolved in the brine. As the concentration of a surface brine increases, the water vapour pressure decreases in the overlying air mass, reaching its lowest value when the brine is saturated (Kinsman, 1976). At very high salinities the pressure difference between the brine and the air immediately above the brine can become so small that evaporation effectively shuts down and the higher salinities necessary to precipitate the bitter salts may not be reached (Figure 2.3a).

Aerodynamically, the evaporation rate of a surface brine is the product of wind velocity and the difference in water vapour pressure between the main air mass and the air above the surface of the evaporating brine. Complete humidity-induced shutdowns are rare as the air above an evaporating brine body is usually

in continual motion, driven by adiabatic, catabaric and onshore breezes. Salinity of a freestanding brine is a function of wind speed, surface roughness and atmospheric stability in the air above the brine (Figure 2.3; Myers and Bonython, 1958).

Elevated above-brine humidity and limited lateral extent (tens of kilometres) creates a natural buffer to evaporation above modern coastal lakes or sabkhas. Lower salinity evaporites, gypsum and halite, are the dominant precipitates in modern coastal lakes beneath humid marine air, such as the coastal pans of the Saudi Gulf coast and the coastal salinas of southern and western Australia. Gypsum with minor anhydrite is the dominant salt in both the capillary zone and the phreatic zone of most modern arid coastal hydrologies such as the sabkhas of Abu Dhabi (Kinsman, 1976). Any efflorescences or crusts of bitter salts cannot last long, and are recycled or washed away by occasional rainstorms and sheet floods.

Evaporitic shutdown will have an interesting effect on the currently falling water level of the Dead Sea basin. Asmar and Ergenzinger (1999) conclude that the actual evaporation rate of the surface brines in the Dead Sea will become zero at a salinity of 483 - 486 g/l. As water loss can then no longer be driven by evaporation, the currently falling Dead Sea level should stabilise when currently increasing salinities reach this level (Figure 2.3b). The evaporation rate data were calculated using a modified Penman method and were fitted as a function of salinity, where salinity (S) is in g/l and evaporation rate (E) is in mm/year. The relationship is

$$E = 1826.1 - 1.6405S + 0.0116S^2 - 3 \times 10^{-5}S^3$$

Asmar and Ergenzinger emphasize that this equation is an estimate and should be used with caution.

Intrabasin variations in temperature and effective evaporation influence the volume and mineralogy of precipitated sediments and there is often a feedback between these various factors. For example, there is a decrease in the efficiency of capillary evaporation wherever a white salt crust covers the surface of a saline mudflat. The decrease is not just related to a humidity increase in the air above the mudflat, but also to the increased albedo (reflectance) created by the white surface of the salt crust. The amount of short-wave radiation absorbed by any soil surface is largely a function of its albedo (a measure of the amount of light reflected). It varies from 0.2 (20%) for a water saturated soil surface to 0.75 (75%) for a salt-encrusted surface (Malek et al., 1990). A salt-encrusted mudflat on a clear calm sunny day makes use of only a quarter of the incoming energy

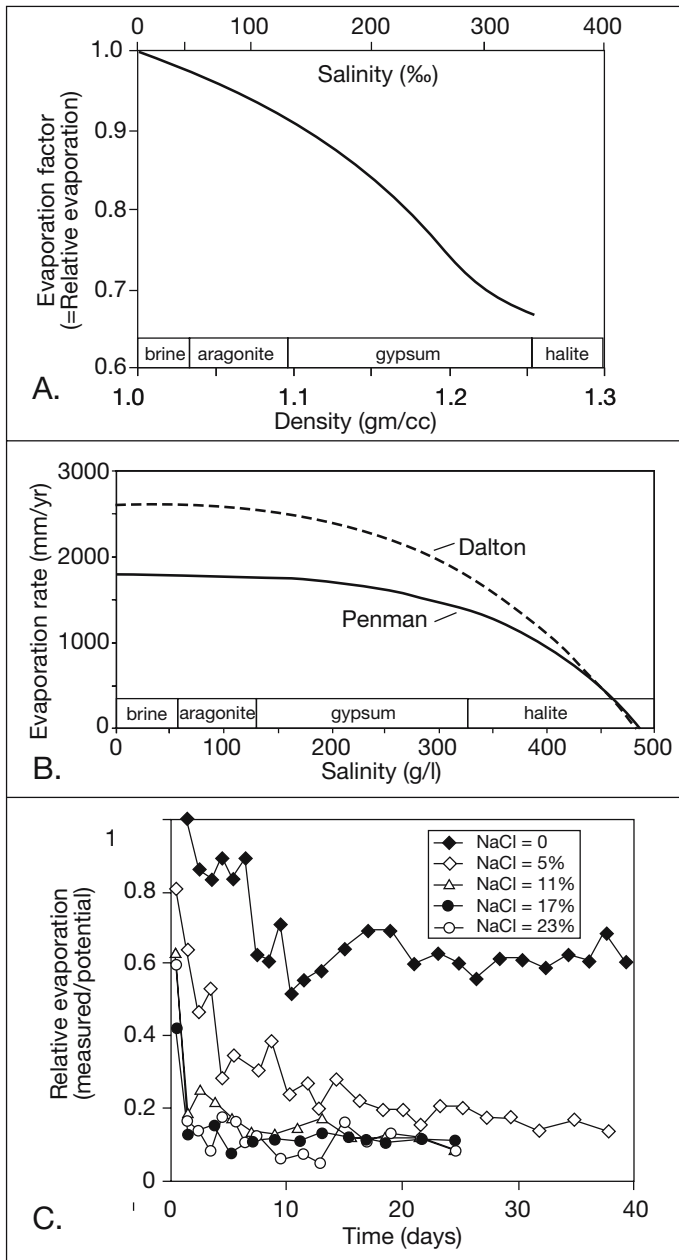

Figure 2.3. Evaporation and salinity. A) Evaporation efficiency decreases as salinity/density of the surface brine increases. Evaporation factor is applied to measured pan evaporation to attain a more realistic estimate. For example, a brine with a salinity around 200‰ has an actual evaporation rate that is only 85% of the measured evaporation rate (after Myers and Bonython, 1958). B) Effect of salinity on evaporation rates in the Dead Sea using the predictive formulae of Penman or Dalton (after Asmar and Ergenzinger, 1999). C) Effect of salt crust formation on the relative evaporation (measured evaporation rate/potential pan evaporation) with waters of variable concentration lying beneath the subaerial crust (after Newson and Fahey, 2003).

(drives evaporation) compared to a damp crust-free seepage mudflat. For the same reason, sediment below a white salt crust will stay moister for longer in the absence of ongoing inflow/seepage.

To quantify the effects of salt crust formation on evaporation rate, Newson and Fahey (2003) conducted a series of laboratory evaporation experiments using artificial soils saturated by water with various NaCl contents ranging from freshwater to concentrations of 23% (mass salt/mass solution). Their aim was to develop an understanding of salt crust formation in order to increase the efficiency of desiccation in mine tailing dams and so improve remediation efficiency. But their results are pertinent to the hydrology of any salt-crust mudflat. Relative evaporation (ratio of actual to pan evaporation) for the freshwater system fell to about 0.6 after about 10 days, and then remained near constant (this indicates capillary equilibrium with fresh water in pores = no salt crust). However, for all other experimental runs using saline water of varying initial concentrations, the relative evaporation ratio was much lower, and once the salt crusts had formed consistently reached values around 0.1–0.2 of potential freshwater evaporation rates (Figure 2.3c). For the high concentration pore waters the reduction occurred almost immediately, and somewhat more slowly for the starting solution with the lowest NaCl concentration ($C = 5\%$). Their results indicate that even a moderate amount of salinity in any feed brine in a semi-arid to arid setting will quickly form a salt crust that severely reduces the relative evaporation rate above the crust.

Their experimental data compares well with observations made for salt-encrusted surfaces on playas and salt lakes around the world. Natural salt encrusted mudflats typically display relative evaporations of the order of 0.03–0.2, for potential evaporation rates of 1.5–3.5 m/year (Malek et al., 1990). For example, the measured effective evaporation rates above salt-free mudflats in Lake Frome, Australia range from 90 to 230 mm/year and average 170 mm/year (Allison and Barnes, 1985). In areas in the same lake covered by white salt crusts the effective evaporation rate falls to 5–30 mm/year (equivalent to relative evaporation of 0.03–0.18; Ullman, 1995).

Newly formed salt crusts are porous, variably buckled layers (pressure ridges and petees) that lack direct contact with the underlying sediment over at least 50% of the crust base (Newson and Fahey, 2003). Air-filled cavities reduce areas beneath the crust where capillary moisture can be transferred in a liquid phase through the salt crust to the air during evaporation. Coupled with this, the high porosity and broader pore throats in newly-formed salt crust, drastically reduces the rate of capillary rise of water compared to a clay or mud and so further reduces the liquid phase continuity to the crust/air interface. Once a crust forms, the only widespread effective mechanism for moisture transfer from the underlying mud to the overlying air mass is by diffusion in the vapour phase. This means mechanisms involved in reduction of the effective evaporation rate from any salt-encrusted mudflat are varying combinations of; 1) an increase in albedo, 2) resistance to moisture transfer and, 3) a decrease in the saturation vapour pressure of the pore fluid.

In a brine pool-entraining modern playa there is substantial cross-playa variation in effective evaporation rate depending on sediment type, proximity of the water table to the landsurface, the presence or absence of salt crusts and the permanence of surface brine sheets. An excellent set of data illustrating this complexity was collected during 1993-1996 in Owens Lake, California using monitored lysimeters and evaporation pans (Figure 2.4; Tyler et al., 1997). Measurements were not made during the period autumn (fall) 1994 to winter 1995 due to playa-wide flooding that marked the end of a long drought period. Rain preceded each summer and autumn measurement period in 1993 and 1994 by at least 15 days and was not significant (1 mm or less). Spring measurements may have been

influenced by prior rainfall, with 3 mm falling 1 day before the 1994 measurements and 19 mm falling 21 days before the 1995 measurements.

Figure 2.4 plots the averaged daily evaporation rate as a function of season of measurement from the three study areas in Owens Lake (sandflat, mudflat and free surface brine; Tyler et al., 1997). Evaporation from the sandflat appears to steadily decline from initial measurements in summer 1993 to autumn (fall) 94 and may reflect the prolonged drought and subsequent decline of the water table in this area. In contrast, evaporation from the salt-crust mudflat shows similar summer rates in 1993 and 1994. The insensitivity to drought in these saline clayey soils may be related to the continued high water contents maintained by capillary rise to elevations well above the water table. The mudflat site also shows highest evaporation rates during spring periods (0.5 mm day^{-1}), when near-surface soil moisture is at its highest level. During these periods, the overlying salt crust is less desiccated and so may also maintain better hydraulic contact with the underlying sediments.

Malek et al. (1990) postulated that loss of hydraulic contact between lake sediment and an overlying salt crust impedes capillary evaporation loss by effectively forming the equivalent to a mulch layer over the clayey substrate. During both spring measurement periods in Owens Lake, no decline in evaporation rate was observed throughout the period of measurement, suggesting that rain before the measurement dates had little influence on the evaporation rates. Winter evaporation rates were slightly higher than those recorded during the autumn months, although they are similar. The winter measurement period was

characterized by warmer than average daytime temperatures, which may have slightly increased the evaporation rates. However, wind conditions were uncharacteristically calm, with maximum daily wind speeds rarely exceeding 1 m s^{-1} , which may have reduced the evaporative flux.

Rates measured in the brine pool in spring 1994 were below those in the previous summer, owing to lower temperatures and decreased net radiation (Tyler et al., 1997). However, evaporation in the brine pool area in the following summer and autumn of 94 were much lower than expected for a free-standing saline water body. The

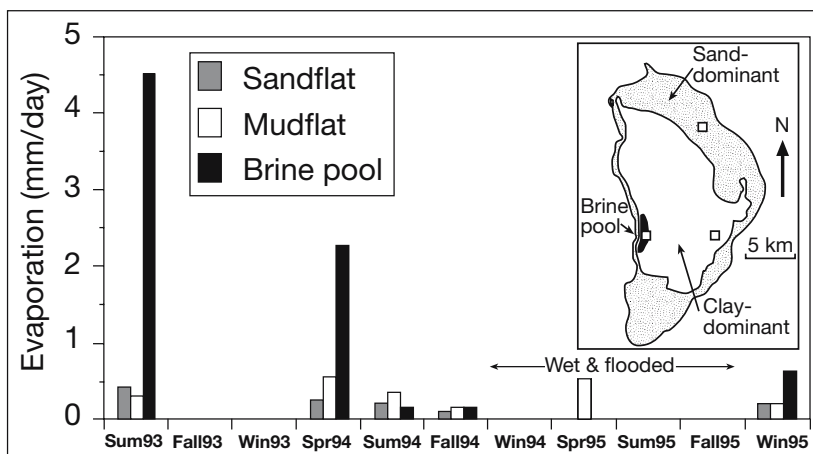

Figure 2.4. Seasonally measured evaporation from the three dominant types of surface sediment in Owens Lake, California. Squares in the inset map show monitored sites (after Tyler et al., 1997).

dramatic reduction in evaporation in 94 was due to a thin (less than 2 mm) floating crust of halite rafts that covered the entire extent of the brine pool. Both periods of measurements in the brine pool were characterized by calm conditions, which allowed the crust to remain intact and effectively cut off evaporation. Winter evaporation rates over the raft-covered brine pool averaged 0.6 mm day^{-1} , almost an order of magnitude below that measured during the raft-free summer of 1993. Rafted crusts are a part of the evaporation setting of most halite-saturated brine pools/sheets and are another reason why brine sheets remain for extended periods in some salt lakes. Surface water sheets in nearby less saline raft-free lakes tend to dry much more quickly. Rafts generally break up and sink or are washed to the lake shore during windy periods.

Yearly estimates of groundwater evaporation from the three dominant surface areas in Owens Lake (sandflat, mudflat, brine pool) were calculated by Tyler et al. (1997) using the data shown in Figure 2.4. Yearly average evaporation was taken as the arithmetic average of the four seasonal rates for each area. For both the sandflat and mudflat areas, autumn rates were well below those measured in the spring, implying that evaporation is more strongly controlled by groundwater conditions rather than potential evaporation rates above the sedimentation surface. Groundwater levels tend to decline in late summer and autumn, owing to evaporative demand, and therefore it is conceivable that winter rates, when the water table is nearer the lake floor, may actually exceed autumn rates. The coincidence of a prolonged drought (1993 to fall 1994) with the main measurement period appears to have affected evaporative flux in both the sandflat area and the brine pool. Consecutive summer measurement of evaporation at both these sites showed a considerable decrease owing to drought conditions. For this reason, summer evaporation rates from 1993 were considered more representative and used to estimate the yearly evaporation from the sandflat to produce a more representative average annual evaporation. At the brine pool site, autumn rates were assumed to be equal to those measured in spring 1994, when open raft-free water was extensive. Using this approach, the seasonally adjusted annual evaporation rate from the sand-dominated areas was $\approx 88 \pm 22 \text{ mm year}^{-1}$. Clay-salt crust-dominated (sabkha) regions in Owens Lake have an evaporation rate $\approx 104 \pm 26 \text{ mm year}^{-1}$. Yearly evaporation from the brine pool surface was $\approx 872 \pm 218 \text{ mm year}^{-1}$ although this is substantially less whenever a cover of salt rafts floats at the air-brine interface.

All these local climatic effects combine to make the high salinities needed to precipitate bittern salts unlikely in most modern marine-fed hypersaline settings. To produce and accu-

mulate primary bittern salts, like carnallite, sylvite and kieserite, to where they constitute a bed, rather than an efflorescent crust, requires a degree of aridity so extreme that it is difficult to envision it as a large-scale process in any modern marine-fed setting and even contemporary continental examples are rare. For example, carnallite is a precipitate in saltwork pans of the Dead Sea where it is the end result of anthropogenic management of fractionated brines (Figure 11.10). The only substantial natural Holocene potash accumulation is a syndepositional karst fill in bedded halites of the Qaidam Basin of western China, located some 1500 km from the nearest ocean. Even there, the potash ultimately comes from reworked subcropping Plio-Miocene potash evaporites. One must go to pre-Quaternary sediments to understand how a widespread potash bed can accumulate with a lateral extent measured in tens to hundreds of kilometres and thicknesses measured in metres (Chapters 5 and 11).

Chemical evolution of surface and nearsurface brines

Until recently, most geologists assumed ancient marine evaporites were precipitated from seawater brines with chemical make-ups very similar to that of today. Now, there is a growing body of evidence that the ionic make-up of Phanerozoic seawater has varied to where magnesium sulphate was not always a dominant bittern precipitate. In modern seawater biterns, it is. As well, varying intensities of evaporite dissolution, dolomite precipitation and hydrothermal flushing contributed varying ionic proportions to the brine feed of ancient salt systems (Hardie, 1984, 1991). This leads to a dilemma in deciding what is marine, what is nonmarine and what is a hybrid brine, based on mineralogical suites found in ancient bedded evaporites.

Marine brines

Chemical composition and phase chemistry

Today the chemical make-up and the proportions of the major ions in seawater are near constant in all the world's oceans. Seawater is dominated by Na and Cl, with lesser amounts of SO_4 , Mg, Ca, K, CO_3 and HCO_3 . Using the brine classification of Eugster and Hardie (1978), modern seawater is a Na-(Mg)-Cl-(SO_4) water, with a density of 1.03 gm/cc and a salinity of $35 \pm 2\%$. When seawater evaporates, a predictable suite of primary evaporite salts crystallise from increasingly concentrated hypersaline waters (Figure 2.5; Table 2.3). The sequence of marine precipitates was first documented by Usiglio

	Brine Stage	Mineral Precipitate	Salinity (‰)	Degree Evap.	Water Loss (%)	Density (gm/cc)
	Normal marine or euhaline	Skeletal carbonate	35-37	1x	0	1.040
Hypersaline	Mesohaline or vitahaline	Alkaline earth carbonates	37 to 140	1-4x	0-75	1.040-1.100
	Penesaline	CaSO ₄ (gypsum/anhydrite)	140 to 250	4-7	75-85	1.10-1.126
		CaSO ₄ ± Halite	250 to 350	7-11x	85-90	1.126-1.214
	Supersaline	Halite (NaCl)	>350	>11x	>90	>1.214
Bittern salts (K-Mg salts)		Extreme and variable	>60x	≈99	>1.290	

Table 2.3. Salinity based classification of mineral paragenesis and brine properties based on concentrated seawater. Hypersaline is defined as >35‰. Biologists working in saline waters use a somewhat different classification of; fresh water (less than 1‰), subsaline (1-3‰), hyposaline (3-20‰), mesosaline (20-50‰), and hypersaline (greater than 50‰). Geohydrologists tend to refer to fresh water as less than 1‰, brackish water as 1-10‰, saline water as 10-100‰, and brine as greater than 100‰.

(1849), while later work by Carpenter (1978) and McCaffrey et al. (1987) focused on the details of the evolving chemistry of the residual bitterns as the various supersaline salts precipitate (Figure 2.5).

As seawater concentrates, the first mineral to precipitate is CaCO₃, usually as aragonite. This begins in mesohaline waters where the brine reaches twice the concentration of seawater (40 to 60‰) and achieves a density ≈1.10 gm/cc. As the brine continues to concentrate and approaches four to five times the concentration of seawater, that is 130 to 160‰, gypsum precipitates from penesaline waters with densities around 1.13 gm/cc (Figure 2.6a). At 10 to 12 times the original seawater concentration (340 to 360‰) and densities around 1.22 gm/cc, halite drops out of supersaline marine waters. After halite, the bittern salts (potassium or magnesium sulphates/chlorides)

precipitate from supersaline waters at concentrations that are more than 70-90 times that of the original seawater. Carnallite and epsomite are the dominant bittern precipitates from modern marine brines. Brine density by this stage of concentration is in excess of 1.30 gm/cc and brine viscosity and feel approach that of olive oil (Figure 2.6b).

Modern coastal lagoonal systems do not naturally attain high salinities until the surface (hydrographic) connection to the ocean is lost and they evolve into marine-seepage groundwater sinks (Figure 5.28). Brines then evolve into mesohaline to penesaline waters with seawater-like (thalassic) ionic proportions (Table 2.4).

Ongoing evaporation of seawater produces two types of high density, high viscosity brine: Na-Cl brines and Mg-Cl-SO₄

Locality	Salinity (‰)	Na	Mg	Ca	K	Cl	SO ₄	HCO ₃	Br

Table 2.4. Examples of the hydrogeochemical make-up of some marine-fed brine systems, salinity is expressed in ‰ and ions in mmol/kg (see Chapters 3 and 4 for discussion of the geology of marine-fed systems).

brines. Na-Cl brines dominate in the salinity range 35-330‰. Brines become progressively dominated by Mg-Cl-SO₄ at higher salinities, indicating preferential removal of Na by halite precipitation. At first, Mg is the dominant cation in the bittern brines, but as the various MgSO₄ bittern crystallise its place is taken by K. Chlorine remains the dominant anion throughout the evaporation sequence (Figure 2.5).

Much of the field and laboratory work done on evaporating water has been done in closed conditions. Usiglio (1849) simply took a container of seawater and monitored its progress as he evaporated it to complete dryness. McCaffrey et al. (1987) studied the evolution of seawater in a series of man-made salt ponds in the Bahamas and supplemented this with laboratory work at higher salinities and densities not found in the ponds. Ideally, after depositing gypsum and halite, supersaline seawater evaporated to complete dryness deposits a predictable suite of Mg and K sulphate minerals (Usiglio, 1849). However when one tries to compare the suite of bittern salts seen in ancient marine evaporites to modern bitterns there are some obvious discrepancies. These problems can be addressed at varying levels of chemical, hydrological and chronological complexity. In the end many of the discrepancies can be related to the simple statement, "In nature, there is no such thing as a totally closed static system."

One of the first to attempt to deal with the chemical discrepancies between a modern seawater precipitation suite and the bittern suites seen in the Permian Zechstein salts of the Stassfurt β

Figure 2.5 Evaporation pathway of modern seawater showing how density increases and the proportions of various ions in solution change as the brine concentration increases. Recompiled from data in appendices in McCaffrey et al., 1987.

was Van't Hoff, a 19th Century German chemist. He reasoned that the best way to study evaporites was to start with a simple solution of two salts and add components one by one, studying the behaviour of the various mixtures at each stage of the experiment. From this work he formulated a series of rules of behaviour for salts in concentrated brines.

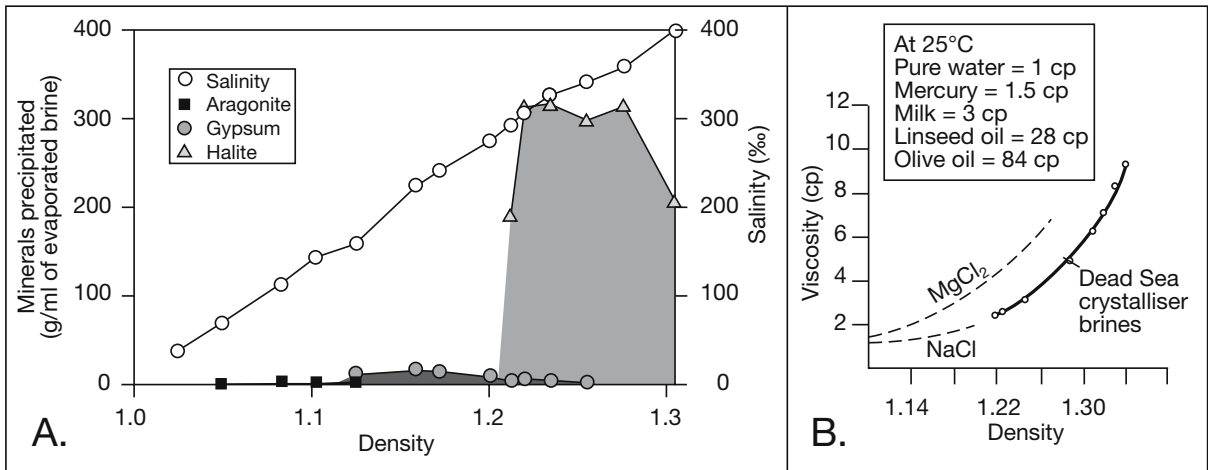

Figure 2.6. Brine evolution. A) Pre-bittern mineral precipitation sequence in a concentrating marine brine (replotted from Table 1 in Briggs, 1958). B) Viscosity increases with brine concentration (replotted from Karcz and Zak, 1987).

- If two salts are in solution, precipitation depends on the relative solubilities of the salts and their concentrations.
- If two salts have a common ion, the solubility of each in a solution of the other is less than in pure water.
- If two salts do not have a common ion, the solubility of each in the other is greater than in pure water.
- Solubility is markedly influenced by increases in temperature, much less so by pressure.

When studying bittern evolution the phase diagrams Van't Hoff developed experimentally are still useful today. Consider a KCl-NaCl system at 25°C and 100°C, this is an example of a salt pairs with a common ion (Figure 2.7a; Borchert and Muir, 1964). Points A and B represent solubilities in pure water at 25°C. Points G and H represent the solubilities in 1:10 NaCl-

KCl solution and 10:1 NaCl-KCl solutions, respectively. Point C represents the point at which the mixture is saturated with respect to both NaCl and KCl salts. Any point below line ACB is undersaturated at 25°C, above it is saturated with the solid salt. Let's now consider the effects of crystallisation and dissolution in this simple system. With concentration, a solution of composition X moves away from the origin until reaching the line ACB at Y, where KCl precipitates (Figure 2.7a). The ratio of NaCl/KCl increases as the solution composition moves along line Y-C (less water, less KCl in brine as NaCl increases). At C, both salts precipitate until dryness. With dissolution, a mixed salt of composition F remains solid until sufficient water has been added to begin its dissolution. At that point

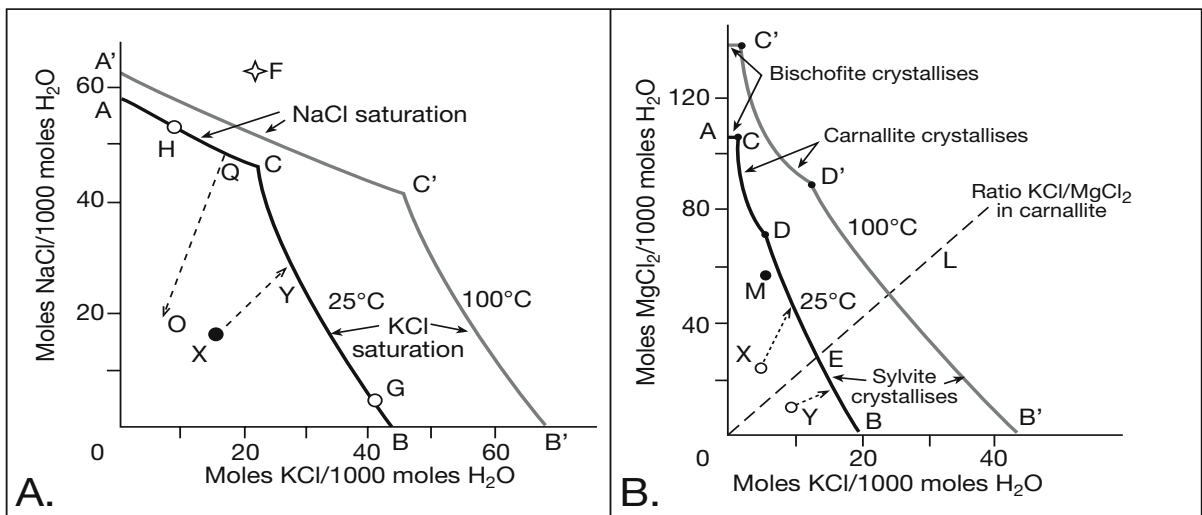

Figure 2.7 Van't Hoff plots. A) Crystallisation of solutions containing NaCl and KCl at 25° and 100°C. B) Crystallisation of solutions containing MgCl₂ and KCl at 25° and 100°C.

both KCl and NaCl begin to dissolve (point C). When all KCl has dissolved some NaCl remains and the composition shifts along C-Q as NaCl continues to dissolve. At Q the final NaCl dissolves and continued dilution moves the composition of the solution toward the origin along line Q-O.

Figure 2.7b is the Van't Hoff plot of the KCl-MgCl₂ system, an example of a salt pair with a common ion forming a double salt. In addition to the two end members (bischofite and sylvite) it has an intermediate double salt KCl.MgCl₂.6H₂O (carnallite). Points A and B represent saturation with MgCl₂.6H₂O (bischofite) and KCl (sylvite) respectively. The dashed line O-L shows the ratio of KCl to MgCl in carnallite. When a dilute solution of composition X is evaporated its composition shifts directly away from the origin until encountering line ACB. At the intersection point sylvite begins to crystallize and continues to crystallize as the composition of the solution shifts along line B-D, well below the composition of the double salt. Only when the solution has reached composition D does carnallite appear. At this point the composition of the solution remains fixed as carnallite crystallizes, both directly out of solution and by partial reaction of dissolved ions with some of the previously precipitated KCl. The resulting solid is a mixture of carnallite and sylvite.

Or with a more KCl-rich initial solution of composition Y, as it concentrates it moves away from the origin until it intersects line ACB where sylvite once again begins to crystallize. It continues to crystallize as the composition of the solution moves up along B-D. At D, carnallite begins to crystallize as the sylvite is used up. If evaporation continues, the composition of the solution now moves along line D-C until it reaches point C, where bischofite crystallizes, along with carnallite. The composition of the solution now remains constant until evaporation is complete.

We can also use this Van' Hoff plot to visualise how carnallite dissolves in this simple system. We begin with carnallite which has an initial composition D. Since this solution is much richer in MgCl₂ it is preferentially dissolved (it lies to the left of the dashed line EL). Once all the carnallite has dissolved, the net result is a solid residue of KCl (sylvite) (incongruent dissolution). Further solution of the residual will move composition of the solution down along line D-B. When it reaches E, the last of the sylvite is dissolved, and further dilution shifts the composition along line E-O (origin).

So, we can describe the section of the saturation line B-D as the 'sylvite region', since here KCl alone is in equilibrium with saturated solutions; CD is the 'carnallite region', and CA

the 'bischofite region'. Point C represents the composition of a saturated solution in equilibrium with both bischofite and carnallite, point D the composition in equilibrium with both carnallite and sylvite. Note that point D differs from point C in that during evaporation it can be approached from only one side, the KCl side, whereas C can be approached from either the carnallite or bischofite side. In other words the bitter precipitation sequence sylvite followed by carnallite, carnallite followed by a bischofite-carnallite mixture, or bischofite followed by a bischofite-carnallite mixture are possible, but never carnallite followed by sylvite.

If two salt pairs do not have a common ion they form a reciprocal salt pair such as a KCl-MgSO₄ system. In an evolved seawater brine it is possible to have four end members plus any number of intermediate double salts. Rather than depicting such a system as this on a simple Van't Hoff binary plot, it becomes necessary to use a ternary diagram. A ternary plot of reciprocal salts is handy, as fixing the relative concentration of three of the four ions also fixes the fourth, providing the system is at equilibrium. This is the basis for seawater ionic reconstructions in many micro-inclusion studies in halite. The most commonly used type of ternary plot in evaporite bitter studies is a Janecke Diagram (Figure 2.8). In many respects it is analogous to the ternary diagrams used in igneous and metamorphic petrology where plotting of two components fixes the relative proportion of the third component and it is very useful in the interpretation of brine inclusion chemistry (Zimmermann, 2001).

Evaporation on a Janecke plot is represented by the reciprocal salt pair MgCl₂-K₂SO₄. The solution remains saturated with NaCl at all times and thus this ubiquitous component can be ignored.

The corners of the diagram are represented by:

- Mg²⁺ = 100% bischofite (MgCl₂.6H₂O)
- K₂²⁺ = 100% sylvite (KCl)
- SO₄²⁻ = 100% thenardite (Na₂SO₄)

Points along the triangle edges are pure salts with only two end members:

- c = carnallite KCl.MgCl₂.6H₂O
- ks = kieserite MgSO₄.H₂O
- hx = hexahydrite MgSO₄.6H₂O
- bl = bloedite Na₂Mg(SO₄)₂.4H₂O
- gl = glaserite K₃Na(SO₄)₂
- e = epsomite MgSO₄.7H₂O

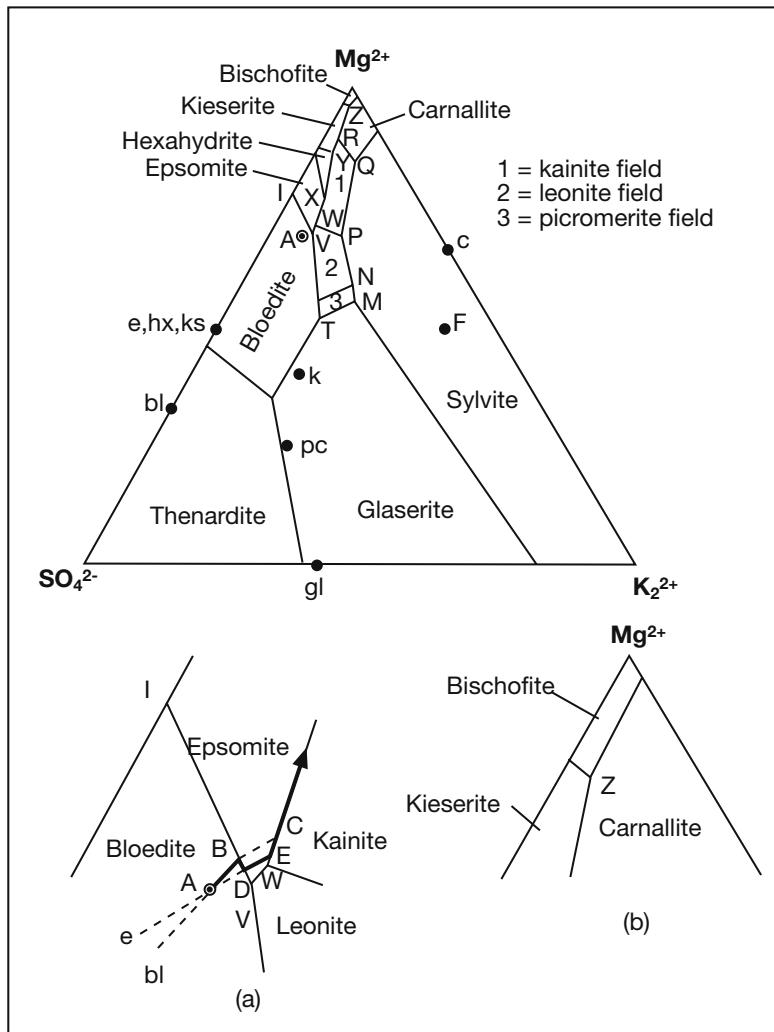

Figure 2.8. Janecke diagram for system $\text{NaCl} \cdot \text{MgCl}_2 \cdot \text{Na}_2\text{SO}_4 \cdot \text{H}_2\text{O}$ at 25°C . Salt points: c = carnallite, bl = bloedite, gl = glaserite, e = epsomite, hx = hexahydrite, ks = kieserite, k = kainite, pc = picromerite. Point A defines the composition of seawater. (a) enlargement near I to show part of the crystallisation path of seawater; (b) shows detail of the Mg corner.

Points within the triangle contain end members such as:

- k = kainite $\text{KMgClSO}_4 \cdot 11/4\text{H}_2\text{O}$
- pc = picromerite $\text{K}_2\text{Mg}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$

If the bulk composition lies within the field, the fields represent the composition of the first salt to precipitate. However, the point representing the actual salt composition often lies outside the field where the ideal salt would precipitate. This is analogous to the previous binary Van't Hoff plots in which point F (carnallite composition) lay far outside the "carnallite region."

In the evaporation of seawater, the average seawater composition is represented by point A on Figure 2.8. This point lies in the bloedite field. Thus, bloedite is the first bittern mineral to crystallize. As bloedite crystallizes the composition moves away from point A along a line which is a projection of the bloedite compositional point projected through point A. At B (seen in the expanded part of the plot) there are two possible pathways:

a) If bloedite has settled out and does not react further, epsomite begins to crystallize and the composition of the salt solution migrates across the epsomite field to point C, the path of migration from point B to C is a projection through B to the epsomite point on the triangle edge.

b) If, however, bloedite is free to backreact with the solution, crystallisation takes a different path. The composition of the solution shifts along line B-D with bloedite being consumed as epsomite forms. At D, the last of the bloedite disappears. At this point the composition of the solution is free to migrate through the epsomite field to point E, which is a projection from the epsomite compositional point at the edge of the triangle through D.

At either point C or E kainite begins to crystallize with epsomite (2 phase boundary) and the composition of the solution moves along the kainite - epsomite boundary. At X, epsomite becomes unstable with respect to hexahydrite. It reacts in the same way, consuming earlier precipitates or not, depending on how isolated precipitates are from the evolving brine. With further evaporation the composition of the solution moves along the kainite-hexahydrite boundary and both crystallize simultaneously. At Y, hexahydrite becomes unstable with respect to kieserite. At R, kainite becomes unstable with respect to carnallite. Thus, we have kainite and kieserite remaining when we leave point R. If concentration continues (we are now well into the bittern field) we move to Z, where we reach a three-phase boundary. Bischofite begins to crystallize with carnallite and kieserite. The solution remains at this point until dryness.

If equilibrium is maintained so that earlier salts are re-absorbed (backreacted) during ongoing crystallisation, the final product should be only three salts (bischofite, carnallite and kieserite), plus halite, plus small amounts of some calcium salts. If equilibrium had not been maintained other salts could be present, but they should be layered in a vertical sequence predicted by the crystallisation path.

The problem with all this 19th-Century laboratory-based bittern phase chemistry is that the prediction rarely matched the reality. For example, polyhalite is an abundant component in the Stassfurt Salt of the Permian Zechstein. This was the salt bed that formed the test case for much of Van Hoff's and Janecke's work, yet polyhalite did not appear in Janecke's plot. One reason for its absence is our inability to precipitate polyhalite from seawater in the laboratory at earth surface temperatures. Little was known about the stability of polyhalite. Where we do find it in the Holocene is as a replacement of gypsum in zones of mixing between marine brines and continental groundwaters. According to the marine brine evolution predicted by the Janecke plot of seawater, kainite should be absent, or present only in the lower portion of the Stassfurt Salt. Yet, in reality it occurs near the top of the Stassfurt bed. Unusual salts, such as loeweite, picromerite, vanthoffite and langbeinite, should not be present at all, yet they are not uncommon in the Stassfurt. A sylvite-kieserite assemblage is forbidden by the phase diagram, but is present in the Stassfurt.

In order to explain some of these problems Van't Hoff suggested that the temperature at the time of salt formation in the Zechstein Basin was as high as 83°C. This explained some of the unusual mineralogies and the sylvite-kieserite association. If the temperature drops to 55°C near the end of the deposition, it allows kainite to be present near the top of the Stassfurt. Geologists found his suggestion of temperatures close to boiling in surface evaporite environments, cooling to 55°C at the end of a cycle, a little unlikely. Janecke proposed that the high temperatures suggested by Van't Hoff were diagenetic and had developed during burial (Borchert and Muir, 1964). He proposed that the problematic polyhalite had formed by secondary alteration as calcium-bearing brines reacted with kainite (addition of calcium, subtraction of chlorine) and that most sylvite formed by incongruent solution of carnallite (loss of magnesium). The more unusual salts, he argued, represented high temperature burial metamorphism. Harvie et al. (1980) recalculated the order of onset for the marine bittern salts in the Zechstein as: glauberite, polyhalite, epsomite, hexahydrate, kieserite, carnallite, bischofite. They concluded that the type of bittern salt and the salinity at which it precipitates varied according to temperature and levels of impurities in the residual brines.

In reality, hydrology of the system is more significant than idealised chemistry in controlling bittern evolution. Brine leakage, mixing with freshened recharge about the basin's margin and the influence of humid air layers lingering above the brine body

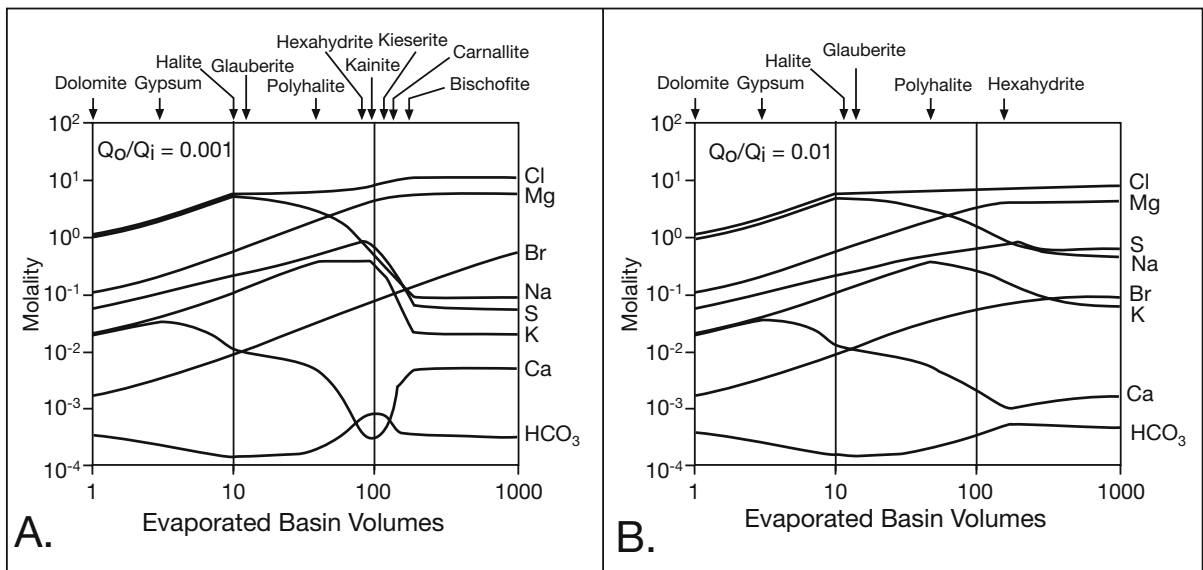

Figure 2.9. Effects of varying levels of basin leakage on ionic proportions and the precipitated mineral suite with a seawater parent brine and measured as a function of the number of evaporated basin volumes (after Sanford and Wood, 1991). A) Leakage ratio of 0.001 (\approx closed basin) shows bittern precipitation. B) Leakage ratio of 0.01, the system never reaches the upper end of the bittern field.

mean a standing body of modern seawater-derived brine liquor rarely moves to the bittern stage in a single primary desiccation cycle. Sanford and Wood (1991) modeled the changes in fluid composition and the sequence of primary salts that would precipitate under a leaky brine hydrology where bottom brine slowly discharges through underlying sediments (leakage via brine reflux). They found that the leakage ratio (ratio of water outflow to inflow) has a profound effect on both the evaporite mineral suites precipitated and the thickness (or volume) of a deposit (Figure 2.9). A system with a leakage ratio of 0.001 (that is, a 1x volume of water escapes from the basin for every 1000x volumes of inflow), the resulting salt evolution sequence is near identical to that of a completely closed system, as first documented by Usiglio (1849). However, with leakier systems there are significant reductions in the maximum salinities that the surface brines can attain and it is increasingly difficult to reach salinities sufficient to precipitate upper-end bittern salts. With a leakage ratio of 0.01 the final brine composition, reached after about 600 basin volumes have evaporated, has higher Na, K and SO_4 compositions and the four most soluble salts, kainite, kieserite, carnallite and bischofite, are not present (Figure 2.9b). This is reflected in the geological reality that textures in most natural bittern salts, such as carnallite and sylvite, indicate nearsurface brine cooling and backreactions drive their crystallisation (Figure 11.3).

There is another problem with much chemical/mineralogic modelling of ancient salts. It is predicated on an assumption that the major ion proportions of seawater do not change with

time. But were the ionic proportions of Phanerozoic seawater constant? Ionic proportions and the precipitation order of ancient seawater bitterns may have changed according to variations in the flux rates of river inflow relative to flux rates through mid-ocean ridges or the volumes of magnesium carbonate accumulating in the world's oceans (i.e., the “zip and split” of supercontinents) may have changed through time. Variations in either mechanism would have changed the proportions of major ions in seawater (Figure 2.30).

Brine mixing drives precipitation or dissolution

Van't Hoff's work also showed that salts can precipitate at a brine interface. All that is needed is mixing of waters of two saturation states with respect to the mineral of interest (Figure 2.10a). When two waters that are saturated with a particular phase are mixed, the resulting solution may be undersaturated or supersaturated with respect to that particular phase (two salt problem discussed earlier). The saturation state during mixing depends on the solubility curve of the mineral phase of interest and the parameter of interest (ion concentration, temperature, salinity, etc.; Runnels, 1969). The only requirement is that the solubility curve for that particular component is nonlinear. Raup (1970, 1982) in a number of experiments showed how halite and gypsum can be precipitated by the mixing of two seawater brines of differing salinity and densities. Figure 2.10b plots experimental results for the mixing of various low and high-density seawater brines and the resulting amount of gypsum precipitated (Raup, 1982). A similar plot can be drawn for the

Figure 2.10. Brine mixing. A) Schematic showing effects of brine mixing on supersaturation in two styles of saturation curves - component system P-X and component system R-Z. Solid lines shows equilibrium saturation curve for their respective systems, while the dashed lines are the mixing lines. When solutions A and B mix in system P-X, the resulting solution is supersaturated and liable to precipitate. When solutions A' and B' mix, the resulting solution is undersaturated and liable to drive dissolution of the component of interest. B) Amount of gypsum (in grams) precipitated by mixing of 50 ml each of two seawater brines in various concentrations at 25 °C (after Raup, 1982).

mixing of more saline seawater brines, where halite is the precipitate (Raup, 1970). For similar reasons, gypsum can precipitate in mixing zones in coastal aquifers when seawater first intrudes and displaces freshwater (Gomis-Yagües et al., 2000).

Mixing brines with different temperatures or salinities can be an important salting mechanism in the calcium sulphate (gypsum/anhydrite) salt system as it follows a nonlinear solubility trend, as does the halite-MgCl₂ bittern system (Raup, 1970, 1982). Figure 2.11a shows the solubility curves of gypsum and anhydrite with respect to increasing temperature in pure water. For gypsum, it clearly shows that when two gypsum-saturated waters of different temperature mix then the resulting solution is undersaturated and gypsum tends to dissolve. It also shows that gypsum follows a prograde solubility curve, whereby in the temperature range where gypsum is the stable CaSO₄ phase (<40°C) it is increasingly soluble with increasing temperature. In contrast, at higher temperatures (>40-50°C) anhydrite and gypsum follow a retrograde solubility curve whereby they are less soluble with increasing temperature. Thus, when two anhydrite-saturated waters of different temperatures mix the result is supersaturated brine with a propensity to precipitate anhydrite. This helps to explain why anhydrite is a commonplace hydrothermal precipitate in many mid-oceanic ridges and smoker chimneys (see discussion in Warren, 1999; p.362 ff.). On land, beneath the surface of the Abu Dhabi sabkha, the heating of desert waters rising through the capillary zone to temperatures above 30°C drives the precipitation of CaSO₄ (Figure 3.13; “thermalites”).

Anhydritic systems drive complex diagenetic effects when CaSO₄-saturated brines are diluted via dispersion into adjacent less saline waters (Figure 2.11b). This happens in brine reflux systems where dense CaSO₄-saturated brine plumes, derived

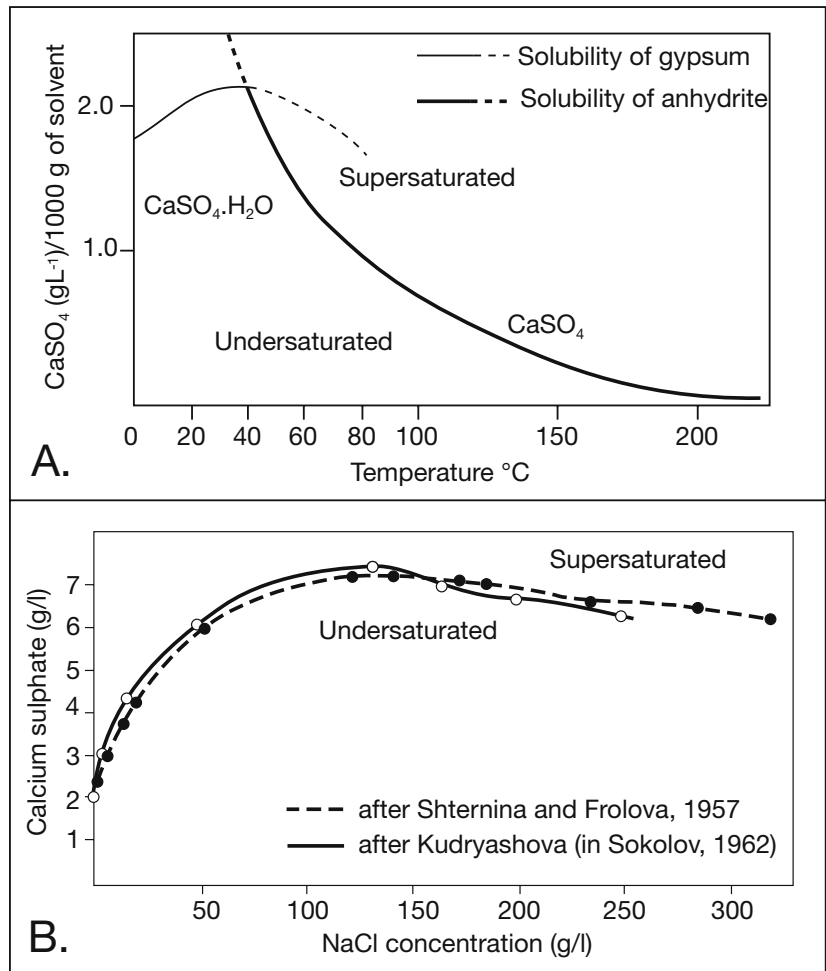

Figure 2.11. Calcium sulphate solubility. A) Idealised gypsum and anhydrite solubility with respect to temperature (after Zverev, 1967). B) Anhydrite solubility first increases then decreases slightly with respect to increasing NaCl content at temperatures of >100°C (Blount and Dickson, 1969).

at the surface at halite saturation, sink into, and interact with less saline brines held in underlying or adjacent anhydritic carbonates. If temperature remains near constant the tendency in this zone of dispersion or mixing is to dissolve anhydrite cements, creating vugular porosity in the interval below or adjacent to a thick salt sequence. If temperature decreases and the brine plume cools, with little change in ionic proportions due to mixing, then the tendency is to precipitate anhydrite. It is not a simple system, with temperature and mixing processes pulling the brine chemistry in opposite directions. It is of economic interest as brine reflux in ancient evaporitic carbonate platforms created diagenetic conditions suitable for the formation of potential hydrocarbon reservoirs via extensive dolomitization (Figure 10.24).

Later in the history of a calcium sulphate bed, during its uplift and dissolution (telogenesis), the mixing of sulphate-enriched waters with waters in adjacent aquifers drives dedolomitization. This is a process that can also create extensive karst in the absence of soil-derived carbonic acid and is doing so today in the Lake Banyoles region of northeast Spain (Bischoff et al., 1994). Lake Banyoles is a karst lake fed by sublacustrine springs, where dedolomitisation-driven karstic collapse drives ongoing subsidence in the immediate vicinity of the lake. The lake lies within the outcrop area of the middle Eocene Banyoles Fm.; a marine marl and mudstone that is organic-rich and pyritiferous. The marls are underlain by the 200–300m thick massive gypsum of the Eocene Beuda Formation, which is in turn underlain by the 100–200m thick dolostones of the Perafita Fm.

Gypsum dissolution drives the local precipitation of calcite, both in the lake and in the aquifer (dedolomitization), thus consuming ions released by dissolving dolomite and facilitating further dissolution in the aquifer (see Chapter 7 for details).

Lake waters reflect this process, they are dominated by Mg–Ca and $\text{SO}_4\text{--HCO}_3$ and are supersaturated with calcite, which is actively accumulating in lake sediments at a rate of $38 \text{ mg} \cdot \text{cm}^{-2} \cdot \text{yr}^{-1}$. Modelling of the regional hydrology based on the chemistry of lake and aquifer waters, along with measures of the annual water flow through the lake, shows that artesian waters create $\approx 9,500 \text{ m}^3$ of subsurface void space per year, enough to create the present karst depression of Lake Banyoles in 1,800 years (Bischoff et al., 1994). One could argue that gypsum dissolution alone can account for 55% of the lake volume. However, when coupled with the ionic removal from the dedolomitization process, gypsum solubility is enhanced by a factor of 1.56, as presumably is the rate of dissolution. Bischoff et al. (1994) go on to argue that gypsum-driven dedolomitization may be

responsible for extensive limestone karst in other exhumed CaSO_4 terrains in semiarid to arid settings, heretofore attributed solely to soil-generated carbonic acid.

Nonmarine brines

Unlike marine-derived brines, evaporating continental waters do not draw on the near isochemical reservoir of an ocean. A more diverse, less predictable, suite of evaporite minerals precipitates during evaporation of continental waters. In nonmarine settings, rivers and groundwaters are the source of most of the ions that are ultimately deposited as evaporite salts. In a closed hydrological system the composition of nonmarine brines depends on the lithologies that are leached in the drainage basin surrounding a salt lake (Eugster and Hardie, 1978; Eugster 1980a). Flow through limestone aquifers in hydrologically-closed basins produces inflow waters rich in Ca and HCO_3 , dolomite dissolution generates Mg, igneous and metamorphic matrices yield silica-rich Ca–Na– HCO_3 waters. Pyritic shales and other sulphide-rich sediments will contribute sulphate ions, whereas basic and ultrabasic rocks tend to produce alkaline Mg– HCO_3 waters.

In all, Eugster and Hardie (1978) distinguished five major water types in what they termed “hydrologically closed” continental evaporite basins (Figure 2.12):

1. Ca–Mg–Na–(K)–Cl
2. Na–(Ca)– SO_4 –Cl
3. Mg–Na–(Ca)– SO_4 –Cl
4. Na– CO_3 –Cl
5. Na– CO_3 – SO_4 –Cl waters

Brine Composition and Source	Major Saline Minerals	Key Minerals
Na–K– CO_3 –Cl– SO_4 Non-marine waters (mainly meteoric)	Alkaline earth carbonates, mirabilite, thenardite, trona, nahcolite, natron, thermonatrite, shortite, halite.	Na_2CO_3 minerals
Na–K–Mg– SO_4 –Cl Seawater, non-marine water or hybrids	Alkaline earth carbonates, gypsum, anhydrite, mirabilite, thenardite, glauberite, polyhalite, epsomite, bloedite, kainite, halite, carnallite, sylvite, bischoffite.	MgSO_4 and Na_2SO_4 minerals
Na–K–Mg–Ca–Cl Non-marine waters (hydrothermal and basinal brines or seawater with different ionic proportions from today)	Alkaline earth carbonates, gypsum, anhydrite, sylvite, carnallite, bischoffite, tachyhydrite, antarcticite.	$\text{KCl} \pm \text{CaCl}_2$ minerals in the absence of Na_2SO_4 and MgSO_4 minerals

Table 2.5. Mineral occurrences and parent brines (after Hardie, 1991).

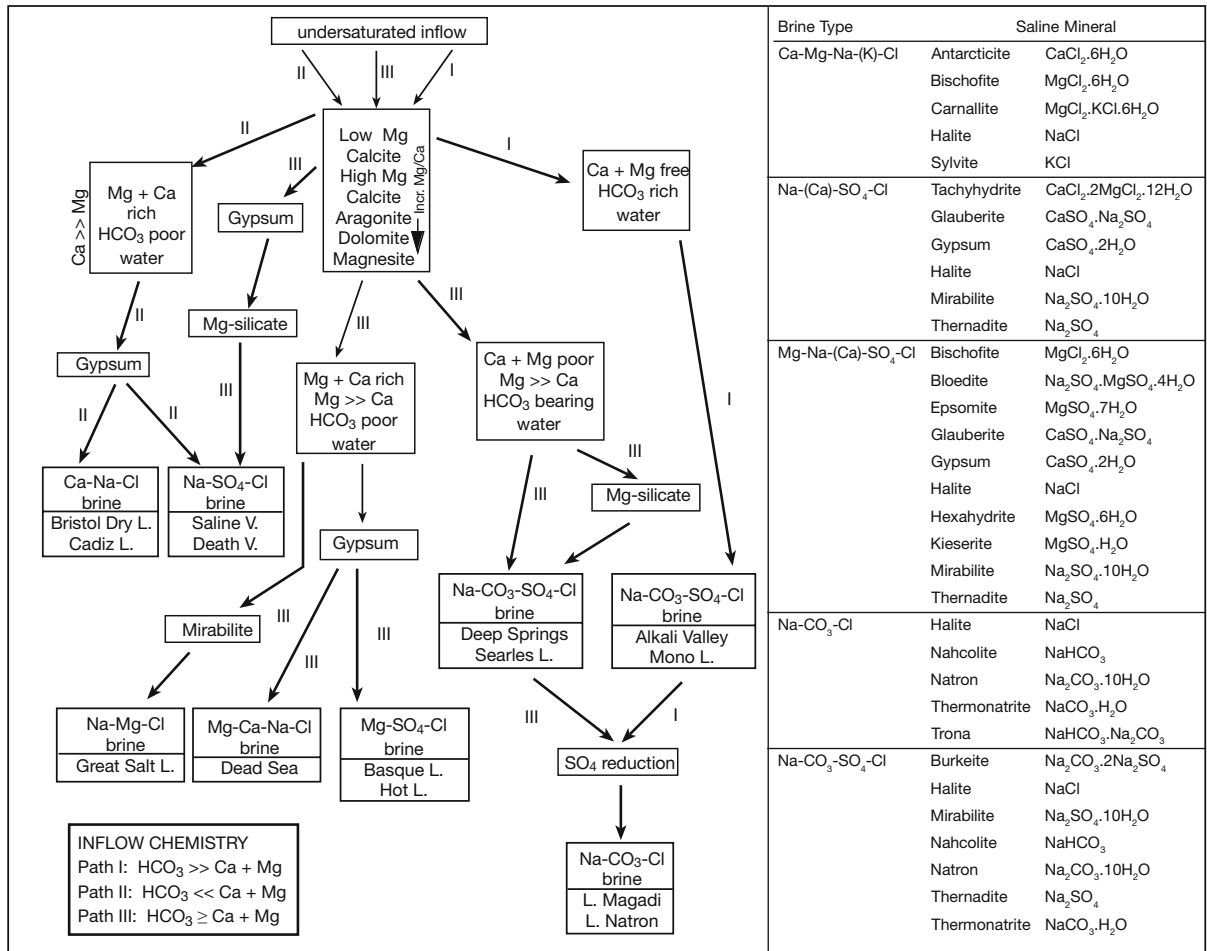

Figure 2.12. Hydrologic classification and brine evolution pathways of concentrating nonmarine waters and a listing of major evaporite minerals associated with the different brine types (after Eugster and Hardie, 1978). L = Lake, V = Valley.

As any one of these waters concentrates within a particular evaporite basin, it deposits a characteristic suite of evaporite minerals (Figure 2.12; Table 2.5). First precipitates are the alkaline earth carbonates: low-magnesian calcite, high-magnesian calcite, aragonite, and dolomite. The mineralogy of this initial precipitate depends on the Mg/Ca ratio of the parent brine. The subsequent evaporation pathway of a basin brine is determined by the proportions of calcium, magnesium, and bicarbonate ions in the brackish inflow waters. It sets up geochemical divides early in the evolution of a lake brine, these divides define the subsequent geochemical and mineralogical evolution of a lake basin.

If the lake waters are enriched in HCO₃ compared to Mg and Ca (i.e. HCO₃ >> Ca+Mg), then the brine follows path I (Figure 2.12). Ca and Mg are depleted during the initial precipitation of alkaline earth carbonates, leaving excess HCO₃ in the brine. As HCO₃ is the next most abundant ion in these waters it

combines with Na in the next stage of concentration. Sodium carbonate minerals, such as trona, natron and nahcolite, precipitate. Little or no gypsum can form from pathway-I brines as Ca is completely used up during the preceding alkaline earth carbonate stage. In contrast, during the evaporation of modern seawater, all the HCO₃ is depleted in the initial alkaline earth precipitates (mostly as aragonite and Mg-calcite). The excess Ca then combines with SO₄ to form gypsum. It is chemically impossible for sodium carbonate to form by evaporation of modern seawater. The assumption that the proportions of calcium to bicarbonate in seawater have not changed much in the last 600-800 m.y. implies that trona salts or their pseudomorphs indicate nonmarine settings throughout the Phanerozoic and much of the Neoproterozoic.

If initial inflow waters have (Ca + Mg) >> HCO₃ then, after the initial evaporitic carbonate precipitates, the brines become enriched in the alkaline earths but depleted in HCO₃ and CO₃,

If the relative volume of HCO_3^- is low, little carbonate can precipitate with further concentration. Brine evolution follows path II, whereby excess alkaline earths (Ca, Mg) left after depletion of carbonate combine with sulphate ions to precipitate large volumes of sulphates (gypsum and/or epsomite). Path II precipitates a suite of continental salts and bitterns similar to that derived from modern seawater. If the ratio of $(\text{Ca}+\text{Mg})/\text{HCO}_3^-$ is near unity (path III) carbonate precipitation can be extensive and voluminous. As Ca is progressively removed there is a progressive increase in the Mg/Ca ratio of the residual brine until large volumes of high-Mg calcites, dolomites and even magnesites precipitate.

Trona- nahcolite chemistry (Path I brine)

Clearly, path I brines cannot be derived by solar evaporation of waters with the ionic proportions of modern seawater. An occurrence of primary trona or its pseudomorphs in Phanerozoic evaporites is evidence of a nonmarine brine with an excess of bicarbonate (Figure 2.12). The three best-known trona deposits in the world are the Pleistocene and Holocene sediments of Lake Magadi, Searles Lake and the Eocene Green River Formation (Table 11.13). All regions show the appropriate bicarbonate excess in their inflow waters that differentiates them from seawater brine. But, as we shall see later in this chapter, there is increasing evidence that early Archean marine evaporites are most likely represented in the rock record by silica replacements of widespread nahcolite or trona, as well as halite. So, it's worth considering in more detail what is the phase chemistry of a sodium bicarbonate system.

By definition, there must always be an excess concentration of bicarbonate ions in an inflow water to force it into a path I composition (Figure 2.12). This means trona-forming brine is always an alkaline solution, typically with a pH above 9, as seen in all modern soda lake waters (Eugster, 1971; Eugster et al., 1978). Alkalinity is the result of the required solution's inherent chemistry. Trona cannot form in acidic waters, it is a matter of basic chemistry. Any carbonate ion in any aqueous solution tends to bump into and react with whatever ionic species are around. When there is not much free hydrogen around, carbonate in effect steals a hydrogen ion from a water molecule, leaving a hydroxyl ion behind and so, *ipso facto*, produces an alkaline solution.

A number of conditions must be present to create natural Path I brines and so produce trona beds: (1) an underfilled tectonic basin in which downwarping exceeds the rate of sedimentation, (2) a closed hydrographic basin in which evaporation exceeds outflow, (3) evolution of solutes in the lake waters that lead to

high $\text{Na}/(\text{Ca}+\text{Mg})$ and $(\text{HCO}_3^-+\text{CO}_3^{2-})/(\text{SO}_4^{2-}+\text{Cl}^-)$ ratios, that is alkaline brines, (4) a more-or-less permanent body of nutrient-rich water, (5) a warm climate favouring high primary productivity by microbes and algae, and (6) a high rate of bacterial sulphate reduction. Given the presence of these requisite conditions, varying intensity of photosynthesis, temperature and changes in the amount or volume of degassing spring waters then control the CO_2 content of the sodium bicarbonate precipitating brines and hence the mineralogy of the sodium bicarbonate precipitates (Figure 2.13a).

Trona evaporites in Lake Magadi accumulate as the surface brine is losing (degassing) a substantial portion of its CO_2 to the atmosphere. As that happens the increasingly concentrated brine follows a path similar to the dashed line moving away from point A (Figure 2.13b; Eugster, 1970, 1980a,b). Trona precipitation then occurs at ambient equilibrium (point B). Natron rather than trona is likely to form when ambient temperature is below 25°C (left hand dashed line). Once native trona deposition in Lake Magadi has begun, the CO_2 resupply from the atmosphere is too slow to allow ongoing equilibrium between atmospheric CO_2 levels and levels of CO_2 in the brine. The deposition of the later salts, along with the observed HCO_3^- depletion in increasingly saline brines (levels not buffered by CO_2), suggested to Hardie (op. cit.) that fractional crystallisation likely controls trona deposition in Lake Magadi. Thermonatrite/halite can sometimes precipitate in the later stages of evaporative concentration in Lake Magadi. At higher temperatures, earlier formed natron and trona can be replaced by thermonatrite.

Kinetic effects, especially those governing equilibration between dissolved and atmospheric CO_2 , are extremely important in determining the final mineralogy of sodium carbonate precipitates (Eugster, 1970; Whittig et al., 1982). Evaporative concentrations under conditions of equilibrium with atmospheric CO_2 at 25°C follow path AB in Figure 2.13b and at B, trona begins to crystallize. Crystallisation of trona, together with further evaporation, results in the solution composition moving towards C, i.e., it causes a decrease in the $\text{HCO}_3^-/\text{CO}_3^{2-}$ ratio because this ratio in trona is greater than that in the solution. However, if equilibrium with atmospheric CO_2 is maintained, this ratio should be buffered, and only trona is produced because addition of atmospheric CO_2 stabilizes (buffers) the $\text{HCO}_3^-/\text{CO}_3^{2-}$ ratio via the following reaction:

Under conditions where atmospheric disequilibrium is promoted, i.e., where the $\text{HCO}_3^-/\text{CO}_3^{2-}$ ratio is not buffered, path

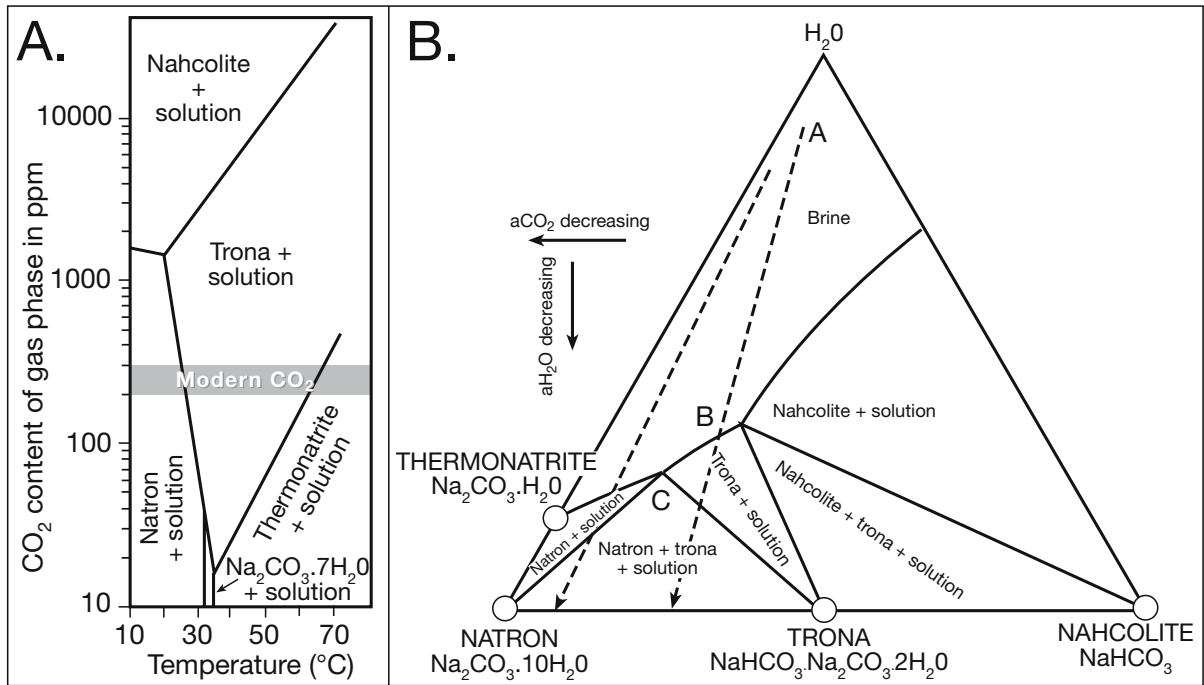

Figure 2.13. Phase chemistry of sodium carbonate salts. A) Sodium carbonate phases in equilibrium with a saturated solution as a function of CO₂ content of the gas phase and temperature. CO₂ content of today’s atmosphere is plotted as a grey band (in part after Eugster, 1971). B) Phase diagram for the sodium carbonate, sodium bicarbonate, water system at 25°C. Trona saturation occurs at B where the brine trajectory arrow passes into boundary of trona stability field (after Eugster, 1971).

BC is followed, producing thermonatrite and trona at C. The removal of HCO₃⁻ along path BC under these conditions also causes a marked rise in the pH (alkalinity), as the solution compensates for HCO₃⁻ removal by the reaction,

In spite of this compensation, the HCO₃⁻/CO₃²⁻ ratio in lake Magadi brines falls well below that of atmospheric equilibrium, especially in nutrient-rich waters with a flourishing photosynthesising microbial community (Figure 2.13a).

The shaded interval in Figure 2.13a shows the range of CO₂ values typically present in brines in equilibrium with present-day atmospheric CO₂. Trona is the stable phase in the 25–60°C temperature range typical of most modern surface brines in modern soda lakes where sodium bicarbonate minerals are precipitating. CO₂ values were higher (10 to 200 times; Kaufman and Xiao, 2003) in the Archean atmosphere (as were CH₄ levels), favouring the widespread co-occurrence of nahcolite with trona along with halite, not gypsum, in marine evaporites of the time (Figure 2.32).

Are most continental salt lakes hydrologically closed?

Hydrogeochemical studies do not always draw the distinction between hydrographic closure (endorheic basin) and hydrological closure (no leakage). The former situation is commonplace in evaporite basins, the latter is rare. Studies of the nonmarine hydrogeochemistry of low-relief desert terranes detailed in this section show that varying degrees of brine leakage, rather than hydrological closure, characterise large-scale endorheic lakes and playas located well into the continental interior. Even in modern near-coastal settings the hydrology tends to be open and leaky rather than a closed cumulative systems. For example, evolved path III continental brines, in combination with varying degrees of brine leakage, explain the diversity of evaporitic carbonate mineralogies in the lakes of the Coorong, South Australia (Warren, 2000a). Individual lakes, less than 1 km apart and with sediment surfaces above sealevel, are filled with up to 6 m of Holocene carbonate and show mineralogies that range from low Mg-calcite to high Mg-calcite to calcian dolomite to magnesian dolomite±magnesite to aragonite±hydro-magnesite to aragonite+gypsum (Figure 4.4a). Calcites and calcian dolomites tend to dominate in lakes with lower average annual salinities, while the magnesian

carbonate phases, along with aragonite/gypsum, tend to dominate lakes with higher average salinities (Warren, 1990). During the desiccated stage of the late summer, halite-MgSO₄ efflorescences form atop carbonate mudflats in many Coorong lakes, but are flushed from the system by winter rains. Mineral variation in the Coorong lakes illustrates the importance of relative rates of brine loss (residence time and leakage) in controlling mineralogy in this hydrologically-open continental system. Average brine residence times in the different lakes ultimately control mineralogic assemblage. Those lakes with leakier basements allow a more rapid throughflush of waters and so show lower longterm salinities and so accumulate less saline precipitates.

Yet in the literature, many of our ideas on the nature and evolution of continental evaporite brines and the resulting salts are based on hydrochemical analysis of high topography, “closed-basin” (effectively non-leaking), rain shadow lacustrine systems such as the Basin and Range province of the southwest USA and the continental lakes of the African Rift system. Uplifted bedrock lithologies surrounding these lakes tend to contain abundant labiles in their tectonically-active high-relief catchments. Bedrock alteration with rapid weathering is a major contributing factor to variations in ionic proportions of the final lake brine (Figure 2.14). In contrast, saline groundwaters in playas and salt lakes of low-relief tectonically-stable deeply leached regions such as the interiors of Australia and southern Africa

tend to have salt lakes with seawater-like Na-Cl dominated brines (Type II or thalassic brines). Many Australian playas are hydrologically open; the outcropping parts of mixed local and deeply circulating regional discharge systems (Chapter 3). Aridity and deeply weathered soil profiles have characterised these areas since the early to mid Tertiary. Ionic proportions and chemical constituents of surface waters and brines vary little, even across regions of variable bedrock lithologies (Table 2.6). Gypsum, with lesser volumes of halite, are common precipitates in some, and all lake floors show varying degrees of brine leakage.

Jankowski and Jacobson (1989, 1990) and Jacobson and Jankowski (1989) showed that in such deeply weathered and leached systems the amount of rainfall in a given part of a catchment area is a more important determinant of the chemical composition of the final playa brine, rather than bedrock lithology. In the Lake Amadeus region of central Australia, higher rainfall regions of the catchment generate playa inflow waters that are bicarbonate-dominated, while lighter rainfall regions generate chloride-dominated inflow waters. Differences in brine chemistry can be related to the rate of cycling of pedogenic carbonate within the catchment profile, not to differences in basement lithology. More carbonate is dissolved in the nearsurface when rainfall is relatively high, and so contributes a greater proportion to the brine composition. Higher rainfall regions also flush greater volumes of water

through the same profile in a given time and so are characterised by shorter residence periods per given water volume for rock/fluid interaction. In low rainfall regions chloride tends to remain mobile in the catchment profile, while bicarbonate is more likely to remain fixed as carbonate minerals in the soil profile (Figure 2.14).

The buildup of more soluble salts as pedogenic residuals in low rainfall regions can be impressive. Salt-rich soil profiles near Lake Eyre, South Australia sit atop a widespread flat-lying and deeply weathered pyritic Cretaceous Bulldog Shale. Deep leaching has created a pedogenic unit of epsomite, with a thickness measured in metres and an area measured in thousands of square kilometres (Lock, 1986). Pedogenic nitrates in the hyperarid Atacama Desert have a similar pedogenesis (Figure 11.42).

Hydrological leakage through a brine-covered lake floor varies over time in response to climate change driving rising and falling watertables. Variation occurs across time frames of hundreds to thousands of years, and periodic deflation is typically part of the sedimentary history of these playas. Variations create regional disconformities in the upper few metres of lacustrine sediment. This hydrological regime begs the question, how useful are the major ions proportions in the present surface waters in understanding the mineralogical evolution of the preserved lake precipitates? In other words, how valid is the assumption, typically made in "closed lake" settings, that the chemistry of the concentrating surface waters gives an understanding of the hydrogeochemical parentage of the preserved sediments?

Studies by Dutkiewicz et al. (2000) underline the significance of varying rates of phreatic leakage (both upwelling and downwelling/reflux) in controlling the mineralogy of lacustrine sediments in more hydrologically open playas. Using a steady-state isotopic model of lacustrine carbonates they concluded that present-day leakage in the Malata-Greenly playa complex in South Australia is 75% to 90% of regional inflow. Mineralogy of nearsurface sediment beneath all the lakes in the Greenly-Malata system is relatively simple, dominated by alternating layers of chemically-precipitated gyparenite and carbonate muds, which are either dolomites or calcites, all with relatively minor amounts of transported calcareous sand (Figure 2.15a; Dutkiewicz and von der Borch, 1995). Under present conditions of high leakage, only low magnesian calcite precipitates are preserved along with gypsum. The lake water experiences somewhat reduced effects of evaporation, gas and vapour exchange and, consequently, reduced isotopic and chemical enrichment compared to more arid times in the past when dolomite accumulated.

Using regional groundwater values, Dutkiewicz et al. (2000) calculate that any precipitated carbonate in a salt lake in the region will be calcite that becomes increasingly Mg-rich as brine concentration continues, until the brine reaches a chemistry favourable for dolomitisation. Thus dolomite intervals preserved in the cores but not forming in the present climate, probably reflect more arid climate or times of slower leakage of brine from the lake. Their modelling predictions are confirmed by isotopic measurements over the length of a 2.5 m core taken in the dolomitized carbonates of the lake complex, where the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ of the lacustrine carbonates show excursions on

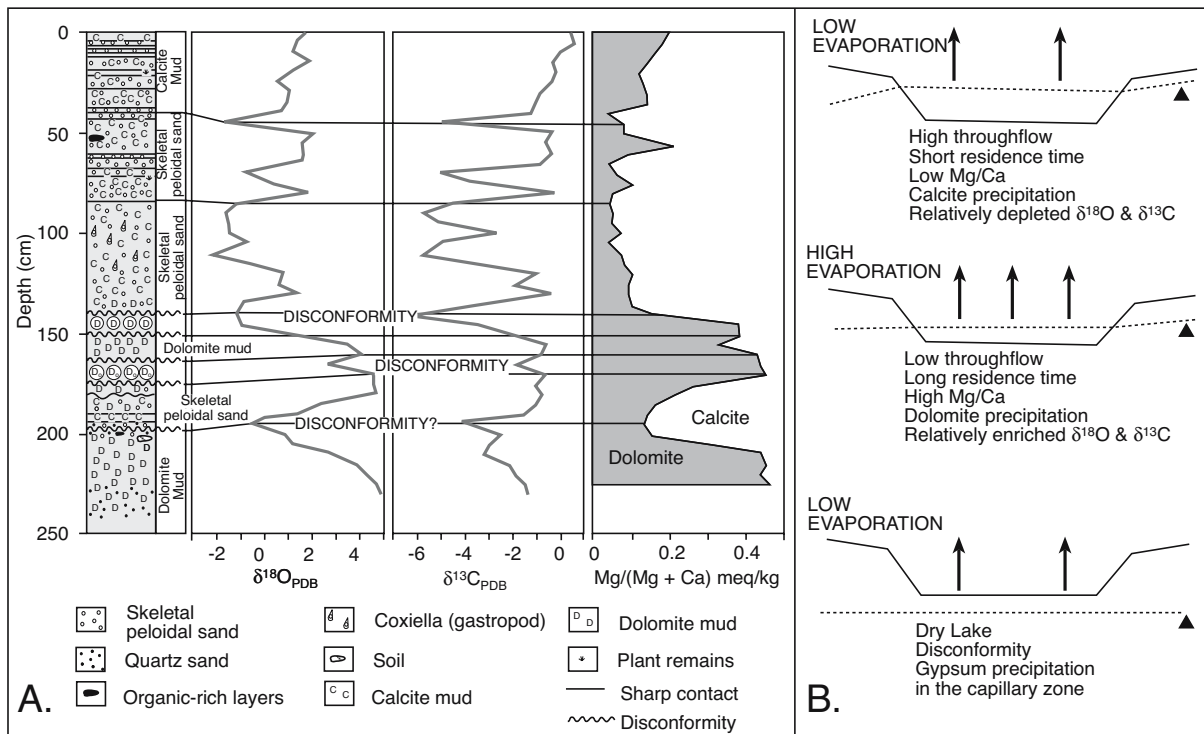

Figure 2.15. Lake Malata-Greenly complex, South Australia. A) Stable isotopes and $\text{Mg}/(\text{Mg} + \text{Ca})$ ratios plotted against depth and sedimentology of core C17 in Lake Greenly. B) Schematic of the three playa hydrological stages with varying water tables indicated by dashed lines (after Dutkiewicz et al., 2000).

the order of 5‰ (Figure 2.15a). At one end of the hydrological spectrum are past times of throughflow-dominated leaky conditions, when low-Mg calcite accumulated (with characteristic depleted $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ levels). These were times defined by a high water table, perennial waters and a humid climate (Figure 2.15b) with relatively short residence times in the pore brines. Then there were times of decreased leakage and higher rates of evaporation. These more arid climatic episodes were characterised by the accumulation of high Mg-calcite/dolomite (relatively enriched in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ (Figure 2.15a). Dolomite precipitation dominated in Lake Greenly when leakage was reduced to some 55% to 70% of present inflow.

Then there is the climatic situation where deflation or a lowering of the regional water table causes the water level to sink into the lake sediment column to become a water table. The system is then driven by capillary evaporation, the formation of widespread erosional surfaces (disconformities) and net loss of sediment (via deflation) from the lake. This creates breaks or disconformities in the sedimentation history and it can effect both dolomite and calcite successions. It tends to occur more frequently during dolomite depositing episodes, as these were times of greater aridity. Using the modern isotopic signatures

of the regional groundwaters as a baseline, signatures in the preserved lake sediments indicate variable, but high, rates of throughflow or leakage throughout the Late Quaternary (55–90% of today's).

Yet, when mass balance calculations are done using the surface water chemistry in the lake and an assumption that Cl and Br are conservative, there is apparent hydrochemical closure in surface waters of the lake system (ionic proportions indicate < 1% leakage of waters from the lake). Clearly, the surface brine chemistry does not match the leakage history shown by isotopic signatures of the preserved sediments beneath the lake floor (Dutkiewicz et al., 2000). Surface waters reflect the ongoing cycling of a seasonal halite crust, which redissolves each winter. The crust formed during the previous summer under conditions dominated by evaporative discharge into the lake. Circulation of surface waters and the periodic creation of secondary surface brines by halite leaching takes place above a separate widespread mixing zone where older lake brines interact with regional groundwater inflow. Thus the annual solute cycle of surface waters and the halite crusts is decoupled from the subsurface water cycle preserved in the carbonates of the playa sediments. This decoupling is true of

many inland playas across Australia, where reflux and mixing of the lake brines into the regional outflow hydrology prevents the accumulation of thick sequences of bedded gypsum or halite (Figure 3.55).

Decoupling also explains a general observation that in many Quaternary salt lakes around the world, the relative abundance of preserved authigenic minerals in the sediment column is different from that predicted by conventional solute mass balance calculations using surface brine compositions. Conventional hydrogeochemical mass balance models assume that chloride (and bromine) behave conservatively over long periods of time. Such models of ionic evolution fail to take into account the role of diffusion, deflation and fractional crystallisation/dissolution of salts. That is, not all water exchange in a saline system is closed and so can be tied to a simple relationship between runoff and evaporation; in reality all salt lakes will reflux, seep and leak brine to varying degrees.

This decoupled hydrogeochemistry illustrates a general observation on evaporite deposition, underlined by Sanford and Wood (1991) and Rosen (1994), namely, there are very few truly “closed” hydrological systems in evaporite basins in either marine or nonmarine settings. All natural groundwater systems in salt-accumulating areas leak to varying degrees. Geological evidence for leakage through the floor of an evaporite basin includes the formation of reflux dolomite, the longterm stability of brine plumes beneath lakes that are accumulating thick salt sequences, the loss of halite porosity by 30 metres burial, the near surface dissolution of marginward portions of salt beds, the diverse suite of early burial alterations and backreactions, and the formation of burial salts in brine curtains beneath saline depositional systems.

As for seawater biterms (Figure 2.9), the geochemical divides defining the evolution of Type I through III nonmarine brines are perhaps more dependant on the ratio of leakage to inflow rather than the lithology of the surrounding basin. Only in high-relief reactive catchments with very low basin floor leakage (near-closed) hydrologies will surface brine chemistry and crust mineralogy correlate with the suite of minerals and salts accumulating as the lacustrine fill. There the rapid rates of subsidence in the lacustrine sink mean the accumulated salts largely reflect catchment lithologies.

In more hydrologically open systems, with slower rates of lacustrine subsidence and sediment accumulation, the rate of solute input from precipitation and meteoric outflow via pedogenic leakage in the surrounding low-relief deeply

weathered and flushed catchment is often more significant in controlling inflow chemistry than the rate of labile bedrock weathering. Hydrogeochemical proportions of ions in waters throughout the continental groundwater profile are then controlled by a combination of rates of leakage and the ionic composition of the precipitation entering the system. Solutes from the shallowest portions of the groundwater profile are recycled through the seasonal formation and dissolution of salt crusts on the lowest parts of the playa floor and so are typically decoupled from the mineralogy in the immediately underlying lacustrine sediments. The proportion of leakage of solutes into the sediment below the cycling crust is controlled by longer term climate change and the interactions between tectonism, subsidence and deflation.

Separating marine from nonmarine

Hydrological requirements needed to accumulate large-scale thick salt deposits complicates our ability to separate marine from nonmarine water sources in ancient evaporites. A high degree of isolation or “continentality” is required for stable longterm evaporative drawdown, which is always needed to accumulate a thick sequence of bedded salts (see Chapter 5 for detail). That is, a marine evaporite basin may have been supplied seawater by marine seepage or occasional surface seawater breakthrough via narrow ephemeral surface inlets, but, if the basin is to accumulate thick salt beds, it must be a longterm topographically-isolated regional low. The inherent hydrological requirement of isolation from any continuous surface connection to the ocean means it is by definition a subsealevel basin surrounded by land with a marine-phreatic groundwater feed. The salt accumulating area is either surrounded by continental sediments and hydrologies or is a depression within or behind a subaerially exposed carbonate platform. Invariably in some parts of the basin, marine chemistries are overprinted by deeply circulated meteoric waters, thalassic surface waters can be diluted by occasional rainstorms and by the effects of pulses of highly labile volcanic ash. This next section is an attempt to present some of the possible complexities that characterise ancient hybrid (mixed marine/continental) brine systems.

Back reactions

Backreactions complicate the interpretation of brine parentage in ancient evaporite salt sequences. At the start of the last century they were recognised as significant controls on mineralogy by van Hoff and others (Figures 2.7, 2.8). Backreactions can occur both at the sediment-brine interface and within shallow subsurface brine plumes that displace and mix with less dense

underlying pore brines. Pseudomorphs and reaction rims are common indicators of this process, as are relict mineral cores encased in the mineral that replaced it. Documented examples include pseudomorphs of halite after subaqueous gypsum, reaction rims of polyhalite and glauberite around earlier gypsum or anhydrite, bloedite after epsomite, relicts of carnallite in secondary sylvite, and pseudomorphs of sylvite plus kieserite after earlier langbeinite (Table 2.7).

Backreaction means relevant bittern chemistry and associated brine evolution is poorly modeled by studying brine evolution in man-made seawater ponds. In such salt works the evolved brines are separated from earlier precipitated mineral species by sluice gates and pumps. The aim of the saltwork engineer is to create harvestable monomineralic or bimineralic salts and brines in the various fractionating pans. Backreaction either does not occur or is kept to a minimum.

Many secondary (replacive and displacive) salts in natural systems, such as sylvite, glauberite and polyhalite, form syndepositionally via interaction between highly evolved nearsurface brines and earlier formed minerals (Figure 2.16; Table 2.7). For example, during the equilibrium evaporation of seawater at 25°C, glauberite and polyhalite form by backreaction of the brine with earlier formed anhydrite and gypsum. Harvie et al. (1980) modeled much of the variability present in the bittern salts of the Permian Zechstein deposits in Germany via a combination of equilibrium batch evaporation interspersed with times of fractionation and backreaction. As seawater concentrates to slightly below halite saturation, anhydrite replaces gypsum. As evaporation continues, anhydrite is partially replaced by glauberite. Glauberite in turn is replaced by polyhalite and levels of anhydrite are further reduced. These replacements change the residual brine composition so that kainite does not supersaturate, a problem that plagued earlier geochemical models of marine-derived potash precipitation in the Zechstein Series. The Harvie et al.

(1980) model not only explained the absence of primary kainite in the Zechstein deposits, but also explained the pseudomorphic replacement of gypsum and anhydrite by glauberite or polyhalite and the replacement of glauberite by polyhalite. Previous authors had attributed these replacements in the Stassfurt Salt to burial-stage thermal and solution metamorphism (Borchert and Muir, 1964).

Likewise, textures in beds of polyhalite in the Lower Werra Anhydrite (Zechstein - Upper Permian) of northern Poland show they are a very early replacement of anhydrite formed within platform sulphates by diagenetic backreaction with a highly evolved marine brine (Peryt et al., 1998). Formation of polyhalite was preceded by the anhydritisation of the original gypsum. Anhydritisation of primary platform and slope gypsum was an early subsurface alteration driven by syndepositional brine plumes, with ghosts of the primary gypsum texture still visible. Later brines, which were potassium and magnesium rich and nearly saturated with respect to halite, were created by ongoing reflux during more hypersaline conditions on the platform. These more highly evolved brines reacted with anhydrite to precipitate polyhalite along the slopes of the Zdrada Platform. The oxygen and sulphur isotopic compositions of

Figure 2.16. Evaporative concentration of modern seawater simulated using the computer program of Harvie et al. (1980) showing cumulative masses of minerals precipitated and resorbed by backreaction as evaporation proceeds. Initial seawater has a concentration factor of 1, with an initial mass of 1 kg of H₂O (after Hardie, 1991).

Secondary mineral phase	Syndepositional origin (<30°C)
Anhydrite CaSO ₄	Dehydration of early formed gypsum as a _{H2O} of evaporating brine decreases.
Bloedite Na ₂ SO ₄ ·MgSO ₄ ·4H ₂ O	Back-reaction between previously precipitated epsomite and concentrating brine.
Gaylussite CaCO ₃ ·Na ₂ CO ₃ ·5H ₂ O	Back-reaction of evaporating alkaline brine with early formed aragonite or calcite.
Glauberite CaSO ₄ ·Na ₂ SO ₄	Back-reaction of evaporating Na ₂ SO ₄ -brine with early formed gypsum or halite.
Kieserite MgSO ₄ ·H ₂ O	Dehydration of early formed hexahydrate as a _{H2O} of evaporating brine decreases.
Polyhalite 2CaSO ₄ ·MgSO ₄ ·K ₂ SO ₄ ·2H ₂ O	Back-reaction of evaporating K-Mg-SO ₄ brine with early formed gypsum, anhydrite or glauberite.
Sylvite KCl	Incongruent dissolution of carnallite in undersaturated waters.

Table 2.7. Examples of diagenetic (secondary) evaporites that form easily below 30°C (after Hardie, 1990; Sanchez-Moral et al., 1998).

sulphate evaporites indicate that marine solutions were the only source of sulphate ions supplied to the drawdown Zechstein Basin.

Hypersaline groundwaters can also react with adjacent nonevaporite minerals to form indicator clays and authigenic phases. For example, in reactive volcanogenic margins associated with many rift-valley evaporites there are suites of authigenic zeolites and clays (Figure 11.61). Many formed by the diagenetic reaction of nearsurface saline pore waters with metastable clays derived by weathering and alteration of labile volcanics. The best studied authigenic phases are the sodium silicates, such as magadiite; the borosilicates, such as searlesite; and the zeolites of the alkaline saline lakes, such as clinoptilolite, erionite and analcime. Sepiolite (meerschaum) clays form beds and nodules in saline lake deposits in the Miocene Eskisehir Lake of Turkey. These Mg-rich clays were deposited by direct precipitation out of silica-saturated saline and alkaline lake waters (Ece and Coban, 1994). The rather unusual inflow water was derived by the weathering of a Cretaceous ophiolite complex that contained abundant serpentinite and magnesite. Many of the saline lakes in this region of Turkey also contain widespread evaporitic micrites dominated by primary magnesite.

Volcanogenic ash and debris can be a substantial component in the drainage basins of salt lakes and playas in active rift and collision belts. For example, in the Central Andes various volcanic formations

overlie Cenozoic evaporites and the longterm meteoric recycling of salts from these labile carapaces into the present endorheic basins is a well documented process. But, pulsed short term recycling of fractionated ions into the salar hydrology following a volcanic eruption is another widespread, yet less well documented phenomena (Risacher and Alonso, 2001).

During a recent eruption of the Lascar Volcano in northern Chile around 10⁹ metric tonnes of air-fall tephra was deposited over the surrounding endorheic basins. Leachate experiments on this ash near the volcano summit and the nearby Talabre Valley produced fluids that were almost pure CaSO₄ and near neutral on the summit ashes, while leachates of valley floor ashes were alkaline (pH as high as 10.5) and more enriched in minor components compared to the CaSO₄ leachate of summit ashes (Figure 2.17; Risacher and Alonso, 2001).

Sulphur isotope compositions of leached sulphate are consistent with volcanogenic recycling from Tertiary gypsum that underlies the volcanic cordillera. Risacher and Alonso (op. cit.) estimate that 700,000 tons of easily soluble CaSO₄ were added to nearby endorheic basins by three days of eruption. The high pH of the valley floor leachates indicates hydration of alkali and alkali-earth metal-oxides via pyrolysis of vegetation during ash fall. Efflorescent salts encrusted on plants and dissolution of volcanic glass also provided some of the minor leachate components.

The almost pure CaSO₄ composition of summit leach waters is compositionally distinct from any present inflow waters in the central Andes. Addition of volcanogenically cycled CaSO₄

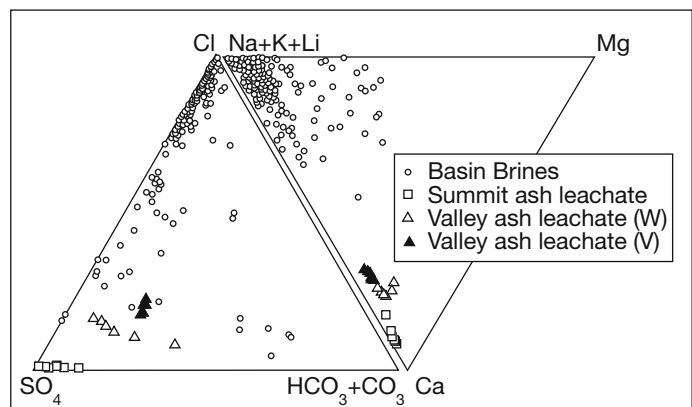

Figure 2.17. Ionic composition of ash leachate from Lascar volcano summit and Talabre Valley floor (V=valley floor, W=valley on west side of volcano) compared with basin brines of northern Chile (after Risacher and Alonso, 2001).

may explain some of the differences between the observed brine compositions and those predicted by computed simulations of the evaporation series based on the chemistry of longer-term inflows. Rapid recycling of sedimentary gypsum and short-term pulses of salts from labile ashfall is probably not restricted to Lascar volcano. The recycling of ancient salts, and possibly the pyrolysis of vegetation, may have been crucial processes in controlling the ionic proportions of closed basins during episodes of intense volcanic activity in the Tertiary. Some of the anomalies in salt mineralogies in ancient salts may reflect pulses of volcanism rather than variations in short term climate or the degree of leakage. Lascar brine chemistry is an example of a decoupled hydrogeochemical brine system where short term brine chemistries are decoupled from longterm chemistries in the drainage basin.

Marine aerosols supply continental lakes

Brine sources in ancient settings are usually inferred by a study of the regional palaeogeography and a definition of drawdown, seepage and hydrothermal brine supply using outcrop or seismic interpretation. Seepage drawdown or periodic storm floods are thought to be the predominant mechanisms for supplying substantial volumes of marine ions to larger ancient basins. But aerosols are a viable ionic supply mechanism in the hydrochemistry of modern continental arid-zone systems up to a thousand kilometres from the coast (Figure 2.18a). There is even a modern aerosol-defined marine versus nonmarine salt-line in the saline depressions of the Vestfold Hills of Antarctica (Gore et al., 1996).

Modern aerosol supply routes are best seen in isotopic signatures of the resulting salt, but this leads a circular argument if marine aerosols are invoked as brine sources for ancient evaporites in continental settings (i.e. I assume a portion of the input is marine therefore a proportion is marine), underpinning once more the numerous difficulties involved in separating marine and nonmarine brine sources for ancient salts.

Aerosols from salt spray can supply substantial quantities of ions to precipitative hydrologies in modern continental salt lake depressions located hundreds of kilometres from the continental margin (Figure 2.18a). For example, the Murray Basin, in southeast Australia, contains a 500m thick sequence of Palaeocene to Recent sediments deposited in fluvial to marine settings (Jones et al., 1994). The upper 100m in the central part of the basin now entrains large volumes of subsurface brines with salinities in excess of 100,000 mg/l. These brines feed many of the discharge playas in the region. They are

type II brines with major solute compositions and proportions very much like that of evaporated marine waters (thalassic groundwater). Their isotopic composition, however, is that of evaporated meteoric water. This led Jones et al. (1994) to the conclusion that the brines have been derived by the longterm accumulation of salt from marine aerosols, mixed with continental waters. The marine salts are blown into the basin either as dry salt suspensions or arrived as rainfall. Evapotranspiration in this semi-arid basin greatly exceeds rainfall and so solutes accumulate as brackish nearsurface waters. These shallow waters are further concentrated via capillary evaporation before escaping into saline discharge lakes. Regionally, the shallow groundwater flow regime is sluggish and not capable of dispelling these brines, so they infiltrate and accumulate above a regional aquitard.

Likewise, the $\delta^{34}\text{S}$ values of gypsum accumulating in modern playa lakes in the ancient landscape of southwestern Australia show little relationship with underlying bedrock types or the $\delta^{34}\text{S}$ values of any nearby bedrock sulphur (Chivas et al., 1991). Analysis of $\delta^{34}\text{S}$ from surficial lacustrine and pedogenic gypsum on a regional scale, in both Western Australia (Yilgarn Block) and South Australia, shows distance-related dispersal patterns over distances of 500 to 1000 km from the coast. The highest values ($\approx 21\text{‰}$) occur near coastlines decreasing to $\delta^{34}\text{S}$ values of $\approx 14\text{‰}$ further inland (Figure 2.18b). Marine sulphate is the dominant source of sulphur to the lakes investigated, with the proportion decreasing from approximately 100% near coastlines to around 55% further inland. For tens of kilometres inland of the modern coast, one can argue for a seepage origin of gypsum in many subsealevel lows (salinas) with active seawater seeps and appropriate drawdown surfaces. Further inland the gypsum in the various salt lakes reside in depressions that intersect a regional continental water table. This water table is metres or more above sealevel and it slopes seaward, so phreatic seawater seepage is not viable, yet the gypsum still has a marine isotope signature.

In some of the more interior Australian salt lakes, there can be a significant weathered bedrock component to the ionic components in the salt lake waters, especially where the bedrock contains abundant soluble sulphur and high levels of iron. Lake Cadibarrawirracanna (inland South Australia), for example, receives approximately 10% of its sulphur from weathering of the pyritic Bulldog Shale (Cretaceous); brine in nearby Lake Amadeus receives up to one-third of its sulphate from leaching of evaporites from the Neoproterozoic Bitter Springs Formation.

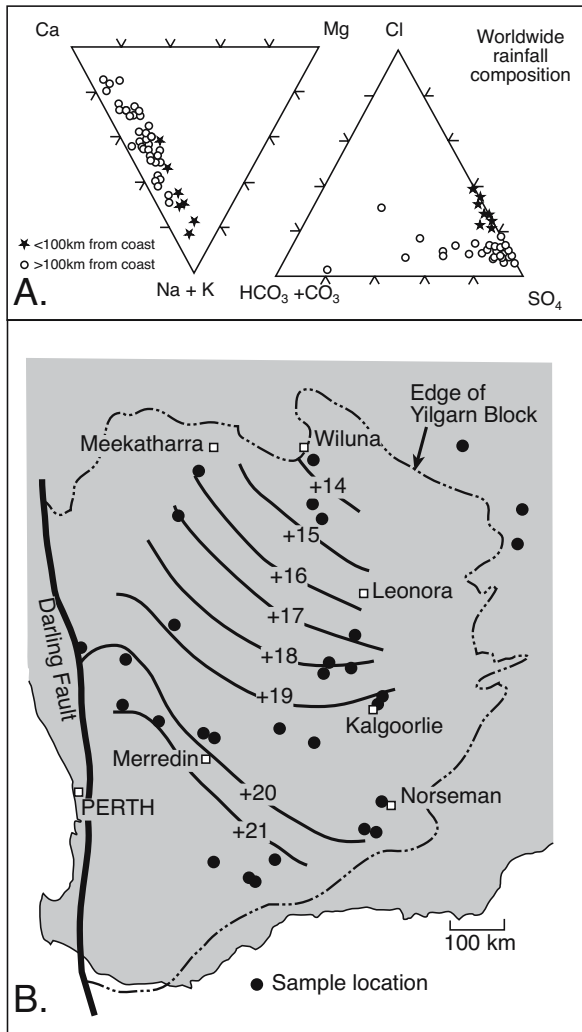

Figure 2.18. Marine aerosols can supply ions in solution to inland playas and lakes in low relief landscapes. A) Major ion content of worldwide rainfall in relation to distance from coastline, compiled from various sources listed in text. B) Changes in sulphur isotope values (mostly gypsum, occasionally from alunite; after Chivas et al., 1991).

Like much of arid inland Australia situated up to a thousand kilometres from the coast, the Namib Desert, which hosts one of Africa's most extensive accumulations of modern pedogenic and playa gypsum, is largely supplied by a variable combination of regolith runoff and marine aerosols (Figure 2.19a; Eckardt and Spiro, 1999; Eckardt et al., 2001). An extensive pedogenic gypsum accumulation forms a 50-70 km wide band parallel to the shore in the Central Namib Desert between the Kuisieb and Omaruru rivers. $\delta^{34}\text{S}$ analysis of calcium sulphate in this belt and the associated brines, along with an analysis of the brine chemistry shows marine aerosols are a major ion contributor

to the gypsum budget (Figure 2.19b). Marine aerosol sulphates are stored within widespread terrestrial gypsum deposits on the hyperarid gravel plain and are traceable as groundwater precipitates, including gypsum, in near coastal sabkhas and inland playas.

$\delta^{34}\text{S}$ values for the gypsum crusts are between +13.0 and +18.8‰, with lower values ($\delta^{34}\text{S} = +3.1$ to 3.4‰) in crusts near local bedrock sulphur sources, which are typically metal sulphide bodies. These Damaran bedrock sulphides show a wide $\delta^{34}\text{S}$ range from -4.1 to +13.8‰ but are significant sulphur sources only on a local scale. Dissolved sulphate in playa, sabkha, spring, borehole and ephemeral river waters have an overall $\delta^{34}\text{S}$ range between +9.8 and +20.8‰ but, unlike Australia, do not show a systematic geographical trend tied to distance from the coast. Even so, marine aerosols are the only viable supply mechanism for pedogenic sulphate over such a large arid near coastal area.

Atmospheric sulphates in the Namib are carried landward as marine aerosols, with a large proportion ultimately derived from decomposition of the dimethyl sulphide of phytoplankton. The plankton are an integral part of high levels of primary production driven by the upwelling of the cool Benguela current, the same oceanic system that creates the onshore aridity. The Central Namib Desert lies onshore from the thickest organic-rich sediment accumulations on the Namibian Shelf (Figure 9.11a). This suggests that some of the sulphate component in Namib gypsum is derived from marine H_2S during the anaerobic decomposition of this organic-rich sediment. The gas is probably carried into the desert by frequent advective fogs. Sea salt, decompositional marine biogenic and local bedrock sulphide sources, once invoked as the main sulphate source in these widespread gypsum accumulations in the Namib Desert, cannot account for the volumes of calcium sulphate unless the substantial dimethyl sulphide from plankton is also included in the sulphur supply cycle (Eckardt and Spiro, 1999). That is, most of the marine aerosol that drives extensive onshore gypsum accumulations is a mixture of marine sources of sea spray and atmospheric non-sea-salt (NSS) sulphate, largely supplied by oxidation of biogenic sulphur compounds - dimethyl sulphide, CH_3SCH_3 (DMS). Many organisms, including plankton and seaweeds, rid their bodies of sulphur (a biochemical waste product) by attaching it to various methyl compounds. They do the same with mercury, antimony and arsenic and other toxins. Such compounds are much more volatile than the original and so readily escape from cellular cytoplasm. Hence, a substantial portion of the sulphur isotope signature of pedogenic gypsum in the Namibian Desert reflects a biogenic marine source for

Figure 2.19. Pedogenic gypsum and the origin of sulphate in waters and sediments of the Namib Desert. A) Model of pedogenic gypsum formation for the Namib Desert where marine-derived dry aerosols are dissolved and mobilized through moisture provided by fog and rain water. Primary gypsum formation takes place in playas and is subjected to eolian and fluvial dispersal. Pedogenic gypsum accumulations increase towards the coast as the volume of marine supplied aerosol increases. B) Schematic representation of hydrogeochemical sulphur cycle along the Atlantic - Namib Desert interface (after Eckardt and Spiro, 1999). Solid arrows show sulphur pathways, potential sulphur pathways are indicated by dashed arrows. Range of $\delta^{34}\text{S}$ composition is indicated in boxed numbers. 1a = Dimethyl sulphide (DMS) released from phytoplankton; 1b = Non-sea-salt (NSS) sulphur; 2 = SO_4 release in sea spray; 3 = mixing of aerosols in the atmosphere; 4 = dry aerosol deposition; 5 = wet aerosol deposition; 6 = runoff and gypsum formation; 7 = infiltration and groundwater flow; 8 = capillary rise and gypsum precipitation; 9 = gypsum dissolution and infiltration; 10 = gypsum dissolution and runoff; 11 = eolian gypsum dust dispersal; 12 = in-situ sulphide and sulphate formation in Benguela sediments; 13 = subcontinental dust input; 14 = sulphide oxidation by groundwater; 15 = H_2S release to atmosphere. (after Eckardt et al, 2001).

the sulphur. The Benguela Current has been a major upwelling system dating back to the Late Miocene (10 Ma) and is likely to have generated DMS for a significant amount of that time.

Likewise, much of the gypsum in Atacama Desert soils below 1300m and within 90 km of the coast receive a portion of their

sulphate from coastal fogs. Soils within 50 km of the coast and below 800m elevation, receive 50% of their calcium and sulphur from marine aerosols (Rech et al., 2003).

In summary, the occurrence of modern continental evaporites, especially sulphates, exhibiting largely marine-like (thalassic) brine ionic chemistries and isotopic signatures, is in part due to marine aerosol input and in part due to regionally open or leaky meteoric hydrologies. Mineralogies of preserved evaporitic sediments in low relief depressions on stable cratons can be largely uncoupled from the surface lake chemistries and salt crusts. This leaky hydrology, in a landscape dominated by deep weathering, deep regionally circulating groundwaters, with variable reflux intensity (leakage) drives the evolution of seawater like ionic proportions in the subsurface. It is common to many modern, low-latitude, tectonically stable desert areas and differs from the less aerially extensive but better documented hydrologies of the Basin and Range and East African rift valleys. Perhaps the hydrologically open setting is the more relevant hydrochemical analog for the continental hydrologies of ancient interior redbed deserts of ancient continents. If so, models based on assumptions of evaporite mineralogies in desert redbeds as being indicators of various "closed basin" hydrologies are largely irrelevant. If so, it makes the hydrochemical distinction between marine and nonmarine evaporites in the geological record even more difficult.

Acid groundwater in continental saline systems

Many playas atop the deeply weathered ancient regolith in central and southern Australia have elevated iron and sulphur contents. Salt lakes with more elongate shapes outline Tertiary palaeovalley fills in palimpsest landforms that were created under a different climate than that of today (Figure 11.8; Clarke, 1994). From the mid-Eocene, the climate in

Australia became progressively drier until by Miocene times much of central Australia was dominated by perennial alkaline lakes (Alley, 1998). The subtropical style of weathering that prevailed in the Early Eocene slowly changed with the passage into the Neogene, resulting in the development of a more arid siliceous and ferruginous regolith. The present elevated iron and sulphur levels in the modern Australian landscape ("the Red Centre") were derived, to a large extent, from earlier deep weathering profiles and even today these relicts of a more tropical time are still cycling through the now-arid Australian regolith. Passage into drier conditions allowed the buildup of minerals such as alunite and gypsum in the weathered profiles. The resulting low relief, gently undulating landsurfaces formed partial etchplains with topography controlled largely by the elevation of the palaeoweathering front and associated erosional topography of an incised Tertiary-age palaeodrainage and duricrusts. Hilltops may today be composed of fresher rock, while valley slopes, pediments and pediplains are typically composed of fresh to saprolitic rock, along with residual ferricretes that form low mesas.

Palaeodrainage fills can locally be more than 100-200 m thick, with many palaeodrainage networks currently occupied by elongate playa lakes, often with lunette margins and separated by wide areas of desert soils and dune sands. Formation of the weathered regolith largely predated the incision of the palaeodrainage which, in its deepest parts, has cut through to fresh rock (Clarke, 1994). The older relict saprolite in the current landscape dates back to the Late Permian-Middle Jurassic. Stripping of this regolith occurred in the Middle Jurassic-Early Eocene during the formation of the seaward-sloping palaeodrainage system. For example, about 400 m of material was denuded from the Yilgarn Craton, to infill the Perth, Eucla and Great Australian Bight Basins. Ongoing deep weathering occurred concurrently with erosion as increasing aridity led to disorganization of the drainage to form numerous chains of lakes, which by the Pliocene had evolved into saline lakes. Some of these palaeovalleys today contain economic capillary uranium (calcrete) deposits.

The great age of the Australian landscape and the buildup of remobilised iron in the modern regolith has led to natural acid brine systems feeding into many inland playas such as Lake Tyrell in Victoria and Lake Yaninee in South Australia. The salt lakes are recharge depressions which supply free-convecting dense saline brine (Na-Cl-SO₄ reflux brines) to their underlying aquifers.

For example, Lake Tyrell, with an area of 185 km², is the largest of three salt lakes in the Tyrell Basin, a structural downwarp located some 10 km east of the N-S trending Tyrell Fault in

the riverine plain of the Murray river in semi-arid northwestern Victoria (Figure 2.20; Macumber, 1992). It is a well-studied example of a lunette-fringed lake where deflation plays a major role in controlling morphology and sediment thickness. It evolved into a dry lake some 32 ka, but is today water-covered for up to 3 months in the winter and early spring (Teller et al., 1982). Despite ongoing deflation, up to 5 metres of lacustrine sediment is found in the lake centre and consists of varying proportions of clay, silt and sand, covered by an ephemeral halite crust up to 30 cm thick. The lakebeds are underlain by the Parilla Sand, a regional sulphate-rich aquifer.

Lake Tyrell is part of the outcropping expression of a regional oxidised acidic groundwater mass with characteristically low pH of 2-4 and salinities between 35 and 115‰. In contrast to the regional acidic system, the reflux brine plume beneath the lake is neutral (pH ≈ 7) but with salinities around 240‰. Direct rainfall in the winter months provides the bulk of the surface water currently entering the lake, whereas regional discharge and evaporation of westward-flowing Parilla groundwaters contributes most of the salt load. Faulting to the west of the lake uplifts the Parilla Sand aquifer and effectively closes the basin to ongoing throughflow or outward seepage and augments groundwater discharge by halving the saturated thickness of the aquifer. An additional groundwater divide separates the shallower parts of the hydrology of Lake Tyrell from that of Lake Wahpool (Figure 2.20).

As the regional Fe and S-rich acidic groundwaters resurge into the spring zone about the saline lake edge they precipitate varying proportions of characteristic lacustrine mineral suites made up of varying proportions of alunite, jarosite, halite, gypsum, opaline silica and iron oxyhydroxides. All these mineral phases are rich in Al, Fe and SO₄ giving the oxidised portions of the spring-zone sediments a classic "red bed" appearance (McArthur et al., 1989, 1991; Long et al., 1992a,b; Alpers et al., 1992; Macumber, 1992; Benison and Goldstein, 2002).

Hemley et al. (1969) showed by experiment that a high H₂SO₄ concentration is needed for alunite (KAl₃(SO₄)₂(OH)₆) and jarosite (KFe₃(SO₄)₂(OH)₆) to form in any low pH lacustrine environment. Associated acid minerals in the alunite-jarosite family include; natroalunite, alunogen, jurbanite, basaluminite, and rostitite (all in the system Al₂O₃-SO₄-H₂O), along with natrojarosite, schwertmannite, halotrichite, melanterite, and copiapite (all in the system Fe₂O₃-SO₄-H₂O; Nordstrom, 1982a, b; Van Breemen, 1982; Bigham and Nordstrom, 2000). Once formed in acid settings, these acid minerals may undergo further reactions, breaking down into more stable forms of iron

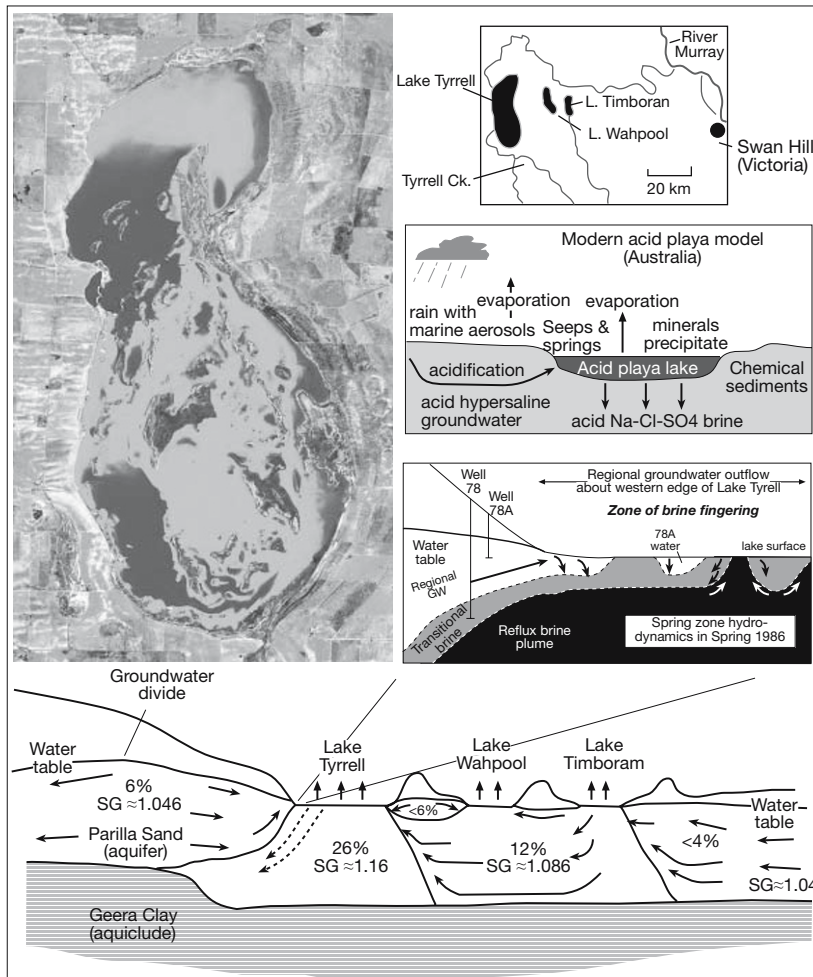

Figure 2.20 Acid lake formation based on modern natural acid lake and groundwater systems centred on Lake Tyrrell in southern Australia (after Macumber 1992; Lyons et al., 1995). These redbed siliciclastic sediments of the Parilla sand aquifer host sulphuric acid-rich saline lakes and groundwaters (pHs of 2–4) which precipitate alunite, jarosite, halite, gypsum, opaline silica, and possibly iron oxyhydroxides. Acidification may occur in the groundwater by processes such as oxidation of pyrite, ferrollysis, and microbial reduction of iron oxyhydroxides. Brine fingering typifies the mixing zone between regional groundwater outflow and the brine reflux prism beneath Lake Tyrrell (Landsat image courtesy of NASA).

oxides (i.e., goethite or haematite; Bigam and Nordstrom, 2000), sulphates (i.e., gypsum or anhydrite; Van Breemen, 1982), and aluminosilicates (i.e., microcline or albite; Long et al., 1992a).

What make them interesting is that these lacustrine redbeds indicate the influence of groundwaters carrying elevated levels of sulphuric acid (pH in the modern systems of Australia typically in the range 2–4) interacting with the neutral hypersaline waters of the lake itself. The regional waters of the regolith are very

different brines to the alkaline waters of well documented continental soda lakes and the marine-fed groundwaters of coastal salinas. Acid groundwaters in arid to semi-arid Australia indicate a landscape that has undergone a transition from tropical to arid conditions, perhaps related in part to Australia's northward drift, but more controlled by climate deterioration created by the transition from greenhouse to icehouse climate mode (Chapter 5).

Similar acid regolith/playa systems probably characterised much of the continental redbed interior of the USA in the Permian. Benison and Goldstein, (2002) argue such acidic saline deposits are commonplace in the rock record but largely unrecognised. They propose the following as criteria for the recognition of ancient acid saline lakes and groundwater deposits: (1) high HSO_4 in fluid inclusions in depositional and early diagenetic halite (or other evaporite minerals); (2) elevated concentrations of Al, as well as Fe and Si, in the same fluid inclusions; (3) identified remains of acidophilic bacteria or other acidophilic microbes; (4) acid minerals such as alunite or jarosite (or, more likely, the diagenetic products of acid minerals, such as gypsum or anhydrite); (5) presence of continental red beds; and (6) lack of widespread carbonate minerals. They go on to argue that many ancient red bed-hosted evaporite saline-pan and saline-lake deposits, which lack widespread bedded carbonates, are likely arid-zone outputs from ancient acidic hydrologies (Figure 5.13).

The spring seep region in the Lake Tyrrell outflow zone was one of the first wet playas documented with sinking brine plume fingers in the axial saucers of polygons of convective upwelling groundwater across the zone of phreatic mixing about the lake edge (Figure 2.20; Lyons et al., 1995). As upwelling regional groundwater reaches the Lake Tyrrell depression, it evaporates

and concentrates and so becomes denser. It then sinks to mix into the regional groundwater crossflow atop the Geera Clay aquiclude. Rather than sinking as a homogenous front these descending waters sink as denser brine fingers surrounded by upward flowing polygonal cells of fresher resurging groundwater that continually resupply the evaporating water surface (Figure 2.20). This convective counterflow creates large variations in fluid composition in short horizontal distances. Migration of the fingers over time creates numerous laterally migrating redox and salinity interfaces where diagenetic minerals can backreact and precipitate. This patchy diagenesis further complicates simple models for the distribution of the original “red-bed” precipitates and explains the complex counterplays of salinity indicators seen in ancient spring-seep strandzones (Chapter 1).

Based upon theoretical and experimental evidence, Wooding (1960) and Tyler and Wooding (1991) postulated that near the evaporating water surface, the downward movement of dense brine is confined to fingers or plumes of dense fluids, surrounded by an upward flow of fresher water supplying the evaporating surface. Similar convective polygons can also occur in freestanding zones of mixing near the strandzone edges of coastal salinas and saltworks. Tyler and Wooding (1991) showed that the conditions necessary for the onset of fingered polygonal convection beneath an evaporative wet playa surface are characterized by a modified Rayleigh number, R_c of the form:

$$R_c = (kg\Delta\rho)/(\mu\varepsilon)$$

where k is the intrinsic permeability (in cm^2), $\Delta\rho$ is the difference in density between the evaporated brine and the regional groundwater (in gm/cc), μ is the dynamic viscosity, ε is the evaporation rate and g is the acceleration due to gravity.

For a playa groundwater system to exhibit brine fingering, Tyler and Wooding (1991) and Ferguson et al. (1992) suggested that the Rayleigh criteria (R_c) must be around 10 or higher. Controlling factors leading to brine instability and convective fingering are sediment permeability, density contrast between the brine and regional groundwater outflow, and the evaporation rate. Using typical playa parameters of $\Delta\rho = 0.3 \text{ g}\cdot\text{cm}^{-3}$ and $\varepsilon = 30 \text{ cm}\cdot\text{year}^{-1}$, then the sediment permeability must be 10^{-9} cm^2 (100 md) or higher for the playa groundwater system to begin to polygonally convect. This permeability lies between that of unconsolidated clay and sand (Figure 10.4), suggesting that spring zones in sandy or permeable carbonate sediments, such as those typically found near playa and marine strandzone margins, are likely to exhibit brine fingering and

laterally migrating redox and salinity interfaces. Perhaps some of the megapolygonal patterns seen in domal stromatolites and tepees about the strandzone of Marion lake and other modern coastal salinas are the result of stable convective polygons in a resurgent brine hydrology (Figure 4.5b, c).

Contributions from evaporite bedrock

Difficulties in distinguishing marine versus nonmarine sources are further complicated by ongoing dissolution of older exhumed evaporites, which can act as chemical feeds into purely continental hydrographically-closed basins. In areas too continental for significant contributions from marine aerosols, this can still create marine-like signatures in the ionic proportions (Na-K-Mg-SO₄-Cl brines). For example, carnallite-sylvite-halite is a modern lake precipitate in Qaidam Basin, northern Qinghai-Xizang on the Tibet Plateau, China (Figure 11.2). This basin lies within a large, tectonically active region that is totally isolated from the effects of the ocean and is filled with Neogene clastics and evaporites. Its modern at-surface discharge playas are subject to intense evaporation and are characterised by ephemeral hypersaline brines as well as halite, potash and borate crusts and layers.

The chemical composition and Na/Cl ratios of the dissolved solutes in the modern brines and waters in the salt lakes of Qaidam Basin reveals three main sources (Vengosh et al., 1995): (1) Inflow of hot springs enriched in sodium, sulphate and boron. Evaporation of these waters leads to a high Na/Cl ratio (>1), a Na-Cl-SO₄ brine and an evaporite mineral assemblage of halite-mirabilite-borate (e.g. Lakes Daqaidam and Xiaoqaidam). (2) Inflow surface river waters, which are modified by preferential dissolution of older halite and potassium and magnesium salts. Evaporation of such waters creates Na-(Mg)-Cl brines with low Na/Cl (<1) and low Br/Cl, Li/Cl and B/Cl ratios. (3) Ca-Cl subsurface brines with chemistries controlled by both salt dissolution and dolomitization processes. Evaporation and salt crystallisation from mixtures of brines (2) and (3) leads to a “marine-like” Na-Mg-Cl brine with Na/Cl ratios <<1. Although more than 1,000 km from the nearest ocean the precipitated sequence of salts in these lakes is similar to that predicted for progressive evaporation of seawater. Lake Dabuxum and Qarhan playa today contain halite-sylvite-carnallite-bischofite successions.

The lower $\delta^{11}\text{B}$ values of the Qaidam basin brines and halites compared to seawater ($\delta^{11}\text{B} \approx 40\text{‰}$) indicate that the boron within these salt lakes is nonmarine (Figure 2.21; Vengosh et al., 1995). The $\delta^{11}\text{B}$ values of the dilute inflow waters to the

Figure 2.21. Boron isotopic and Na/Cl ratios of waters and brines in the Qaidam Basin, China (after Vengosh et al., 1995). See Figure 11.2 for locations.

Qaidam Basin range from -0.7 to $+10.9‰$, while brines in the various salt lakes range from $+0.5$ to $+15.0‰$ (Vengosh et al., 1995). Both groups overlap and are similar to those of associated granitic rocks ($\delta^{11}\text{B} = -2.12$ to $+3.7‰$) and hence indicate the nonmarine origin of these fluids.

In contrast to the Qaidam playas, the boron isotopic composition of brines, groundwaters and sediments of modern inland salt lakes located nearer the coast across southern Australia have a marine component, probably from aerosols (Vengosh et al., 1991). $\delta^{11}\text{B}$ values of brines in these salt lakes are 25 – $48‰$, with values up to 54 – $59‰$ in volcanic maar lakes in the higher rainfall areas near coastal region of southeastern Australia. Modern seawater has a $\delta^{11}\text{B}$ of $39‰$ (Figure 2.21).

Indicators of brine parenthood

Chemical and isotopic studies of various evaporite salts have been used for more than four decades in an attempt to define brine parentage. Bromine concentration and chlorine isotopes values have been used in this way to separate marine from nonmarine evaporite source brines, but are perhaps better indicators of salinities and stabilities of the parent brine. Sulphur isotopes can be used to indicate parentage, while the boron isotopic signature from brine inclusions in chevron halite is perhaps the best currently used tool for separating a marine from a nonmarine brine source. The lack of fractionation even with alteration and the creation of new indicator minerals well into the metamorphic realm means a boron isotopic signature in meta-evaporitic tourmalinites is still a reliable separator (Peng et al., 1998). Brine inclusions in unaltered sedimentary

halites are also useful indicators of both temperature and salinity, especially when microanalytic techniques are used to interpret the original brine chemistry. In the last two decades the microanalysis of brine inclusions in marine halites has led to a paradigm shift in our notions of the ionic stability of Phanerozoic seawater (Figure 2.30).

Bromine profiles - brine genesis or stability?

Trace elements in halite and other salts can sometimes help support an interpretation of a marine origin of the mother brine, especially if microanalytic techniques are used to determine fluid inclusion contents within the salts of interest and the sampled crystals retain primary sedimentary textures, such as bottom-aligned chevrons in halite. Bromine is fourth in anion abundance in seawater anions after Cl, SO_4 and HCO_3^- ($0.0671\text{ gm}/1000\text{ gm}$ seawater). With an ionic radius of 1.96 \AA it easily substitutes for chlorine (1.81 \AA) in the halite crystal lattice as well as in the other chloride salts. Numerous experiments have found halite's Br-concentration increases in tandem with the bromide concentration of the parent brine, its level in a halite crystal also increases with increases in parent brine temperature and in the speed of crystallisation.

Fixation of Br in the halite lattice is also dependant on the level of other ionic species present in the solution. Cl is strongly preferentially partitioned over Br into Na, K and Mg halogen salts during their precipitation and Br preferentially remains behind in solution (Figure 2.5). Br content decreases with increasing MgCl_2 content in the mother brine and with any increase in the degree of secondary recrystallisation (Dean, 1978). Its conservative behaviour in marine brines means that it has commonly been used as a salinity indicator in ancient halites and other chloride minerals.

The distribution of bromine between a halite crystal and the co-existing solution is described by its partition coefficient (D):

$$D = (\text{Br}_{\text{mineral}}/\text{Cl}_{\text{mineral}})/(\text{Br}_{\text{solution}}/\text{Cl}_{\text{solution}})$$

During initial evaporation of seawater, both Br and Cl increase in concentration in the residual brine, and the Br/Cl content of these waters does not vary (Figure 2.5). When halite saturation

is reached, Cl is preferentially removed over Br from the brine. A small fraction of the Br is also partitioned out into the halite, but most remains behind in the brine. As saturation with the bitterns (K-Mg-Cl) salts is reached, the slope of the Br-Cl curve flattens out as these minerals discriminate somewhat less in terms of Br incorporation (higher partition coefficients).

In earlier studies the Br content of ancient rock salt was used to separate marine from nonmarine precipitates (Dean, 1978; Holser, 1979; Wilgus and Holser, 1984). Fresh seawater contains around 65 ppm bromine and reaches 500 ppm by the onset of halite precipitation (Figure 2.5). Halite from a normal marine feed purportedly contains 50 to 100 ppm bromide and it should increase up to a maximum of around 270 ppm at the onset of bittern precipitation (Valyashko, 1956, p. 578). Halite that has been recrystallised in a second cycle of solution and reprecipitation in a brine of lower Br content than the original brine should have a bromide content of 20 ppm or less, especially if the recycling waters were nonmarine. But variations in salinity and the dilution by shallow to ephemeral residual brines, along with recrystallisation and backreaction, all influence the final Br content of any halite crystal in both marine and nonmarine settings (Figure 2.22a). Hardie (1984) discussed the limitations of using whole rock Br content as a depositional indicator and clearly showed the possible confusion that results if Br levels in wholerock halite samples are used in an attempt to separate marine from nonmarine halite.

Even if Br content of halite is not always a reliable indicator of the source of the mother brine, perhaps it can tell us something about brine stability at the time a salt was precipitated. Figure 2.22b plots bromine profiles from halites in two saline giants, the Paradox and the Prairie evaporites where values change in a predictable fashion upsection. Increasing upward trends indicate an increase in average annual brine salinity, while decreases indicate freshening (shown by arrows in Figure 2.22b). The trend to very high values (Br > 250 ppm) near the upper part of salt member 5 of the Hermosa Formation in the Paradox occurs beneath a potash bed and indicates higher salinities needed for the precipitation and preservation of bittern salts. The upward trends for the Prairie evaporite, although sampled at a some-

Figure 2.22. Bromine in halite. A) Bromine levels in halite in marine and nonmarine settings clearly showing that bromine levels have a degree of spread that does not support the assumption that nonmarine or recycled halite will always show values less than first cycle precipitates (in part after Hardie, 1984). B) Br profiles from the Paradox Member, Hermosa Formation in the Paradox Basin and the Prairie Evaporite in the Alberta Basin. All wells drawn to the same depth scale (after Holser, 1966, 1979).

what coarser spacing than the Hermosa, show similar brining upward profiles beneath potash beds. In a similar fashion Bein et al. (1991) used Br variations in brine inclusions in halite to define a southerly brine source for Permian San Andres halite in the Palo Duro Basin, Texas.

Contents of most other trace elements in marine evaporite salts are typically very low and not diagnostic of brine source. Iodine has very low partition coefficients in halite, sylvite, carnallite and the other bitterns, so they contain very little iodine. Its relatively large ionic radius impedes its replacement of chlorine ions in the respective lattices, so any residual liquor (marine or nonmarine) is strongly enriched. Iodate salts form pedogenic phases in the hyperarid Atacama desert (Chapter 11). Fluorine minerals occurs principally in sulphate deposits and salt clays that possibly have been influenced by hydrothermal inflows, although some Russian authors have argued for a marine evaporite association (Figure 7.68). There is no published data on fluorine behaviour during seawater concentration. However, if fluorine concentrates at the same rate as Cl during evaporation, then seawater should have a fluorine concentration around 10 mg/l at the onset of halite saturation. Rubidium and ammonium substitute for potassium in crystal lattices of the bittern chlorides (e.g. sylvite, carnallite). Cesium does not occur in halite, and lithium in water-soluble form is only found in concentrations up to 0.2 ppm. The colouring of halite often feigns higher amounts of heavy metals. Only 2 ppb of trivalent iron can give halite a yellow colour, while a few more parts per billion can turn salt red (Sonnenfeld, 1995).

Sulphur and oxygen isotopes

Modern seawater sulphate has a homogeneous and well-defined isotopic composition for both sulphur and oxygen:

$$^{34}\text{S}_{\text{SO}_4} = +20 \pm 0.5\text{‰ CDT}$$

$$^{18}\text{O}_{\text{SO}_4} = +9.5 \pm 0.5\text{‰ SMOW}$$

Likewise, the fractionation of sulphur and oxygen, which occurs during the transition from aqueous to solid state of sulphate is also near constant at earth surface temperatures. For gypsum, the mean values of the isotope enrichment factor are (Pierre, 1988):

$$\epsilon^{34}\text{S}_{\text{gypsum-SO}_4} = 1.65\text{‰}$$

$$\text{and, } \epsilon^{18}\text{O}_{\text{gypsum-SO}_4} = 3.5\text{‰}$$

Thus the $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ values of sulphate evaporites are directly related to the state of the aqueous sulphate reservoir where precipitation occurred. A plot of ancient marine CaSO_4 evaporites shows the sulphur curve for seawater has varied across time from +30‰ in the Cambrian, to around +10‰ in the Permian and it increased irregularly in to Mesozoic to its present value of +20‰. Oxygen values show much less variability (Figure 2.23a). Variations are reflected in all major marine evaporites and were most likely controlled by major input or removal of sulphides from the oceanic reservoirs during changes in tectonic activity and weathering rates. Simple removal of oceanic sulphate (increase in evaporite formation) would probably not be accompanied by such dramatic isotopic effects.

Rather, variations within the global sulphur cycle are controlled by a redox balance, which is also linked to the carbon cycle and the atmospheric oxygen budget. The oxidative part of the global sulphur cycle is governed by continental weathering (especially of marine black shale), riverine transport and evaporite deposition, while the reduced part is controlled by levels of fixation of reduced sulphur-bearing compounds in the sediment column, mostly as pyrite via bacterial sulphate reduction. The latter process will preferentially remove isotopically light sulphur from seawater and so increase its $\delta^{34}\text{S}$ value in the ocean and any subsequent marine evaporite salt. Another cause of variation in the evaporite-derived sulphur isotope curve of seawater is variation in the rate of high-temperature flushing of seawater through the ocean ridge system and varying input of mantle sulphur to the labile volcanics of the mid-ocean ridges. Thus, the sulphur isotopic composition of seawater sulphate in marine evaporites documents variation in longterm earth-scale processes (i.e. uplift and erosion, mantle input) and aspects of biological evolution (e.g. bacterial sulphate reduction).

The ^{18}O content in seawater sulphate is more stable than sulphur values over geologic time. The isotopic composition of sulphate minerals varied only slightly from the Neoproterozoic to the Palaeozoic decreasing from +17 to +14‰ (Figure 2.23a). Values then rose during the Devonian to reach +17‰ during the Early Carboniferous (Mississippian). Values then fell to +10‰ during the Permian, mimicked by a similar decline in sulphur values in the Late Permian to Early Triassic. Since a rise to +15‰ in Early Triassic values of marine sulphate minerals have remained close to +14‰ (add 3.5‰ to mineral determined value to give ambient seawater value). Overall, oxygen values show little correlation with marine sulphate variation and are perhaps controlled by sulphide weathering reactions that contribute sulphate to seawater and the dissolution of sulphate evaporites Further discussion on global controls

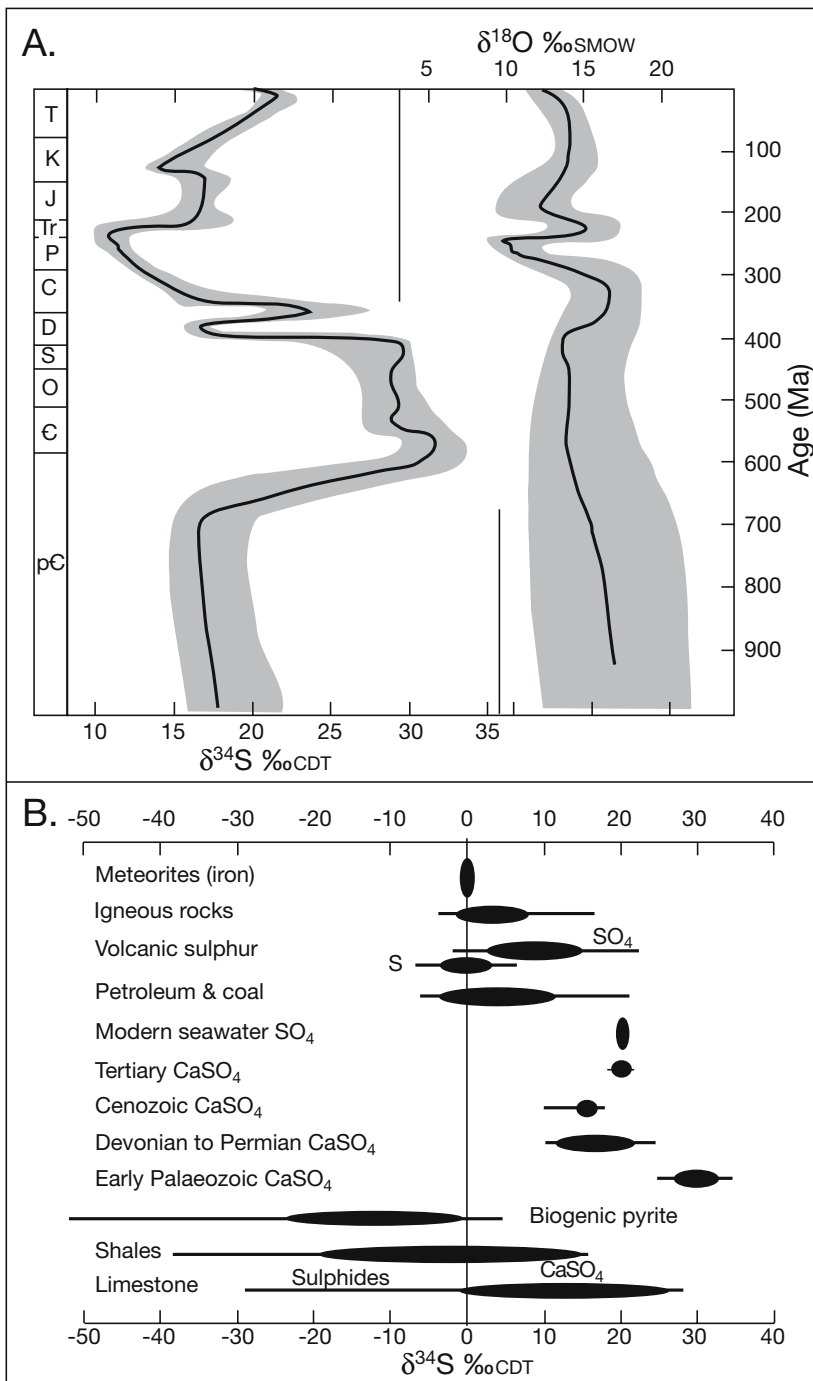

Figure 2.23. Sulphur and oxygen isotopes. A) Sulphur and oxygen isotope age curves for marine sulphate evaporites. The heavy lines are the best estimates of $\delta^{34}\text{S}$ and $\delta^{18}\text{O}$ values of calcium sulphate minerals in equilibrium with world ocean sulphate at that time. Shaded areas are estimated uncertainty envelopes of these curves. B) Isotope range of various systems and selected seawater sulphate (after Pierre, 1988; Veizer et al., 2000).

of isotope chemistry lies outside the evaporite focus of this book. What is significant is that, given the now well established sulphur isotope age curve, a comparison of a measured $\delta^{34}\text{S}$ value from an anhydrite or gypsum of known geological age to the curve allows an interpretation of a possible marine origin to the salt. A value which differs from the marine signature does not necessarily mean a nonmarine origin, but at the least it does mean diagenetic reworking or, more likely, a groundwater-induced recycling of sulphate ions into a nonmarine saline lake (Pierre, 1988). Such oxygen and sulphur isotopic crossplots have been used to establish the continental (nonmarine) origin of the Eocene gypsum of the Paris Basin and the upper Miocene gypsum of the Granada basin, with sulphate derived from weathering of uplifted Mesozoic marine evaporites (Fontes and Letouolle, 1976; Rouchy and Pierre, 1979; Pierre, 1982). Sulphur in evaporitic sulphate can come from a number of sources other than reworked marine evaporites, likely isotopic ranges of possible sources are given in Figure 2.23b.

Crossplots of oxygen with carbon or deuterium isotopes are useful in defining the origin of evaporitic carbonates. If these carbonates are interlayered with gypsum or anhydrite at the mm scale, then their signatures are very useful in determining the origin of the waters precipitating both the carbonates and the sulphates. This was the rationale used by Bellanca and Neri (1986) in a study of the origin of gypsum and associated carbonates in the Messinian of Sicily. The oxygen and hydrogen isotope compositions of crystal water from the laminar gypsum indicate primary precipitation of the sulphate from marine waters concentrated by evaporation (Figure 2.24a). The iso-

topic data also show compositional changes due to periodic influx of continental waters into the depositional basin seen by the clustering of the laminar gypsum values along the SMOW concentration-dilution line with a regression coefficient of 0.98. The massive gypsum signature indicates rehydration by meteoric waters (probably modern). Open-marine-water incursions probably led to the deposition of carbonate layers overlying the laminar gypsum. These contain abundant aragonite with textural features and isotopic compositions suggesting precipitation in shallow and quiet marine waters slightly enriched in ^{18}O by evaporation (Figure 2.24b).

Sulphur is largely resistant to isotopic fractionation during burial alteration and transformation (Worden et al., 1997). Primary marine stratigraphic sulphur isotope variation is preserved in anhydrites of the Permian Khuff Formation, despite subsequent dehydration to anhydrite during burial ($\approx 1,000\text{m}$) and initial precipitation as gypsum from Permian and Triassic seawater. Gypsum dehydration to anhydrite did not involve significant isotopic fractionation or diagenetic redistribution of material in the subsurface. At depths greater than 4300 m, the same sulphur isotope variation across the Permian-Triassic boundary is still present in elemental sulphur and H_2S , both products of the reaction of anhydrite with hydrocarbons via thermochemical sulphate reduction (Figure 9.44). Clearly, thermochemical sulphate reduction did not lead to isotope fractionation. Worden et al. also argues that significant mass transfer has not occurred in the system, at least in the vicinity of the Permian-Triassic boundary, even though elemental sulphur and H_2S are both fluid phases at depths greater than 4300 m. Primary differences in sulphur isotopes have been preserved in the rocks and fluids, despite two major diagenetic overprints

that converted the sulphur in the original gypsum into elemental sulphur and H_2S by 4300 m burial and the potentially mobile nature of some of the reaction products. That is, all reactions occurred must have occurred *in situ*; there was no significant sulphur isotope fractionation, and only negligible sulphur was added, subtracted, or moved internally within the system.

Boron Isotopes

Boron isotope determinations on halite, borate salts, and brines are all capable of distinguishing between marine and nonmarine sources (Figures 2.25; Vengosh et al., 1992; Swihart et al., 1986). Marine evaporites are characterised by distinctly higher $\delta^{11}\text{B}$ values (+18.2 to +31.7‰) than non-marine evaporites (-30.1 to +7.0‰; Swihart et al., 1986). The latter span the range typical of the boron isotope signatures of most other rock types (Palmer and Helvacı, 1997). Likewise, there is a clear isotopic separation between marine and nonmarine brines (Figure 2.25a, c).

The separation reflects the enrichment of the ^{11}B isotope in seawater compared with both oceanic crust and continental crust. Differences are due to the original isotopic fractionation that occurred when boron was extracted from seawater into detrital clays, weathered basalts and carbonate minerals. Continental evaporite brines are derived from the weathering of these various lithologies, while the boron in seawater comes straight from the concentration of seawater. Much of the boron signature that is measured when whole rock halites and other salts are analysed comes from the fluid inclusions and not from boron in the lattice structure. The low level of fractionation between the brine and its precipitate at the time of halite deposition

means boron isotope analysis can reliably distinguish nonmarine and marine brine parents in modern salts, even in complex multisource systems such as Lake Qaidam (Liu et al., 2000).

Beyond the halite precipitation field $\delta^{11}\text{B}$ values tend to increase with increasing concentration in both brine and the associated bittern precipitates. In all fields the $\delta^{11}\text{B}$ values and boron contents are higher in brine than in its precipitated halite suite (Figure 2.25b; Vengosh et al., 1992). However the boron is not

Table 2.8. Boron isotopes in the brines and halite crusts of various salt lakes in the Qaidam Basin, China (after Liu et al., 2000).

behaving in an absolutely conservative fashion and there is a deficiency of boron in the increasingly saline brines and a concurrent increase in the boron content of the associated salts (Table 2.8; Liu et al., 2000). The highest δ¹¹B values in the Qaidam Basin are associated with fluids with low B/Li ratios, indicating selective removal of elemental boron and ¹⁰B by

adsorption onto clay minerals along the flow path into the basin (Table 2.8; Liu et al., 2000). The magnitude of ¹¹B enrichment due to adsorption differs by 15-20‰ from the supply, and thus nonmarine brines are still distinguished from marine-derived evaporitic brines, which have much higher δ¹¹B signatures in the range +39 to +59‰ (Figures 2.25a, d).

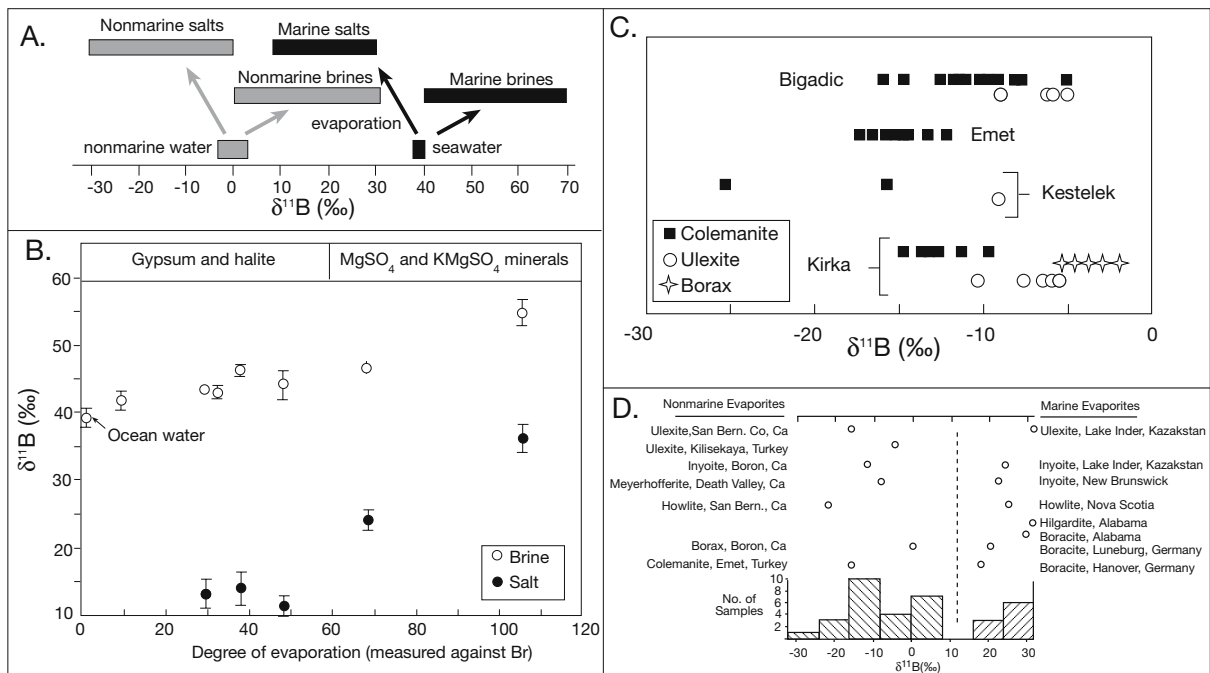

Figure 2.25. A) Isotopic distribution of boron in evaporatively formed marine and nonmarine brines and salts related to signature of original water source. B) δ¹¹B values of evaporated seawater (open circles) and co-existing precipitated halite (closed circles) versus degree of evaporation as calculated from Br values. Note the relative enrichment of ¹¹B in brines relative to salt and the difference in magnitude of enrichment during different stages of evaporation (after Vengosh et al., 1992). C) Ranges of boron isotope values in various minerals in the main Turkish borate deposits- see also Figure 11.30 (after Palmer and Helvacı, 1997). D) Isotopic analysis of evaporitic borates worldwide showing clearly separate fields for marine and nonmarine samples (dashed line). The upper part of figure shows analytical determinations from various deposits, the lower part shows a histogram where these values are grouped (after Swihart et al., 1986).

Palmer and Helvacı (1997) found that the isotopic values of the main borate minerals in the major Turkish borate deposits are largely controlled by their mineralogy and the pH of the brines from which they precipitated. For example, the differences in the $\delta^{11}\text{B}$ values of the three main borate minerals at Kirka (colemanite, ulexite and borax) are greater than would be expected if they had precipitated in equilibrium with one another from a solution with the same $\delta^{11}\text{B}$ value and pH (Figure 2.25c). The data are consistent with all three minerals being primary precipitates from a concentrated brine, with colemanite precipitating from a brine of lower pH than ulexite, and borax precipitating from a brine of higher pH than ulexite. The only other Turkish deposit in which there are significant amounts of coexisting primary borate minerals is at Bigadic, which contains coexisting ulexite and colemanite (Figure 11.31). There the average $\delta^{11}\text{B}$ value of ulexite is -6.8‰ , this is 3.6‰ higher than that of colemanite -10.4‰ (Figure 2.25c). This difference suggests that colemanite precipitated at a lower pH than ulexite (Palmer and Helvacı, 1995).

Chlorine isotopes

Unlike the stable isotopes of boron and sulphur, which can be used as indicators of parent brine type, ^{37}Cl interpretation is more problematic due to its inherently low levels of fractionation during evaporation. Prior to the early 1980s, this meant analytical methods lacked the precision needed to detect small variations in chlorine isotopes levels that occur

in nature. Measurements have now improved to where even small fractions in natural halites can be reliably and accurately determined (Long et al., 1993). Earlier work also suffered from a poor understanding of evaporitic fractionation mechanism and it was only in the mid 1990s that our understanding of ^{37}Cl determinations evolved into a useful environmental tool in an evaporite basins (Eggenkamp et al., 1995). Ongoing impermeability and a lack of reactivity away from the edge of a halite mass means that depositional isotope values will persist, even in tectonised evaporites or in evaporites that have undergone recrystallisation (Eastoe and Peryt, 1999).

Eggenkamp et al. (1995) determined a fractionation of $0.26 \pm 0.07\text{‰}$ between halite and a NaCl solution at 25°C . Halite crystallising from a 0.00‰ NaCl solution will therefore have an initial value of $0.2\text{--}0.3\text{‰}$. Halites precipitated from seawater brines show decreasing values from 0.2‰ at the onset of halite precipitation to -0.5‰ by the hexahydrite precipitation stage (Eastoe et al., 1999). Using seawater, Eggenkamp et al. (1995) showed that the $\delta^{37}\text{Cl}$ value decreases in the halite stage from 0.0 to -0.45‰ . During the subsequent kainite and carnallite stages the fractionation factor is close to unity and the $\delta^{37}\text{Cl}$ of the brine is only 0.04‰ . In the subsequent bischofite stage the fractionation factor is < 1 and $\delta^{37}\text{Cl}$ increases during the final stages of evaporation. The $\delta^{37}\text{Cl}$ values of precipitates in the halite stage decreases from 0.26 to -0.19‰ (Figure 2.26). In the kainite stage, the precipitate (a mixture of salts) has a $\delta^{37}\text{Cl}$ that decreases to -0.34‰ and then to -0.47‰ in the carnallite stage. However in the last stage, typified by the precipitation of bischofite in the mix, the $\delta^{37}\text{Cl}$ value increases from -0.55‰ back into positive values in the very latest stages of evaporation before complete dryness. Error ranges in determinations increases after the end of the halite stage. Because $\delta^{37}\text{Cl}$ values decrease monotonically with concentration in the halite stage, it is possible to use $\delta^{37}\text{Cl}$ values in unaltered halites (chevron halite) to estimate the concentration stage at the time of precipitation of an ancient halite (palaeosalinity determination). At later bittern stages this methodology is less effective and more subject to ambiguities (Eggenkamp et al., 1995).

Figure 2.26. Calculated $\delta^{37}\text{Cl}$ values of the precipitate and residual brine during seawater concentration. The shaded area indicates the error range for the precipitates (solid line), while the area between the dashed lines is the error range for the residual brine. Note the discontinuities in the curve for the precipitates (after Eggenkamp et al., 1995).

That this methodology works is clearly seen in a study of the $\delta^{37}\text{Cl}$ signatures of the ZIII interval of the Permian Zechstein salts in the TR-2 well in the Netherlands (Figure 2.27a). The interval is a combination of halite and bittern stage salts. The halite-dominated interval (Z.III.2a) has a simple salt chemistry with minor amounts of carnallite, bischofite and kieserite. $\delta^{37}\text{Cl}$ values tend to decrease upward into the overlying carnallite-kieserite interval at 1660 m, implying increasing salinities as the unit passes up into the bittern-dominated succession. Sam-

ples in the bittern-dominated intervals (Z.III.1b and Z.III.2b) show high levels of carnallite, kieserite and bischofite and values that tend to be toward the lower end of the $\delta^{37}\text{Cl}$ value scale, consistent with higher supersaline salinities needed to precipitate these salts, sylvite ore brines show a similar highly negative signature.

Other ancient bedded halites also lie in the marine supersaline range. For example, bedded Permian halites in the Palo Duro basin, situated immediately above and below a halite bed preserving chevrons, show primary $\delta^{37}\text{Cl}$ values of 0.4 to around 0.0 ‰ (Figure 2.27b). Waters driving the recrystallisation cannot have been generated by later meteoric dissolution and recrystallisation. Rather, these recrystallised halites preserve their Permian depositional signatures (Eastoe et al., 1999). This conclusion supports the notion that subsurface salt beds intercalated with remnant chevrons are largely impervious closed systems that dissolve from the edges inward (Figure 8.7). It means any temperature and salinity values measured in brines in microinclusions in the chevron halite will indicate ambient conditions at the time of halite precipitation (e.g. Figure 2.28). It is also why viable Permian haloarchaea can be cultured from such inclusions (Vreeland et al., 2000).

In contrast, nonmarine chloride contributions to a basinal brine precipitate halite with a more positive $\delta^{37}\text{Cl}$ value. Carpathian (Middle Miocene) halokinetic halite has $\delta^{37}\text{Cl}$ values greater than 0.4 ‰, as do some halites in the Gulf of Mexico, the North Sea and the Paris Basin (Figure 2.27b). Such positive values cannot arise solely from seawater evaporation and require a considerable input of nonmarine chloride, either from a continental meteoric or igneous/hydrothermal source (Eastoe and Peryt, 1999).

The contrast between halite with a hydrothermal signature and that preserving original syndepositional values is clear in

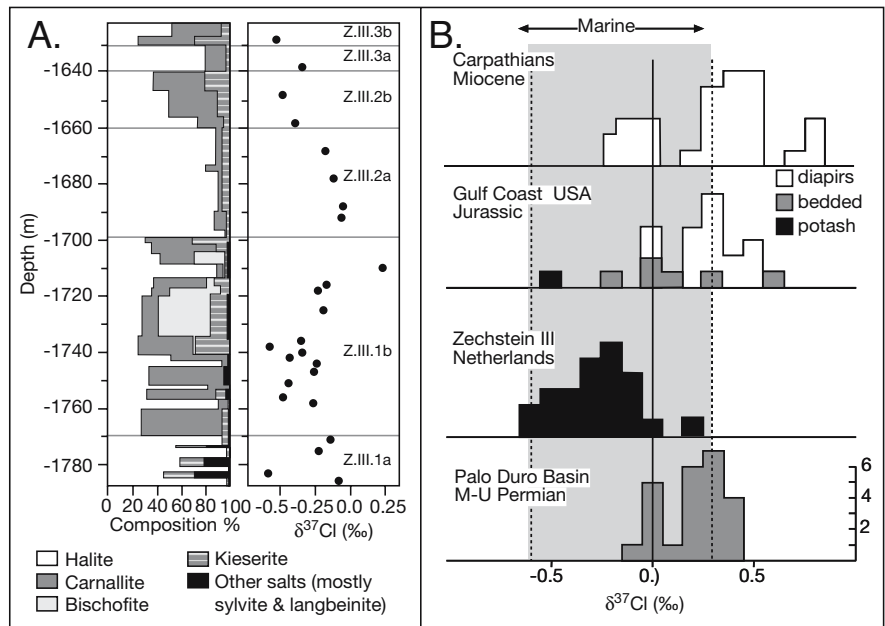

Figure 2.27. $\delta^{37}\text{Cl}$ isotope as an environmental indicator. A) Isotopic and mineralogic composition of Zechstein III showing that in these marine salts the $\delta^{37}\text{Cl}$ isotopic values are typically higher in the halite layers than in carnallite and bischofite layers (after Eggenkamp et al., 1995). B) Isotopic values of selected halites showing marine values are typically less than 0.4 ‰ and centred on 0.0 ‰ (after Eastoe et al., 2001).

Jurassic halite in the Gulf Coast Basin (Eastoe et al., 2001). Halite has a $\delta^{37}\text{Cl}$ range of -0.5 to 0.3 ‰ in most bedded salt and 0.0 to 0.5 ‰ in diapiric salt. The values for bedded salt are consistent with a $\delta^{37}\text{Cl}$ value of 0.0 ‰ for Jurassic seawater chloride, as in modern oceans. The slightly higher values for diapiric salt are possibly caused by incongruent solution of halite (Figure 8.30).

Chloride isotopes in subsurface waters can indicate their provenance and show a $\delta^{37}\text{Cl}$ range of -1.9 to 0.7 ‰ (Eastoe et al., 2001). Formation waters in the Gulf of Mexico with $\delta^{37}\text{Cl} < -0.6$ ‰ are confined to geopressed Eocene to Miocene strata at depths of 2500m or greater. Strongly negative values do not occur in Plio-Pleistocene strata, which retain the values of seawater (connate brines), nor do they occur in Mesozoic strata, which are marine carbonates. It seems that the strongly divergent values come from chloride in waters released from shales undergoing the smectite-illite transformation in the zone of geopressure.

Low $\delta^{37}\text{Cl}$ values in such waters are related to low $m_{\text{Cl}}/m_{\text{Na}}$ (a parameter indicating dewatering) but show no general relationship to Cl/Br ratios (Eastoe et al., 2001). They are consistent with diffusion of chloride from an allochthonous brine. Dif-

fusion can generate domains of water with negative $\delta^{37}\text{Cl}$ on a scale of hundreds of metres in 10^4 – 10^6 years, and may also generate positive $\delta^{37}\text{Cl}$ chloride in residual source brine. The expulsion of such brines into an evaporite basin may account for most non-0 ‰ chloride sources in evaporite basins.

The experiments of Eggenkamp et al. (1995; Figure 2.26) were limited to a single seawater evaporation cycle, but evaporites accumulating in shallow pans in marine and continental settings are subjected to multiple cycles of dissolution and partial reprecipitation before their burial. This can bring about measurable changes in $\delta^{37}\text{Cl}$, but also leaves little residual halite within the total halite mass.

Fluid Inclusions and brine temperatures

When halite and other salts are precipitated, they can capture and enclose inclusions of ambient brine. Such inclusions form the cloudy lamina that outline milky halite chevron and cornet textures and are used to indicate primary growth orientations of crystals in ancient salt beds (Figure 1.32a). Inclusion-rich bands indicate episodes of rapid growth, while clearer bands indicate slower growth rates. Chevron banding may indicate diurnal temperature changes in a shallow brine pan, with rapid growth spurts encouraged by the cooling of brine each evening.

Halite's high solubility and potential for deformation sometimes raises doubts about long-term preservation of the integrity of fluid inclusions. Even ancient halite that still retains abundant growth-aligned textures, if exposed to even moderate heating it may contain fluid inclusions that have leaked. Halite's propensity to flow also means its fluid inclusions are more vulnerable to stretching, leaking, and necking-down compared to most other minerals. But Petrichenko (1979) and Roedder (1984a,b) have shown that even when deformation has occurred, only the outer portions of halite crystals are affected, the centres of crystals typically remain unaltered. Alteration textures in ancient bedded halites with crystals suitable for micro-inclusion analysis are thus defined by altered, clear, outer rims and unaltered, cloudy, primary inclusion-rich cores that retain meaningful inclusion data (Petrichenko, 1979; Roedder, 1984a,b). The problems of defining inclusion leakage, coupled with the possibility of bedded and halokinetic salt being used as repository sites for radioactive waste, has generated valuable research on the validity of fluid inclusion data in halite (Chapter 12).

Lowenstein and Spencer (1990) obtained some of the first reliable and consistent estimates of ancient syndepositional brine temperature estimates using solid-liquid homogeniza-

tion temperatures of sylvite daughter crystals in halite from the Devonian Prairie Formation. They show Devonian brine temperatures were similar to those in Quaternary continental equivalents and that many ancient potash deposits still retained evidence of very early diagenetic features, created by the cooling of syndepositional reflux brines.

Many geologists have maintained a healthy scepticism toward fluid inclusion data derived from evaporites, especially from non-chevron halite (Roedder and Skinner, 1968; Kovalevich, 1975, 1976; Petrichenko, 1979; Roedder and Bassett, 1981). Work by Roberts and Spencer (1995) and by Benison and Goldstein (1999) has shown how petrographically controlled microthermometric testing can define and avoid zones of inclusion alteration in ancient halite. If the tests suggested by these authors show that primary fluid inclusions have not been altered since entrapment, then fluid inclusions from the unaltered portions of a salt bed may be considered representative of evaporative parent waters and can even be used to define palaeotemperatures of the mother brine (Figure 2.28). This is now a widely used approach for determining surface water palaeotemperatures from ancient halites whose fluid inclusions lack daughter crystals (Benison and Goldstein, 1999).

An all-liquid primary inclusion in halite at room temperature indicates mineral growth below approximately 50°C (Kovalevich, 1975; Petrichenko, 1979). Vapour bubbles can be nucleated artificially in some all-liquid inclusions by placing samples in a freezing chamber so that homogenization temperatures below 50°C can be measured. Roberts and Spencer (1995) found that when primary fluid inclusions in newly precipitated halite in ephemeral-lake salt-pans in Death Valley, California, were cooled (in order to nucleate vapour bubbles) and homogenization temperature were measured, the resulting temperature ranges were equivalent to the measured temperatures of the shallow brine sheets from which the halite had precipitated (Figure 2.28a).

Likewise detailed inclusion analysis, centred on chevrons and cornets in unaltered portions of halite beds in the mid-Permian Nippewalla Group of Kansas gave cooling-induced homogenization temperatures representative of the temperature range of the original mother liquor (Figure 2.28b, c). What was even more interesting was the intimate and consistent relationship between temperature and position in the inclusion rich layer in the chevron bands in this mid Permian halite (Figure 2.28b, c). It probably preserves daily temperature changes and shows the propensity of inclusion-rich bands to precipitate when the overlying halite saturated brine cools each evening or with the passage of a cold front.

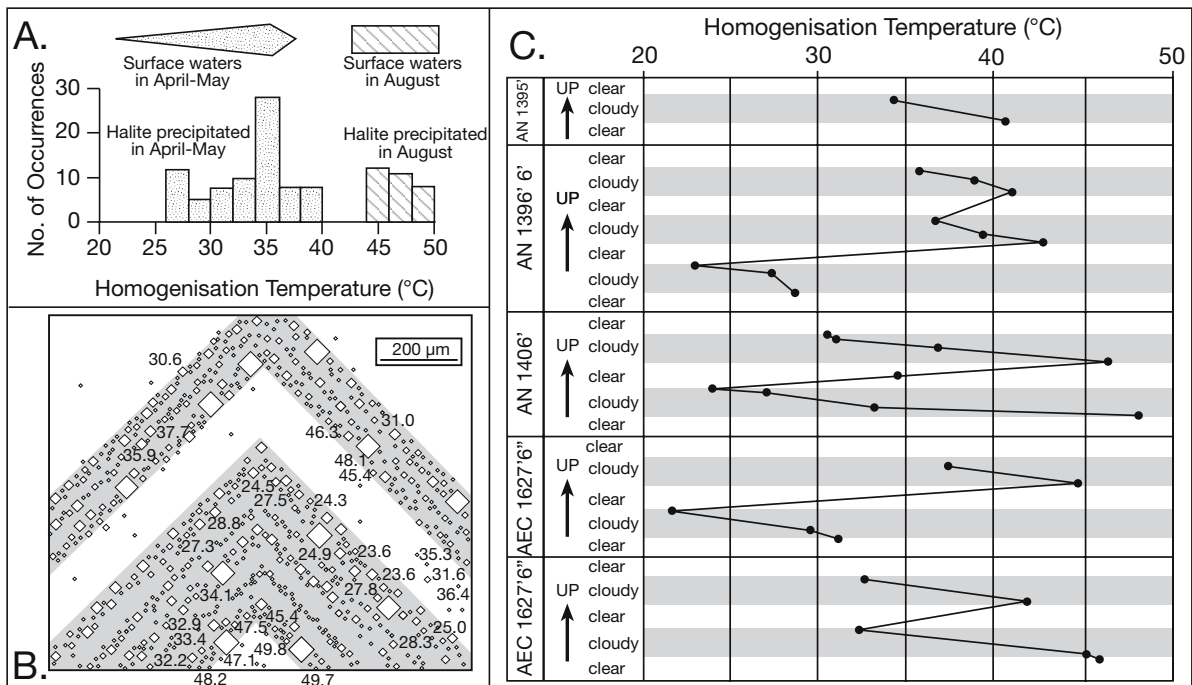

Figure 2.28. Inclusions in chevron halite. A) Histogram of homogenization temperatures measured by the ‘cooling nucleation’ method in initially all-liquid primary fluid inclusions from modern Death Valley halite. Plotted above the histogram are the temperature ranges of the brines from which these halite crystals grew (after Roberts and Spencer 1995). B) Representation of chevron bands in a halite crystal from the Anadarko Davis No. 1 core (1406 ft depth). Note homogenization temperatures in relation to bands; although homogenization temperatures are consistent within individual fluid inclusion assemblages thin, high frequency growth bands, they decrease from base to top of chevrons (after Benison and Goldstein, 1999). C) Graphic representation of homogenization temperature trends within and among cloudy, inclusion-rich and clear, inclusion-poor growth bands in five chevron halite crystals from the Nippewalla Group. Black circles mark average homogenization temperatures within thicker chevron growth bands. Lines connecting black circles are extrapolated temperature trends. Upward decrease in homogenization temperatures from base to top of individual cloudy chevron bands probably reflect daily fluctuations in surface water temperatures perhaps related to evening cooling (after Benison and Goldstein, 1999).

The fact that halite can retain such intimate precipitational detail supports the notion that growth-aligned chevrons are subsurface survivors. This means microanalysis of the chemical make-up of a brine inclusion in an unaltered halite chevron or cornet is indicative of the chemical composition of the water that precipitated the crystals (Timofeef et al., 2001). This gives an ability to map temporal changes in the ionic proportions of seawater and once again also suggests why Permian halobacteria can be cultured from brine inclusions in Permian salt (Vreeland et al., 2000).

Seawater evolution

So far in this chapter three things are clear: 1) it is difficult to separate marine and nonmarine parent brines based on mineralogy; 2) isotopes and microinclusions can sometimes separate brine parentage; 3) it is increasingly obvious that the proportions of major ions in seawater are probably not constant

across geological time. The significance of various indicators of chemical evolution of seawater over time is now considered in two parts. First, in the Phanerozoic where actual salts are available for sampling and analysis. Second, in the Precambrian, where much of the evidence of brine composition comes from pseudomorphs of evaporite salts.

A Phanerozoic dilemma: marine versus nonmarine potash?

Phanerozoic potash evaporites fall into two categories: 1) potash deposits with MgSO₄ salts, such as polyhalite, kieserite and kainite; and 2) potash deposits with halite, sylvite and carnallite, and entirely free or very poor in the magnesium-sulphate salts. This latter group makes up more than 60% of ancient potash deposits (Hardie, 1990). The former group may well be marine-derived as they contain the bittern suite predicted by the evaporation and backreaction of modern marine brines,

but the latter group must have precipitated from Na-Ca-Mg-K-Cl brines with ionic proportions quite different from that of concentrated modern seawater.

MgSO₄-depleted potash evaporites have been explained by some as modified marine evaporites thought to result from backreactions during burial diagenesis of normal marine evaporites (Borchert, 1977; Dean, 1978; Wilson and Long, 1993). If so, then they were derived from an ancient seawater source with modern ionic proportions that were altered via; a) dolomitization, b) sulphate reducing bacterial action, c) mixing of brines with calcium bicarbonate-rich river water, or d) rock-fluid interaction during deep burial diagenesis.

Alternatively, Hardie (1990) suggested that MgSO₄ depleted potash evaporites formed from sulphate-depleted inflow waters seeping into an evaporite basin via springs and faults. Springs were fed either by CaCl₂-rich hot hydrothermal brines or by cooling resurging deep basinal brines. Such fault-fed deeply-circulating evaporite brines occur today in springs in the Dead Sea, Qaidam Basin, Salton Sea and the Danakil Depression. The upwelling of the brines in these regions is driven either by thermally induced density instabilities related to magma emplacement, or by the creation of topographic gradients that force deeply-circulated basinal brines to the surface. Ayora et al. (1994) demonstrated that such a continental Ca-Cl system operated during deposition of sylvite and carnallite in the upper Eocene basin of Navarra, southern Pyrenees, Spain (Figure 8.10).

Thirdly, there is the distinct likelihood that seawater chemistry has evolved throughout the Phanerozoic and that changing ionic proportions define whether or not MgSO₄ salts were typical marine evaporites. Work by Kovalevich et al. (1998)

on inclusions in primary-bedded halite from many evaporite formations of northern Pangaea, and subsequent work using micro-analyses of fluid inclusions in numerous chevron halites (Lowenstein et al., 2001, 2003a), shows that during the Phanerozoic the chemical composition of marine brines has oscillated between Na-K-Mg-Ca-Cl and Na-K-Mg-Cl-SO₄ types. The former does not precipitate MgSO₄ salts when concentrated, the latter does.

A detailed analysis of the ionic make-up of Silurian seawater using micro-inclusion analysis of more than 100 samples of chevron halite from various Silurian deposits around the world was recently published by Brennan and Lowenstein (2002), and clearly supports the notion that ionic proportions in the world's Silurian oceans were different from those of today (Figure 2.29). Samples were from three formations in the Late Silurian Michigan Basin, the A-1, A-2, and B Evaporites of the Salina Group, and the Early Silurian in the Canning Basin (Australia) in the Mallowa Salt of the Carribuddy Group. The Silurian ocean had lower concentrations of Mg²⁺, Na⁺, and SO₄²⁻, and much higher concentrations of Ca²⁺ relative to the ocean's present-day composition. Furthermore, Silurian seawater had Ca²⁺ in excess of SO₄²⁻. Bittern stage evaporation of Silurian seawater produced KCl-type potash minerals that lack the MgSO₄-type late stage salts formed during the evaporation of present-day seawater and allowed sylvite as a primary precipitate.

There is now convincing evidence that the chemistry of seawater has varied across the Phanerozoic, what is not so well understood are the processes driving this change (Figure 2.30a). Spencer and Hardie (1990) and Hardie (1996) have argued that the level of Mg in the Phanerozoic oceans has been relatively constant, but changes in the rate of seafloor spreading have changed the levels of Ca in seawater. Their postulate was also supported

Flux Ratio	Na	K	Ca	Mg	Cl	SO ₄	HCO ₃	Order of appearance of saline minerals during evaporative concentration of seawater
0.96	490	3.7	4.8	111	548	59.0	2.7	CaCO ₃ - gypsum - anhydrite - glauberite - halite - polyhalite - epsomite - hexahydrate - kieserite - kainite - carnallite - bischofite
1.00	470	10.2	20.3	106	548	53.9	0.6	CaCO ₃ - gypsum - anhydrite - glauberite - halite - polyhalite - epsomite - hexahydrate - kieserite - carnallite - bischofite
1.05	448	17.6	36.2	101	548	53.8	0.6	CaCO ₃ - gypsum - anhydrite - halite - polyhalite - sylvite - carnallite - kieserite - bischofite
1.10	427	24.3	51.8	97	548	51.4	0.4	CaCO ₃ - gypsum - anhydrite - halite - sylvite - carnallite - bischofite - tachyhydrite
1.25	376	41.2	91.4	85	548	45.3	0.3	CaCO ₃ - gypsum - anhydrite - halite - sylvite - carnallite - antarcticite - tachyhydrite

Table 2.9. Predicted composition of seawater (meq l⁻¹) as a function of variations in the ratio of mid-ocean ridge hydrothermal brine flux compared to river water flux into the ocean, and the saline mineral paragenesis of the resulting seawater (after Spencer and Hardie, 1990). Only the first appearance of each mineral is listed (see Figure 2.12 for backreaction effects).

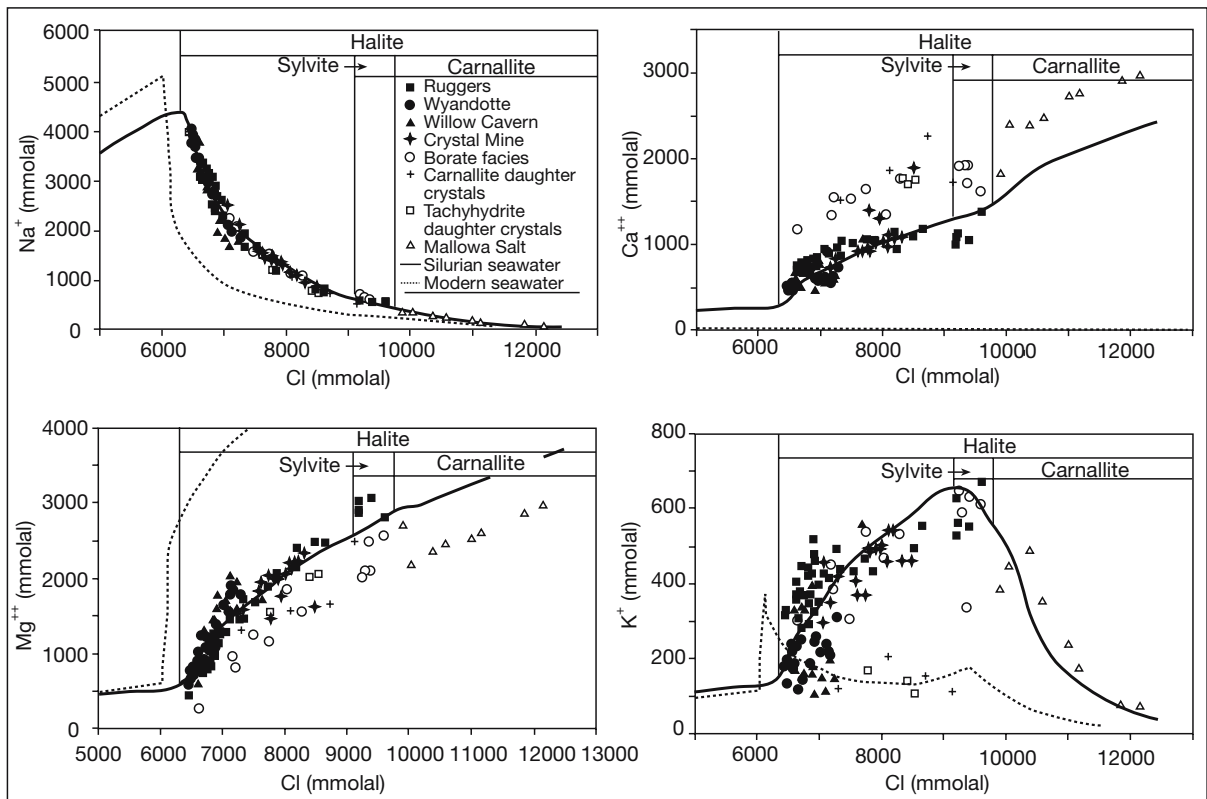

Figure 2.29. Plots of the major-ion concentrations of the fluid inclusions versus chloride concentrations in Silurian salt with preserved primary structures (after Brennan and Lowenstein, 2002). Closed symbols represent fluid inclusions from pristine marine halites, open symbols represent suspect fluid inclusions from halites associated with potash mineralization or high degrees of evaporation. Only the closed symbols were considered for determining Silurian seawater. The evaporation pathway of modern seawater is shown with a dashed line, and the best-fit evaporation pathway for the Silurian data is shown with a solid line. All the plots show that the evaporation pathways defined by Silurian fluid inclusions are different from the modern seawater pathways. The Silurian fluid inclusions all have an excess of calcium, and no measurable sulphate. Modern seawater evaporated to halite saturation has abundant sulphate, and negligible amounts of calcium. Salts expected to precipitate at given Cl concentrations in evaporated "best-fit" Silurian seawater are indicated along the top of each plot. Sylvite is a primary precipitate from concentrated seawater with these ionic proportions.

by Lowenstein et al. (2001, 2003). Timing of the increase in the amount of Ca in the world's oceans was synchronous with a decrease in the SO_4 ion concentration, which at times was as much as three times lower than the present concentration of that ion in seawater.

Simple mixing models show that changes in the flux rate of mid-oceanic hydrothermal brines can generate significant changes in the Mg/Ca, Na/K and SO_4/Cl ratios in seawater (Table 2.9). Such changes of molal ratios in seawater would have generated significant changes in the type and order of potash minerals at the bittern stage. For example, Spencer and Hardie's model predicts that an increase of only 10% in the flux of mid-ocean ridge hydrothermal brine over today's value would create a marine bittern that would precipitate sylvite and calcium-chloride salts instead of the Mg-sulphate miner-

als expected during bittern evaporation of modern sea water. This Ca-Cl ocean corresponds to times of "calcite oceans" and contrast with the lower calcium, higher magnesium "aragonite oceans" of the Permo-Triassic and the Neogene (Figure 2.30a; Hardie, 1996).

Yet many sources have argued, including earlier work by Hardie, that bittern salts lacking MgSO_4 components indicate a nonmarine CaCl source. The strong possibility of temporal changes in Phanerozoic seawater chemistry from a MgSO_4 to a KCl ocean confuses a mineralogical distinction between marine and nonmarine brine sources. It can be used to argue that many extensive ancient evaporites, such as the Devonian Prairie Evaporite Fm. of Canada and the Cretaceous Maha Sarakham salts of Thailand are in fact marine and formed by the evaporation of a KCl ocean.

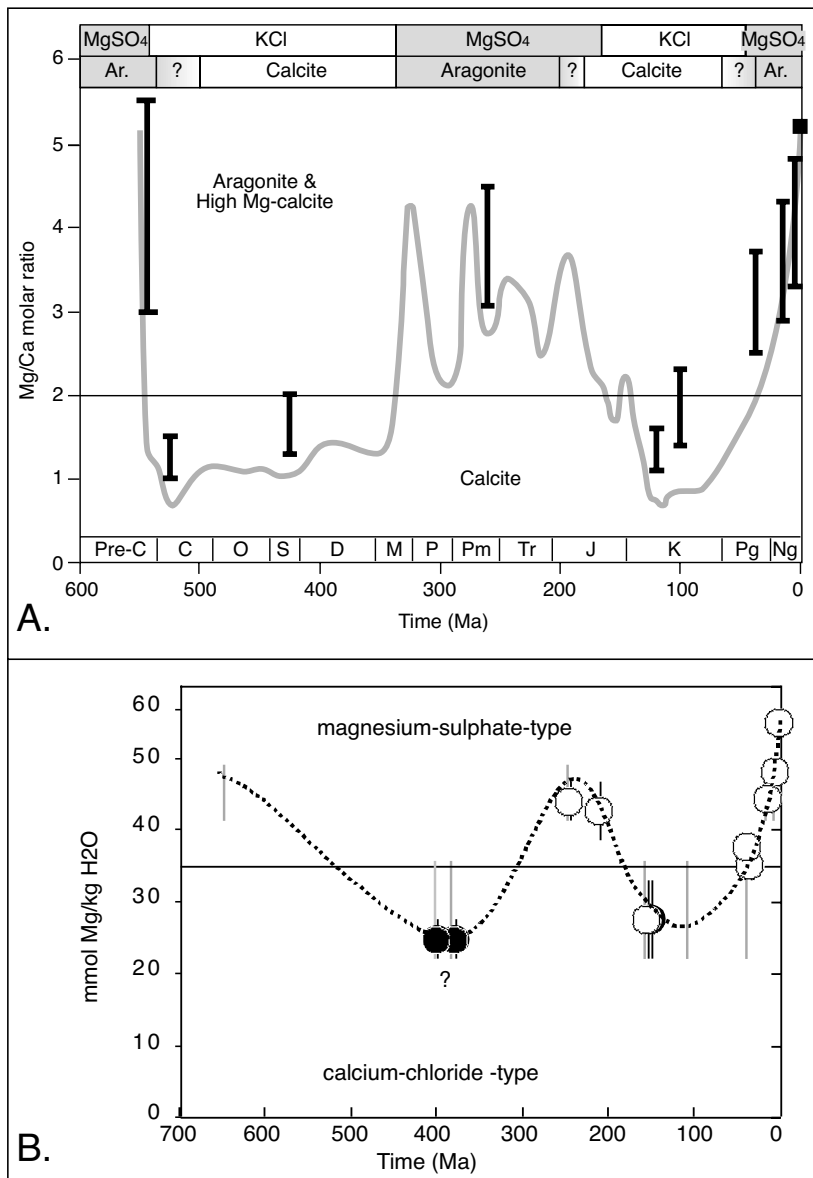

Figure 2.30. Potash and the secular evolution of Phanerozoic seawater. A) Secular variation in the Mg/Ca ratio of seawater estimated from fluid inclusions in marine halites (vertical bars), compared to predicted seawater secular variations. The horizontal line at Mg/Ca = 2 is the approximate divide between calcite seas and aragonite seas. Also plotted are the temporal distributions in the primary mineralogies of Phanerozoic nonskeletal carbonates (calcite and aragonite) and periods of KCl and MgSO₄ evaporites (after Lowenstein et al., 2001). B) Secular changes in seawater chemistry based on microanalysis of fluid inclusions in marine halites (after Zimmermann, 2000a).

Holland et al. (1996), while agreeing that there are changes in ionic proportion of Phanerozoic seawater and that halite microinclusions preserve evidence of these changes, recalculated the effects of changing seafloor spreading rates on global

seawater chemistry used by Hardie and others. They concluded changes in ionic proportions from such changes in seafloor spreading rate were modest. Instead, they pointed out that the composition of seawater can be seriously affected by secular changes in the proportion of platform carbonate dolomitized during evaporative concentration, without the need to invoke major changes in global seawater composition. In a later paper, Holland and Zimmermann (2000) suggest changes in the level of Mg in seawater were such that the molar Mg/Ca ratio of Palaeozoic global seawater (based on dolomite volume) was twice the present value of 5.

Using micro-inclusion studies of halites of varying ages, Zimmermann (2000a, b) has proposed that the evolving chemistry of the Phanerozoic ocean is more indicative of changing volumes of dolomite than it is of changes in the rates of seafloor spreading (Figure 2.30b). Using halite inclusions she showed that the level of Mg in seawater has increased from ≈ 38 mmol/kg H₂O to 55 mmol/kg H₂O in the past 40 million years. This increase is accompanied by an equimolar increase in the level of oceanic sulphate. Over the longer time frame of the Palaeozoic to the present the decrease in Mg/Ca ratio corresponds to a shift in the locus of major marine calcium carbonate deposition from Palaeozoic shelves to the deep oceans, a change tied to the evolution of the nannoplankton. Prior to the evolution of foraminifera and coccoliths, some 150 Ma, the amount of calcium carbonate accumulating in the open ocean was minimal. Since then, a progressively larger portion of calcium carbonate has been deposited on the floor of the deep ocean. Dolomitization of these deep water carbonates has been minor. Reasons for the increase in Mg in the past 40 million years are still not clear.

Ayora et al. (2001) called for caution in applying general models of secular changes in seawater chemistry based on assumptions of worldwide sulphate depletion at various times in the past. They reconstructed the chemical evolution of several European Mesozoic and Tertiary marine evaporite basins using mineral associations, primary fluid-inclusion analyses, and numerical simulations of evaporation scenarios. The solute proportion recorded in the fluid inclusions in all basins could be explained using the evaporation of present-day seawater as a major re-charge. Sulphate depletion in the brines was responsible for the type of potash deposit formed, namely potassium-magnesium sulphates or sylvite. But this sulphate depletion was due either to dolomitization or to the addition of a CaCl_2 -rich solution to the basin. Sulphate depletion occurred in varying intensity in basins of the same age, as well as throughout the evolution of the same basin negating the notion of changes in seafloor spreading. They concluded changes in potash mineralogy and sulphate depletion based on fluid inclusions are not conclusive arguments in favour of secular variations in the composition of the ocean.

But, most evaporite workers would now agree that based on a growing database of worldwide synchronous changes in brine chemistry in fluid inclusions in chevron halite (e.g. Figure 2.29) there were secular changes in seawater chemistry, which drove the two potash endmembers. What is not clear is the magnitude of this change or the dominant driving mechanism (seafloor spreading versus dolomitization) nor why the proportion of K in seawater appears to change very little throughout the Phanerozoic. What is also not considered by some involved in the argument are the pitfalls and analytical needs for exact fluid inclusion interpretation in sediments that may have been subject to subtle diagenetic alteration (see Goldstein 2001 for an excellent review and discussion of inclusion studies).

Precambrian oceanic chemistry

Given that ionic proportions of major ions in seawater have probably changed through the Phanerozoic, how constant was the chemistry of the world's oceans since the early Archaean? For example, does the evaporite evidence support the possibility of a primordial reducing atmosphere or higher levels of bicarbonate in an ancient ocean?

Some authors postulate that there have been no significant changes in the major ion proportions in seawater for the past 4 Ga (Morse and Mackenzie, 1998). Others assert that the Archaean was dominantly a time of little or no atmospheric oxygen and that ocean waters were reducing fluids (Krupp et

al., 1994). Yet others propose that the bicarbonate to calcium ratio was so high in Archaean and Palaeoproterozoic seawater compared to today that all the calcium was used up in widespread abiotic marine aragonite and Mg-calcite precipitates (Sumner and Grotzinger, 2000). In this case trona or nahcolite are likely marine evaporites in the early Archaean. Still others have theorised cyclic changes in oceanic chemistry occurred throughout the Phanerozoic and much of the Precambrian. Such changes were related to changes in styles and rates of sea floor spreading-hydrothermal circulation in midoceanic ridges (Channer et al., 1997) and the development of tonalitic continents (Knauth, 1998). Can Precambrian evaporites and their pseudomorphs give some indirect clues as to which scenario is the more likely?

Given the paucity of preserved evaporite salts prior to the Mesoproterozoic, the discussion must centre on mineralogical evidence left as evaporite pseudomorphs. The resulting detail is far less than when modelling Phanerozoic chemistries, which can use micro-inclusions and isotope signatures of marine salts.

Pseudomorphs, especially of halite hoppers, occur in marine rocks as old as Archaean, but are far more common, as are the actual salts, in Proterozoic and Phanerozoic strata (Figure 2.31). Halite or its pseudomorphs characterise areas of widespread marine chemical sedimentation from the Archaean to the present. CaSO_4 distribution is more enigmatic. Possibly the oldest documented CaSO_4 pseudomorphs are cm-sized growth-aligned barytes that are interpreted to replace bottom-nucleated gypsum in 3.45 Ga metasediments in the Pilbara/North Pole region of Western Australia (Figure 7.71; Barley et al., 1979; Lowe, 1983; Buick and Dunlop, 1990). They were precipitated in volcanoclastics in association with what are possibly the world's oldest stromatolites (Hofmann et al., 1999). Similar growth aligned baryte crystals, which are also possible gypsum pseudomorphs, formed in the Nondweni greenstones in South Africa some 3.4 Ga (Wilson and Versfeld, 1994).

Sequences in both regions are now completely silicified or barytised. At the time they were first documented, the recognition of what were considered shallow-water Early Archaean gypsum pseudomorphs at North Pole, Pilbara Craton, caused a re-evaluation of models of a totally reducing Archaean atmosphere (Dimroth and Kimberley, 1975; Clemmey and Badham, 1982). The presence of free sulphate in surface brines of the Archaean world was thought to imply at least locally oxygenated hydrosphere. Gypsum precipitating in Archaean ocean waters also meant calcium levels in the ocean waters were in excess of bicarbonate, as is in the modern oceans (Figure 2.5). The presence of free-standing gypsum on the seafloor is

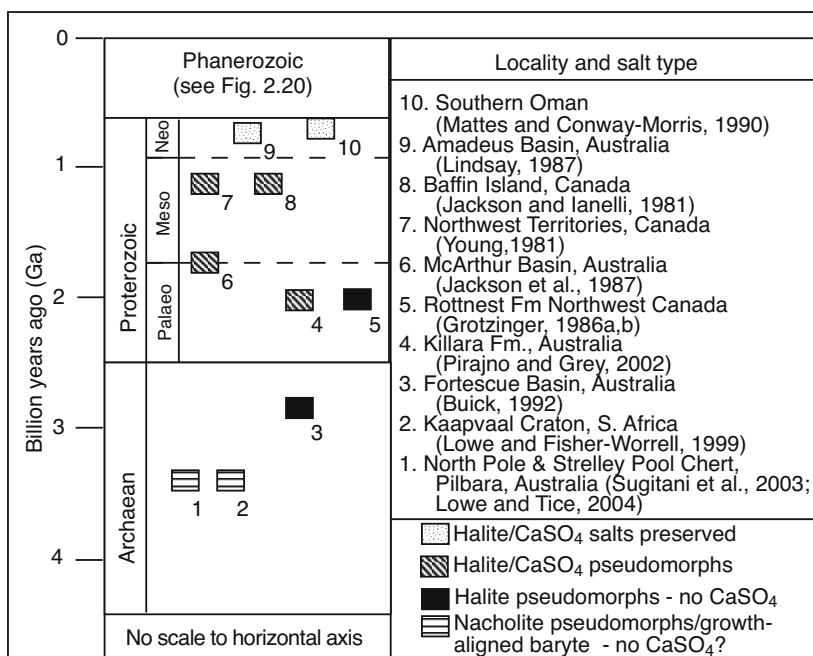

Figure 2.31. Precambrian evaporite occurrences and mineralogies (compiled from listed sources).

incompatible with any model of the Early Archaean ocean as a “soda lake.”

However, in both the Pilbara and the South African sequences there are no actual calcium sulphate evaporites preserved, only growth-aligned crystal textures now preserved as baryte. Textures in baryte ore from Frasnian sediments in Chaudfontaine, Belgium, are near identical to those observed at North Pole, Australia. The Belgian barytes are primary sea-bottom precipitates with no precursor mineral phase (Dejonghe, 1990). Some workers in the Pilbara feel that the growth-aligned baryte in this region is also a primary precipitate, formed in the vicinity of hydrothermal vents (Vearncombe et al., 1995; Nijman et al., 1999; Runnegar et al., 2001). As such, it is not secondary after gypsum. A similar hydrothermal discharge model has been developed for aligned barytes in the Barberton Greenstone belt (de Ronde et al., 1994, 1996).

Levels of Archaean sulphate in the world ocean were probably less than a few percent of the current levels and probably remained so until the evolution of an oxygen-producing biota well into the Proterozoic (Habicht and Canfield, 1996; Kah et al., 2004). Barium sulphate is highly insoluble in modern oxygenated seawater. To carry large volumes of barium or sulphur (as sulphide) in solution to the precipitation site re-

quires anoxic conditions. If the aligned baryte crystals are primary, their formation still requires sulphate to be locally present on the seafloor, at least in the vicinity of the depositional site. A possible source for local sulphate production in the shallow waters that characterised the North Pole site was shortwave ultraviolet photooxidation of volcanic SO₂ (Runnegar et al., 2001). According to Nijman et al. (1999) the occurrence of the North Pole baryte in sedimentary mounds atop growth faults meant sulphate was locally derived via boiling of escaping hydrothermal vent waters enriched in Ba, Si and sulphide. As these hydrothermal waters vented in waters perhaps 50 metres deep, they boiled or violently degassed. Consequent mixing with normally stratified seawater, caused instantaneous oxidation of sulphide into sulphate that then, on cooling, combined with the Ba to precipitate as growth aligned baryte crystals on the seafloor.

Conflicting notions (replaced gypsum versus primary baryte) mean that at this stage of our understanding, the bedded baryte evidence cannot be reliably used to support an evaporite paragenesis of gypsum and so infer an Archaean ocean with ionic proportions similar to those of today.

Archaean and Proterozoic distributions of gypsum have been further complicated by the misidentification of primary aragonite splays and pinolitic siderite marbles as gypsum replacements (Warren 1999; Chapter 8). When these misidentifications are removed from the record it is obvious that calcium sulphate precipitating directly from Archaean seawater to form widespread beds did not occur, and that precipitation of aragonite as thick crusts on the sea floor was significantly more abundant than during any subsequent time in earth history. In contrast to gypsum, halite pseudomorphs are found throughout the Precambrian (e.g. Boulter and Glover, 1986; Figure 2.31; Table 7.1).

Grotzinger and Kasting (1993) argue that high levels of atmospheric CO₂ meant HCO₃⁻/Ca ratios were much higher in the Archaean and the Palaeoproterozoic oceans than today. All the calcium in seawater was deposited as marine cementstones

and other alkaline earth precipitates well before bicarbonate was depleted and there was no Ca left over to precipitate as gypsum. The early Archaean ocean was perhaps a Na–Cl–HCO₃ sea, and not the Na–Cl ocean of today (Kempe and Degens, 1985; Maisonneuve, 1982). This early Archaean hydrosphere had a chemistry similar to that found in modern soda lakes like Lake Magadi and Lake Natron (pathway I brines in Figures 2.12, 2.13). This rather different marine brine chemistry would have precipitated halite and trona/nahcolite, not halite/gypsum. It probably meant that if gypsum did ever precipitate from Archaean seawater it did so only in minor amounts well after the onset of halite precipitation. Excessive sodium in the ocean may help explain the ubiquity of stratiform albitites in much of the Archaean. They would have formed throughout the marine realm as early diagenetic replacements of labile volcanoclastics/zeolites in volcanogenic/greenstone terranes (See Chapter 11, zeolite).

A case for nahcolite (NaHCO₃) as a primary evaporite, along with halite in the 3.42 Ga rocks of the Barberton greenstone belt was documented by Lowe and Fisher-Worrell (1999). Sugitani et al. (2003) reported silicified nahcolite (the high CO₂ form of sodium carbonate salts; see Figure 2.13a) in ≈3.2 Ga rocks in the northern part of the Eastern Pilbara block, Western Australia. Coarse, upward-radiating, silicified evaporite crystals in the ca. 3.47–3.46 Ga Strelley Pool Chert (Lowe, 1983) show the same habit, geometry, and environmental setting as nahcolite in the Barberton belt and also probably represent silicified NaHCO₃ precipitates (Lowe and Tice, 2004).

Marine nahcolite in the 3.5–3.2 Ga sedimentary record is thought to be evidence of surface temperatures around 70±15°C (Figures 2.13a, 2.32; Lowe and Tice, 2004). Con-

temporary early Archaean nahcolite (NaHCO₃) as a primary evaporitic mineral in a very aggressive weathering regime, in the absence of land vegetation, is best explained by a mixed CH₄ and CO₂ atmospheric greenhouse. CH₄/CO₂ ratios were <<1 and pCO₂ was at least 100–1000 times the present value, perhaps as high as several bars (Kaufman and Xiao, 2003). The formation of large areas of continental crust at 3.2–3.0

Figure 2.32. Schematic diagrams showing proposed atmospheric pCH₄ and pCO₂ evolution during Archean and earliest Proterozoic, 3.5–2.2 Ga (after Lowe and Tice, 2004). Diagrams show atmospheric evolution A) without and B) with glaciation at 2.9 Ga. High surface temperatures, 70±15°C, were maintained from before 3.5 to at least 3.2 Ga by mixed CO₂ and CH₄ atmospheric greenhouse with CH₄/CO₂ << 1. Starting ca. 3.2 Ga (point a), enhanced weathering associated with continent formation began to deplete atmospheric CO₂, leading eventually to CH₄/CO₂ ≈ 1 some 2.9 Ga (point b) and formation of organic haze, which began to reduce pCH₄ along a path defined by CH₄/CO₂ ≈ 1. Declining pCO₂ and pCH₄ at 2.9–2.7 Ga resulted in global cooling and possibly glaciation (point c in lower diagram). Reduced weathering and continued tectonic recycling 2.7–2.6 Ga led to increasing pCO₂ (line c-d-e), allowing a coupled increase in pCH₄ while maintaining CH₄/CO₂ ≈ 1. When upper limit of CH₄ production was reached (point d), CH₄/CO₂ became <1 and methane haze formation ceased. Enhanced weathering ca. 2.6 Ga (point e) associated with continent building at 2.7–2.5 Ga once again initiated rapid depletion of atmospheric CO₂ and decline in surface temperatures. Increased O₂ production—associated with latest Archaean spread of oxygenic photosynthetic microbes onto large, shallow-water, continental shelves developed on older (pre-3.0 Ga) blocks of continental crust (point f)—concurrently lowered pCH₄, maintaining CH₄/CO₂ < 1 and preventing the formation of organic haze. Widespread glaciation at 2.4–2.2 Ga resulted from decreasing pCO₂ due to weathering and declining pCH₄ due to oxidation.

Figure 2.33. Proterozoic marine sulphate concentrations. Filled ovals mark data determinations (after Kah et al., 2004). Marine sulphate concentrations probably remained below 2mM until about 1.3 Gyr ago, rose to, 4.5mM by 1.2 Gyr ago, and possibly as high as 7–10mM by the mid-Neoproterozoic, although near-complete reduction of oceanic sulphate may have occurred during Neoproterozoic glacial intervals (arrow). Increased sulphate concentrations coincide with changes in marine $\delta^{13}\text{C}$ associated with biospheric oxygenation and are marked by the appearance of bedded gypsum (stars) in the late Mesoproterozoic and more frequent gypsum deposition in the last two-thirds of the Neoproterozoic.

Ga, including the Kaapvaal and Pilbara cratons, resulted in the gradual depletion of atmospheric CO_2 through weathering and a lack of marine nacholite since the early Archean. By 2.9–2.7 Ga, declining $p\text{CO}_2$ was associated with climatic cooling and siderite-free soils.

Transitory CH_4/CO_2 ratios of ~ 1 may have resulted in the sporadic formation of organic haze from atmospheric CH_4 , and are reflected in one or more isotopic excursions involving global deposition of abnormally ^{13}C -depleted organic carbon in sediments of this age. Surface temperatures of $<60^\circ\text{C}$ after 2.9 Ga may have allowed an increase in the distribution and productivity of oxygenic photosynthetic microbes (and a decrease in sulphur dependant thermophiles). Eventual lowering of new formed continental blocks by erosion, reduced loss of atmospheric CO_2 due to weathering, and continued long-term tectonic recycling of CO_2 resulted in rising $p\text{CO}_2$ and decreasing CH_4/CO_2 ratios in the later Archean and eventual re-establishment of a mainly CO_2 greenhouse. Similar events may have been repeated in the latest Archean and earliest Proterozoic, but gradually rising production of O_2 effectively kept CH_4/CO_2 ratios to $\ll 1$.

By 2.2–2.0 Ga, reliable examples of pseudomorphs after primary calcium sulphate first appear in the rock record (Figure 2.31; Table 7.9). Undeniable pseudomorphs are widespread in the Late Palaeoproterozoic to Mesoproterozoic sediments of the McArthur Basin, Northern Territory, Australia, and in rocks of Great Slave Lake in northern Canada. For example, in the Malapunyah Formation of the Northern Territory, Australia, the outer portions of numerous decimetre to metre-diameter silicified anhydrite nodules still retain outlines of felted anhydrite laths (pers. obs). The oldest reliable sulphate pseudomorphs after anhydrite and gypsum come from Palaeoproterozoic cherts in the 2.0–2.2 Ga Bartle Member of the Killara Formation, western Australia (Pirajno and Grey, 2002). These cherts locally retain small amounts of anhydrite (verified by XRD, as well as appearing as highly birefringent flecks in thin sections). Other widespread but younger sulphate pseudomorphs occur in the 1.2 Ga Borden Basin, Baffin Island, and the 1.2 Ga Amundsen Basin in the Canadian Arctic Archipelago. Currently the world's oldest documented CaSO_4 beds outcrop in the 1.2 Ga Society Cliff Formation in Baffin and Bylot Islands of the Canadian Archipelago (Kah et al., 2001, 2004). Sulphate evaporites in all these basins formed beds up to tens of metres thick and with lateral extents measured in hundreds

of square kilometres. All were laid down in shallow marine, coastal, and alluvial environments under an oxygenated Mesoproterozoic atmosphere (Jackson et al., 1987; Walker et al., 1977). By then the hydrosphere contained free sulphate and Ca/HCO₃ ratios were lower.

The work of Kah et al. (2004) shows that prior to 2.2 Ga, when oxygen began to accumulate in the Earth's atmosphere, sulphate concentrations in the world's oceans were <1 mM and possibly <200 μM (Figure 2.33). By 0.8 Ga, oxygen and thus sulphate levels had risen significantly. Sulphate levels were between 1.5 and 4.5 mM, or 5–15% of modern values, for more than a billion years after initial oxygenation of the Earth's biosphere some 2.2–2.4 Ga and mid-ocean depth waters were anoxic for most of that time (Brocks et al., 2005). Marine sulphate concentrations probably remained low, no more than 35% of modern values, for nearly the entire Proterozoic. A significant rise in biospheric oxygen, and thus oceanic sulphate, may not have occurred until the latest Neoproterozoic (0.54 Ga), just before the Cambrian explosion, when sulphate levels may have reached 20.5 mM, or 75% of present day levels. This is a time when thick sulphate platforms first characterised the salt basins of Oman.

In yet another proposal of hydrosphere-atmosphere evolution, Huston and Logan (2004) argue that the presence of relatively abundant bedded sulphate deposits before 3.2 Ga (as baryte) and after 1.8 Ga (as CaSO₄ salts), and the peak in banded iron formation abundance between 3.2 and 1.8 Ga, and the aqueous geochemistry of sulphur and iron, when taken together suggest that the redox state and the abundances of sulphur and iron in the hydrosphere varied widely during the Archean and Proterozoic. They propose a layered hydrosphere prior to 3.2 Ga in which sulphate was enriched in an upper oceanic layer, whereas the underlying layer was reduced and sulphur-poor. The sulphate was produced by atmospheric photolytic reactions with volcanic gases in a reducing atmosphere. Mixing of the upper and lower water masses allowed the banded barytes to form prior to 3.2 Ga and created an ocean chemistry where nahcolite was a marine evaporite. Between 3.2 and 2.4 Ga, decreasing volcanogenesis and sulphate reduction removed sulphate from the upper layer, producing broadly uniform, reduced, sulphur-poor and iron-rich oceans.

As a result of increasing atmospheric oxygenation around 2.4 Ga, the flux of sulphate into the hydrosphere by oxidative weathering was greatly enhanced, producing layered oceans, with sulphate-enriched, iron-poor surface waters and reduced, sulphur-poor and iron-rich bottom waters. Gypsum evaporites

were increasingly likely as marine precipitates. The rate at which this process proceeded varied between basins depending on the size and local environment of the basin. By 1.8 Ga, the hydrosphere was relatively sulphate-rich and iron-poor throughout. Gypsum was now a widespread marine evaporite. Variations in sulphur and iron abundances suggest that the redox state of the oceans was buffered by iron before 2.4 Ga and by sulphur after 1.6 to 1.8 Ga.

Gypsum in combination with halite was the marine evaporite association from then until now. Seawater was a Na-Cl-SO₄ ocean. Neoproterozoic sulphates along with widespread bedded halite, occur in the Bitter Springs Formation of the Amadeus basin, central Australia, its equivalents in the Officer Basin, the Callana beds of the Flinders Ranges and the Infracambrian salt basins of the Arabian (Persian) Gulf (Wells, 1980; Cooper, 1991; Mattes and Conway-Morris, 1990; Edgell, 1991).

The transition to calcium sulphate textures in evaporite pseudomorphs mirrors a marked change in the style of marine carbonates around 2.2 to 2.3 Ga when herringbone calcite and precipitated carbonate beds become much less common and the precipitation mode shifted from the seafloor to the water column (Figure 1.13; Sumner and Grotzinger, 1996, 2000). The boundary also corresponds to the “rusting” of the oceans when oxygen levels became high enough to precipitate widespread banded iron deposits on the seafloor. Microdigitate stromatolites cross this boundary with little effect, suggesting the marked decrease in dissolved iron exerted little influence on them.

The relative scarcity of actual Pre-Phanerozoic salts, not pseudomorphs, especially in the Archaean has been used by some to argue that conditions were less favourable for widespread evaporite deposition in the early Precambrian (Cloud, 1972). Others, myself included, feel that the relative scarcity of preserved evaporites in older sequences reflects the greater likelihood of fluid flushing, evaporite dissolution and metasomatism in progressively older rocks. It may well be that sulphate evaporites were less common in the Archaean, and that sodium carbonates mixed with halite were dominant evaporite salts in seawater-fed saline giants of the Early Archaean. But widespread evaporite deposition from sodium-dominated brines did occur throughout the Archaean in large drawdown basins isolated from a surface connection with the ocean. A paucity of preserved bedded evaporite salts in the Precambrian reflects an increased probability of partial or complete evaporite dissolution, remobilisation and metasomatism with increasing geological age.

Figure 2.34. Temporal evolution of $\delta^{34}\text{S}$ from marine chemical sediments (anhydrite, gypsum, baryte) during the terminal Neoproterozoic and early Palaeozoic (after Strauss et al., 2001 and references therein).

So, by the Late Neoproterozoic marine sulphates are preserved as actual chemical sediments (anhydrite, gypsum, baryte). Their impermeable nature means their isotopic signatures are useful supplements to the much better preserved marine carbon and sulphide records in defining the transition from the Terminal Neoproterozoic into the early Palaeozoic. Holser 1977, 1984 was the first to address the specific conditions required to produce the rapid rise in $\delta^{34}\text{S}$ of seawater sulphate during the terminal Neoproterozoic which he termed the “Yudomski event” after the regional stratigraphy preserved in SE Siberian evaporites. His model of stratification-stagnation and subsequent ventilation of the deep ocean and mixing of different sulphur isotope signatures for dissolved marine sulphate between surface and deep water was reinforced by subsequent workers (Goodfellow and Jonasson, 1984; Logan et al., 1995). Recently it has been placed in the contextural framework of a possible “Snowball Earth” (Figure 2.34; Strauss et al., 2001). The enrichment in $\delta^{34}\text{S}$ signature of chemical sediments across the boundary is real, but its ultimate cause is still a matter of debate.

Holser (1977) favoured brine generation and density/salinity stratification of the Neoproterozoic ocean. Alternatively, Hoffman et al. (1998) proposed extreme climatic conditions and coverage of the global ocean with sea ice (Snowball Earth) followed by a rapid termination of glacial conditions as a consequence of the build-up of large quantities of volcanogenic CO_2 in the deeper ocean. Subsequent mixing of water masses triggered the precipitation of large quantities of cap carbonates

following the glacial horizons. This scenario (sometimes called “freeze then fry”) results in a major reorganisation of the biogeochemistry for the entire water column and is interpreted by some to be documented in the extreme fluctuations of the carbon isotopic composition, which must reflect major changes in the make-up of the world's carbon cycle as we move across the boundary (Chapter 5).

The Precambrian-Cambrian sulphur cycle preserved in marine evaporites is intimately linked to the carbon cycle (Holser et al., 1988). This is expressed through a negative correlation of their isotopic compositions i.e. carbonate carbon and sulphate sulphur, reflecting the biological aspects of the exogenic cycle (Figures 2.23, 2.34; Strauss et al., 2001). The temporal record of

the carbon isotopic composition displays intervals of strongly ^{13}C -enriched values preceding the Neoproterozoic glacials, a decline in $\delta^{13}\text{C}$ immediately prior to the glacial horizons, and low $\delta^{13}\text{C}$ values in the cap carbonates followed by an evolution back to more ^{13}C -enriched values (Figures 2.33, 5.2c).

In part, this may reflect severe changes in primary productivity associated with varying sea ice coverage. Hand in hand with evolving anoxic conditions in the water column under sea ice, heterotrophic recycling of organic matter by sulphate reduction became an important process in the water column, leading to ^{34}S -enriched seawater sulphate. This is clearly documented in the isotopic composition of resulting sedimentary sulphides (e.g. Strauss, 1997). Deglaciation and rapid ocean turnover then transferred ^{34}S -enriched water on to the shelf, where marine-fed sulphate evaporites record this isotopic signature.

Next in the geological history of Precambrian seawater as preserved in evaporite chemistry comes what is, at least from an anthropocentric viewpoint, the most significant time in the evolution of life. It is when metazoans evolved mineralised hardparts and there was the concurrent evolution of the phylum Chordata (animals with backbones and our distant ancestors). Comparisons of chemical compositions of primary fluid inclusions in marine halite chevrons from terminal Proterozoic Ara Salt (≈ 544 Ma) and Early Cambrian (Toyonian) Angarskaya Formation of eastern Siberia (≈ 515 Ma) indicate that Ca

concentrations in seawater increased approximately threefold across the Precambrian–Cambrian boundary and into the Early Cambrian (Figure 2.35; Brennan et al., 2004).

The timing of this marked increase in Ca in seawater broadly coincides with the Cambrian explosion in life, as well as a brief drop in marine $^{87}\text{Sr}/^{86}\text{Sr}$ values, and an increase in tectonic activity at mid ocean ridges (see earlier in this chapter for discussion of how midoceanic spreading rates may link to oceanic chemistry). Their coincidence suggests a link between the advent of biocalcification, increased hydrothermal mid-ocean-ridge brine production, and the changed composition of seawater (Figure 2.35).

Brennan et al. (2004) suggest that the evolution of widespread biomineralization might be a metabolic detoxification process induced by large increases in intracellular Ca^{2+} as identified by increases in Ca levels in halite inclusions. During the Early Cambrian, the ambient oceanic calcium level may have risen to such a degree that cells could no longer effectively exclude or expel Ca^{2+} ions, causing intracellular Ca^{2+} in certain marine organisms to reach toxic levels (Simkiss, 1977, 1989; Kempe and Kazmierczak, 1994). Furthermore, high phosphate levels in Early Cambrian seawater may have amplified the uptake of Ca^{2+} by organisms (Kempe and Kazmierczak, 1994). Opportunistic organisms may have modified their existing cellular waste-removal systems by binding Ca^{2+} as relatively insoluble minerals (calcium carbonate or calcium phosphate). This

Figure 2.35. Geological and biological changes in oceanic realm during terminal Proterozoic and Cambrian (after Banner et al., 2004 and references therein). Stages in Early Cambrian are Nemakit-Daldynian (N-D), Tommotian–Atdabanian (T-A), and Botomian–Toyonian (B-T); Middle (M) and Late (L) Cambrian are also shown. There was dramatic increase in diversity of animal classes and orders starting in Tommotian time. Phylogeny and corresponding crown group first appearances (time line) show diversification of animal clades from the earliest Cambrian. Crown groups are the last common ancestor of all living members of a clade plus all its descendants. Decrease in marine $^{87}\text{Sr}/^{86}\text{Sr}$ ratios ≈ 530Ma during an otherwise increasing trend in $^{87}\text{Sr}/^{86}\text{Sr}$ ratios likely indicates increase in mid-ocean-ridge spreading rates. Bars indicate possible ranges of oceanic Ca^{2+} determined from inclusions in chevron halite; open circles represent average values with measured ranges shown in parentheses in inset table of computed values of seawater composition for the terminal Proterozoic and Early Cambrian with the composition of modern seawater listed for comparison.

transition in oceanic chemistry, preserved in halite inclusions, could have been the starting point of the complex process that led to exo- and endo-skeletons (and us!).

Hydrology is depositional style

Grains in siliciclastic sediments indicate sediment source or provenance, grains in a carbonate setting indicate biological parentage, mineralogy and textures in an evaporite indicate the nature of the hydrology that created them. During deposition, the hydrologic framework of an evaporite basin consists of surface and near subsurface waters flowing into and out of the areas accumulating salts. It is the upper part of a larger geohydrology made up of several regimes: 1) the active phreatic/vadose, 2) the compactional, 3) the thermobaric, and 4) the active-phreatic-

exhumation/uplift regime (Figures 1.1b, 2.36a). Boundaries are typically indistinct and transitional. The remainder of this chapter concentrates on syndepositional hydrologies of the active phreatic regime, where fluid circulation is driven by solar evaporation and gravity (eogenesis and mesogenesis). Chapter 8 takes this discussion deeper into the subsurface of evaporite basins in thermobaric, compactional and uplift regimes (mesogenesis and telogenesis). In the deep subsurface, where ancient salt masses have spent most of their time, rates of brine flow are slower, alteration events are longer term and driven by a combination of temperature, pressure and density differentials.

Brines and meteoric waters in the zone of active phreatic flow move under the influence of density/salinity or temperature gradients at rates controlled by the permeability of the aquifer.

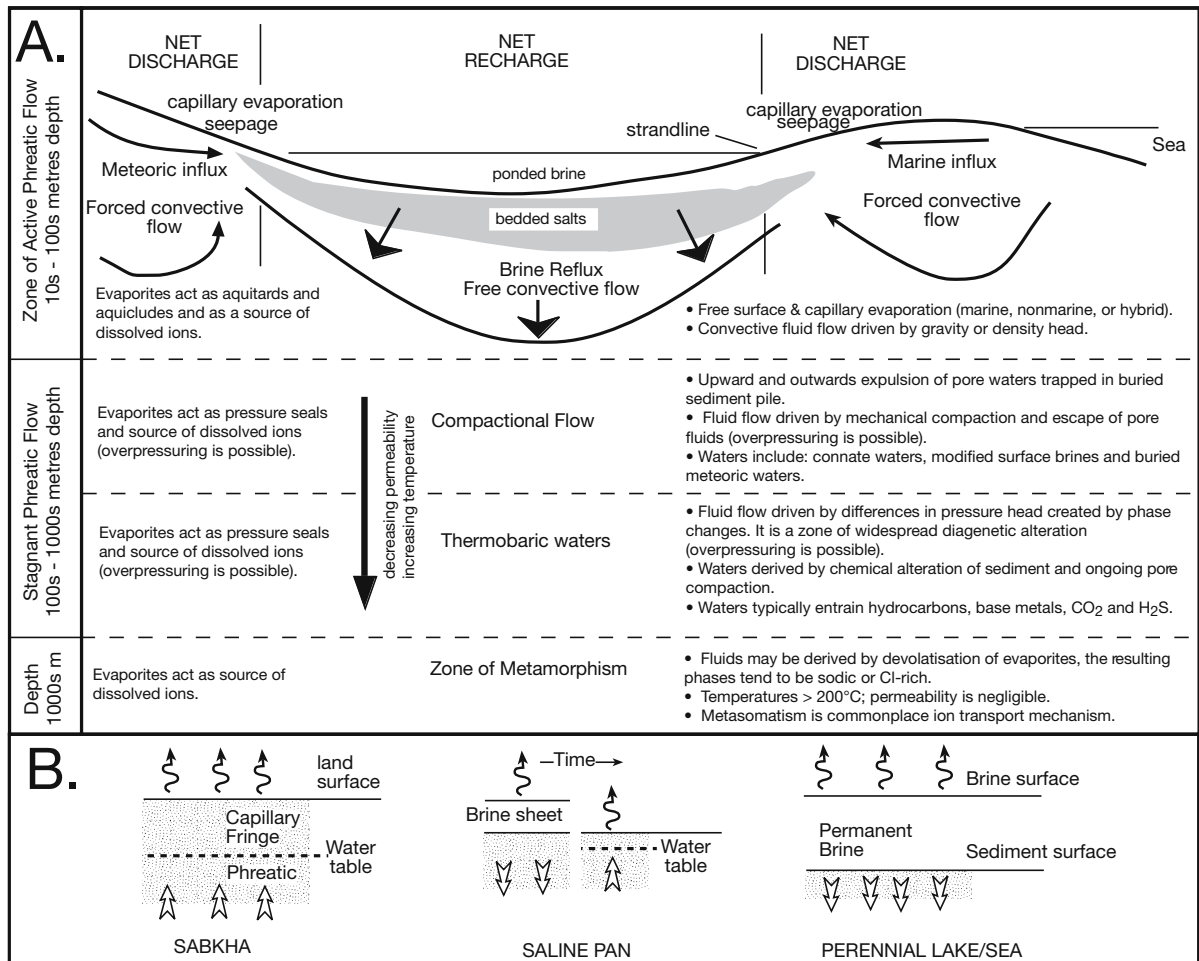

Figure 2.36. Hydrological regimes and processes in evaporitic systems. A) Depth related mechanisms and processes influencing evaporites. B) Simplified hydrology of the three depositional settings that accumulate evaporites.

Where areas of strong topographic relief define the basin margin, as in a continental rift valley or in a transtensional basin-and-range setting, unconfined and confined meteoric water typically discharge into the edges of a brine-saturated depression. Further out, beneath the more central and topographically lowest parts of the depression, density-induced brine reflux, and not meteoric throughput, is the dominant process driving shallow subsurface flow (Figure 2.36a). In a large evaporite drawdown basin, such as in the Mediterranean in the Late Miocene, the level of the discharge zone and the water surface of the perennial brine discharge lake was at times thousands of metres below sea level. Gravity seepage then moved huge volumes of marine/meteoric waters into the depression.

Active phreatic/vadose regime

All primary and syndepositional evaporites first precipitate from brines outcropping at the top of the active phreatic zone or its capillary fringe. This setting is capable of maintaining the density or gravity heads necessary to drive, pond and concentrate large volumes of brines needed to deposit and preserve thick salt beds. An active phreatic flow regime encompasses the zones of seepage outflow, brine ponding, brine reflux and meteoric flow (Figure 2.36a). The surface of a perennial brine lake or seaway is the outcropping expression of the regional water table. In the surrounds, where the regional water table comes near the landsurface, the top of a capillary fringe may be the outcrop expression of the same regional water table and evaporitic mudflats dominate. Solar evaporation drives water loss at the surface of both settings to form bottom nucleated and pelagic salts in a standing water body and capillary salts in a mudflat. Depressions with surface and nearsurface brines in arid settings indicate groundwater discharge zones and their ongoing desiccation creates discharge playas and ancient evaporite seaways. Water lost is replaced by water seeping in from the surrounds creating a replenishment hydrology sometimes described as evaporative drawdown. The replacement water can be continental or marine, and can be supplied via unconfined nearsurface aquifers or via deeply circulating artesian systems.

Hydrologies in saline basins

Hydrologies that precipitate salts can be divided into two end members (Figure 2.36b), 1) a perennial brine lake or seaway (saltern) that at times is density stratified and 2) an evaporitic mudflat (sabkha) with a landsurface defined by deflation at the top of the capillary fringe. A common intermediary stage is an evaporitic mudflat occasionally covered by thin sluggish

brine sheets (salt pan). Before discussing the significance of hydrology to evaporitic sedimentation, we first must define some general hydrological principles (Figure 2.37).

The hydrology of an evaporitic saline mudflat and its landward surrounds (dry mudflat or sandflat) is controlled by the position of the water table in the sediments (Figure 2.37a). Pores below the water table are filled by water of variable salinity and constitute the phreatic or saturated zone where the water volume saturation is total (equals 1 or 100%). The phreatic zone is the region where gravity-driven groundwaters seep down the potentiometric slope toward discharge zones (forced-convection) and dense free-convecting brines, which are created by the evaporation of free surface waters, sink into underlying strata (brine reflux).

Above the water table is the vadose zone, where pores are filled by a combination of soil air and varying levels of water and brine, water volume saturation is less than one. The vadose zone in dry mudflats or sandflats contains an uppermost interval known as the soil moisture zone where the water content can vary considerably over short time frames. Light rains typically penetrate the soil moisture zone but are not sufficient to saturate the whole vadose zone. Pore water returns to the atmosphere, via evapotranspiration, without ever replenishing the water table. Fluctuating evapotranspiration levels in this zone vary widely between storms, reflected in variable metabolic activities of the soil biota, variable mean moisture contents, and varying O₂ and CO₂ levels. Pedogenic carbonates and more soluble salts are typically precipitated as surface crusts and near surface cements as a result of these fluctuations. With the next heavy rain the less soluble carbonate precipitates remain, while any more soluble salts tend to be flushed back into the subsurface, through a now saturated vadose profile, to re-enter the phreatic water mass.

Sediments	Capillary Rise (cm)
Fine silt	750
Coarse silt	300
Very fine sand	100
Fine sand	50
Medium sand	25
Coarse sand	15
Very coarse sand	4
Fine gravel	1.5

Table 2.10 Representative thickness of the capillary zone in various host sediments.

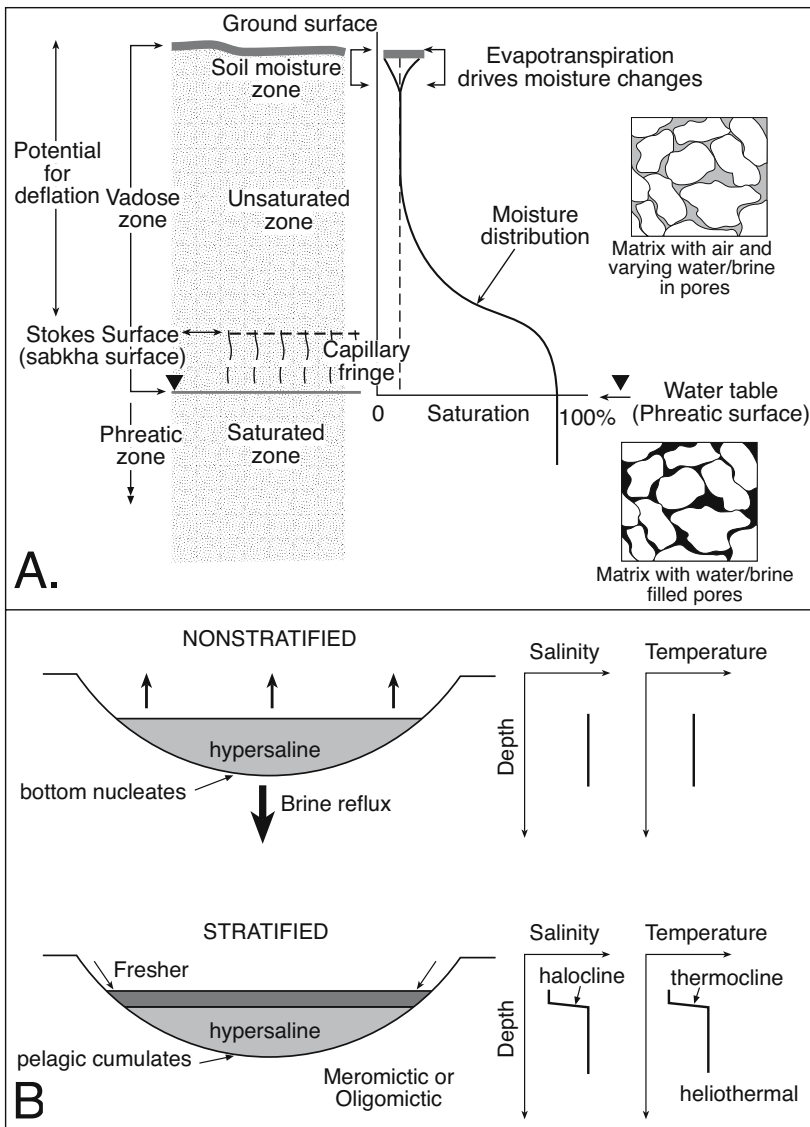

Figure 2.37. Hydrological classification in saline settings. A) Hydrological zonation in the mudflat and its landward surrounds. B) Water mass zonation in a perennial brine lake or seaway.

The process of flushing surface waters to the phreatic zone is known as infiltration. In a homogeneous medium it requires the whole vadose profile to be water saturated. In an inhomogeneous medium, such as a karstic or a fractured and fissured evaporitic landscape, replenishment to the water table can be more focused. Once the more soluble ions are back in the phreatic mass they continue to flow as dissolved load down the potentiometric gradient and ultimately into the discharge depression where, driven by solar concentration, emerging waters once again can precipitate salts in sabkhas, pans, brine lakes and seaways.

The lower part of the vadose zone beneath a dry mudflat is made up of the capillary fringe (aka tension-saturated or wetting zone). In a saline mudflat the capillary fringe extends all the way to the landsurface. The diameter of pore throats in the capillary zone controls the thickness of the capillary zone; the smaller the throat, the thicker the capillary zone. It is a few mm thick in sands and metres thick in fine clays (Table 2.10). Pores in the capillary fringe are not completely filled with water until its lowermost regions, there 100% water/brine saturation defines the top of the phreatic zone and the position of the water table (Figure 2.37a). Water film and gas phases coexist in the interstitial pore space of much of the capillary zone. The relative humidity of the gas phase (saturated vapour pressure) is, however, equal to the thermodynamic activity of water, and so no evaporative concentration can occur in the capillary zone unless it is very close to the landsurface. Loss of pore water from the capillary fringe in a mudflat typically only occurs in its uppermost few centimetres.

There are some simple principles of soil physics associated with capillary fringes in groundwater discharge zones (sabkhas) that at times have been ignored in sedimentological models of sabkha deposition. First, if the capillary fringe is relatively thick, say 0.5 - 1.0 m, then host sediments must (by definition) have small pore throats and so must have low permeabilities. A sabkha, by definition, is a zone characterised by the growth of displacive and replacive capillary salts. Salinity of pore water in this capillary fringe is elevated (indicated by the preservation of gypsum, anhydrite, halite etc.). This low permeability means that high rates of transient short-term rapid lateral or vertical flow through a sabkha capillary fringe is impossible. When a sheet flood covers the 0.5-1.0 m thick saline capillary fringe of a sabkha with a sheet of fresher surface water (rainwater or

seawater) this water does not begin to infiltrate until its density exceeds that of water in the underlying capillary pores. Then, even when densities do exceed that of the underlying waters, the low permeability of the narrow pore throats means the rate of recharge is slow.

To accumulate salts in the capillary fringe the overall solute-carrying water flow vector over time must be upward, not downward. It also means that almost all of the water in occasional fresher water sheets covering a sabkha are lost to the atmosphere. Low permeabilities mean a sabkha is not capable of maintaining longterm downward reflux flow of water or solute to the phreatic mass. This is true in all evaporitic mudflats. This notion of *per ascendum* rather than *per descendum* hydrologies is correctly accommodated in water flow models for most continental sabkhas and mudflats. This was less so in some sedimentological models of modern marine margin sabkhas, or at least this was so until the last decade when detailed hydrological data sets were collected, and coastal sabkha hydrologies quantified, rather than assumed.

As Wood et al. (2002) has clearly shown in the Abu Dhabi sabkha (Figure 3.12b) and Dutkiewicz et al. (2000) demonstrated in Lake Greenly mudflats and pans (Figure 2.15), solute flux in the capillary fringe of saline mudflats is largely decoupled from the effects of water cycling in ephemeral sheets of surface water and their salt crusts. Most of the solute load precipitated as salts in a sabkha comes from rising, sometimes deeply circulating groundwater. It does not come from recharge by occasional surface floods atop the sabkha. Floods (marine or meteoric) in a sabkha tend to do little more than redissolve and reprecipitate surface salt crusts and flush the dissolved contents to the sea or the basin pan. Floods of surface waters to a sabkha flat tend to evaporate, not infiltrate. We shall return to this discussion in more detail in Chapter 3, for now we will just note that any secondary salts actively accumulating in a sabkha or evaporitic mudflat at depths of more than a few centimetres below the landsurface are precipitated by physical and chemical changes in ascending, not descending, pore waters.

Quantified hydrological observations in the capillary zone of Owens Lake mudflats by Tyler et al. (1997) underline some other significant general characteristics of the hydrology of evaporitic mudflats (Figure 2.4):

- 1) Effective evaporation rates are higher over brine pools than evaporitic mudflats, especially those mudflats covered by a salt crust.
- 2) Depth to the water table in a mudflat is a significant control

on the volume of capillary salt precipitated in an evaporitic mudflat or saline pan. That is, much higher volumes of salt accumulate in regions where the saline water table resides closer to the sediment surface for longer periods of time.

3) Because winter and spring water tables are higher (typically cooler with more precipitation) than summer water tables, the rate of capillary salt accumulation in some mudflats can be greater than in the hottest and driest part of a year, when water tables are lower.

The top of the capillary fringe is the landsurface in those parts of an evaporitic mudflat (sabkha) that are actively accumulating surface salt crusts. Heating of pore waters moves liquid water into vapour that leaks into the atmosphere only in the uppermost few centimetres of the capillary zone, immediately beneath the landsurface. The salinity of the residual brines in this uppermost zone increases to where various salts precipitate (Figure 2.38). Lost waters are replaced by the rise of capillary waters from below in the process known as capillary rise.

There is another general principal of soil physics in operation here that many sedimentologists working in sabkhas have ignored. To concentrate a brine to where water is lost in large amounts happens largely in the uppermost parts of the capillary fringe, not throughout its whole extent. This is why in every capillary fringe in every discharging sabkha in every modern example, the most saline pore waters (and the most saline salts, sometimes including bitterns) occur in the uppermost portion of the capillary fringe or in the efflorescent crusts at its surface (Figure 2.38). The underlying capillary waters show upward increasing salinities but never attain the salinities of this uppermost few centimetres where salts can evaporatively precipitate (Figure 2.38).

And yet, from the displacive evaporite textures seen in the capillary fringe of most sabkhas and evaporitic mudflats it is obvious that sabkha salts do not only precipitate as surface and uppermost nearsurface efflorescences and crusts (Figure 3.6c). This leads to the conclusion that preserved calcium sulphate salts in the classic Abu Dhabi sabkha and probably many other sabkhas are a type of retrograde evaporite precipitate known as thermalite salts (Wood et al., 2005). Such salts form passively and displacively in the bulk of the capillary fringe, below the uppermost interval of ephemeral evaporative halite and bitterns. The precipitation mechanism is heating of a rising capillary pore water solution that is dominated by a retrograde phase (anhydrite, gypsum) to temperatures above 25–30°C (see Chapter 3 for details). Sabkha salts in a capillary zone are “true” evaporites in that the overall precipitation hydrology is driven by solar evaporation, but the local precipitation mechanism in

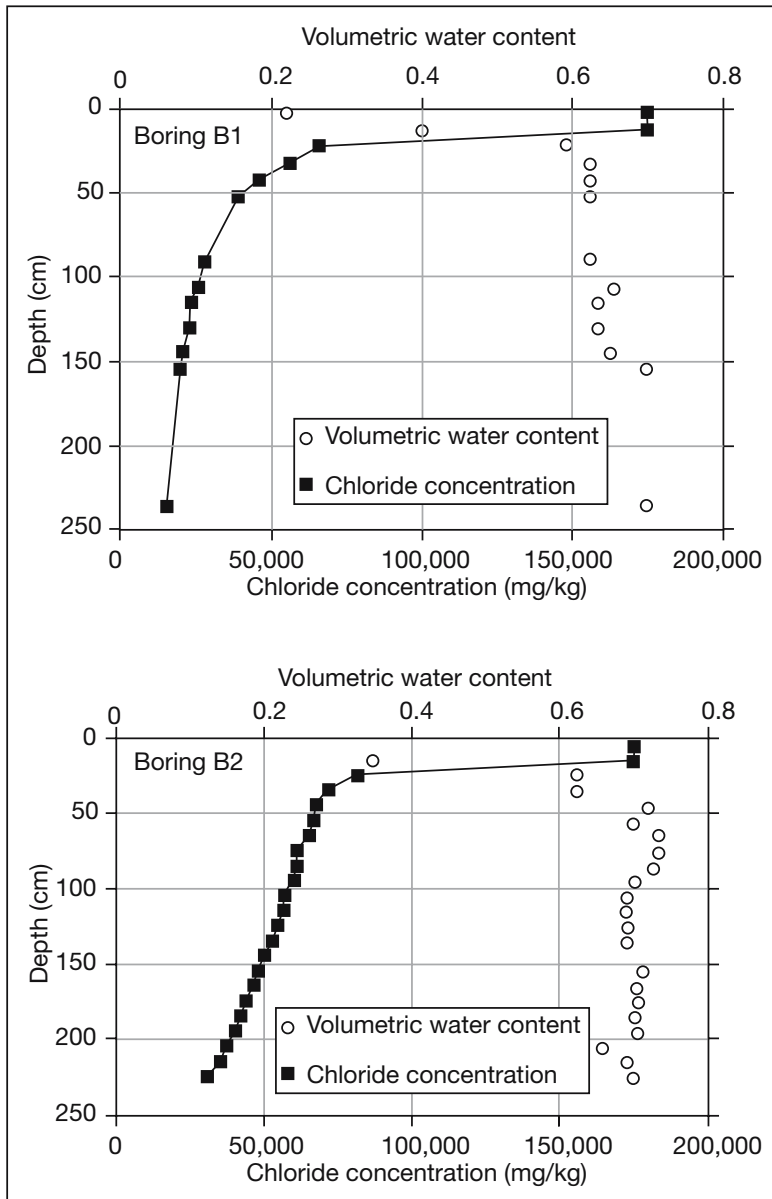

Figure 2.38. Measured moisture and chloride profiles in the vadose zone of two monitored boreholes in the salt-crust clay-dominated saline mudflats in Owens Lake, California. Measurements were made in summer of 1994 and 67 days after last recorded rain in the region (after Tyler et al., 1997). A water saturated profile would have a volumetric water content or saturation of 1 or 100%. See figure 2.4 for location, both boreholes are from the saline mudflat site.

the bulk of the capillary zone is more a response to temperature change than to evaporative concentration.

In contrast, the hydrology that preserves modern bitterns (carnallite) in the bedded halites of Qaidam Basin is not that of a capillary fringe in a sabkha about the lake edge. By defi-

nition, sabkha pore waters are rising and heating. Rather, the precipitation mechanism in Qahan salt flats is one of sinking and cooling dense brines precipitating prograde salts, following an episode of halite karstification (Figure 11.3c). Modern carnallite precipitation is a passive pore filling process that takes place *per descendum*, beneath a freestanding and concentrating holomictic brine sheet, which is feeding a dense descending brine plume (brine reflux). It is a recharge mechanism and not a capillary rise process.

Surface waters within freestanding perennial brine lakes or seaways routinely fluctuate between stratified and nonstratified conditions. In the stratified system an upper fresher (less dense) water mass sits atop a more saline (denser) lower water mass (Figure 2.38b). The narrow zone of transition between the two masses in the brine column is called the halocline. Often a stratified saline lacustrine system is also thermally stratified, with warmer waters in the lower water mass and a zone of transition is called the thermocline. Its position is typically identical in the column to that of the halocline. Thermal stratification with a cool top and a hot base is opposite to that found seasonally in many temperate freshwater lakes and so is sometimes called reverse stratification and also described as heliothermal layering. The term meromictic is used to describe a permanently stratified water mass where surface layers may mix, but the bottom layer does not disappear. The upper water mass that periodically mixes is the mixolimnion, the lower permanent mass is the monolimnion. Oligomictic is used to describe stratified water masses that mix or homogenise for short irregular periods every few years.

Mixing in a saline water mass is controlled by the evaporation and concentration of the upper water mass until it reaches a density equivalent to the lower water mass. Then mixing or overturn occurs. Substantial density differences between the

upper and lower masses in most density stratified systems means diffusive mixing across the halocline is insignificant. A stratified system is a stable system, so that when a hypersaline water mass is density stratified there is little bottom precipitation of salts. Sedimentation is mainly by a pelagic rain of crystallites, which first formed either in the uppermost part of the upper water mass or by brine mixing at the halocline. Whenever the upper and lower water masses equilibrate and homogenise, bottom nucleation of salts is possible even at the base of deep brine columns, as is occurring in the Dead Sea today (Chapter 4). Whenever a homogenised water mass restratifies, the rate of brine reflux in to sediments below the sediment brine interface slows and ultimately stops, for there is no ongoing mechanism to resupply brines denser than pore waters in the substrate.

Refluxing brine plumes beneath homogenized surface water masses sink and at the same time start to spread laterally toward the basin fringes where they mix with incoming forced-convection waters of the seaway or playa margin. Ultimately plume waters can return to the surface in a diluted form as a component of spring or seep waters or they can be lost to the regional hydrological flow. Reflux-driven convective flow is an effective way of moving salt load through large volumes of basin sediments in modern saline depressions (e.g. Lake Tyrell, Australia: Figure 2.20) and also explains the distribution of salts, pseudomorphs and dolomites in ancient sediments that underlay or were adjacent to areas accumulating bedded salts.

Mudflat aggradation mirrors water table changes

Unconfined meteoric and marine groundwaters seeping and discharging into the edges of an evaporitic depression have a potentiometric head defined by the position of the regional water table. The unconfined meteoric water table surrounding a modern coastal marine-seepage lake is typically a few centimetres higher than sea level. In a continental saline lake or an ancient drawdown saline giant, the water table about the basin margin is higher than the brine level within the evaporite-accumulating depression (Figure 2.39a). Once meteoric/marine groundwater seeps into discharge zones within the salt-accumulating region of the central depression, it comes into contact with more saline and denser surface and pore brines. On average, the throughflowing waters beneath a mudflat or bajada margin are less dense (fresher) than hypersaline waters in the brine-saturated lowermost parts the saline depression. After a heavy rainstorm or a flood, a shallow fresher groundwater layer forms along the strandline edge of the permanent brine lake or seaway as freshwater floats atop a wedge of denser hypersaline pore waters (Figure 2.39a, b).

Shallow meteoric sheets and groundwater lenses are typically transient mudflat features, so without ongoing recharge, these freshened groundwater outflows within the mudflat dissipate via capillary evaporation and are replenished by more saline pore waters. Alkaline earth carbonates and lower salinity salts can precipitate as surface crusts or nearsurface pedogenic nodules and crystals in the vadose portions of the basin edge. During prolonged dry spells, capillary evaporation continues to lower the saline mudflat water table until flow directions may be reversed. Brines in aquifers from the basin centre and more deeply circulating region groundwaters begin to seep into the margin to replace the lost capillary fluids. Increasingly saline pore waters in a saline mudflat, mean salts, which crystallised earlier, can now evolve into more saline precipitates via backreaction and replacement (Figure 2.39c).

With the next influx of freshened recharge the water table rises once more in the marginward vadose zone of the saline depression. At the same time a thin sheet of fresh rainwater or seawater can cover the surface of the saline mudflat. This redissolves highly soluble salts of the uppermost capillary zone, along with any of the more soluble surface efflorescences (Figure 2.39b). A wedge of freshened water now floats above a stable body of dense brine, both atop pore waters of the saline mudflat and atop a dense lower brine mass the central density-stratified perennial brine lake. This blanket of freshened water shuts down evaporation of saturated waters and prevents further accumulation of salts, both in the uppermost parts of the capillary mudflat and in the salt brine covered regions of the perennial lake or seaway. The style of surface sedimentation at this time is sheet flood sands followed by accumulation of suspended load clays.

Then, as the depression begins to dry out, the brine sheet shrinks until it only covers the lowermost parts of the lake depression, the zone of perennial lake waters. Once the saline mudflats are re-exposed, capillary evaporation begins once more. At some point in this desiccation stage, surface water becomes saturated and crystallites formed at brine surface sink through the brine column to the lake/seaway floor (pelagic sedimentation of carbonate and gypsum). Bottom nucleation and intrasediment prograde precipitation of reflux salts beneath a standing brine lake recommence when the rising salinity (density) of the upper water mass comes to equal that of the lower brine mass. The two water bodies then mix and precipitation of bottom salt begins anew (Figure 2.39a).

Near surface sediments in saline mudflat margins experience the effects of schizohaline pore waters. Salinities in sediments beneath perennial (meromictic) brine-covered depressions

tend to be more stable, although a body of freshened surface water comes and goes. Textures in schizohaline salt beds are dominated by ongoing re-equilibration reactions, backreactions, dissolution-precipitation and haloturbation, while textures in beds deposited in perennial brine seaways and lakes tend to be more stable and dominated by large growth-oriented crystal beds and brine reflux re-equilibration textures below.

As an evaporite basin aggrades toward its hydrological equilibrium level (Figure 2.39c) the depositional surface aggrades into ephemeral brine sheet (pans) and ultimately mudflats (filled accommodation space). The progression brine lake to

a mudflat induces schizohaline textures in the uppermost parts of each shallowing upward hydrological cycle. If there is no rise in regional watertable, the same textural shoaling occurs across the whole discharge zone.

Indicators of fluctuating water tables

Because evaporites form by the evaporation of discharging and ponding waters, any longterm water table fluctuations in an evaporite basin influence sedimentation style and mineralogy on scales coarser than the stacked gypsum and tepee truncation layers and parasequences described in Chapters 1, 3 and

Figure 2.39. Cross sections showing hydrological stages in the active phreatic zone in an evaporitic seaway or a continental lake. A) Perennial saline lake accumulating widespread subaqueous evaporites from a nonstratified brine body. Capillary evaporation of fresher water lenses about the lake margin. B) Perennial saline lake or water full stage with subaqueous brine lens isolated from solar evaporation processes by a layer of surface water. This shuts down widespread crystallisation in lower brine body and slows brine reflux. C) Playa stage where ongoing evaporite fill, or lowering of regional water level, means the sediment surface is mostly subaerial and in capillary equilibrium with saline lake water table. This is a classic evaporitic mudflat or sabkha hydrology. No fresh water lens exists until after the next flood event.

4. Longterm aggrading water tables (or regional subsidence) in an evaporite basin enable the capture of formerly vadose sediment by the damp, sticky to wet conditions that characterise the capillary and phreatic zones and so facilitate the preservation of formerly vadose and nonevaporite sediment in the depositional system - sediment that would otherwise be blown away (e.g. Newell, 2001). It is aggrading water tables that ultimately preserve almost all ancient sabkha, brine lake and dune sediments.

Falling water tables enable entry of vadose conditions into former capillary and phreatic sediments. This leads to the dissolution of salt beds, to eolian deflation and to the formation of residual sediment layers that come to lie at or just above the regional water table. Episodes of active deflation in the Late Quaternary have periodically fed the extensive quartzose and gypsum sand dunes that abut numerous playas in Australia, Saudi Arabia and the southwest USA. Deflation to the top of the capillary fringe creates the characteristic flat surfaces of many modern playas, sabkhas and interdunal depressions. The hydrological process has been called watertable bevelling as it is tied to the erosional top of the capillary zone (Bowler, 1986, Warren and Kendall, 1985). The capillary surface erosionally truncating underlying sedimentary structures is termed a Stokes surface.

Stokes surfaces

Stokes surfaces accompany changes in the base level of erosion/deflation and are commonplace in eolian sand seas or ergs abutting ancient evaporite beds. At the local scale a Stokes surface defines the top of the sedimentation surface in a degrading wet interdunal depression (Table 2.11; Stokes, 1968). A succession of such truncation surfaces can be preserved atop a number of depositional cycles as successive packages of sediments aggrade

and stack, driven by longterm water table rise. Changes in water table level may indicate climatic change or episodic basin floor subsidence. At the regional scale an extensive truncation surface in an ancient desert succession, which passes through various arid lithofacies, is called a super-surface or a super bounding surface by sequence stratigraphers, but it is really a glorified Stokes surface.

Stokes surfaces create sharp planation surfaces in eolian crossbeds, sometimes outlined by a thin veneer of lag sediment (Fryberger et al., 1983, 1984). Water table control on their creation is clearly seen in the Umm Said portion of the Qatar coast south of Doha where large transverse and barchan dunes still migrate into the sea (Figure 2.40a). This eolian-fed progradation of the shoreline and the creation of the associated Stokes surface has been taking place since the early Holocene sea first intersected the sand sheet (Figure 2.40b, c). The Stokes surface is the surface of uppermost eolian preservation and it migrates seaward as the dunes build out into the Arabian Gulf. In all modern coastal dune successions the Stokes surface is the top of the capillary zone and it approximates sealevel.

Erosion surfaces, defined by the top of the capillary zone also truncate anhydrite nodules or enterolithic folds in the upper parts of the coastal sabkhas of the United Arab Emirates (Figure 3.4g). In the fine grained matrices of a sabkha the erosional truncation of an evaporite is typically up to a metre above the water table. Stokes surfaces are an integral part of the capillary hydrology of a sabkha and are very useful in distinguishing ancient mudflats from subaqueous evaporites (Warren and Kendall, 1985).

Aggrading water tables in discharge depressions in sand-rich eolian environments can promote the passive precipitation of pore cements in the uppermost part of the capillary zone. In

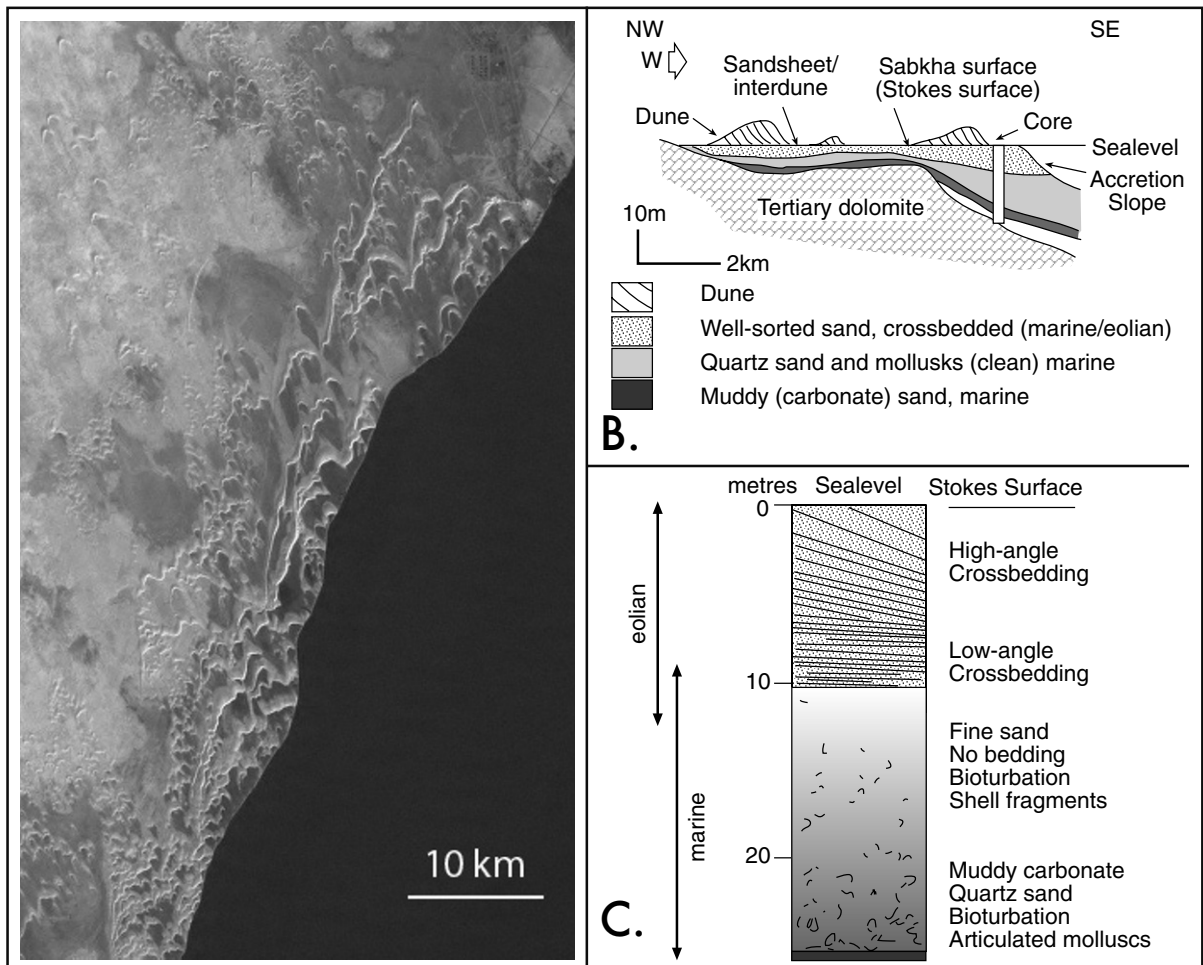

Figure 2.40. Umm Said Sabkhat, Qatar. A) Transverse and barchan dune moving seaward atop sandflat and coastal sabkha (Image courtesy of NASA). B) Cross section and core from an Umm Said sabkha in coastal Qatar showing how the deflation surface that defines sealevel and the top of modern coastal sabkhas is also a Stokes equilibrium surface (indicates the top of the capillary zone). C) Schematic core taken in position shown in B. (B and C after Shinn, 1973).

modern dunes and sandflats these aggrading salt-cemented intervals are sometimes called salcretes, the evaporite equivalent of capillary calcretes. They are made up of passive pore-filling cements (gypsum or halite), not the active displacive nodules and crystals that typify sabkhas. Schenk and Fryberger (1988) noted such massive phreatic-gypsum cemented zones act as a lower limit to any subsequent eolian deflation in the gypsum dunes of the White Sands dune field, New Mexico. They create a cemented near-horizontal base level to erosion, now seen as a widespread Stokes surface in the interdunal corridors. Aggrading salcretes, tied to a rising water table, can help preserve capillary and eolian sedimentary structures. Salcretes were the main reason why dune topography is preserved in some transgressive settings where ancient ergs are overlain by evaporite beds (e.g. Entrada-Todilto and Rotliegende-Zechstein formations).

Megapolygonal desiccation cracks are another expression of the hydrology associated with a Stokes surface and form in deflating mudflat or playa sediments in conjunction with a regionally falling water table (Figure 2.41). Megapolygons can be up to 300 m wide and separated by fissures up to 5 m deep, they characterise the modern surfaces of a number of Basin and Range playas in Oregon, Nevada, California, Arizona and New Mexico (Neal et al., 1968). Fissures are hosted in fine-grained playa sediments rich in clays and carbonate minerals. The fissures, which are up to 1 metre wide, are routinely filled or partly filled with wind blown sands (mixture of quartz and gypsum). Individual fissures tend to be discontinuous across the playa surface and often display en-echelon patterns.

Megapolygons are the result of shrinkage in fine-grained lake sediments and indicate water loss following a fall in the piezometric head. In some cases the water table lies 3-20 m below the megapolygonal surface. As pore waters evaporate from the upper part of the newly created vadose zone, tensile stresses accumulate in the muds until they eventually rupture into the polygonal fissure network. Neal et al. (1968) interpret the fissures as indicating vigorous desiccation over a number of years. Some playa fissures may be related to overexploitation of the local groundwater resources in the last 50-100 years, most indicate the rigorous climatic transformation that occurred during the Pleistocene-Holocene transition. Identical sand-filled fissures, up to 18 cm wide and 5.7 m deep, have been documented in the Pennsylvanian Hermosa Formation of southeastern Utah (Loope and Haverland, 1988).

Figure 2.41. Megapolygonal desiccation cracks, partly filled with sand captured as it salted across the deflationary playa surface. Fissures formed by a lowering of the regional water table and the associated shrinkage during drying of lacustrine clays (after Neal et al., 1968).

Stokes surfaces and palaeohydrology

Recognition of Stokes surfaces, associated interdunal sabkhas and wet mudflats/interdunes has broader scale implications in terms of regional hydrological evolution over time frames measured in thousands of years and to permeability models. Most modern Stokes surfaces either are a coastal groundwater response to progradation since the last rise in sea level some 6,000 years ago, or are a hydrological response related to marked climatic changes in deserts from the Late Pleistocene to the present, usually toward increasing aridity (Table 2.11).

Changes in the level of ancient regional water tables and aggradation of base level (creation of accommodation space) is often preserved in ergs (sand seas) abutting the edges of evaporite basins in the USA and elsewhere (Mountney and Thompson, 2002). For example, Havholm and Kocurek (1994) used the presence of regional discontinuities in the erg succession to interpret the depositional history of the Jurassic Page Sandstone of the Colorado Plateau, USA (Figure 2.42). The Page Sandstone was deposited in a coastal erg where there was a constant rise and fall of the strandzone of the adjacent epeiric seaway. These eolian sediments encompass a number of regional erosion surfaces known as super bounding surfaces or supersurfaces. Sometimes the interdunal portions of these supersurfaces preserve giant (5 m high) stromatolites indicating flooding and longterm at-surface brines in the interdunal corridors (Eisenberg, 2003).

Correlation of super-surfaces between outcrops defined inter-relationships between the dune sands and the interlayered

Figure 2.42. Accommodation space for Jurassic Page Sandstone (30-50 m thick) sedimentation was controlled by interaction during subsidence between deflation (solid curve) and changes in the level of the water table (dashed curve). Surface a is overlain by sabkha sediments that were not eroded, surface b is overlain by partly eroded sediments, and surface c is an erosional surface with polygonal fissures. Numbers 1-4 on sedimentation curve indicate type of activity: 1) dune accumulation, 2) deflation, 3) sabkha formation or formation of polygonal fissures, 4) deflation of surface features (from Havholm and Kocurek, 1994).

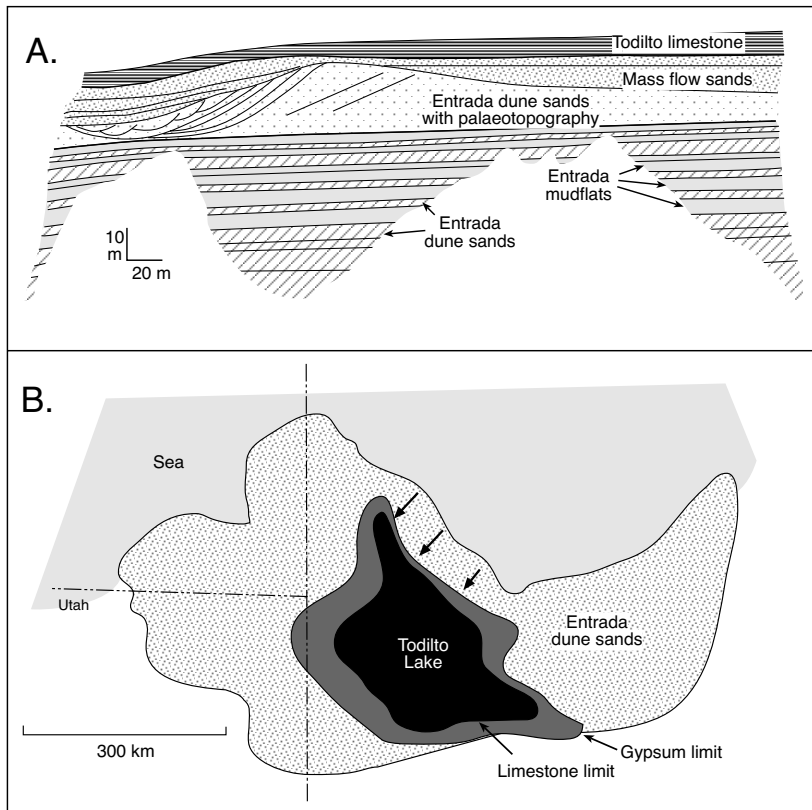

Figure 2.43. A) Outcrop drawing showing preserved dune palaeorelief with onlapping structureless sandstones and overlying limestones of the Todilto Formation. The Entrada Sandstone underlying the preserved relief consists of interbedded dune sets and evaporitic mudflat (sabkha) deposits (after Benan and Kocurek, 2000). B) Approximate Late Callovian-Oxfordian(?) palaeogeography of the Four Corners area after partial marine transgression of the Entrada. Extent of the Todilto Formation shown with concentric limits of limestone and gypsum within the unit, with surrounding eolian units (after Lucas and Anderson, 1994).

sabkha and interdunal successions (Figure 2.42; Havholm and Kocurek, 1994). Sand accumulation in the Page was episodic and punctuated by the formation of supersurfaces tied to substantial lowerings of the regional water table. This created both Stokes surfaces and megapolygonal fissures. Sabkhas and interdunes aggraded as the water table rose until sedimentation surfaces sat above the top of the capillary zone. Then vadose sedimentation, typically eolian crossbedded dunes sands, dominated once more. Thus the Page Sandstone is a collection of desert dune-interdune successions preserved in accommodation space created by an overall rise in the water table (basin subsidence). The smaller scale sequence packaging (dune alternating with wet interdune) reflects periodic rises in the water table, tied to shorter-term variations in climate, tectonics (subsidence) and changes in the strandline positions of nearby seaways or lakes.

The Jurassic Entrada Formation shows a similar water table control with its sea-marginal setting, promoting numerous internal truncation surfaces tied to deflation to the top of the capillary fringe (Crabaugh and Kocurek, 1993). Sediments deposited in the passage of the Entrada Fm. into the overlying evaporitic Todilto Fm. are unusual for an eolian system. The upper part of the Entrada is characterised by mass flow deposits and preserved eolian dune palaeotopographies beneath sandy subaqueous strata, rather than the more typical erosional top with the eolian unit passing up into continental deposits (Figure 2.43a; Benan and Kocurek, 2000). Preserved dune remnants have relief of up to 35 m and are buried by onlapping, subaqueous, largely structureless sandstones. The latter are derived by mass wasting of the upper portions of the dunes as regional water levels rose. Eolian sands were redeposited as sediment-gravity flows, which infilled depressions between the dunes. Preservation of dune palaeotopography beneath mass-flow deposits argues that flooding of the Entrada dune field was geologically rapid and energetically gentle.

Flooding heralded the onset of a restricted density-stratified brine lake/seaway, which deposited the evaporitic Todilto Formation. This seaway was a marine-seepage fed drawdown depression within what was the lowest part of the erg. This type of seepage encroachment converting the erg to a lake meant there was no transgression of a high energy marine coastline across the top of the sand sea (Figure 2.43b). Rather, aggradation of the saline water table was a relatively gentle process, with preservation of dune topography beneath lacustrine laminites perhaps aided by the formation of ephemeral capillary-fed salcrettes. Salcrettes precipitate where the capillary zone intersects the eolian landscape in any arid zone transition from an erg to a brine lake. A similar preserved dune palaeotopography, also with ephemeral salcrettes, formed atop the Permian Rotliegend/Wiessliegend sands of the North Sea and heralded the onset of evaporite deposition in the saline giant that deposited the Zechstein salts (Glennie and Buller, 1983).

The position of the water-table in many ancient sand seas controlled the depositional style and facies continuity of various windblown sand units (Figure 2.44). Less permeable lenses of salcrete-cemented, damp and wet interdune strata and interdunal sabkhas exhibit an intertonguing, transitional relationship to the toe-sets of adjacent and overlying eolian dune units (Mountney and Thompson, 2002). Intercalation signifies vadose dune migration (eolian cross beds) was contemporaneous with water table-controlled accumulation in adjacent interdunes. Eolian crossbedding can only form in the vadose zone. Down-wind changes in the geometry and facies of the interdune units indicate periodic expansion and contraction of the interdunes in response to changes in the elevation of the groundwater table with respect to the landsurface. Changes in geometries and extents of the various vadose, capillary and lacustrine units in an erg are a response to climatic change, subsidence and episodic flooding.

Understanding that hydrology (depth to watertable) creates permeability layering during deposition of ancient dune sand succession adds another level of reality to previous dry erg models for fluid flow in eolian reservoir sands deposited below evaporite seals. Older engineering models guiding hydrocarbon recovery from oil and gas fields from eolian sands below evaporite seals typically assumed that the spectrum of internal flow discontinuities in the eolian sands were largely defined by 1st- through 4th-order bounding surfaces, that is, the primary sedimentary structures control permeability. At the reservoir scale the sands were assumed to respond as largely homogenous flow units during hydrocarbon extraction, with permeability variation tied to grain size variation. This is after all what is seen in the impressive Quaternary ergs of

the Sahara, Arabia and Mongolia. But these analogs are all purely continental settings, located a long way from the ocean and from any other permanent body of surface water with a hydrology capable of depositing a widespread evaporite seal over the top of the erg.

Figure 2.44. Spectrum of interdune geometries generated by variations in the frequency and magnitude of water-table change, the rate of dune migration and the net eolian sediment budget. (a) Entrada Sandstone, (b) Navajo Sandstone, (c) and (d) Helsby Sandstone Formation, (e) Cedar Mesa Sandstone, (f) White Sands (after Mountney and Thompson, 2002 and references therein).

The reality is that homogenous eolian sand reservoirs are not all that commonly associated with bedded evaporite seals that overlie windblown sediments. Typically, thick homogenous dune sand units are not preserved at or immediately beneath the contact with an encroaching evaporite seal. The encroaching hydrology associated with the passage from an eolian system to an evaporite system simply does not allow widespread vadose conditions during the transition. Rising water tables feed capillary salts that patchily cement the reservoir sands during passage into deposition of an evaporite seal. Reservoir quality in these systems is typically a reflection of intergranular cement intensity (anhydrite or halite) and is not a direct reflection of primary depositional geometries or primary sedimentary structures. By the time an evaporite seal covers a unit dominated by windblown sands any loose sands have already blown on and away into the interior, as is the case in the central Arabian Peninsula, or have been dispersed into the shoreface, as in the southeastern Qatari and northeastern Saudi coastal zones (Figure 3.57).

Preserved sandflats about the edges of most aggrading and transgressive evaporite seaways are tied to deflation controlled capillary fringes and aggrading marine water tables. Such a hydrology must deposit evaporite cements wherever the capillary fringe intersects the land surface and reflux cements where brine plumes sink into the underlying sands beneath brine-filled interdunal corridors (Figures 10.40 - 10.42). In this hydrological setting the sabkhas, mudflats and salcretas that characterise the transition to the seal facies create low permeability cement patches within any underlying eolian sediment sheet. Thick piles of more homogenous vadose crossbedded dune sand that may have once been present in the region prior to the encroachment of the evaporite precipitating hydrology now lie deeper in the succession, and so are of less interest in terms of modelling hydrocarbon production from sediment beneath the evaporite seal.

Reservoir models for flow response in eolian sandflats sealed by evaporites should not assume intraformational continuity in the sands beneath the seal. Instead, a competing model with two end-members is more appropriate. At one end of the depositional spectrum are damp/wet interdune strata in wet eolian sandflats with shallow water tables. At the other end of the depositional spectrum are dry dunes with deep water tables that are flooded by the rapid entry of seawater into the continental depression. Inputs to the model can be quantified by the relative proportion of dry eolian versus wet interdune structures seen in core or core-calibrated FMI imagery. Scaling of reservoir geometries can be done using analogues

for the various styles of watertable encroachment on coastal dunes as seen in modern marine and lacustrine settings (e.g. Figures 3.58 - 3.61).

A climbing dune model (relevant for much of the Entrada Sandstone, in Utah) requires moderate-high sediment supply in balance with a relatively deep water table. It has a relatively low potential for widespread capillary salcretas and fine-grained interdunal sediments (Figure 2.44a). The non-climbing dune model at the other end of the hydrological spectrum is characterised by widespread episodes of non accumulation or hiatus (relevant for climatically controlled supersurfaces as in the coastal zone of modern NE Saudi Arabia, Sabkha Matti in the UAE, the White Sands of New Mexico, the Late Quaternary sandflats surrounding Lake Eyre and their Pre-Khuff counterparts in the subsurface of Saudi Arabia). It requires periodically low rates of sediment supply, high rates of deflation and long term low rates of creation of watertable controlled preservation space for the sand sheets. It has a much higher potential for large areas of the system to be deflationary, for large areas of the sedimentation surface to intersect the capillary fringe and for the preservation of widespread capillary salcretas (Figure 2.44f).

Defining which of the various intervening styles of sediment accumulation in the eolian succession under study is important in modelling porosity and permeability extents and in correlating lateral extents of high permeability zones in ancient sand bodies (Mountjoy and Thompson, 2002; Figure 2.44b-e). Textures indicative of dry or wet eolian systems and interdunal sabkhas are discussed in the next chapter. Wet interdune textures are described in detail by Goodall et al. (2000).

Degrading hydrology and playa capture

Aside from Stokes surfaces, the effects of a degrading (falling) hydrology and associated deflation are seen in sediment and drainage patterns in many Late Quaternary playas, including those in Central Australia located in and around Lake Amadeus and Curtin Springs (Jacobson et al., 1989). Long term reduction in groundwater levels associated with increasing aridity at the end of the Pleistocene led to a change in the status of some inland playas from discharge playas to recharge playas (with solution fissures and karst holes) via a process known as playa capture. It occurs when a fall in the level of regional groundwater, perhaps driven by the deflationary deepening of one playa floor leads to the removal of one or more adjacent playas from the discharge level of regional groundwater outflow (Figure 2.45; Jacobson and Jankowski, 1989). Groundwater head in the Curtin Springs area has decayed over the last several thousand

Figure 2.45. Schematic of playa capture or abandonment via decay of groundwater head. Samphire Lake was once a discharge playa (dashed line indicates former water table) that was accumulating gypsum, but it was converted to a recharge playa as Glauberite Lake progressively captured the regional groundwater flow system (after Jacobson and Jankowski, 1989).

years and so changed the nature of playa sedimentation. A few thousand years ago Samphire Lake was a discharge playa and it still retains thick deposits of groundwater-derived lacustrine gypsum from that time (Figure 2.45). Today the discharge system is no longer active in the lake as the regional water table lies metres below the playa floor. Samphire Lake has evolved into a vegetation-covered recharge playa and regional discharge is focused into nearby Spring Lake and Glauberite Lake. This has rendered the Samphire Lake surface sediment susceptible to eolian deflation, karstification and vegetation coverage. Over time Glauberite Lake will become the primary focus of groundwater activity in this region and will ultimately form a regional groundwater sump.

Falls in local hydrological base level can be driven by changes in climate, uplift or tectonic isolation. It drives local processes such as karstification and carnallite precipitation in bedded halites in the Quaternary playas of Qaidam Basin, China and in Lake Asal, Djibouti (Figures 11.2, 4.56). An impressive example of the effects of a local lowering of the saline base level on karst intensity is seen in evaporite-cemented sediments that increasingly exposed about the margins of the Dead Sea in the Middle East. Lake water level has been falling since the 1940s and the rate of fall has accelerated since the 1960s with increasing anthropogenic extraction of fresh water (Figure 4.42a). This fall in water level drags with it the brackish groundwater lens that floats atop dense lake brines about

the lake edge (Figure 2.46; Salameh and El-Naser, 2000). Sediments that were evaporite-cemented and mineralogically stable when bathed by hypersaline lake brines become subject to dissolution and collapse with the encroachment of brackish to fresh pore waters. The process of dissolution is especially obvious at the contact between the less permeable Lisan Formation and the overlying salt-cemented gravels.

Away from the pervasive collapse dolines tied to the retreating shoreline, other areas of reactivated subsidence in the Dead Sea depression are tied to fault intersections and radial uplift fractures atop and about areas of active diapir uplift in the Lisan Straits (Closson, 2005). Groundwater preferentially flows along faults, joints and fractures so that chemical and physical erosion of saline sediments takes place along such weaker zones. Underground voids then appear, creating growing cavities, which come up to the surface after successive roof collapses (Chapter 12). For example, the falling water levels of the Dead Sea lake has created problems for the salt works in the Southern Basin with newly-formed solution collapse structures weakening some of the dykes enclosing the evaporation ponds. Between 2000 and 2002, the Arab

Figure 2.46. Dissolution and removal of salts due to lowering of water level and the associated flow of freshwater along the interface of the sandy gravels and the salty Lisan Formation deposits at the Dead Sea margin and the accompanying cavity, collapse, and sinkhole formation in the gravels (after Salameh and El-Naser, 2000).

Potash Company (APC) lost two salt evaporation ponds due to solution-breaching of dykes resulting in a loss of \$70 million. The breached zones show a strong structural control tied to regional lineaments. The southern Dead Sea is by far the most affected by sinkholes and decametric to kilometric subsidence phenomena.

At a broader scale, longterm watertable falls in any saline basin drive a redistribution of salt sinks within large isolated drawdown sedimentary basins. Drawdown changes the distribution of marginal versus basin-centre evaporite accumulations (Figure 5.40b). It can create regional mega-surfaces or unconformities, which are recognisable on seismic sections and can cross continental and marginal marine sequences (e.g. the Messinian M-horizon of the Mediterranean). These surfaces are sometimes described as mega-bounding surfaces by sequence stratigraphers. If they are incorrectly interpreted as eustatically induced contacts, rather than watertable or climatic responses to subaerial exposure in a continental settings, they can greatly complicate any attempt at age fitting a sealevel curve to the seismic sequence stratigraphic signature (Chapter 5).

Salinity stratification and textures

The occasional surface input of freshened waters into the central discharge depressions of evaporitic seaways (salterns) or perennial saline lakes tends to create stratified surface water bodies with less-dense lower-salinity waters floating atop more-dense saline bottom brines (Figure 2.37b). If there are large salinity contrasts between the two water masses, they tend not to mix until their densities equilibrate. The emplacement of a freshwater body atop a lower dense brine slows and stops the concentration process in the lower brine body that drives brine reflux. It can start up again once the freshwater body has concentrated to where it mixes with the underlying brine. This ongoing stop-start mechanism probably explains the finer scale layering seen in the many anhydrite cements and replacement dolomites created by reflux hydrologies.

Brine stratification occurs today in marine-fed coastal salinas in Australia, in perennial saline lakes in the African Rift Valley and in the Dead Sea, Israel (Chapter 4). Lake Hayward, a coastal salina in Western Australia, typifies such a stratified brine system and has ionic proportions in the bottom brines similar to that of seawater. Carbonate muds are accumulating on the microbially bound floor of its small perennial brine pool (2-3 m deep) under a limnology that is density and thermally stratified for much of the year (Rosen et al., 1995). Meteoric inflow creates a well-defined longterm mixolimnion; this upper,

less dense and cooler water mass has salinities ranging from 50,000 to 210,000 ppm. It exists from late autumn to early summer (May to February) as it floats atop a lower denser and warmer water mass (monolimnion) with salinities in the range 150,000 to 210,000 ppm (Figure 2.47).

Stratification disappears for a few months each year from mid-summer to mid-to-late-autumn (Figure 2.47a). During summer the waters of the upper water mass evaporate and concentrate as their bicarbonate content steadily increases. From the onset of stratification in late autumn, across mid winter and on into to early summer the temperature trends of the two water masses are parallel. They form a heliothermic system where the lower water mass is some 15-20°C hotter than the upper water mass. By mid summer (e.g. January 1992) lower water mass begins to cool, while the temperature of the upper water mass continues to rise. Once the temperatures (and densities) of the two water masses equalise they mix as the lake overturns. Waters of the lower water mass (the monolimnion) now come into contact with the atmosphere once more. While the water masses are stratified, the chemocline and the thermocline are sharply defined across a 10cm interface with a salinity contrast that may be as much as 135,000 -140,000 ppm and a temperature difference of up to 19°C.

The time of mixing is immediately preceded by a sharp fall in the level of bicarbonate in the mixolimnion, suggesting the precipitation of calcium carbonate (mostly aragonite) occurs in the upper water mass from late summer to autumn (Figure 2.47a; Rosen et al., 1995). The lower water mass in Lake Hayward was supersaturated with respect to gypsum and anhydrite from late 1990 to February 1992 (Figure 2.47b; Rosen et al., 1996). When the lake mixed from January 1991 to May 1991 and from March 1992 until early May 1992, the entire water body was at gypsum saturation, but slightly undersaturated with respect to anhydrite. A 'whiting' (a cloudy white appearance to the water body) was observed in the lake in March 92, just at the time of first mixing of the lake. Analysis by scanning electron microscopy (SEM) of the collected filtrate indicated that the 'whiting' was composed of gypsum and diatom tests. At that time, there was also a thin (10-20 mm) crust of gypsum on the lake floor. After the 'whiting', when the water was unstratified, both the monolimnion and mixolimnion were near saturation with respect to gypsum.

After mixing, the stratification begins to reform with the next influx of meteoric waters onto the lake surface. In the early stages of setup leading into the longterm stratification it appears stratification is not stable and the water bodies may

Figure 2.47. Hydrogeochemistry of Lake Hayward waters, Western Australia. A) Plot of temperature regime in upper (mixolimnion) and lower (monolimnion) water masses and bicarbonate content. As the lake mixes, the thermal and density stratification disappears. Immediately prior to mixing the bicarbonate concentration decreases suggesting precipitation of calcium carbonate (aragonite) (after Rosen et al., 1995). B) Saturation state with respect to gypsum. The monolimnion was saturated with respect to gypsum from summer 1991 to autumn 1992 and was again near saturation at the start of summer 1992-1993. The mixolimnion was only saturated when the lake water column was homogeneous (after Rosen et al., 1996).

remix before stable stratification sets in by mid winter (e.g. May-June 1992; Figure 2.47). Lake Hayward illustrates an aspect of pelagic evaporite precipitation that is probably more generalised in many “deep water” density-stratified settings. Namely that evaporite crystals grow on the bottom only when the water column is unstratified. This is so even when the lower water mass is at saturation almost year round (Figure 2.47b versus Figure 9.31).

Another well-documented heliothermal brine lake is Solar Lake, a small monomictic hypersaline lake located on the Sinai coast of the Gulf of Aqaba (Cytryn et al., 2000). The lake is separated from the ocean by a narrow sand bar (Figures 4.10, 4.11). Water is supplied via seawater seepage through the sand bar and occasional winter precipitation. Brine depth fluctuates between 4 and 6 m, driven by seasonal changes in the intensities of evaporation and the related levels of seawater seepage and brine reflux. High evaporation and aridity in the summer months raises the lake salinity to 200‰. At that time the brine column is completely mixed (holomictic) and the entire water column is oxygenated (Figure 2.48a). Temperature/salinity vary little throughout the brine column and sulphide/methane concentrations are very low.

By autumn, the water column is stratified with a newly introduced seawater brine (50‰) layer overlying residual, highly saline bottom water (180 - 200‰). A well-defined density gradient (halocline or pycnocline) now separates an upper oxygenated cooler (16°C) brine mass (epilimnion) from the lower hotter (45-55°C) anoxic sulphide-rich brine mass (hypolimnion; Figure 2.48b). High sulphide concentrations develop in anoxic waters below the halocline from the activities of sulphate-reducing bacteria, both in the water column and in the underlying cyanobacterial mats. Crossing the halocline into the

lower brine there is a rapid downward increase in sulphide concentration, which reaches a maximal value of 1,240 μM proximal to the sediment brine contact (Cytryn et al., 2000). At the same time a peak in methane concentration develops directly below the halocline, where a maximum value of 6.5 μM was measured in the December 1997 profile and was in part a reflection of the decomposer activities of the methanogenic haloarchaea (Chapter 9).

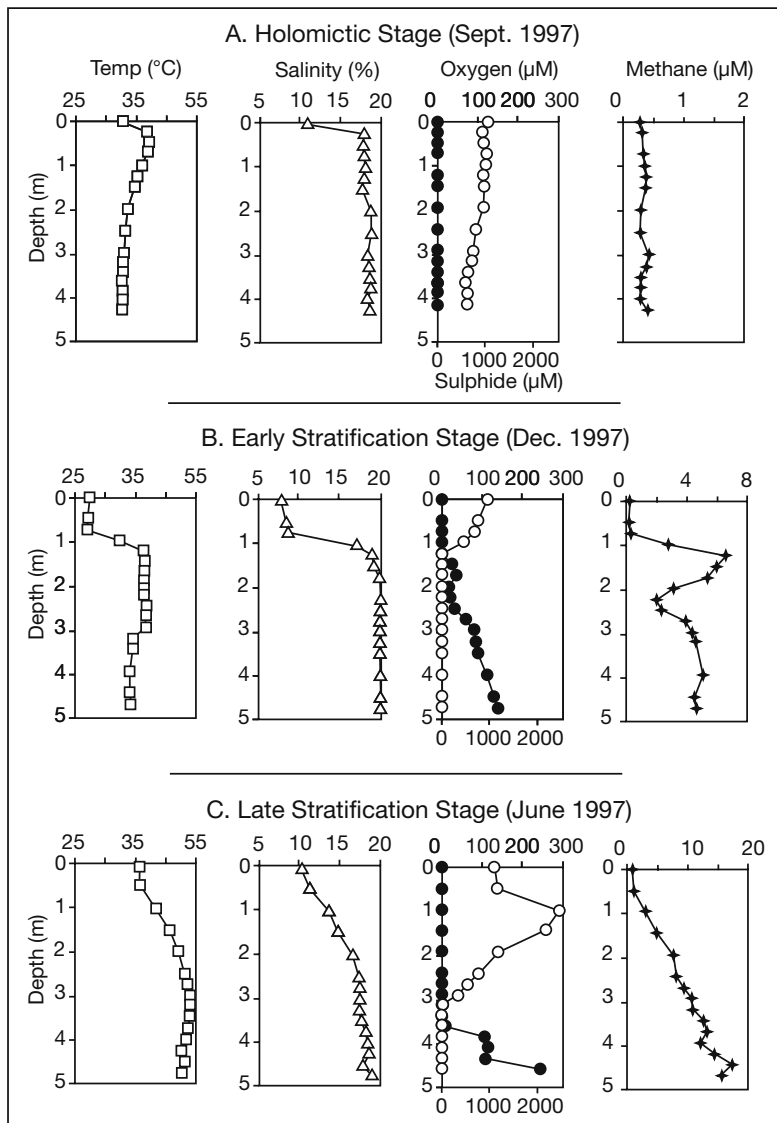

Figure 2.48. Effects of the seasonal development of heliothermic stratification in Solar Lake, Middle East (after Cytryn et al., 2000). Open circles = O_2 , filled circles = sulphide.

As winter passes into spring, a gradual heating and increase in the salinity of the upper water mass degrades the halocline. The data shown in Figure 2.48c was collected in June 1997 and portray a transitional state between late stratification and the beginning of holomixis. Salinity and temperature gradients across the halocline are more gradual and deeper in the water column than those observed in the December 1997 profile. The deepening halocline allows oxygen to penetrate much deeper than in the earlier stages of stratification, and the chemocline is now located 3.25m below the water surface. The oxygen

concentration in the upper water mass reaches a maximum value of $300 \mu\text{M}$ at a depth of 1 m below the water surface. These supersaturated values of oxygen imply intense photosynthetic activity at these depths. Below the chemocline, a sharp rise in sulphide concentration occurs, reaching a maximum value of $2,150 \mu\text{M}$ at the water-sediment interface (Cytryn et al., 2000). Methane concentration increases linearly from the surface and reaches a maximum value of $17 \mu\text{M}$ adjacent to the lake bottom, implying methane, like the bacterially derived H_2S , is escaping from the sediments. Subsequent increasing evaporation rates further disrupt the stratification and ultimately lead to summer holomixis identical to that in the September 1997 profile.

Thick cyanobacterial mats carpet the Solar Lake sediment surface and contain a highly diverse microbial community of cyanobacteria and haloarchaea. Their metabolic activities, along with the lake's planktonic microbes greatly affect the hydrogeochemistry of the lake waters by exporting oxygen, sulphide, and methane into the brine column. Biological interactions with evaporite sediments and brine columns are discussed in detail in Chapters 4 and 9.

Although the daily temperature/stratification records of Lake Hayward and Solar Lake are probably the best documented examples of the hydrology of a naturally stratified brine column, both regions have a number of inherent limitations when attempting to use them as direct analogues for the hydrology of ancient stratified brine seaways. Unfortunately, neither are saline enough nor isolated enough from their seawater feeds to accumulate substantial thicknesses of halite. Neither are hydrological analogues for bottom-nucleated salt beds, such as gypsum or halite units that dominate the central portions of ancient evaporite seaways and lakes. They also suffer from the scale limitations that enfeeble all modern marine-associated evaporite analogues (Figure 5.3). Their small aerial extent ($\leq 0.6 \text{ km}^2$) prohibits a direct hydrological comparison with

bedded salt accumulations in ancient saline giants (areas > 10⁶ km²). Their centripetal unconfined meteoric inflow hydrologies, driven by winter rains and a lowering of evaporation intensity, means they cannot be directly compared to ancient brine seaways where strandlines moved up to hundreds of kilometres in a wet-dry cycle and where unfractionated meteoric waters or seawaters were insignificant in the freshening process in the subaqueous basin centre.

Brine stability and evaporite textures

In ancient evaporitic seaways and lakes the style and permanency of brine stratification is best interpreted from the preserved depositional textures (Lowenstein and Hardie, 1985; Warren and Kendall, 1985). But there are some physical principles common to modern and ancient brine hydrologies. If a stratified brine column forms above a growing crystallisation surface, solar driven crystal growth of gypsum or halite in the bottom waters first slows then stops (Figure 2.37b; Figure 2.49). Once a water body is stratified, no solar mechanism is available to further

Figure 2.49. Growth-aligned gypsum shows internal textures are controlled by the gypsum growth surface interacting with the stability and salinity of bottom brines. In the early stage of fill, when the brine lake is deeper, the bottom brines are stable and salinities do not ever decrease to where they become undersaturated with respect to gypsum. "Zig-zag" textures result. When the sediment surface aggrades to where bottom brines freshen, then the periodic dissolution of the upper part of the growth surface dissolves and mm-laminated textures form. The present stage of sediment fill is where the brine lake has been filled to equilibrium with the local water table, eolian reworking of seasonal gypsarenite precipitates is the dominant mode of deposition (after Warren, 1982b).

concentrate the bottom waters. Subaqueous crystallisation can only continue in a stratified system in zones of brine mixing or bottom temperature change near subaqueous spring seeps. Once the freshened inflow ceased, ongoing evaporation concentrates the upper brine body until its density matches that of the lower brine body. The two water bodies then mix (holomixis) and crystal growth on the bottom can begin anew (Figure 2.49). This type of holomictic bottom crystal precipitation, where the crystallisation surface is never in contact with undersaturated bottom water, deposits layered euhedral growth-aligned crystal beds on the brine floor (e.g. chevron halite or aligned swallowtail gypsum; Figure 2.49).

If, on the other hand, the freshened upper water body does come into contact with the crystallisation surface of the salt bed then subaqueous horizontal planation surfaces develop. Subhorizontal planation occurs both in saline basins subject to complete desiccation and in those parts of evaporite seaways covered by perennial brine sheets (tens of cm deep) that were subject to periodic freshening. A desiccation stage, followed by a freshened water flood, creates a near horizontal planation surface with intercrystalline karst, which marks a time when the water table was lowered into the salt bed immediately prior to a subsequent freshening event (Figure 1.27). In contrast, freshening of perennial bottom brine creates a horizontal planation surface atop the salt bed with little or no intercrystalline karsting (laminated coarse-grained gypsum in Marion Lake; Figures 2.49, 4.5f).

In both cases the freshened surface water sheet only dissolves the uppermost portion of the salt bed, it does not displace the much denser pore brines that saturated the bulk of the underlying salt bed. A planation surface defines the top of saturated pore brines. Vadose karst in a desiccated salt pan can only extend down to the top of this dense pore brine layer. Below it the pore brines are saturated, above it the waters are undersaturated or nonexistent.

These flat, laterally extensive dissolution surfaces typically truncate the tops of previously growing crystals, be they trona, halite, gypsum or any other bottom nucleating salt (Figure 2.49). As the freshened water body

begins to concentrate it may precipitate a less saline mineral phase, which settles onto the planation surface. It may also be the time when clays, formerly suspended in the floodwaters or blown in by the wind, begin to flocculate and sink through increasingly saline surface waters. As the freshened water body continues to concentrate into salinities that precipitate the dominant salt phase the aggrading crystals that underlie the planation surface can now poikilitically enclose the less saline precipitates (e.g. laminae of aragonite pellets in laminated coarse-grained gypsum; Figure 2.49).

Brine reflux drives substrate alteration

Brine reflux occurs when ponded or concentrating holomictic brines atop the floor of an evaporitic seaway or lake become dense enough to displace underlying pore fluids and so percolate into the underlying succession (Figure 2.50). Descending brines can have chemistries that are supersaturated with different mineral phases to the matrix through which they are flowing and so drive various alteration processes such as dolomitization, backreactions and pseudomorphing. It may also drive the precipitation of widespread authigenic K-feldspars in siliciclastic hosts at burial depths that are much shallower, and in authigenic stages much earlier than those of equivalent precipitates in non-evaporitic siliciclastics (Sandler et al., 2004).

One of the most widely recognized effects of brine reflux is the formation of dolomite in units underlying and adjacent to a thick evaporite sequence. When evaporitic carbonate or gypsum precipitates in hypersaline areas on such platforms, the surface

Figure 2.50. Schematic illustrating the process of brine reflux creating secondary dolomite in a carbonate platform (after Warren, 1991).

brine densities are in the range 1.1 to 1.2 gm/cc (Figure 2.5). Concurrent Mg/Ca ratios of the remaining brines rise compared with their seawater seep feed, and so dense Mg-enriched solutions sink through the underlying platform sediments. They displace connate pore fluids with densities around 1.03 gm/cc and slowly seep basinward through underlying platform limestone aquifers. In this way large volumes of Mg-rich brine pass through previously deposited shelf limestones, precipitating dolomite both as a pore fill and as a replacement in the former shelf limestones (Figure 10.24). The first evaporite-generated brine reflux model for ancient dolomites was by Adams and Rhodes (1960). Their model explained the dolomitization of the Permian Capitan reef complex of west Texas; whereby backreef, shelf and lagoonal carbonates are intensely dolomitized, while the shelf edge and slope carbonates are not. They envisioned reflux dolomitization through porous sediments to depths of several hundred metres below the brine source.

By the mid 1960s, seepage reflux dolomitization as proposed by Adams and Rhodes had gained a large number of proponents working in ancient evaporite-associated dolomites (Hsu and Siegenthaler, 1969) but needed, under the dictates of strict geological uniformitarianism prevailing at the time, to be verified in the Holocene (Warren 2000a). In 1965 Deffeyes et al. reported modern Mg-rich brines in a marine spring-fed gypsum salina (Pekelmeer Lagoon) on Bonaire in the Netherlands Antilles in the Southern Caribbean. From the water chemistry, they predicted that concentrated lagoonal brines should be sinking and forming reflux dolomite in underlying sediments. They observed micritic dolomite in Holocene lagoon muds beneath gypsum crusts but, with only a soft-sediment coring device to work with, could not penetrate the cemented Pleistocene base. Outcropping on the opposite end of the island, well away from the present lagoon, they located a dolomite replacing what they interpreted as Pleistocene limestone and inferred that this had formed during an earlier episode of brine reflux.

Lucia (1968) subsequently drilled beneath the Pekelmeer Lagoon and found no widespread dolomites in the underlying Pleistocene carbonates. He also found that porewaters were of normal marine salinity in areas where brine was predicted by a seepage reflux model. A thin clayey ash layer of generally low permeability was found forming a hydroseal that separated sediments below with normal salinity from lagoonal sediments with elevated salinity. Thus, reflux dolomitisation was not occurring beneath the lagoon. Springs supplying seawater to the salina were in areas where the ash bed was broken or missing and formed the terminations of flow pathways in the underlying Pleistocene/Pliocene (Murray, 1969). For most of the year seawater seeps into the Pekelmeer springs driven by

evaporative drawdown. However, during a short period in the late summer, the springs are inactive and the hydrostatic pressure on the landward side is greater than that on the seaward side. Murray concluded that return flow or reflux could occur at such times, but did not appear to do so with sufficient volumes of brine crossflow to form replacement dolomite.

The claim that the Pekelmeer was forming extensive seepage reflux dolomites beneath an evaporite lagoon was further challenged when Sibley (1980) concluded that the solutions responsible for extensive dolomitization in Tertiary sediments on Bonaire (dolomites that were earlier used as evidence for reflux dolomite) were probably fresh to brackish meteoric waters mixed with seawater, and were not derived by reflux of the modern Pekelmeer hydrology. Later work by Fouke et al. (1996) on dolomite in the Seroe Domi (Miocene), a unit more than 20 m thick that extends 115 km across the Netherlands Antilles, has reinforced Sibley's conclusions. However, Lucia and Major (1994) continue to argue for a significant input of marine/hypersaline waters during Neogene dolomitization in the region.

There are, nevertheless, other islands in the tropics where localized brine reflux, associated with hypersaline conditions, is apparently forming local-scale Holocene dolomites. Müller and Teitz (1971) documented brine-reflux dolomite replacing earlier carbonate cement in skeletal grainstones on the shoreline in Fuerteventura in the Canary Islands. Kocurko (1979) found brine-reflux dolomite a few metres above the high tide line, in the spray-zone pools of the shoreline of San Andres, Columbia. Aharon et al. (1977) described small volumes of reflux dolomite forming in Holocene sediments of Solar Lake. Thin, localized brine-reflux dolomites can also be found about the present-day edges of Ras Mohammed on the Sinai Peninsula (Chapter 3). It seems small-scale examples of brine reflux dolomites exist, but pale in comparison to obvious and extensive reflux dolomites of the past (Figure 5.3).

Hydrological modelling of ancient reflux systems by Shields and Brady (1995), using very conservative assumptions of brine head and drawdown, show that reflux can explain platform dolomites within geologically realistic time frames of burial (Figure 2.51). Their flow model used flow lengths varying from 1 to 1000 km and the relative densities of seawater and brines of two end member compositions (Figure 2.51a): brine 1 is anhydrite-saturated (density $\rho = 1120 \text{ kg/m}^3$) and brine 2 is halite-saturated ($\rho = 1200 \text{ kg/m}^3$). Brine 1 is approximately 9.3% denser than seawater ($\rho_{\text{seawater}} = 1024.5 \text{ kg/m}^3$), and brine 2 is 17.1% denser. Using a 100m tall and 1 m wide flow cell

(Figure 2.51b), brine 1 has approximately 9.3 m more hydraulic head than a comparable column of seawater, while brine 2 has a differential hydraulic head of 17.1 m. Shields and Brady (1995) assume a pure calcite precursor and a final product that

is 100% dolomite with 7% porosity; this requires 350 kg/m³ of magnesium. The results (Figure 2.51c) show that reflux flow could circulate the Mg necessary to completely dolomitise carbonate platforms with radii of a few tens of km in a few million years. Shelves with shoreline to basin distances of the same order can be completely replaced in a similar period. Larger platforms require more time or that the evaporite recharge areas migrate with time. Carbonate platforms tens to several hundred kilometres across could be dolomitized by such epeiric hydrologies.

The relative abilities of rocks to transmit brine will control where the bulk of the fluid flux occurs within platform limestones of any age. It is unrealistic to think of reflux dolomitization as a homogenous process uniformly overprinting all platform limestones. The inherent permeabilities of the various precursors clearly play an important role in dolomite intensity. The most permeable lithologies beneath the evaporite lagoon will focus the bulk of flow as the brine seeps seaward. Whatever unit acts as the aquifer at the time of reflux will also be the subject of the most intense dolomitization. High permeability units within flow paths of tens to hundreds of kilometres can channel the volume of necessary brine in time frames \approx 1 Ma. Such high permeability units also have the potential to be dolomitized in regions well removed from the brine source (Figure 10.24).

In a recent paper that models brine circulation and retention in platform evaporites. Jones et al. (2002) has shown that the effects of a single 100,000 year platform evaporite episode can generate a reflux plume that persists for as long as 10 million years in underlying carbonates before it is once again displaced by geothermally driven brines (Figure 2.52). They call this long term effect "latent reflux,"

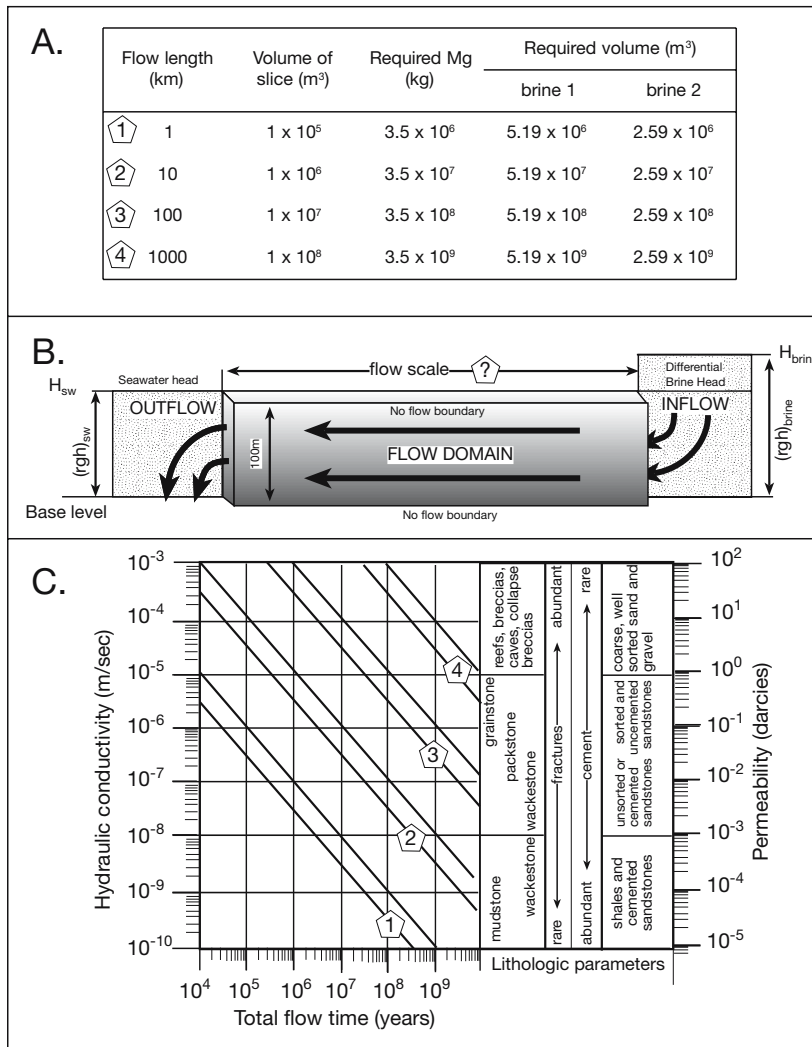

Figure 2.51. Dimensional analysis of seepage reflux (after Shields and Brady, 1995). A) Table of brine properties and amount of Mg required to covert calcite to a dolomite with 7% porosity. B) Dimension of slice model used in their calculations. Slices are similar except that flow length varies from 1 to 1000 km. Base level is 100 m in all cases and head drops are 9.3 m for anhydrite saturated brine 1 and 17.1 m for halite saturated brine 2. C) Dimensional analysis of Darcy's Law for a regional brine reflux system with 100 m base level. Diagram illustrates the time necessary for the minimum volume of dolomitizing brine to flow through a rectangular slice. All slices are 100 m thick and 1 m wide with varying flow lengths (1-4). It is assumed 350 kg/m³ of Mg are required to dolomitise the block. The lower curve for each flow path represents brine at halite saturation with a Mg exchange efficiency of 47%. The upper curve represents brine at anhydrite saturation with a Mg exchange efficiency of 36%. Permeability conversions assume an average brine density of 1160 Kg/m³ and a viscosity of 8.904 x 10⁻³ kg/(m/sec) and a temperature of 40 °C.

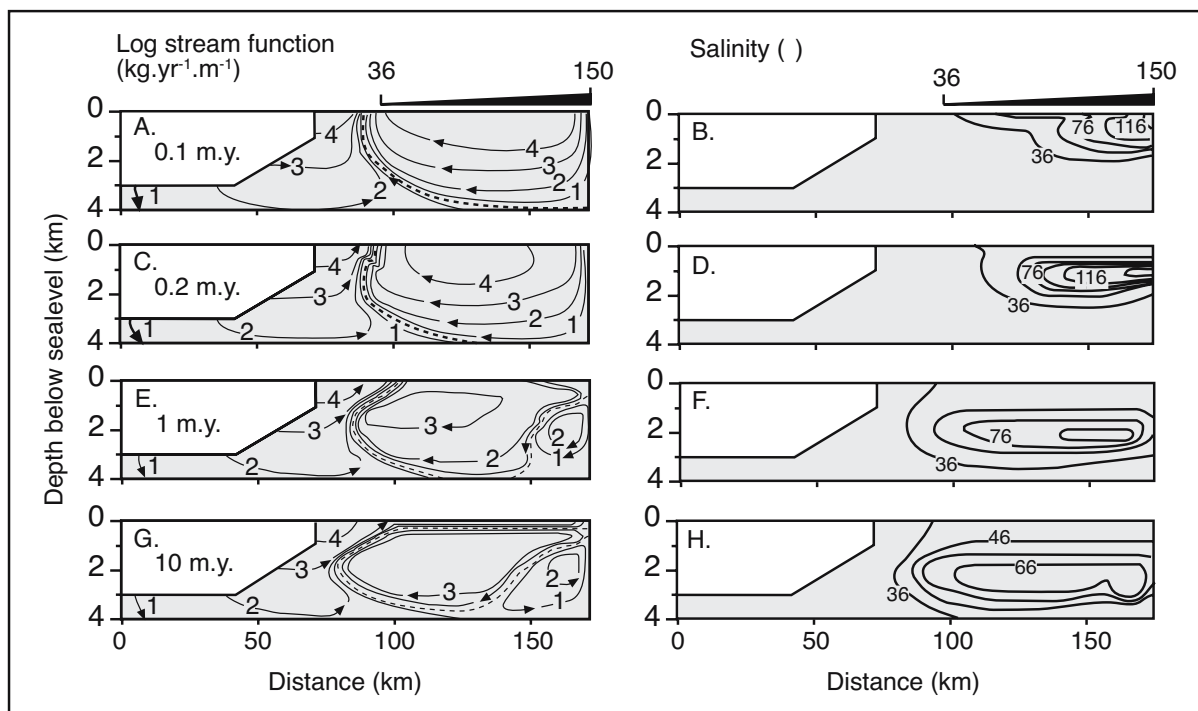

Figure 2.52. Evolution of groundwater circulation and salinity persists for as much as 10 m.y. after a single reflux event at gypsum saturation which lasted 0.1 m.y. Dashed line in the stream-function plots represents interface between geothermal reflux and latent reflux. Only the upper 4 km of platform is plotted; vertical exaggeration = 9 (after Jones et al., 2002).

it documents a hydrological situation where the effects of a sinking reflux brine persist long after the at-surface brine lake or seaway has disappeared. The modelling utilised a single depositional episode and a surface brine at gypsum saturation (150‰). They went on to note that higher salinity waters and longer episodes of evaporite precipitation would generate more widespread and longer acting brine plumes in the underlying sediments (Jones and Xiao, 2005).

Detailed mapping of dolomite distribution across the Permian Capitan shelf, the type area for the brine reflux model, clearly shows reflux works in ancient evaporitic platforms (Melim and Scholle, 2002). Dolomite extent is greatest beneath and adjacent to the drawdown lagoon facies. In contrast, dolomite distribution through the Capitan reef and into the fore reef outlines the distribution of those brine aquifers that were more active at the time of brine reflux, namely fractures and fore reef debris aprons. Aquifers carrying the descending brines out into the adjacent basin were dolomitised, while tighter aragonite-cemented intervals between aquifers were largely isolated from the flushing brines and so remained undolomitised. Garber et al. (1990) used a similar model of reflux but called upon bittern brines, derived from the very saline Salado Formation,

to explain magnesite, not dolomite, distribution in the same basin. They argued that when a brine has a Mg/Ca ratio > 40 it will precipitate a magnesite replacement rather than the more commonly observed dolomite. Similar reflux processes, driven by the deposition of Zechstein evaporites, may have precipitated authigenic magnesite cements in siliciclastic dune sands of Rotliegende reservoirs in the North Sea (Purvis, 1989).

Reflux dolomitisation in a platform setting can often be distinctive, even in core, as the intensity of total dolomitization decreases the further down core or laterally one moves from the evaporite-carbonate contact (Figures 2.53, 10.24). If not completely re-equilibrated during later burial dolomitization, the oxygen isotope signatures in platform dolomites formed by reflux typically follow a lightening trend away from the evaporite unit; that is, the further one moves from the contact, the less was the sediment's isotopic signature influenced by the heavier reflux-derived brines. If the sediments are not extensively recrystallised by later burial dolomitization, trace elements, along with stratigraphic position, can give another clue to a reflux association. In a study of dolomite from Neogene to Permian age, Sass and Bein (1988) found that evaporative dolomites associated with gypsum/anhydrite tend to show

Figure 2.53. Wireline signature and the interpreted core description of the Humble #1 Beltex Well, Bowie County, Texas. Shows a close relationship between Buckner anhydrite and dolomitization in the underlying Smackover Formation. Note changes in proportion of dolomite and porosity in terms of proximity to evaporite contact (after Moore et al., 1988).

50-57% CaCO_3 and the highest levels of sodium (up to 2700 ppm). Marine nonevaporitic subtidal dolomites have a similar range of compositions, but sodium concentrations of only 150-350 ppm.

The present may be the key to the past but it is simply not a good time to document depositional or diagenetic analogues for ancient platform and basinwide evaporites, nor their associated reflux hydrologies. There are no modern depositional counterparts to most types of ancient marine-platform and basinwide evaporites, hence there are no modern counterparts to brine-reflux dolomites (e.g. Figure 5.27). Holocene evaporites are accumulating within an “icehouse” climatic phase. The current “icehouse” mode, typified by waxing and waning polar icesheets, has dominated the earth’s climate for the last 12 million years. “Icehouse” times, with their high frequency sealevel oscillations, are not conducive to the formation of thick platform evaporites. In contrast, “greenhouse” time, with their inherent lack of polar ice sheets and low amplitude sealevel changes, favour the formation of platform evaporites and hence widespread reflux dolomitization of platform carbonates. Basinwide evaporites and their associated dolomites form via tectonic controls on basin isolation that are independent of “icehouse versus greenhouse” sealevel scenarios.

Most brine reflux models published to date utilise a platform evaporite setting. Examples include: the Cambrian Ouldburra Formation in the Officer Basin, Australia (Kamali et al., 1995); the Devonian Birdbear (Nisku) Formation of Canada (Whittaker and Mountjoy, 1996); Pennsylvanian platform carbonates of west Texas (Dickson et al., 2001) Permian San Andres Formation, USA (Leary and Vogt, 1986; Ruppel and Cander 1988; Elliott and Warren, 1989); the Permian Tansill and Yates Formations of the Central Basin Platform, USA (Andreason, 1992; Garber et al., 1990); the Jurassic Smackover and Haynesville Formations of the Gulf of Mexico (Moore et al., 1988); the Lower Cretaceous Edwards Formation of Texas (Fisher and Rodda, 1969) and the Middle Palaeocene Beda Formation, of the Sirt Basin, Libya (Gara and Braithwaite, 1996). Hydrological geometries of reflux dolomite associated with drawdown basinwide settings are different and are discussed in Chapter 5 after the various styles of saline giant are presented, while a number of oil field examples are discussed in detail in Chapter 10.

As well as long term effects in underlying carbonates, reflux also has significant syndepositional effects on nearsurface salt beds. Sinking supersaturated brines force backreactions and replacement processes in salt beds immediately beneath an evolving brine body. Hovorka (1992) recognised reflux of halite saturated brines through gypsum beds as the dominant control in the formation of halite pseudomorphs of subaqueous gypsum (Figures 1.30, 2.54). The replacement process is driven by the fact that gypsum precipitation is favoured by low temperatures and low salinities, while anhydrite precipitation is favoured by higher temperatures and higher salinities. At the warm temperatures that typify modern low-latitude brine pools (25 to 50°C), the gypsum-to-anhydrite transition is predicted to occur somewhere between the initial precipitation of gypsum and initial precipitation of halite. In contrast, brines at halite saturation are undersaturated with respect to gypsum, while saturated with respect to halite. Textural relationships in such settings, where bottom-aligned gypsum is replaced by halite, are shown to be controlled by nearsurface diagenesis and related to brine pool evolution (Hovorka, 1992).

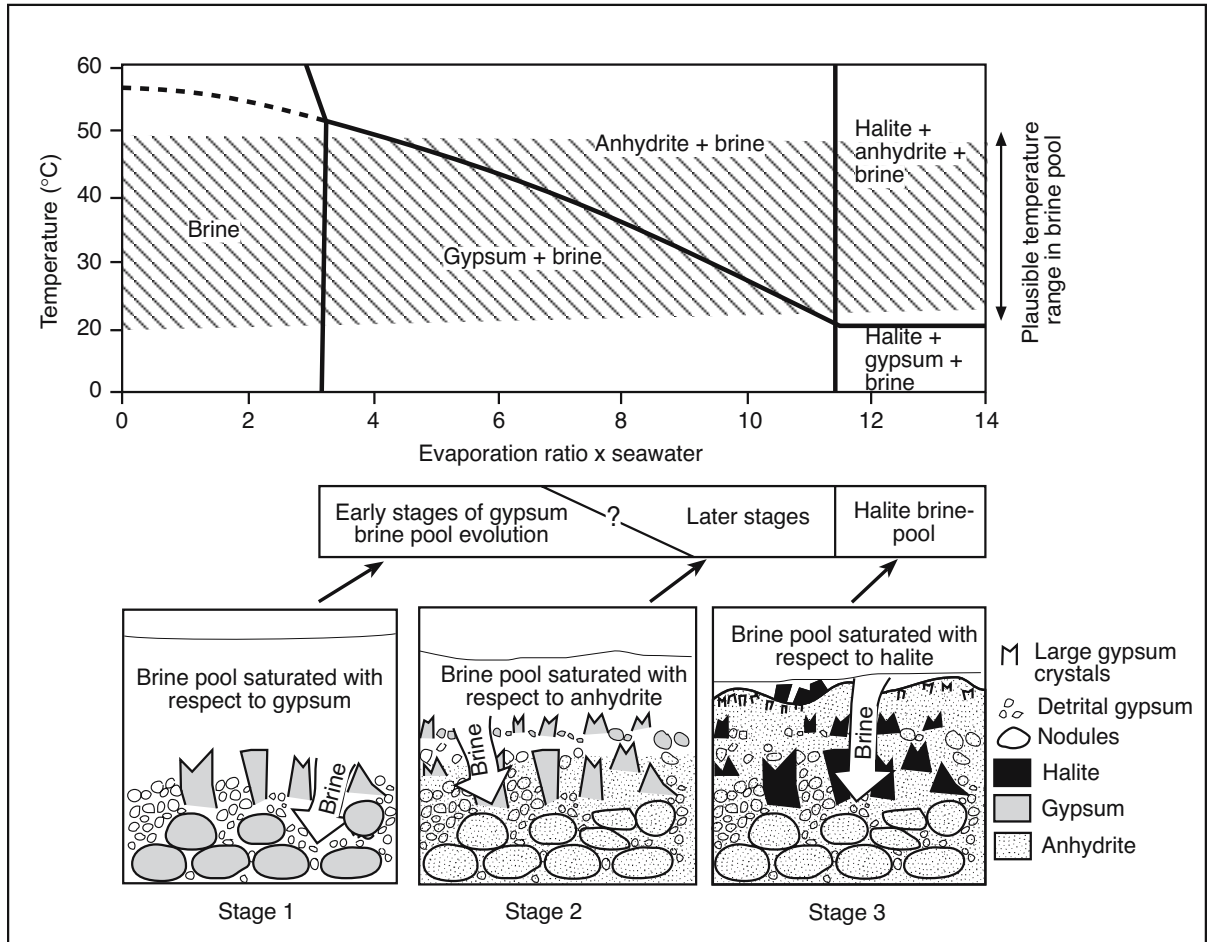

Figure 2.54. Gypsum replacement by halite during brine reflux. Upper part shows phase relationships between the gypsum and anhydrite in NaCl brine. Lower part shows how the alteration and replacement is dependent on the evolution of the overlying brine supplying waters that are refluxing through the gypsum bed. Stage 1: Large gypsum crystals grow vertically from the floor of the brine pool, and gypsarenite accumulates between the crystals. Gypsum is stable in diagenetic fluids concentrated three to approximately six times seawater concentration: alteration to form nodules occurs in shallow subsurface environments. Stage 2: As salinity increases from six to ten times seawater concentration, gypsum continues to precipitate metastably, but is dehydrated to thermodynamically stable anhydrite in the shallow diagenetic environment. Stage 3: When the brine pool evolves to concentrations about 10 times seawater concentration, halite begins to precipitate. Halite-saturated brines introduced into the shallow burial environment dissolve any remaining gypsum and replace it with halite (after Hovorka, 1992).

During Stage 1 the perennial brine body is four to six times the concentration of seawater and is at gypsum saturation (Figure 2.54). In stage 2 brines are at the upper end of the calcium sulphate field (6-10x seawater) and are in the anhydrite stability field. Metastable gypsum continues to precipitate on the brine pool floor, but reflux of this brine converts gypsum to nodular anhydrite. By stage 3 the surface brines lie in the halite saturation field (>10-11x seawater) so that halite is precipitating on the floor of the brine pool. The refluxing brine is now undersaturated with respect to gypsum so that it is dissolved in the shallow subsurface and the resulting voids are filled by

halite cements. This replacement process is thought to take place in the first few metres of burial, but like reflux dolomite has yet to be documented as more than a localised process in a Holocene gypsum deposit. As thick halite beds are tightly cemented by 100m of burial, surface-driven brine reflux and associated backreactions in ancient salt beds are most intense in the first few tens of metres of burial.

In a related paper Schreiber and Walker (1992) argue that pseudomorphous replacement of gypsum by halite at the transition between bedded sulphate and chloride documented

Figure 2.55. Salient features of the metastable gypsum-halite phase curves at 35°C (after Schreiber and Walter, 1992). A co-saturated brine, as plotted at A from 50°C when entering the 35°C environment will be out of equilibrium. Gypsum must dissolve and halite must precipitate in order to move brine A composition to equilibrium at B.

by Hovorka (op. cit.) in cyclic evaporite sequences of Permian age is an early diagenetic reflux process. But they argue it is a thermal disequilibrium process and can not be directly tied to simultaneous conversion of gypsum to anhydrite (Figure 2.55). They argue that in solar salt ponds, hot brines at halite saturation are undersaturated in gypsum and oversaturated in halite with respect to the cooler, previously accumulated gypsum substrate. This is what causes the halite to replace gypsum when suitably hot brine is in contact with the substrate. If this is the mechanism driving replacement it too would take place at or very close to the sediment brine interface.

Solar heating of the brines and production of porosity within the gypsum crystals, both of which are key features of the replacement mechanism suggested by Schreiber and Walker (1992), are materially aided by red pigments from halophylic activity (see Chapter 9). If this is the mechanism driving replacement then it cannot be related to the large-scale transition of gypsum to anhydrite (as argued by Hovorka, 1992). Diluted brines

created by the replacement of gypsum by anhydrite would corrode halite rather than precipitate it. Modern examples of a thermally driven replacement process are rare, perhaps because the appropriate brines are decanted for commercial collection of halite and are not allowed to backreact.

Can reflux really work?

Some have argued that brine reflux cannot be a geologically significant process because we do not see modern marine brines capable of displacing substantial volumes of pore waters at sufficiently rapid rates to drive brine reflux. Rather the deposition of bedded salt creates a “hydroseal” (discussed in Chapter 5). I have just stated and will argue in detail in Chapters 5 and 10, that marine-fed reflux dolomite is not a widespread process in today's marine platforms but is a significant process in ancient evaporitic settings.

Today's carbonate platforms are characterised by laterally discontinuous buildup geometries. They are a response to high-amplitude high-frequency eustatic signals of the current icehouse climate mode whereby continuous reef rims and shoals do not form. Subsealevel marine seepage inflows into an isolated platform lagoon, and consequent reflux of dense brine is impossible in the hydrologies of icehouse mode carbonate shelves. Likewise, there is no where on the world's surface today where subsealevel marine basin floors are totally isolated from the ocean, so no basinwide evaporites and reflux dolomites are accumulating in modern examples of this setting. But the viability of reflux hydrology and its ability to quickly descend into underlying strata can be seen in modern continental systems where man has interfered with natural hydrologies and created saline hydrologies in regions where there were none before. This is perhaps our best set of hydrological analogs to characterise modern counterparts of the hydrologies of ancient platform and basinwide evaporite systems.

One of the best examples comes from Owens Lake, California, where the water needs of the City of Los Angeles converted a moderately saline perennial lake (salinity $\approx 90\%$) into a hypersaline pan accumulating bedded halite and trona. Starting in 1913, the streams that fed the Owens River, which in turn fed Owens Lake, were diverted by Los Angeles Department of Water and Power to feed the Los Angeles Aqueduct. The lake level started to drop quickly and by 1924 the lake had completely dried out. Prior to this the lake was saline, but perennial.

In order to study the Quaternary history of the lake, the US Geological Survey collected a 323 m long core from the lake

(Bischoff et al., 1993). The core encompasses the last 800,000 years of basin fill and was analysed for water content, pore water salinity, sulphate and chloride values (Figure 2.56). Water content, a measure of compaction, varies erratically down the core, generally decreasing from about 60 wt % at the top to about 20 wt % at 240 m (Bischoff et al., 1993). Below 240 metres and to the bottom of the core the water content sharply increases to between 40 and 60 percent by weight. This zone is characterized by an abundance of sandy units. Salinity varies with depth in a smooth pattern, with a minimum at 30 m, gradually increasing to a single broad maximum at about 150 metres depth, and sharply declining thereafter to steady low values at 210 metres and below.

The salinity of the modern lake prior to diversion of the Owens River, was about 9% (Bischoff et al., 1993). Assuming that similarly elevated salinity characterizes previous interglacial times when Owens Lake was the terminus to the Owens river, and that fresh waters must have characterized the glacial periods of intense overflow, Bischoff et al. expect about 8 salinity oscillations during the past 800 kyr time span of the core. Such cycles are seen in the solid components of the sediments, particularly for carbonate and organic carbon content (Bischoff et al., 1993)

indicating the lake did indeed experience such climate changes. Yet the salinity-depth profile has been drastically smoothed by post-depositional diffusion of dissolved salts. This is not a hydrologically closed system.

Remnant water, a leftover from the last glacial is the likely explanation only for the first salinity minimum seen at 30-40 m depth (Bischoff et al., 1993). The smooth and gradual increase of salinity in the older sediments below this depth to a maximum at about 150 m is likely the result of diffusional smoothing of waters of older cycles. Diffusion should have had more than sufficient time, therefore, to smooth salinity gradients even lower in the core. The abrupt and erratic decrease of salinity from 150 to 210 m depth, and the erratic and generally low salinities from 210 to the bottom of the hole points to an open throughflow system for the basal pore fluids. The most likely explanation for this pattern is that deeply circulating fresher waters are actively moving through the sandy units below 200 m, diffusively harvesting solute from the overlying fine-grained sediments in the process. Thus ground water is moving at different velocities in the varying permeable sandy units. A diffusional steady state and smoothing of the salinity gradients has not been achieved. This particular depression in the Basin

Figure 2.56. Core OL-92 a 327 m core collected in Owens Lake, California. Shows depth plots of sand and water content (%), salinity (%), chloride and sulphate content (mmol) of pore waters squeezed from the core (replotted from data in Table 1 in Bischoff et al., 1993).

and Range province of the USA, is in the type region for what has been argued are “hydrologically closed” lake systems, clearly is not. It is leaking waters vertically and laterally at a rate sufficient to smooth any former climatic layering.

But what is most impressive in the lake's hydrology is what has happened in the upper 20 metres in the last 80-90 years. The pre-1900 waters of Owens Lake had a salinity less than 9%, the lake was alkaline and probably had a pH \approx 9-10. The extremely high salinity of the top 20 metres is not a reflection of the pre-1912 natural lake. Rather, it is a consequence of river diversion and almost complete desiccation of the lake basin since 1924, and the associated downward migration of dense residual-brines (Bischoff et al., 1993). As the post-1924 lake dried out, Na-carbonate minerals precipitated to form a 1 to 2 m thick salt bed now covering the lower parts of the lake depression. Residual brines from the salt bed were denser than the underlying 9% pore water and were also relatively enriched in Cl. Modern brine percolated downward by gravity displacement and ionic diffusion, so that high salinity pore waters now dominate down to about 15-20 m.

Reflux brines derived by the accumulation of 2 metres of bedded salt have penetrated some 20 m of relatively fine-grained water-saturated sediment in 80 years. The original now-displaced pore waters had a salinity up to three times that of seawater and so would have been more difficult to displace than seawater brines in an ancient carbonate platform undergoing reflux, which would have had salinities around 3-4%. Clearly once a holomictic bedded salt system has formed, associated reflux is rapid and ongoing. What is more, the total system leaks water and brine at all levels in the cored hydrology. It possesses an open hydrological base to the lake depression even though the underlying nonevaporite sediments are more than 90% clay. Reflux rules the upper portions of the hydrology, deeper artesian circulation rules the lower part of the hydrology. It is a small, but temporally impressive, example of the hydrological processes that would be active in ancient drawdown platform or basinwide evaporite settings (e.g. Figures 5.7, 5.32).

Chapter 3: Sabkhas, saline mudflats and pans

Introduction

This chapter looks at Quaternary depositional styles in ephemeral saline waters, focusing on evaporitic mudflats (sabkhas) and saline pans (Table 3.1). Until the 1960s there were no well documented modern counterparts to ancient arid zone sediments that entrained evaporite nodules or isolated euhedral crystals floating in a nonevaporite matrix. Then nodular anhydrite was discovered in the mudflats of the saline coastal plain of the southern Arabian Gulf, centred on Abu Dhabi. Models of this saline mudflat setting, now widely known as the Abu Dhabi sabkha, began to be published. For the next 10-15 years the supratidal sabkha model came to dominate depositional interpretations of most ancient nodular sulphates. By the early 1980s subaqueous alternatives for widespread units of calcium sulphate salts had been documented in a number of small-scale Holocene marine-fed salinas. At the same time the concept of what is a sabkha had been expanded to encompass both continental and marine saline mudflats, with continental examples typically located next to ephemeral saline pans.

Ancient sabkhas are typically dominated by matrix, with capillary salts occupying less than 30-50% of a stack of m-scale erosion-capped beds. Saline pans accumulate as metre-scale

stacked masses of salt crusts overprinted by karst and capillary cements. Subaqueous sequences tend to be purer and thicker with far fewer exposure surfaces. Chapter 4 looks at Quaternary examples of subaqueous beds accumulating beneath perennial saline waters (salinas and saline lakes), while Chapter 5 compares models based on Quaternary systems with much larger and thicker ancient evaporites and attempts to answer the question, "Is the present the key to the past?"

What is a Sabkha?

Sabkha is an Arabic word for a salt flat. In the local terminology of the Arabian Gulf region it describes extensive, barren, salt-encrusted, and periodically flooded, coastal and inland mudflats. Geological usage implies intrasediment evaporite growth beneath a flat geomorphic surface with an elevation dictated by the top of the capillary fringe (Warren and Kendall, 1985). Modern sabkhas in the Arabian Gulf (sabkhat is the correct form of the Arabic plural) are occasionally covered by ephemeral marine and continental floodwaters that until recently were thought to be the major suppliers of ions to salts growing displacively in the sabkha matrix. We know now that this is not the case and that deeply circulated resurging continental

Sea-margin saline mudflat (sabkha) with carbonate matrix	Sea-margin mudflat (sabkha) with siliciclastic matrix	Lacustrine mudflat (sabkha) and saline pan - siliciclastic matrix
Abu Dhabi sabkhas, coastal plain of the United Arab Emirates (eolianite, beach ridges and interdunal)	Kadmah Bay Coast, Kuwait, Arabian Gulf (alluvial fan/sand flat/delta)	Salar di Uyuni, Bolivia (ephemeral lacustrine)
Al-Khiran sabkha, Kuwait (beach ridges)	Shatt al Arab, transitional mudflats, Arabian Gulf (delta/estuarine)	Lakes Eyre, Frome, Torrens and Callabonna, South Australia (ephemeral lacustrine and interdunal)
Tidal mudflats at the head of Gulf St Vincent and Spencers Gulf, South Australia (beach ridge and interdunal)	Sabkhas of the Sulaymaniya lagoon, Red Sea coast, Saudi Arabia (beach-ridge and estuarine)	Bristol Dry Lake, Deep Spring Lake and Saline Valley, Basin and Range, California (ephemeral lacustrine)
Tidal mudflats at the southern end of Shark Bay, Western Australia, as well as in nearby interdunal corridors locally known as "boinkas" (eolianite, beach ridges and interdunal)	El Qaa sabkhas, Gulf of Suez, (coastal plain/beach ridges)	Salt Flat Playa, west Texas, USA (ephemeral lacustrine)
	Bitter Lakes, sabkhas, Nile Delta, Egypt (eolianite interdunal corridors)	Sabkha Yotvata, Israel (ephemeral lacustrine)
	Laguna Madre mudflats, Texas (sandflat-barrier coast)	Sabkhas near Dharhan, Saudi Arabia (interdunal) and coastal sabkhas near Half Moon Bay
	Guerrero Negro area, Baja California, Mexico (interdunal)	Ranns of Kutch (eolian and deflation flats)

Table 3.1. Occurrences of Quaternary evaporitic mudflats (sabkhas) and saline pans, parentheses indicative of the origin of dominant matrix hosting the salts. These examples are discussed in detail in this chapter.

Figure 3.1. Sabkha classification using depositional setting of the matrix material (modified from Handford, 1981).

groundwater is the major supplier of salts to the sabkha. The mudflat surface is dry and subaerial for most of the time. It is held in place by capillary moisture, fed from a shallow saline water table lying a few centimetres to a metre or two below the sediment surface.

The first sedimentological studies of sabkhas were in the Arabian (Persian) Gulf (e.g. Curtis et al., 1963), but similar sediments were soon described along the coast of Baja California, Mexico (Phleger, 1969; Shearman, 1970), the coast of Sinai (Gavish, 1974; Levy, 1977a, b), and in various continental playas worldwide (Moiola, 1965; Surdam and Wolfbauer, 1975).

Occasionally, the term sabkha is used in a narrow sense to describe anhydritic mudflat sediments deposited in a marine coastal or sea-margin sabkha, exemplified by the Arabian Gulf coastal sabkha. But when sabkha is used to imply “salt flat,” it should include both coastal and continental sabkhas and encompass displacive growth of other intrasediment capillary salts like halite or glauberite as well as calcium sulphate. Some coastal sabkhas, such as those along the At Taf coastal strip (formerly known as the Trucial Coast), pass laterally in to continental sabkhas (e.g. Sabkha Matti) without any noticeable change in surface morphology (Kinsman, 1969; Goodall

et al., 2000). The seaward side of a modern coastal sabkha is characterized by a matrix of marine sediments, while the continental portion is characterised by nonmarine sediments and continental groundwaters.

Sometimes, the term playa is used as a geological equivalent to continental sabkha. But, as used in the southwest USA, playa is a much wider ranging descriptor than sabkha. In addition to the salt-crustured evaporitic mudflat (sabkha) a playa encompasses other related settings including, distal alluvial fans, sand flats, saline pans and dune fields. Continental sabkhas may also be encompassed in local usage of other wider ranging terms such as vloer/pan (southern Africa), salt lake (Australia), nor (Mongolia), takir (Russia), kavir (Iran), salar (Chile) and alkali flat/salada/dry lake/playa (southwest USA). Terms in local usage may not necessarily identify geomorphologically and geologically identical features. Even the original usage of the term playa does not mean salt flat, rather its Spanish usage covers the terms beach, shore, strand or coast. Its usage first came across into English to describe abandoned beaches or strandlines that can be seen on the margins of many inland salt lakes and saline pans. Using sabkha and playa interchangeably is very poor usage of what is already a poorly defined set of terms (see Briere, 2000).

In an attempt to clarify the geological usage of the term sabkha so it can be more easily applied to a particular vertical sequence in ancient evaporitic sediments, I define sabkha as a groundwater driven sedimentary system indicated by syndepositional intrasediment capillary evaporites, which precipitate in both marine and continental saline mudflats (Warren and Kendall, 1985; Warren, 1989). The hydrology of precipitation, via capillary evaporation, is the same in both marine and continental settings. Even so, the matrix typically shows evidence of its marine or continental pedigree, as can the hydrogeochemistry of the pore waters. In other words, sabkhas are hydrological settings where resurging groundwaters form displacive and replacive evaporite

minerals (gypsum, anhydrite, halite, polyhalite, glauberite, etc.) in the capillary fringe above a saline water table or in the brine-saturated muds immediately below. The whole capillary sequence is typically made up of more than 50% non-evaporite matrix and is capped by an erosion surface or Stokes surface (Warren and Kendall, 1985). The advantage of this definition is its utility in subsurface studies of ancient sediments where it can be applied using sedimentary textures in a single core; the surrounding depositional sequence does not need to be interpreted. The common thread is the growth of intrasediment salts in the capillary zone and in brine-saturated phreatic muds immediately below the water table, with the whole succession capped by a syndepositional erosion surface (Stokes surface). Sabkha hydrology controls the thickness of an evaporite unit, the style of intrasediment crystal (euhedral outlines to nodules) and most importantly generates the characteristic erosional or hydraulic “jack-up” surface that caps a sabkha cycle.

The host matrix in which sabkha salts grow by capillary evaporation is the sedimentological basis of most sabkha classification, (Figure 3.1: Handford, 1981; Warren 1991). Matrix in modern and ancient sabkhas is deposited as:

- Marine coastal
- Fluvio-lacustrine
- Eolian

Sabkha salts are mostly gypsum or halite and less often anhydrite, or even more unusual salts such as trona, borax or glauberite. Dominance of one of the matrix associations gives rise to sea-margin, continental, or eolian sabkhas. An eolian sabkha can be a subset of both sea-margin and continental sabkhas.

Marine coastal sabkhas

Modern sea-margin sabkhas form as narrow belts along many coastal arid to semi-arid deserts including; the western and southern coasts of the Arabian Gulf, the coast of western and southern Australia, Northern Africa, and the Sinai (Table 3.1). The most complete documentation of modern carbonate sabkhat centres on the southern coast of the Arabian Gulf (Persian Gulf) in the emirate of Abu Dhabi, while siliciclastic sabkhas typify the Saudi Arabian coast between Qatar and Kuwait, and fluvio-deltaic coastal sabkhas are forming atop the Shatt al Arab delta at the northwestern end of the Gulf. Elevated pore water salinities along the coasts of the Arabian Gulf (aka Persian Gulf), reflect a combination of frequent winds (mostly blowing from between 315° and 15°), high temperatures (up

to 45 to 50°C), low precipitation (typically less than 5 cm a year), low fluvial input (except for the Tigris, Euphrates and Karun rivers in the extreme north of the Gulf) and the restricted silled connection via the Strait of Hormuz between the saline waters of the Arabian Gulf and the normal salinity waters of the Gulf of Oman and the Indian Ocean.

Physiographically, the Arabian Gulf is an almost enclosed subrectangular basin that trends in a northwest-southeast direction, it is approximately 850 km in length with a maximum width of 330 km (Figure 3.2a; Wyn-Hughes, 1997; Evans, 1995). The basin floor is markedly asymmetrical, forming a ramp that dips gently (35 cm per km) away from the tectonically stable Arabian side (typical depths of 20 to 40 m), and more steeply (175 cm per km) away from the tectonically active Iranian side (depths of 40 to nearly 100 m). The greatest water depth (100 m) is reached near the entrance to the Gulf at the Straits of Hormuz (Purser and Seibold, 1973).

In terms of its regional tectonic setting, the Arabian Gulf is an epicontinental sea within a foreland basin, located between the geologically stable, low-lying, Precambrian Arabian Shield and the high, geologically unstable Tertiary fold belt of the Zagros Mountains of Iran. The fold belt is a compressional suture, active since the Early Miocene along the Zagros Thrust Zone and driven by the subduction of the Arabian Plate beneath the Eurasian Plate (Wyn Hughes, 1997). The Gulf's bathymetric asymmetry comes from Pliocene to Quaternary tectonic loading on the Iranian side, and tilting of the Arabian Peninsula in the Neogene, during the opening of the Red Sea. The southeastern part of the Arabian Gulf is a very gently sloping ramp. The Qatar Peninsula forms a distinct feature on the near-linear Arabian coastline, and causes anomalous trends in current direction, and possibly of sedimentation, along the southeastern Gulf.

Ramp carbonates, including sabkhas, define the coast along much of the cratonic southern side of the Gulf, while the northern coast is dominated by more steeply dipping siliciclastic alluvial aprons passing landward and northward into the Zagros Mountains. Moving south from the deepest Gulf floor, the bottom changes from deepwater micrites through grainstones and reefs of the Great Pearl Bank into reworked dune and eolianite barrier shorelines into the coastal carbonate sabkhat (the shorelines of the Emirates, Qatar and Saudi Arabia). Entry of siliciclastic sediment to the present Arabian Gulf is mostly longitudinal via the Shatt Al Arab delta at the northwestern end of the Gulf. The Shatt Al Arab is the confluence of the Tigris, the Euphrates and the Karun rivers. It has constructed a huge wedge of fluvio-deltaic sediments, with thin patchy sabkha capstones landward of

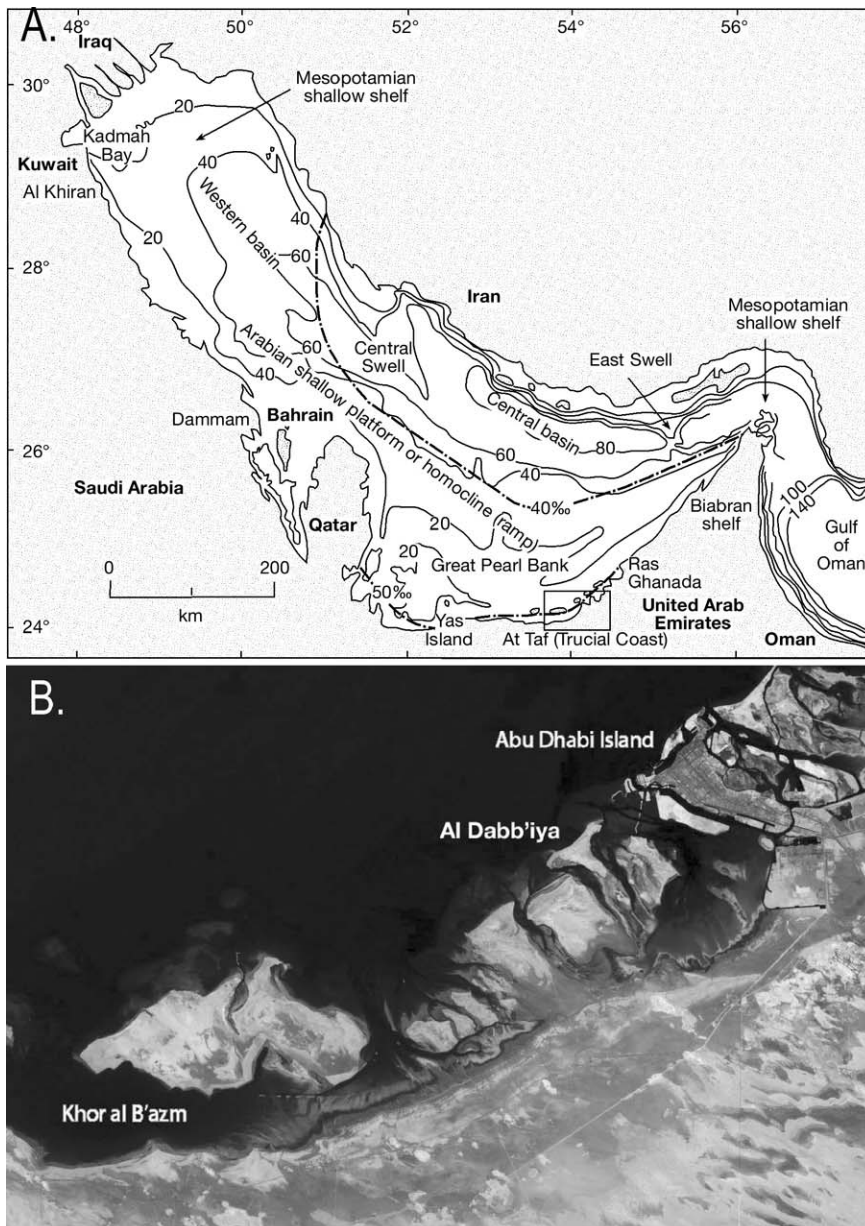

Figure 3.2. Sabkhas of the Arabian (Persian) Gulf. A) Physiography (m) and salinity (‰) in the Arabian Gulf (after Purser, 1973a; Evans, 1995, Wyn Hughes, 1997). B) General sediment distribution of the Trucial Coast of the United Arab Emirates from the entrance to the Khor al B'azm Lagoon to Abu Dhabi Island, showing the shallow water areas of the lagoon and the oolitic ebb-tidal deltas on the seaward side of the tidal channels between the islands (see Figure 3.4). The intertidal zone, defined by intertidal algal mats, is clearly visible as zones of dark-coloured sediment. Landward of the intertidal zone is the supratidal zone of the sabkha, which in turn passes into dune sands across the mesa that defines the erosional edge of the Miocene plateau (Landsat image courtesy of NASA).

the shoreline (coasts of Iraq and Kuwait). Siliciclastics enter also from wadis along the northeastern side of the Gulf and from encroaching dunes along parts of the Saudi coast. Eolian

transport is driven by the north-westerly Shamal winds (*shamal* is Arabic for north) and carries both siliciclastic and carbonate fines well out into gulf waters. In the Late Pleistocene much of the Arabian Gulf floor was covered by active seif dunes. Interestingly, detrital dolomite rhombs make up around 15% of the non-clay component of modern bottom sediments in the northern Arabian Gulf and up to 60% of the 30-125 μm fraction (Al Bakri et al., 1984). Morphologically they are near identical to much of the authigenic sabkha dolomite rhombs that first caused so much interest in sabkhas in the Emirates in the 1960s.

Geologically the Arabian Gulf is unique as it is the only modern example of a modern shallow inland sea in which widespread ramp carbonates are accumulating. This is attributed to its low latitudinal position and relatively clear waters, the result of low terrigenous input, making much of the seafloor suitable to a tropical carbonate-secreting biota (Wyn-Hughes, 1997). The depth of the euphotic zone is around 20 m in turbid waters above the muddy sediments along the Abu Dhabi coastline, but increases to 30 m in the clearer deeper waters in the axial parts of the seaway.

Although it is a marine carbonate system today, 20 ka when sealevel was 120 m below its present level, the whole Gulf was a desiccated basin with active eolian dunes covering much of what is the present seafloor. The Pleistocene-Holocene (Flandrian) transgression covered and reworked much of this dune sand as the gulf waters returned

to the present coastline some 7-10 ka. Much of the Holocene marine carbonate section in the southern Gulf is now underlain by these eolian siliciclastics.

Carbonate-hosted coastal sabkhas in the southern Arabian Gulf

The Arabian Gulf sabkha, centred on Abu Dhabi city, is the eastern part of a sabkha belt known as Sabkhat al Salamiyah that extends along the coast of the United Arab Emirates between Yas Island and Ras Ghanada (Figures 3.2b, 3.3). Further west, adjoining the eastern base of the Qatar peninsula is Sabkha Matti, one of the largest tectonically-induced sabkha depressions in the region (see eolian sabkhas). The sabkha-dominated At Taf coastal strip is approximately 320 km (200 miles) long and the coastal sabkha belt is up to 24 km (15 miles) wide; on average it has prograded 1.5 km (1 mile) every 1000 years. Seaward slopes on the sabkha are low and range from 1:3,000 to 1:4,000, this means whenever water a few centimetres deep arrives on the sabkha, the strandline on the brine sheet will have migrated kilometres.

It was the occurrence of modern nodular anhydrite and dolomite in the sabkhas of Abu Dhabi and Qatar that first attracted the attention of the geological community during the 1960s. The work of Curtis et al. (1963), Illing et al. (1965), Evans et al. (1969), Kinsman (1969), Shearman (1963), Butler (1966, 1969, 1970), and Kendall and Skipwith (1969a, b) provided observational data on which most of our current sabkha models are based. Fieldwork since the 1960s tended to consider specific sedimentological problems within the sabkha setting, such as hydrological zonation (Patterson, 1972; Hsu and Schneider, 1973; McKenzie et al. 1980; Patterson and Kinsman, 1981), the origin of dolomite (McKenzie, 1981; Patterson and Kinsman, 1982), or it has reinforced the facies model of earlier workers (Bush, 1973; Butler et al. 1982; Kendall and Warren, 1988). Excellent recent reviews of this literature and some new insights are given in review papers by Alsharhan and Kendall (2003), Kirkham (1997) and Evans (1995). The most recent addition to this substantial knowledge base is a drastic revision of our understanding of the dynamics of sabkha hydrology by Wood et al. 2002. It changes our understanding of evaporite capillary salts from one of marine-derived floodwaters to one of solutes precipitated in a Holocene marine matrix, but sourced from resurging basinal waters.

To understand sabkha deposition requires an understanding of the climatic and hydrological factors that create conditions suit-

able for sabkha progradation into the southern Gulf. The Arabian Gulf is the warmest sea in the world; in the open Gulf the surface temperatures range from 20°C in February to 34°C in August, with an annual average around 29°C in waters located offshore from Abu Dhabi. Water temperatures on the open platform in the vicinity of Abu Dhabi Island range from 23° to 34°C and from 15° to 40°C in the inner lagoon. Shallow waters in the lagoon can experience daily changes of 10°C. Air temperatures on the adjacent mudflat can be as low as 5°C in the winter and as high as 50°C in summer, with average temperatures ranging from 23° to 33°C. Sediment surface temperatures on the sabkha are even more variable, with reported values up to 60° to 80°C atop dark-coloured microbial mats (Kinsman, 1965). Temperatures a few centimetres below the sabkha surface range from 22° to 40°C. In summer, the sabkha is extremely humid, especially at night, when the humidity reaches 100%. Salinities in the open Gulf are 3 to 4‰ above normal open marine salinities. Where coastal islands restrict exchange with the open Gulf, as in the vicinity of Abu Dhabi Island, lagoon salinities range between 54 and 67‰, near double that of the open ocean.

Evaporation levels on mudflats along the southern coast of the Arabian Gulf are influenced by prevailing onshore winds. In winter the intensity of the onshore winds increases as the Shamal blows seawater and sediment from the lagoon onto the mudflat. At other times offshore winds blow continental dune sand into the back side of the sabkha. Thus the sabkha is furnished with matrix sediment from two sources, carbonates from the lagoon and siliciclastics from the hinterland. Many earlier sabkha models tended to ignore the eolian input, yet some areas of the mainland side of the Abu Dhabi sabkha (e.g. Al Du'yybaya sabkha) have quartz silt and sand as the major matrix material and it is the dominant aquifer supplying water to the coastal plain. Rainfall along the sabkha coast averages 70 mm/year and is very irregular, in some years no rainfall is recorded. In the 6-year period from 1958 to 1964 the highest annual reading on the sabkha was 6.73 cm, the lowest 0.33 cm. When rain does fall it can be torrential. Bottomley (1996) notes that in the last 30 years there was at least one 24 hours period when more than 200 mm of rain fell on the sabkha. Although infrequent, such desert rains can be torrential, especially in coastal sabkhas near the foot of the Oman Mountains, such as at Rams, where flooded wadis typically carry continental sediments as sheet floods many kilometres into the sabkha (Warren, 1991). Rain floodwaters can sometimes cover portions of the sabkha for one to three months and so dissolve and recycle surface and nearsurface halite/bittern crusts, as occurred in late 2003.

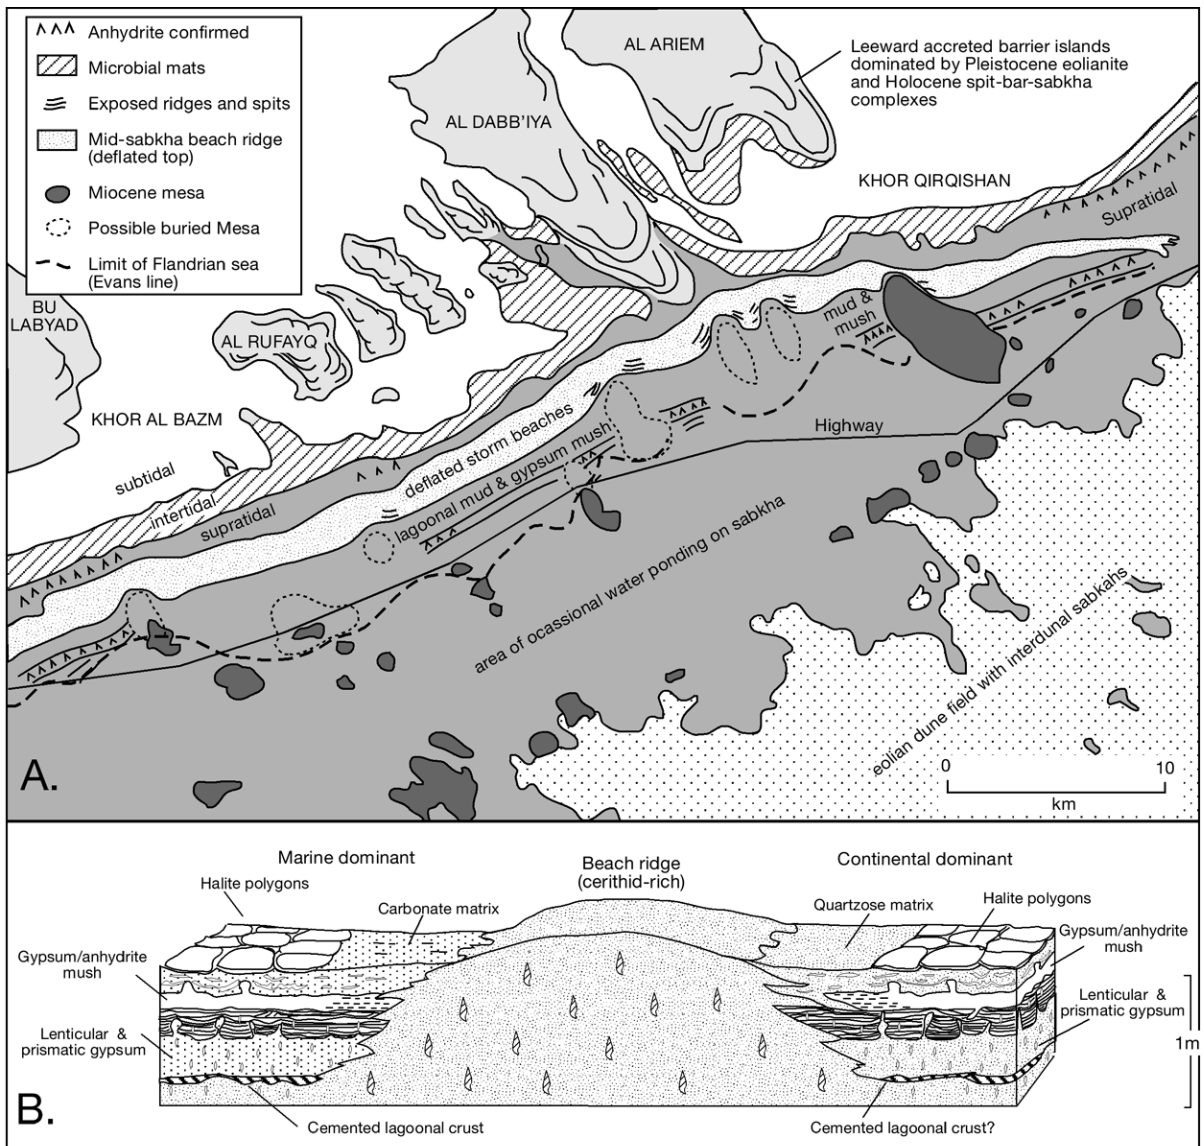

Figure 3.3. Abu Dhabi sabkha. A) Sabkha facies located to the west of Abu Dhabi showing beach ridges encased in sabkha sediment in the vicinity of Bu Labyad - Al Du'yybaya (after Kirkham, 1997). B) Sabkha cross section based on facies present in the vicinity of the beach ridges south of Al Du'yybaya Peninsula and the Mussafah Channel wall (after Warren and Kendall, 1985).

Physiographically, the Abu Dhabi sabkha is characterized by billiard table flatness, a direct reflection of its control by capillary wicking fed from the underlying water table. The sabkha surface is a Stokes surface (Figure 3.4a). In general, the water table control to any sabkha gives them one of the flattest forms of any arid landscape feature. Below this flat surface the Abu Dhabi sabkha preserves an evaporitic mixed-carbonate-siliciclastic stratigraphy (Evans et al., 1969; Kinsman, 1969; Kirkham, 1997). Deposition began some 7,000 years ago when

a rapid transgression flooded interdunal (eolianite) depressions with a veneer of marine-reworked, predominantly quartzose sediments. About 4,000 years ago the Arabian Gulf shoreline reached its maximum Holocene strandline and the edge of this flooding event is defined by a line of well preserved beach-ridge sediment sometimes called the “Evans line.” This was followed by pulsed progradation of the sabkha sequence to its present configuration.

Abu Dhabi facies associations

The peritidal belt that defines the Abu Dhabi sabkha is divided into three: subtidal, intertidal, and supratidal (Figure 3.3a). Tidal range is 2-2.5 m along the seaward side of the islands of the southern Gulf, but it can be as little as 1 m in the more restricted lagoonal areas, which are locally known as khors. As the strandzone progrades, the peritidal belts of the lagoon, cyanobacterial mat and sabkha, all located landward of the present barrier island belt, are stacked one atop the other to create an archetypal shallowing-upward sabkha cycle. We will discuss each peritidal belt in detail, but first let's look at a largely ignored part of the southern Arabian Gulf peritidal trilogy, the island shoal and bank facies. This is the unit that protects the muddy coastal lagoons in the vicinity of Abu Dhabi and allows the various carbonate sabkhas to form. Facies belts basinward of the island shoal are classic carbonate ramp sediments, while peritidal sediments landward of the island shoal make up the sabkha association.

Island shoal and bank facies

Cemented coastal-beach-dune barriers form the core of a belt of northeast trending carbonate islands that are the easternmost extent of the "Great Pearl Bank" (Wyn Hughes, 1997). These barriers enclose lagoons or tidal estuarine sequences and in places may directly abut the mainland (Warren, 1991). Most of the islands are eolianite-cored shoals, composed of varying proportions of Holocene and Pleistocene ooids, along with skeletal and quartz sands. Island cores are stationary, fixed in place by carbonate cements, and are separated by active tidal channels up to several kilometres wide and 7 to 10 metres deep (Figure 3.2b, 3.3a; Purser and Evans, 1973; Loreau and Purser, 1973). Further up the coast on the Qatar Peninsula and along parts of the Saudi coast their place is taken by marine-reworked quartzose eolian dune sand shoals, which still have counterparts building directly into the Gulf (see eolian sabkhas for details). The coastal barriers and spits along the At Taf coastal strip, which form the depositional frame for the Holocene sabkha, formed in the late Pleistocene via carbonate accretion atop reworked eolian quartzarenites as the desert dunes were inundated during the final phase of Flandrian rise (Purser and Evans, 1973; Kirkham, 1998). Up to 9 m of Pleistocene eolian material and 2.7 m of Holocene carbonates overlie Miocene marine carbonates in the vicinity of Abu Dhabi city (Butler et al., 1982). Miocene strata also form mesas and outliers on the landward side of the sabkha (Figure 3.3a).

Holocene vadose and phreatic cements stabilised the transgressive island shoals at the position of the Pleistocene-Holocene stillstand. Previously, the coastal dune/shoreface had migrated

landward in front of the rising late Pleistocene sea. The early Holocene stillstand, in combination with cementation meant the islands evolved into wave-resistive structures fronted by coralgal reefs. This in turn preserved a barrier lagoon, even in the early Holocene when wave-resistive reefs had yet to grow on the seaward side of the now stationary barrier islands. Cemented sands formed a stable substrate for subsequent coralgal reefs and today maintain a relatively fixed focusing grid for wave, longshore and tidal currents.

Island stability in turn maintains the position of numerous active tidal channels as fixed breaches in the cemented eolianite topography. Tidal channels between the islands allow exchange of seawater with the more saline waters of the inner lagoon. The longterm stability of the island shoal facies explains the formation of thick ooid ebb-tidal delta sands on the seaward ends of many channels along the Abu Dhabi coast. Where these ooid sands accumulate above sealevel they are blown into Holocene coastal eolianites, adding volume to the island shoal sediment pile (Figure 3.2). If the islands were not cemented stationary structures, then tidal channels and islands would migrate laterally, ebb sands would spread out as much thinner accumulations and form barrier geometries more akin to classic "drumstick" tidal deltas in mesotidal barrier coasts.

Subtidal Facies

Subtidal sedimentation along the Abu Dhabi coastline can be divided into sediments accumulating seaward of the island shoal facies and sediments in the lagoon (Evans 1995):

1. *Open marine sedimentation* occurs along the seaward side of the northeast trending barrier island coast and has largely buried the underlying Pleistocene eolianites and seif dunes (Figure 3.2). Seaward terminations of shallow channels draining the lagoon are flanked by tidal ebb deltas composed of oolitic sand. These Holocene lobes form lens-shaped bodies 2 to 10 km wide and 1 to 5 m thick. They occur in wave- and tide-agitated areas where ooids are piled into shoals by opposing onshore waves and offshore ebb-tidal currents. The ooid sands (ooid grainstones) are fashioned into various bedforms including break point bars, along with large and small-scale ripples. Skeletal fragments in the shoals indicate a limited macrofauna of molluscs, echinoids and burrowing crustaceans. Broken fragments of this fauna typically form the core or nuclei to ooids.

Within the sand pile the ooid grain size and cortex thickness decreases away from the channel levees. Cemented crusts (aragonite and Mg-calcite) and crust fragments can also be found in the sand pile, much in the same way they occur in

Figure 3.4. Arabian Gulf sabkha, Abu Dhabi. (A) Sabkha surface covered in an ephemeral halite crust; (B) Lagoonal sediments of Khor Al B'azm showing peloidal grainstones and packstones with growing clumps of brown algae covered with calcareous epibionts (photo courtesy of Xris Kendall); (C) Cusped, laterally accreting beach ridge on seaward side of Al Du'yybaya sabkha, Abu Dhabi; (D) Truncated and grazed edge of laminated polygonal mat at the edge of a tidal pool, southern Khor Al B'azm; (E) Core of laminated mat with displacive euhedral gypsum and an overlying unit of supratidal gypsum and anhydrite, sabkha south east of Abu Dhabi City (scale bar = 5 cm); (F) Core of cyanobacterial peat (?pustular mat) with lenticular gypsum and an overlying unit of supratidal gypsum and anhydrite, sabkha south east of Abu Dhabi City (scale bar = 5 cm); (G) Nodular and enterolithic anhydrite with obvious truncation surface preserved in middle of unit, Al Du'yybaya sabkha.

the less active portions of Bahamian ooid shoals. At a water depth of about 2 m on the spillover front of the Abu Dhabi ooid shoals there is an abrupt change into mixed ooid-bioclastic grainstones/packstones. Storms and the wind drive ooid sands onto the island shoal belt and so continue to supply sediment to the barrier islands. High eolian dunes form where active ebb tidal deltas are building out onto the cemented island core. Bedding in these parabolic dunes is inclined landward and retains continental indicators such as occasional rhizoconcretions and insect burrows.

Patchreefs are growing immediately seaward of the Pleistocene-cored islands (island shoal facies) in areas between the ooid shoals. Reefs also extend landward along the sides of some of the more stable open-marine tidal channels, but do not extend far into the more restricted sections of the lagoon. There the waters quickly become too saline for the reef to remain healthy (Kinsman, 1969) and are subject to intense temperature and salinity variations during Shamal storms (Figure 3.5; Riegl, 2003). Shinn (1976) attributed massive coral die-back in the southern Gulf (Qatar) to a severe Shamal, which caused cooling to 4°C at sea surface and to 14.1°C at 18 m depth. Shamals may generate storm seas of up to 6 m wave height (65 kph winds), driving erosion, turbidity and complete vertical mixing of lagoon waters and partial mixing offshore. Clearly, rapid cooling by Shamals, sometimes coupled with extremely low tides, amplified by negative storm surge, are a significant stress factor causing repeated coral mortality and bleaching throughout the southern Arabian Gulf (Riegl, 2003).

When compared to the reefs of the open Indian Ocean, the coral fauna, even on the open marine side of the islands of the Emirates, is somewhat sparse and restricted. It is dominated by genera of *Porites* and *Acropora* with *Platygyra*, *Cyphastrea*, and *Stylophora* calcareous and binders dominated by coralline algae (*Lithothamnion*, *Lithophyllum*, and *Goniolithon*). The reduced reef biota is a response to temperature and salinity stresses inherent to the restricted waters of the Arabian Gulf. Salinity and turbidity oscillations mean many of the corals growing along the sides of tidal channels feeding the lagoons appear unhealthy and at times are covered by flourishing coats of green algae. Like corals, echinoids die out in the lagoons

Figure 3.5. Schematic of hydrodynamics in the near offshore and lagoon/sabkha of the southern Arabian Gulf (after Riegl, 2003).

although asteroids, and more particularly ophiroids, extend much further into the lagoons or khors.

Seaward of the islands is a broad gently sloping Holocene platform covered by skeletal sands, which pass offshore into progressively deeper and finer-grained carbonate silts and muds of the Gulf centre. This sloping profile is one of our better modern analogues for ancient carbonate ramps (Evans 1995), while the Great Pearl Bank makes an excellent Holocene analog for Cretaceous rudistid buildups (Wyn Hughes, 1997).

2. *Restricted marine (khor) sedimentation* takes place along the landward side of the barrier islands in areas dominated by lagoon and sabkha sediments (Figure 3.4b). The tidal inlets and khors (*khawrs*) are unique subtidal settings formed behind the grainstones of the island shoals and constitute the protected seaward edge of many sabkhas. They vary in shape and size from large elongate lagoons such as Khor al B'azm and Khor al Baghi (behind Abu Dhabi Island) to the estuarine inlets of Umm Al Qwayn (Warren 1991). Many are dendritic in outline, but lack any permanent surface freshwater inflow (Warren, 1991), except for those khors located close to the mountains near the Straits of Hormuz, which can be periodically flushed by meteoric runoff. Today many khors in the Emirates are dredged to form accessible waterways and sheltered harbours. Some deepened channels can now accommodate large dhows and other seagoing vessels, whereas undredged natural tidal channels into the khors are typically less than a metre or two in depth, even at high water.

Tidally scoured lagoonal channels join the open-marine settings to the restricted-marine lagoons or khors. Channels are floored with skeletal and peloidal sands, which are reworked by tidal and wave action into crossbedded skeletal/peloidal grainstones. Toward their inner parts, in the lagoon proper, the channel floor sediments become sandy muds (peloidal/skeletal packstones and wackestones). Wherever they poke through a thin lag of

coarse shell and intraclasts, cemented calcareous eolian sands (eolianite) sometimes crop out on the channels floors.

Extensive shallow-water lagoons, filling with bioturbated packstones and wackestones, occupy the shallower parts of the khors away from the channels. Because of their higher elevation relative to the lagoonal channel floors, subaqueous areas of khor away from the channel are sometimes described as lagoonal terraces. Terrace sediments entrain a diverse biota made up of many benthic species but relatively few phyla (Kendall and Skipwith, 1968b). Molluscan sands and peneroplid foraminifera dominate the more open terrace areas, whereas pelleted carbonate mudstones with a sparse fauna accumulate in the more protected reaches. Cyanobacterial grain coats and biofilms are abundant on the lower-energy terrace sediments and encourage healthy populations of cerithid gastropods, which through their grazing contribute a large proportion of the pellets in the lagoon. Terrace sediments are also heavily burrowed by crustaceans and worms. The somewhat elevated temperatures and salinities on the lagoon floor drive seafloor cementation of these ubiquitous pellets. In the more marine parts of the terraces various sea grasses and seaweeds (brown algae) form dense carpets on the channel floors, along with healthy epiphyton coats of bryozoans and calcareous algae (Figure 3.4b). There are four species of seagrass in more open marine parts of the khors and further offshore: *Halodule uninervis*, *Halophila stipulacea*, *H. ovalis* and *Syringodium isoetifolium*. *Halodule uninervis* is undoubtedly the dominant species of seagrass in the southern Gulf and is the major food-plant taken by herds of grazing dugongs in the UAE.

Isopachous crystalline rinds and micrite crusts, composed of aragonite and Mg-calcite, bind large areas of the lagoon terraces into cemented layers. Ongoing expansion of the layers creates dm-scale tepee structures, which can also be traced upslope into the base of the intertidal zone (Kendall and Warren, 1987). Tepee-overprinted ridges on the lagoon floor create a stable substrate or holdfast for much of the larger epiflora as well as a healthy population of borers. Seaweeds tend to attach themselves to tepee ridges in preference to the less stable muddy bottom veneer that forms the lagoon bottom away from the tepee crest.

Intertidal facies (strandline sands)

Waves can drive loose terrace sediments shoreward to build narrow sandy beaches and berms of peloidal and skeletal grainstone, typically with landward-directed cross stratification (Figure 3.2a, b, 3.4c, 3.6a; Evans, 1995; Warren and

Kendall, 1985). Cerithid gastropods, which populate the more landward parts of most khors, are a major skeletal component of the ridge sands, as are bivalve fragments and benthic forams. In areas more exposed to wave action the beach ridge sediments are coarser, ranging from coarse sands to skeletal gravels (rudstones). Locally, low-relief tidal levees and ridges enclose mangrove swamps where sediments tend to be highly bioturbated muds crosscut by rhizophores. More typically, the narrow beach ridges in a sabkha coast are transitional into the cyanobacterial-dominated intertidal sediments that typify much of the intertidal zone of the inner lagoon (Figure 3.3a).

I have trenched and cored buried equivalents of these beach ridges within various parts the Abu Dhabi supratidal sabkha succession, they are most obvious in the sabkha to the south and west of the Al Du'yybaya peninsular (Figure 3.3b). They have not been well documented as a facies within the Abu Dhabi sabkha as the tops of older ridges landward of the modern strandline are typically deflated and buried beneath a halite crust (Figure 3.6a). Southeast of Khor al B'azm a line of deflated beach ridges lies behind the currently active area of sabkha sedimentation. It is some 3-4 km inland of the present edge of the lagoon and forms the seaward edge of a 10 km wide belt of older Holocene sabkha sediments (Figure 3.3). Remnants of an older sequence of beach ridges define the maximum extent of the Flandrian (Holocene) transgression (aka the "Evans Line"), the initiation of the seaward progradation of the Holocene sabkha coastline and the occurrence of supratidal CaSO₄ facies. Portions of this system are now buried beneath lagoonal muds. The contact between more oxidised beach-ridge pore waters and the reducing waters of the lagoon muds is defined by an iron-stained band of lenticular and prismatic gypsum (Figure 3.6a).

The presence of Holocene beach ridges along the coast on the seaward side of the present day sabkha supratidal, the presence of older largely buried and deflated Holocene beach ridges in the mid sabkha, and the relicts of early Holocene ridges defining the most landward extent of the Flandrian transgression clearly show Holocene sabkha progradation is not a simple seaward progression of peritidal facies. It is a punctuated and possibly forced regression (Warren and Kendall, 1985; Warren, 1991; Kirkham, 1997). Similar beach ridges within Holocene sabkhas are described from the northern Emirates by Al-Farraj (2005), from Kuwait by Picha (1978) and from northeast Qatar by Shinn (1973).

Figure 3.6. Styles of CaSO_4 occurrence exposed in the Mussafah Channel, Abu Dhabi: The trench is actually the wall of a man-made shipping canal cut into the sabkha near the Mussafah Industrial Area. The locality is over 7 kilometers landward of the present-day restricted lagoon and 25 kilometers from the open Arabian Gulf waters. A) Buried beach ridge gastropod rudstone showing landward-directed storm cross bedding and gypsum at the contact with overlying mud (inset shows detail of cross bedding). B) Buried algal mat (dark blebs) overlain by ridge and lagoon sediment, with lenticular gypsum growing in the overlying lagoonal muds. Site is located about 50 m seaward of ridge in 3.6a. C) Enterolithic anhydrite in the supratidal sabkha which is a lateral equivalent of gypsum in 3.6b, the site is located around 200 m northwest of the gypsum in 3.6b. Scale bar is 10 cm long.

Intertidal Facies (Lagoon-edge muds)

Away from the active beach ridges, the intertidal zone is divided into upper and lower intertidal facies, although the lower intertidal facies of some workers is equivalent to the lagoonal terrace facies of others. The confusion stems from the presence of a wide cemented flat along the mainland shore of the various khors; a flat that is covered by rippled peloidal sands or muddy sands (peloidal grainstones and packstones) and hosts a dense population of cerithid gastropods. Some authors place this flat in the shallow subtidal as an extension of the lagoonal terrace, while others place it in the lowermost intertidal. The lack of firm definition of its distribution is due to the flat, shallow nature of the southern Gulf. This means minor variations in wind direction, speed and the barometric

pressure can cause the predicted tides in the khors to remain either “out” or to advance several kilometres further “in” than predicted. Longer term seasonal variations follow a more defined if unusual pattern, with inundation of many otherwise “supratidal” areas, that is large areas of sabkha flat, not occurring until late autumn (post-equinox). Hence, the lateral extent (strandzone) of the intertidal area of sedimentation in the UAE is large, but poorly defined. Even the terms tidal to describe sheets of lagoon water that at times cover the uppermost parts of the sabkha “intertidal” is a little misleading as the process driving the sheets landward is typically the shamal.

Geologically, what defines the muddy intertidal facies is evidence of cyanobacterial (aka algal) mats. Mats first occur as degraded cyanobacterial peats in a transitional 100-200m-wide

Figure 3.7. Distribution of cyanobacterial mats in relation to tidal range, flooding frequency and cerithid grazing on the Abu Dhabi coast. Inset shows van Krevelen plot of protokerogen type in mat organics (after Park, 1977; Alsharhan and Kendall, 2003).

zone where the bare lagoonal flats pass landward into a belt of well-preserved laminated mats (Figure 3.4e, f, 3.6b; Kendall and Skipwith, 1968a, Park, 1977). Hence, the lower intertidal is defined by degraded oxidised peats composed of the bioturbated remnants of cyanobacterial mat. The upper intertidal facies is variably defined by laminated microbial mats across an extensive belt up to 1 to 2 km wide. These biolaminites accumulate in moist intertidal areas where salinities and temperatures are too hostile for cerithid gastropods and the other grazing animals of the lagoon flat (Figure 3.7). Many mats have sharp edges on their seaward side due to the grazing activities of the cerithids and other salinity-tolerant gastropods (Figure 3.4d). Sediments in the microbial flat are dominated by mm-laminated mudstones up to 50 cm thick composed of cyanobacterial remnants interlayered with aragonite muds. Periodic exposure means many mats are crosscut by desiccation cracks and are termed polygonal mat. Measured TOC contents of the mats vary

between 0.5 to 2.7%, with hydrogen indices between 510 and 675 in a range of type I-II protokerogens, with a $\delta^{13}\text{C}_{\text{PDB}}$ range from -8.41 to -10.78‰ (see inset in Figure 3.7 and Kenig et al., 1990)

Most of the literature on the sabkha gives the impression that laminated cyanobacterial mat is the only type of mat accumulating in the upper intertidal zone. Yet, in almost every area of mat I have visited along the mainland shores of the various khors of the Arabian Gulf, the laminated mat tends to occur beneath the floors of shallow channels and pools (waters a few centimetres deep), separated by interchannel areas of rugose or pustular mat. The sedimentary signature of the pustular mat is a poorly layered organic-rich mush, often with patches of lenticular gypsumarenite. Thus, the intertidal zone in an ancient equivalent need not

be laminated to be microbial in origin.

Many intertidal mats are crosscut by desiccation cracks that contain euhedral or lenticular (diagenetic?) gypsum crystals up to 2 mm long (Figures 3.4e, f, 3.6b). Gypsum is especially common in areas of pustular mat and along the landward side of the cyanobacterial belt, where it passes into the gypsum mush zone. Aragonite, magnesite, and dolomite locally cement surface sediments of the cyanobacterial flat (Butler et al., 1982). When microbially-bound intertidal muds are buried beneath prograding supratidal sediments, they can be extensively dolomitized (McKenzie, 1981). Such dolomites were first documented by Wells (1962). Arabian Gulf sabkhas and are one of two or three areas on the world's surface where Holocene dolomites are forming over aerially extensive regions, even if the extents are somewhat thin and patchy (Warren, 2000a).

Supratidal Facies

That part of the sabkha landward of the microbial mats and active beach ridges is further subdivided into three subfacies: lower, middle and upper supratidal (Figures 3.3, 3.8).

Lower Supratidal Lower supratidal sediment accumulates in a belt just above the high water mark (hwm) in a zone up to 2.5 km wide and flooded perhaps once or twice a month during high spring tides. It is characterized by a mushy gypsum bed, up to 30 cm thick, which passes seaward into cyanobacterial mat. Its lower part is an aragonite mud, crisscrossed by cyanobacterial filaments and isolated gypsum prisms (Figure 3.3b). The upper part is a thixotropic mush of small, mostly sand-sized lenticular gypsum, with an occasional 1-1.5 cm long crystal. Much of the mush is thought to grow as displacive crystals within the capillary zone, from pore waters not saline or hot enough to precipitate anhydrite. The surface of the mush can alter to white bassanite ($\text{CaSO}_4 \cdot 1/2\text{H}_2\text{O}$), or to anhydrite during even longer hot, dry periods.

Middle Supratidal The middle supratidal is a belt of sediment up to 1.6 km wide covered by lagoonal water at less than monthly intervals. It is characterized by growth of nodular anhydrite or gypsum within the sediment matrix. In the subsurface, well away from the lagoon, there is a lateral transition from gypsum to anhydrite (Figure 3.8). Subsurface and surface anhydrite nodules can increase in size and number

in a landward direction until in some areas they eventually form interlocking polygons. Along the Al Du'ybyaya sabkha, pockets of gypsum crystals are mixed with anhydrite nodules and layers, especially on the landward side of this zone, where they are dispersed in a matrix of reworked eolian quartz sand and silt. The middle sabkha surface is sometimes covered by an ephemeral halite crust and thin patches of loose blowing siliciclastic and carbonate sands.

At the same time anhydrite occurs above the water table, displacive and pore-filling gypsum is found in sediments immediately beneath the sabkha water table (Figure 3.6c). Crystal growth breaks up and destroys laminar textures in some buried biolaminites (Figure 3.4e, f). The seaward part of the middle supratidal is also the zone where dolomite is most common. It grows best as a pore cement in aragonite muds and can replace portions of the lower supratidal and intertidal mud facies (McKenzie et al., 1980; Butler et al., 1982).

Upper Supratidal In the vicinity of Abu Dhabi city the upper supratidal zone is up to 4.8 km wide and is rarely flooded by seawater (less than once every 4 to 5 years). In this, the most landward zone of the sabkha, the gypsum mush can be completely replaced by coalesced nodules of "chicken-wire" anhydrite to form near pure intervals that are up to 30 cm thick and lie mostly above the water table, not immediately below the landsurface (Figure 3.4g, 3.6c). Ongoing growth of irregular

Figure 3.8. Lithofacies distribution in subsurface across the upper intertidal to middle supratidal along the southern shore of the SW Khor al B'zam south of Al Qanatar Island, western Abu Dhabi (after Alsharhan and Kendall, 2003).

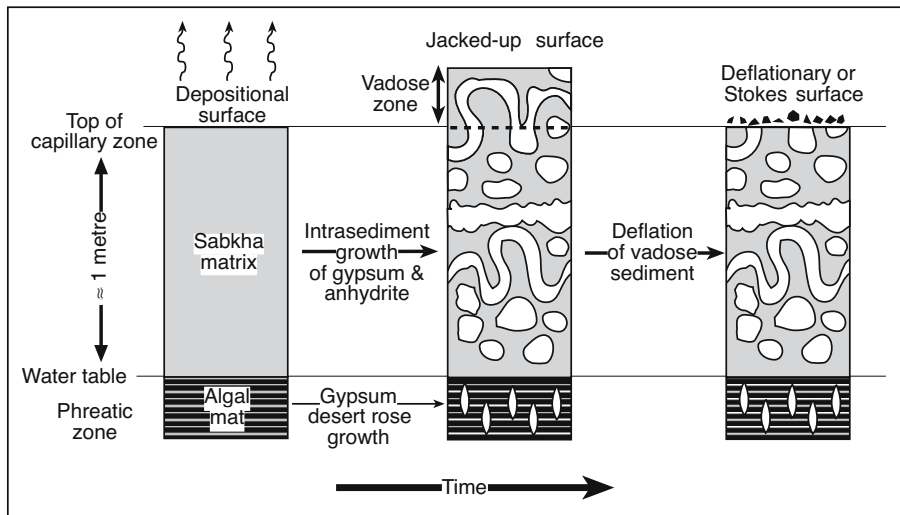

Figure 3.9. Capillary evaporation in the sabkha precipitates nodules and crystals of gypsum and anhydrite in the capillary zone. This increasing volume lifts the upper part of the sediment column out of the zone of capillary water into the vadose zone where it deflates to leave behind the characteristic erosional surface that caps modern and ancient sabkhas. It is a type of Stokes surface (after Warren, 1991).

anhydrite layers creates thrust folds, ptygmatic and enterolithic folds, and diapir-like protuberances. Beneath this zone much of the original cyanobacterial lamination is partially or completely obliterated by the growth of clusters of large prismatic to lenticular gypsum crystals (6 to 25 cm in diameter, locally known as desert roses). Anhydrite and gypsum also fills the interior of hollow aragonitic shells, especially the former living chambers of cerithid gastropods. Sediment accumulating in the upper supratidal zone contains little or no new dolomite. Along its most landward extent, the upper supratidal anhydrite layer can contain gypsum after anhydrite, with some nodules constructed of mixtures of both gypsum and anhydrite.

Widespread displacive calcium sulphate growth in the capillary zone sediments raises the sabkha surface out of the capillary zone to form a widespread erosional surface. As the rising sediments enter the vadose zone they dry and are blown away to leave behind the characteristic erosion surface of a sabkha sequence, covered in places by a deflation veneer (Figure 3.9). This erosion surface, especially where it truncates enterolithic or ridge anhydrite is one of the most useful indicators of the sabkha hydrology. Like other Stokes surfaces it defines the top of the capillary fringe (Figure 3.4g). Its presence in an ancient sabkha clearly distinguishes this style of truncated nodular anhydrite layering as penecontemporaneous and cannot be the result of burial conversion of gypsum to nodular anhydrite.

In drought times much of the middle and upper sabkha is covered by a pock-marked crust of halite, crosscut by pressure ridges and petees. This crust contains a range of efflorescent bittern and nitrate salts, but is dissolved and the soluble products flushed seaward with the next intense rainstorm or sheet flood. It is an ephemeral crust with a decoupled hydrology much like salt crusts in Australian salt lakes, as described in the previous chapter. Cm-sized displacive halite crystals can grow below these ephemeral salt crusts in the uppermost few centimetres of the upper supratidal sediments,

attesting to the infrequency of surface water in this region. The coming and going of the halite crust at the depositional surface of aggrading sections of the Abu Dhabi sabkha strongly influences textures in the remaining “supratidal” sediments (Figure 1.28; Goodall et al., 2000).

Sabkha hydrology and hydrogeochemistry

Hydrologically, much historic argument in the Abu Dhabi sabkha has dealt with the ultimate origin of the pore waters precipitating supratidal sulphate, i.e. marine flooding versus continental storm runoff (Figure 3.10a). Hydrogeochemical work in the 1960s and 1970s argued for a largely marine origin of the sabkha brines, which were supplied and replenished by occasional Shamal-driven tidal/storm seawater floods (Kinsman, 1969; Butler et al., 1973). The seawater flooding model was the first to provide a mechanism for cycling ions through capillary sediments and so account for the observed dolomite and calcium sulphate (Figure 3.10a). An alternate “evaporative-pumping” model was proposed by Hsu and his coworkers (Hsu and Siegenthaler, 1969; Hsu and Schneider, 1973) and included in the layered seawater flood/upwelling models of McKenzie et al. (1980), which suggested a compartmentalised hydrology made up of aquifers and aquitards and that capillary evaporation from the sabkha induced lateral flow of both seawater and continental groundwater (Figure 3.10a). All these early models suggested that seawater, either by flood

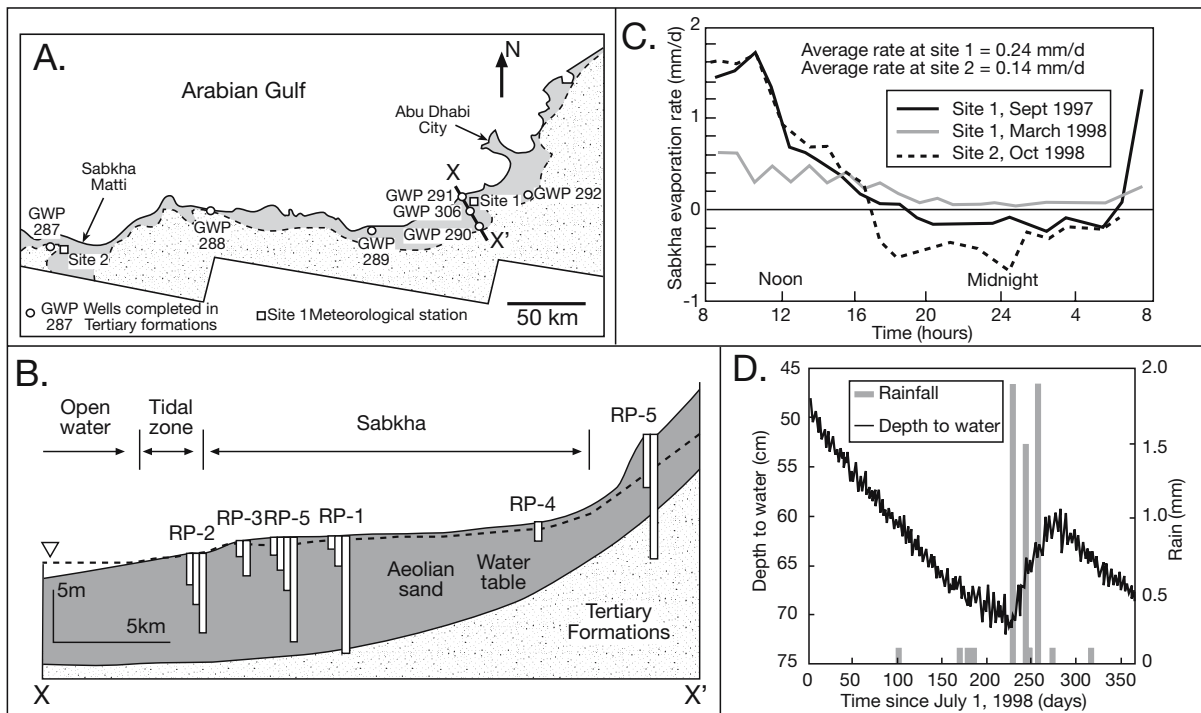

Figure 3.11. Hydrology of the Abu Dhabi sabkha (from Sanford and Wood, 2001; Wood and Sanford, 2002; Wood et al., 2002; Wood et al., 2005). A) Localities of selected monitoring wells, transects and sites. B) Measured evaporation rate at sabkha surface using a humidity chamber. C) Geological section showing thickness and piezometer nests along transect X-X'. D) Groundwater level and rainfall over a year (beginning July 1998) at site 2 in Sabkha Matti.

Potential (pan-measured) evaporation rates of fresh surface water on the sabkha are $\approx 3,500$ mm/year. But free surface water rates are not the same as actual rates of evaporation of pore waters held in the sabkha capillary zone by pore surface tension (Figure 2.3). Measured evaporation rates, using a humidity chamber, were around 0.24 mm/day at site 1 and 0.14 mm/day at site 2, with rates of evaporation changing with time of day (Figure 3.11c, d). These values are 3% of the pan evaporation rates at both measurement sites and correspond roughly to the mean annual rainfall throughput at both sites (90 mm/year for Abu Dhabi City and 50 mm/year at Sabkha Matti). The estimated rainfall recharge to the sabkha occurs at a rate of $640 \text{ m}^3/\text{year}$ in the representative volume illustrated in Figure 3.12. A mean value of 69 mm/year (from humidity chamber values) for evaporation gives a value of $690 \text{ m}^3/\text{year}$ for the volume of water lost in the sabkha, as shown in Figure 3.12. This volume of evaporative loss is about 15 times that of upward leakage from the underlying Tertiary aquifer ($45 \text{ m}^3/\text{year}$), and there is a meteoric-evaporation deficit of $\approx 50 \text{ m}^3/\text{year}$. Put simply, the sabkha is taking up Tertiary groundwaters like a sponge.

The humidity chamber measurements also showed that water flux during the night can be reversed at times when the humidity in the air above the sabkha exceeds the activity of

water on the surface of the salt crusts, causing night dew and some redissolution of the crusts. Periods of reversal are the times when the sabkha evaporation values are less than zero in Figure 3.11c.

Ongoing capillary evaporation means water level in the sabkha is typically around 1 metre below the sabkha surface (Table 3.2). Pore waters above this level are held in the pore throats by capillary pressure. Measurement of squeezed pore waters shows most salinities in the unsaturated zone are in the gypsum/anhydrite saturation range, as are waters at and just below the water table (130–290 mg/l), with brine densities ranging from 1.070 to 1.187. Measured conductivity (permeability) of the sabkha sediment is between 0.3 and 2.0 m/day (≈ 3 –10 md), and is relatively uniform across the sabkha. Using a hydraulic conductivity of 1 m/d, and a density-corrected piezometric gradient of 0.0002, results in a lateral flux of between 7 and 8 cm/yr (Wood et al., 2002). Dividing the flux by porosity from an average of the measured porosities (0.38) gives a seepage velocity of 18–21 cm/yr. This range in itself negates any notion of lateral marine seepage from the lagoon ever being capable of supplying the volumes of solute needed to precipitate the Holocene evaporites of the sabkha coast. These transmissivity calculations show that solute-carrying water simply cannot seep into the sabkha from its sides in sufficient volume to explain the

volumes of capillary salts now in the sabkha. Solute-carrying waters must be coming from below.

Between 47,600 and 55,500 years are required for a molecule of a conservative (i.e., nonreactive) solute to traverse the 10 km width of the sabkha in the considered rectilinear volume (Figure 3.12). If it is assumed that the average residence time is one-half of the total time required for a conservative solute to traverse the full length (10 km) of the rectilinear volume by horizontal flow, the average steady-state residence time of a conservative solute in this sediment volume is $\approx 26,000$ yr. Because the calculated residence time is greater than the age of the sabkha-aquifer system, it is clear that steady state for the solute flux has not been achieved. Capillary salts are still accumulating across the sabkha and it is this mechanism that is driving the jack-up and formation of Stokes surfaces.

In terms of the water cycle (not the solute cycle), direct rainfall onto the sabkha and subsequent groundwater recharge to the underlying aquifer accounts for 90% of the annual water input to the system; the remaining 10% comes from both lateral and ascending saline groundwater flow (Wood et al., 2002). Less than 1 m³/yr of pore water enters and exits by lateral groundwater flow into a representative rectilinear volume of sabkha aquifer measuring 1 m wide, 10 m deep, and 10 km long (Figure 3.12a). Some 45 m³/yr enters by upward vertical leakage, 640 m³/yr enters by recharge of rainfall, while 690 m³/yr is lost to evaporation. But, and this is what earlier work had not expected, the water and solutes in the sabkha are largely from different sources; they are decoupled as they are in the playas and salt lakes of Australia (Chapter 2). The bulk of the solute load precipitated in the Abu Dhabi coastal sabkha comes from the resurgence of deeply circulated groundwater returning to the surface in the coastal plain via Tertiary limestone aquifers. Solute in the capillary salts are not from seawater or from direct rainfall onto the sabkha. Approximately 100 kg/yr

Table 3.3. Hydrogeochemistry of source of solutes in Abu Dhabi sabkha; hydrogen and oxygen isotopes in SMOW. Sulphur in PDB (after Wood and Sanford, 2002; Wood, 2005).

of solute enters from lateral flow; ≈ 15 kg/yr enters by rainfall; and ≈ 3700 kg/yr enters by ascending vertical leakage (Figure 3.12b). Some 200 kg/yr is discharged to the Gulf by lateral flow. Upwelling groundwater originally entered the system in feeder zones in the Oman Mountains some tens to hundreds of kilometres to the east and picked up much of its solute load by water-rock interaction on its way to the coast.

Vertical gradients and hydraulic conductivity suggest that approximately seven pore volumes of water from the underlying Tertiary formations have discharged to the original coastal sabkha-aquifer system in the 7,000 years since deposition of those Holocene formations (Wood et al., 2002). Wood et al. (op. cit.) go on to argue that, if there are no other sources or sinks of solutes, then the concentration of a conservative solute should be approximately seven times the concentration of the input Tertiary brine. Bromine, a conservative element in brines, should have a concentration ratio close to the seven fold predicted by the hydrologic analysis if fed by Tertiary aquifers, and this expectation is realized (Figure 3.13a).

Loss of halite from the pore water is clearly shown by the low concentration ratios of both sodium and chloride. Sulphate and calcium concentrations are less than seven because of the precipitation of calcite, anhydrite, and gypsum in the unsaturated zone in the sabkha. Magnesium should be generally conservative in this system because there is no significant mass of clay that could act as an ion exchanger or structural sink for the mineral. Magnesium, like bromine, is not being removed by mineral precipitation of chloride bitterns within the aquifer. The current chemical conditions in the majority of the sabkha aquifer do not favour dolomitization (low concentrations of bicarbonate, low pH, and magnesium/calcium ratio of $\approx 1:1$; Table 3.3; Wood et al., 2002). It means that dolomite observed by previous workers in the sabkha is related to the original volume of trapped seawater. Significant masses of magnesium are not lost or gained from sources other than the brine, and the concentration ratio is approximately seven (Figure 3.13a). Like bromine, it is behaving conservatively.

In solutions without significant concentrations of carbonate species, magnesium hydroxide complexes [MgOH⁺ and Mg(OH)₂] can control the pH (Wood

et al., 2002). Observed pH in sabkha brines, which declines with increasing magnesium concentrations is consistent with this hypothesis (Figure 3.13b). The relative concentrations of calcium and sulphate can also be used to define the source of the solutes. Hydrochemical divides, as conceptualised by Hardie and Eugster, 1970, mean that mineral precipitation in a relatively closed system, such as the sabkha, will cause the concentration of one element of a precipitating mineral to approach zero, while the other element or elements will increase in concentration (Figure 2.12). The initial input concentration of the elements determines which element will be limiting. In the case of seawater, there is a greater equivalent

of sulphate compared to calcium; thus, with precipitation of calcite, anhydrite, and gypsum, the thermodynamic activity of calcium will approach zero. In the case of the Tertiary brines and oilfield waters, the average equivalents of calcium are greater than the average equivalents of carbonate and sulphate (Table 3.3). Thus, precipitation of anhydrite and calcite from the concentration of Tertiary brines will result in sulphate and carbonate levels in the brines approaching zero, while calcium increases in concentration. In the Abu Dhabi sabkha system the observed calcium is increasing, and sulphate approaches zero in most cases (Figure 3.13c), consistent with a Tertiary brine source for the sabkha anhydrite and gypsum. The few analyses in which sulphate is greater than calcium are from the supratidal zone nearest the lagoon. The concentration of sulphate does not go to zero because of hydrated complexes formed with magnesium and calcium; however, the thermodynamic activity does approach zero (Wood et al., 2002).

This interpretation of ionic proportions assumes that no other process, such as bacteriogenic sulphate reduction, is removing sulphate from solution. The regional groundwater system is oxidizing, with dissolved oxygen values between 4 and 5

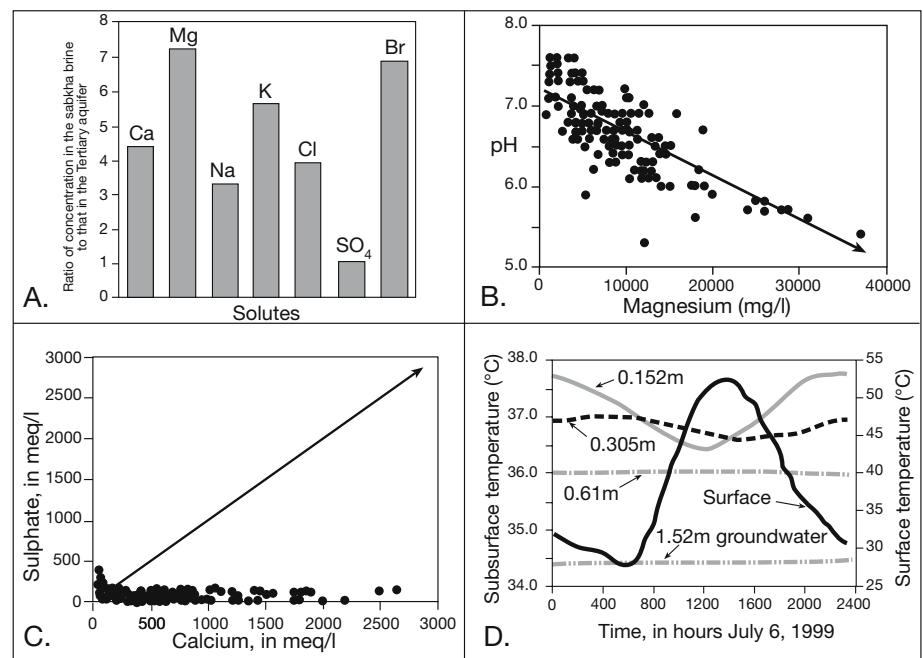

Figure 3.13. Hydrogeochemistry of pore waters in the Abu Dhabi sabkha (after Wood et al., 2002). A) Concentration factor (ratio of existing concentration in the sabkha-aquifer to input concentration of Tertiary brines) in the sabkha aquifer. B) Decline in pH with increasing magnesium in sabkha aquifer. C) Sulphate as a function of calcium in sabkha aquifer. D) One day temperature record of the surface, at various depths in the capillary zone, and of groundwater at site 1 in the coastal sabkha of the Emirates of Abu Dhabi.

mg/l, except at the distal edge of the sabkha. Therefore, it is not likely that bacterial sulphate reduction is removing a substantial mass of sulphate to significantly alter the Ca/SO_4 ratio as this bacterial process requires anoxic pore waters.

Periodic intense recharge by rainwater in the coastal plain dissolves halite and other soluble minerals on the sabkha surface, causing the surface and near surface waters to become more dense and sink (reflux) to the bottom of the aquifer where it vertically mixes with less dense ascending basal brines (Wood et al., 2002). With the next drying cycle solutes are once again returned to the surface by capillary forces (a cycle that is largely decoupled from external solute supply). Thus, the system becomes vertically mixed, but there is essentially no horizontal mixing of seawater with groundwater. In the same way bittern salts are flushed from the uppermost parts of the unsaturated sediment column.

Any observed seawater solutes in the undersaturated zone come from interstitial seawater trapped by the rapid progradation of the sediments into the Arabian Gulf or from marine aerosols, they are not refluxed or laterally mixed marine pore brines as was inferred in the previous hydrological models. For example,

Figure 3.14. Moles of CaSO_4 precipitated per kilogram of water as a function of temperatures for a representative solute sample from the sabkha of the Emirates of Abu Dhabi (after Wood et al., 2005).

Müller et al. (1990) observed a seaward gradient in strontium isotope values perpendicular to the coast, which they attributed to lateral mixing of continental brines and seawater within the sabkha (Figure 3.10b). Wood et al. (2002) reinterpret the significance of this distribution, noting that the inferred lateral mixing is as readily explained as the function of the number of pore volumes of resurging continental brine contributed to a specific area on the sabkha. That is, the distance from the shoreline and the number of pore volumes of Tertiary brine recharged to the sabkha-aquifer system are directly proportional and it is this that controls the Sr isotope values in the Abu Dhabi sabkha, not lateral recharge of seawater. In other words it is not necessary to invoke lateral mixing or transport to obtain the observed strontium isotope distribution.

Wood et al. (op. cit.) go on to note that the area of dolomitization (as identified by Patterson and Kinsman, 1982) is the region closest to the Abu Dhabi shore. This is the zone that retains the largest amount of seawater solutes because it is the area most recently prograded. The mass of dolomite formed on the sabkha is limited to that derived from the magnesium and carbonate concentrations in the initial pore volume of seawater trapped by the prograding sediments. The actual evaporative geochemical mechanism for dolomite formation, as proposed by Patterson and Kinsman (1982) appears to be correct; it is just that there is no ongoing seawater reflux occurring in this dolomitizing system. Arguing that all that is needed is more time to explain extensive dolomite cycles by prograding a set of sabkhas across ancient platforms is not hydrologically viable, syndepositional ancient platform dolomites require a different set of hydrological drives than icehouse sealevel (Chapter 5).

The hydrological mechanism driving the accumulation of calcium sulphate salts in the sabkha is the rise of deeper circulating groundwater to replace waters lost by evaporation. The process moving capillary waters and their solute load through the unsaturated zone of the sabkha is solar driven and so the calcium sulphate in the sabkha is a true evaporite mineral (Chapter 2). Within this evaporative framework, Wood et al. (2005) argues that brine warming drives calcium sulphate precipitation in the Abu Dhabi sabkha. That is, gypsum and anhydrite precipitate in the capillary zone because of their retrograde solubility. As well as belonging to the broader family of “true” evaporites, they are also “thermalites.” A thermalite is defined by Wood (op. cit.) as a mineral formed by changes in temperature, independent of other processes that alter the thermodynamic properties of the solution. He argues that the capillary zone is critical to the development of the authigenic thermalite salts in any sabkha.

Any capillary fringe is the result of two sets of forces: mutual attraction between water molecules (hydrogen bonding), and molecular attraction between water and the different minerals that form the aquifer (Figure 2.37). Thus, for any given mineral, the smaller the interstitial pore size, the greater the vertical rise of water (Table 2.10). The zone of capillary rise (also known as the “zone of tension saturation” or the “wetting front”) is the saturated zone above the water table in which the interstitial pore space is completely filled with water, but this water is under less than atmospheric pressure. There can be no evaporation within this zone of tension saturation (no pore water passing into its gas phase) because water completely fills the narrower pore spaces and the atmospheric pressure is negative. If it does not, capillary rise cannot occur. Above the zone of tension saturation in the unsaturated zone is a zone in which the water film and a gas phase coexist in the interstitial pore space. The relative humidity of this gas phase is, however, equal to the thermodynamic activity of water, and no evaporative concentration can occur in this interval as well.

The physics of the capillary zone means evaporation in the Abu Dhabi sabkha (or any other sabkha) can only occur at the surface, or in the pore spaces a few cm below, in the interval where the relative humidity of the gas phase is less than the thermodynamic activity of the water. Thus, any minerals precipitated lower in the capillary zone must be thermalites with precipitation driven by the retrograde solubility of calcium sulphate and not by an evaporation driven increase in the salinity of the pore fluids (Figure 3.14). The notion of thermalites explains the typical occurrence of the bulk of the CaSO_4 in the sabkha. Nodules and prisms are most common in the interval about the water

table and toward the base of the capillary fringe, not in the few centimetres immediately below the landsurface. This would be the position of maximum anhydrite growth if evaporation of capillary waters, not their heating was the dominant process driving CaSO_4 precipitation.

Wood (op. cit.) argues this conceptual model of thermalite precipitation applies to mineral deposition in the capillary zones of most coastal sabkhat. Water and solutes are transported upward by capillary forces from the shallow water table in response to water evaporating at the surface. As water passes into the gas phase and is removed from the uppermost few centimetres it leaves behind evaporatively precipitated salt residues, including bitterns in the uppermost part of the capillary fringe. It is a diverse suite, dominated by halite (NaCl), but encompasses other more saline salts such as carnallite ($\text{KMgCl}_3 \cdot 6\text{H}_2\text{O}$) and antarcticite [$\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$] as well. Below this uppermost zone, minerals exhibiting retrograde solubility, such as anhydrite (CaSO_4), calcite (CaCO_3), dolomite ($\text{CaMg}(\text{CO}_3)_2$), and gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), are precipitated as thermalites. They are the result of increasing temperature experienced by solute-rich deeply circulated groundwaters as it moves through the capillary zone toward the surface during the summer months.

A representative summer day temperature profile (July 6, 1999) illustrates a positive gradient of approximately 25°C m^{-1} in the Abu Dhabi sabkha at site 1 (Figure 3.13d). A reverse thermal gradient (upward cooling) in the winter permits dissolution of some of the previously precipitated retrograde minerals. Because the negative thermal gradient is less in the winter than in the summer with nearly the same water flux, the water does not have the capacity to dissolve all of the mineral mass that was precipitated in the preceding summer. Thus, there is a net accumulation of these retrograde (thermalite) minerals in the capillary zone (Wood et al., 2005). Figure 3.14 illustrates the difference in mass of salts precipitated and dissolved as a function of temperature for anhydrite based on measurements made in the sabkha. It clearly shows the relatively small temperature window in the sabkha ($5\text{--}25^\circ\text{C}$) during which winter dissolution can occur.

Detailed hydrological studies of the coastal sabkhas of the Abu Dhabi region show they are no more than the outcropping expression of outflow zones of regional artesian aquifers. Clearly the ascending brine model of Wood et al. (2002), and his subsequent conclusions of sabkha salts accumulating beneath the halite crust as thermalites, contrast significantly with both the seawater-flooding and evaporative pumping models previously proposed and widely accepted as explaining the source of solutes to the coastal sabkha of the Emirate of Abu

Dhabi (Figure 3.10a). Wood's conclusions show solute cycling in the coastal sabkha setting is decoupled and similar to that in continental sabkhas and chotts in many inland deserts with seawater like ionic proportions, as in the Sahara or central Australia (Chapter 2). Outflow of deep seepage throughput in the Abu Dhabi coastal sabkha is focused by a phreatic seawater wedge associated with the modern shoreline. Sediment matrix in some parts of the sabkha may be marine, but the hydrology and the authigenic overprint (mostly CaSO_4) comes largely from ions supplied by a deeply circulating continental aquifer. This new understanding of the large scale sabkha hydrology has significant implications for the preservation potential of ancient marine-margin sabkhas.

Siliciclastic-hosted coastal sabkhas, western and northern Arabian Gulf

An excellent literature base dealing with the sedimentology of the seaward side of the Abu Dhabi sabkhat creates an impression that coastal sabkhas in the Arabian Gulf are characterised by capillary salts hosted in marine carbonate matrices. But this is not the case and many marine-margin capillary salts in the Arabian (Persian) Gulf are hosted in siliciclastics or even in desert loess blown into coastal depressions. Even in the type area, the Abu Dhabi sabkhat, at least 50% of the coastal plain sediments that host capillary evaporites do so in a matrix of mixed carbonate-siliciclastic or pure siliciclastic. Many ancient counterparts to strandzone sabkhas have siliciclastic matrices. Well-documented examples include the Permian sandflats of Europe and much of the Guadalupian lagoonal sediments of the Central Basin Platform in west Texas and New Mexico (e.g. Figure 10.40-10.42). The following section describes some modern coastal sabkhas of the Arabian Gulf with capillary salts growing in mixed siliciclastic/carbonate and pure siliciclastic matrices.

A predominance of siliciclastics in the sabkhas of Kuwait and Saudi Arabia in the northwest of the Gulf versus carbonate in sabkhas along the At Taf coastal strip in the southeast of the Gulf simply reflects sediment transport and coastal dynamics in the seaway (Figure 3.2a). The northwestern shore of the Arabian Gulf passes from the siliciclastics of the shallow Mesopotamian Shelf to the carbonate shoals of Bahrain, Qatar and the At Taf coastal strip. The northern Gulf is an arid, micro to mesotidal region with tides ranging from 1 to 4 metres (Gunatilaka and Mwango, 1988). Anticlockwise tidal currents of the northern Gulf and the prevailing northwesterly Shamal winds produce a shore-parallel largely southeasterly-directed wind-wave energy system, which supplies a combination of desert sand

and loess to this part of the Gulf coastline, with an increasing fluvial contribution toward the northernmost gulf.

Arabia, south of Dammam, is characterised by a north-south elongated belt of eolian dune sand, which approaches the coast

From the coast to inland areas along the northwestern Gulf there are three broad depositional environments (Lomando, 1999). Along the coast is a near continuous belt of modern mixed carbonate-siliciclastic deposits with a wide range of depositional styles from interdunal to estuarine to barrier coast. To the immediate landward is a discontinuous belt of active and abandoned marine sabkhas, which pass into a broad desert system of continental sabkhas, desert flats, and dune fields. The inland desert system is the flattest area of Kuwait and northern coastal Saudi Arabia and is part of a zone of regional deflation, providing wind-blown sand to the Jafurah Sand Sea and ultimately accumulating in the northern areas of the Rub Al Khali in Saudi Arabia (Figure 3.57).

Coastal sabkhas of eastern Saudi Arabia

Sabkhas of eastern Saudi Arabia are divisible into coastal and inland sabkhat, both are surrounded and underlain by Pleistocene and Holocene dune sands (Figure 3.15a). Eolian sandflat sediments of the coastal region were documented by Fryberger et al. (1983,1984) in a study of the Jafurah Sand Sea margin and are discussed in detail toward the end of this chapter. The Eastern Province of Saudi

Figure 3.15. Sabkhas of Saudi Arabia southeast of Dammam. A) Distribution of coastal and interdunal sabkhas in areas of shallow groundwater resurgence along the Dammam coastline. The coastal region defines the modern marine edge of the Jafura sand sea where isolated subsealevel coastal depressions are today filling with capillary salts in a mostly siliciclastic matrix. In the last glacial this sand sea extended well out into the Arabian Gulf (Landsat image courtesy of NASA, wind vector after Fryberger et al., 1984). B) Semi-circular marine seepage sabkhat behind Ras Qaryah and adjacent to the eastern edge of Sabkhat ad Danan.

between Doha Dhalum (Half Moon Bay) and Al-'Uqayr (Figure 3.15a). To its immediate north are the Tertiary limestones and dolomites highlands that define the outcrop expression of the Dammam dome (cored by a salt diapir). This coastal zone is surrounded by siliciclastic sand sheets passing upwind into active barchan sand dunes that are still moving sand into and across the coastal sabkha to a prograding siliciclastic shoreline. Sand movement is principally towards the south-southeast and sand is driven seaward by the Shamal (Figure 3.15a). In areas where the water table approaches the landsurface, sabkha evaporites are growing in sand sheets in both sea-margin coastal sabkhas and in interdunal sabkhas located further inland (Figure 3.15a, b).

The dominant capillary salt is gypsum (Figure 3.16a-c) in both inland and coastal sabkhas in the Eastern Province on Saudi Arabia, with small local areas of halite and anhydrite in the most saline parts of both the inland and coastal sabkhas. Some of the large coastal sabkhas, such as Sabkhat ad Danan, have gypsum lunettes along the sabkha edge (Figure 3.16c). Gypsum is also a widespread pedogenic precipitate in much of the arid landscape of eastern Saudi Arabia. The level of carbonate matrix in the Saudi sabkha increases with proximity to the present coastline with a few wet dune seeps adjacent to the coast even supporting a healthy mollusc population. Coastal margins to the sabkhas show a range of cemented carbonate crusts with some modern lagoonal shorelines showing megapolygons in marine-cemented layers identical to those of the Abu Dhabi lagoonal margin (Figure 3.16d). The important difference in the sabkha between the two areas is the amount of eolian siliciclastics in the upper intertidal and lower supratidal sediments.

Brine seeps through the sand aquifers and replenishes areas depleted by drawdown from capillary evaporation within the lower parts of the sabkha depressions. Gypsum crystals grow in the pore spaces near the water table, poikilolithically enclosing sand grains, to form spectacular crystal clusters or desert roses (Figure 3.16b). Individual crystals can be up to a metre across, but most are measured in centimetres. The proportion of gypsum in the crystals is more than the porosity of the adjacent loose sand, showing that gypsum is not only growing in the pore spaces, it is also displacing the sand as it grows (Warren, 1991).

Gypsum typically grows in a matrix of dark-coloured quartz sand and silt in a capillary zone that can actively precipitate gypsum up to 50 cm above the water table. Some sabkhas, such as Sabkhat ad Danan are currently deflating so that parts of the surface of the sabkha are paved by thousands of isolated

prismatic gypsum blades standing up along fracture polygons and the edge of the adjacent sabkha is lined by a dissected terrain of gypsum lunettes (Figure 3.16c). Most of the crystals at the surface are weathered white and have split along cleavage planes. Immediately below the sabkha surface the gypsum crystals are still entire. The Stokes surface overprint indicates a fall in the regional water table, which has moved the crystals into the vadose zone and may in part reflect regional uplift driven by the nearby salt diapir-cored Dammam dome, which is currently rising at a rate of 5.5 metres per million years (Weijemars, 1999). More likely, it indicates the local vagaries of erosion associated with ongoing autocyclic gypsum crystal growth jacking overlying sediment up and out of the capillary zone, where it is subject to intense wind deflation. In the lowermost parts of the regional sabkha plain there are local depressions a few kilometres across where brines pond and the sediment surface periodically lies below the water table. There salt pans are forming and are filling with successive crusts of chevron halite, rather than the more typical displacive gypsum of the regional sabkha (Figures 3.15b, 3.16e). Around the high salinity edges of these halite pans are zones of nodular anhydrite rather than the ubiquitous sabkha gypsum (Figure 3.16f).

Sabkhas of coastal Kuwait

Modern sea-margin sabkhas in coastal Kuwait are not developed at the same broad scale as those of Abu Dhabi or the Dammam region, but are nonetheless interesting as they illustrate a transition from an alluvial fan-fluvial supplied sabkha in Kadmah Bay (aka Kuwait Bay) to a mixed eolian siliciclastic-carbonate matrix sabkha in the Al Khiran region to the south (Figure 3.2a). Inland Kuwaiti sabkhas are also widespread in depressions more than 10 km from the coast. Both inland and coastal sabkhas of Kuwait are largely hosted in sheets of reworked medium-grained quartz dune sand (Al-Hurban and Gharib, 2004). Compared to inland sabkhas, the detrital matrices in coastal sabkhas are slightly muddier, contain less gravel and show higher levels of gypsum due to their proximity to marine aerosols and marine seeps (Figure 3.17).

Sabkhas of Kadmah Bay

To the north of Al Khiran sabkha, the Holocene sediments of Kadmah Bay (Kuwait Bay) represent the western-most limit of the siliciclastic Shatt Al-Arab delta and the southern limit of the alluvial fans of Jal Az-Zor escarpment (Saleh et al., 1999; Al-Sarawi, 1988). Most of the sediment matrix in the western part of the Kadmah Bay hypersaline system is deposited at the distal end of large alluvial fans, downdip of the Jal Az-

Figure 3.16. Coastal sabkhas of the Eastern Province, Saudi Arabia. A) Flat puffy algal-bound (petee) surface of the Sabkhat ad Danan. B) Typical displacement gypsum (desert rose) growing within a half a metre of the sabkha water table in Sabkhat ad Danan. Crystal is 10 cm across. C) Gypsum lunette showing characteristic eolian cross bedding (outcrop face \approx 1.5m high) D) Megapolygonal tepee ridges in marine cemented intertidal lagoon crusts in southern Half Moon Bay (area locally known as "wrong way spit"). E) Pressure ridges in the halite pan facies (lowest point) of the Ras Qaryah sabkha shown in 3.9b in March 2004. The water table at this time of year is no more than a tens of cm below the sabkha surface. F) Displacive nodular anhydrite growing in the capillary zone in fine detrital clay about the edge of this saline pan facies in the Ras Qaryah sabkha (scale division is in cm).

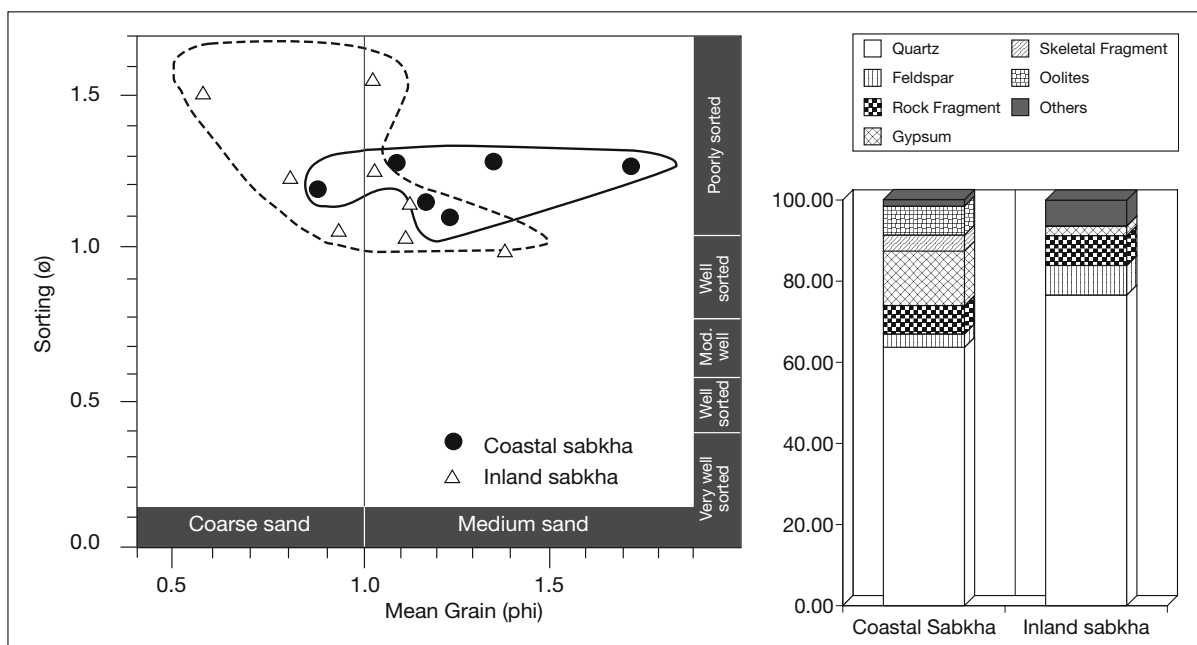

Figure 3.17. Grain-size and mineralogical comparison between sediments of inland and coastal sabkhas of Kuwait (replotted from Al-Hurban and Gharib, 2004).

Zor Escarpment (Figure 3.18 a, b). In contrast, sabkha matrix in the northeastern part of the bay is fed substantial volumes of finer-grained sediment by longshore drift of sediment sourced in distributaries of the Shatt el Arab delta sediments. This higher volume of sediment supply means sabkha at the northeastern end of the bay has prograded further into the bay waters (Figure 3.18a). Today, the bay is about 20 km wide, has a tidal amplitude of almost 2 m and is around two-thirds exposed during very low tide. Although very shallow, the lack of wave energy and the proximity of the muddy Shatt al Arab, means the central bay fill is very muddy and is near impossible to cross on foot at low tide.

Four sedimentary settings define the northwestern Kadmah Bay margin; namely alluvial fans, playas, sabkhas and beaches (Figure 3.18b; Al-Zamel and Al-Sarawi, 1998). Coastal sabkha deposits extend landward to where they interfinger with the distal ends of modern alluvial fans, much like the sabkhas of Ras Al Khaimah at the other end of the Arabian Gulf (Warren, 1991). Distal fan sediments are typically plane-laminated sands interlayered with playa lacustrine muds and are often encrusted by a gypcrete carapace. Mid fan sediments are dominated by crossbedded and parallel laminated sands, while proximal fan sediments are poorly sorted imbricated gravels and poorly stratified pebbly sandstones.

Evaporitic Kadmah Bay sabkha sediments can be divided into two subfacies: (1) dark brown silt mixed with very fine sand,

rich in prismatic gypsum, gypsum roses and gypsum nodules at the level of the water table, along with some halite and aragonite and very minor amounts of anhydrite; and (2) light brown silts mixed with local anhydrite nodules in fine sands in the upper parts of the sabkha plain. Gypsiferous sabkhas dominate.

An erosional or deflationary regime now characterizes the sabkha of the coastal plain of Kadmah Bay (Saleh et al., 1999). Maximum marine flooding of the supratidal area is dependent on the coincidence of high water spring and/or storm tides with southeasterly winds and is an uncommon event. This results in a very limited portion of the tidal zone (0.6-0.7 km wide) being subjected to flood recharge during the normal tidal cycles. Away from the immediate bay waters, much of the active Kadmah Bay sabkha is best described as an evaporitic 'wind flat' or sandflat rather than a diurnally flooded carbonate mudflat. The closest comparable modern setting documented in the sedimentological literature is probably the evaporitic mudflat of the Colorado River delta (Shelton et al., 1978). Once again, this is a continental system that just happens to be at the edge of a modern sea and its hydrology is largely continental.

The dominantly-southeast Shamal wind means coastal sabkhas in Kadmah Bay are distinct from carbonate-dominated coastal sabkhas further south in the Gulf. The Shamal blows continental sediment into the bay so that the sabkhas are the seaward edges of deflation flats with matrices characterized by abundant

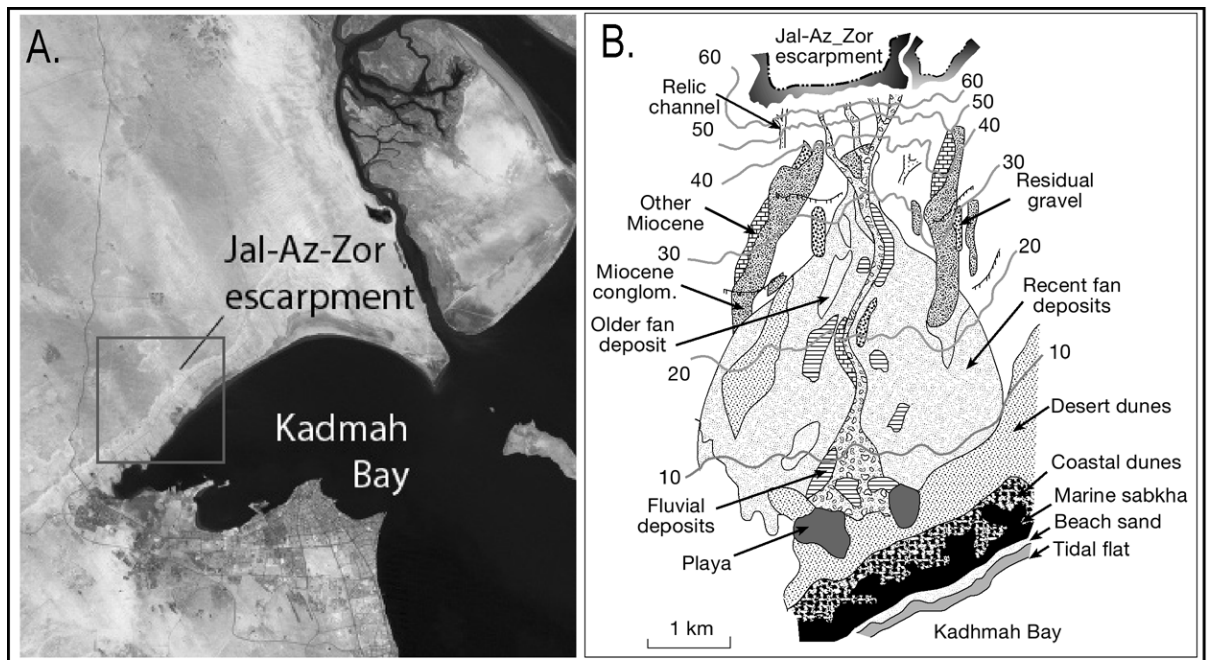

Figure 3.18. Kadmah or Kuwait Bay A) Shows the development of an extensive but narrow coastal sabkha with a siliciclastic matrix on the northern margin of the bay (Landsat image courtesy of NASA). B) Surface geology of the region where Al-Khuwaisat alluvial fan passes south into Kadmah Bay sabkhat, Kuwait (after Al-Sarawi, 1988).

siliciclastics, not carbonates. The dry windy setting means there is an absence of healthy laminated cyanobacterial mat along much of the intertidal sabkha strandline. It is simply too dry, so laminated cyanobacterial mat is mostly confined to small moister areas on the floor and the immediate vicinity of tidal channels. The mud-size fraction in the Kadmah sabkha ($\approx 5\%$ of sediment volume) is dominated by carbonate minerals, but this carbonate is detritus from the north, not diagenetic or marine supplied material from the bay (Saleh et al., 1999; Al-Bakri et al., 1984). Much of it is low-Mg calcite washed in from the surrounding plain where capillary calcretes (*gatch*) are commonplace. Similarly, almost all of the dolomite in the northern Arabian Gulf, including that on the floor of Kadmah Bay is detrital and derived either from longshore transport from the Shatt el Arab delta or is blown in by the Shamal as it scours the desert plains of Iraq (Al-Bakri et al., 1984). Numerous primary sheet flood and eolian structures are preserved beneath the prograding supratidal flat, with only minor disruption to these structures caused by local growth of intra-sedimentary gypsum. Gypsum and other capillary salts never dominate mineral proportions in the supratidal zone of Kadmah Bay (Figure 3.18).

The windblown and deltaic siliciclastic coastline of Kadmah Bay has been prograding into the bay for 3,000 years at a rate of 1.5 to 2 km per 1000 years. More landward, the preceding “Early Holocene” transgressive coastal sediments are made up of patchily distributed, autochthonous carbonates (aragonitic oolites, pellets and micrite), similar to the early Holocene beach ridge carbonates of the At Taf coastal strip. The Mid-Holocene transition to a siliciclastic matrix along the north coast of Kadmah Bay indicates the time when longshore currents flooded the northern bay with reworked muddy fluviodeltaics from the prograding Budyah channel (see Shatt al Arab sabkha).

Al-Khiran Sabkha

To the south, near the Kuwaiti border with Saudi Arabia, Late Pleistocene and Holocene sediments are exposed in and about the sea-margin sabkhas in the Al-Khiran area (Figures 3.2a, 3.19; Gunatilaka et al., 1987; Al-Sarawi et al., 1993). The Al-Khiran sabkha is a carbonate-hosted lagoonal system some 60 km² in area. It lies behind a chenier belt of four oolitic beach-dune ridges where large parts of the inter-ridge sabkha depressions are no longer subject to marine flooding. The oldest and most landward exposed beach ridge is older than the Flandrian transgression. The four younger, accreted ridges, mapped by Al-Sarawi et al. (1993), were dated at 6,800, 5,800, 3,000 and 2,000 years BP.

Sabkha plains in the inter-ridge depressions were formed by sedimentary offlap driven by the relative fall in sea level since the last Holocene transgressive maximum approximately 4.5–4.7 ka. Sabkha evaporites (gypsum and anhydrite) in the inter-ridge depressions are hosted by aragonite-rich pellet muds, which also entrain significant amounts of comminuted marine shell material. Thin layers of blowing sand now cover portions of the sabkha to varying thicknesses depending on depth to the top of the capillary fringe. Some of the anhydrite in the Al Khiran sabkha is unusual compared to the Abu Dhabi sabkha in that it first nucleates in zones of moisture stress around plant roots and so is an evaporitic form of dikaka or rhizoconcretion (Gunatilaka et al., 1980).

In an annual cycle, modern marine waters are confined to two tidal creeks cutting the Al-Khiran sabkha (Gunatilaka et al., 1987). Occasionally, perhaps a few times in a year, a narrow strip up to a 100 m wide adjacent to the creeks is by covered by tidal waters, brought there by exceptionally high spring tides. An absence of significant marine flooding over the rest of the sabkha means much of the current hydrology and pore chemistry is almost entirely controlled by influxes of conti-

mental groundwater. This topographic-continental hydrologic framework is also reflected in the formation of diagenetic continental dolomite in some depressions on the salt flat, as well as the isotopic make-up of the dolomite, which indicates a continental or nonmarine source.

Major ions show a steady evaporative concentration across the sabkha from inland to the coast, with a “high” chloride plateau in the central parts of the marine sabkha similar to the plateau that occurs in the Abu Dhabi sabkha (Robinson and Gunatilaka, 1991). Monitoring of groundwater over a three-year period indicated that: (a) when the water table depths are < 1.2 m, the sabkhas are in a state of depositional equilibrium; (b) water table fluctuations (due to drawdown or recharge) exceed 0.5 m/yr; and (c) calculations based on measured fall in water table levels, porosities of the sediments, and the volume of anhydrite formed in the sabkha all suggest that over the last 4,700 years, since progradation commenced, only 2–4 cm/yr (net) of groundwater is lost from the sabkha surfaces. This is a surprisingly low rate for this arid region and indicates significant replacement by resurging continental groundwaters. This groundwater replenishment maintains longterm stability

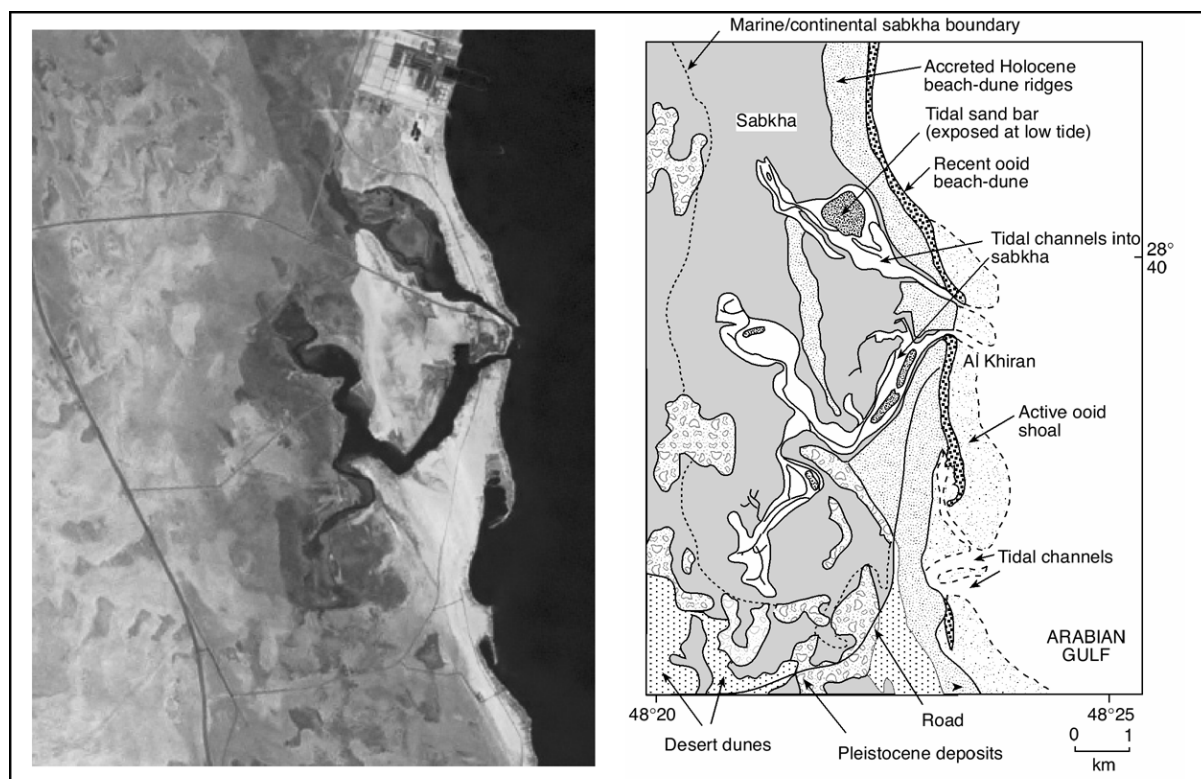

Figure 3.19. Surface geology of part of the Al-Khiran sabkha, Kuwait, showing the importance of accreted ooid beach ridges in forming the structural framework of the coastal sabkha estuary and the passage into dune sands in the sabkha hinterland (Landsat image courtesy of NASA, surface geology after Gunatilaka et al., 1987).

of the sabkha sequence. Without it, deflation would dominate and most of the older sediment would be planed off to the level of the intertidal/subtidal crust, much like what has occurred on the backside of Kadme Bay.

Supratidal anhydrite in the Al Khiran sabkha has three distinct morphologies (Gunatilaka, 1990): (a) hair-cream anhydrite which occurs exclusively in association with the halophytic saltbush *Halocnemum strobilaceum*; (b) nodular/laminated cottage cheese anhydrite, which is associated with a bacterial-cyanobacterial mat. This nodular anhydrite forms massive layers up to 4 cm thick with the anhydrite initially pseudomorphing gypsum crystals in the mats. In laminated anhydrites it can form aphanitic layers up to 7 cm thick, made up almost entirely of microcrystalline anhydrite; (c) anhydrite formed by the alteration of prismatic gypsum crystals now exposed in the lowermost parts of some now abandoned and desiccated drainage channels.

With “hair cream” anhydrite, climate and biological influences play a significant role in what is often an annual mineralogical change between gypsum and anhydrite, depending in part on rainfall intensity. On the death of the halophyte, hair-cream anhydrite reverts to microcrystalline alabastrine secondary gypsum and then to a gypcrete. The gypsum-anhydrite transformation is a reversible dissolution-precipitation process and

there appears to be an intimate relationship between the plant, its “soil water” requirements and the hydrodynamic behaviour of capillary groundwater brines in the vadose zone, which interact to control the mineralogy. Compared to “hair cream” anhydrite, type (b) anhydrite is more likely to be preserved as anhydrite, not gypsum, at least into the shallow subsurface above the watertable. Type (c) anhydrite is rare and possibly only forms with complete drying of the channel bottom, it is always susceptible to deflation or rehydration and so has low preservation potential compared to types (a) and (b).

All anhydrite in the Al-Khiran sabkha forms from a gypsum precursor at temperatures $> 30^{\circ}\text{C}$ and brine chlorinities > 4 mol Cl/kg. Al-Khiran is the northernmost occurrence of widespread patches of anhydrite in the coastal belt of the Arabian Gulf (gypsum dominates further north). It also defines a change in lagoonal matrix in the coastal plain to the fluviodeltaic sabkha coast of northern Kuwait and Iraq.

Other coastal sabkhas

Outside of the southern coast of the Arabian Gulf there are many other coastal deserts where evaporation of a combination of marine and continental waters precipitates capillary salts in a matrix of marine-reworked sediment.

Figure 3.20. Sinai Peninsula showing distribution of some of the studied Holocene sabkhas and salinas in the Quaternary coastal fringe (Landsat image courtesy of NASA).

Gulf of Suez

Sea-margin sabkhas form along both sides of the Gulf of Suez. Small sabkhas are patchily developed along the seaward edge of the El-Qaa, in a coastal strip that runs from Abu Rudeiz to Ras Muhammad (Figure 3.20; Gavish, 1974, 1980). The El Qaa is a near-flat alluvial plain, mostly composed of alluvial silicate minerals weathered from Precambrian metasediments and granitic massifs to the east. The El Qaa area experiences some of the hottest and driest conditions in the Sinai, yet it lacks substantial accumulations of anhydrite. Capillary evaporites where they do occur are mostly scattered patches of interstitial gypsiferous cements within a few hundred metres of the coast (Figure 3.21). Nowhere in the Sinai coast are sabkha salts as extensive as in the Arabian Gulf sabkha (Gavish, 1974). Gypsiferous capillary cements in marine-reworked siliciclastic matrices, are also patchily developed in a narrow coastal strip on the opposite (African) side of the Gulf of Suez (Keheila et al., 1989). At Ras Shukheir the sabkha is unique in that it is developed atop and around one of the world's few examples of a Late Pleistocene coastal salina, which was once filled with laminated subaqueous gypsum, although now the succession is heavily eroded (Figure 4.15).

The sabkha fringe to the Gulf of Suez coastal plain typically extends from the marine shoreline to the seaward base of an alluvial fan apron or bajada, which lines a faulted escarpment located up to a kilometre or more in the hinterland. The sabkha itself usually occupies the first few hundred metres immediately landward of the shoreline where the bajada watertable approaches the landsurface (Figure 3.21a). Matrix sediments are mixtures of clastic fine-sands, derived from alluvials, and marine carbonate washover sands composed of skeletal fragments, pellets, ooids, and some intraclasts (Sellwood and Netherwood, 1984). Finer-grained marine carbonates typically occupy the seaward side and coarser-grained alluvial clastics occur on the landward side, so that the proportion of carbonate decreases upward in a prograding sabkha cycle. In many places there is an elevated sandy berm or a strip of pebbly beachrock defining the upper limit of the intertidal zone and a sabkha flat is developed behind the berm (Figure 3.20a). The supratidal zone generally extends a few hundred metres inland, its width being dependant on the regional slope. Further landward the top of the capillary fringe passes below the landsurface. Storm surge waters occasionally cover large portions of the supratidal flat and a thin ephemeral crust of pressure-ridged chevron halite may form a cm-thick cap to the sabkha as the surface waters disappear. The crust too disappears in the next flood or rainstorm. Once again, it is highly likely the hydrology of the crust is decoupled from that of the underlying sabkha.

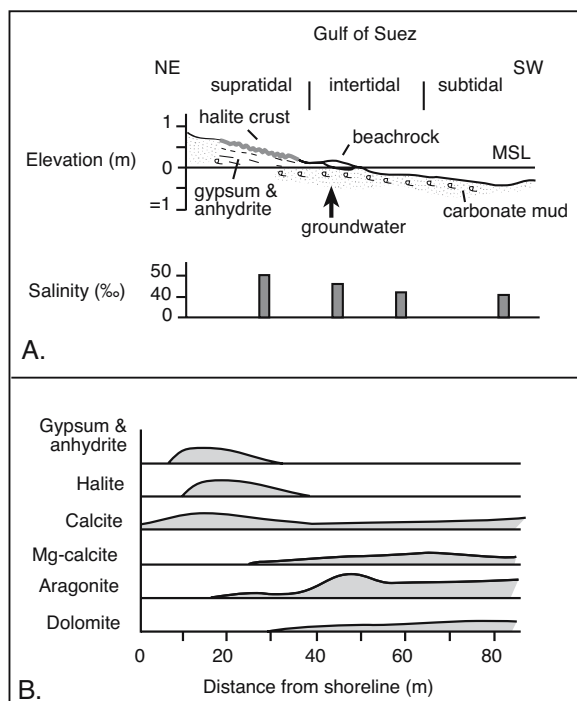

Figure 3.21. Gulf of Suez sabkhas. A) Generalised cross section through sabkhas of the coastal zone of the Gulf of Suez and typical pore water salinities (after Gavish, 1980). B) Distribution of various mineral phases in terms of distance landward from the marine shoreline. Gypsum, anhydrite and halite are the main evaporite minerals (after Gavish, 1980).

Evaporite mineral distribution in a typical Gulf of Suez sabkha is very similar to the mineral suite in an Arabian Gulf sabkha but the volumes of capillary salts are less and depositional belts are much narrower. Like the Arabian Gulf, the Gulf of Suez sabkhas precipitate evaporites mostly as displacive crystals within the supratidal zone (Figure 3.21b). Capillary driven concentration precipitates salt in a matrix-rich supratidal evaporite unit, which is no more than 60 - 80 cm thick - the thickness of the capillary fringe. Most of the gypsum is precipitated as passive pore cements immediately above the water table. Gavish (1974, 1980) attributes most of the ion supply to landward seepage of seawater, driven by capillary evaporation, as per the model of Hsu and Schneider (1973). The hydrology of the Gulf of Suez sabkhat has not been re-assessed since the work by Wood et al. (2002) on sabkhas of the At Taf coastal strip.

One of the most obvious differences between the Gulf of Suez sabkhas and the Arabian Gulf sabkhas is the distribution of the two calcium sulphate phases (Gavish, 1974). In the Gulf of Suez, gypsum is the dominant sabkha mineral in all active parts of the sabkha. Only very minor traces of anhydrite are found and

only in the older more elevated portions of the sabkha where it has locally recrystallised or replaced a gypsum precursor.

Beach-dune and fluvial sabkhat on deltas

Modern sea-margin settings where large river systems are building deltas into the marine realm in arid settings are areas that set up shallow water tables and so can host local near-coastal sabkha systems. They form where the capillary fringe intersects the land surface and so tend to be preserved either in more protected subsealevel depressions behind coastal beach ridges (Nile Delta) or as fringes to coastal lagoons fed by occasional storm surges and marine floods (Bardawil Lagoon).

Western Nile delta coast, Mediterranean Egypt

Interdunal sabkhas of the Nile delta are forming today along the Mediterranean coast near El Hammam, a region halfway between Alexandria and El Alamein (Figure 3.22; Bellah and Hassouba, 1995). There the coastal zone consists of nine or more Quaternary shore-parallel carbonate beach-dune ridges.

All the ridges are cemented with a hard caliche cap, except the most recent dune known as the “coastal ridge.” Lagoonal and desert loess sediments fill large swaths of the elongate depressions between the ridges and act as host matrices to the sabkha precipitates.

The first sabkha depression is situated immediately behind the “coastal ridge” of oolitic sand and is more than 8 km long and a few hundred metres wide (Figure 3.22; Ali and West, 1983; West et al., 1979). Displacive nodular gypsum (with minor palygorskite/attapulgite) is growing in the capillary zone of the carbonate-rich desert loess that has filled this most seaward interdunal depression. Landward and to the south, beyond the Abu Sir limestone ridge (Pleistocene), there are other interdunal sabkhas forming about and within various halite-encrusted, cyanobacterial-mat-fringed lakes.

Sediment behind the third ridge back from the coast is very interesting in that it contains a laminated gypsum fill, which is possibly the preserved remnant of a Pleistocene subaqueous deposit (pers.obs). The beds there are extensively quarried

and well exposed, but as yet its geology is poorly documented and it is not known if it formed as a marine-fed salina or as a lacustrine chott fill. The fact that this laminar gypsum alternates with thin limestone layers preserving articulated shells of *Cardium sp.* argues perhaps for a marine seepage origin.

All the sabkhas in the inter-ridge depressions are characterised by gypsiferous capillary zone units up to 60 cm thick made up of a combination of lenticular to prismatic gypsum crystals, and small spherical to elliptical nodules 1 to 4 cm wide composed of silt-sized gypsum. There is no anhydrite growing in the capillary fringe. Matrix sediment is a mostly brown, laminated, very fine quartzose silt and carbonate sand. It was depos-

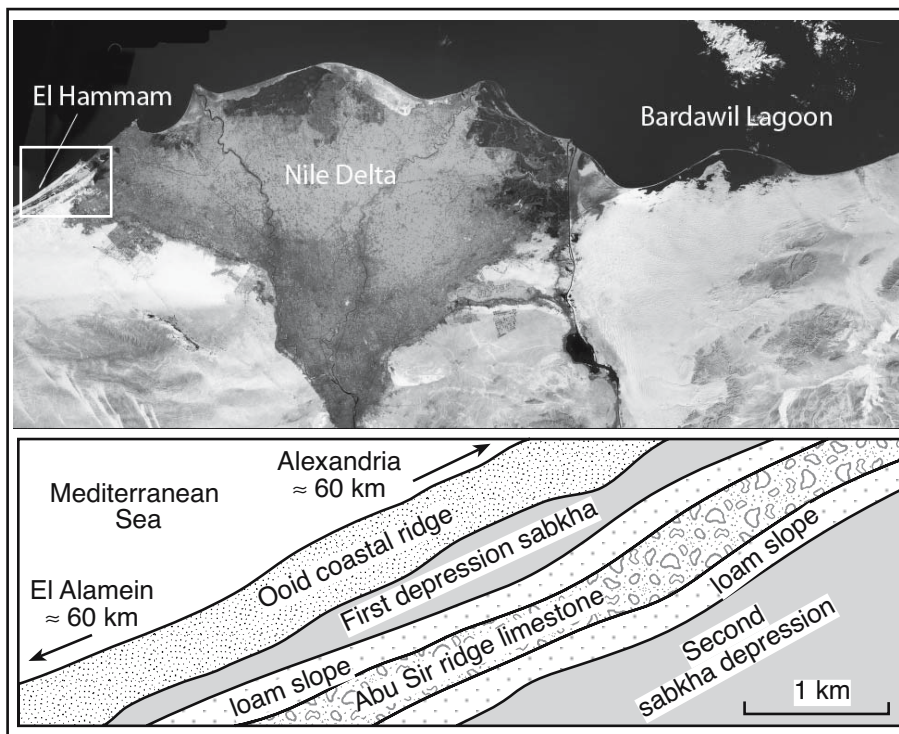

Figure 3.22. Egyptian coast centred on the Nile Delta. Interdunal coastal sabkhas occur on the eastern end of the vegetated Nile cone (rectangular inset, while Sabkhat Yathal Yam occur on the southern side of Bardawil Lagoon beyond the eastern end of the Nile delta (Landsat image courtesy of NASA, surface geology after West et al., 1979).

	No. of samples	Na	K	Mg	Ca	Cl	SO ₄	HCO ₃	Sr	Salinity
Zone V	6	77,500	5,200	21,800	100	173,000	49,200	trace	21	327‰
Zone IV	4	46,000	3,000	11,100	1,100	66,000	19,700	trace	45	148‰
Zone III	6	24,700	1,200	2,500	1,500	54,000	19,300	trace	42	103‰
Zone II	9	16,300	600	2,000	1,000	31,000	7,800	trace	40	59‰
Seawater	-	10,600	380	1,270	400	18,980	2,650	140	8	34‰

Table 3.4. Average compositions of 25 interstitial waters squeezed from evaporitic sediments in the first interdunal corridor, Abu Sir sabkha, Nile coast. Bicarbonate was below the detectable limit in all samples (after Ali and West, 1983).

ited as desert loess and is occasionally reworked by sheet floods shed from the adjacent ridges. Nodules grow most efficiently in Zone III and IV of the inter-ridge sabkha, with more saline pore waters above and less saline waters below (Figure 3.23). Nodules in zone IV and the uppermost part of Zone II are soft, very friable, uncemented and still maintain high intranodule porosity and permeability. Zones of coalesced nodules can create local upward-bulging enterolithic structures. Nodules made of small gypsum crystals typically overlie nodules composed of larger crystals. The relationship between crystal size and distance from the sabkha surface shows that nodules are precipitating in the active capillary zone and do not form by replacement of an anhydrite precursor. As capillary gypsum crystals continue to grow, the nodule expands by pushing aside and deforming adjacent sediment laminae. The fine-grained nature of the hosting loess encourages displacive growth rather than passive interparticle poikilotopic growth. Minor amounts of authigenic calcite and dolomite are also precipitated.

A marine-seepage origin for the gypsum nodules was inferred by Ali and West (1983) based on the seawater-like proportions of the interstitial brines and periodic gypsum saturation in waters of zones III and IV in the waters of the first inter-ridge depression (Figure 3.23; Table 3.4). But as we saw in Chapter 2 seawater-like proportions in a groundwater do not necessarily mean a seawater origin in continental

areas with caliche. Salinities of phreatic groundwaters in Zone II vary from 40-80‰, with a mean of 59‰, which is almost twice as concentrated as seawater. Na, Mg and Cl are present in thalassic proportions, Sr is somewhat in excess, as are Ca and SO₄, an association that probably indicates ongoing dissolution of gypsum. Above Zone II, salinities increase upward in zones III and IV. Zone IV, with a predominance of growing gypsum nodules has an average pore water salinity of 148‰ (Figure 3.23). The uppermost part of the sabkha interval has the highest salinity pore waters, averaging 327‰, a salinity value that is five times that of zone II. Na and Cl maintain their relative

Figure 3.23. Inter-ridge gypsum sabkhas on the Nile delta, Egypt showing idealised vertical section through the first sabkha depression and the interpreted capillary-driven subsurface evaporation hydrology forming the gypsum nodules that define the sabkha sequence (after West et al., 1979; Ali and West, 1983).

Figure 3.24. Southern coast of Bardawil lagoon, northern Sinai, Egypt, shows beach-lagoon and interdunal sabkhas within the coastal portion of a sand sea dominated by longitudinal (seif) dunes. Sabkha deposition was a response to a rise in the regional water table driven by the end-Pleistocene rise in sea level to its present position some 6 ka (Image courtesy of NASA).

proportions tied to brine concentration in Zones II through V (five-fold increase from Zone II to V). K rises nine-fold over the same interval and Mg about eleven-fold. In contrast the Ca content is almost constant in zones II through IV and drops sharply in zone V, showing that gypsum is actively precipitating in zones III and IV. Sr shows a similar trend to Ca, although it does not decrease as sharply in Zone V. SO_4 increases upward to a concentration in Zone V than is a six-fold increase over its levels in the groundwaters of Zone II.

Ali and West (1981) utilised the measured hydrogeochemistry of the interstitial waters to argue for gypsum precipitation by capillary evaporation of thalassic seepage waters via “per ascendum” rather than a “per descendum” model, although at the time they published their work the latter was the prevailing interpretation for a sabkha hydrology.

This series of Egyptian coastal sabkhas is of interest as it is an active sabkha plain in the low-fluvial-supply (desert loess) coastal portion of the prograding Nile delta. It also shows that extremely arid conditions are not a requirement for evaporite nodule growth; it only needs the appropriate seepage hydrology where the capillary fringe intersects the land surface. These sabkhas are actively accumulating gypsum in a region where annual rainfall is ≈ 18 cm. Once again, like the At Taf sabkha, it demonstrates the lack of preservation potential of any salts precipitated in the seepage hydrology of all modern coastal sabkhas. Once the gypsum nodules are buried into Zone II they are seen to dissolve in rising phreatic brines, which are undersaturated with respect to gypsum (Figure 3.23). Gypsum is being recycled through the upper parts of a subsiding profile and its preservation potential is low (implications of this are discussed further later in this chapter).

Eastern Mediterranean Coast of the Nile Delta and Northern Sinai

On the other side of the Nile delta, the northern Sinai coast is bordered for about two-thirds of its length by the Bardawil Lagoon (Figures 3.22, 3.24; Levy, 1977a, b, 1980). It is a broad marine lagoon with smaller evaporitic sabkha/lagoons in interdunal depressions along its southern coastal interface. The southern part of the Bardawil also defines the coastal desert edge of an extensive sand sea or erg dominated by longitudinal or seif dunes. Regional climate is arid, evaporation rates are high (≈ 2 m/yr) and precipitation is low (≈ 100 mm/yr). Marine-influenced sabkhas on the southern side of the lagoon occur wherever the capillary fringe intersects the landsurface and are of two types: 1) coastal sabkhas (also called lagoon-beach sabkhas-see Warren, 1991), which are at present connected to the lagoon and flooded occasionally by seawater - examples include the inner lagoons and Nahal Yam, and 2) near coastal interdunal sabkha depressions, which are now cut off from the lagoon by sand dunes - examples include Sabkhat Mahzin and Sabkhat Hafirdim (Figure 3.25a). Both types of sabkha formed as a rising marine water table, created by the Late Pleistocene-Holocene transgression, encroached upon the erg. There is also a third type of sabkha in the region; it is typified by large inland eolian sabkhas such as Sabkhat el Mustabag and Sabkhat Bir Kasiba. This group of sabkhas is carbonate rich and formed under a Late Pleistocene paludal hydrology, which was active at the edges of this desert sand sea in more humid climatic periods. Eolian-lacustrine sabkhas are discussed in more detail toward the end of this chapter.

The largest documented coastal-beach sabkha, Sabkhat Nathal Yam, is about 7 km long and extends about 1 km inland. To the south of the lagoon beach sabkhas, coastal interdunal sabkhas

extend inland to a distance of about 1-4 kilometres and are accumulating capillary salts from hypersaline capillary water lenses surrounded and underlain by slightly less saline continental phreatic wedges. These “inland” eolian sabkhas tend to be a few kilometres long and less than a kilometre wide (Figure 3.25a). They define a coast-parallel hydrological transition from marine seepage into continental groundwaters carried in the unconfined aquifers of the regional sand sea or erg.

Both types of sabkha are typified by siliciclastic matrices with displacive gypsum within supratidal evaporitic units up to 60 cm thick (Figures 3.25b, c). The intertidal zone in the beach-lagoon sabkha of Nathal Yam is 200-300m wide and is regularly flooded by tidal waters of the lagoon. The intertidal is characterised by cyanobacterial mats, interlayered with low Mg-calcite muds and containing marine gastropod and

lamellibranch shells derived from the lagoon. Lenticular and prismatic gypsum crystals are growing in the cyanobacterial mat layer in the more landward parts of this zone; it is very similar to the gypsum mush zone of the At Taf coastal strip. Landward of the intertidal zone is a 100m-wide outer flood recharge zone, it experiences no more than an occasional marine flood (a few times a year) during a fortuitous combination of storms and high tide. There the cyanobacterial mat is covered by a thin layer of detrital quartz sand and otherwise lies atop the same basic sequence of sediments found in the intertidal zone. Landward still at the southern end is a 500m-wide supratidal zone. This area is not currently flooded by lagoon waters, even during storms and defines the interval where the capillary zone intersects the land surface. Under an ephemeral halite crust it hosts displacive gypsum lenses and prisms in a matrix that is otherwise identical to its more seaward counterparts.

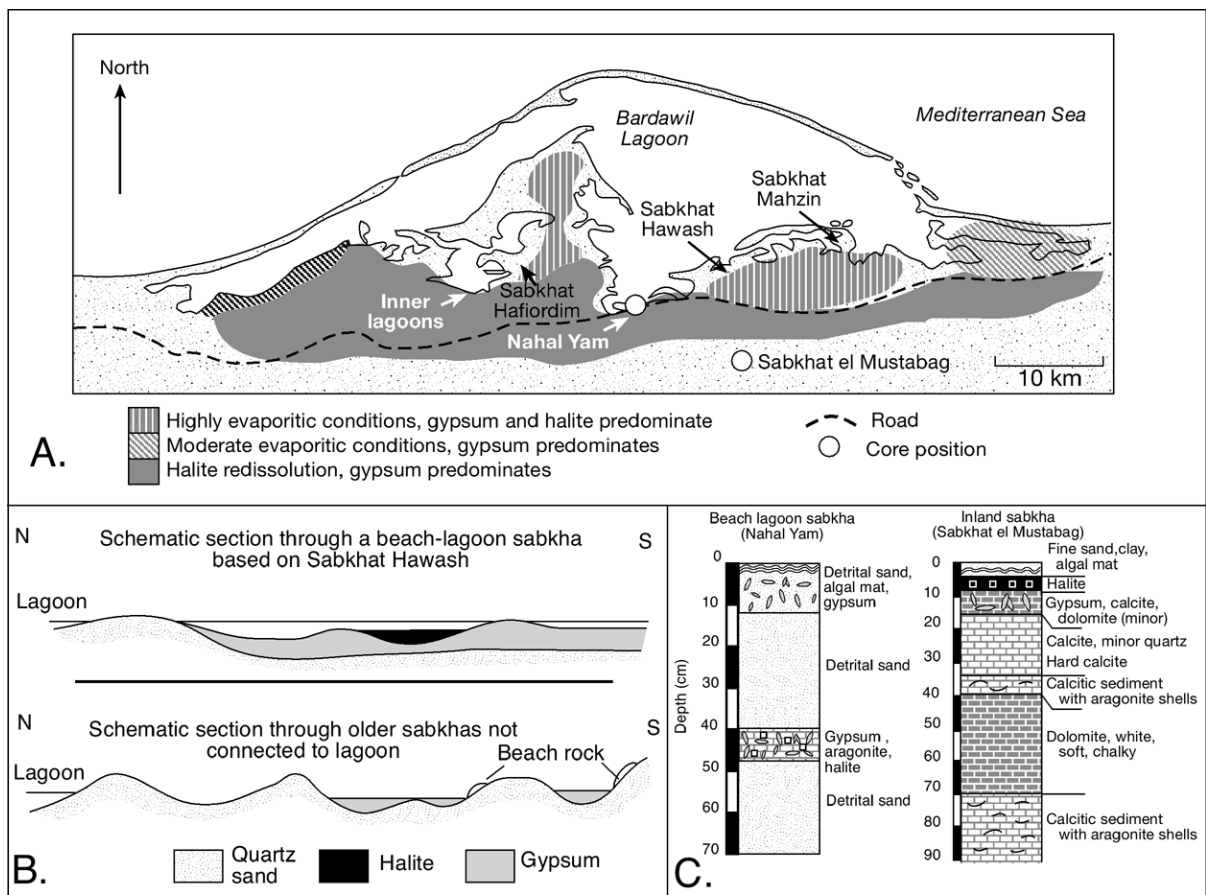

Figure 3.25. Sabkhas of the Bardawil lagoon, Mediterranean Coast, northern Sinai (after Levy, 1977; see Figure 3.22 for locality). A) Distribution and mineralogy of sabkha salts south of the Bardawil Lagoon. B) Schematic cross section through a beach-lagoon sabkha based on Sabkhat Hawash, showing differences in lateral scale with older inter-ridge sabkhas. C) Composite vertical section in a beach-lagoon sabkha based at Nathal Yam, it is based on cores taken at 20m, 500m and 700m from the beach line.

Unconfined continental groundwater, moving north toward the shoreline, periodically seeps into the supratidal zones of all the beach lagoonal and near coast “inland” sabkhas along the southern side of Bardawil Lagoon. Rising water levels occur after heavy winter rains and create ponds of surface water that rapidly evaporate to precipitate thin halite crusts and efflorescences. In fact, most of the present freshened inflow into the supratidal zones both beach-lagoon and coastal interdunal sabkhas comes from a winter groundwater flood from the nearby dunes and not from any influx of storm-derived seawater. This rising water table dissolves most surface halite crusts, as well as some of the gypsum precipitated in the more isolated parts of all sabkhas in the previous summer. The inherent fractionation explains why ephemeral halite crusts are typically found in depressions located seaward of the gypsum-dominated inland sabkhas.

The calcium sulphate mineral in both styles of near-coastal sabkha is a gypsum pore cement, it is not anhydrite. The setting is not saline enough, nor arid enough, to favour the preservation of anhydrite. Groundwater floods in the winter means most crystals of capillary gypsum are periodically flushed by meteoric waters and so show internal layering and lenticular shapes indicative of alternating stages of precipitation and dissolution. Mg-calcite, dolomite and halite are minor authigenic components in some near-coastal sabkhas.

Large inland sabkhas, such as Sabkhat el Mustabag, were possibly once connected to the Bardawil Lagoon, although dunes now cut off all the inland sabkha depressions from the sea (Figures 3.24, 3.25b). More likely, they formed in the Late Pleistocene in an earlier paludal phase at the seepage edge of the Sinai sand sea, when the seacoast was tens of kilometres further out on the exposed shelf. Soft chalky-white calcian dolomite (layer up to 20 - 30 cm thick) caps the upper portions of the sediment fill in some of the larger inland sabkhas (Figure 3.25b). The age of the carbonate precipitates in these older sabkhas is not well constrained. Beneath the dolomitic carapace are well preserved aragonitic gastropod shells, typically embedded in a muddy calcitic groundmass. Radiocarbon dating shows that the dolomite and the underlying unit is older than 35,000 years (Figure 3.25c). It is a lacustral continental sabkha, possibly deposited in a Pleistocene pluvial, with little tie to the present largely vadose hydrology of the inland sabkhas along the landward edge of the Bardawil coastal prism.

Shatt el Arab estuarine sabkha, Iraq

The Shatt el Arab delta lies at the northwestern end of the Arabian Gulf, immediately northeast of Kuwait (Kadmah) Bay. It is an area where three rivers (Tigris, Euphrates, Karun) merge to form the Shatt el Arab delta (Figure 3.26). It is an unusual region in that it is one of a few modern examples of a large modern river delta feeding into an enclosed saline sea and where the amount of eolian sediment in the delta (via the northwesterly Shamal wind) may equal the volume of waterborne fluvial sediment (Evans, 1995).

The Shatt el Arab is fed by a broad funnel-shaped estuarine channel with wide levees on either side. Spreading out from the levees are dense surrounding marshes of reed beds (locally known as *ahwar*). The region was drained under the genocidal policies of Saddam Hussain, but is now being re-engineered to return the reedbed system to its natural state. These areas are flooded each spring and early summer by waters fed from snowmelt in the river headwaters. Large crevasse splays spread into interchannel areas, which in the lower deltaic plain are dominated by brackish to freshwater lakes and dense surrounding reed-bed marshes (Aqrawi and Evans, 1994). Lakes are floored by bioturbated sandy silts and clayey silts, which preserve abundant meshworks of plant roots and a brackish shelly fauna. Crevasse sediments feeding the lakes are well-stratified sandy silts and muds. At its most seaward extent and across Budiyah island an extensive plain of estuarine sabkha takes the place of the reedbed.

Matrix in both the sabkha and the *ahwar* regions is similar. It is rich in detrital carbonates as well as quartz, reflecting the large volumes of outcropping carbonate in the hinterland. What separates the two settings is the lack of higher plants on the estuarine sabkha (instead of root meshworks there are widespread cyanobacterial mats and some local mangroves) and the widespread authigenic precipitation of high-Mg-calcite, calcite, calcian-dolomite, gypsum and perhaps pyrite as capillary salts in the sabkha matrix. Palygorskite is present in the sabkha as both authigenic and allochthonous phases (Aqrawi and Evans, 1994).

The extremely low wave energy attacking the front of the Shatt el Arab delta separates it from other arid-zone deltas, such as the Indus, which show similar 2-3 metre tidal ranges. Due to this low wave energy (limited fetch), only narrow beaches and small coastal dune systems form along the leading edge of this arid zone delta. Rapid progradation of fines forms widespread saline mudflats and sandbars across much of the seaward parts of the delta plain, dissected by tidal channels along the delta

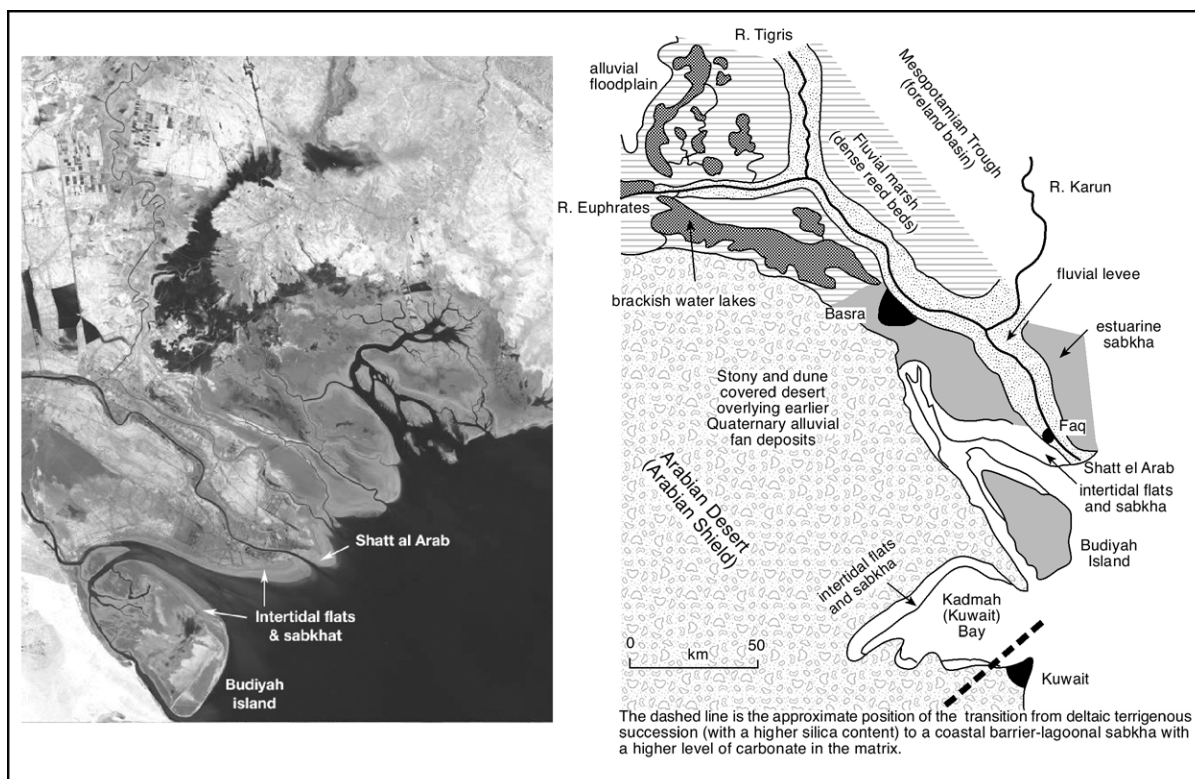

Figure 3.26. Distribution of fluvial related facies including estuarine sabkha with a siliciclastic matrix along the lower length of the Shatt el Arab River. Note Kuwait Bay in lower centre of geology map (Landsat image courtesy of NASA, surface geology after Evans, 1995).

front. Saltpans and gypsiferous sabkhas form behind low relief beach ridges and chenier ridges where surface seawater is trapped after very high tides and storm floods. The resulting evaporitic zones are characterised by crusts of halite and capillary precipitates of gypsum. Anhydrite after gypsum occurs in the most exposed and saline portions of this system.

The seaward extent of this evaporite capped large volume of deltaic sediment is not well established, but the delta lobe probably extends some 100 km from the modern shore (Figure 3.2a; Evans, 1995). Away from the active fluvial-fed portions of the delta lobe, quartzose sands are reworked into a shoalwater complex of elongate tidal bars that passes seaward in prodeltaic marls, which in turn enclose the reef capped Kharg Island off the Iranian coast.

Sabkha sediments, passing updip into dense reed beds, show affinities to similar facies on the Nile Delta. In both, the increasing distance from the active part of the delta explains the change from a quartzose matrix in the delta sabkhas to a more carbonate-rich barrier-lagoon style of sabkha (e.g. Figure 3.26 - dashed line).

Interpretive limitations of models based on Holocene sabkhas

Capillary salts and surface crusts precipitated in Holocene marine-margin sabkhas and many continental sabkhas have low preservation potential. They precipitate in a hydrological fringe underlain by undersaturated waters and below a land surface subject to periodic freshening and flooding. Whether capillary salts form by cooling (thermalites) or pore brine evaporation is irrelevant in terms of their ultimate preservation potential. To pass into the rock record any sequence must, by definition, subside. As it does so, the sabkha nodules, crystals and crusts at the edge of a body of brine of normal seawater salinity must pass back into waters undersaturated with respect to the minerals precipitated in the capillary fringe. At best, what will be preserved of the original salts in the prevailing hydrology at the edge of a normal marine water body will be partially dissolved remnants of the salts and nodules. More likely, the capillary fringe precipitates will become a thin interval of haloturbation textures and dissolution collapse. If, on the other hand, a sabkha succession sits on the edge of a hypersaline saline pan (as in some modern continental sabkhas) or on the

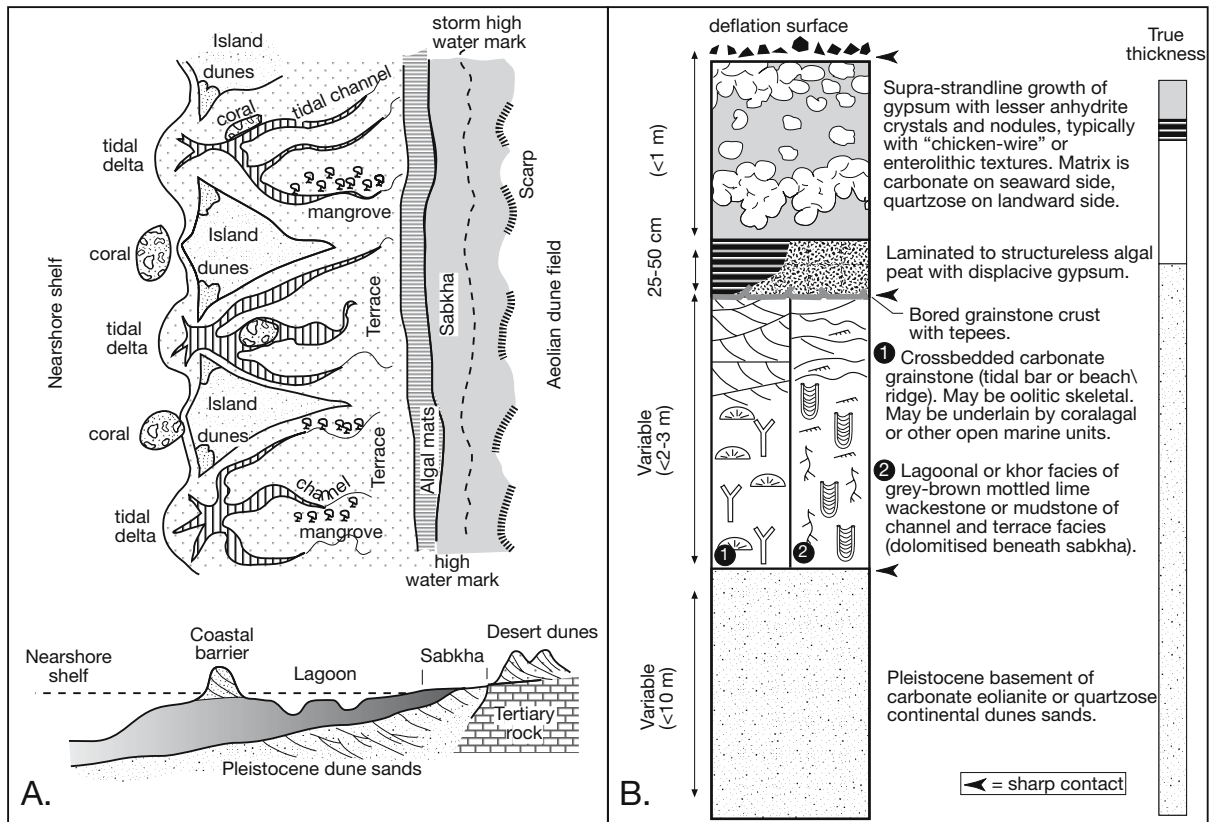

Figure 3.27. Generalised geological model. A) Based on the distribution of the main carbonate facies belts in Abu Dhabi - Khor al B'azm region (in part after Evans, 1995). B) Characteristic vertical succession of sea-margin carbonate sabkha showing typical thickness for each unit, right column shows true relative thickness (in part after Warren, 1991).

edge of an ancient saltern or seaway, then the capillary salts pass into a saturated brine curtain or into the edge of a reflux plume, and so preservation of the original capillary textures is more likely (Figure 5.29).

There are other implications of the sabkha signature always forming in a capillary fringe. A typical sediment distribution model for an ancient sabkha, based on the Abu Dhabi Holocene, looks something like that presented in Figure 3.27. Such models typically do not consider hydrology, bed thickness, lateral extent or structural controls when compiling the sabkha units; they merely use Walthers Law to stack the various peritidal sequences into a vertical succession. Because of this, the Abu Dhabi sabkha analogy is sometimes used to interpret ancient evaporitic platform successions composed of marine carbonate beds interlayered with nodular anhydrites (platform evaporites), without a full understanding of the implications of the requisite sabkha hydrology.

An Arabian Gulf carbonate-hosted sabkha is part of a prograding Holocene ramp where the total succession is composed of subtidal, intertidal, and supratidal sediments. It is capped by a Stokes surface and typically backed by a siliciclastic sand sheet/dune association. The complete Holocene section is no more than 3 metres thick and in the type area centred on the Abu Dhabi region the Holocene sequence is composed predominantly of subtidal lagoonal carbonates. The evaporitic intertidal and supratidal cap is up to a metre thick and always reflects the thickness of the capillary fringe.

Underlying Pleistocene sediments are up to 12 m thick in the vicinity of Abu Dhabi; they are permeable Pleistocene dune sands that directly overlie the Miocene carbonate aquifer supplying solutes to the sabkha (Figure 3.27a). In terms of sediment volume, scaling and perhaps even geometries of accommodated sediment, much of the Abu Dhabi sabkha is best considered to be an eolian sabkha with a water table closer to the landsurface because of proximity to the ocean (eolian sabkhas are discussed in more detail at the end of this chapter).

In its strictest sense, based on relative unit thicknesses, an Abu Dhabi sabkha should only be used as an analogue for ancient successions made up a transgressive subtidal lagoonal carbonate (1-3m thick) with a 0.5 m thick matrix-rich cap containing capillary salts, which is in turn capped by an erosional surface (Figure 3.27b). The whole succession should have been deposited atop a much thicker marine-flooded eolian dune aquifer system (Achauer, 1985). In most Holocene-based analogues for ancient evaporite systems, we modify notions of Holocene thickness and stacking to accommodate great changes in scale and thickness needed to typify ancient epeiric settings. Sometimes this is done without considering inherent hydrological limitations and the laws of fluid physics are unknowingly ignored (see Chapter 2 for hydrological details of various saline hydrologies).

For example, many thick, ancient sequences of pure nodular anhydrite have been interpreted as sabkha deposited under conditions of slowly rising sea level (transgressive systems tract). There are hydrological and preservation restrictions associated with this hypothesis that are not considered in many sabkha reconstructions. The thickness of nodular anhydrite in any supratidal unit is limited by the thickness of the capillary fringe. Any evaporite sediment lying above the top of the capillary zone is blown away or dissolved (Figure 3.27b). Aside from the preservation issues mentioned earlier, this means that the supratidal evaporite phase in a single sabkha cycle (stillstand) can be no more than 0.5-1 metres thick and by definition it is matrix dominated (Warren and Kendall, 1985). Matrix must exist before capillary salts can grow. Hence the difficulty in explaining metres-thick pure nodular anhydrite as a thick sabkha without any encapsulated erosion surfaces. If in an ancient succession a nodular anhydrite is relatively pure and lacks internal erosion surfaces it cannot be a sabkha, it is some sort of subaqueous succession or subsurface replacement front.

The only exception to ancient sabkha sequences being dominated by non-evaporite matrix is when the matrix is composed of mechanically deposited sulphate or halite, perhaps derived by storm or eolian transport from a nearby saltern or saline pan. If such a succession was buried, the result would be a nearly pure sulphate or halite unit composed of sabkha cycles, each 1 to 2 metres thick, interlayered with saltern or saline pan units many metres thick. No modern examples of this style of evaporite deposition exist outside of the stacked saline pan halites in the South American salars discussed in the next part of this chapter. Modern sulphate equivalents are unknown, although they can be commonplace in stacked saltern-dominated marine-fed platform successions such as the Cretaceous Ferry

Lake Anhydrite of the Gulf of Mexico and the Permian Werra Anhydrite of the Zechstein (Chapter 5).

The need to stack sabkhas into hypersaline, not marine, groundwaters also means that wherever matrix-rich beds of nodular anhydrite are metres to tens of metres thick with no intrabed erosional surfaces (Stokes surfaces) then the sequence is not a sabkha. It may be a reflux-cemented marine platform carbonate, or an interval overprinted by burial cements. In my experience many ancient normal marine platforms overprinted by later patchy diagenetic anhydrite nodules and axe-head cements are often misinterpreted as sabkha indicators. In many sequence stratigraphic reconstructions this leads to such intervals being misinterpreted as being formed in times of lowered sealevel. This is especially so in studies by stratigraphers looking for evidence of times of sealevel lowering in platform successions. They tend to ignore the possibility of diagenetic evaporites or the marked differences in eustatic amplitude and frequency that characterise icehouse and greenhouse climate modes (Chapter 5). The presence of a few anhydrite nodules in a core or an FMI image, floating in a matrix of carbonate or siliciclastics, is not sufficient evidence to interpret the sequence as an ancient sabkha.

In the modern sabkha, the evaporites of the sabkha supratidal zone overlie restricted lagoonal sediments; they never overlie open-shelf carbonates. Yet in ancient platform evaporites, many beds of nodular anhydrites have been interpreted as sabkha. Such units typically seal dolomitized open-marine shelf carbonates. Perhaps insufficient time has elapsed in the Holocene for sabkha progradation to form a geologically realistic sabkha cap atop marine platform carbonates. Or perhaps ancient nodular anhydrite beds were deposited in a subaqueous saltern at a time when the platform was an isolated drawdown lagoon (Figure 5.16).

In a few millennia, and only if the At Taf coastal strip undergoes suitable subsidence, the succession of sabkha evaporites, and its formative hydrology, may prograde over the Holocene carbonates of the oolite shoals and the open shelf. And yet, the modern sabkha progrades across the inshore lagoon in response to the protecting action of the offshore oolite-reef shoal. The barrier islands screen the soft sabkha muds and evaporites from the erosive forces of the open gulf waves and the Shamal storms. Once the sabkha has infilled the lagoon behind this buffer, it is unlikely the sabkha will prograde much further seaward without the deposition of another sand shoal or reef a little further offshore.

Yet the sabkha “Trilogy” used by many to interpret ancient nodular anhydrite is supposedly composed of three laterally continuous facies belts with subtidal overlain by intertidal overlain by supratidal sediments, all merrily marching out into a subsiding basin without a change in facies. In reality, sabkha progradation, using an Arabian Gulf analog, must be a punctuated process over geologically significant time scales with the evaporite salts unlikely to be preserved (Warren and Kendall, 1985). A sabkha succession cannot be a simple continuous seaward movement of the “Trilogy”, never broken up by coquinas, barrier islands, ooid shoals, beach ridges or reefs.

Lastly, models used to interpret ancient sabkhas typically regard the Arabian Gulf as a carbonate province with the siliciclastic components ignored, or mentioned only in passing. This should not be the case. In almost all coastal areas along the southern Arabian Gulf the most landward portion of the sabkha is a sediment belt 2 to 6 kilometres wide with gypsiferous evaporites accumulating in an eolian derived siliciclastic matrix. This zone passes seaward into a predominantly carbonate matrix. There are, in fact, numerous modern siliciclastic continental sabkhas both in the Arabian Gulf and elsewhere, all of which show lateral extents more akin to larger scale ancient counterparts than do any modern carbonate-hosted coastal sabkhas (see eolian sabkha section at the end of this chapter).

Lacustrine sabkhas and pans

So far this chapter has focused on sabkhas and evaporitic mudflats in modern sea-margin settings. But at the 10 ka scale these are aerially-limited and ephemeral hydrologic systems, tied to the Holocene coastal highstand, with inherently poor preservation potentials. To study sabkhas that can stack to greater thicknesses and have sizes and volumes comparable to some of the smaller ancient evaporite systems we must move to Quaternary continental lacustrine settings and include hydrology of the saline pan in our modelling of preservation potential.

Modern continental sabkhas contribute to salt deposits with thicknesses of more than a hun-

dred metres and areas measured in thousands of square kilometres. Evaporites in continental sabkhas grow by displacive crystal growth in the capillary zone or in immediately underlying brine-saturated muds. Ongoing growth of capillary salts above the water table pushes the sabkha surface up out of the capillary zone into the vadose zone. This raised and dried continental sediment deflates to create the characteristic erosion/truncation surface. As in models based on modern marine-margin sabkhas, the presence of a Stokes surface is a key feature in recognising an ancient continental sabkha succession. Brine concentration in the saline mudflat is driven by the intensity of capillary evaporation and occurs adjacent to areas of saline pan and even adjacent to perennial subaqueous salt beds. Pans and holomictic brine lakes are needed to generate stable brine plumes or brine reflux curtains that preserves a stacked sequence of salt beds. The presence of a pan or perennial lake next to a sabkha defines the hydrology needed to preserve subsiding sabkha sequences. Their longterm absence is why Quaternary marine-margin sabkhas have little or no preservation potential.

Depositional characteristics

A continental sabkha is the part of a playa mudflat complex where the capillary fringe intersects the landscape. It sits within a sedimentary transition from the basin margin to the lowest parts of the brine-saturated basin floor (Figure 3.28; Eugster and Hardie, 1978):

alluvial fan/ephemeral stream/floodplain → sand flat → dry mudflat → saline mudflat → salt pan

Figure 3.28. Continental sabkha/playa showing various facies belts and processes of solute supply that include surface runoff, meteoric and hydrothermal groundwaters (in part after Kendall, 1992; Eugster and Hardie, 1978).

Figure 3.29. Continental sabkhas. A) Dry mudflat with local eolian dunes on the edge of Owens Lake, California. B) Laminated dolomite-gypsum sediment where capillary gypsum is growing above the water table, the hosting matrix is made up of former perennial lake sediments with dark organic rich layers, Salt Basin Playa, west Texas. C) Transition between dry mudflat and wet flat on with a tepee-overprinted dolomite crust, Salt Basin Playa, west Texas. D) Transition between saline mudflat and saline pan facies, Bristol Dry lake, California. E) Highly etched and disturbed salt crust of completely desiccated saline pan (Devil's golf course; Death Valley). F) Panorama of Death Valley showing juxtaposition of alluvial fan with sabkha/saline pan facies due to steepness of valley walls.

The more landward parts of this depositional association are composed of terrigenous alluvial sediments and their reworked eolian residues in the dry sand flat (Figure 3.29a). The water table is usually deep within these alluvials and so sediments do

not retain the more saline capillary salts, which are the focus of this discussion. They can contain caliche horizons formed by soil moisture fluctuations and perched capillary evaporation. We will come back to these less saline margins settings

in our discussion of various specific examples of modern continental sabkhas. For now, we will focus on those parts of the playa system that do preserve substantial volumes of the evaporite salts, namely, the saline mudflat and the outer edge of the saline pan.

The saline mudflat

The saline mudflat, along with the haloturbated parts of the dry mudflat, define the sabkha belt of a continental sabkha and together make up what is also often called the ephemeral saline lake belt (Figure 3.28, 3.29a; Eugster and Hardie, 1978). The sabkha passes basinward into beds of the saline pan, which are made up of stacks of predominantly subaqueous salt crusts, and landward into dry mudflats, sandflats and alluvial fans. Additional sedimentary facies may be found within the sabkha tract at any of several positions depending on short and long-term changes in the basin hydrology. They include dunefields and lunettes, which are composed of terrigenous sands, mud pellets, or evaporite grains; travertine springs or tufa mounds; and shoreline/strandline features such as sheet deltas, beach ridges, or spits.

Continental saline mudflats (sabkhas) are extensive vegetation-free flats composed of fine-grained sediments with displacive intrasediment precipitates of halite, gypsum and anhydrite or, less often, of more exotic salts such as glauberite, mirabilite and trona. Displacive salts may grow randomly in the capillary fringe as crystals and nodules or be concentrated in dm-thick layers (Figure 3.29b). Backreactions, periodic freshening and progradation may drive alteration, leaching and replacement of salts in this zone and mineral precipitation is sometimes aided by bacterial processes (Rosen and Warren, 1990).

Dry mudflats, with their requirement of a somewhat deeper water table, typically lie closer to the landward edge of a playa and form the rim to saline mudflats and saline pans. Sediments are mostly fine-grained, characterised by primary structures formed under alternating upper and lower flow regime conditions, such as sand-rich layers deposited by sheetflood, along with palaeosol horizons indicating periods of landscape stability. Dry mudflats do not retain evaporite salts, but may show disrupted to massive textures created by earlier intrasediment evaporite growth and dissolution (haloturbation), related to earlier times of higher water tables. Occurrences of actual salts on modern dry mudflats are limited to puffy surface efflorescences related to humidity fluctuations in the soil moisture zone and are destroyed/dissolved with the next light rain or fog.

A feature common to many dry mudflats is a pervasively cracked surface with crack diameters ranging from centimetres to giant polygons tens of metres across. Giant polygons or megapolygons indicate a long-term drawdown of the regional water table associated with longer-term climatic change (Figure 2.41; Neal et al., 1968). Cracks may not be a simple V, but may step across layers, show evidence of multiple stages of growth and be filled by a variety of sediments ranging from sands to muds.

Groundwater transport and fractionation in saline mudflats

Sheet floods in ephemeral lakes are relatively rare, most salts move about the lake flats as soluble load in shallow groundwaters, not as mechanically reworked sediment. Surface water and groundwater always flows to the lowermost point on the playa surface. Groundwater on this journey can come near or to the playa surface a number of times in zones defined by capillary salts and ephemeral efflorescent crusts. Crusts and salt assemblages in early stages of their formation can contain metastable high salinity salts such as epsomite and thenardite, which can even occur at the surface of the most landward parts of a mudflat. But when subjected to fluctuating humidities or light rains the less stable (more soluble) salts are quickly leached back into the dissolved load of the groundwaters and continue their journey basinward down the potentiometric gradient. Brines derived from the partial dissolution of efflorescent crusts are usually simple chemical solutions dominated by one or two major solute species (e.g., NaCl, Na₂SO₄, Na₂CO₃). The less-soluble mineral fraction is then left behind, in the more landward parts of the saline mudflat where it forms a carbonate crust, such as the dolomitic crusts of Salt Flat Playa, west Texas. There, the ongoing accumulation of capillary carbonate has forced the surface crust to buckle and crack into lacustrine mudflat tepees (Figure 3.29c; Hussain and Warren, 1988).

Farther out into a salt basin, ongoing capillary evaporation precipitates new salts as efflorescences on the lake surface or as intrasediment nodules and the process of fractionation can begin all over again. Ongoing repetition of this process means shallow sabkha groundwaters become increasingly saline as they seep toward the lowest part of the lake floor – so saline that even the more soluble salts become stable and can accumulate as intrasediment precipitates (e.g. displacive halite, glauberite, thenardite). Only the most soluble salts are carried into the lowermost portions of the lake basin, so that crusts deposited in salt pans define mineralogically simple bull's-eye patterns with the most soluble salts accumulating only in the lowermost portions of the ephemeral lake floor. Such concentric

or “bull’s-eye” fractionation patterns are often assumed for salts making up ancient sabkhas and pans, with the most soluble salts indicating the deepest part of the basin. But this simple pattern can be complicated by periodic near-unidirectional flooding fed from a single inflow channel, as seen today in some of the sabkhas in the salt lakes of central Australia (e.g. the Warburton Channel into Lake Eyre; Figure 3.51).

Saline pan

Saline pans in modern continental salt lakes are closely tied to the formation of saline mudflats and dry mudflats (Figure 3.30; Lowenstein and Hardie, 1985). They define zones on the salt lake floor where surface brines pond and concentrate long enough to stack into layers and beds composed of aggrading salt crusts (Figure 3.30; Stage II). Pans typically form in drainage sinks

Figure 3.30. Evolution of a depositional cycle in a saline pan setting (after Lowenstein and Hardie, 1985).

situated in the lowest parts of the playa surface. A pan is typically surrounded by a saline mudflat and is frequently underlain by older bedded or layered salt units (Figures 3.28, 3.29d). In Lake Magadi, for example, the pan is defined by a trona bed 40 m thick, while in Bristol Dry lake the saline pan facies can be found intercalated with saline mudflat facies throughout the 400 metres of core recovered from the basin centre.

Pans range in size from small features a few km across to gigantic continental salt sinks as in Salar di Uyuni where the pan area is more than 9,000 km² (Rettig et al., 1980). Textures in the stacked salt layers are a combination of subaqueous aligned features (e.g. chevrons and swallowtails) and exposure overprints (e.g. microkarst pits, subhorizontal erosional bevels and salt-filled polygons) that formed each time pan dried and its surface was exposed (Figure 3.29e). Stacked crusts are usually dominated by halite, but other minerals such as gypsum, mirabilite and trona can be important.

When the pan dries eolian dust is trapped by capillary adhesion on its moist, rough surface or filters down cracks and fissures in the salt crust. Storm waters cover the pan after the next lake flood and the upper part of the salt crust dissolves, while flocculating muds settle onto the solution surface and sink into intercrystalline karst cavities (Figure 3.30, Stage I; Shearman 1970). Ongoing evaporation then creates a new subaqueous salt crust atop the dissolution surface. The knobby surface seen on some playa salt crusts is the result of continual precipitation and fretting of a subaerial salt layer, fed brine by “capillary wicking.”

The halite in the initial crust is often composed of upward-pointing subaqueous halite chevrons (Figure 3.30; Stage II). The freshening episodes plane off the upper part of the chevrons as undersaturated waters eat into the crust along the inter-chevron boundaries and form brine filled pores (Chapter 1). Capillary evaporation and brine reflux then fills the porosity with clear halite cement. Continued dissolution and reprecipitation of halite and other soluble salts in the vadose and capillary portions of the crust can destroy much of the initial aligned chevron texture. The end result of alternating freshening and drying episodes is a bedded stack of salt crusts with pores filled by halite spar, occasional relict zones of aligned chevrons and numerous internal truncation surfaces (Figure 3.30; Stage III).

At the broader scale, the continual addition of new salt crystals from evaporating pore waters causes an increase in the volume of the surface crust, which, once the pan desiccates, lies at the top of the capillary zone. Thickness of the capillary fringe

limits any continued vertical growth of the crust and focuses precipitation into the uppermost parts of the crust, so the crust attempts to expand horizontally. The force of crystallisation creates a biaxial stress in the crust that ultimately forms cracks that grow into overthrust salt polygons or pressure ridges. Freshly exposed thin halite and gypsum crusts in modern pans and sabkhas around the world show this style of polygonal ridging and crestal cracking. But the mechanism creating mature m-thick pressure ridged beds is not crust expansion driven solely via the force of crystal growth. There is also the addition of detrital sediment to the crust via infill of newly formed fissures. Wind-blown detrital sediment fills fissures with successive linings.

Ongoing capillary precipitation means pressure ridges rarely retain the simple inverted V cross section of the infill formed in the initial break in the salt crust. Ongoing salt growth, fissuring and dissolution, along with infiltration of eolian silt and sand into cracks and fissures, deforms and anneals the crust into a variety of knobs, ridges, and pinnacles with a relief of up to a metre above the adjacent mudflat floor (Figure 3.29e). Underlying clays often heave up and out through the axis of the megapolygon suture. Ancient counterparts to salt hosted pressure ridges and megapolygons have been recognised in the Messinian salts of Sicily (Lugli et al., 1999) and the Triassic salts of Cheshire, UK (Tucker, 1981) where they are used as indicators of times of exposure in thick halite sequences. Fissure fills in these ancient counterparts can cut up to 6 metres vertically across stacked halite beds.

Each salt layer in a thick salt pan unit, is in large part derived from the recycling of older salt layers. Layers are separated and crosscut by mud partings composed of detrital material carried in by floodwaters or eolian detritus blowing across the emergent salt surface. The final buried sediment is a thick bedded-salt composed of randomly aligned recrystallised evaporites. Saline pans form relatively pure salt units, which are metres thick, layered, and crosscut by fissures filled with eolian or detrital impurities. This type of bedded salt, which has been subjected to ongoing exposure and capillary evaporation, contains randomly aligned and overprinted crystals precipitated from a brine hydrology characterised by crystallisation, dissolution and recrystallisation. It contrasts with bedded salt deposited in the relatively stable perennial brine hydrologies of a more-or-less continually subaqueous saline lake where, even after burial, the crystals in the stacked crusts still retain a growth aligned fabric of upward pointing large gypsum crystals, chevron halites, or trona prisms (see perennial lake discussion in the next chapter).

Styles of continental sabkhas

Mudflats, sabkhas and saline pans occur as parts of three saline lacustrine settings (Hardie et al., 1978);

- Alluvial fan–ephemeral saline lake
- Ephemeral stream floodplain - dune field–ephemeral saline lake
- Perennial stream floodplain–perennial saline lake

Settings are not static and changes in tectonics or climate can cause one setting to evolve into another. Texture of the capillary precipitates are similar in all three, but differences in lacustrine hydrology means continental sabkhas are more widespread in ephemeral lake systems than in perennial lake systems, which seem to require steeper sided basins (Table 4.7).

Alluvial fan–ephemeral saline lake

The alluvial fan–ephemeral saline lake depositional complex typifies fault-bounded, orogenic basins in tectonically-active arid areas. Tectonism generates topography and increased contrast in thermal gradients, so that water volumes seeping into the evaporitic mudflat (continental sabkha) and adjacent pan can be quite high, fed predominantly from groundwater and occasional storm runoff. Such arid intermontane lows can be covered by extensive continental sabkhas, with areas of saline pans in the lowermost positions on the playa floor (Figure 3.31). Modern examples range across various tectonic settings and include intermontane playas in the Basin and Range of North America, salars of the Central Andes, some East African rift valleys, saline valleys at the southern end of the Dead Sea transform, and playas on the Tibetan Plateau and Mongolia. Of the two ephemeral lake settings, it is the one where thick sequences of evaporitic salts are more likely to be preserved due to rapid subsidence. Ancient counterparts of this style of deposit include the saline mudflat and pan facies in the Wilkins Peak Member of the Eocene Green River

Formation, Utah, the Tertiary borate deposits of Turkey and Cambrian Lake Parakeelya of the Officer Basin, South Australia (Fischer and Roberts, 1991; Helvaci, 1995; Southgate et al., 1989). Let us now look in more detail at the geology of few Quaternary examples.

Sabkha Yotvata, Israel

Sabkha Yotvata is a continental sabkha with an aerial extent of 45 km²; it infills the entire 10 km width of the southern Arava Valley (Figure 3.31a; Amiel and Friedman, 1971). It is located some 45 km north of the Red Sea and 110 km south of the Dead Sea in the Great Rift Valley, the transform depression separating

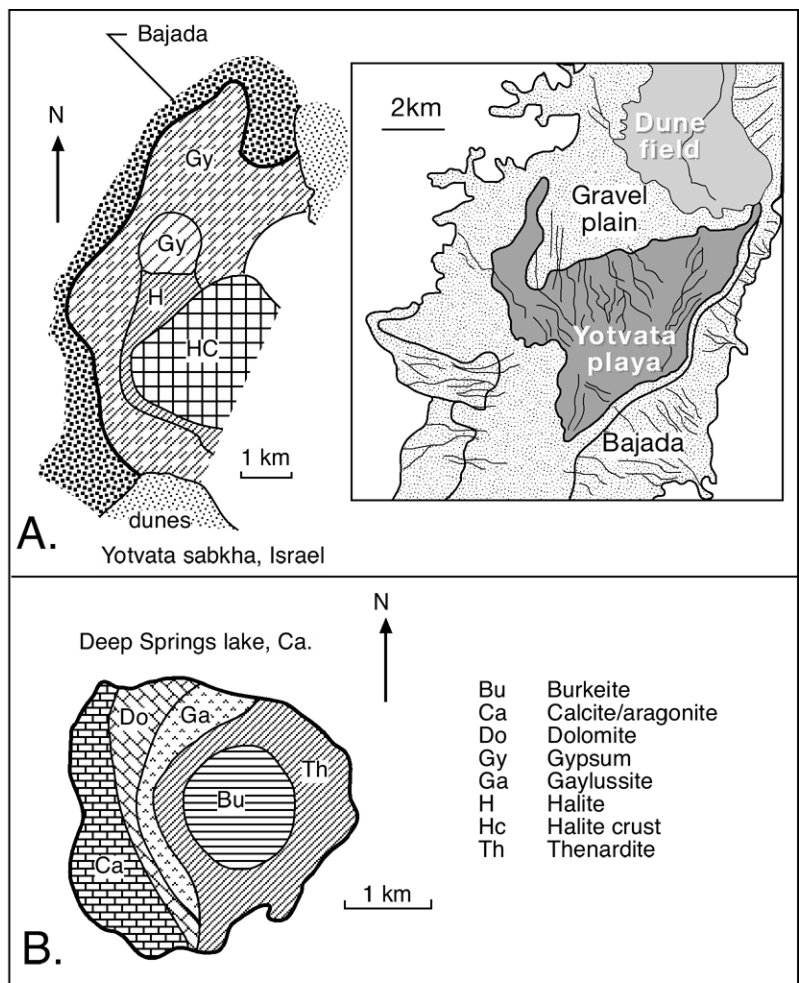

Figure 3.31. Surficial geology of continental sabkhas. A) Sabkha Yotvata, Israel, (Amiel and Friedman, 1971; Amit et al., 1999) and, B) Deep Spring Playa, California (Eugster and Hardie, 1978). Note the off-centre bull's-eye pattern in the distribution saline salts indicating nearsurface seepage fractionation and the accumulation of the most saline salts in the lowermost part of the playa floor.

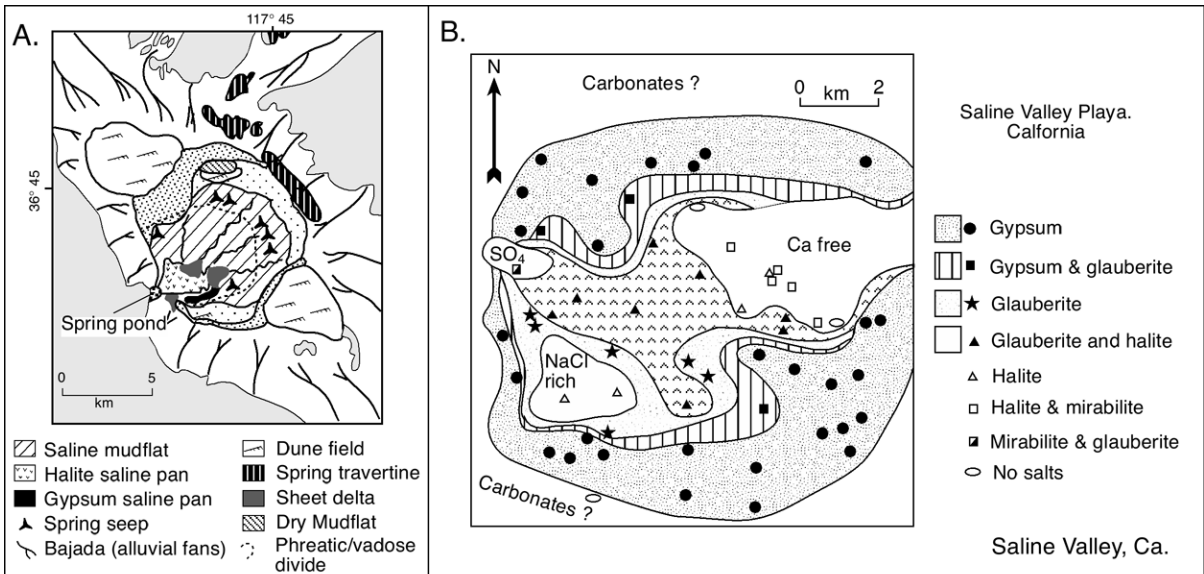

Figure 3.32. Saline Valley Playa, California. A) Regional sediment distribution (after Hardie et al., 1978). B) Distribution of intrasediment evaporite salts in the saline mudflat (sabkha) part of the playa. The concentric of “bull’s-eye” pattern with the more soluble salts in the lowest parts of the area indicates fractionation and progressive concentration of groundwater seepage (after Hardie, 1968 and Smoot and Lowenstein, 1991).

the Jordanian and Palestinian plates. The Yotvata valley floor is only 75 m above sea level. To the east and west the sabkha is bordered by steep-sided valley margins; to the east the valley wall rises up to 1300 m above the valley floor while to the west it rises up to 600 m. Differences in relief are a response to current movement on the Avrona Fault zone. Some 1km wide and 35 km long, the Avrona Fault extends in a NNE direction from the western margin of the northern coast of the Gulf of Elat across the Avrona Playa and up along the steep eastern side of the Yotvata Playa (Amit et al., 1999). North of the Yotvata Playa it dies and merges with the prominent strike-slip fault that trends north to become the Dead Sea Fault.

Steep valley walls have led to the development of an extensive bajada, which interfingers with the evaporitic sediments of the sabkha. In the valley to the north of the sabkha is an extensive dune field extending some 40 km up the valley. To the south is another smaller dune field, which partially covers the southernmost sediments of the sabkha.

Matrix sediments are furnished to the sabkha by sheetfloods and a series of short ephemeral streams (wadis) on the bajada, fine silts and sands are blown into the sabkha by northerly winds from the dunes. Matrix grain size in the sabkha shows a bull’s-eye pattern of distribution with fine to coarse sands and pebbles about the margin and silty to sandy clays in the centre. North and south the grain-size bull’s-eye is complicated by the

presence of dune sands. The displacive evaporite salts of the sabkha grow in the capillary and phreatic zones and also follow a bull’s-eye pattern related to efflorescent/capillary fractionation of the groundwater; gypsum dominates the periphery and halite the lowermost central portion of the sabkha. The water table is as deep as 4 m about the bajada periphery and shallower than 1 m beneath the sabkha. Puffy ground and dissected halite crusts form the ephemeral saline pan facies in the lowest part of the valley, whereas displacive nearsurface gypsum grows in the capillary zone of the adjacent saline mudflat.

Basin and Range playas, USA

Saline lakes with extensive mudflats and smaller areas of saline pans, both surrounded by extensive alluvial aprons (bajada) characterise many of the depressions in the arid zone of the south western USA. These saline systems are locally known as playas. Tectonically, the depressions hosting the sabkhas are a response to extension and transform faulting.

Deep Springs Lake, California

Deep Springs Lake is a small 5-km wide playa in Deep Springs Valley in eastern California, just east of Owens Valley (Figure 3.31b; Jones 1965). Holocene faulting has dropped the valley floor some 1500 m in the southeastern corner to form a 5-km² playa with a 1-km² saltpan near its centre. The playa is fed by

a series of tufa springs with waters that have been in contact with igneous and metasedimentary rocks. The pan in the lowest part of the playa floor is occupied by soluble, mainly Na-rich salts—thenardite, burkeite, trona and halite—deposited as a bedded crust deformed into overthrust pressure ridges. Dolomite precipitates in the more peripheral, less saline areas (Peterson et al., 1963). The playa is surrounded by the distal sediments of a series of alluvial fans with carbonate-cemented tufa springs at their feet. Volumetrically the capillary and pan salts are a minor portion of the valley-fill which is dominated by alluvial fan and sand flat (distal fan) facies.

Saline Valley playa, California

Saline Valley playa is a small continental sabkha-salt pan playa in a fault-bound graben located east of Owens Lake across the Inyo Mountains. Amalgamated alluvial fans (bajada), fed from adjacent mountains, are dominated by debris flow deposits; their slopes are short and steep with little sandflat development around their bases (Hardie, 1968; Hardie et al., 1978). In contrast, fans at the NW and SE ends of the depression are more longitudinal to the basin axis and so show lower gradients allowing eolian sand sheets and dunes to accumulate adjacent to wind-reworked fan toes (Figure 3.32a). Zones of groundwater seepage are marked by Pleistocene travertines and active spring mounds.

Sabkhas (saline mudflats) cover a large portion of the basin floor and are dissected by sinuous seepage channels, while a halite-floored saline pan defines the lowest part of the playa. Pan facies are made up of dm-thick halite beds separated by mud layers with abundant intrasediment crystals of halite, glauberite and thenardite (Figure 3.32b). Glauberite crystals and moulds of mirabilite, now filled with glauberite, are common in the sabkha or saline mudflat. Along the southern zone of the saline mudflat is a belt of layered aligned gypsum that probably formed by intense capillary fringe evaporation like the texturally identical capillary gypsum crusts defining the sabkha edge of Bristol Dry lake (Rosen and Warren, 1991). The sulphate-rich northwest corner of the mudflat is tied to ponding and evaporation of seepage waters from a nearby spring.

Bristol Dry Lake, California

At the surface, the Bristol Dry Lake basin in the Basin and Range province of California exhibits what appears to be a slightly off centre bull's-eye distribution of surface and near surface salts (Figure 3.33; Handford 1982; Rosen 1991). Low-gradient alluvial fans ring the 10-km wide playa, while extensive calcretes and pedogenic calcites, associated with halophyte plants, cement mid-to-distal fan gravels and sands. Basinward of the distal fans, in the playa margin facies, is a gypsiferous sabkha some 300 m wide where celestite precipitation forms

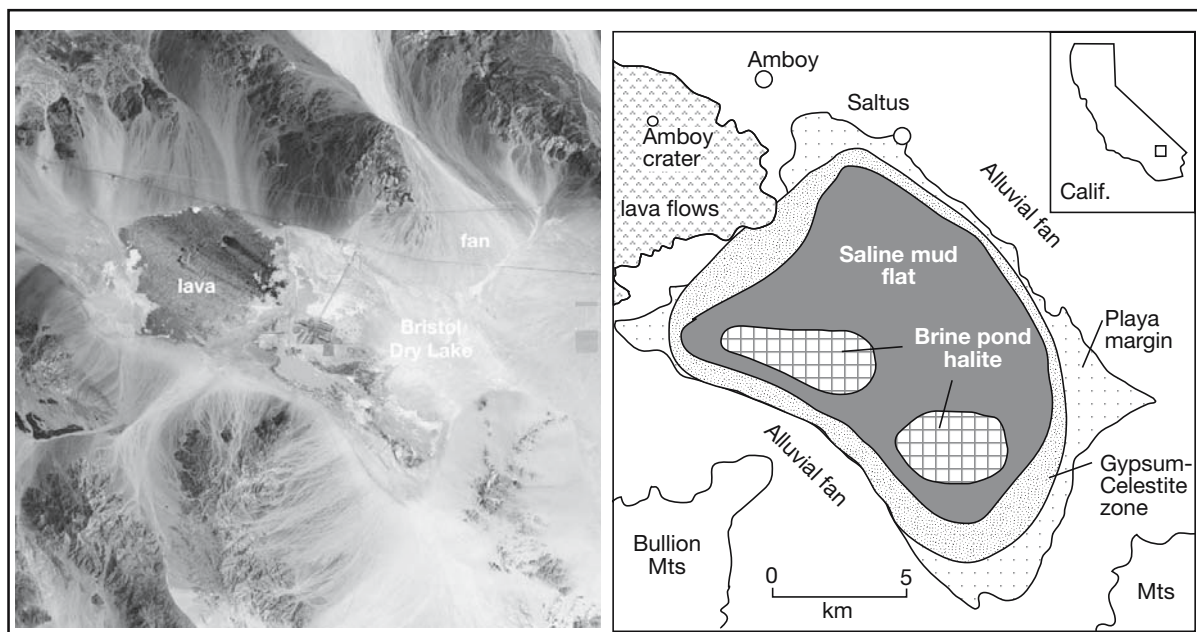

Figure 3.33. Bristol Dry Lake, California. The continental sabkha facies shows concentric pattern of intrasediment salt growth with an outer gypsum capillary pavement and an inner halite saline mudflat, the halite pan facies is slightly offset from the centre and occurs in the lowest parts of the lake in the southern part of the depression (Landsat image courtesy NASA, surface geology after Rosen and Warren, 1990).

Figure 3.34. Generalized stratigraphy based on Bristol Dry Lake from the alluvial fan margin into the saltflat saline pan centre. (after Handford, 1991; Rosen and Warren, 1990).

large decimetre-size nodules that can coalesce into metre-size patches. The gypsum unit is characterised by a growth-aligned fabric created by competitive alignment of gypsum prisms in a zone of capillary wicking (Figure 3.34; Rosen and Warren, 1990). Once these gypsum crystals are buried and converted to aligned anhydrite nodules it would be next to impossible to

distinguish them from the much more commonplace subaqueous textures. Basinward of the playa margin facies, halite hoppers (up to 0.5 m in diameter) form displacive intrasediment precipitates in brine-saturated muds of the saline mudflat facies. Finally, in the basin-centre depression a 0.2-m thick chevron-halite crust (salt pan) is forming by evaporation of ponded ephemeral waters.

The lateral facies distribution seen at the surface also stacks throughout the entire length of deep cores collected in the playa (Rosen 1991). Saline pan halite beds alternate with halite-saturated siliciclastic muds in a 500-m core from the basin centre. Playa margin cores exhibit alternating beds of playa margin sediments and saline mudflat (sabkha) units for most of their length. Towards the base of the deepest playa-margin core, distal alluvial fan sediments are also present. Rosen (op. cit.) notes that a delicate balance between subsidence and mechanical/chemical deposition of minerals was necessary to maintain a vertically-consistent ephemeral brine environment during the deposition of over 500-m of basin fill.

I would say this is not really an example of some rather unusual delicate balance preserved in the sedimentary signature, so much as it is evidence of a hydrological/deflation forcing mechanism.

It is the same Stokes surface hydrology that drives sedimentation in the sabkha and pan regions of most Quaternary continental playas and sea margin sabkhas. Accommodation space in the Bristol Dry Lake depression is created by subsidence in a tectonically active region, in what has been a variable but

mostly arid climate throughout the basin's Quaternary history. The basin's hydrology dictated the contrast in accumulation styles between the salt rich succession in the basin centre and the coarser siliciclastic dominated basin edge. The volume of sediment accumulating in the basin centre in Bristol Dry Lake can never surpass the ability of the wind to blow any dried sediment out of this depression centre into surrounding areas. That is, the surface of the sedimentation in the basin lowermost parts is maintained by deflation at a position that is always near the water table. The only types of sediment that can remain in the arid basin centre are in equilibrium with the water table and the top of the overlying capillary zone. When the water table was a metre or so below the sedimentation surface, aggrading sediments were held in place by meniscus forces inherent to the capillary fringe and accumulated in saline mudflats as sabkha sediments. When the water table rose to become a water surface, it created a semipermanent saline brine pan that then deposited and stacked salt pan crusts.

Basin edge sedimentation was not hydrologically forced but built up as volumes of centripetally-supplied sediment accumulated. This in turn facilitated the creation of an aggrading potentiometric head feeding ground and surface waters to the basin centre lows. About the edges of Bristol Dry Lake, where the accumulating clastic sediment is closer to its source, it is coarser grained and less liable to deflation. Clastics are accumulating in sufficient volumes to build facies belts situated well above the regional water table, hence the accumulations of alluvial fan, dune and sandflat sediments. At times when the subsidence rate exceeds the rate of sediment supply in this area, its hydrology becomes more like that of the basin centre and saline mudflat facies come to dominate over much of the playa floor. Such a hydrologically forced system means that when regions of maximum subsidence in a basin change position, it moves the position of the hydrologically forced sediments into the new lowermost areas on the playa floor. Ultimately, once the rate of subsidence decreases to where the rate of clastic sediment supply exceeds the ability of the wind to deflate, the margin sediments will cover the whole basin and evaporite sedimentation will cease.

Death Valley playa, California

Death Valley is probably the best known playa of the Basin and Range setting in the USA, yet Death Valley is a very steep sided and unusual lacustrine depression. Its floor is some 24 m below sea level, making it the lowest continental locality in the Western Hemisphere. Its steep sides mean it is likely to become a perennial saline lake with minor changes in climate

(Chapter 4). In many areas of Death Valley the coarse-grained debris flows of the alluvial fan directly abut the salt crusts of the sabkha and the saline pan. Sandflats and dry mudflats, so obvious in most Basin and Range playas, are poorly developed or absent in Death Valley. This too reflects the steep valley walls (Figure 3.29f) and its relatively high water table in relation to the lake surface. It is a rapidly subsiding saline lacustrine system in which more than 50% of the Quaternary sediment fill beneath the lowest parts of the lake floor are dominated by saline lake and pan halite rather than matrix-rich evaporitic mudflat (sabkha).

This is clearly seen in a 90 metre length of core (DV93-1), which returned an interbedded salt and mud sequence extending back some 200,000 years (Figure 3.35; Li et al., 1996, 1997; Lowenstein et al., 1999). Minerals intersected in the core include sodium chloride (halite), sulphate minerals (glauberite, gypsum, and thenardite), and carbonate minerals (calcite and dolomite). Glauberite, gypsum, and thenardite occur in mud layers or partings as randomly oriented, mud-incorporative crystals. They are thought to be early diagenetic and to have precipitated from nearsurface ground waters within saline mudflat or sabkha settings. Carbonate minerals calcite and dolomite occur as rhombs to irregularly shaped crystals that are less than 5 μm in diameter. Vertically, there are significant mineral assemblage variations in the core. Abundant glauberite and gypsum, and relatively small amounts of calcite (13%-35% of > 1 μm size insoluble fraction) are associated with both sabkha and subordinate saline pan settings. They formed in relatively dry periods from 0 to 10 ka and 60 to 100 ka (0-8 m and 60-90 m depths in the core, respectively). Sabkha sediments (0.25-7 m, 60-78 m, 87-90 m) consist of muddy silts with sand patches and mud cracks and accumulated during long periods of desiccation. They indicate sedimentary accretion via formation and incorporation of efflorescent salt crusts in the accreting sediment matrix. These episodes of sabkha and subordinate saline pan deposition indicate periods when Death Valley was relatively arid and the sedimentation surface was the top of the capillary zone over much of the valley floor, similar to the modern setting.

In contrast, most of the remaining intervals in the core are characterised by sparse CaSO_4 -bearing minerals and relatively high amounts of calcite (20%-50% of the >1 μm -size insoluble fraction). These are intervals where much of the sediment is halite rather than mud-dominated. It defines a time 10 to 60 ka (8-60 m) when the basin-floor water table was above the sedimentation surface for long periods of time, including the 25,000 year wet period when Death Valley contained a perennial

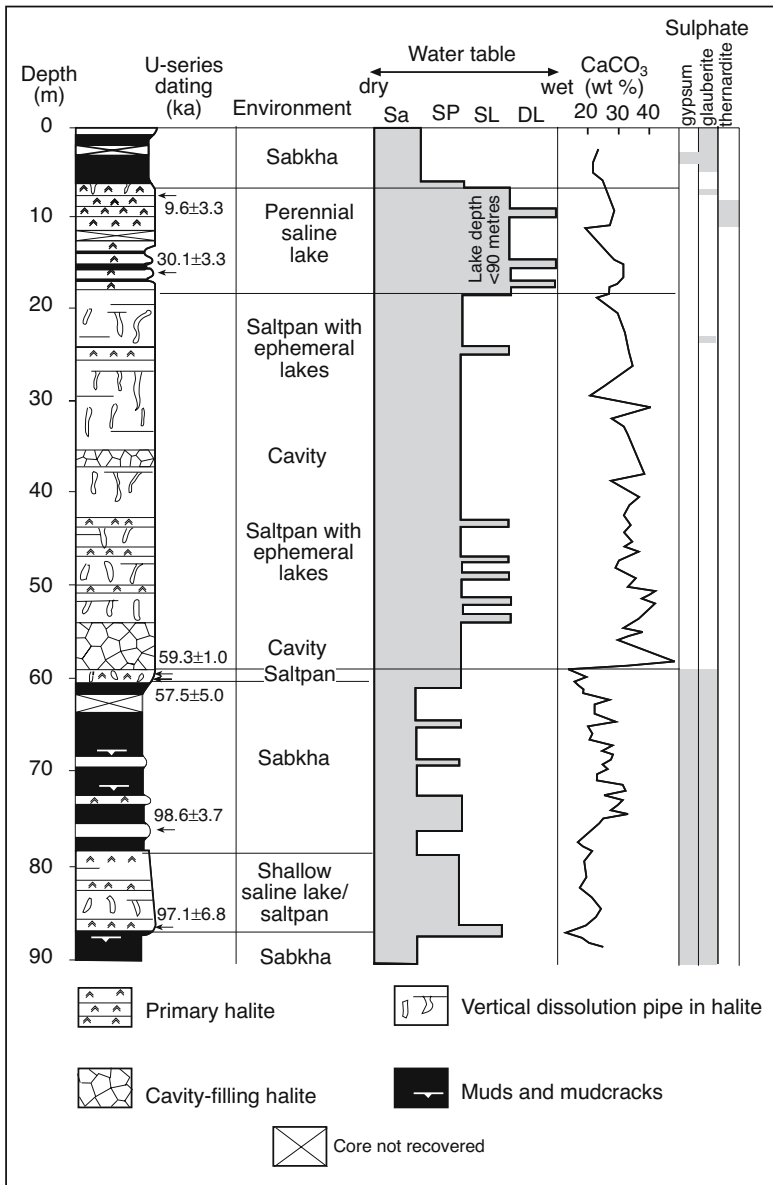

Figure 3.35. Stratigraphic column of upper 90 metres of core DV-93-1 from Death Valley, California (after Li et al., 1997). Lake levels and water table fluctuations are shown ranging from driest (sabkha) through saline pan (SP) to the wettest lacustrine phases of saline lake (SL) and deepest lake (DL). The dominant evaporite mineral is halite and the position of the sulphate evaporites in the core, as well as the weight percent CaCO₃ in the > 1 µm fraction, are also shown.

halite lake (10 to 35 ka; 8-18 m) and the 25,000 year period when the floor of Death Valley consisted of saline pan-ephemeral saline lake environments (35 to 60 ka; 18-60 m; Figure 3.35). Core intervals through saline pan sediments are composed of interbedded halite, chaotic muddy halite, and mud. The halite contains abundant vertical dissolution pipes, cemented with clear halite, indicating the water table periodically dropped below

the surface of the stacking halite crusts. These sediments record repeated flooding by dilute waters, dissolution of subaerially exposed surface salt crusts, deposition of mud from suspension, precipitation of halite during the saline lake phase, and cementation by diagenetic halite (Li et al., 1996). Such deposits document a relatively wet climate with a high ratio of water inflow to evaporation compared to today. Ostrocodes in mud layers represent the least saline, deepest lake phases when, based on the position of beach deposits in the valley walls, water depths in the deepest part of the lake were as much as 90 metres. Halite layers are made of fine-grained cumulates and clear, vertically oriented crystals precipitated during shallower, perennial lake stages. The near complete absence of syndepositional dissolution textures in saline minerals precipitated in the perennial saline lake interval, imply that the accumulating salts were permanently protected from dissolution by an overlying perennially-saline at times holomictic water column (see detailed discussion in Li et al., 1996).

According to Li et al., 1997, the interval with little glauberite and gypsum, and relatively abundant calcite, dated from 10 to 60 ka (8-60 m), corresponds to the last glaciation, i.e., stages 2 and 3 of the marine oxygen isotope record. This was a relatively wet period in Death Valley. The intervals with abundant glauberite and gypsum and relatively low calcite correspond to the Holocene and to stages 4 and 5 of the Quaternary marine record, which were two relatively dry periods in Death Valley. Therefore, mineral assemblages correlate with wet and dry climate cycles in Death Valley (lake versus mudflat), which shows once more that mineral assemblages, depositional style and brine chemistry are all linked to climate changes (Chapter 2).

Salars of South America

The greatest thicknesses and volumes of evaporites currently accumulating anywhere in the world are doing so in the various collision related intermontane depressions and deserts of South America. More than a hundred salt-crusts pans or playas, locally known as salars, characterise depressions in the high-relief arid region of the central Andes and constitute salt deposits with areas ranging from more than 9000 km² to less than 1 km² (Figures 3.36, 3.37). Some have been harvested on a small scale since the mid 19th century for their chloride, nitrate, borate and iodide salts. Huge state-of-the-art brine extraction/processing plants have come to operate in some of these salars in the last two decades and have taken much of the world market from similar older smaller facilities in North America (Chapter 11).

Salars occur within a tectonically active region of largely interior (endorheic) drainage over an area of more than 400,000 km². It extends from the arid to semi-arid deserts of the Andean highland plateau (Altiplano Puna) down to the hyperarid Atacama desert, an area that is so arid that nitrate salts form widespread (and mineable) pedogenic precipitates (Figure 11.42). Altiplano Puna was uplifted in the Miocene and is characterised by an average elevation greater than 3000m and widespread endorheic drainage. Salars of the Puna are either “wet” or “dry” and similar styles of arid deposition have dominated their fills throughout their Neogene histories (Alonso et al., 1990).

Dry salars are characterized by high rates of evaporation and are starved of detrital sediment. Fluvial input is restricted to rare flash floods and groundwater seepage is the dominant source of solutes. Stacked crusts of salar halite are typically in direct contact with basin margin gravels. Desert indicators are abundant in the clastic edge and include, eolian sands, polished clasts, varnished cobble, desert pavements and gypcrete soils. Volcanism, either by ash fall or hydrothermal circulation is the parent to almost all solutes accumulating in the basin. Examples include; Salar de Uyuni, Salar de Atacama, Salar Grande and Salar Arizaro.

Wet salars are fed by permanent streams, in addition to groundwater seepage. These salars have perennial brine lakes and evidence of fluvial deposits, especially alluvial fan deposits, is more significant in the fill than in dry salars. Salar fill is typically alternating beds of clastics and evaporites. The slightly wetter (but still arid) environment of deposition is indicated by mud cracks, raindrop prints, bird tracks, ripple marks, desiccation breccias and preserved plant fragments. Modern examples include the Pastos Grande and Hombre Muerto salars.

The hyperaridity of much of this region of South America reflects a confluence of a number of desert-forming conditions (Table 2.2). First, it lies in the Horse Latitudes, a region of permanent subtropical highs locally blocking influence of the semi-permanent South Pacific Anticyclone and so limiting the influence of winter storm tracks from the south. Second, offshore upwelling of the cold northward Humbolt current creates an atmospheric temperature inversion ($\approx 1000\text{m}$ elevation) that prevents inland penetration of Pacific moisture. And third, the Atacama Desert lies on the western flank of the high Andes and so sits in a rain shadow not subject to tropical/subtropical moisture from the east. The driest part of the Atacama, which is 50 times more arid than Death Valley, California, in effect lies in a “double” rain shadow with the Andes to the east and the Coastal Range to the west (Figures 3.36, 3.37).

The region has experienced arid to semi arid climate as far back as the Middle Miocene, when the modern Andes were first uplifted to form a barrier to easterly trade winds. Uplift anchored the South Pacific Anticyclone to the western bend in the South American continent. Uplift of the Andes to its present elevation may have occurred as early as 15-19 Ma, although palaeobotanical evidence suggests the Central Andes were at half their present elevation some 10 Ma (Vandervoort, et al., 1995; Gregory-Wodzicki, 2000). The Humbolt current has been active since the Early Tertiary, but reached its present intensity either during a major expansion of the Antarctic ice sheet 15 Ma or after the Isthmus of Panama formed some 3.5 Ma (Chapter 5). Onset of Miocene aridity also shut down the meteoric flushing that drove supergene enrichment needed to create the giant porphyry copper deposits of the Southern Atacama (Sillitoe and McKee, 1996).

There are four Neogene evaporite domains in the Andean highplain (Figure 3.38a; Alonso et al., 1990). Deposits change from only travertine in the north, to a mix of travertine, gypsum and minor borate, to completely evolved halite dominated successions in the south, with borate-rich sequences along the eastern Puna. Older halite-rich successions are often caught up in subsequent tectonism and become halokinetic sources to modern salars such as Salar de Uyuni and Salar Atacama. The southward change from travertine to halite is consistent in deposits ranging in age from the Miocene until the present and probably indicates a consistent trend of increasing aridity from north to south since the Andes first arose in the Miocene (Alonso et al., 1990).

Present day rainfall in the Andean Highlands ranges from <50 mm in the vicinity of Salar di Maricunga and nearby areas in

Figure 3.36. Saline lakes (salars) of the desert belt of South America, shows the proximity of many salars to active rhyolitic/andesitic volcanoes in the Altiplano (refer to Figure 3.37 for location of individual lakes and salars (Landsat image courtesy of NASA).

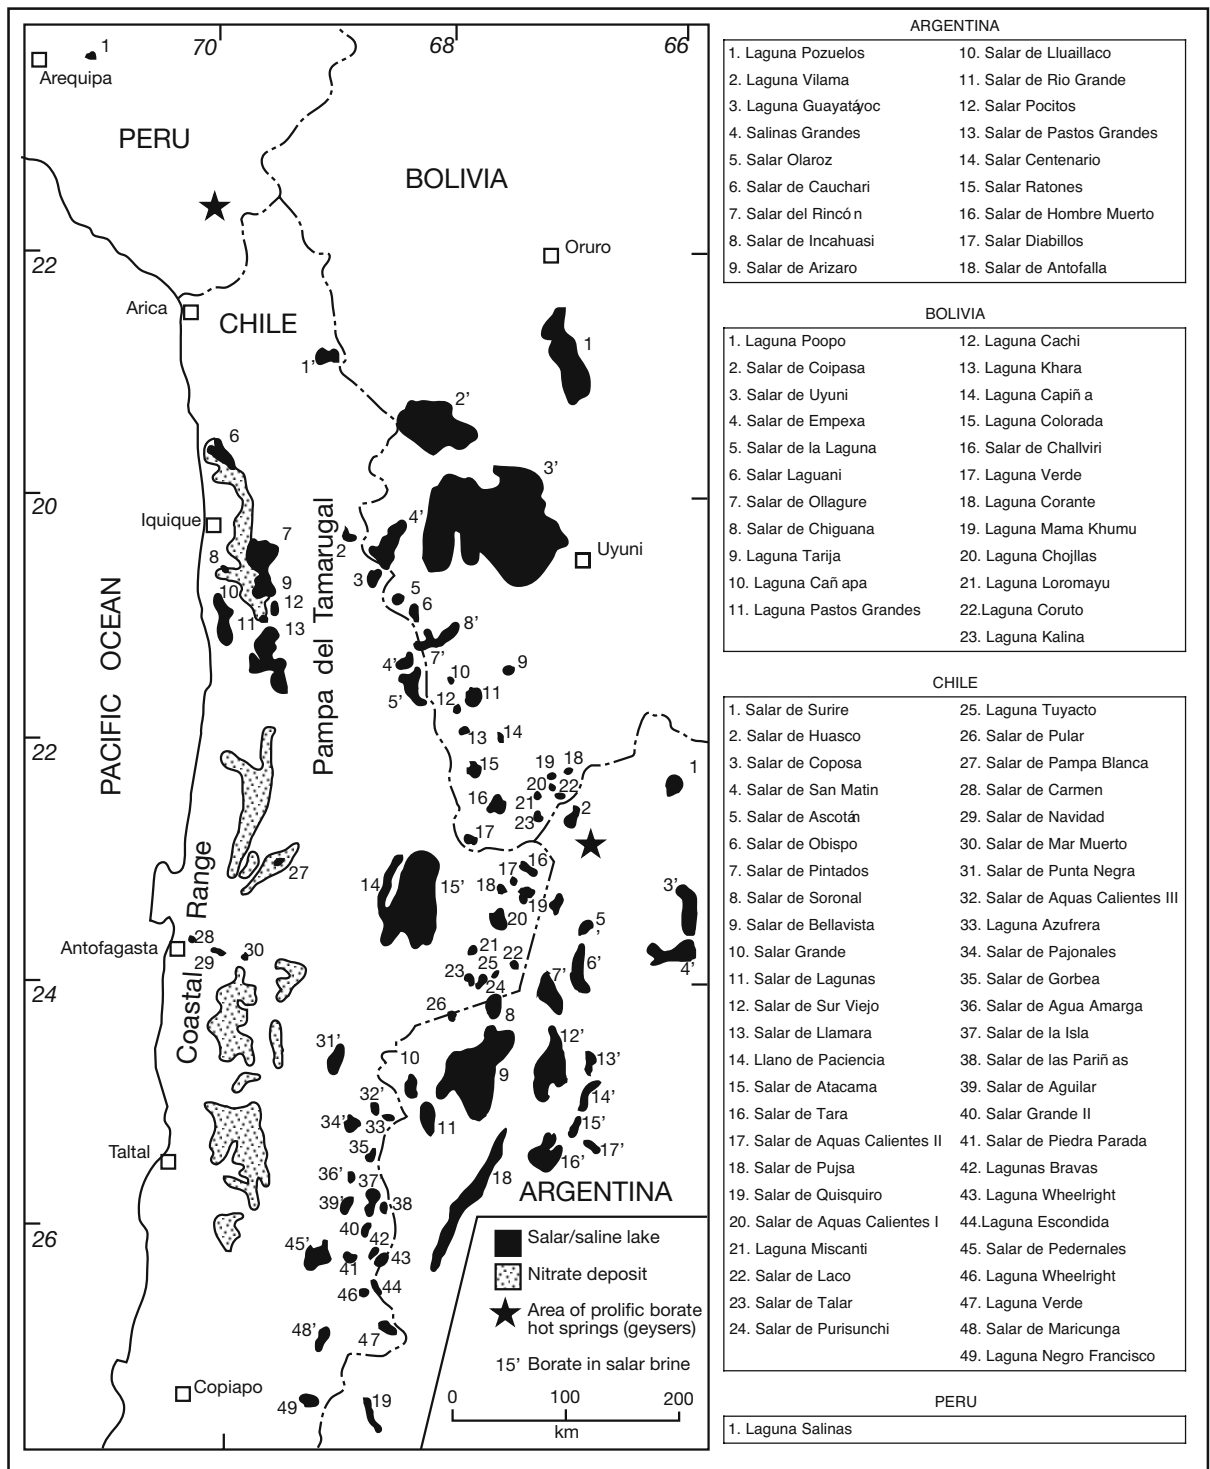

Figure 3.37. Index of the main salars and salinas and nitrate deposits in the central Andes, South America (after Ericksen, 1993).

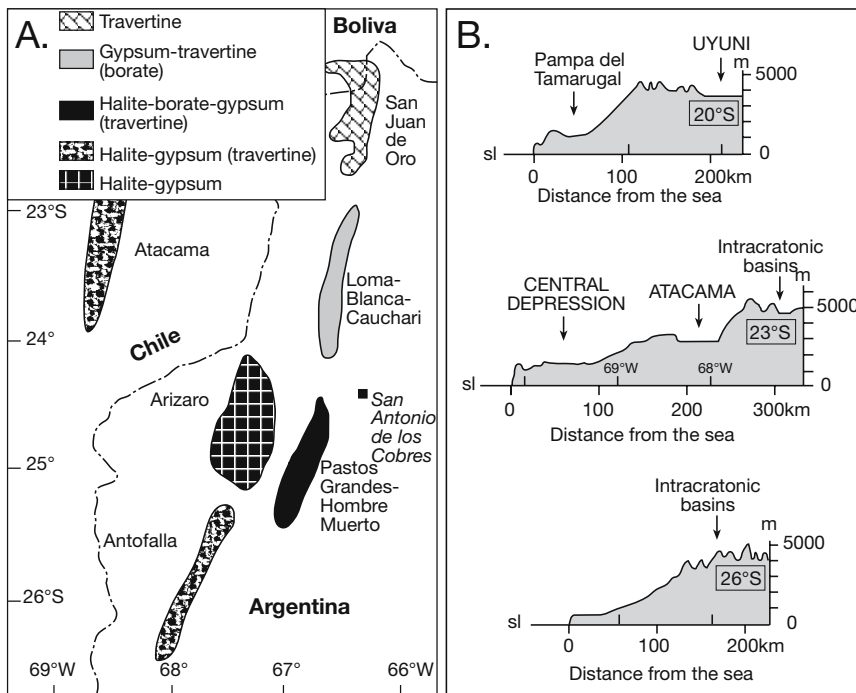

Figure 3.38. A) Evaporite belt and physiography, Andes, South America. A) Generalized latitudinal distribution of Pliocene-Miocene evaporite belts (after Alonso et al., 1990). B) Physiographic profiles at various southern latitudes across the Andes (after Risacher et al., 2003).

Bolivia and Argentina to nearly 300 mm in the area around Lake Titicaca and southern Peru (Figure 3.37; Erickson, 1993). In contrast, the Atacama Desert lacks an annual rainfall and it may rain as infrequently as once every 10 - 20 years. Much of the groundwater in the desert is sourced from runoff in the Andean Highlands. Unlike the playas in the southwest of the USA, dry salars are dominated by pan facies rather than mudflats, perhaps reflecting higher relief and lower permeability substrates in this region creating more opportunities for flooding, followed by extended times of brine ponding.

Active continental volcanism is ongoing, with several west-northwest trending volcanic ridges cutting the Puna. This divides the Puna into several stagnant endorheic basins, further subdivided by north-south trending structural blocks creating local sources for alluvial fans and groundwaters. Thus, many of the salars show elevated lithium and boron contents in their surface and interstitial brines, with solutes sourced in abundant highly reactive volcanics, mostly rhyolitic ash-flow tuffs. Ions are redistributed to the salar by runoff and

ongoing hydrothermal circulation (Figure 2.17; Table 3.5; Erickson, 1993). Evaporative concentration of salar brines leads to the depletion of Ca, HCO_3 , B_2O_3 and SiO_2 , and the enrichment of Li, K and Mg. Ca and SO_4 are removed from the concentrating waters as gypsum, while Ca and HCO_3 are removed early in brine evolution as cyanobacterial limestones, ostracode carapaces and inorganic precipitates, mostly travertines (Risacher et al., 2003). Boron precipitates as ulexite (see Chapter 11), while SiO_2 is removed by incorporation into widespread diatom tests in the fresher water lakes and spring pools. The proportions of Li, K and Mg tend to remain constant in a single lake basin, but vary from basin to basin owing to varying proportions of contributing lithologies from one drainage basin to another.

According to Risacher et al. (2003), sea salts and desert dust are blown eastward over the Cordillera, where they can constitute an appreciable fraction of the solute load of very dilute waters feeding the salars (salt content < 0.1 g/l). But

weathering of volcanic rocks contributes most components to inflow waters with salt content ranging from 0.1 to 0.6 g/l. However, the average salt content of all inflows is much higher, about 3.2 g/l. Chemical composition, Cl/Br ratio, and ^{18}O - ^2H isotope contents point to the mixing of very dilute meteoric waters with present lake brines for the genesis of most of the saline inflows. Saline lakes and subsurface brines are a steady-state hydrologic regime. The average residence times of conservative brine components ranges from a few years to some thousands of years and indicate permanent leakage of the brines through bottom sediments. The infiltrating brines are recycled in the hydrologic system where they mix with dilute meteoric waters. High heat flow is the likely driving force that moves the deep waters in this magmatic arc region. According to Risacher et al. (2003), active Chilean salars cannot be considered as terminal lakes nor, strictly speaking, as truly "closed" basin lakes. They leak (see Chapter 2). Almost all incoming salts ultimately leave the basin and are transported elsewhere. Moreover, the dissolution of fossil salt crusts in some of the active salars also carries away important fluxes of components in percolating brines. In effect, the regionally leaky salar hydrology constitutes a broad scale fractionating system that can accumulate relatively pure salts in each of the large salt basins.

Although there is a longterm north to south trend of increasing salinity, evaporite basins and aridity have migrated eastwards with time, driven by the Miocene evolution of the Andean Range. Consequently, many of the westernmost salars, such as Salar Grande, are presently not regions of internal drainage (Pueyo et al., 2001). Worldwide, this migration of precipitative activity in "piggy-back" salt basins characterises the evolution of many evaporite deposits that accumulate in collision belts (e.g. Figure 5.43). The Central Depression is bounded on the west by the Coastal Range and the Pacific Ocean and to the east by the Andean Pre-Range (Figure 3.38b). Throughout the Neogene, it acted as a significant drainage basin for pluvial input from the east that flowed into the area without reaching the sea. Its alluvial fan systems reach dimensions of tens of kilometres wide and hundred of metres in thickness. In the more distal parts of the fans, both perennial and ephemeral lakes developed (e.g. Calama-Chiu Chiu, Batea, Quillagua-Soledad, Bellavista-Pintados, Pisagua basins). The topography responsible for this drainage arrangement was generated during the Upper Paleogene, as a result of the Incaic orogenic pulse. From this time to the Pliocene the Central Depression was an endorheic area, and the Coastal Range acted as a barrier to drainage to the sea.

In plan view, sediment patterns in most of the South American salars with salt fills show a central zone, consisting of a relatively thick stack of halite crusts, surrounded by a thin marginal sulphate zone consisting of a variety of sulphate minerals, as well as minor halite and ulexite (Ericksen, 1993). The zoning may be symmetrical (bull's-eye pattern) with sulphate surrounding a central halite core, or asymmetrical with the halite zone crowded against one side of the salar. This is the situation in Salar de Atacama where tectonic tilting has displaced the lowest part of the brine sink to the southern end of the playa. Alternating arid and pluvial climatic episodes, since the mid-Miocene, means most salars/playas are filled by alternating beds of salt and siliciclastics.

Salar di Uyuni, Bolivian Altiplano

The Salar of Uyuni, at an elevation of more than 3600m in the central Bolivian Altiplano, is an active ephemeral saline lake (salt-crusted saline pan) where substantial salt thicknesses have accumulated across an area of a little less than 10,000 km², making it the world's largest salt-filled saline pan (Figures 3.39, 3.40a; Risacher and Fritz, 2000). A 121 m deep well, drilled in the central salar, intersected a complex evaporitic sequence made up of 12 saline pan intervals separated by 11 mud layers deposited mostly as saline mudflats or sabkhas (Figure 3.40b). The thick saline pan beds are composed of stacked salt crusts and alternate with thinner mud units in the lower half of the well. The mud beds show obvious lacustrine features and thicken upwards as salt beds thin. The well indicates a longterm hydrology where tectonics, as well as climate, controlled the level of the regional water table.

Bromine contents of the recovered pan halites range from 1.3 to 10.4 mg/kg (Figure 3.40b). Such low values mean the various halite beds were not precipitated by simple evaporation of meteoric and surface waters. This would be indicated by Br contents of tens of mg/kg in the pan halites (Risacher and Fritz, 2000). Rather the brines were created by dissolution of older evaporites, which subcrop in the drainage basin. Halite from one such nearby gypsum-capped diapir has a very low Br content of 2 mg/kg, strongly suggesting that most of the halite deposited at Salar di Uyuni originated from the leaching of similar diapiric salt. The ubiquity of this salt source is indicated by the numerous gypsum-capped diapirs, which still outcrop in the Altiplano (Figure 3.40a).

The very low and fairly constant Br content (1.6-2.3 mg/kg) of the lower salt beds, along with an abundance of detrital minerals, suggest the deeper and thicker halite beds were

Figure 3.39. Salar di Uyuni, Central Altiplano, Bolivia. Halite crust appears light blue, the moat fringe dark blue, and the Rio Grande delta can be clearly seen in the southwest part of the salar (Image courtesy of Fachrichtung Geoinformatik, FU Berlin).

deposited as saline pan intervals in ephemeral lakes (Figure 3.40b). Thereafter, perennial water episodes of increasing

duration, flooded the central Altiplano. This change is tied to an increase in the volume of dilute meteoric waters entering the

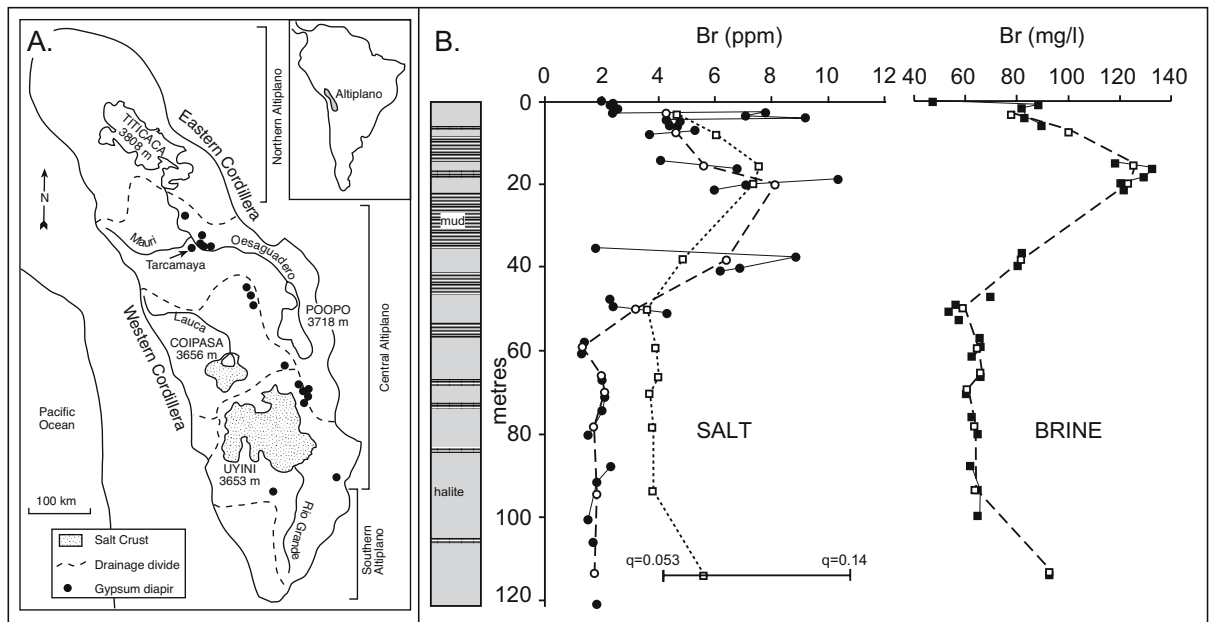

Figure 3.40. Salar di Uyuni, Andean Altiplano. A) Locality map showing hydrological relations with drainages of other salars and lakes of the Altiplano as well as its proximity to diapires. The dissolution of diapor salts has sourced much of the salt accumulating in the Salar di Uyuni. B) Lithology and Br profiles from a 121 metre well in Salar di Uyuni (after Risacher and Fritz, 2000).

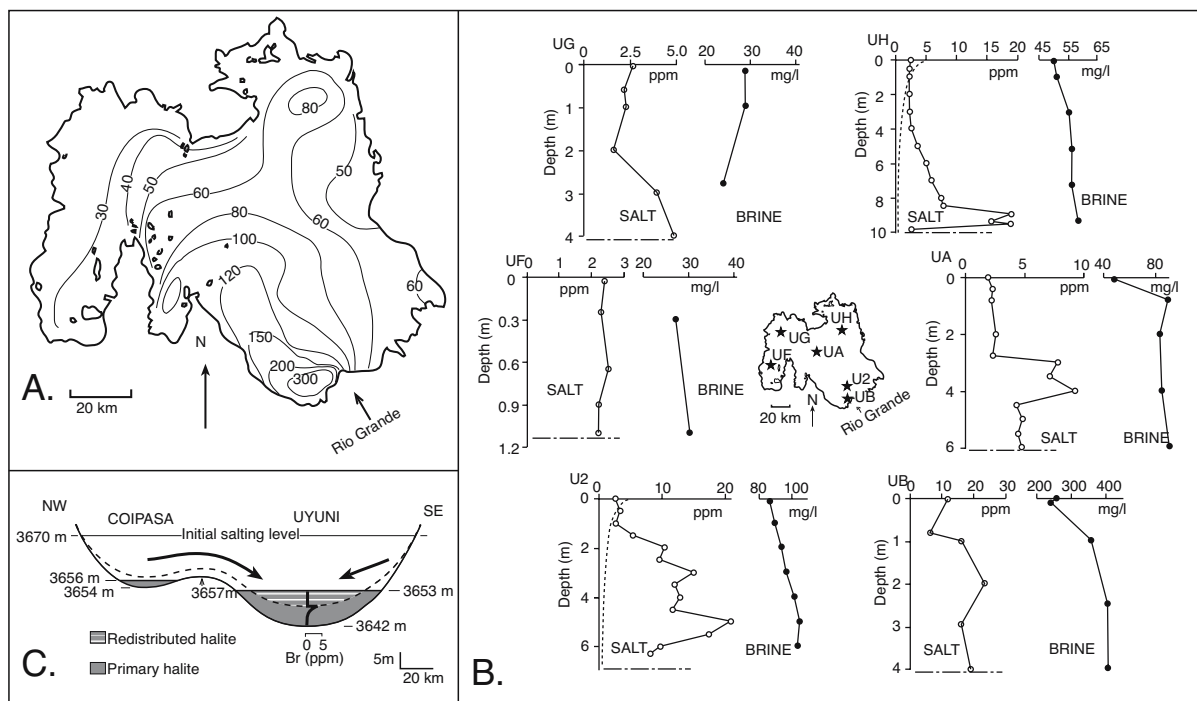

Figure 3.41. Distribution of Br in shallow saline pan sediments of Salar de Uyuni. A) Distribution of Br in nearsurface brine. B) Br profiles of pan halite and interstitial brines from selected shallow cores. C) Schematic showing how low bromine salt is reworked and redistributed from initial marginward crusts by a lowering of the perennial water table (after Risacher and Fritz, 2000).

Uyuni drainage basin and in the proportion of mud beds in the salar core. These waters had lower Cl/Br ratios, indicated by an increase in Br to 6-10 mg/l in the pan halite beds between 10 and 40 m depth (Figure 3.40b). The change may have also coincided with the exhaustion of diapiric halite as a source of ions, perhaps related to a decrease in the intensity of tectonism that was driving diapiric salt to the surface. Paleolake levels in the central Altiplano rose at this time, while those in the northern Altiplano (the Titicaca basin) were simultaneously falling. This reflects progressive fluvial erosion of the threshold between the northern and the central Altiplano, which lowered the levels of the northern lakes and allowed more dilute waters with lower Cl/Br ratio to flood the central Altiplano and so move into Salar di Uyuni. The three uppermost salt crusts show a decrease in bromine content, which may reflect a recent modification to the inflow regime.

The salt of the uppermost salt pan layer began to accumulate around 10,000 years ago and continues today. The halite shows a bromine distribution that is low in the shallow parts of the bed (≈ 2 mg/l) but unexpectedly increases with depth to values in excess of 8-10 mg/l (Figure 3.41a, b). This increase is thought to indicate an episode of exposure and recycling of earlier formed marginward salt crust into the current brines

(Figure 3.41c). As the lake dried some 10,000 years ago, the resulting salt crust was initially distributed over a wider area than the crust of the present pan. It covered the topographic surface of the salar depression up to the level of the lake where halite brines first reached saturation (Figure 3.41c). Ongoing lowering of the Holocene water table, and the associated dissolution of the higher parts of the salt crust about the more marginward parts of the pan depression recycled ions (including Br) from crusts about the margins of the lake into the brines feeding the lowered brine levels located further toward the salar centre. Ongoing recycling explains the progressively lowered Br contents in successive pan crusts in the more central parts of the salar. Clearly, the increasing aridity and lowered water table that typifies the current episode of saline pan aggradation has cannibalised earlier versions of itself as ongoing longterm drying of the lake raised marginward crusts above the salar water table.

Many parts of the lake surface about the lake edge still show evidence of salt dissolution and crust recycling. Circular holes appear in the lake crust, especially about the salar edge; surface expression of the holes can be a few tens of centimetres wide but they are typically underlain by brine-filled swallow holes

Figure 3.42. Stratigraphy (a) and B-Li content (b) of brine in the southwestern portion of Salar di Uyuni in the Rio Grande delta. Arrows indicate brine flow, Brine chemistry shows a peak in both B and Li at the chemical interface between halite saturated lake brines and the delta prism, but the ulexite precipitates by capillary evaporation at the brine table interface beneath the delta prism (after Risacher and Fritz, 1991). See Figure 3.40 for location of delta.

opening out in to salt cavities that are metres deep and wide. It makes driving on some parts of the salar edge quite hazardous. The local name for these small holes at the surface is “Eye of the Devil” (*ojo del diablo*). Local karst development about the edge of a bedded salt mass is an early diagenetic overprint common to many modern and ancient salt pans. It is driven by changes in the lake water table and the encroachment of

regions of less saturated water into the margins of the bedded salt. The associated preferential leaching and fractionation drives the syndepositional formation of many potash and borate accumulations (e.g. Figure 11.16).

The main fluvial feed to the salar is from the Rio Grande, which enters the salar depression in its southwestern part. There it has

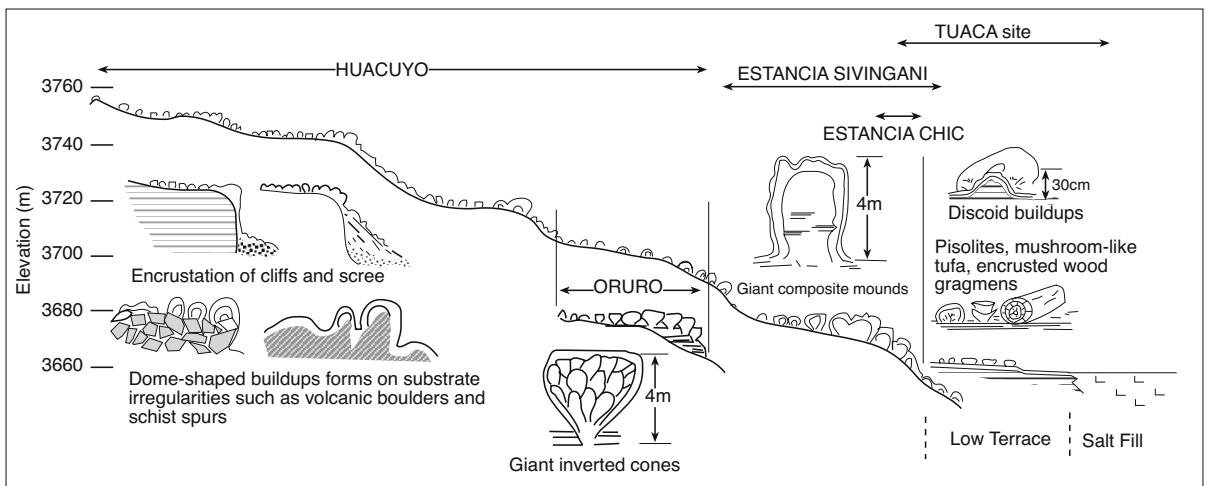

Figure 3.43. Schematic of the distribution of various types of algal bioherms within the outcropping as carbonate veneers in the surrounds of Salar di Uyuni. At the time the bioherms were actively accumulating these areas were shoal water portions of a perennial lake (after Rouchy et al., 1996).

built up a 300-km² delta, characterised by a lens of fresher water and sediment that intertongues with the halite crust unit (Figure 3.39). The delta itself is a complex of silt and clay with local sand lenses indicating fluvial channel fills. Clays are mostly smectite with some illite and minor kaolinite. Overall, the delta prism is characterised by low porosity and permeability (Risacher and Fritz, 1991). Paludal muddy lacustrine sediments underlie both the delta prism and the halite crust facies. The contact between the delta wedge and the halite unit is a brine interface and the watertable of the delta prism today lies close to the surface. It converts much of the delta prism situated some distance from the fluvial channels into an evaporitic mudflat, where capillary evaporation is driving fluid flow. This in turn drives a slow circulation in the underlying mixed waters and so precipitates calcite, gypsum and ulexite ($\text{NaCaB}_5\text{O}_9 \cdot 8\text{H}_2\text{O}$) toward the edge of the delta prism (Figure 3.42). This has created one of the largest borate accumulations in Bolivia where the ulexite interval in the delta prism has an average thickness of 0.1 m over a 120 km² area with a water content of 50% (Risacher and Fritz, 1991). Total boron reserves in this area are estimated to be around 1.6×10^6 tons.

The Salar di Uyuni surrounds also preserve evidence of Upper Pleistocene sedimentation, this was a time when the Central Altiplano of Bolivia was repeatedly flooded by deeper and extensive saline lakes (Rouchy et al., 1996; Baker et al., 2001). These freshening episodes in the Salar di Uyuni area are marked by the development of microbial bioherms defining at least three major periods of lacustrine highstand (Figure 3.43). These calcitic tufas discontinuously cover the 300-km-long and up to 100-km-wide lacustrine slopes and terraces of the surrounds of Uyuni up to an elevation of 100 m above the surface of the modern halite crust. Clearly, Salar di Uyuni was a perennial mega-lake when the bioherms were growing and deepwater diatomaceous siliceous muds were accumulated across the same area where subaerial crust are accumulating today.

The distribution, size and shape of the bioherms are diverse, reflecting various factors such as the nature and morphology of the substrate and the hydrodynamic conditions that prevailed during bioherm growth (Figure 3.43; Rouchy et al., 1996). Build-ups on the larger palaeoterraces

coalesced to form platform-like carbonate reef mound accumulations. Although the morphologies closely resemble those created by cyanobacterial binding, they were predominantly constructed by other plant communities largely dominated by green algae. Cyanobacterial communities flourished in association with the plants, but they did not contribute significantly to the architecture of the bioherms; rather they encrusted the plant stems and microbial bushes, or formed thin laminated layers that covered the last stages of build-up growth. Buildups located between 3660 and 3680 m elevation show one or more of three growth stages or envelopes: (1) a massive inner core formed before 40 ka during an early Minchin highstand; (2) a large peripheral envelope deposited at about 40 ka (late Minchin) and (3) a thinner outermost crust formed during a late glacial event. Many bioherms show composite growth layering indicating episodes of microbial growth during lake highs separated by times of subaerial exposure and moderate erosion.

Figure 3.44. B) Sedimentology of core 2005 (after Bobst et al., 2001; Jordan et al., 2002).

Salar de Atacama, Chile

Salar de Atacama is the lowest drainage sink in another endorheic basin in the pre-Andean depression of the Atacama desert and contains more than a kilometre of interlayered halite and siliciclastics (Jordan et al., 2002; Rech et al., 2002). At an elevation of 2,300 m above sea level with an area of 3,000 km², it is the third largest saline pan in the world and an excellent barometer of Pleistocene climate change in the southern hemisphere (Figures 3.36, 3.37).

Today the San Pedro River forms an ephemeral stream feed along the western margin of the northern sector of the salar and defines the edge of a saline mudflat dominated by sulphate, carbonate and siliciclastic sediments (Bobst et al., 2001). The mudflat surface is dominated by brown halite-rich crusts and is underlain by silty clays with sand, displacive halite and locally organic-rich mud. A “sulphate marginal zone” dominated by ephemeral streams, eolian dune fields, sand sheets, dry mudflats and spring-fed ponds and marshes, forms

the eastern edge of the salar and lies to the east of the saline mudflat (Figures 3.44, 3.45a). This northern region captures the majority of the siliciclastics entering Salar de Atacama. In general its water table is between tens of centimetres and several metres below the deflationary land surface. Uppermost sulphate zone sediments are typically covered by and cemented with efflorescent sugary gypsum and minor halite. When trenched these gypsum crusts form discontinuous bowl-shaped concave-upward layers tens of centimetres in diameter.

A thick layer or crust of halite today covers the halite nucleus of modern Salar de Atacama (Bobst et al., 2001). The top 40 cm of this crust is made up of millimetre-scale “sugary” inclusion-poor halite crystals along with interstitial mud. The crystals show a well-developed interlocking polygonal texture. At the broader scale the crust appears “wormy” with numerous subvertical to randomly oriented tubular microkarst voids. The crust surface is broken by metre-scale polygons with typical upturned edges showing up to a metre of relief. Mud typically ponds in the centres of saucers between the megapolygonal salt ridges. This

uppermost crust is interpreted as an efflorescent crust formed largely by the capillary evaporation of groundwater brines and contains only a few growth-aligned chevrons.

Below the surficial crust the halites of the saline pan nucleus are massive and mainly composed of cm-sized interlocking crystals separated by mud-filled voids. Most of this halite is clear and inclusion poor indicating slow subsurface growth. Occasional freshwater influx drives dissolution of surface efflorescent halite crusts and creates large voids that then fill with clear cm-scale euhedral halites growing in toward the

centre of the void. This dissolution-precipitation of halite is an ongoing process with evidence of numerous overprinting episodes destroying most primary chevron structures. Layering is poor to nonexistent.

A deep core (No. 2005) through the halite nucleus facies recovered some 100 metres of evaporitic sediment and sampled some 100,000 years of salar sedimentation (Figure 3.45b; Bobst et al., 2001). Deposition was dominated by arid conditions similar to today, with two significant wetter intervals. From 100 m to 62.8 m the core is composed of clear interlocking halite with

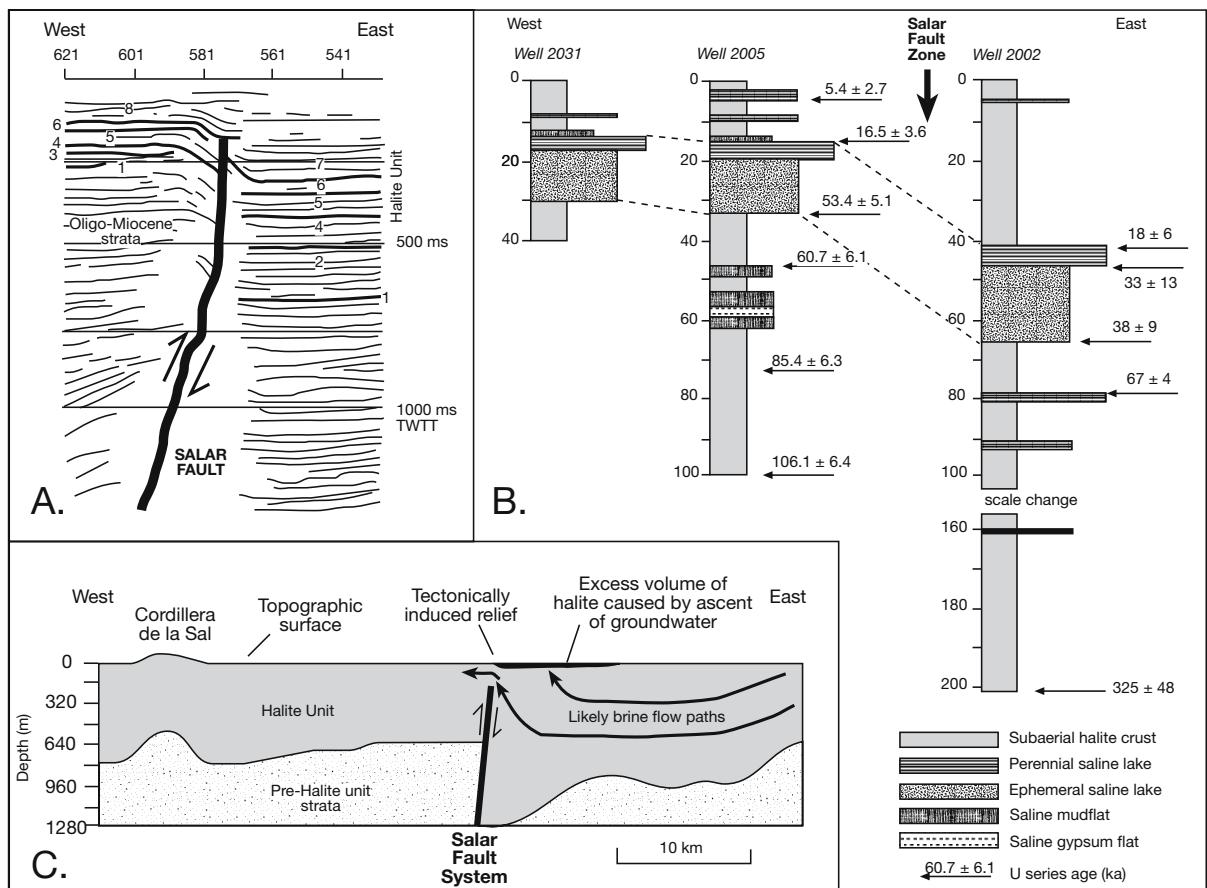

Figure 3.46. Interactions between the Salar de Atacama fault zone and halite sedimentation (See Figure 3.45a for location of seismic line and wells; after Jordan et al., 2002). A) Interpreted seismic line ig 022 across the Salar reverse fault showing monoclin flexure and thickening of beds across the fault. Fault trace dies out before reaching current halite surface. B) Summary of halite facies in sequence 8, documented in SQM cores. Boreholes 2031 and 2005 are located west of the Salar fault system, whereas borehole 2002 is located east of the Salar fault system. U-series dates from boreholes 2005 and 2002 and comparisons of halite depositional environments at the three sites allow temporal correlation among the cores. The top of the perennial saline lake facies, dated as ca. 16.5 ka, is readily identifiable in all three locations. That horizon occurs at similar depths in cores 2005 and 2031, but is vertically displaced ≈ 28 m across the Salar fault system. C) Conceptual model of enhanced halite accumulation east of the Salar fault system, which leads to a horizontal depositional surface across the fault trace. Under the conditions of a desiccated surface environment, halite accumulates because of evaporation of groundwater-fed brines. A drop in permeability at the fault (either due to juxtaposition of lower permeability rocks in the western fault block or due to properties of the fault zone itself) blocks the westward flow of topographically driven groundwater, forcing a high rate of upwelling in the downthrown eastern fault block.

patches of millimetre-scale sugary halite. These textures are near identical to those forming at the surface today and indicate dry mostly subaerial accumulations. From 62.8–47.0m (75.7–60.7 ka) there is a vertical succession passing from mudflat gypsum to mudflat/shallow pond to subaerial halite and mudflat deposits that represent a progressive increase, then a decrease and finally an increase in water supply to Salar de Atacama. This occurred within what were moderately wetter conditions (saline lakes and saline mudflats) than the subaerial conditions of today (Bobst et al., 2001). A similar somewhat wetter interval occurred from 53.4 to 15.3 ka, with the wettest perennial lake interval from 26.7 to 16.5 ka. Short relatively wet periods (chevron halite) also occurred in the Holocene from 11.4 to 10.2 ka and from 6.2 to 3.5 ka. The remaining sections are dominated by halite textures similar to the subaerial dominated capillary fringe conditions of today.

Seismic collected across Salar de Atacama shows a north-northwest–striking fault system that extends for at least 30 km across the salar and can be seen intersecting the lower part of the halite nucleus (Figure 3.46; Jordan et al., 2002). In the southern sector of the salar there is at least 700 m of Pliocene–Quaternary down-to-the-east reverse motion across the fault, but locally the salar fault system deforms the lower halite unit into a monocline with 400 m of structural relief (Figure 3.46a). Rates of displacement throughout the Quaternary have been on the order of 0.1–2.0 mm/yr. And yet, despite these large displacements and large displacement rates so obvious in the seismic, no modern topographic scarp exists in the halite nucleus. Seismically-defined stratal geometries and thicknesses reveal variation between former times when there was a topographic scarp at the deformation zone and times, like today, with no topographic expression. The available borehole data suggest that both the times with and without a topographic scarp were likely dominated by halite accumulation adjacent to the salar fault system (Figure 3.46b).

Jordan et al. (2002) propose that unique sedimentation processes in a groundwater-fed evaporite environment are responsible for the lack of topographic expression of a major fault system that intersects the salt. During desiccated times, groundwater derived from topographically driven flow on the east side of the salar would have been forced upward by a barrier created at the fault zone, enhancing the supply of solutes to the zone immediately east of the fault (Figure 3.46c). This mechanism generates a higher rate of accumulation of halite east of the Salar fault system than to its west. The enhanced deposition on the eastern fault block is sufficient to prevent scarp formation during times of moderate displacement by the Salar fault system, though during times of especially high rates of offset,

this depositional mechanism was not sufficient to prevent temporary formation of scarps. It is not yet known how common “truly blind” faults are beneath the dry salt pans of other salars, but they are not unique to the Atacama basin. Similar occurrences of blind faults beneath the depositional surface of the ephemeral saline pan facies characterise; Salar de Antofalla and Salar de Hombre Muerto in the Altiplano, along with the Badwater salt flat in Death Valley, California and Great Salt Lake in Utah (Figure 4.19; Jordan et al., 2002). Like Salar de Atacama, they indicate the rapid deposition/accumulation rates that typify brine-saturated salt accumulating depressions.

Salar Grande, Central Andes of Chile

The Salar Grande is a 45-km-long (N-S axis), 4–5-km-wide, fault-bounded (pull-apart) Neogene forearc evaporitic basin, located in the Cordillera de la Costa of northern Chile (Figure 3.47). The altitude of the Salar Grande salt surface is currently 640–750 m above sealevel and halite deposition is inactive compared with salars to the east (Pueyo et al., 2001). The salar fill is composed almost exclusively of dry massive halite around 100 m thick, with dry salt in the deepest parts more than 160 m thick (Pueyo et al., 2001; Diaz et al., 1999; Ericksen, 1993). The salt is very pure, locally 99% NaCl, with a lakewide average of 95% over an area of 280 km². It has been mined at least since the mid 19th century and today it supplies all of Chile’s needs, as well as being exported, mostly to Japan.

Halite is in direct contact with igneous lithologies about the salar edge, while something like 10 m of alluvium separates the bottom of the salt body from its andesitic Mesozoic basement. There is no evidence of a concentric pattern of mineral fractionation in the salar, nor of any significant volume of salts other than halite (Diaz et al., 1999). Only a patchy anhydrite belt, several metres thick, caps portions of the salar edge (Ericksen and Salas, 1989). It is made up of saccharoidal CaSO₄, which sometimes retains selenite pseudomorphs (dm-diam), as in the SE margin of the salar (Figure 3.47). This sulphate bed can be traced into the adjacent western Llamara area.

The Neogene depositional history of Salar Grande is closely tied to an adjacent Tertiary lacustrine basin, the Llamara-Quillagua basin to its east (Figure 3.48a). Phreatic waters flowing into the Salar Grande depression from the east (now the Precordillera and Altiplano) were progressively enriched in solutes by interaction with volcanic rocks. These fluids had first drained into the Llamara-Quillagua lacustrine system of the Central Depression to deposit thick sequences of diatomites, carbonates, evaporites and clastic sediments. This lacustrine area eventually filled

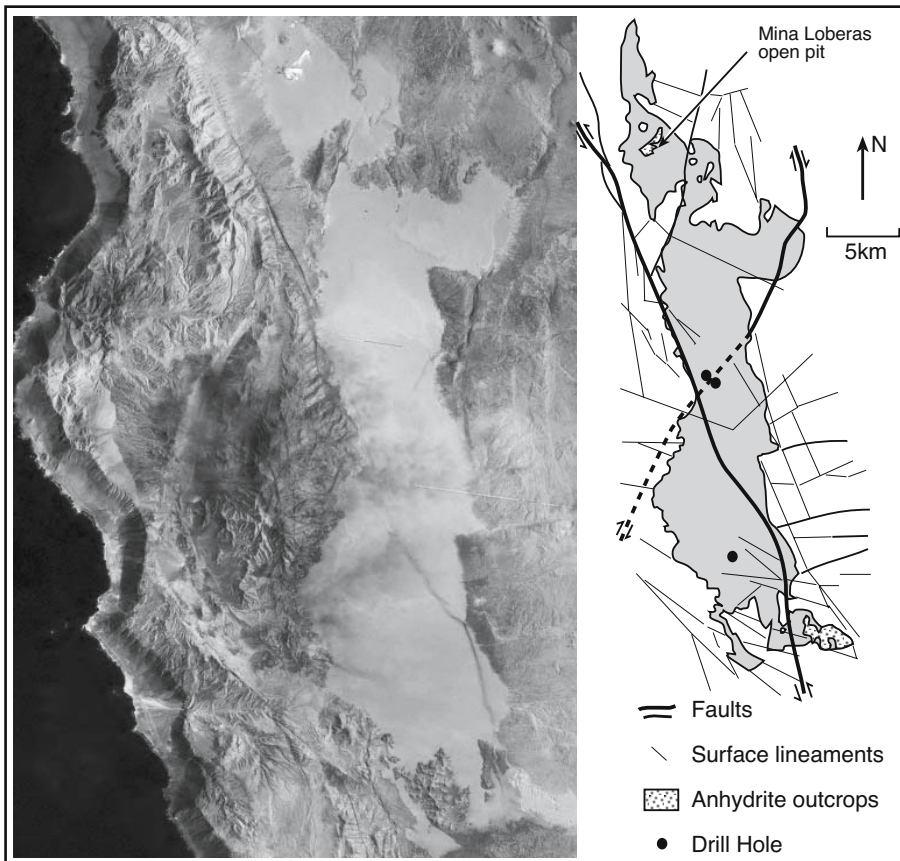

Figure 3.47. Salar Grande, Northern Chile Geological map shows position of 3 drill holes drilled in the 1920s for potash, which established salt in the central portion of the salt was more than 162 thick and underlain by dry alluvium. Also shows main fault of Atacama fault system trending SE-NW as well as other faults and lineaments in and around the salar (Landsat image courtesy NASA).

and dried to where it became a salar filling with anhydrite and halite. During this stage (Late Miocene-Pliocene), the evolved brines of the Llamara-Quillagua area seeped eastwards along structural paths (fractured bedrock?), to reach the Salar Grande basin, which acted as their final sink. Proof of this connection is the anhydrite/selenite bed that overlies the halite in both lakes and links the western Llamara to the southeastern Salar Grande areas via the Montón de Gloria pass (Diaz et al., 1999).

Phreatic brines were subsequently lost from the basin in Pliocene times when the Loa River canyon reached the sea. This was the beginning of the current exorheic hydrology and the opposite of its previous endorheic hydrology. Drainage into the ocean was reflected in a fall of the regional water table, the drying of the salt body and the underlying alluvium, and the creation of a hydrologic situation in Salar Grande that still exists today (Ericksen, 1993).

Large halite sinkholes, up to 10 - 20 m deep are best developed on the eastern side of the salar, while others developed along fault lines where they transect and weaken the now dry salt body (Diaz et al., 1999). Some sinkholes are funnel-shaped, while others are cylindrical, all may be connected laterally by a network of caves. Etched profiles in the sinkholes walls indicate they were brine-filled pools prior to the drainage of brine from the salar much like the "eyes of the devil" in Salar di Uyuni.

The regionally extensive Atacama Fault zone, a major tectonic feature in the region, transects the Salar Grande with its position marked on the salt crusted surface by irregular elongate depressions and mounds, low scarps and fractures (Figure 3.47). Other active faults, defined by open fracture networks, outline tectonic zones in the surrounding and underlying

bedrock. The appearance of the fault trace at the surface of Salar Grande is in marked contrast to Salar de Atacama, which lacks any expression of its active faulting at the surface. That the regional fault intersects the surface of Salar Grande and not the surface of Salar de Atacama shows that the halite accretionary process is today much less active in Salar Grande. Accretion of halite requires a saline water table within a few decimetres of the lake surface; the water table of Salar Grande is much deeper.

Dripping fogs (*camanchacos*), in combination with deflation, capillary evaporation and rain, have sculpted a knobby and pressure-ridged surface to the modern salt crust with relief up to 50 - 60 cm. At the larger scale some pressure ridges outline megapolygons in the salt with saucer diameters measured in tens to hundreds of metres, as well as smaller polygons measuring several metres between ridges (Ericksen, 1993).

Ongoing reworking of the upper boundary of the massive salt crust by fog moisture and the incorporation of eolian, detrital and insoluble clays through time has created a dirty brown salar-capping halite crust, up to 1 metre thick, atop thicker, drier, purer halite.

Mining and coring in the northern part of Salar Grande shows the lower 10m of the salt fill was deposited on the floor of a mostly brine covered saline pan. It is made up of thinly-layered halite composed of cm-mm-sized bands of chevron halite, separated by syndepositional dissolution surfaces. It is depositonally similar to the shallow saline pan facies of Salar di Uyuni and the saline lake facies of Salar de Atacama (Figure 3.48b). Minor amounts of sulphate salts (mostly mm-sized glauberite, thenardite and polyhalite) and clay minerals cap each dissolution surface, indicating settle-out and freshening related to periodic flooding of the basin. The overlying Massive Halite was deposited as displacive or intrasediment halite, still in a saline pan but now

accumulating in the capillary fringe of a pan that was subject to ongoing desiccation and evaporation, much like the majority of the halite filling Salar de Atacama.

The transition between the Lower Banded Halite and the Upper Massive Halite takes place over an interval several metres thick, which shows alternations of both units. Lower banded halite passes by an increase in crystal size into the Upper Massive Halite, which is made up of two halite crystal classes (< 4 cm diam and > 4 cm diameter). The random nature of crystal alignment in the massive halite shows its precipitation as multiple overprints of displacive crystal growth from saturated phreatic and capillary waters at a time when the salar surface was mostly subaerial.

Minor thenardite (Na_2SO_4) crystals occur in the Upper Massive Halite at levels 2 and 3 in the Mina Loberas pit where it appears to be an early, perhaps syndepositional, cement between

displacive halite crystals (Diaz et al., 1999). Thenardite locally replaces the halite, but typically shows poikilotopic textures with solid inclusions of glauberite, clay and micrite. Polyhalite ($2\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot \text{H}_2\text{O}$) is the most abundant sulphate mineral in Salar Grande; it outlines grain boundaries and dissolution surfaces in the Massive Halite.

Pockets of very coarsely crystalline halite (>50 cm diameter) occur in the Massive Halite and in parts of the underlying Banded Halite. They show centripetal or geode-like patterns of halite growth and infill. This very coarse halite is thought to be an earlier dissolution tube fill precipitated when the water table was higher. It is a common texture in many other South American salars where it precipitates as halite karst-fill cement in the Ojo de Diablo.

Work on the sedimentology of the halite pans in the South American salars over the last two decades has substantially improved our

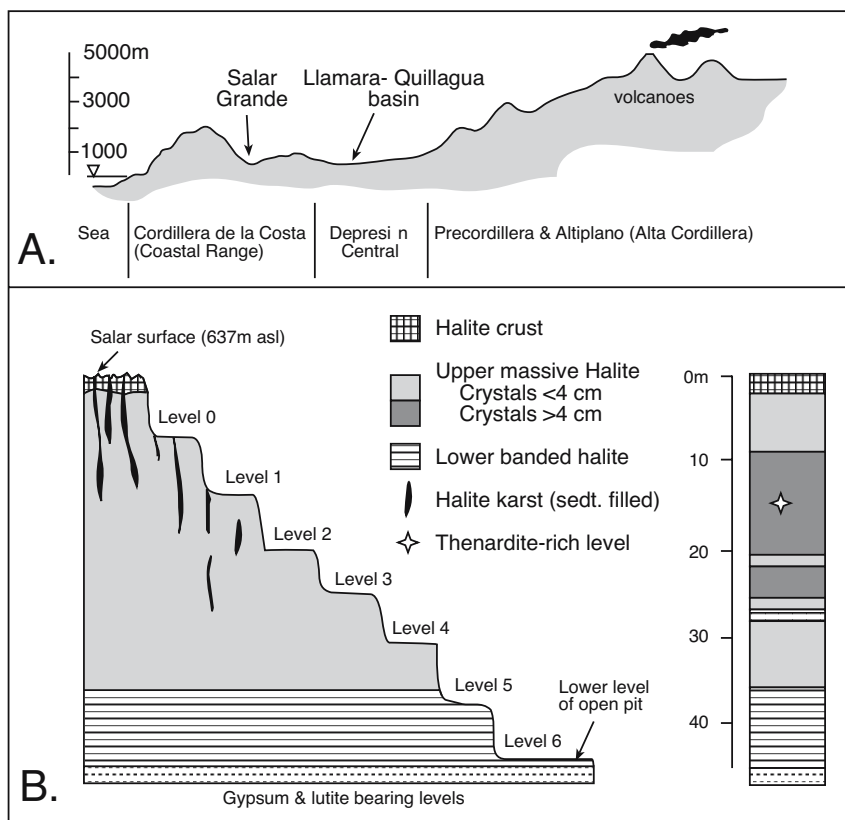

Figure 3.48. Salar Grande. A) Schematic of main physiographic subdivisions and the relative position of the Llamara-Quillagua Basin. Total section length is about 100 km. understanding of the hydrological significance of halite textures. It has added a third group of textures to prior notions of: 1) matrix-dominated displacement halite forming in the capillary fringe of a sabkha sitting in a zone of ascending waters above a less saline phreatic water mass and 2) subaqueous chevrons, overprinted by subaerial microkarst forming in areas of ephemeral waters in saline pans. This third textural style is exemplified by the halite units currently forming in Salar de Atacama and dominating the Massive Halite fill of Salar Grande. It is a form of chaotic displacement halite with little or no non-evaporite matrix and little or no preserved chevron textures. It is porous and forms mostly in the capillary fringe above a groundwater fed halite-saturated brine mass or brine curtain. As it forms it cannibalises itself to such a degree that little or no primary texture is preserved.

Ephemeral stream floodplain - dune field–ephemeral saline lake

The ephemeral stream floodplain–dune field–ephemeral saline lake complex typifies tectonically-stable low-relief areas usually located within arid-zone subtropical high-pressure belts. Continental saline mudflats (sabkhas) are commonplace in regions of shallow water tables in this lacustrine complex, but low rates of subsidence and high rates of deflation mean evaporites are less likely to be preserved compared to rapidly subsiding alluvial fan–ephemeral saline lake settings. Rather, sediments are composed of varying combinations of saline mud flats or sandflats, with the more saline intervals showing widespread haloturbation, but little or no preserved salts. The latter were recycled as ≈1m thick at-surface crusts, dissolved and reprecipitated after each flood event.

Most of the large ephemeral lakes in this setting occur in regional outflow zones of large artesian hydrologies or regional artesian seeps in low relief terranes. The rise of less saline resurging water inhibits development of a thick brine curtain or reflux plume beneath the pan and the mudflat, a requirement for longterm preservation of salt beds (Chapter 5). Surface inflow is a combination of local storm runoff and long distance ephemeral floods, with intense flood events often spaced years apart. Lake sediments are subject to the vagaries of climatic changes outside the immediate vicinity of the saline lake. These lakes generally lie at the edges of sand seas or ergs. They tend to preserve relatively thin lacustrine sediment piles with numerous truncations that indicate ongoing deflation. Wind reworking of vadose lacustrine and fluvial sediment supplies substantial volumes of sediments to these adjacent sand seas.

Ephemeral braided stream floodplains, sheet deltas, dunes and sandflats are the dominant facies in the depositional basin, not bedded evaporites. Lake Eyre (9,500 km²), Lake Amadeus (1,032 km²), Lake Frome (2,700 km²), Lake Gairdner (4,351 km²), and Lake Torrens (5,745 km²) in inland Australia are modern well-documented examples of this depositional style (Figure 3.49; Pell et al., 2000). Major flood events are mostly fed by long distance southward transport from intense monsoonal outbursts in northern Australia (Figure 3.49).

Likewise, Lake Chad in North Central Africa, another well documented example of this style, is fed via the Chari/Logone river system from monsoon rains that typically fall in June, July and August. The subtropical position of all these examples means vertical sequences retain evidence of Pleistocene fluctuations in monsoonal intensity. Many lake complexes in southern central Australia (Lake Callabonna, Lake Eyre, Lake Frome, Lake Gairdner, and Lake Torrens) were freshwater to brackish water lakes some 35,000 years ago, yet today are saline

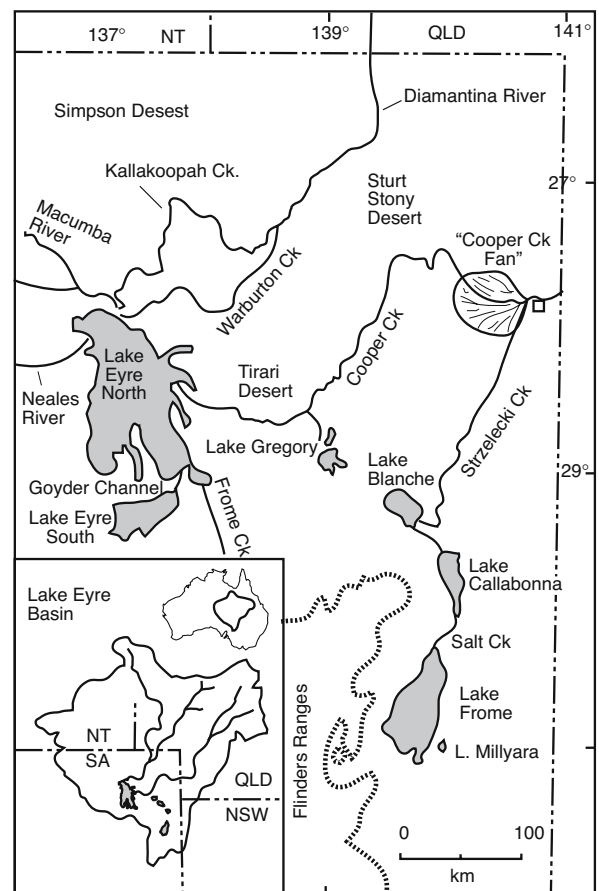

Figure 3.49 Drainage into and between lakes in the Lake Eyre Basin of South Australia.

mudflats with only short-term episodes of filling. Likewise, Lake Chad has undergone massive fluctuations in size and salinity; at one point during the Pleistocene it extended to the Tibesti Mountains in northwest Chad, at another point it was sufficiently saline to precipitate natron (Eugster and Maglione, 1979). Droughts since the 1970s have decreased Lake Chad levels so that it is now extremely shallow and divided into northern and southern pools. This drying is not unusual, the lake has dried up completely a number of times in the last 200 years. What is unusual in the lake's long history is the environmental stress created by too many people attempting to eke out a living in and around the lake.

Ancient counterparts to the ephemeral stream floodplain-dune field-ephemeral saline lake association include portions of the Lower Permian Rotliegende of northern Europe, Permian red beds of the US interior centred on Kansas; the Late Triassic of northwest Europe and the Palaeoproterozoic Whitworth Formation of the Mt Isa Block, Australia (Glennie, 1989a, b; Benison and Goldstein, 2000; Talbot et al., 1994; Simpson and Eriksson, 1993).

Lake Eyre, Australia

Lake Eyre North has an area of some 8,430 km² and is 144 km long and 77 km wide. It is joined by the narrow Goyder Channel to Lake Eyre South, which is 64 km long and 24 km wide with an area of 1,260 km². The lowest part of Lake Eyre North is the eastern part of Belt Bay with some areas slightly deeper than -15.2 m and, making it the lowest point on the Australian continent (Figure 3.50). The floor of the Lake is very flat with bottom slopes $\approx 2 \times 10^{-5}$, so the definition of the exact location of the deepest point is rather arbitrary. For the same reason, boundaries of its sedimentary facies tend to migrate large distances with little change in the lake water level. In dry times the lower parts of Lake Eyre North in Belt Bay and Madigan Gulf are covered by a bedded halite crust around 0.5 metre thick. The 4×10^8 tonnes of salt held in this crust completely dissolves during major floods, so the lake floor actually deepens topographically during a flood (Dulhunty, 1977). When the lake is dry, the saline pan crust is surrounded by a saline mudflat facies where gypsum grows displacively in the capillary fringe (Figures 3.50, 3.51).

Figure 3.51. Lake Eyre, South Australia. Image on left taken on January 1, 2000 at a time prior to a major flooding event. Partly cloud-obscured image on right taken on April 6, 2000 after a major monsoon-fed flood influx into lake from northern part of lake. The elongate interdunal sabkhas and pans in the northern part of the image constitute the Kallakoopah Pans. Note the water-filled Warburton Channel transecting the northern lake floor (Landsat 7 satellite images acquired and processed by ACRES).

The northern portion of Lake Eyre is where most of its ephemeral streams enter the lake depression. Entry points are defined by a number of low flat amalgamated sheet deltas, which are dominated by fine sands and silts. The lower part of the sheet delta facies are cut by low channels, the largest of

which is a north-south depression that transects the northern two thirds of the lake and is known locally as the Warburton Channel. When the lake floods these channels quickly drain the floodwaters into the lowest part of the lake and dissolve the salt crust (Figure 3.51).

Table 3.6. Evolution of the Lake Eyre brine chemistry following the 1984 flood event (after Kotwicki, 1986). Note the marine-like proportions. Values in ppm.

Lake Eyre is an ephemeral playa-salt lake that lies asymmetrically in the southern portion of one of the largest internal drainage basins in the world (1.14 million km²) and covers one-sixth of the Australian continent (Figure 3.49). Drainage topography is flat, with extensive areas of sandy and stony deserts. There are regions with some relief near the boundaries of the drainage basin, but only 30% of the area is elevated more than 250 m above sea level. All streams flowing into Lake Eyre are characterised by extreme variations in discharge and flow duration (Figure 3.50). Mean annual runoff across the basin is 4 km³, equivalent to a water layer 3.5 mm in depth, the lowest runoff level of any major drainage system in the world. The Lake Eyre Basin is large but dry, its drainage spans a number of climatic zones, including the tropical monsoon system to the north and the mid-latitude westerly circulation belt to the south. Some 5 x 10⁵ km² of the drainage basin receives less than 150 mm of rainfall per year (on average). The highest rainfalls, with annual averages around 400 mm, occur in the northern and eastern margins, where rainfall comes from the edge of the monsoon belt.

^{3.1}The El Nino - Southern Oscillation (ENSO) is a global climatic phenomenon marked by see-saw shifts in air pressure between the Indo-Australian and eastern regions of the Tropical Pacific. El Nino and La Nina refer to extreme phases in the 2-7 year cycle. During the warm 'El Nino' phase, the Australian seaboard cools, SE trade winds slacken and extended periods of drought are experienced in the Australian interior. In the cool 'La Nina' phase, the seas around Australia warm, the SE trade winds intensify, and widespread rain and flooding occurs.

The northern end of the Lake Eyre catchment lies barely on the periphery of the planetary monsoon system. The Northern Australian monsoon is erratic both in space and time. Recent lake floods are related to La Nina phases of the El Nino-Southern Oscillation (ENSO^{3.1}) and are out of phase with the Pacific Dry Zone rainfall and El Nino events (Kotwicki and Allan, 1998). Changes in the intensity of the monsoon have controlled the frequency and permanency of Lake Eyre waters throughout much of the Quaternary (Magee et al., 1995; 2004).

Monsoonal outbursts supply water to the Lake Eyre via its eastern tributaries; Cooper Creek, Diamantina and Georgina rivers systems. This water takes weeks to reach the lake and floods much of its flow path on the way, as it deposits sediment in a unique set of anastomose arid-zone fluvial deposits, known locally as "the Channel Country" (Gibling et al., 1998). Trustworthy data on the filling of Lake Eyre reports flooding in 1938, 1955, 1963, 1968, 1973, 1974, 1975, 1976, 1984 and 1989 with exceptional floods occurring every 25 to 30 years (Figure 3.50; Kotwicki, 1986; Kotwicki and Allan, 1998). In 1974, in the largest flood on record, water flowed from Lake Eyre North to Lake Eyre South between March and October when an equilibrium level was obtained. More than 39.3 km³ of surface runoff flowed into the lake at this time, completely dissolving the salt crust. The crust reformed in the following two years as more than 39.5 km³ of water was evaporated (Dulhunty, 1977; Kotwicki, 1986). Large quantities of salt, estimated at 30 million tons (7.5% of Lake Eyre North content), were

transferred into Lake Eyre South during this event, creating, in its lowest portion, a salt crust up to 29 cm thick for the first time on record (Dulhunty, 1977).

As well as the monsoon feed from the north, significant runoff can originate in the desert west of the basin, where it is drained by the Neales and the Macumba Creeks. The 1984 filling, with a total volume of 10 km³, was a relatively minor one but it proved that the western tributaries can fill Lake Eyre in a matter of days. During the 1984 flood, maximum water depths were 5.7 m in Lake Eyre North and 3.7 m in Lake Eyre South. Lake Eyre South this time filled first - an event never previously recorded and considered to be extremely unlikely - and overflowed to Lake Eyre North, reversing the usual flood pattern in the lake (Allan et al., 1986).

Monitoring of the chemistry of the lake brines in the 1984 flood shows the conservative behaviour of all the major ions in Lake Eyre with the exception of Ca, which, relative to the other ions, started to deplete after October 1984 and to sulphate, which flattened its still rising concentration rate. This coincides with the onset of gypsum precipitation around October 1984. Its seawater like brine evolution is typical of most inland waters in Australia (Table 3.6 and Chapter 2).

In 1989 another western-fed flooding event occurred, coinciding with the filling of Lake Torrens on the other side of the Flinders Ranges. Lake Torrens is the second largest Australian playa after Lake Eyre and in 1989 it filled for the first time since 1878. Short term inflow rates into Lake Eyre during both the 1984 and 1989 flooding events were enormous: for example

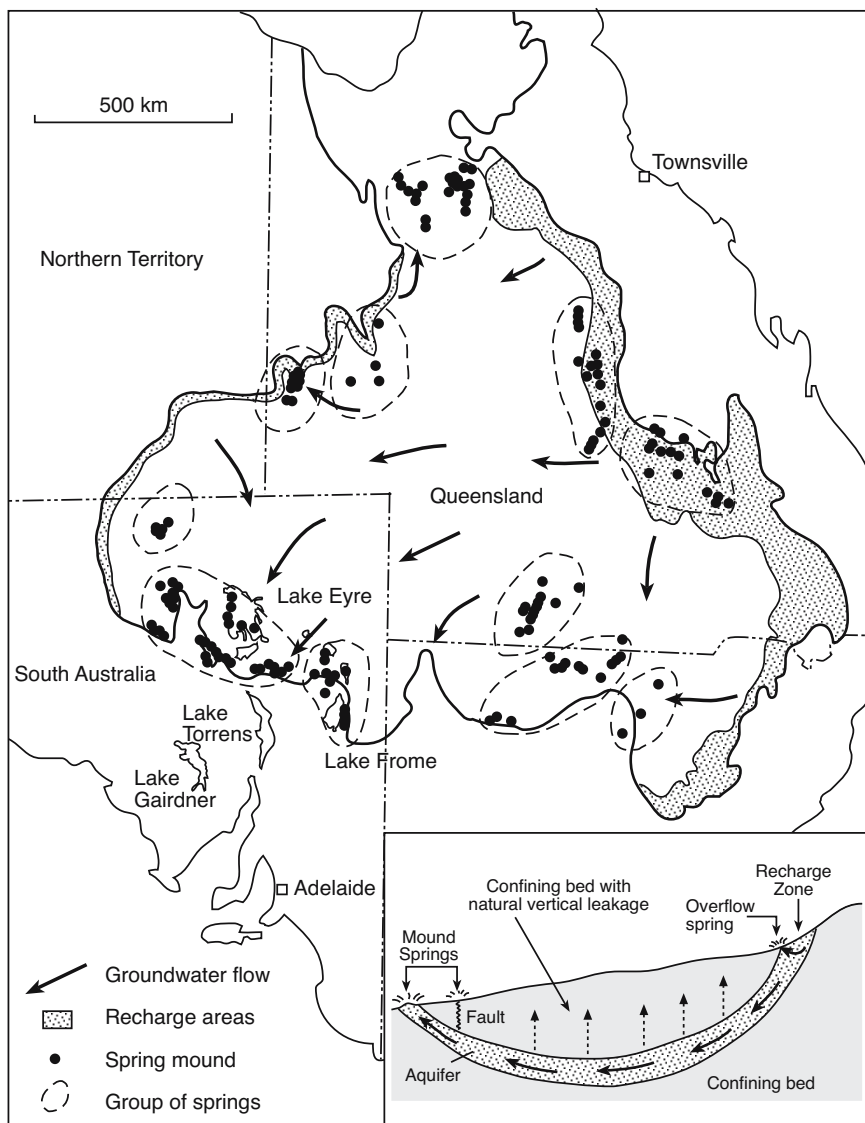

Figure 3.52. Location of spring mound, spring groups and artesian groundwater flow paths in the Great Artesian Basin, Australia. Shows a high density of mounds in the vicinity of Lake Eyre and Lake Frome (after Habermehl, 1982)

in 1984 and in 1989 Lake Eyre received some 8 km³ from western tributaries in three days, which implies discharges of the order of 30 000 m³/s, or one-sixth that of the Amazon. The 1989 “wet” continued into 1990 when, after some of the most devastating floods of the Channel Country in Australian history, water from the Cooper Creek reached Lake Eyre for the first time since 1974.

As well as the being the regional sink for its surface runoff, Lake Eyre’s position also defines the southern outflow or seepage area of the Great Artesian Basin (GAB), which covers an

area of 1.7 million km² (Figure 3.52). The GAB consists of several contiguous sedimentary basins with confined aquifers of Triassic, Jurassic and Cretaceous continental quartzose sandstones, underlain by an impervious pre-Jurassic base (Habermehl, 1980, 1982, 1996). It forms a large synclinal structure, uplifted and exposed along its eastern margin, leaving the overall basin tilted southwest. Recharge to the GAB occurs primarily along the uplifted eastern margins and also on the western margins where the aquifers are exposed or overlain by sandy sediments. Confined groundwater then percolates very slowly towards the terminal base level of Lake Eyre and saline lake sumps, reaching the Lake Eyre area after a calculated travel time of up to three million years (Figure 3.52).

Natural discharge from the GAB comes from two principal processes: 1) diffuse vertical leakage towards the regional water table and, 2) from focused outflow via 600 springs located in 11 groups along the western and southern boundaries of the Lake Eyre basin (Figure 3.52). Many spring mounds define linear fault-controlled surface trends. Flow from the mounds totals 0.03 km³/year and is a minor discharge component of the overall diffuse artesian discharge to the water table. But it creates distinct carbonate spring mounds with the potential to be preserved (Ponder 1986; Mudd, 1998, 2000). Measured flows from various springs range from 0.0001 to 0.23 m³/s totalling around 1 m³/s. Salinities range from 700 to 80,000 ppm, pH from 7.1 to 8.0 and water temperatures from 30 to 40°C.

A typical mound consists of a central pool of water, an outer rim of reeds and vegetation, an outflow channel, and successive layers of carbonate (Figure 3.53). They are composed of micritic marls, invertebrate remains, microbial tufa, pisolites and micrite-cemented eolian sands and are surrounded by gypsiferous sabkha mudflats. Spring mounds are especially obvious in the southern part of Lake Eyre (Habermehl, op cit).

Active mounds are up to 8 m in height and up to 30 m across. The now extinct Hamilton Hill Spring Mound rises more than 40 m above the surrounding hypersaline playa floor, suggesting that late Pleistocene artesian pressures have been higher (Habermehl, op cit.). Flow rates from Lake Eyre springs are directly proportional to the area of wetland vegetation that the spring supports (Williams and Holmes, 1978).

The shores of modern Lake Eyre erode the edges of some now inactive spring mounds and a number of lunette-cored islands within the lake. The southeastern lake coastline, which today consists of eroded dune sand cliffs, is being rapidly cut back, with an erosion rate in the order of 5 m per major flood. The presence of several older strandlines some 0.7, 1.6 and 2.8 m above the 1974 water level, indicate previous unrecorded major flood events. According to Kotwicki (1986), the above levels represent approximate storages of 35, 48 and 67 km³ respectively. The highest potential available storage in the Lake Eyre depression is more than 200 km³, i.e. almost seven times greater than the 1974 storage. The terms “full” or “flooded to capacity” should therefore be used cautiously in Lake Eyre in relation to historical flooding events.

The Lake Eyre basin has been an area of lacustral sedimentation since the Mesozoic. The first documented lacustrine sediments are of freshwater Lake Walloon, which occupied central eastern part of the Australian continent some 150 Ma (Middle Jurassic). By the late Cretaceous (85-75 Ma) it had shrunk to become the much smaller 5 x 10⁵ km² Lake Winton. By the early Miocene (21 Ma) the freshwater lake had assumed a position closely resembling that of Lake Eyre, it even had an indigenous species of freshwater dolphin. This freshwater system in turn evolved into Lake Dieri, a Pleistocene “greater Lake Eyre” which underwent large scale variations in size and salinity from a perennial freshwater lake up to 25 metres deep,

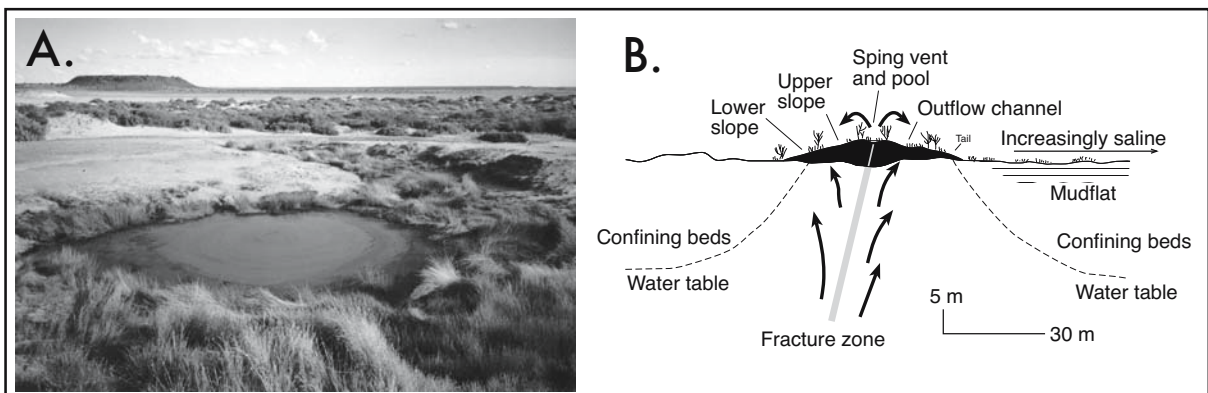

Figure 3.53. A) Active mound spring in the southern margin of the Great Artesian Basin artesian where water up to 3 million years old returns to the surface. B) Schematic cross section of typical Lake Eyre Basin mound spring.

to a groundwater-controlled playa marked by substantial sediment deflation to enter the Holocene as a dry salt pan subject to occasional flooding (Magee et al., 1995; Magee and Miller, 1998). Four Late Pleistocene shorelines have been recognised in those parts of the present Lake Eyre surrounds not located downwind of the depression. They are: a 40 ka shoreline at -10m AHD (Australian Height Datum), a 65 ka shoreline at -3.5m AHD, a 80 ka shoreline at +5m AHD shoreline and a 125 ka shoreline at +10 m AHD, which corresponds to Stage 5e on the Quaternary eustatic curve (Figure 3.54; Magee et al., 2004; DeVogel et al., 2004).

Greatest effective aridity in Lake Eyre in the past 150 k.y. occurred in marine oxygen isotope stage (MIS) 6, when basin deflation was 4.3 m lower than today (Figure 3.54). This arid event was followed abruptly by formation of the deepest perennial lake (phase V at +10m relative to the Australian height datum [AHD—mean sea level]), a level 10 metres above sealevel and some 25 metres above the modern playa floor. At least 6 m of finely laminated gypsiferous and calcareous clay were deposited at this time in conditions characterised by salinity stratification and strongly reducing bottom conditions (Magee et al., 2004). At the same meandering inflowing streams deposited thick, lateral-accretion sediments and fluviodeltaic sediment at the stream mouths.

After this acme level, the lake then shallowed and briefly dried at least once, but no evidence is seen of deflation or pedogenesis (Magee et al., 2004); then the lake refilled to +5 m relative to AHD between 100 and 75 ka (Phase IV), when lacustrine deep-water clays, calcareous nearshore and beach sands, and clastic gypsum evaporites were deposited coevally with renewed fluvial aggradation. Fluctuations in lake level and salinity noted by Magee et al. (op cit.) suggest decreasing regularity of inflow and gradual diminution of the monsoon toward the end of Phase IV.

Sediments of Phase IV were pedogenically modified and eventually truncated by deflation when the lake dried at 75–70 ka and disrupted gypsiferous playa sediments were transported downwind. Incision of tributary rivers into previous fluvial and lacustrine sediments, extending down almost to the modern level, documents a transition to significant aridity.

Lacustrine conditions returned at 65–60 ka (phase III), depositing lake sediment and a prominent beach sand, rich in the brackish water gastropod *Coxiellada gilesii* at -3m relative to AHD; coeval fluvial aggradation and vertical accretion of

Figure 3.54. Late Quaternary changes in lake level in Lake Eyre (after Magee et al., 2004).

overbank muds occurred. Though having shallower water and shorter duration than Phases V and IV, Phase III had significantly deeper water and longer duration than the modern ephemeral events and represents the last deep-water perennial lake in the basin and the last influence of moderately effective monsoon precipitation.

A major deflation episode between 60 and 50 ka excavated the present Lake Eyre basin to deposit gypsum- and clay-rich lunettes at a number of sites around the lake edge as well as covering former shorelines on the windward side of the lake. After deflation ceased, a thick secondary gypsum soil profile (gypsite) developed on the dunes early in oxygen-isotope stage 3. Between about 30,000 and 12,000 yr. B.P. Lake Eyre was at least as dry as it is today. At many sites a lunette-like, playa-marginal, eolian unit formed from saline mudflat sediments deflated from the playa floor. After 10,000 yr B.P. a minor lacustral phase occurred (Phase I) until the modern ephemeral playa regime became established at 3000–4000 yr B.P.

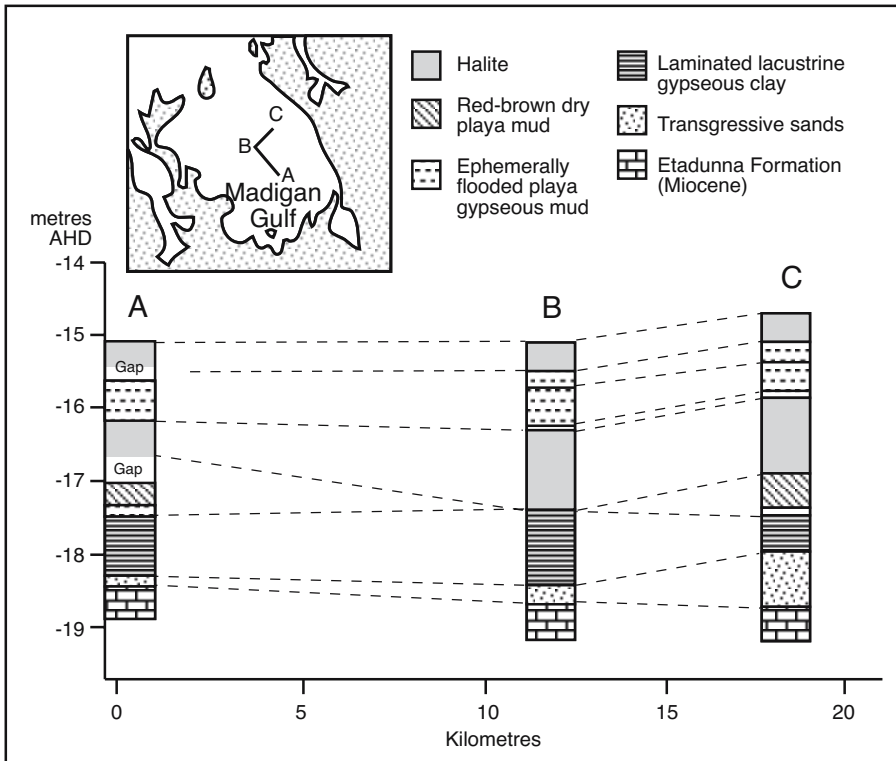

Figure 3.55. Distribution of buried saline pan halite beds and associated sediments in Madigan Gulf, Lake Eyre North (after Magee et al., 1995).

Given the large volumes of water periodically entering the lake depression, and its long history extending back to the Mesozoic, one would perhaps expect large volumes of salt to have at times accumulated in the lake sediments. Certainly, Lake Eyre (Madigan Gulf) is the only Australian playa to retain buried Pleistocene halite beds (Figure 3.55; Magee et al., 1995), but both beds are less than a metre thick. The total Pleistocene thickness is only 3 metres in this the saltiest part of Lake Eyre North. A lack of preservation/accommodation space, tied to ongoing lake floor deflation, reflects the meteoric/artesian recycling hydrology that characterises most large low relief playas of inland Australia (Chapter 2).

Gillespie et al. (1991) interpreted the buried halite in Madigan Gulf is a former salt pan unit, which was partially dissolved during the onset of a minor halite phase in the early Holocene and then preserved by the deposition of the overlying gypsiferous clays. But with thicknesses of less than a metre for each of the two preserved saline pan beds it is not a geologically significant body of halite. Inherent low relief and artesian hydrologies means the ephemeral stream floodplain – dune field – ephemeral saline lake playas of Australia and elsewhere are

unable to accumulate thick sequences of bedded salt in the lowest parts of the drainage basin. It simply blows away. Haloturbation of siliciclastics in continental sabkhas in association with widespread redbed fluvial and eolian deposition is the dominant signature of this style of deposition.

Lake Frome, Australia

Lake Frome, South Australia, is another example of an ephemeral stream floodplain – dune field – ephemeral saline lake complex in the major outflow zone of the Great Artesian Basin (Figures 3.52). Lake Frome is approximately 100 km long and 45 km wide with an area of 2700 km² and lies to the south of Lake Eyre (Figure 3.49). Sediments come

mainly from the west via a series of short, relatively steep gradient streams, originating in the Flinders Ranges some 40 to 50 km away. Overflow waters from Lake Eyre sometimes spill into the north of the lake via Warrawoocara Channel, which also connects lakes Gregory, Blanche and Callabonna. This spillover prevents Lake Eyre water from today rising to a height of more than 12 metres above the Australian height datum (AHD).

The lake contains many islands mainly in the south, where the lake floor is at its lowest, some 2 m below mean sea level (Figure 3.56). These islands are the erosional remnants of earlier now largely deflated Pleistocene sediments and are composed of gypsiferous quartz sands atop a clay surface. Around the edges of the lake there are quartzose spits and bars, beach deposits, and delta fans, as well as Pleistocene transverse and longitudinal desert dunes (Draper and Jensen, 1976). As in Lake Eyre, sheet delta fans define the entry points of the larger ephemeral streams and are built by the coalesce of flat lenses of ephemeral stream sediment and dominated by low angle layering. Stream channels are shallow, straight to gently curved features with few point bars. Oxidised organic-rich muds define lowest parts of the channels. Fine-to-coarse sands

with minor gravels form the bulk of the sheet delta sediment. Interchannel areas are composed mostly of reworked eolian sands. Marginward evaporitic flats with widespread capillary gypsum form large areas peripheral to, but sometimes, atop the sheet delta sand prisms.

Further out into the lake the channels die out and pass into the sands and muds of the saline mudflat, which dominates the lake basin. The bulk of the mudflat matrix is a quartzose sandy

mud or mud with displacive gypsum forming in the capillary fringe and displacive halite in the uppermost 10 cm. Mudflat sediments tend to be massive but can locally show indistinct wispy organic lamination. In the lowest part of the lake floor is the saline pan made up of an ephemeral halite crust up to 20 cm thick and composed of halite rafts and chevrons. The crust completely dissolves during times of flood and is continually underlain by water-saturated muds with large crystals of lenticular and prismatic gypsum.

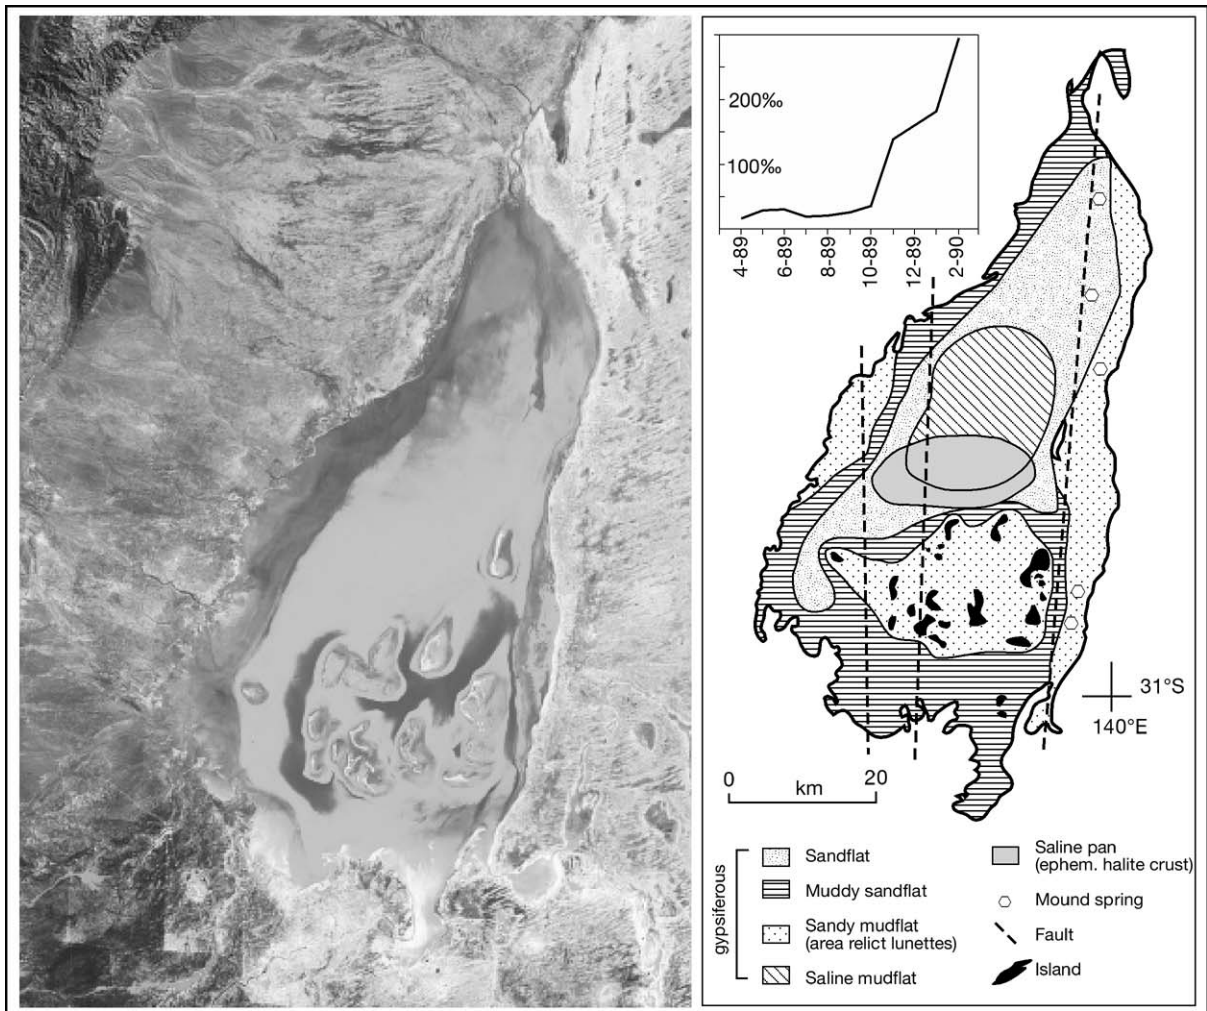

Figure 3.56. Surface sediments in Lake Frome, South Australia. The Flinders Ranges are visible in the upper northeast corner of Landsat image. Sediments in the lake depression show an off-centre bull's-eye pattern related to the presence of a deflationary high in the southern centre with islands dominated by lunette gypsum. The clastic distribution is also inverted with high proportions of sand in the more central positions of the saline mudflat rather than along the current lake strandline. This unusual matrix position indicates detrital flooding from the north fed by overflow from the Warrawoocara Channel, which feeds overflow from Lake Eyre into the northern end of the lake. Note also the association of aragonitic spring mounds along the eastern side of the lake with their positions controlled by upwelling along a north-south trending fault. Inset shows salinity evolution of surface waters after the April 1989 flood (Landsat Image courtesy of NASA, surface geology in part after Draper and Jensen, 1976).

Like Lake Eyre, the lake also displays large active spring mounds along its eastern side. Mound sediments are made up of varying proportions of detrital sediment and authigenic aragonite, calcite, and dolomite cements forming an microbial tufa bindstone. An apron of gypsum fringes the active mounds. As in Lake Eyre, the mounds indicate fault-focused outflow fed from aquifers of the Great Artesian Basin and line up parallel to the major north-south normal fault system that characterises the area.

The inset in Figure 3.56 shows the salinity evolution of a brine sheet from April 1989 until complete desiccation 11 months later in March 1990. The rate of salinity change in the brine sheet was climatically controlled. In April 1989 it was a sheet of mesohaline water (<50‰) covering the previously dry lake floor. Much of the salinity in the water sheet soon after flooding came from dissolution of the salt crust that had previously occupied the central depression. The brine sheet remained for 6 months through the cool months of winter and spring, with little change in its mesohaline salinity. Then, with passage into the hot summer of the Australian interior, brine sheet salinity rose rapidly. In less than a month it moved from its previous salinity plateau into gypsum saturation and then into the halite saturation field before desiccation three months later. By end March-early April, 1990 (almost a year after the flood) the lake floor had dried out and its 30 cm-thick salt crust had reformed. This style of salinity increase, with a long plateau of mesohaline waters, is important to life in the lake as it allows sufficient time for a halotolerant macro and microfauna to breed and survive into adulthood. Plateaus in salinity evolution can control the intensity of the “feast or famine” response in many saline water bodies worldwide (Chapter 9).

Lake Callabonna, Australia

Lake Callabonna, located between Lake Eyre and Lake Frome (Figure 3.49) is another example of climate deterioration in the ephemeral stream floodplain setting in large saline lakes in the Australian interior. Some 0.2-0.7 Ma the lake was a predominantly freshwater lake surrounded by grassy plains and subject to periodic shrinkage and desiccation (Wells and Tedford, 1995). Compared to today this was a time of greater monsoonal supply to the Lake Eyre Basin. Today Lake Callabonna is a dry playa, surrounded by desert. Then the Pleistocene lake was of variable salinity but was several times the size of the present Callabonna saline mudflat and never as dry as it is today. Plant remains associated with this time suggest a more arborescent flora than that near the present-day edge of the evaporitic mudflat but

one containing taxa that still exist in the surrounding region. These facts indicate a seasonal climate with fluctuating water table but a regionally more effective rainfall than at present (the Australian version of Lake Chad?).

This savannah-style vegetation supported large numbers of Diprotodon, a hippopotamus-sized marsupial and the largest marsupial known to ever exist in Australia, as well as other large marsupials including giant kangaroos. These large-bodied vertebrates were mired in the clays during times of low-water or desiccation, while attempting to cross the floor of the lake. Today, fossil carcasses can be found beneath thousands of mud-covered evaporite-cemented mounds littering the exposed lake floor. Geosystems modelling of the Pleistocene hydrology by De Vogel et al. (2004) shows that lakes Callabonna and nearby Blanche were the last two remaining water holes in the catchment whenever the system dried at the end of each wet interval.

Perennial stream floodplain–perennial saline lake

Perennial stream floodplain–perennial saline lake depositional complexes, the third saline lacustrine depositional style of Hardie et al. (1978), occur in several high relief tectonic settings and usually lack extensive sabkhas. Any sabkhas that are present tend to be localised muddy embayments about the lake shoreline. Most perennial saline lakes such as the Dead Sea and the Great Salt Lake are characterised by steep slopes surrounding the lake. The steep slope allows saline water to pond in an arid climate and the lack of sabkhas is often the result of the steep basin sides, with the associated lack of an aerially extensive outcropping of the capillary fringe. These perennial lakes are discussed in detail in the next chapter.

All the ephemeral saline water systems discussed in this chapter have one very obvious feature in common, that is, all are subject to an unpredictable and variable rate of water inflow. Researchers who have not experienced a heavy desert rainstorm often do not appreciate how much and how quickly moisture can enter the system and move large volumes of sediment. It creates debris-charged raging torrents in normally dry streambeds of the hinterland, crossbedded and rippled sheet sands, vast areas of muddy floodplain and in a day or two can convert a saline pan sump into a lake filled with brackish water and teeming with a halotolerant biota (Chapter 9). Table 3.7 lists extreme rates of rainfall in some of the areas that occasionally can feed huge volumes of surface flow into the saline lake depressions. Once this huge volume of water has moved large volumes of

Location of event	Date of event	Annual av.	Storm rainfall (mm/time)
Aozou, Sahara	May, 1934	15 mm	370 mm in 3 days
Tamanrasset, Sahara	Sept., 1950	27 mm	44 mm in 3 hours
El Djem, Tunisia	Sept. 1969	275 mm	319 mm in 3 days
Bisra, Algeria	Sept., 1969	148 mm	210 mm in 2 days
Sharja, UAE	1957	107 mm	74 mm in 50 minutes
Swakopmund, Namibia	1934	15 mm	50 mm
Dead Sea, Middle East	Nov., 1995	90 mm	150 mm in an hour (2.5 mm per minute)
Mt Dare, Australia	March, 1967	126 mm	149 mm in 1 day
Alice Springs, Australia	March, 1988	275 mm	205 mm in 1 day
Innamincka, Australia	Jan., 1974	172 mm	356 mm in 3 days
Balcanoona, Australia	March 1989	200 mm	341 mm in 2 days
Chicama, Peru	1925	4 mm	394 mm in single storm
Lima, Peru	1925	46 mm	1524 mm (more than 30 times annual)

Table 3.7. Rates of extreme rainfall events that create sheetfloods in the arroyos, ephemeral fans and "channel country" fluvial systems feeding surface waters into saline lakes and pans.

siliciclastic sediment into the lake depression, it dries out within weeks to months and the system then can stay dry for years. With desiccation the newly deposited sediment is subject to the vagaries of deflation and with longer term climatic change and lowering of the regional water table can evolve into what can be extensive eolian sand and dust sheets.

Eolian sabkhas

So far, this chapter has described and defined sabkha deposition in either marine-margin or continental settings. In both situations the interpretation of ancient counterparts comes from the matrix, not the salts. Put simply, nodular anhydrite accumulating in a marine sabkha is hosted in and intercalated with marine (fossiliferous) fine-grained sediment, while continental sabkhas are intercalated with, and hosted in fine-grained nonmarine fluvio-lacustrine matrices. But there is a third sabkha association, that of eolian sabkhas where nodular anhydrites, gypsums and displacive halites are hosted in muddy eolian matrices (Figure 3.1). Eolian sabkhas can form in either marine margin or continental lacustrine settings. In either setting their depositional proximity to eolian sands means eolian sabkhas tend to be intercalated with potential eolian reservoirs and can form lateral discontinuities in the eolian sands (Figure 2.44). For this reason I have broken out modern occurrences of eolian sabkhas as a separate topic.

I define an eolian sabkha as being characterised by capillary salts accumulating in any eolian-derived matrix and sitting below a Stokes surface. It may form in interdunal depressions, in sand sheets on the marine or lacustrine edges of ergs, or even in areas of desert loess. By definition, eolian sabkhas, like all sabkhas, require the upper part of the capillary fringe to intersect the landsurface. Fluctuating water levels and water tables will move a sabkha strandline back

and forth over the lower parts of an arid drainage so that eolian sabkha sediments are often intercalated with units deposited in either the ephemeral saline pan or in sand sheets. The ratio of siliciclastic matrix to capillary evaporite in an eolian sabkha unit means it can be further classified into: 1) detritally-dominated (wet eolian sabkha) with a capillary succession showing haloturbation but little or no preserved capillary salts (possible hydrocarbon reservoir), and 2) chemically-dominated (saline eolian sabkha) with abundant capillary salts preserved (possible seal).

Matrix in wet eolian sabkhas has a characteristic association of sedimentary structures associated with ephemeral water and eolian overprints ranging from; subaqueous current and wave ripples, wavy laminae and contorted bedding (wet-surface conditions), through adhesion structures, bioturbation structures, desiccation cracks (damp-surface conditions), megapolygons and Stokes surfaces (falling water tables) to wind-ripple lamination (dry-surface conditions; see Chapter 2; Mounney and Thompson, 2000; Goodall et al., 2000). Similar sedimentary structures occur in chemically-dominated eolian sabkhas but they tend to be overprinted and disturbed by pervasive chaotic salts and associated haloturbation.

Probably the best modern area to study the interrelationships between eolian sabkhas and dune systems is the Arabian Peninsula (Figure 3.57). At least six generations of dunes can be identified on satellite images of the United Arab Emirates and Saudi Arabia (Glennie, 1998). Geomorphic relations indicate

that older periods of Pleistocene dune formation have been modified by later periods of eolian activity, including modern wind flow patterns. In addition, at least two periods of older eolian sedimentation lie beneath the modern dunes. Some dunes sands have a high content of comminuted marine shells and along with wind-reworked oolites have been cemented into calcareous eolianite, locally known as miliolite. They were sourced in sands blown out of the exposed marine shelf during glacial induced sealevel lows (Figure 3.57). Thus, the modern eolian sabkhas on the Arabian Peninsula indicate a complex combination of groundwater overprints interlayered into active dunes and palaeodune bedforms. Those dunes cemented into calcareous eolianites (miliolites) tend to be associated with sea margin sabkhas, as in the vicinity of Al Liwa oasis in the UAE, others form in siliciclastic matrices at the edges of ergs in continental interiors, as at Umm as Samim in Oman.

Older literature discussing eolian sabkhas typically assumes an elongate geometry, inherited from groundwater-driven infill between the partially preserved topography of the underlying

dune ridges (Figure 3.1; Handford, 1981). But dunes are merely loose sediment blowing around above the water table, if the dunes blow on, the remaining sediment is held in place by the capillary fringe and so this type of eolian sabkha can have a sheet-like geometry. It also means the edges of many active ergs are flat laterally extensive erosional sandflats with deflation limited by the top of the capillary fringe. Thus, sheet-like sandflat-hosted styles of eolian sabkha about the edge of a sand sea are much more commonplace in continental interiors than the more typically cited elongate interdunal sabkha geometries (Figure 2.44). Elongate interdunal geometries tend to be most obvious where changing climate or subsidence pushes a rising water table and fluvial floods further into a sand sea. They are typical of low energy desert coastlines preserving the Flandrian transgression, and they are often associated with carbonate-rich (miliolite) hosts. Interdunal geometries are also typical of rising water levels at lacustrine-dune contacts, for example the edge of Lake Chad where rising lake levels pushed the water table to outcrop in nearby dunes in the last 10,000 years and drove the formation of silicates and sodium bicarbonate salts in the

interdunal capillary fringe. Muddy interdunal sabkhas also dominate areas where ephemeral streams flood into a sand sea.

Sea-margins with elongate eolian sabkhat

For an elongate interdunal geometry to be preserved during a marine transgression requires relatively low energy in the zone of marine encroachment. Otherwise, the encroaching high-energy coastal shoreface will erode and transform the depositional signature and destroy any sabkha salts. The landward side of the barrier-lagoon northeast of Abu Dhabi is such a low energy setting located at the sandflat edge of a large sand sea (erg) in the triangle between Abu Dhabi, Dubai

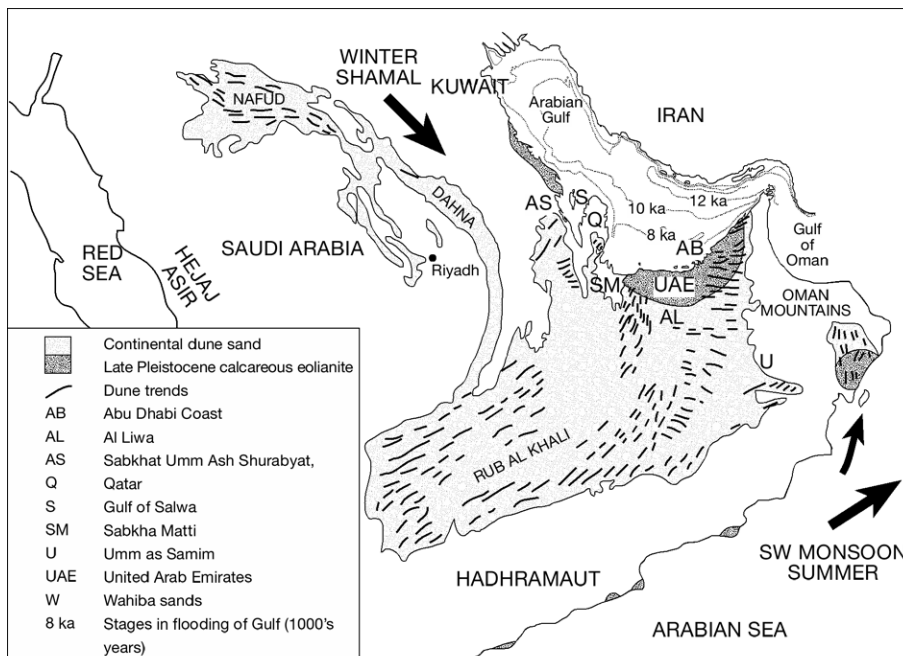

Figure 3.57. Extent of dunes and orientation of their crests on the Arabian Peninsula and approximate extent of the postglacial marine transgression into the Arabian Gulf basin at 12, 10, and 8 ka (after Glennie, 1998; Teller et al., 2000). Dominant modern wind directions are shown by arrows. Occurrence of late Pleistocene eolianite (Miliolite) is indicated by a darker pattern along coast, especially along southern coast of the Arabian Gulf around the Salwa Gulf and in the United Arab Emirates (UAE) where these palaeo-dunes extend as far south as about Liwa Oasis (AL), which is just north of the Saudi Arabian border. AB, SM, U and AS show the position of Abu Dhabi coast, Sabkha Matti, Umm as Samim and Sabkhat Umm Ash Shurabyat, all examples that are discussed in this section on eolian sabkhas.

and Al 'Ayn (Figures 3.57, 3.58a; Abu-Zeid et al., 2001; Teller et al., 2000; Glennie, 1998). Close to the coastal plain these dunes contain a high proportion of marine derived calcareous sand grains (miliolite). The dunes were at their most active in the late Pleistocene glacial maximum when strong winds blew from the west across the Eastern Emirates. Dune surfaces have been subsequently modified by the modern NNW Shamal winds. At the time they were at their most active the ocean had receded from the Arabian Gulf and the Tigris-Euphrates River reached the sea east of the Strait of Hormuz. Along the At Taf this facilitated transport of exposed shelf sediments into a series of E-W trending seif dunes and draas. Then, between 12 and 6 ka, the sea transgressed more than 1000 km from north-west to fill the formerly subaerial Arabian Gulf and in so doing cut off the supply of eolian sand to the dunes of the At Taf (Trucial Coast). At the same time the rising water table and the encroachment of the Flandrian seashore converted the present day coastal area from an eolian-dominated system to the Holocene coastal sabkhat documented earlier in this chapter.

Today the lagoon sabkha system between Abu Dhabi and Ras Ghanada shows broad-scale E-W curvilinear trends that are partially truncated by marine encroachment, so that sabkha-lined dune-cored spits now protrude into the lagoon (Figure 3.58a). To the south, similar now sabkha-covered dune ridges constitute the core to the elongate

trend of the Abu Dhabi and Al Du'yybaya spits. In fact much of the classic sabkha coast of the southern Arabian Gulf shows broad scale thickening patterns in the Holocene section that indicate an initial relatively passive marine encroachment into interdunal depressions (Warren, 1991; Kirkham, 1998).

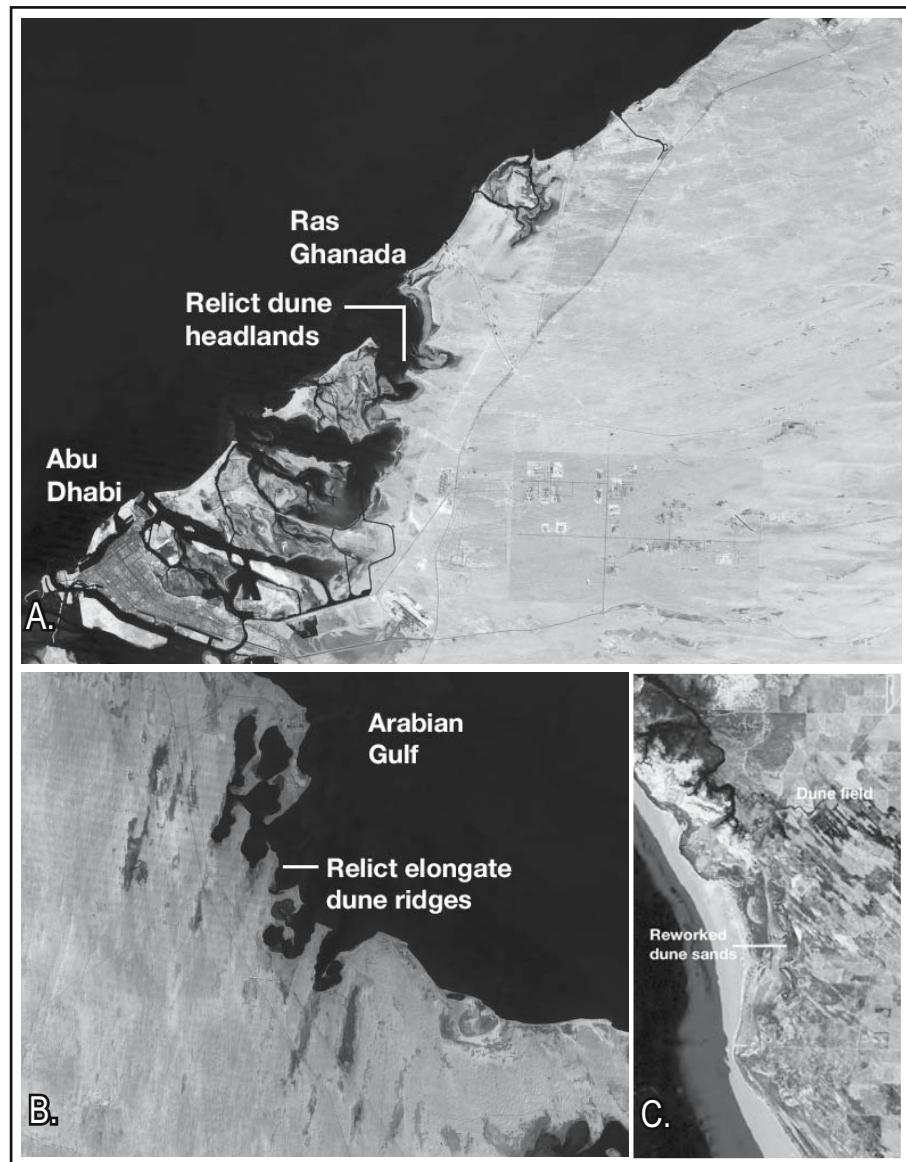

Figure 3.58. Examples of modern eolian sabkhas created by the Flandrian sea level rise and the encroachment of a seawater wedge into what were formerly continental interdunal corridors. A) Embayed sabkha-lagoonal coastline in the coastal zone between Abu Dhabi and Ras Ghanada, UAE. B) Embayed interdunal sabkhas in the coast south of Munfah, Saudi Arabian coast of the Arabian Gulf. C) Interdunal seepage sabkhas near Tickera, Spencer Gulf, South Australia. (All Landsat images are courtesy of NASA).

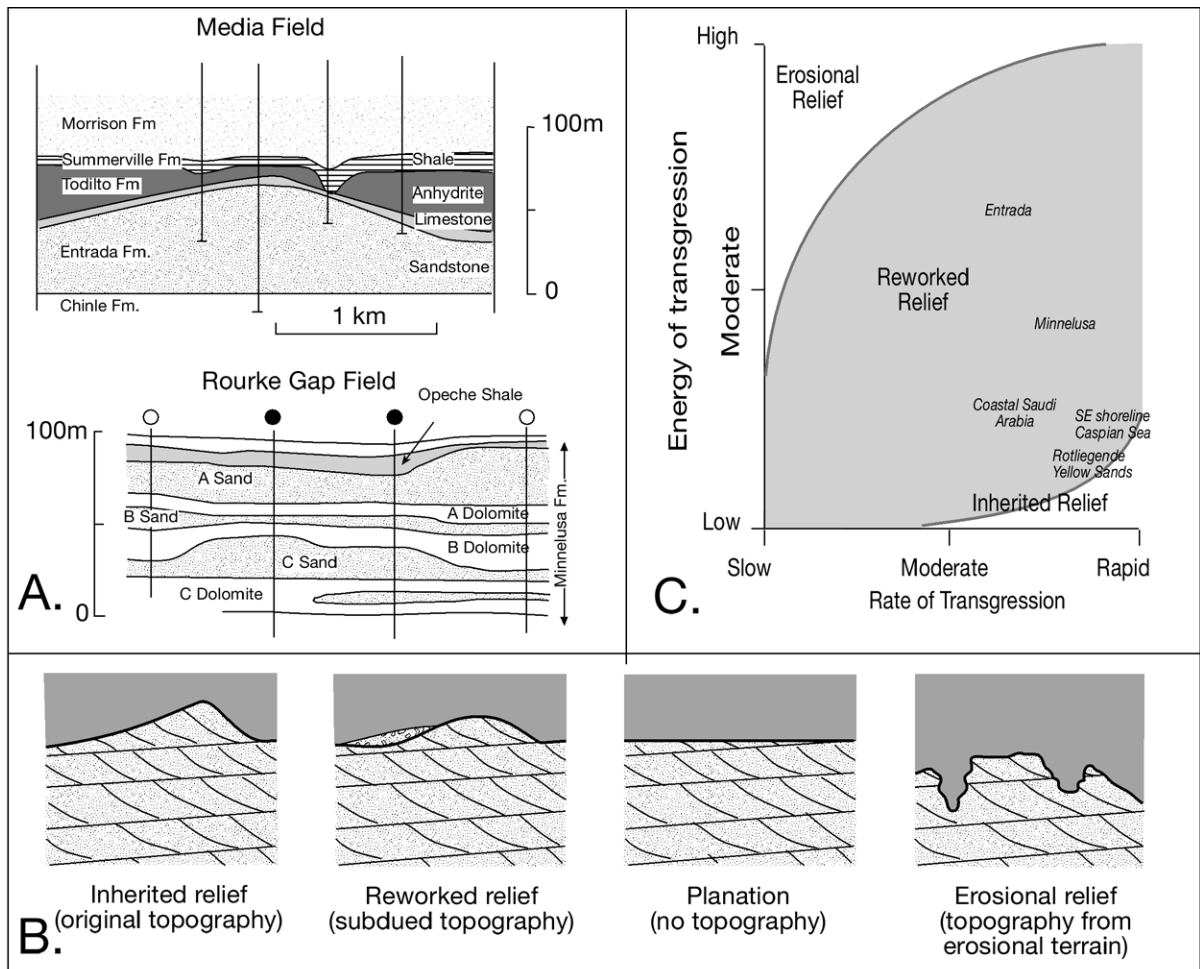

Figure 3.59. Preservation of marine-margin eolian sabkha. A) Ancient dune-hosted oil fields encased by an eolian sabkha seal (after Vincelette and Chittum, 1981; Achauer, 1982). B) Schematic of varying dune-sabkha contacts in transgressive marine-margin situations. C) Controls on the preservation of relict dune topography during a marine transgression (B and C after Eschner and Kocurek, 1988).

Interdraa coastal eolian sabkha geometries are even more obvious further along the coast in the region south of Munfah, Saudi Arabia (Figure 3.58b). There interdunal depressions are dominated by muddy sands with fringes of mm-scale biolaminites and displacive and lenticular gypsum growing at or above the water table (pers obs). Yet another coastal association of low-energy marine encroachment onto interdunal ridges is clearly seen on the northeastern Tickera coast of Spencer Gulf, South Australia (Figure 3.58c). In this case the encroachment was more energetic than on the Saudi coast. Many of the coastal sabkhas near Tickera lie parallel to the coastline in an area immediately behind coastal dune ridges. The most seaward quartzose dune sand ridges were reworked into these coast-parallel beach ridges, so the most seaward portions of the sabkha flat shows a coast parallel orientation.

It changes to a more obvious interdunal orientation a little further from the coast. All three systems are found in coastal zones on the edges of marine gulfs with limited fetch. Solute feeds to the three systems are all from groundwaters, although the proportions of marine versus continental inflow in the feed are still debated.

According to Eschner and Kocurek (1988) and Fryberger (1986), the geometry of preservation of an eolian dune system when undergoing transgression and possible encasement by an evaporite seal, is classifiable into inherited, reworked, and/or erosional dune morphologies at the contact with the sabkha evaporite (Figure 3.59a, b). Their modelling was done prior to our current understanding of the hydrological requirements needed to create platform and basinwide evaporite seals. We

now know that most laterally extensive marine evaporites are seepage fed systems that form when a basin is hydrographically isolated. There are no modern same scale marine analogs for this hydrology (Chapter 5); the dune-embayed coast of the southeast Caspian Sea is perhaps our closest modern analogy. Transgressing brines in an evaporite basin are an inherently low energy system and this is why ancient dune morphologies are best preserved below evaporite seals (Weissliegende and Entrada sands beneath Zechstein and Todilto seals, respectively).

Reworked dune relief, a preservation style which shows significant destruction of original dune topography, but with remnants preserved, is the most typical situation when an erg experiences marine encroachment or transgression in both the modern and the ancient. Modern examples include relict dunes of coastal Australia and the Arabian Gulf (Figure 3.58), Ancient examples include marine transgressed parts of the Jurassic Entrada Sandstone of the San Juan basin, and the Pennsylvanian-Permian Minnelusa Formation of Wyoming (Vincelette and Chittum, 1981; Achauer, 1982).

Whether inherited or reworked, how much dune relief is preserved in a marine transgression depends on the sand budget of the dunes and the erg, the degree of capillary cementation prior to transgression, and to the level of coastal energy in the transgressive environment (Figure 3.59c; Eschner and Kocurek, 1988; Fryberger 1986). Sand budget refers to the maintenance, gain, or loss of dune sand prior to and during initial transgression. Sand can be conserved and the dune form stabilized by vegetation, early capillary salt cementation, or a wind regime conducive to "sand trapping" by the dune as it is encroached by the sea (Eschner and Kocurek, 1988).

With thicker evaporite seals to the preserved dune morphology, the base of the seal tends to be a sabkha cement, hosted in the dune sands or its reworked equivalent, which in turn passes up into subaqueous evaporitic carbonates and salts of the evaporite proper. Cementation is typically due to capillary salts and so is tied to a shallow water table. Hence, the most intense capillary cementation can be associated with interdunal rather than high dune positions in the landscape. This creates a carbonate/evaporite cemented carapace that is more resistant to erosion than mobile loose sands of the draa crests. Upon transgression, this can create an inverted remnant topography with the cemented carapaces forming higher parts of the beleaguered landscape and corridors of marine embayment preferentially entering and reworking the more easily eroded loose draa sands (Fryberger, 1986). Remnants of this style of cementation beneath a platform or basinwide evaporite seal

can give strong directionality to permeability and create fluid flow corridors in the upper parts of an eolian reservoir sand beneath the seal.

Dune building and interdunal cementation can continue during initial transgression by maintenance of sand-drift paths, best accomplished by offshore winds, as seen today along the marine edge of southeastern Qatar (Figure 2.40). In contrast, dune forms can be degraded by deflation, a cutoff of the sand supply, and a variety of marine processes as is seen today along the At Taf coastal strip and the northern end of Sabkha Matti. Factors related to the nature of the transgressive environment and ultimate permeability in the reservoir sand include; (1) orientation of the dunes to destructive marine processes, (2) types of processes, (3) energy level, (4) type and rate of sedimentation, and (5) rate of marine encroachment (Eschner and Kocurek, 1988).

Preservation of inherited to reworked relief requires that the dunes ridges become stabilized or remain active into the early phases of the transgression. Effects of destructive marine processes are minimized by; 1) resistant, early capillary cement in the encroached dunes, 2) an orientation of the dunes such that marine energy is dissipated along a minimum area of the dunes, 3) low-energy, non-wave-dominated transgressive marine environment and 4) rapid transgression that reduces the length of time for reworking, or by high rates of marine sedimentation burying dune forms (Figure 3.59c).

Sheets of eolian sabkhat

This style of eolian sabkha is not as widely documented as elongate interdunal sabkhas. Yet modern examples characterize numerous continental interior situations where a rising water table in a deflationary sand sheet creates conditions suitable for the preservation of eolian sabkhas. They tend to be geomorphologically stable areas in that within a yearly sedimentation cycle they experience less erosion or deposition than nearby dunes sheets. In fact, because they lie in a moist hydrological zone below the top of the influence of the shallow water table, sheets of continental eolian sabkha tend to have much higher preservation potential than most of the crossbedded sands of the dunes. The latter sit above the water table and so have a tendency to blow on through (Figure 2.44f). Eolian sabkha sheets lie beneath exposed surfaces with high rates of sand cross-drift, a direct result of their saline watertable-induced flat topography and lack of vegetation. That is, in regions of shallow desert groundwater the flat bedded eolian sabkha sheets with characteristic capillary salts and Stokes surfaces

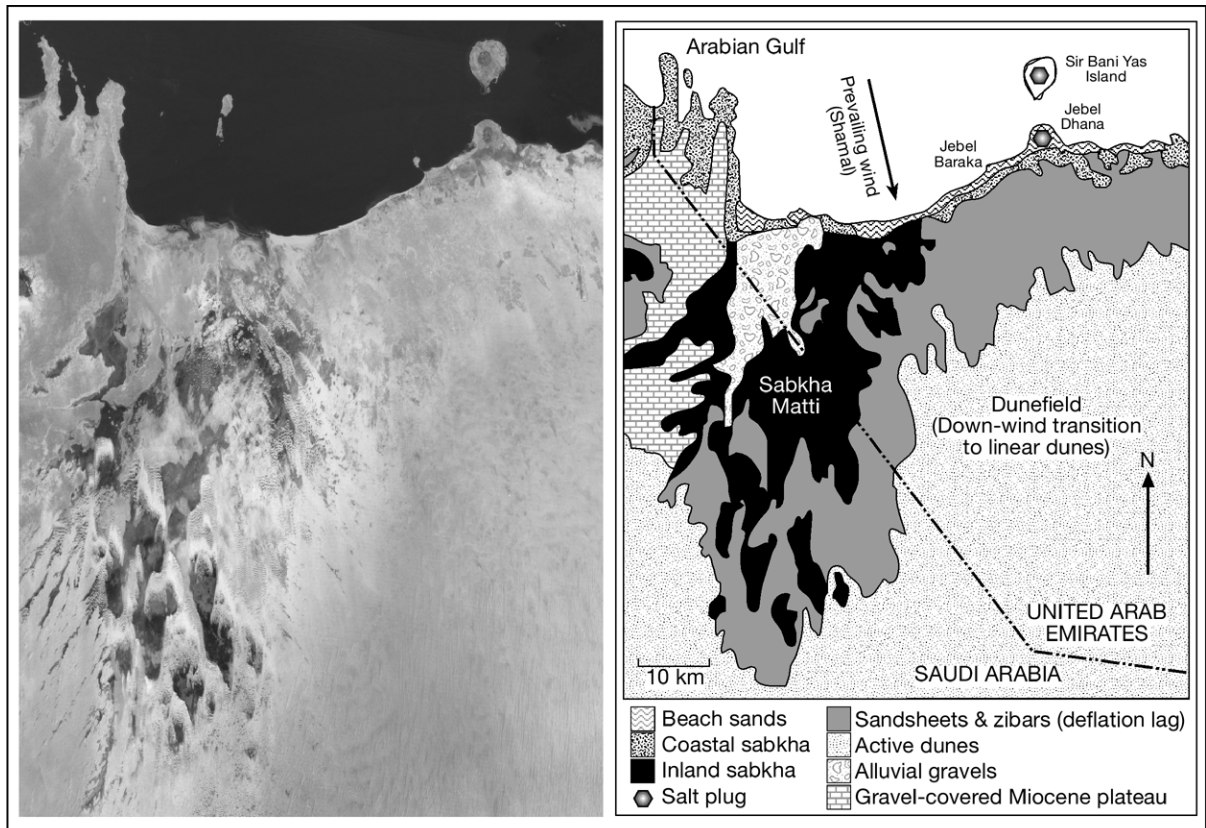

Figure 3.60. Sedimentary facies in Sabkha Matti, and inland sabkha in the southern central Arabian Gulf (in part after Alsharhan and Kendall, 2003; Landsat image courtesy of NASA).

are preserved more often than cross-bedded eolian sand, which by definition is deposited in a vadose environment and subject to ongoing deflation.

Depending on grain size of sediment in the capillary zone and the time of the year, the surface of a modern eolian sabkha sheet can lie up to a metre above the regional water table in the driest times of the year. Fluctuations in the regional water table in ergs can lead to the deflation of gypsiferous inter-draa sabkha and the creation of an eolian gypsum component to the dunes. This is the case in the near coastal region of Saudi Arabia where deflation has formed gypsum lunettes along the deflated pan margin of the gypsum encrusted Sabkhat ad Danan (Figure 3.16c.). Similar long term deflation of saline mudflats led to the downwind formation of extensive quartz dune fields as in the Late Pleistocene Chott Rharsa Basin of Tunisia (Blum et al, 1998) and to the growth of Holocene gypsum dunes along the edge of Lake Lucero in White Sands, New Mexico (Langford, 2003).

Continental eolian sabkha surfaces can be accretional or deflationary, depending on the availability of sand, subsidence rate and whether the water table is rising or falling. Deflationary eolian sabkhas typically leave behind little more than an evaporite-cemented Stokes surface and so have little preservation potential. Modern deflationary sabkhas are commonplace occurrences at the arid endorheic ends of large areas of monsoonal drainages, as in the Kallakooopah interdunal sabkhas and pans north of Lake Eyre and in the extensive dune fields of the Lake Chad Basin. Both are examples of the ephemeral stream-dune field-ephemeral saline lake association, discussed earlier in this chapter.

Accretionary eolian sabkha sheets have higher preservation potential and tend to characterise areas where eolian and alluvial sediment is piling up within rising artesian saline groundwater and surface water outflow zones. Such conditions are typically found at the foot of mountain ranges or in arid continental regions characterised by subsidence (alluvial fan-ephemeral saline lake association). This is the case at Umm as Samim (“Mother of Worries”) sabkha in Oman, which is fed matrix

sediment from the Oman Mountains and groundwater from the limestone aquifers of the Tertiary Umm Er Radhuma Formation. Accretionary sabkhas also occur in the Sabkhat Umm Ash Shuraybat in Saudi Arabia, where a combination of artesian resurgence and encroaching eolian sands facilitate an aggrading and prograding saline water table (pers. obs.).

In the region of subsidence that defines Sabkha Matti, for example, capillary salts are growing in zones of shallow watertables across large expanses within and adjacent to the flat surface of its deflationary sand sheet (Figure 3.60; Goodall et al., 2000). In the Sabkhat Matti region, the supratidal salt flats of the marine margin sabkha grade southwards into inland flats of the continental eolian sabkha with no distinct break in surface topography. The inland sabkha extends southwards for about 130 km and, in this distance, the land surface rarely rises more than 80 m above sea level (Figure 3.60; Goodall et al., 2000). This region constitutes a modern accretionary eolian sabkha sheet and is adjacent to dry mudflats and sand sheets. This in turn passes downwind into an active sand sea that is piling up at the foot of the Oman mountains. Sabkha Matti sand sheets form a sandy plain around the deflationary edge of the sabkha (Figure 3.60; Goodall et al., 2000). There is little information available on rainfall for the inland areas of Sabkhat Matti, but measurements taken on the coast show that average annual rainfall is less than 40 mm and it will be less further inland.

Evaporation of occasional ephemeral brine sheets reforms the salt crusts, which today cover large areas of Sabkha Matti for most of the year. The thickest salt crusts (1 ± 5 cm), with large megapolygonal pressure ridges characterise the Sabkha Matti surface situated within 5–10 km of the modern coast, further inland the Sabkha Matti surface is characterised by thinner salt crusts (≈ 1 cm) and smaller, lower-relief, pressure ridges, along with more numerous blisters and petees interacting with wind-blown sediments to form characteristic haloturbated structures (Fryberger, et al., 1979; Goodall et al., 2000).

The surface of the sabkha-hosting sand sheets of Sabkha Matti are planed by wind action (Stokes surface). Internally the eolian sabkha sheet consists mostly of low-angle eolian stratification (cm-scale laminae) created by migrating ripples and grainfall that can be altered by ongoing haloturbation. Quartz sand fills the saucers between eroded salt ridges and locally gives the Sabkha Matti surface a “leopard-skin” appearance (Goodall et al., 2000). The end result of ongoing wetting and drying in this sandsheet host is a highly disturbed sheet-like body of sediment entraining a variety of distinctive sedimentary fabrics.

They indicate salt-growth sediment deformation, salt-solution sediment collapse, sediment aggradation and compound mixtures of these processes. Salt-crust processes also produce features that may be confused with eolian adhesion structures (Goodall et al., 2000).

Some modern accretionary sabkha sheets are situated adjacent to zones where eolian dune sediment is also accumulating. They tend to be nearer to zones of sediment supply (reworked fluvio-lacustrine sediment) or be in regions where playas abut actively encroaching sand seas, often in association with ephemeral river breakout through the dunes. Sabkhat Umm Ash Shuraybat, an hour's drive southwest of Dammam in Saudi Arabia is one of the more accessible areas to see capillary processes in action in an accretionary eolian sabkha at the edge of a sand sea. It forms a zone of aggrading sabkha sedimentation in association with occasional floodwater ponding behind a sand sea (Figures 3.16a, 3.61a). The dunes are still active and form a cover to the aggrading outflow zone of a regional artesian aquifer. The dunes also store waters from rare periods of heavy rainfall. Because of this, the water table intersects the edges of some dunes and oases can form. They define areas where local fresher water seeps support a halophyte fringe and with evaporation also create the salts of the adjacent sabkha sheet. Spring mounds, cyanobacterial blisters and petees dominate in the seepage zones immediately downstream from the outcropping water tables that define the edge of the dunes (Figure 3.61b). In places the seepage waters are fresh enough to support a flourishing biota of ostracodes and brine shrimp (pers. obs.). Away from the seepage zone the accretionary eolian mudflats (a combination of desert loess and fluvially-supplied sediment) host displacive capillary gypsum, identical in morphology to that described for the coastal sabkhas of Saudi Arabia. Further down the fractionation trend in Sabkhat Umm Ash Shuraybat, the saline waters ponded in the lower parts of the depression and precipitated stacks of saline pan halite crust (Figure 3.61c). The resulting halite beds are up to 4 metres thick and layered at the decametre scale by thin laminae and partings of clay and anhydrite (Collenette and Grainger, 1994).

In addition to its currently active eolian sabkhat the Umm Ash Shuraybat area preserves evidence of a late Pleistocene river, which flowed into the Gulf but is now largely covered by dunes. Ephemeral streams which follow remnants of this old channel still flow into the dunes as periodically water-filled channels before being dammed by the dunes. Ponded water is then lost to the dunes via seepage. Historically, there is no record of the main stream channel breaking through the dunes to the coast in this region, although the satellite imagery suggests

Figure 3.61. Sabkhat Umm Ash Shurabyat, Saudi Arabia (Figure 3.15a for location). A) General location of the sabkha at the edge of the dune field clearly shows the position of the intersection between landscape and dune water table at position 1 where fresh to brackish phreatic water held in the erg seeps into the sand flat margin to create an oasis (position 1 as seen in 3.54b). B) View from puffy ground atop gypsum mudflat (eolian sabkha) and looking north toward oasis at the edge of the sand sea. C) Stacked saline pan halite facies with eolian silt laminae. Sample was extracted from position 3, each pan halite layer is between 5 and 10cm thick.

this may have happened in the last few thousand years. Better examples of catastrophic breakout of flooded rivers through an erg to the sea can be seen in Namibian ergs of the Skeleton Coast of southwest Africa (Svendsen et al., 2003). The result of periodic flooding, ponding and occasional breakout of a stream channel into any dune field is a number of clayey fluvial lenses in the interdunal corridors, which then act as a host for capillary sabkha salts. Such elongate or interdunal geometries fed by streams and deposited in corridors dominated by interdunal fluvial and carbonate marls (pedogenic), have been documented in the Permian sandstones of Utah and Colorado

(Driese, 1985) and in Tertiary “oases” in the Namibian desert (Smith and Mason, 1998).

It seems that some ancient counterparts of continental eolian sabkha sheets are preserved in regions where little or no crossbedded dune sand is preserved; these sheets do not show the elongate interdunal geometries that much of the literature seems to require for an eolian sabkha interpretation. Rather, they possess a sheet geometry associated with capillary evaporite-cemented and haloturbated muddy sands accumulating in large erosional capped flatlands (Figures 2.44f, 3.59b). Their sheet-

like distribution is the sedimentary response to their water table-capillary zone origins. Such sheet-like eolian sabkha systems typify the flat topped depositional setting of the Permian Yates Formation reservoir sands of west Texas and portions of the reservoir sands of the Rotliegende Formation in the northern Netherlands (Chapter 10). It is also the case for muddy sand sheets in parts of the Lower Triassic Sherwood Sandstone Group of offshore NW England (Cowan, 1993; Herries and Cowan, 1997) and parts of the Lower Permian Rotliegende Group in the North Sea (Goodall, 1995). In the North Sea examples, which are offshore reservoirs for gas, the change in understanding of the origin of these facies from fluvial shoestrings to haloturbated sand sheets has had profound implications in planning for the exploitation of the entrapped gas.

This is not to say all evaporite-cemented intervals in reservoir sands beneath an evaporite seal are preserved eolian sabkha caps. But sabkhas will be a commonplace signature of the transition from a completely isolated continental basin into the outcropping hydrology required for widespread evaporite deposition. The limited fetch of hydrographically isolated evaporite seaways, the widespread capillary cementation in the strandzone and across the basin at the onset of evaporite accumulation, along with the consequent low energy of the transgressing hypersaline water edge, will tend to better preserve dune topography. There will be less high energy coastal reworking of sediment compared to a marine transgression into a sand sea (Figure 3.58c). Excellent examples are preserved in the transition from the Rotliegende-Weissliegende into Zechstein evaporites in the Permian Basin of NW Europe and in the transition from the Jurassic Entrada into the Todilto evaporites in the San Juan basin of the USA.

In summary, eolian sabkhas are a response to areas of shallow subcropping water tables within or about the edges of continental sand seas (ergs). The matrix for the displacive evaporite growth comes from the sediments of the dunes blown onto the areas of shallow subcropping water table, or is supplied by fluvial processes periodically cutting through a sand sea. In many cases the geometry of the eolian sabkha is not an elongate shoestring or interdunal trend. Rather the capillary salts accumulate in areas of shallow water table in aggrading sand/mud sheets. Thus, in the rock record, narrow (1-2 km) elongate interdunal eolian sabkha trends have much lower preservation potential than areas of capillary cementation in eolian sand sheets (>5-10 km wide) accumulating in regions of rising water tables (Chapter 2). A rising water table can be driven by subsidence, changing climate, or by a rise in the regional hydrological base level driven by sea level rise. In these situations the eolian sabkha is more

likely to be deposited as the evaporite-cemented portions of a sand sheet with textures dominated by adhesion ripples and haloturbation rather than by preserved salts. High water tables and high salinities in “wet” or chemically-dominant sabkhas can induce widespread early cementation, which through its retention or dissolution may control lateral variations reservoir quality in ancient counterparts. Episodes of deflation during the aggradation of the eolian sabkha are indicated by “Stokes surfaces,” which are easily recognised in ancient eolian counterparts (Newell, 2001).

Salt pans (marshes) and diapirs

So far, we have discussed the various pans and sabkhas in a hydrologic framework of endorheic depressions, with the topography doing little more than supply the gradient to an arid groundwater and hydrographic sump. But there are also a few modern deserts where the drainage topography is not passive, rather it is salt-cored and replenished by halokinesis even as the diapiric salt is simultaneously recycled into salt encrusted depressions. Earlier in this chapter in the various South American salars, such as Salar de Uyuni and Salar de Atacama we saw a more passive mode of diapiric supply whereby ions derived from the dissolution of at-surface diapirs supplied significant volumes of ions (along with weathered acid volcanics), to the groundwater as it seeped into saline sumps floored by hardrock basement. But in parts of the Iranian interior, centred on the holy city of Qum located north of the Zagros Mountains and south of the Alborz Mountains, the role of the diapirs in controlling the drainage and groundwater network is much more active. There the diapirs and their namakiers create the landscape, the drainage patterns and supply ions to various suprasalt groundwater sumps so that recycled diapiric salt (Miocene) accumulates in salt-rich Quaternary playas atop suprasalt rim synclines (Figure 3.62).

The region is known as the Dasht-e Kavir or great salt desert; it is some 800 km long and 320 km wide, located southeast of the Alborz Mountains in north central Iran. It is a huge saline desert basin with endorheic drainage and named after the large kavirs (salt marshes) that characterise salt-floored depressions in the landscape. The Kavir Buzurg (Great Kavir), some 320 km long and 60 km wide, constitutes the lowest part of the desert depression. It lies in a rainshadow desert that is almost rainless. Strong surface evaporation in the salt marshes and wet saline mudflats in the lower regions of the kavir sump precipitates stacked crusts of pan and capillary salt with a high proportion of the ions in the crusts coming from the dissolution of nearby diapir crest. The ease of breaking through the

Figure 3.62. Diapirs composed of Miocene salt pierce the surface of the Great Kavir, Central Plateau of Iran (see also Figure 6.8b). Salt is dissolved from the diapir crest and redeposited in a saline pan facies in the rim synclines created by salt withdrawal adjacent to the diapir crest. (Diapir on the left is diapir No 10 in Jackson et al., 1990; Image courtesy of NASA).

surface salt crusts into hot dark saline mush beneath makes travel across the kavirs quite dangerous. The kavir's aridity and hostility means it is almost uninhabited and only partly explored; human settlement is largely restricted to the hills and mountains surrounding the kavir. Extending south from the Dasht-e Kavir is the Dasht-e Lut, which is a more typical sand and stone desert, some 480 km long and 320 km wide. It is dominated by dry mudflats and sandflats with extensive sand dunes and deflationary lag plains. Together the two deserts occupy most of the central Iranian plateau.

Salt in the various active diapirs that have surfaced in the Kavir plateau of Iran is much younger (Lower Oligocene-Miocene) than the Hormuz namakiers of SE Iran (Figure 6.45). This part of North Central Iran is undergoing north–south shortening between the Alborz mountains in the north and the Zagros mountains in the south (Talbot and Aftabi, 2004). Diapirs tend to emerge along releasing bends that have been pulled apart along major dextral transpressive faults in the central plateau of Iran. These structures include the small but mature salt fountain of Kuh-e-namak (mountain of salt in Farsi) near the holy city of Qum. This is probably the salt mountain best known to most Iranians because it dominates the western skyline of Qum, the religious capital of Iran some 140 km SSW of Tehran. It is probably the best described namakier and brief descriptions of Qum Kuh are given in Gansser (1957), Richter-Bernberg (1980), Aghashahi and Zomorodian (1981) and Jackson et al. (1990), with a more detailed analysis by Talbot and Aftabi (2004). Qum Kuh is of economic interest as centimetre to

decimetre thick beds of sylvinite ($KCl \pm NaCl$) are interbedded with the halite and repeated by folds in the extrusion.

The shapes of these extrusions of Tertiary salt indicate that they have followed a history similar to that of extrusions of the older Hormuz salt in the Zagros (Figure 6.45). Gansser (1957) and Jackson et al. (1990) noted that salt deformation in the central Iranian Plateau involves two Tertiary-age salt sequences: a clean white salt at the base of the ductile marls and shales of the Lower Oligocene Lower Red Fm, and a rhythmic sequence of multicoloured salt at the base of the salty marls of the Lower Miocene Upper Red Fm. These

two salt sequences are generally separated by limestones of the Qum Formation that do not surface in emergent salt structures (Talbot and Aftabi, 2004).

Influence of the diapir-induced topography is clearly seen in the position of the various modern saline pan facies, which tend to stack in the lows atop secondary rim synclines adjacent to outcropping salt ridges of the diapir high (Figure 3.62). The dissolution of this Miocene salt supplies most to the salt accumulating in the depressions. Further away from the diapir crest is the saline mudflat interval, which tend to dominate atop turtle-structure anticlines. Based on the Landsat imagery this mudflat succession is topographically higher than the sump of the saline pan floor, arguing that the zone of maximum salt withdrawal (indicated by maximum subsidence at the landsurface) has migrated progressively closer to the stem from the position of the original primary rim syncline (see Chapter 6 for a discussion of topography associated with diapirs and turtles).

Although as yet poorly documented, the sedimentology of this diapir-cored landscapes offers an excellent modern analogue for syndepositional responses to halokinetic highs such as those that once characterise the salt beds of the Triassic Kueper Fm. in Germany and the Cretaceous Maha Sarakham Fm. of Thailand. (Mohr et al., 2004; Warren, 2000c).

Chapter 4: Subaqueous salts: salinas and perennial lakes

Introduction

Ancient shoalwater platform (saltern) and deepwater (slope and basin) evaporites are subaqueous precipitates and, together with saline pan and mudflat evaporites, encompass all the ancient depositional settings where solar-driven evaporites can precipitate (Chapter 5). But, as for mudflats and pans, when we seek analogues for ancient subaqueous salts in the Quaternary marine record we find our choices are limited. As we shall see in Chapter 5, there are two main reasons for this dichotomy between examples of Quaternary and ancient marine-fed evaporites. First, we live in an icehouse earth characterised by climate-driven high-amplitude high-frequency changes in sea level. In marine settings this can only form small-scale coastal ponds and mudflats with limited preservation potential. Widespread marine seepage-fed platform evaporites simply cannot be preserved in this hydrology, they require the hydrological stability associated with much gentler sea level fluctuations that characterised greenhouse earth climate. Second, there are no sizeable areas on the world's surface today where the appropriate combination of tectonics and climate have hydrographically isolated and desiccated whole ocean basins and so turned them into subsealevel seepage-fed marine basins. What we are left with today as depositional analogues for ancient marine

subaqueous systems are transient, limited-scale sea-margin settings or somewhat larger high-relief saline lakes in closed intermontane basins (Table 4.1). Neither setting approaches the scale or setting of most ancient marine-fed systems. To form a permanent body of saline water in the Quaternary, with a lateral extent of more than a few tens of kilometres, and with salt beds accumulating to thicknesses of more than a 50 metres, requires a high relief tectonically-active continental closed basin. It needs a landscape characterised by subsidence of the lake floor and the maintenance of a longterm brine or reflux plume (brine curtain) within and beneath the accumulating salt beds.

Until the 1970s most subaqueous evaporite textures had been documented in ancient halite-rich basins (e.g. Dellwig, 1955) and very few examples of modern subaqueous gypsum or halite deposition had been published. Then Holocene subaqueous gypsum was documented in sea margin settings in Baja California, the Mediterranean, Southern and Western Australia and the Middle East (von der Haar and Gorsline, 1977; Aharon et al., 1977; Schreiber and Kinsman, 1975; von der Borch et al., 1977; Arakel, 1980). This work led to a new understanding of the significance of laminar and bedded textures (both sulphate and

Table 4.1. Some examples of perennial saline evaporite settings in Quaternary coastal and continental settings.

halite), so that in the last 10-15 years many ancient evaporites, previously interpreted as sabkhas, have been re-evaluated and found to be combinations of a number of mostly subaqueous settings. In the last twenty years we have also documented the beginnings of a partial Holocene analog for ancient deep water evaporites via the ongoing hydrological transformation of the Dead Sea into a halite-accumulating perennial lake.

Let us now look at some modern examples of subaqueous evaporites, first in small coastal subsealevel (sea-margin) settings then in larger Quaternary lacustrine depressions.

Sea-margin subaqueous salts

Modern subaqueous evaporites are forming today in shallow marine-fed coastal lakes or salinas around the edges of the

Mediterranean, the Black Sea, the Red Sea and along the southern and western coast of Australia. All these marine-fed systems are subsealevel depressions, all lack a permanent surface connection to the sea (hydrographically isolated) and are supplied solutes via seawater seeps (marine-fed).

Coastal salinas of Australia

Holocene salinas occupy isolated depressions within Quaternary calcareous coastal dunes along the southern and western coasts of Australia (Figure 4.1). Most are filled, or are filling, with bedded subaqueous evaporites; some are filled with evaporitic carbonates (e.g. Coorong dolomite lakes and Sleaford Mere in Southern Australia, Lakes Clifton and Haywood in southwestern Australia), while others are filled by combinations of carbonate, gypsum and halite (Marion Lake, Lake Macdonnell and Lake MacLeod complexes). Solutes in all the salinas are supplied by

resurging groundwaters, no salina has a surface connection to the sea if subaqueous evaporites are accumulating (hydrographically isolated). Seawater seepage, plus varying amounts of meteoric water, supply coastal salinas filling with gypsum or halite, while carbonate-filled salinas are largely supplied by resurging continental groundwaters. Winter temperatures typically reach 10° to 20°C and rarely fall below freezing, summer temperatures are often in the 30's but can occasionally climb into the 40's. The CaSO₄ phase in coastal Australia is always gypsum, not anhydrite, temperatures are not high enough, nor the basins arid enough, to deposit anhydrite. Its lack tempts one to propose that primary sedimentary anhydrite only forms as a capillary salt in hot arid mudflats (?thermalites) and never forms as a subaqueous precipitate at the sediment-brine interface in nonhydrothermal waters.

The three salina styles -carbonate versus gypsum versus halite- can be separated using annual

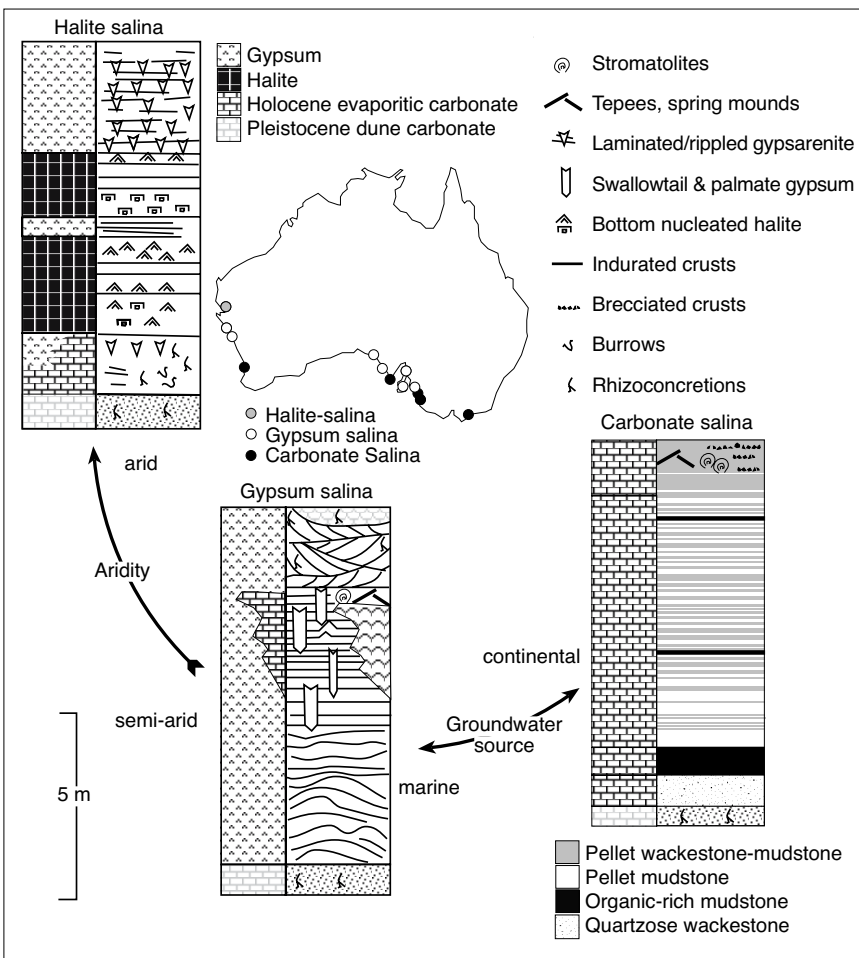

Figure 4.1. Climatic and groundwater spectrum, textures and mineralogies in the Holocene coastal salinas of southern and western Australia (after Warren 1982a,b; 1990).

Figure 4.2. Algal tufas of Sleaford Mere, Southern Eyre Peninsula, Australia. A) Tufa reef mounds define the lake strandline (kangaroo for scale). B) Looking down on the cracked, knobby and crenulated surface of indurated calcite tufa mounds (coin for scale).

rainfall, an indirect measure of the degree of coastal aridity. Carbonate salinas dominate in the higher rainfall parts of the southeastern coast of South Australia and the southwestern coast of Western Australia, where annual rainfall is 450-800 mm. Gypsum salinas typically form best along the semi-arid southern Australian coast where annual rainfall is between 300 and 450 mm/year, while the halite-filled salinas such as Lake MacLeod form in arid areas of the central western coast of Australia where annual rainfall is less than 300 mm.

Carbonate salinas

The best documented and most voluminous carbonate fills of Holocene salinas, including some salinas filled with Holocene dolomite, are found in Pleistocene interdunal corridors behind the main Coorong lagoon in South Australia (Figure 4.2). There are numerous less well documented examples of Holocene lacustrine carbonates accumulating in coastal salinas in other parts of southern and western Australia, such as Sleaford Mere on Eyre Peninsula, and Lakes Clifton and Haywood in southwest Australia (Figure 4.1). Actively growing tufas dominate the strandlines in these other settings, they are indurated reef mounds (thrombolites and tufas) unlike many of the leathery Holocene cyanobacterial mats and mounds of the Coorong Lakes. Further out into these tufa-fringed salinas, where water depths can be up to 4-5 metres, bottom sediments are laminated ostracodal pellet wackestones and mudstones. Bioherm shapes around the salina edge range from elongate reef terraces to isolated domal and conical mounds, some with Conophyton-like shapes. Individual mounds can be 2 metres high and extend as reefal terraces for up to 6 km along the salina strandline (Figure 4.2; Warren 1982a; Coshell et al., 1998; Konishi et al., 2001).

The Coorong Region was first documented as an area of modern dolomite precipitation by Mawson (1929), but was not studied in any detail until the work of Alderman and Skinner (1957), von der Borch (1965, 1976), von der Borch and Lock (1979), Rosen et al. (1988, 1990), Rosen et al. (1989) and Warren (1988,

Figure 4.3. Coorong region in the area centred on the township of Salt Creek, South Australia. Part of the 120 km long barrier island, composed of carbonate sand (Youngusband Peninsula), is visible, backed by the waters of the Coorong Lagoon, which is floored by mm-laminated aragonite muds. Laminated lacustrine carbonates, including dolomites, are accumulating in lakes in isolated interdunal corridors behind the Coorong Lagoon -see Figure 4.4 (Landsat image courtesy of NASA).

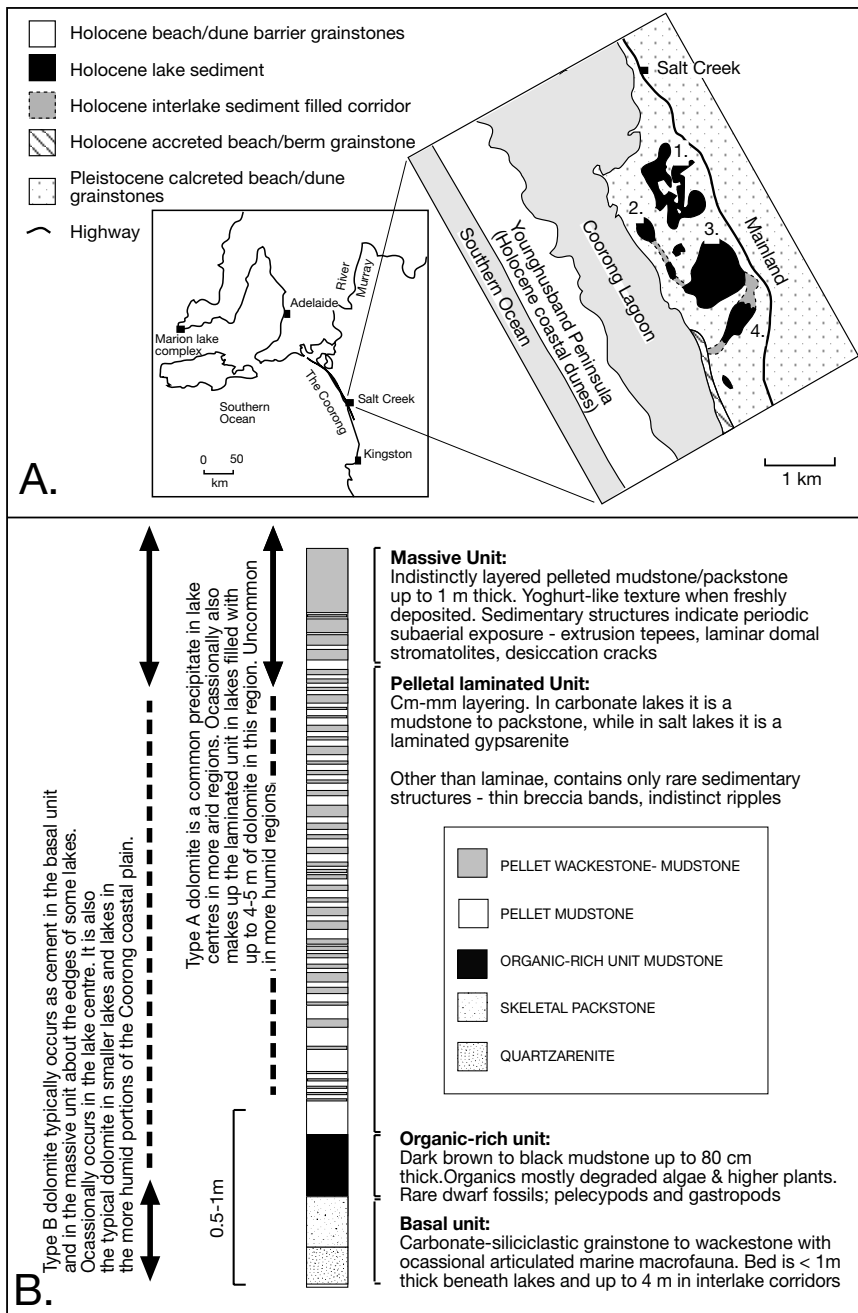

Figure 4.4. Coorong Lakes, South Australia. A) Locality and map of the Coorong region. Geological plan of the Salt Creek region shows how three of the four major lakes are joined by an interdunal corridor and were connected to the Coorong lagoon earlier in the Holocene. Milne Lake, the best dolomite accumulator in the Coorong coastal plain, never had a surface connection with the Coorong Lagoon. Mineralogies: Lake 1 = Milne Lake (dolomite + magnesite), Lake 2 = Halite Lake (gypsum + aragonite overlain by hydromagnesite + aragonite in massive unit and currently covered by ephemeral halite crust), Lake 3 = Pellet Lake (dolomite + hydromagnesite + aragonite), Lake 4 = North Stromatolite Lake (hydromagnesite + aragonite; minor dolomite in basal unit and about lake edge) (after Warren, 1990). B) Typical vertical sequence in Holocene evaporitic lakes of the Coorong coastal plain. (after Warren, 1990; 2000a).

1990). Most work in the region concentrated on salinas that contained dolomite, but there are many salinas, probably the majority, where the fill is dominated by carbonate mineral phases other than dolomite (Warren, 1990). Fills include low and high Mg-calcite, magnesite, hydromagnesite, aragonite, and less commonly gypsum (Figure 4.3). Von der Borch (1976) observed that Holocene dolomite occurs in areas of the coastal plain where rainfall is less than 700 mm, encompassing the area between Kingston and Salt Creek (Figure 4.4a). He suggested that south of the 700 mm isohyet, reduced evaporation rates and higher rainfall prevented the concentration of lake waters to salinities where dolomite could precipitate. Regional sampling of lakes across the area tied to climate confirms his postulate and shows that the more magnesian-rich dolomites tend to occur in the more arid northwestern portion of the Coorong coastal plain, centred on lakes in the vicinity of Salt Creek, while Mg-calcite and calcite filled salinas are increasingly common in the cooler moister parts to the southeast (Warren, 1988, 1990).

Textures in carbonate salinas are largely independent of mineralogy and can be related to salinity, brine depth and permanence (Figure 4.4b; Warren, 1990; 1991). If the salina possessed an early Holocene connection to the marine waters of the Coorong Lagoon, then the lowermost Holocene unit is a marine/estuarine skeletal grainstone/

Figure 4.5. Salina geology. A) Domal stromatolite; North Stromatolite Lake. B) Extrusion tepee; North Stromatolite Lake C) Domal stromatolites capping tepee polygons Marion Lake. packstone, similar to Holocene units flooring the more saline salinas of the Marion lake Complex and Lake MacLeod. If there was no marine connection to the Coorong lagoon then the basal unit is a quartzose packstone to wackestone. These lowermost sediments can contain small percentages of diagenetic calcian dolomite (Rosen et al., 1989). Above the lowermost unit is a variably-developed massive to faintly laminated organic-rich

unit. In lakes with an early marine connection the levels of total organic carbon (TOC) in this unit can be as high as 12%, usually as an oil-prone proto-kerogen. Its formation indicates a seasonally stratified water column where fresh water seasonally overlay stagnant marine water during the transition from a surface connected marine estuary to a totally isolated groundwater-fed salina.

Above this is a mm-laminated unit of pelletal packstone to mudstone, deposited on the floors of perennial, but schizohaline, density-stratified brine lakes, which formed in the Salt Creek region once the estuarine connection to the open Coorong Lagoon was cut off by beach-ridge accretion at the entrance to the chain of salinas (Figure 4.4a). The proportion of faecal pellets in the laminated unit is a direct reflection of energy level and organic binding on the subaqueous salina floor. In areas of higher wave energy/bottom currents and little or no algal binding, the sediment is a packstone. Such sediments are more common about the salina edge and in the shallower parts of the more central sediment fill. In areas of lower wave energy in relatively deeper water, or in areas of algal binding, the sediment is a wackestone or at times a mudstone. Muddier sediments are more common in the central parts of a salina. In a few coastal salinas with no early Holocene marine connection, such as Milne Lake, the laminated unit is composed of magnesian dolomite up to 5 metres thick (Figure 4.4a). More typically it is composed of varying proportions of aragonite, hydromagnesite, magnesian calcite and low magnesian calcite. In one marine-seepage lake (Halite Lake) it is made up of laminated gypsum/aragonite couplets.

Capping the lake sediments is a “massive” unit of poorly layered packstone/mudstone. It is usually less than 60-80 cm thick and shows varying degrees of induration from brecciated crusts about the salina edges to domal leathery stromatolites in some of the more central water covered areas. Domal stromatolites seem to flourish in Coorong salinas filling with a mixture of hydromagnesite and aragonite (Figure 4.5a). This, the uppermost part of the sediment fill, usually holds the bulk of the evaporative dolomite in the majority of carbonate salinas containing dolomite, especially in the vicinity of Salt Creek. But the Massive Unit can also be composed of aragonite, hydromagnesite, magnesian calcite and magnesite. It contains numerous terrestrial burrows and root traces, as well as mud cracks, extrusion tepees and breccia fragments - all features indicative of at least occasional desiccation and thorough bioturbation (Figures 4.4b).

Whatever the mineral assemblage, the dominant textural feature in the sediment column of a carbonate salina is lamination passing up section into a more massive unit with evidence of seasonal subaerial exposure of the sedimentation surfaces. Tepee-overprinted carbonate crusts are especially common in the desiccated strandzones of the lake margins (Figure 4.5b), while domal stromatolites and cyanobacterial are common in the area of more permanent brine, especially in salinas precipitating hydromagnesite and aragonite. Brackish lakes, such

as Lake Fellmongery, in the southeastern part of the Coorong coastal plain have well-developed algal tufa fringes, with some tufas first precipitated as monohydrocalcite and quickly altering to calcite. Surfaces of all the carbonate-filled salinas in the Coorong coastal zone are half a metre or more above sea level indicating the current nonmarine supply of waters (as groundwater cannot flow up hill). Some lakes had a marine seepage connection in their earlier stages of infill (e.g. Halite Lake; Figure 4.4a).

Volumetrically, most salina carbonates form by the evaporation of unconfined magnesium-rich continental groundwaters, driven to the surface along the coastal zone as they float up over a more dense seawater wedge. That most dolomite forms where large volumes of resurging continental waters can evaporate explains why the thickest Coorong dolomites form adjacent to the present coast. However, mineralogically similar dolomites are also precipitating 20-40 km further inland as thin capping

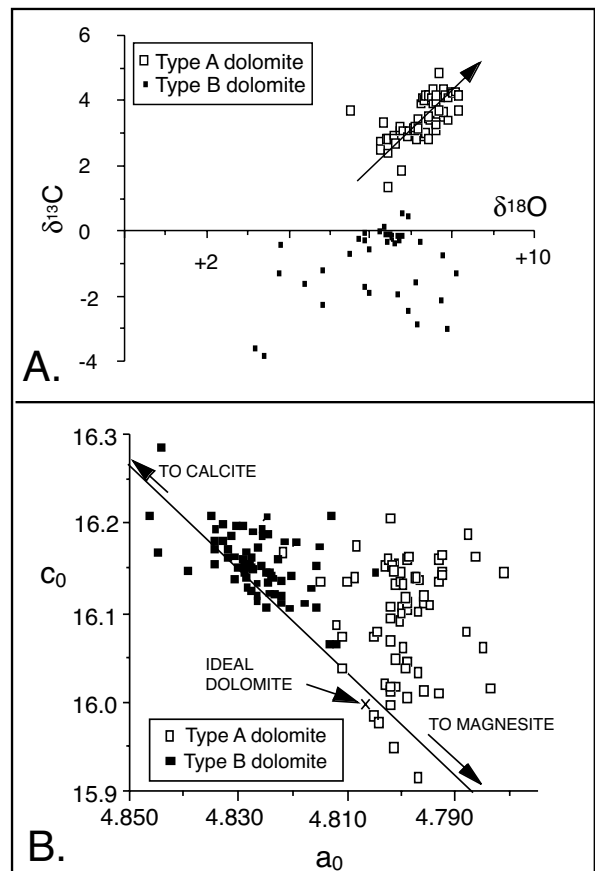

Figure 4.6. Geochemistry of Coorong dolomites. A) Isotopic signatures of Type A and Type B dolomite. B) Unit cell parameters of type A and Type B dolomite (after Rosen et al., 1989; Warren, 1990).

units in fully continental ephemeral lakes. These areas are well away from the seawater wedge, but still in areas where the regional water table intersects the land surface and continental groundwaters can pond and evaporate.

Dolomites in salinas in the Salt Creek region precipitate as two geochemically and isotopically distinct types (Type A and B), typically in association with other carbonate minerals. Type A dolomite has a slightly heavier oxygen isotope signature than type B, and is 3 - 6‰ heavier in ^{13}C (Figure 4.6a). Type A dolomite also has distinct unit cell dimensions (Figure 4.6b). It tends to be magnesium-rich with up to 3 mole percent excess MgCO_3 , while type B is near stoichiometric or calcian-rich. Type A dolomite commonly occurs in association with magnesite and hydromagnesite, Type B with Mg-calcite. Transmission electron microscopy (TEM) shows that Type A dolomites have a heterogeneous microstructure due to closely spaced random defects, while type B dolomites exhibit a more homogeneous microstructure implying that excess calcium ions are evenly distributed throughout the lattice. TEM studies show that the two types of dolomite are distinct and are not intermixed with other mineral phases; they are primary precipitates, and not replacements (Miser et al., 1987).

Dolomites in carbonate salinas are evaporitic carbonates, once thought to only form in areas free of preserved evaporites (von der Borch and Lock, 1979). Yet, Milne Lake, a salina filled with 4 metres of laminated dolomite-magnesite, lies less than a kilometre from Halite Lake, a depression filled with 2-3 metres

of laminated gypsum-aragonite (Figure 4.4a; Warren, 1990). Milne Lake was fed seaward-flowing continental groundwaters throughout its infill history. Halite Lake during the gypsum stage of its fill was fed by landward-flowing marine groundwaters (evaporative drawdown stage). Today Halite Lake is filled to its hydrological equilibrium level; its present depositional surface lies above the level supplied by marine seepage and it no longer accumulates laminated gypsum-aragonite. Above its laminated gypsum-aragonite unit is a 10-50 cm thick capstone bed of pelleted aragonite-hydromagnesite, a mineral association that indicates the current surface hydrology is dominated by a nonmarine groundwater feed (Warren 1990). Other Coorong Lakes in the same climatic zone, but located further inland, and more isolated from resurging marine groundwaters, are completely filled with this aragonite-hydromagnesite association (Figure 4.4a; North Stromatolite Lake and South Stromatolite Lake).

Gypsum salinas

Gypsum-filled coastal lakes are located mostly to the west of the Coorong coast (Figure 4.1) and are best documented in the region of Marion Lake on the southwestern tip of York Peninsula (Figure 4.7a). Groundwater feeds to these salinas are dominated by seawater, so the current hydrological equilibrium surfaces (Stokes surface) in all the gypsum salinas are still up to 50 cm below sea level. In plan view the surface sediments of a gypsum salina define bull's-eyes, consisting of a carbonate seepage rim and a more central gypsum zone (Figure 4.7b).

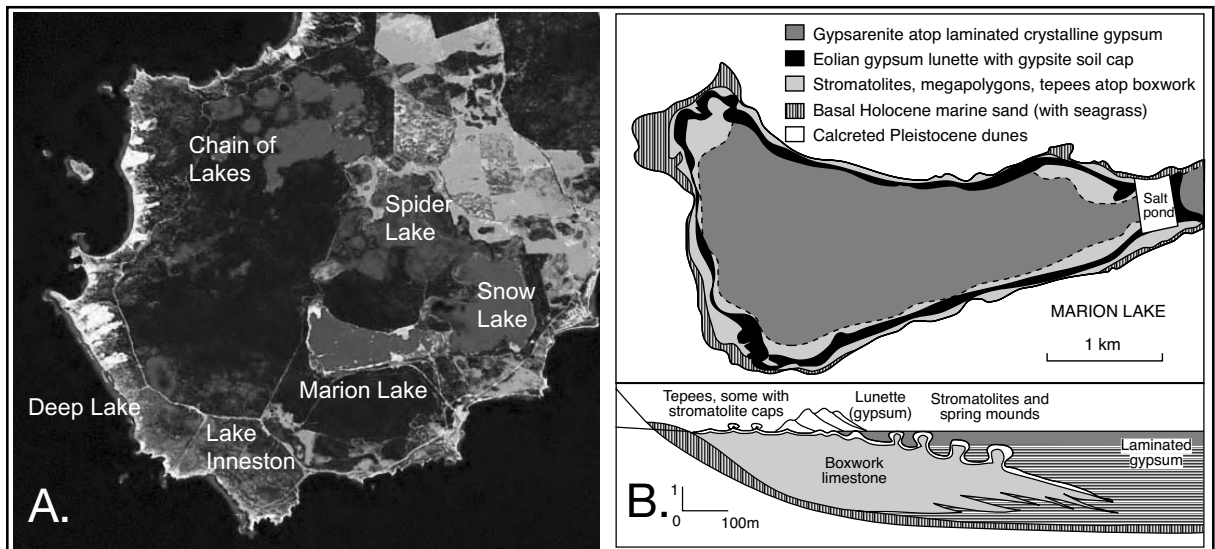

Figure 4.7. Gypsum salinas. A) Seepage fed coastal salinas of the Marion Lake complex at the southwest tip of Yorke Peninsula, South Australia. B) Surface geology and cross section of Marion Lake are after Warren, 1982a,b. (Landsat image courtesy of NASA).

Figure 4.8. Gypsum facies in South Australian salinas, after Warren 1982b, showing domes overlain by laminites and the eolian reworking of upper portions of the lake sediments into gypsite-capped lunettes. For simplicity, the carbonate rim is not shown (see Figure 4.7b).

Individual gypsum-filled salinas measure up to 20 x 12 km (Lake Macdonnell on the coast of the Great Australian Bight) with centres filled by laminated gypsum units up to 10m thick.

A carbonate unit forms a seepage rim about the salina edge and is composed of a boxwork limestone unit (up to 4 to 5 m thick) overlain by a fenestral limestone sheet or crust, which is less than 1 m thick (Figure 4.7b; Warren 1982a). Boxwork limestone is a diagenetic unit created by the cannibalization of earlier marine-lacustrine carbonates and sulphates by inflowing “fresher,” but still saline, marine-derived groundwaters. The “boxwork” contains relict algal structures, evaporite pseudomorphs and other highly altered bedded fabrics in proportions depending on pre-existing sediment types. Some areas of the limestone sheet above the boxwork limestone consist of tepee-overprinted crusts, others of mm-laminated subaqueous stromatolites and algal mats.

Taller stromatolites in Marion Lake grew as current-aligned mm-laminated elongate domes (up to 40 cm tall) in a brine-filled feeder channel, that focused the flow of marine seepage waters into the perennial gypsum lake of the salina centre (Figure 4.7b). Other smaller domal and encrusting stromatolites define the water-saturated cyanobacterial terrace of the lake strandzone where indurated biolaminites define areas of very shallow and sometimes ephemeral surface waters (von der Borch et al., 1977; Warren, 1982b). Stromatolite domes cap tepee structures in some marine-fed seepage areas (Figure 4.5c). Like stromatolites,

the tepee structures are confined to the capping carbonate unit and form an extensive fenestral limestone sheet up to 60 cm thick. Tepees form readily in areas of resurging groundwater, where seasonal changes in the groundwater head encourage tepee growth (Warren, 1982b). Most of the limestone sheets caught up in the tepee structures are capillary crusts composed of fenestral lime mudstones containing stromatolite-like voids, pisolites, laminar cements, and geopetal internal sediment partially filling pores and vugs. A similar lake-margin recharge hydrology controls the formation of stromatolite-capped tepees in Holocene Lake Walyungup in coastal Western Australia (Coshell et al., 1998).

Salina gypsum in the central portions of Marion Lake is coarse-grained, porous, bottom nucleated and growth aligned; it retains intercrystalline porosity of 15-25%; pore infilling gypsum cement is rare (Figure 4.8). South Australian salinas are one of a few Holocene occurrences where subaqueous gypsum is deposited as widespread units of coarsely crystalline bottom-aligned swallowtail and palmate crystals (Table 4.1; Warren, 1982a). Worldwide, gypsum in most modern salinas is a layered gypsarenite. The cm-scale gypsum crystals are usually more than 90% pure and laid down as characteristic shallowing-upward growth-aligned crystal aggregates (Figure 4.1). At the base of an idealized succession are massive, poorly layered domes of coarsely crystalline palmate and swallow tail crystals (aka selenite; Figure 4.8). Modern growing examples of this style can be found regrowing on the floors of flooded mined-out

salinas such as Lake Inneston (Figure 4.5d). The elongate gypsum prisms in the early stages of dome growth show little or no preferred orientation, with carbonate pellets and flakes distributed randomly through the gypsum porosity. Active domes on the floor of Lake Inneston are coated by microbial slime and can be considered to be a type of coarsely-layered gypsum stromatolite.

Higher in the section the degree of lamination increases and dome amplitude decreases until domes pass into sub-horizontally layered and laminated units of aligned crystals (Figure 4.5e). Higher still, individual laminae of pelletal and micritic aragonite appear to crosscut large upwardly-aligned gypsum crystals (Figure 4.5f, 4.8). Such large crystals at first sight appear secondary and their Miocene equivalents in the Sicilian Basin were once interpreted as secondary gypsum after anhydrite (Ogniben, 1957). Studies of identical Holocene gypsum in the South Australian salinas have shown that the crystals (30 to 50 cm long) are primary, not secondary. They grow with their long axes perpendicular to bedding, an effect of crystal impingement and growth alignment (Figure 2.49; Warren, 1982b).

Gypsum is not only deposited as coarse-grained gypsum (selenite) in South Australian coastal lakes. Some salinas are filled with laminated gypsarenites and are probably as common, if not more common, than those filled with the geologically more interesting coarsely-crystalline gypsum. Laminated gypsarenite fills large interdunal corridors near Streaky Bay and Point Fowler in South Australia and Hutt and Leeman Lagoons in Western Australia (Figure 4.1).

In salinas with coarse-grained fills, the coarsely-crystalline laminated gypsum (selenite) unit, punctuated by carbonate laminae, is in turn overlain by a mm-laminated, sand-sized gypsarenite accumulation (Figure 4.8). Parts of the horizontally laminated gypsarenite unit, especially near the salina strandzone, can be reworked into wave-oscillation ripples. Laminated and rippled gypsarenite is in turn overlain by a thin, massive, poorly-bedded gypsarenite unit deposited under seasonally vadose or subaerial conditions and represents accumulation in the salina capillary fringe.

Topping the whole succession is a unit of cross-stratified eolian gypsum and, in areas stabilized by vegetation, a pedogenic cap of gypsite (silt-sized). This gypsum soil is a degradational profile that is slowly cannibalising depositionally inactive regions of both lacustrine and eolian gypsum throughout coastal and inland Australia (Figure 4.5g).

Carbonate laminae in the various gypsum units form by the precipitation and accumulation of aragonite pellets during the spring and early summer (Chapter 9). The pellets come from the faeces of ostracodes and brine shrimp, mixed with the micritised remnants of algal tubules. At first the pellets mantle any underlying gypsum and often are captured by a cyanobacterial mat that covers the gypsum. During the ensuing summer and autumn, as the lake maintains its gypsum saturation, the pellets are encased by the upward poikilitic growth of large gypsum crystals (Figures 2.49, 4.5e, f).

Figure 4.9. Lake MacLeod, Western Australia. It is the largest evaporite-filled coastal salina in the world. Marine-fed brine springs and sheets are visible in the central western and northwestern strandzone, while solar ponds are visible in the south. The interdunal depression only started to accumulate Holocene salts after its surface connection to the ocean at its southern end was cut off by longshore sand drift (Landsat image courtesy of NASA).

Halite salinas

Lake MacLeod is a halite-filled salina some 120 km long and 40 km wide, lying just to the north of Shark Bay (Figure 4.9; Logan 1987; Handford et al., 1984). Climate is arid, with average rainfall around 230-260 mm and annual potential pan evaporation in excess of 2,600 mm. The surface of much of Lake MacLeod still lies well below sea level indicating evaporative drawdown and a groundwater feed from the nearby Indian Ocean. Some parts of the lake depression, especially near the marine seeps, are still covered with semipermanent water sheets. In its northern part, and across the current lake surface, the lake fill is a Holocene gypsarenite unit; it is as much as 5 metres thick along the northern and western (seaward) sides of the lake (Figure 4.10). To the south and beneath the laminated gypsum unit is a widespread halite bed up to 7 m thick. It is made up of stacked halite crusts, dominated by growth-aligned chevrons and cornets. Brines from this halite unit in the south are pumped into saltwork ponds to produce halite for the chemical industries of southeast Asia. Gypsum is also dredged in the northern part of the lake and is mostly used for wallboard manufacture (Chapter 11) Both the gypsum and the halite overlie a thin unit of Holocene lagoonal carbonate deposited prior to the depression's transition from marine embayment to coastal seepage lake.

Lake MacLeod never possessed a surface (hydrographic) connection to the ocean at any time in its salt-accumulating Holocene history. Seawater seeps onto the subsealevel lake floor via a series of marginward carbonate-precipitating spring pavements and beds, fed from fractures and caves in the underlying and surrounding calcareous coastal dune aquifer. As the escaping water exits the dune aquifer it degasses and concentrates to salinities where it precipitates seepage or strandzone carbonates. Aragonite pisolites and tepees are still forming today, especially about seeps along the eastern and northern edges of the MacLeod salina (Handford et al., 1984).

The northern part of the lake is a perennial seepage pond, called Ibis Pond, where perennial waters are over a metre deep (Figure 4.9). When the water first escapes into the pond it has normal to near normal marine salinities and supports a restricted population of halotolerant marine gastropods and small fish. A similar marine biota can be found in marine seepage ponds on the seaward side of gypsum-filled Lake Macdonnell of coastal South Australia. Spring-fed normal marine waters are thought to have supplied the Lake MacLeod brine lake for the last 5,000 years, ever since the Australasian Sea rose to a level that was within a metre or two of its present level. At that time a series of laterally accreting beach ridges cut off the lake's southern

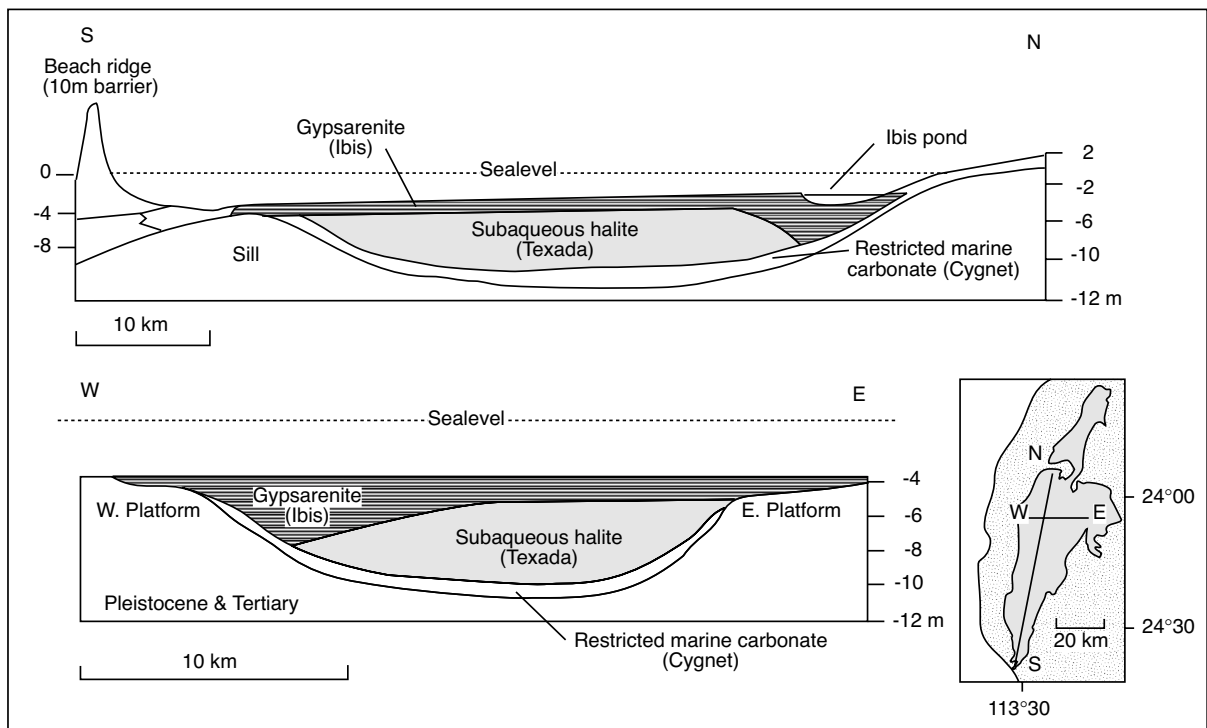

Figure 4.10. Lake MacLeod, Western Australia. Stratigraphic cross sections showing distribution of halite and gypsum as well as the effect of seepage decreasing the salinity so that the gypsum thickness increases toward areas of carbonate seepage defined by Ibis Pond and the western platform (after Logan and Brown, 1986).

surface connection to the Indian Ocean (5,100 years ago). Since then, evaporative drawdown has pulled seawater into the lake depression and bedded salts have accumulated.

From 5,300 to 3,800 years ago, seawater seepage concentrated to halite saturation and deposited some 6 billion tons that is the Texada Halite, with a remaining brine-filled porosity of around 30%. As the salina filled with beds of stacked chevron halite, the depositional surface rose. This meant that the groundwater head drawing water into the lake was reduced. At the same time the once perennial brine lake, depositing the halite and the gypsum, began to dry out each year and evolved into a saline pan. Meteoric input became more important in this later stage in the depositional fill, much in the same way it did in the South Australian salinas (Warren, 1982a). This meant the salinity of the surface brine sheet was reduced to where gypsum was the stable mineral phase throughout the brine lake and the Ibis Gypsite^{4.1} unit was deposited across the lake. Local springs fed the lake throughout its Holocene history, so that aragonitic carbonate was deposited adjacent to the springs, while gypsum and halite filled the salina in an asymmetrical fashion away from these water sources (Handford et al., 1984).

along the northern part of the Gulf the mountainous granitic and metamorphic massif meets with gulf waters to produce a narrow steep shorezone composed of slump blocks, coarse beachrock plates and narrow reef flats. Locally wadis extend as fan deltas into the gulf to produce wider, flatter coastal plains. Small brine ponds or salinas can develop in sub-sealevel depressions in this narrow coastal plain. Probably the best known of these is Solar Lake, a salina located immediately north of a large fan delta (Wadi Murah) some 18 km south of Elat (Figures 3.20, 4.11a).

Coastal salinas of the Middle East

In the coastal deserts of the Middle East there are a number of small-scale coastal depressions filling with subaqueous evaporites, mostly aragonite and gypsum. They are flooded by perennial brines and replenished by phreatic seawater drawn into the lakes by evaporative drawdown. Like the Australian salinas, these Holocene fills have low preservation potential and will be largely flushed and dissolved during the next glacial and its sealevel low.

Solar Lake, Gulf of Elat

The Sinai coast of the Gulf of Elat is characterized by steep rifted-margin topography and a clearly defined fringing-reef (Aharon et al., 1977; Gavish, 1980). In most areas

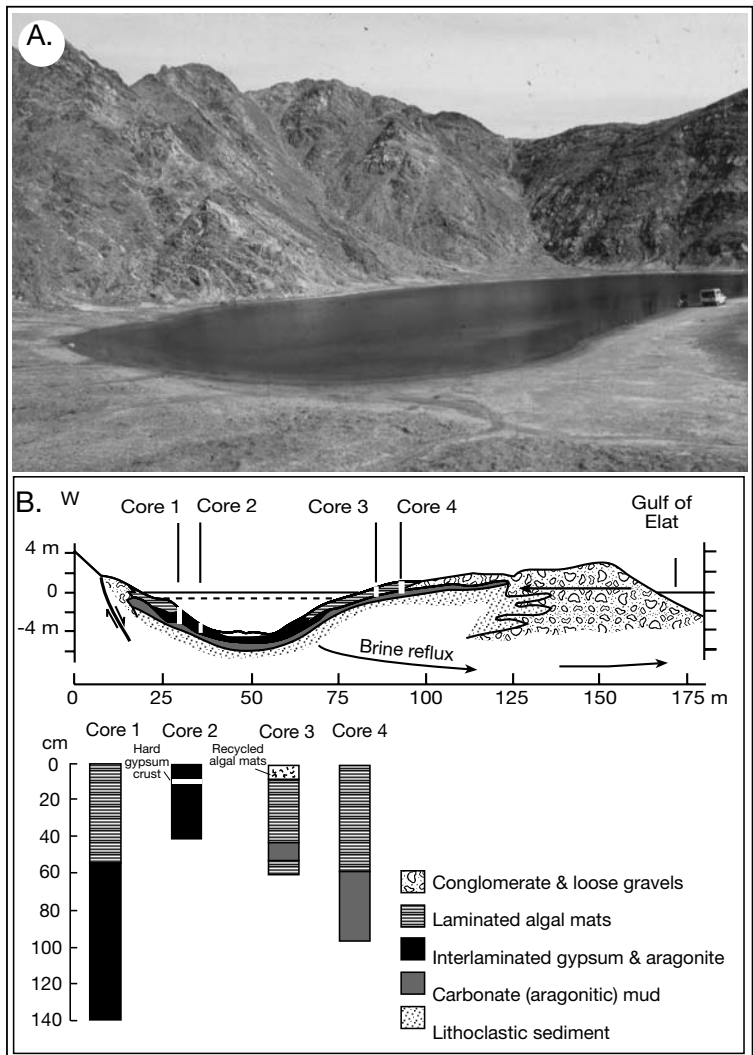

Figure 4.11. Solar Lake, Gulf of Elat. A) View shows cyanobacterial mats rimming the more central gypsum area. Note the steep-sided surrounds of the Precambrian Massif (photo courtesy B. Lyons). Vehicle for scale. B) E-W topographic and lithologic cross section based on cored sediments showing peripheral algal facies and a more central gypsum zone (after Aharon et al., 1977).

Solar Lake is a meromictic brine pond, about 140 m long and 65 m wide, with a maximum depth of 5 m. It is separated from the open sea by a porous beach-barrier, some 60 m wide and up to 3 m high, composed of coarse sand and pebbles of igneous and metamorphic rocks, along with abundant molluscan shell debris (Figure 4.11b). Water is drawn to the pond by evaporative drawdown especially during high tide when the piezometric head is at its maximum. Minor amounts of seawater may also enter the pond by splashing over the barrier during occasional winter storms. Evaporation exceeds inflow each summer, raising the total dissolved solids of the pond brine to 160-180‰ in an unstratified or mixed brine column (May-September). In winter, the combination of lessened evaporation, ongoing inflow of seawater and minor amounts of rainwater combine to create an upper water layer of lower salinity (70-100‰) atop an anaerobic hypersaline hypolimnion (\approx 180‰) and a corresponding seasonal thermocline separating the two brine masses and making the lake a meromictic system (Figure 2.48).

The heliothermal brines of Solar Lake are typical of many density-stratified coastal brine lakes. Its bottom water temperatures reach 57°C in the winter and spring, while year-round surface water temperatures range from 20 to 28°C (Figure 2.48). During stratification, as the lower brine layer absorbs heat, convection between the two layers is inhibited, and the bottom layer becomes hot and anoxic with relatively high levels of H₂S. By summer, the evaporation of the upper water body causes a weakening of the density stratification and finally the overturn of the water body. At that time the water level in the pond is as much as 0.5 m below sea level. With overturn, the water body becomes homogeneous and aerobic, it also cools by convective heat loss to a consistent 28°C.

Sediments accumulating in the pond reflect the style of water supply and the meromictic stratification of pond waters. Down to a bottom depth of 2 metres the margins of the pond are covered by thick halotolerant cyanobacterial mats atop carbonate mud. Slopes of the pond are composed of a white crust of interlayered bottom-nucleated gypsum crystals and aragonite mud, while the deep pond bottom is covered by black mud and a loose gypsum mush (Figure 4.11b; Lyons et al., 1984). There the halobiotial biomass changes to halophilic cyanobacteria with soft flocculent fabrics and an associated increase in the numbers of sulphur-dependant anoxy-photobacteria (Krumbein et al., 1977).

^{4.1}Use of the term gypsite by Logan and coworkers to describe a unit that is laminated and dominated by sand-sized gypsum prisms is unfortunate. Outside of the University of Western Australia, the use of the term gypsite follows general sedimentological usage to define a very fine grained silt or mud-sized sediment (e. g. pelite, micrite, etc.).

A total of about 70 cm of biolaminated sediment has been deposited in 2400 years about the lake margin. Seasonally exposed portions of the biolaminates are crosscut by well-developed polygonal cracks giving the cyanobacterial mat a “lily-pad” appearance identical to the “lily pad” mats of the Abu Dhabi sabkha and the Ras Muhammad pool. Cracks open to their maximum extent during the late summer and autumn when the water level is at its lowest and the mat surface is subaerially exposed. Carbonates in the mat laminae and in the gypsum are composed of aragonite, with lesser Mg-calcite, dolomite and calcite with dolomite forming as a replacement of the aragonite (Friedman et al., 1973; Aharon et al., 1977). The bulk of the dolomite occurs in gypsiferous sediment and not in the algal mats. The dolomite indicates a throughflow of hot hypersaline brines, with a Mg/Ca ratio increased by the precipitation of gypsum, it is a local-scale brine reflux dolomite, possibly facilitated by bacterial sulphate reduction (Aharon et al., 1977). Beneath the cyanobacterial and gypsum layers of the pond is an earlier muddy aragonite unit with numerous *Cerithium* gastropod shells, indicating less saline deposition during the initial isolation of the pond.

Submersed sediments of Solar Lake are rich in organic carbon, a one metre deep core showed TOC values consistently in the range of 5-20% (Schidlowski et al., 1985). Lyons et al. (1982) found significant levels of dissolved organic carbon, in the range 119-818 mg/l, in the pores of the same sediments. They concluded this material is not a “photosynthetic exudate,” rather it is a build up from the early stages of the organic maturation, a response to early-onset catagenesis driven by high temperatures and high salinities attained in the sediment mass (see thermal maturation and early cracking in Chapter 9).

Ras Muhammad Pool, Southern Sinai

At the southernmost tip of the Sinai there is a small peninsula, called Ras Muhammad, constructed by tectonically uplifted Pleistocene reefs (Figures 3.20, 4.12; Gavish, 1980; Kushnir, 1981). At the termination of this spit is a 1 km long tidal inlet with a small perennial brine pool at its end called Ras Muhammad Pool; the pool is an oval feature about 100 to 170 m in diameter and not more than 50 cm deep. It is separated from the inlet by a porous barrier, some 250 m wide, composed of reef material and carbonate sand (oolitic) that can be blown or washed into the pan. Most of the water in this subsealevel pool seeps in via a series of seawater springs around the pool’s edge (Figure 4.13a). It means the pool never dries up, although the extent and depth of water in the pool varies with the seasons. During summer and fall, the water volume in the pond is reduced by

Figure 4.12. Ras Muhammad pool, Southern Sinai Peninsula, clearly shows seepage feed to the perennial pool, tectonic alignment and proximity to seawater source in the tidal inlet (photo courtesy of G. M. Friedman).

high evaporation levels and salinities in the pond can be more than 300‰. In winter and spring the pond expands and surface water salinities fall to 100‰ (Figure 4.13b).

Sediments below the perennial pool are composed of alternating layers of gypsum mush and algal mats; there is no primary or diagenetic anhydrite (Figure 4.14; Kushnir, 1981). Thickness of gypsum layers ranges between 0.3 and 6 cm and averages 1.8 cm. Porosity in the gypsum layers ranges between 64

and 69 percent. The gypsum in the layers is mainly prismatic (crystals up to 6 mm long) and associated with minor amounts of aragonite, calcite, quartz and feldspar. The gypsum in the upper younger layers (e.g. layer 2) consist mainly of small crystals whereas the deeper older layers (e.g. layer 29) have a broader, coarser size distribution (Figure 4.13c). Mid-positions of cores taken through the cyanobacterial sediments can contain lenticular and prismatic gypsum crystals that have grown displacively within these biolaminites. The continued growth of gypsum eventually destroys the original lamination, as in the sabkha of Abu Dhabi. Likewise, much of the evidence of the original nearsurface organic binding (cyanobacterial filaments) is destroyed by the activities of heterotrophic decomposers that live below the surface of the mat. The final fabric as revealed in the lowermost layers of the cores taken by Kushnir (about 80 cm deep) is a laminated and disturbed gypsum mush with thin interlaminae of carbonate crusts and ooids with very little identifiable cyanobacterial material (Figure 4.14, insert).

Strandzone sediments around the pool edge are cemented by an ephemeral halite crust, while beneath the crust and above the water table are rare concentrations of anhydrite after gypsum, but salts in these strandzone sediment are dominated by gypsum. Pore fluids become increasing saline below the sediment surface

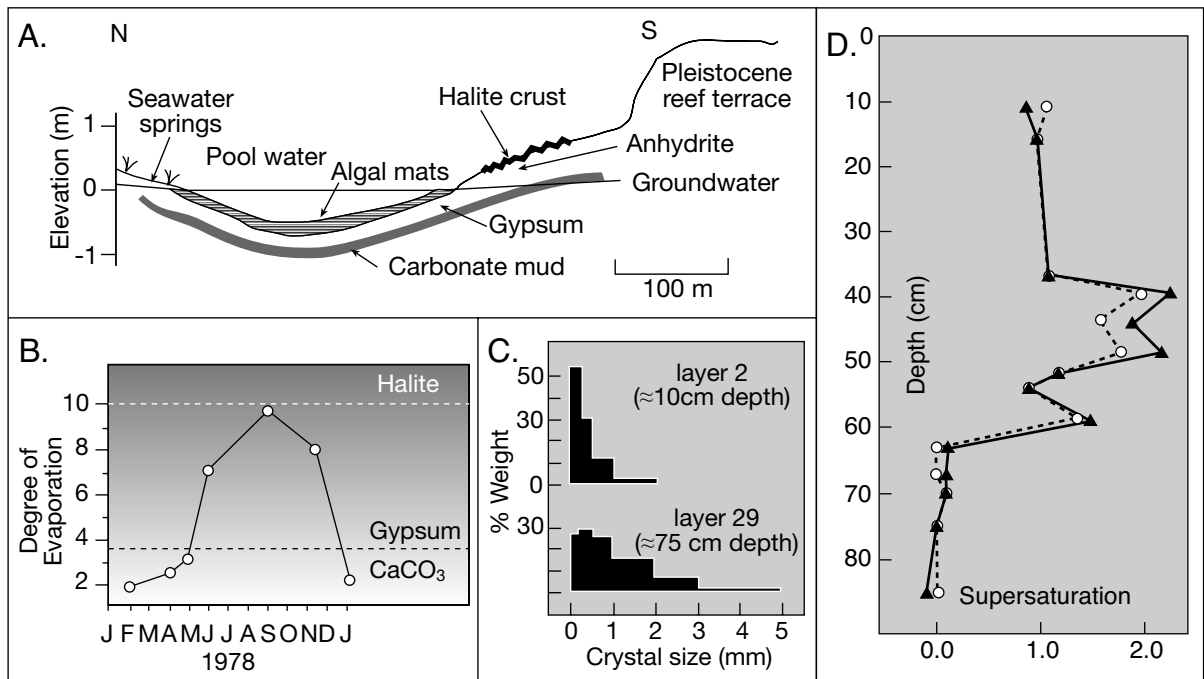

Figure 4.13 Ras Muhammad pool, southern Sinai Peninsula. A) Generalised cross section through the pool showing asymmetrical sediment distribution controlled by zones of seepage outflow. B) Annual brine concentration cycle of surface waters for 1978 - Seawater is unity on the degree of concentration scale. C) Gypsum crystal size distribution in a shallow and a deep sediment layer. D) Gypsum saturation versus depth, using interstitial waters squeezed from gypsum layers (after Kushnir, 1981).

Figure 4.14. Polygonal microbial mats ("lily pads") from the strandzone of Ras Muhammad pool. Mats are seasonally desiccated and underlain by biolaminites and gypsum. Scale bar of core inset is 5 cm and there is a geological hammer atop the mat in the centre of the image. (Originals courtesy of G. M. Friedman).

and down to depths of 50-60 cm can be supersaturated with respect to gypsum by upward of a factor of 2 (Figure 4.13d). High levels of gypsum supersaturation are relieved by the precipitation of gypsum and the growth of coarser prismatic crystals, as is seen in the coarser crystal sizes of layer 29 some 75 cm below the sediment surface (Figure 4.13c). According to Kushnir (1981) precipitation of larger gypsum crystals in the uppermost capillary intervals is perhaps inhibited by high levels of organics in the supersaturated pore fluids (Kushnir 1981). Alternatively, the coarser gypsum just above the water table may indicate thermalitic precipitation. It is very likely that the precipitative mechanism for gypsum in the capillary fringe in Ras Muhammad is the same as in the Abu Dhabi upper intertidal section.

Late Pleistocene salinas on the Egyptian Red Sea Coast

Ongoing aridity along the tectonically stable area of the Egyptian coast of the Red Sea, has locally preserved Pleistocene remnants of embayment salinas (khors) that filled with laminated subaqueous gypsum during the Last Interglacial (Eemian, 5e = 5.5 Marine Isotopic Substage; Plaziat et al., 1995; Orszag-Sperber, et al., 2001). Heavily eroded remnants of the sediments in these small gypsum-filled khors, each up to a kilometre across, are scattered along a 400 km-long narrow coastal strip, backing on to Precambrian basement, between Ras Shukheir on the Gulf

of Elat and Ras Banas on the Red Sea coast (Figure 3.20). Evaporitic sediment was initially deposited as shelly and subaqueous laminated gypsum in erosive depressions elongated parallel to the present shore and behind a subcontinuous Late Pleistocene fringing coral reef (Figure 4.15a, b). The entrenched geometry and the marine to brackish evolution of the pre-evaporite faunas indicate deposition in a hydrographically isolated depression behind a reef rim. Gypsum precipitation occurred during a brief relative sealevel drop that cut off the surface connection with the Red Sea. Both the reefal and gypsum units are

Late Pleistocene with a consistent set of U/Th dates around 123 ka bp. Ages from reef and gypsum are at times so close that there is no statistical difference between their respective ages in spite of the large number of dates collected by Orszag-Sperber et al. (2001).

This is not a matter of poor precision in dates, but indicates the very rapid rate of gypsum infill once the khor lost its surface connection to the waters of the Red Sea. Narrow-mouthed embayments along the present coast quickly develop into kharms or khors that with further isolation and closure of the surface connection to the adjacent ocean of the Red Sea could become evaporitic drawdown basins filling with subaqueous gypsum units composed of coarse growth aligned gypsum crystals up to 5-10 cm long (Plaziat et al., 1995). There is a possible Holocene counterpart to these systems on the Red Sea coast at Ras Shukeir (Aref et al., 1997) but laminar aragonite, rather than gypsum, dominates the fill in all modern kharms (Plaziat et al., 1995).

Textures indicating permanent Late Pleistocene salina waters atop the aggrading gypsum and the mm-laminae of carbonate that interrupted gypsum crystal growth suggests it was very similar in both its marine seepage hydrology and its depositional setting to the salinas of southern Australia and to Lake Asal (Figure 4.15c). That is, it was an anchialine salina

system (littoral saline lake) fed by permanent seawater seeps through the reef.

Tops of the laminated subaqueous gypsum outcrops locally grade up into polygonal gypsum pressure ridges near the top of the gypsum unit implying that the level of freestanding salina waters was about 3 m below the locally derived mean sea level as deduced from the shoreline of the former Late Pleistocene reefal unit (Orszag-Sperber, et al., 2001). This reflects the evaporitic drawdown of the salina water level necessary to drive seawater seepage and gypsum precipitation.

Laminated salina gypsum in the Late Pleistocene Red Sea backreef is transitionally overlain by a massive pedogenic gypsum subunit (with root traces, burrows) interpreted by some as an emergent sabkha facies (Aref et al., 1997). It can grade laterally into older alluvial-fan substratum to become sloping gypsum-crusts (gypcretes) cementing the gravels.

These gypcretes and the sabkha facies clearly differ in process of formation and perhaps solute source from the laminated subaqueous gypsum. Likewise for the gypsum cements in coarse gravelly sand and sandy gravel about the khor edge, which were fed by a combination of marine aerosols and saline continental phreatic waters, seeping slowly seaward (Figure 4.15b). Capillary rise of phreatic seawater is prevented by the elevation and coarseness of the host-material. Holocene gypcrete crusts throughout the Red Sea coast indicate a combination of marine aerosols and sulphate-rich continental water leaching halokinetic Miocene gypsum, which outcrops near these Late Pleistocene salina remnants.

Slightly inland from the coast there are similarly textured laminated gyparenite lenses in small depressions with heights ranging between 17.5 and 110 m above sea level. These are continental not marine fed salinas and are similar to continental salt lakes inland of El Alamein west of the Nile Delta (Figure

Figure 4.15. Remnants of a Pleistocene salina, Red Sea coast, Egypt showing the geometry and age distribution of Late Pleistocene units and their Early Pleistocene alluvial fan substrate at Quseir el Qadim (A. map; B. cross section), C) vertical section at wadi Abu Sbikhaia. The Late Pleistocene marine khor carbonates give U-Th dates similar to those of the overlying salina gypsum (after Orszag-Sperber et al., 2001).

3.22). The sediment fill lacks the basal marine fossiliferous sands that define the basal succession of many Late Pleistocene coastal salinas. Their watertable heights are so far above sea level that seawater seepage is impossible. Marine aerosol sources are a distinct but as yet untested possibility.

The highly dissected nature of all these 1-km scale examples of Late Pleistocene marine-fed evaporite khors of the Red Sea Coast attests to the low preservation potential of Quaternary coastal salina evaporites worldwide. The high frequency (100,000-year), high amplitude (100 m+) sealevel changes, that are diagnostic of icehouse climate, drive substantial dissolution of marine salts even in the very arid climate of the Red Sea (Chapter 5).

South American coastal salinas

One of the more interesting accumulations of modern evaporitic carbonate to be documented in the last decade occur in a series of coastal depressions centred on Lagoa Vermelha, which is a small shallow isolated hypersaline coastal salina east of Rio de Janeiro, Brazil. Its Holocene fill provides the best evidence to date of the likely involvement of particular species of sulphate-reducing bacteria in producing primary dolomite (Vasconcelos and Mackenzie, 1997; van Lith et al., 2003). Ca-dolomite is crystallizing in Lagoa Vermelha muds at the sediment-brine interface under anoxic hypersaline conditions within a black aragonitic sludge layer (Figure 4.16a).

Unlike the Coorong salinas, the source brines for these evaporitic carbonates are thought to be marine or connate groundwaters drawn into the salina by evaporative drawdown. Marine-fed salinas in the Coorong occupy similar hydrographically-isolated subsealevel depressions (e.g. Halite Lake), but in a more arid setting and precipitate laminated gypsum-aragonite, not dolomite. Both the initial precipitation and early diagenetic evolution of Lagoa Vermelha dolomites is strongly mediated by microbial activity. In fact, sulphate-reducing bacteria from Lagoa Vermelha samples, cultured in brines at low temperatures from artificial seawater, produced highly ordered dolomite in the laboratory at earth-surface temperatures (Vasconcelos and Mackenzie, 1997; Warthmann et al., 2000).

Evaporation lowers the lagoon water level in the dry season and drawdown then allows seawater to enter via seepage through the dune barrier. Elevated organic productivity in the lagoon leads to anoxia at the sediment-water interface and the formation of a black organic-rich carbonate sludge on the meromictic salina floor. The highly saline waters have elevated sulphate levels,

which in the shallow subsurface provide a sulphur source for bacterial sulphate reduction, as well as elevated magnesium that is precipitated as Mg-calcite and calcian dolomite. Microbial activity in the sludge mediates the precipitation of these primary carbonates. Eventually microbial activity ceases, but the diagenetic precipitation of dolomite continues atop the microbially precipitated crystal substrate.

Vasconcelos et al. (1995) first suggested that sulphate-reducing bacteria in hypersaline waters promote the essential conditions needed for dolomite precipitation. Van Lith et al. (2002), after a detailed study of the hydrochemistry in the lagoons, concluded that elevated salinity and sulphate reduction are the main factors inducing dolomite precipitation in these lagoons (Figure 4.16b, c). Their detailed measures of water and sediment conditions during an annual cycle (1996–1997) demonstrated that dolomite formed in May–June which was a time of high salinity. High $\delta^{34}\text{S}$ of pore water sulphate and high sulphide concentrations correlated with dolomitic horizons, demonstrating the association of bacterial sulphate reduction with dolomite formation.

Dolomite forms year round in another small nearby salina, Brejo do Espinho; perennial precipitation is a direct response to its higher year-long salinity compared to Lagoa Vermelha. High salinity apparently provides the ions and saturation state necessary for dolomite precipitation, while the observation that dolomite formed at times or in zones of decreased sulphate concentrations underlies the likely importance of bacterially-driven sulphate reduction in Brejo do Espinho. Bacterially-driven sulphide oxidation may also drive dolomite precipitation in other as yet untested high salinity lakes in the same region (Moreira et al., 2004). The precipitation of dolomite in the lab at earth surface conditions using various strains of halotolerant sulphate-reducing bacteria (Van Lith et al., 2003) underlines the fundamental role of microbial metabolism in many saline environments (Chapter 9; Warren 2000a).

Sulphate ions form strong ion pairs with Mg^{2+} ions and are held together in space like a single particle. When sulphate-reducing halotolerant bacteria metabolize SO_4 ions, they also use the accompanying Mg^{2+} ions inside their cells. Magnesium is essential for many vital physiological functions in the bacterial cell, and makes up 0.5% of the cell's dry weight in halotolerant strains. During bacterial metabolism, excess Mg is released together with other byproducts of sulphate reduction, such as bicarbonate ions and hydrogen sulphide (Chapter 9). Saturation with magnesium in microenvironments around the bacterial cell probably creates conditions favourable for preferential precipitation of dolomite, as is observed in lab-based bacterial culture experiments (Van Lith et al., 2003).

Using the Lagoa Vermelha system as their starting point, Vasconcelos and Mackenzie (1997) proposed a new actualistic model for dolomite formation that they call the microbial dolomite model (Figure 4.16a). An anoxic turbid layer at the sediment surface creates a special environment where photosynthetically produced organic matter can be microbially recycled by sulphate-reducing bacteria on a submicron scale, with concomitant precipitation of high-Mg calcite and Ca-dolomite. In contrast to the sulphate-reduction model of Kastner (1984), which required a lack of sulphate, this model requires a

continuing supply of sulphate in order for halotolerant bacteria to metabolise and so precipitate dolomite (Figure 4.16a). Living sulphate-reducing bacteria are required to overcome the kinetic problems of dolomite formation.

Once dolomite bionucleation has occurred, the Ca-dolomite ages; as is indicated by depth-related trends of larger crystal size, more negative $\delta^{13}\text{C}$ values and increased stoichiometric ordering of the dolomite lattice. Bacteria apparently remain important in shallow burial, as seen by the continued presence

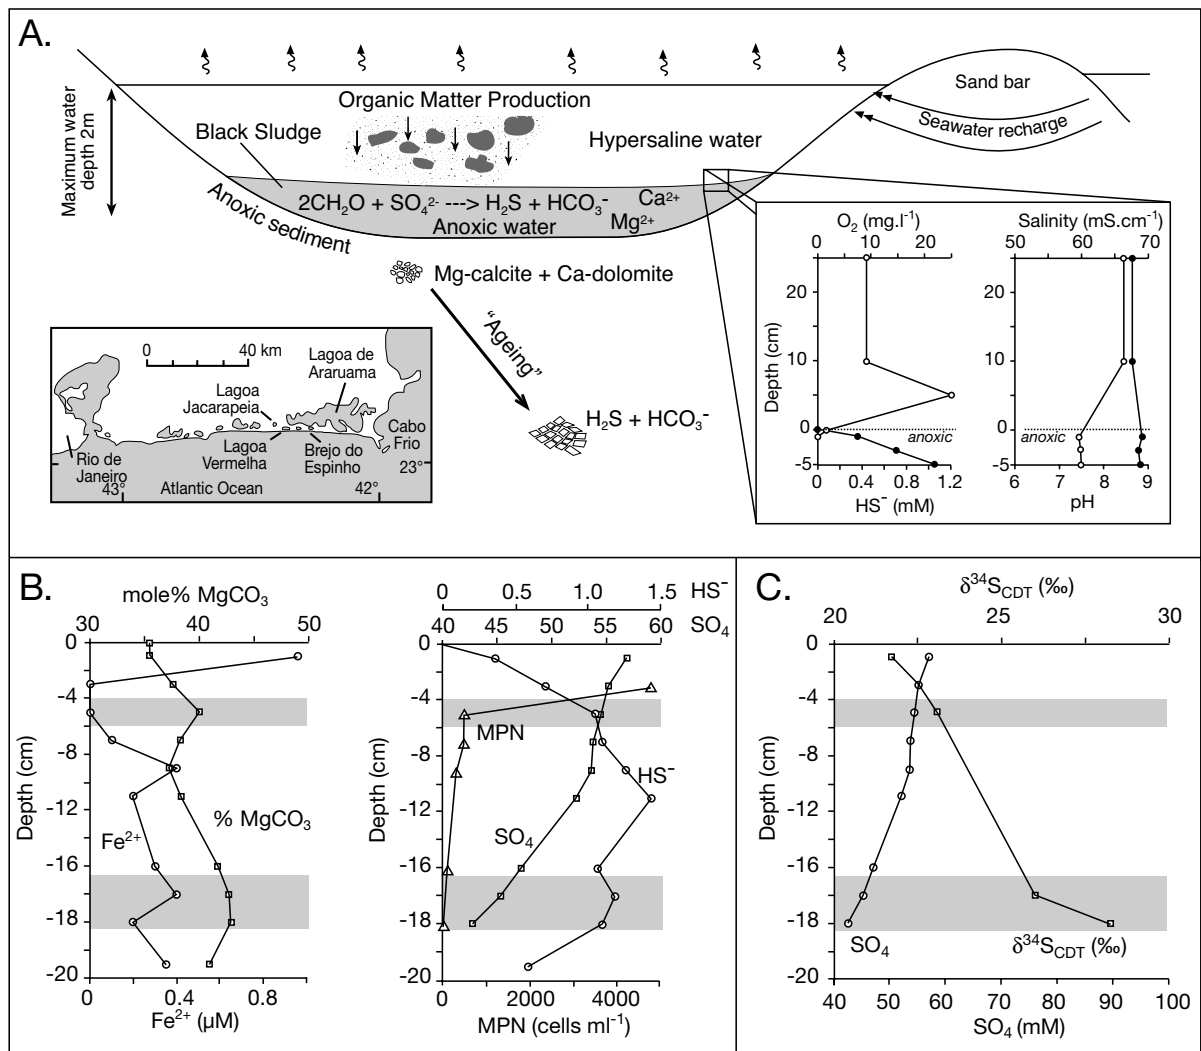

Figure 4.16. Lagoa Vermelha, Brazil. A) Schematic of microbial dolomite formation in Lagoa Vermelha and Brejo do Espinho, Brazil. Insets show the location of the salina on the Atlantic Coast and the pore water conditions immediately above and below the sediment brine interface. B) Mol% MgCO_3 in carbonate, Fe^{2+} , HS^- , and SO_4^{2-} concentrations, and most probable numbers (MPN) of sulphate-reducing bacteria in Lagoa Vermelha sediment from 0–24 cm depth. C) Dissolved sulphate concentration in pore waters of Lagoa Vermelha and its sulphur isotopic composition ($\delta^{34}\text{S}_{\text{CDT}}$). In April 1999 the core illustrated in B and C was taken and pore water extracted. The gray bars indicate Ca-dolomite horizons. (after Vasconcelos and Mackenzie, 1997; van Lith et al., 2002).

of nanobacteria on the surfaces of the “aging” crystals. With time, and deeper in the sedimentary section (70–90 cm), the crystals grow by a layer-by-layer mechanism that creates smoother and euhedral crystals. Apparently, once the dolomite is nucleated, crystals can continue to grow by inorganic processes, but each new layer still appears to be composed of coalesced submicron-size bacterial balls (spheroids). The microbial dolomite model requires an ongoing supply of sulphate to maintain the microbial activity promoting dolomite precipitation. In contrast, it may be that the presence of sulphate in a sterile (bacteria-free) environment may act to inhibit dolomite precipitation as shown in the laboratory experiments of Baker and Kastner (1981) and Morrow and Ricketts (1988).

Wright (1999) and Wright and Wacey (2005) present a similar set of microbial arguments and laboratory experiments to explain the ease of dolomite precipitation in some of the carbonate salinas of the Coorong. In the realm of bacterially mediated dolomites some authors have attempted to draw a dichotomy between bacterial mediation and evaporitic conditions, but this is an extreme view. Both the Brazilian and Coorong salinas pore waters where the bacteria flourish are hypersaline, their waters evaporitic. How else do they thrive at the expense of a less halotolerant biota at salinities up to 4–5 times that of seawater? It is the elevated salinities in surface and near surface waters that allow appropriate halotolerant sulphate-reducing bacteria to flourish in waters that can be marine, nonmarine or hybrid (Chapter 9). High salinity and bacterial mediation of natural primary dolomite are associated, not separated, features in many natural hypersaline waters.

Continental subaqueous basins

Examples of subaqueous evaporite deposits discussed so far occur in hydrographically-isolated subsealevel coastal depressions fed solutes by an inflow of marine groundwaters. The resulting sediments accumulate at limited scales (1–20 km across) with limited thicknesses (<10m). Such deposits have

little or no longterm preservation potential within the rapidly migrating shorezone hydrologies that typify icehouse eustasy (Warren, 1991). To find examples of thicker more widespread subaqueous evaporites in Quaternary successions, we must move to continental lacustrine settings in lake depressions characterised by perennial saline water bodies. This setting corresponds to the third category of Hardie et al.’s (1978) classification of saline lacustrine settings described in Chapter 3; namely the perennial stream floodplain - perennial saline lake. In such a setting Quaternary evaporites have filled lake basins measuring up to a 100 km across with stacked salt bed units that are more than tens of metres thick.

Perennial saline lakes

Subaqueous lacustrine beds typically alternate with brine pan and sabkha salt beds in most continental saline lakes. Changes from one depositional style to another relate to changes in inflow volume and chemistry and often indicate a change in climate, fluvial inflow or tectonics. Perennial lakes and pans typify the topographically lowest part of an endorheic lake basin. Most subaqueous lake sediments are dominated by carbonates

and siliciclastics, higher salinity salts are less common. This reflects the hydrology needed to form a permanent lake. That is, to maintain a perennial above-surface brine body requires continuous water inflow to the lake depression, either from river inflow or from spring seeps. This means most perennial lakes occur in the bottom-most parts of steep-sided endorheic depressions (Figure 4.57).

The definition of what surface salinity constitutes a modern saline lake varies between the Northern and Southern Hemispheres; Hardie et al. (1978) chose a minimum concentration of 5,000 ppm to define saline lake waters based on Beadle's (1974) definition of the upper salinity tolerance of freshwater organisms. In contrast, most Australian limnologists use 3,000 ppm to separate freshwater and saline biotas (Geddes et al., 1981).

Regardless of its minimum salinity, a perennial brine lake and its biota is at the mercy of variations in the local climate and inflow intensity. Lake water levels and salinities are subject not only to seasonal changes but to long-term fluctuations in climate and tectonism. In the short term the volume of inflow water increases after a storm or winter snow melt; in the long term a change to a more humid climate increases the volume of water in the lake depression, while a change to more arid conditions decreases the volume of water and may convert a perennial saline lake into a saline pan or evaporitic mudflat. Tectonic uplift also affects deposition, it can convert what was formerly a hydrologically open basin into an endorheic basin, or vice versa, volcanism and lava flows can do the same. Tectonism can also change the position of the topographically lowest point in the lake, and through uplift can change the volumes of surface runoff, groundwater seepage and inflow chemistry.

The chemical make-up of continental lake brines is much more variable compared to the near isochemical seawater reservoir that supplies mostly gypsum and

halite to modern coastal salinas (Table 4.2). Proportions of the various ions in perennial saline lake waters are controlled by chemistries of the dilute inflows, which are a combination of rainfall intensity and the lithologies in the drainage area surrounding the lake (Chapter 2).

Great Salt Lake, Utah

Great Salt Lake is a perennial water body and has been so for the last 30,000 years. It is one of the largest perennial saline lakes in the world, measuring some 120 km (75 miles) long and 55 km (35 miles) wide, with a water surface elevation that oscillates around 1,280 m (4,200 ft) above sea level (Figures 4.17, 4.18). At this elevation the lake brines cover an area of 4,180 km² and have a maximum depth of 10 m. In a typical year the water surface fluctuates around 30-60 cm, reaching its highest level in May-July (after snow melt) and dropping to its lowest level in October-November. Since 1847 the water level of Great Salt Lake has varied from a low of 1,277.5 m in 1963 to a high of 1,283.75 m in 1986-87 (Figure 4.18). Because the lake is so shallow and its floor so flat, small changes in water level correspond to large migrations of the strandline.

Figure 4.17. Great Salt Lake and the Bonneville Salt Flat, Utah and the adjacent peaks of the Wasatch Mountains east of the lake depression. A railway causeway that transects the northern arm of the lake is visible, as are solar evaporation ponds. The Lake Bonneville salt flats (lighter coloured) lie to the west of the Great Salt Lake. (Landsat image courtesy NASA).

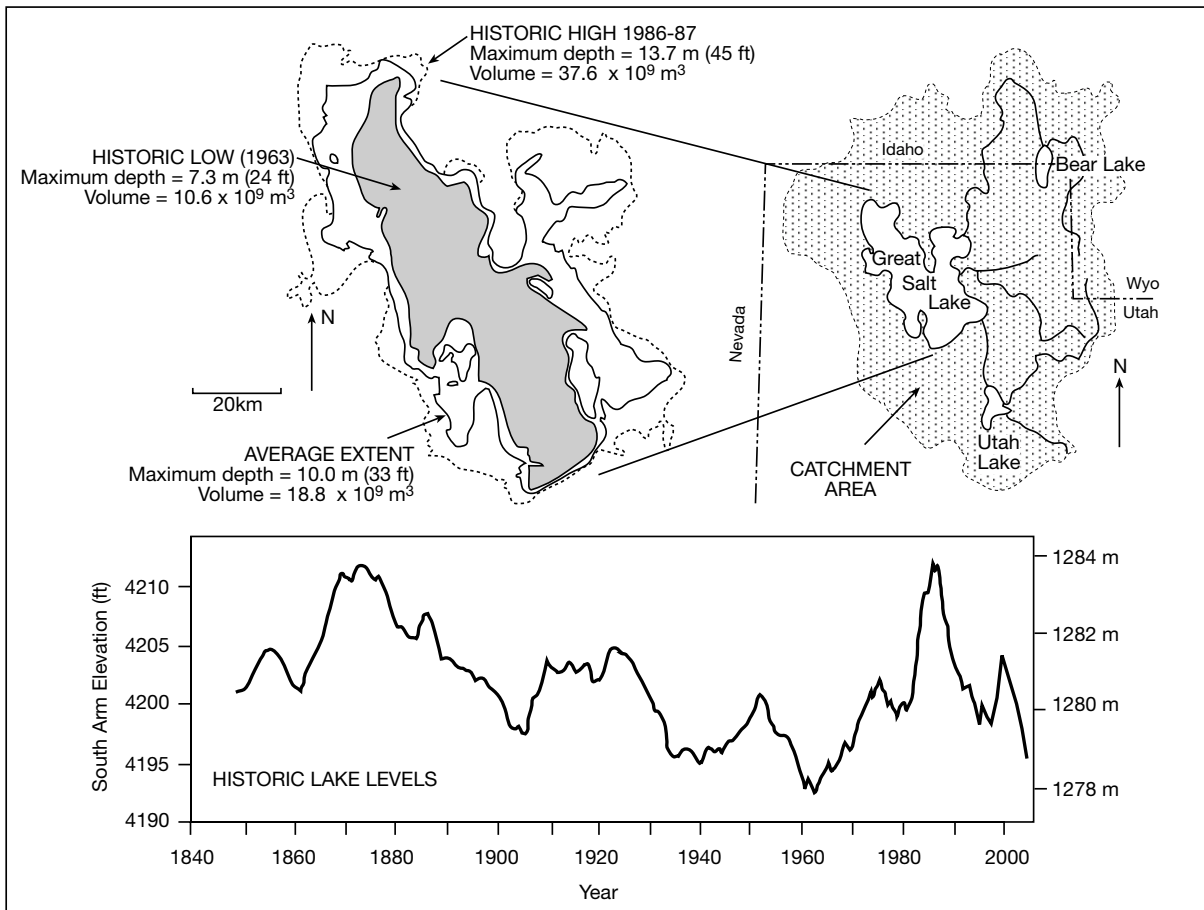

Figure 4.18. Great Salt Lake, Utah. The lake is subject to large changes in the extent of its perennial water body. The upper figure shows the different extent of its highest and lowest levels in historical time. The chart plots yearly changes of lake water level since 1847.

Great Salt Lake lies in an endorheic basin with no surface outlet. The main rivers entering the lake are the Bear River from the north, the Weber and Ogden Rivers from the east, and the Jordan River from the south. Together with small volumes of bajada runoff, they supply around two thirds of the water currently entering the lake. Direct precipitation into the lake supplies some 31 percent, while ground water supplies the remaining 3 percent. The drainage basin of the lake covers an area of about 57,000 km² (21,500 mile²). Water is lost from the lake mostly through evaporation, with something like 3,500 km³ of water evaporating annually (Figure 4.18). When inflow equals evaporation, the level of the lake remains constant. If inflow is greater or less than evaporation, the level of the lake will rise or fall, respectively.

Being situated along the Wasatch Front at the eastern edge of the tectonically active Basin and Range Province, means the size, shape, and location of the Great Salt Lake depression

has been a response to variable intensities of subsidence and faulting, overprinted by the intense climatic vagaries of the Late Pleistocene. Present-day Great Salt Lake is a remnant of a much larger and fresher water body that was once linked into the Pleistocene Lake Bonneville system, as were Utah Lake, Sevier Lake, and the Bonneville Salt Flats (Figure 4.19a). Areas of perennial fluvial inflow into Pleistocene Great Salt Lake are defined by classic “bird’s-foot” or “Gilbert-style” hanging deltas (Figure 4.19a). The downcutting of the current hydrology and the presence of Pleistocene shoreline terraces on higher levels of the delta prism suggest deltas were most active during Pleistocene lake full stages (Lake Bonneville time) when the lake was not accumulating evaporite salts.

Modern strandzone deposits are mostly shorezone spits and bars, which are dominated by aragonitic ooid and peloidal sands (mostly brine shrimp pellets). Carbonates also precipitate about the lake strandline in spring mounds, algal mounds, and

in stromatolites (Figure 4.19b; Eardley, 1938; Halley, 1977). Older algal reef mounds are located further out in the lake and are now buried by lake muds; they grew earlier in the Holocene when lake water levels were lower than today (Colman et al., 2002). Oolite shoals today form sand waves that define the lake strandzone (Figure 4.19b). Individual ooids are aragonite with a radial crystal structure. When and how the individual ooids grew is not well understood, but halobacteria and organic matrices are thought to play a role (Sandberg, 1975; Pedone and Folk, 1996; Reitner et al., 1997).

Laminated mudstones, in large part composed of the faecal pellets of brine shrimp, are currently accumulating further out in the lake (Eardley, 1938). The pellets are a mixture of aragonite and detrital matter, mostly quartz, clays and organics. The brine shrimp *Artemia gracilis* thrives in the lake, it is a filter feeder that flourishes in spring and summer. It supplies a seasonal rain of faecal pellets to the lake bottom and its droppings represent a sampling of the mineral matter suspended in the water column. This implies aragonite is a seasonal precipitate within the upper part of the meromictic water column (see Chapter 9 for biology and feeding styles of brine shrimp and other halozoa).

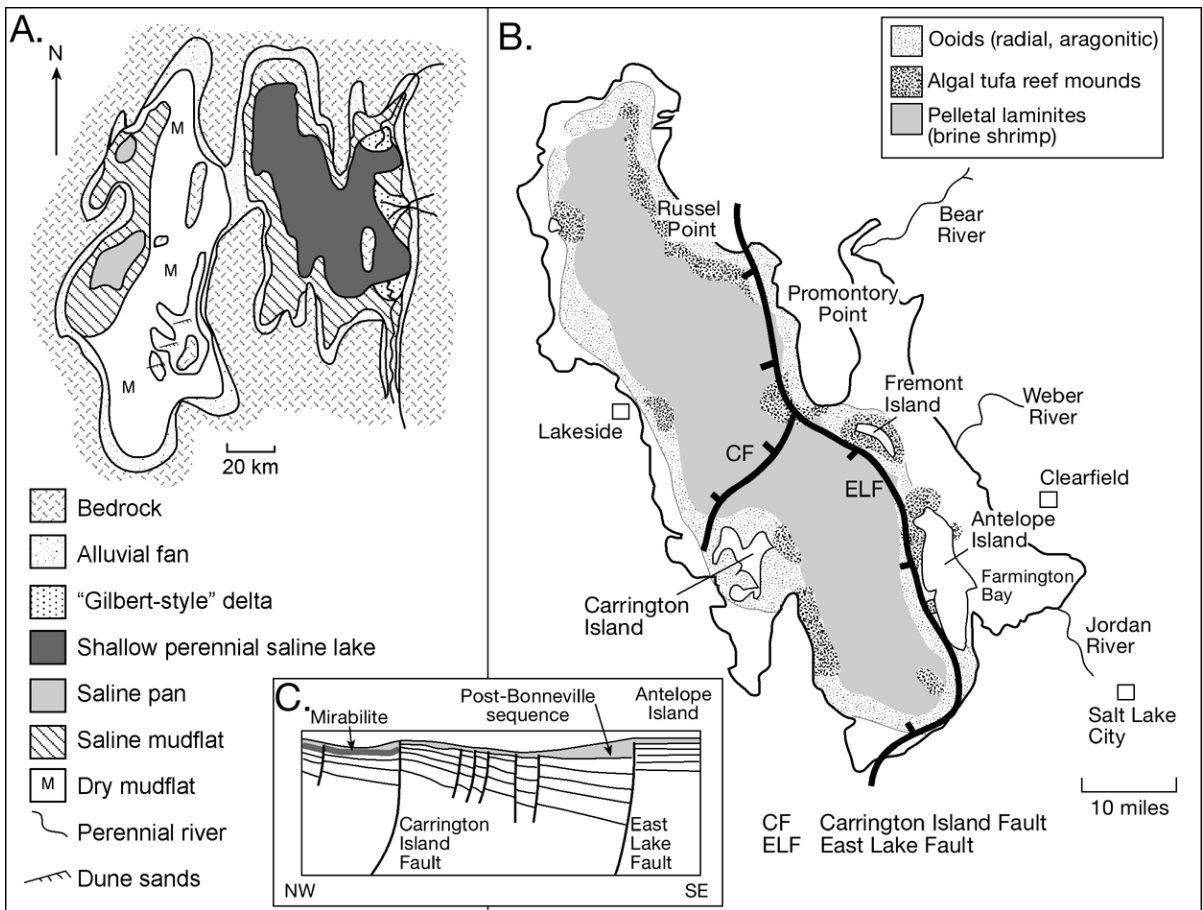

Figure 4.19. Sediment distribution in Great Salt Lake and surrounds. A) Distribution of depositional settings in the Bonneville/Great Salt Lake basin, Utah. The lake itself is a perennial water body fed by rivers with "bird's-foot" deltas at the older entry points into the lakes. The saline pan facies are halite-rich with lesser glauberite, while the dry and saline mudflats are subaerially exposed parts of the old subaqueous floor of Lake Bonneville. Carbonate mudstones, mostly aragonite pellets, dominate sediments currently accumulating on the subaqueous lake floor (after Smoot and Lowenstein, 1991). B) Distribution of algal tufa reefs and ooid sand shoals about the strandzone at the edge of the perennial water body in Great Salt Lake. Positions of the East Lake Fault (ELF) and the Carrington Island Fault (CF) are shown (after Eardley, 1938; Colman et al., 2002). C) Schematic cross section based on seismic lines between Antelope Island and Carrington Island showing the importance of syndepositional faulting in controlling thickness of post Bonneville (<13.5 ka) sedimentary packages (grey) and the distribution of the mirabilite bed in the lake (after Colman et al., 2002).

Rippled sand lamina alternate with mud in the deeper water deposits, with many deeper beds disrupted by the growth of now-dissolved evaporites (Unit I; Spencer, 1983). Remnants of bedded Holocene halite still remain on the deepest parts of the lake floor, preserved by longterm density stratification in the overlying waters. Spencer (1983) recovered euhedral gypsum in the upper 1-2 metres of the now water-covered aragonitic sediments of the lake centre. This sediment also shows evidence of haloturbation and pinch-and-swell bedding. Below this is a 1 m-thick bed of finely laminated aragonitic clay and algal mat partings, which passes laterally into bedded mirabilite (Unit II; Spencer 1983). A later shallow seismic survey showed this mirabilite unit is restricted to a fault-controlled depression north of the Carrington Island Fault (Figure 4.19c). Laminated aragonite is underlain by a laminated calcitic clay with lamination-poor ostracod-rich horizons. Spencer (1983) interpreted this bed (his Unit III) as the deepest water unit recovered in his coring program. Only one core penetrated below this deeper water unit to recover clays and muds of what may be a subaerial mudflat (Unit IV).

Prior to 32 ka, the basin was an ephemeral pan - saline mudflat system (Unit IV). Since then, Great Salt Lake has mostly been a perennial water body, initially a shallow saline brine lake, then a brackish lake between 25 and 19.5 ka. Between 19.5 and 17.5 ka a fresher but somewhat restricted lake occupied the basin, with a water surface near the Provo level (water was 195 m deep). Fresh water conditions and a standline near the Bonneville level existed from about 17 to 15 ka (waters around 310 m deep). A sharp drop in lake elevation occurred about 15 ka. Between 15 and 8 ka the lake was at extremely low levels and at times was divided into two separate saline basins. For the past 8 ka the lake has fluctuated near its present level. Much of the salt now contained in the Great Salt Lake was originally dissolved solute in the waters of Lake Bonneville. An additional two million tons of dissolved salts now enter the lake each year via river and spring inflow, which carries leachate from the surrounding soils and rocks.

Recent study of a single long core that records the last four glacial/interglacial sequences in the Great Salt Lake Basin has shown that salt/freshwater marshes as documented by Spencer (op cit) were common during the interglacials (Balch et al., 2005). Deep freshwater conditions correspond with the maximum global ice volume in Oxygen Isotope Stage 2, and before a maximum in global ice during Oxygen Isotope Stage 6. Immediately following each deep lake period the lake level crashes via rapid desiccation and it resulted in the deposition of thick evaporite units.

Fault-accommodated subsidence in the Great Basin has now filled the depression with more than 3700 m of continental sediment, with most of the sediment carried in by the major rivers. Two currently-active faults underlie Great Salt Lake (Figure 4.19b, c; Colman et al., 2002). The East Lake Fault passes along the west edge of Antelope and Fremont Islands and on northwards by the west side of Promontory Point. The Carrington Fault extends northeastward from Carrington Island to merge with the East Lake Fault of the southwest tip of Promontory Point.

Most of the current strandzone facies along the eastern side of the lake are tied to the topographic escarpment created by the East Lake fault, many now buried Holocene tufa-reef mounds also sit atop subsidiary faults in the lake. Similar broader-scale fault-controls to Late Pleistocene lacustrine geometries are seen in seismic facies throughout the lake basin. Colman et al. (2002) concluded that the Great Salt Lake basin has been, and continues to be, an area of active extensional tectonics and that tectonics has exerted a major effect on the distribution and type of sediments in the lake. Currently, the East Lake Fault is at least as active as any of those along the Wasatch Front, showing at least three episodes of significant faulting since lake water level fell around 13.5 ka from its Pleistocene high. The upthrown side of the Carrington Fault today forms a sill, with a seismically resolvable tip that is only about 5 m below present lake floor. Fluid flow into the lake along this and other fault planes may explain some of the indurated bioherm mounds and pavement sheets present on the lake floor.

A fall of the lake waters marked the end of the high Bonneville phase and led to the formation of a basin-wide seismic horizon associated with lowered lake levels (Colman et al., 2002). Mapping of this reflector shows that the southern basin comprises a distinct sediment wedge thickening toward the East Lake Fault, a geometry that contrasts, to some degree, with the smooth symmetry of the current lake floor (Figure 4.19c). Seismic facies maps also show the lake level during the early Holocene was considerably lower than today; it was a time when the lake was an intermittently flooded playa and when up to 13 metres of post-Provo halite accumulated near the East Lake Fault. At that time small remnant water bodies probably ponded in local lake-floor grabens along the downthrown sides of active fault scarps. Thus fault-controlled tectonics controlled the distribution of the various early Holocene pan evaporites, including the mirabilite/halite beds (Figure 4.19c).

Within this tectonic framework, Late Quaternary climate change across the Great Basin altered solute proportions in the lake

inflows and so influenced mineralogies in the evaporite suites accumulating in low water stages in Great Salt Lake. Spencer (1983) defined three major styles of inflow to the lake system; 1) concentrated Na-Cl dominant spring waters, 2) dilute Ca-HCO₃ river waters, and 3) dilute Ca-HCO₃ precipitation (rainfall and snow melt). During the fresh-water period of the Lake Bonneville and other pluvial times, the inherently higher levels of meteoric discharge to the lake meant inflow chemistries were dominated by calcium bicarbonate waters. Saline stages, as in most of the Holocene, were characterised by lowered meteoric inflow volumes and so fault-fed hydrothermal springs became an increasingly significant solute source. Between 15 and 8 ka the lake waters were cold and relatively depleted in Cl. Mirabilite accumulated on the lowermost parts of the cold, largely subaqueous parts of a meromictic lake floor, in a setting much like the subaqueous salts of the modern meromictic saline lakes of the Canadian interior (Figure 11.51). Since that time, conditions became drier and warmer, with higher proportions of Cl-rich waters entering the perennial lake. Halite was precipitated prior to mirabilite during hypersaline or droughty episodes in the lake and this mirabilite is still an ephemeral mineral in the pans of the North Arm. Before the lakewide drawdown that ended Lake Bonneville, the dominant lake carbonate was calcite. Since that time a more arid climate has dominated and aragonite is the dominant carbonate precipitate.

Mono Lake, California

Mono Lake, an endorheic meromictic saline lake in a volcanically active area at the edge of the Sierra Nevadas (Figure 4.20), has been accumulating laminated lacustral sediments since 760 ka. Current free surface brine volume is $\approx 3.2 \text{ km}^3$, surface area is 184 km^2 , annual total inflow is around $283.7 \times 10^6 \text{ km}^3$ and current salinity is around 90,000 ppm. Major anion

content of lake brines is divided almost evenly between chloride, sulphate, and bicarbonate. The high pH (≈ 9.8) and alkalinity of lake waters leads to high concentrations of volcanic elements that ordinarily have short residence times in lakes (i.e. lanthanides and actinides, including naturally high levels of arsenic in bottom brines; Tomascak et al., 2002). Calcium carbonate (calcite and aragonite) precipitates spontaneously from the lake waters and makes up 3-10 % of the laminite sediment on deeper tufa-free bottoms, the remainder is detrital. Some of

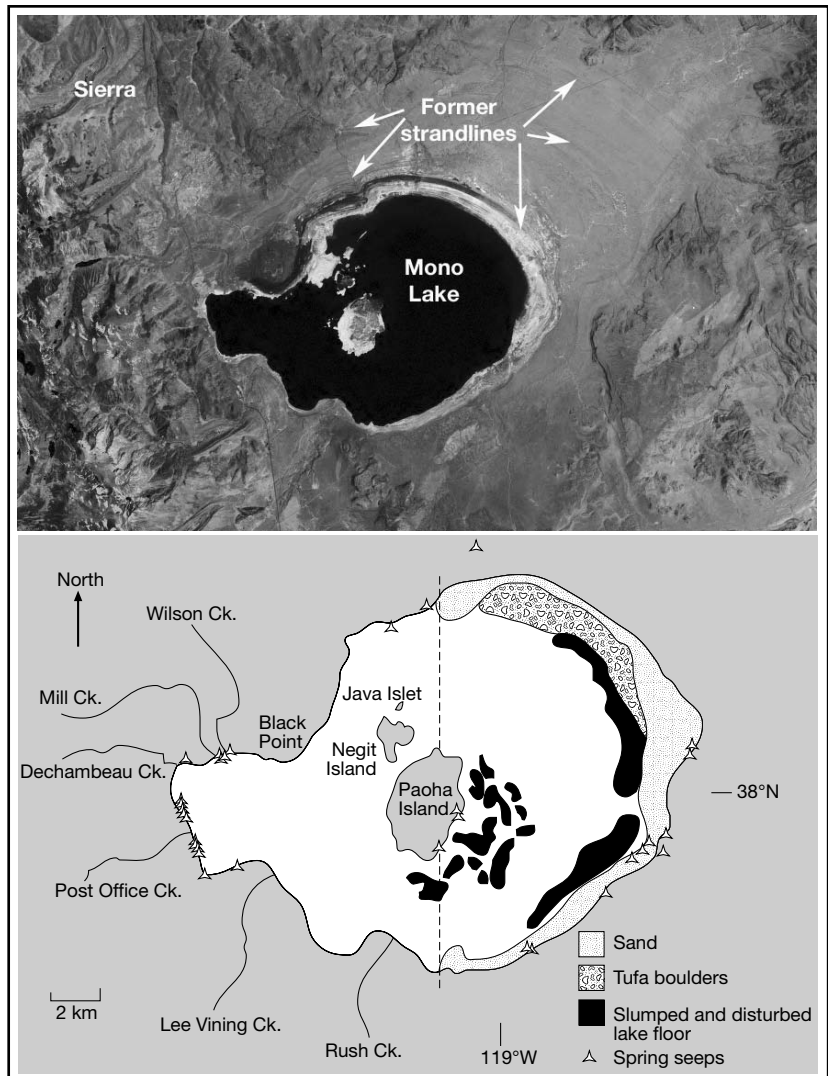

Figure 4.20. Mono Lake, California. Successive strandlines associated with lake shrinkage are visible in the Landsat image, as are the volcanic centres of Paoha Island and the adjacent lake plain to the northwest. High relief drainage source to the west in the Sierra Nevada is clearly seen in the high proportion of creeks entering the western side of the lake (Landsat image courtesy of NASA). Geological interpretation of the type of sediment is only published for the eastern half of the lake - extent indicated by dashed line (in part after Benson et al., 2003).

the lake bottom laminites are slumped, possibly initiated by ongoing volcanic disturbance (Figure 4.20; Benson et al., 2003). Calcite accumulates, sometimes with an ikaite precursor, where resurging groundwaters degas on the lake floor and can form spectacular biogenically-bound towers of tufa.

Lake levels and conditions

From 1850 until the middle of last century the lake water level rose some 5 metres, then the water needs of the City of Los Angeles caused a drastic water fall. In 1941 the distributaries that fed Mono Lake were diverted into the Los Angeles aqueduct. In the 50 years since this diversion, the lake water level dropped more than 10 metres, the lake water volume was cut in half, while the alkalinity and salinity of the lake waters doubled (Figure 4.21). Before the diversions of Mono's tributary streams the water level was as high as 1958 metres above sealevel. Subsequent lower lake levels exposed numerous calcitic tufa mounds and pinnacles on the lake floor and enlarged the portion of the lake floor covered by saline mudflats.

To prevent the complete destruction of the lake, some water from the former distributaries has been rediverted back into Mono Lake, which is now slowly refilling after reaching an all time low of 1942.2 m asl in 1982 (Figure 4.21). The current lake level is 1945 m asl (December, 2004). The projected stabilized lake elevation is 1948.3 m, which should be attained within the next 10-15 years. Interestingly, the anthropogenic lowering of lake water level in the last half-century and the associated increase in lake salinity is still well within the range of natural fluctuations experienced by Mono Lake in the last 4,000 years (Figure 4.22a, b).

In 1982 and 1983 exceptionally large volumes of freshwater runoff led to a rapid 2.6 m rise in surface elevation of the lake and the onset of meromictic stratification (Jellison and Melack, 1993). In 1984 this chemical stratification accounted for a density difference of $1.2\text{--}1.5 \times 10^{-2}$ gm/cc between the 2 and 28 m water depths. At the same time the midsummer density difference between 2 and 28 m depths that was due to temperature was approximately 0.5×10^{-2} gm/cc. Salinities ranged from 77 to 98 gm/l across the interface and sodium, chloride, sulphate, and carbonate were the major ions in both the upper and lower water mass.

Another transition from monomixis to meromixis occurred from 1994 to 1995 (Melack and Jellison, 1998). During the preceding monomictic conditions in 1993 and 1994, the lake had thermally stratified in March and had mixed to the bottom by December. During meromictic conditions in 1995, 1996 and 1997, the absence of holomixis during winter resulted in persistent anoxic conditions beneath the chemocline, the accumulation of ammonium in the monolimnion, its depletion in the mixolimnion, and low mixolimnetic chlorophyll concentrations in the spring and autumn. A comparison of density differences between the 2 and 28 m water depths indicate thermal stratification predominated in 1993 and 1994, while chemical stratification dominated the density differences in 1995, 1996 and 1997.

Tufa mound and pinnacles

The most visually striking geological features of Mono Lake are its metres-tall tufa columns, which protrude from lake waters and line parts of the lake edge. These mounds and needle-like

Figure 4.21. Mono Lake levels from 1850 - present (replotted from online data of Mono Lake Preservation Society accessed on March 27, 2004 at <http://www.monolake.org/live/lakelevel/yearly.htm>).

pinnacles of calcium carbonate frequently define linear trends that are the seepage expression of underlying faults and joints (Figure 4.23). Columns are surrounded by soft bottom sediments and many columns are rooted in massive domal buildups of calcite. Dominant growth orientation is vertical and defines the rapid upward rise of less saline CO_2 -rich waters. Branching of lithoid columns is rare and “pseudo-branches” easily explained by the collapse of one or two adjacent columns imply much of the precipitation mechanism is via inorganic degassing of groundwater on reaching the lake floor. Microbial biofilms coat active tufa surfaces beneath the lake waters and create characteristic knobby grumous microtextures in the reef mounds and pinnacles as they capture the precipitated carbonate (Figure 4.23b).

In today's lake waters calcite and aragonite are the carbonate minerals with long-term stability and they dominate the non-siliciclastic fraction accumulating in the lake (Benson et al., 2003). But during the colder Tioga glacial period of the Late Wisconsinan (12 to 9 ka), and during the present day winter season, ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$), was the dominant carbonate precipitate (Whiticar and Suess, 1998). Ikaite is a metastable cryogenic carbonate and the low temperatures needed for ikaite stability are obvious in winter in Mono Lake. In the winter of 1985 ikaite crystals were visible as coatings on the subaqueous surfaces of active spring seep tufas about the shallow lake edge (*pers obs.*). If these small ikaite crystals were removed from the icy cold winter waters of the lake and held in an ungloved hand, the increase in ambient temperature caused the ikaite to deliquesce, so that in a few minutes it disappeared leaving behind a pool of milky water. Council and Bennett (1993) and Bischoff et al. (1993) argued that during winter, calcite precipitation in Mono Lake is inhibited by low temperatures and high concentrations of phosphates and organic carbon. The same factors allow metastable ikaite to form. Ikaite decomposes into calcite during the spring warming, occasionally leaving pseudomorphs of the primary precipitate in the calcitic tufa.

At a broader scale Council and Bennett (1993) demonstrated a strong hydrological control on the position of many of the larger lithoid tufa mounds. The unconfined aquifer that domi-

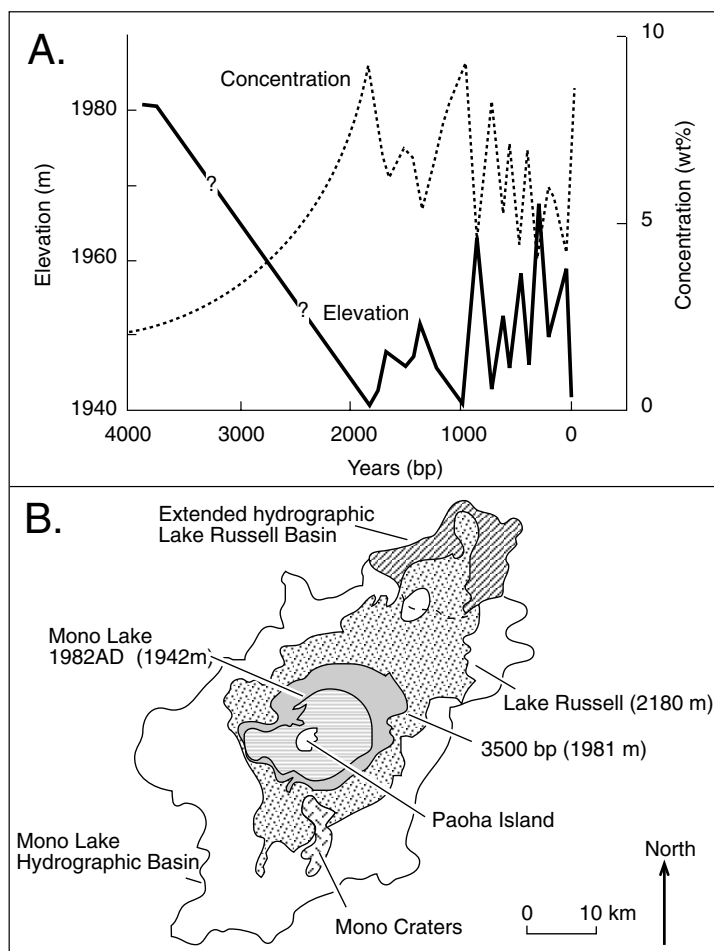

Figure 4.22. Mono Lake, California. A) Hydrological conditions for the last 4,000 years (after Stine, 1990). B) Map outlining different lake areas related to changing water elevations through time (after Rogers and Driese, 1995a, b).

nates the western side of the basin is composed of fluviodeltaic sediment and it controls the modern discharge at many points about the current lake shoreline (Figure 4.23a, c). Currently active diffuse low flow rate seeps are dispersed across the strandzone, and extend from $\approx 200\text{m}$ above the present lake shore to around 1 metre below the present lake water surface (Figure 4.20). Diffuse outflows are geologically defined by flat beachrock-like zones of encrusting tufa and tufa flowers, and most active about the present lake strandline.

Further offshore, where the aquifer is largely confined by lake muds, CO_2 -saturated groundwaters discharge through fault and fracture focused conduits. The associated tufa mounds precipitate along linear trends tied to positions where faults transect the confining clays to intersect the lake floor. Other

Figure 4.23. Mono Lake, California. A) Tufa pinnacles forming linear growths on the saline linear ridges in the lake floor in Nov. 1985. B) Close up of algal-bound crenulated pinnacle surface and subhorizontal layering (scale bar is 15 cm long). C) Schematic cross section showing aquifer control on the development of modern tufa mounds on the margin of Mono Lake California (after Council and Bennett, 1993).

older, now exposed and mostly inactive linear tufa mounds and encrustations define prior times of higher lake water levels and water tables. Modern springs along the western side of Mono Lake originate along the Sierra front and discharge Ca-HCO_3 waters that are neutral to slightly acidic, whereby their degassing drives present day tufa precipitation. In contrast, springs along the eastern shore typically discharge Na-HCO_3 waters, have lower hydraulic heads and are not generally associated with the formation of modern tufa sheets.

The identification of modern ikaite (pseudo-gaylussite) suggests that portions of many Pleistocene and Holocene tufas in the Mono Basin and other cold saline lakes in the Great Basin first precipitated as ikaite (Whiticar and Suess, 1998; Shearman et al., 1989). These palaeo-ikaite have long since recrystallised to form their calcitic pseudomorphs ('thinolites'). Ikaite pseudomorphs are also found in recent and ancient sediments of polar re-

gions where they are known as 'glendonites', or colloquially as "devil's horns". The environmental occurrence of ikaite and their pseudomorphs deem them as potential palaeoclimatic indicators of cold environments including saline lakes. Larger crystals are typically restricted to colder, deeper organic-rich marine sediments or groundwater outflow zones in cold moderately saline evaporitic basins (Buchardt et al., 2001).

Aside from Mono Lake and its spectacular tufa mounds, the other obvious geological feature in the immediate area of the lake is the Mono Craters (Figure 4.22b). These are the remnants of 24 domes of explosive rhyolite, which erupted over the last 40,000 years, with the last eruption occurring less than 700 years ago to form Panum Crater (actually a plug-dome volcano) located just above the south shore of Mono Lake. Black Point, Negit Island, and Paoha Island are all recent volcanic features of the lake geomorphology, Paoha Island emerged from the lake waters within the last 350 years. This recent volcanism drives hydrothermal circulation and is still active in the surface and subsurface hydrochemistry of the Mono Lake waters. It supplies elevated levels of sodium and bicarbonate ions compared to chlorine, along with higher concentrations of arsenates and rare earths (Tomascak et al., 2002).

Hydrological and hydrogeochemical evolution

Up to 2 km of lacustral and volcanogenic sediments underlie Mono Lake, and saline groundwaters (>18,000 ppm) extend to the bottom of the basin's sediment fill (Rogers and Driese, 1995a, b). The position of the saline-fresh groundwater interface within the lake basin reflects a balance between a dense saline brine plume or curtain beneath the lake and the force of inflowing fresh groundwaters fed from the Sierras and discharge

near the lake's western shore. The rain shadow of the Sierra Nevada to the immediate west of the lake has had a dramatic effect on the asymmetry of surface and groundwater inflow to the lake depression. More than 114 cm of precipitation falls at the Sierra crest, which then supplies waters to the western side of the lake's drainage basin, mostly by surface drainage. Lee Vining Ck., Mill Ck., Rush Ck. and Wilson Ck. together supply $\approx 1.75 \times 10^{11}$ l/a to the lake (Figure 4.20; Tomascak et al., 2003). Less than 13 cm of precipitation falls on the eastern shore of Mono Lake. Altogether surface inflow supplies around 75% of the lake's water and springs supply the remainder.

The much higher recharge rates for fresh surface and groundwater seepage along the western or Sierra Nevada side of the lake have pushed the saline-fresh water interface basinward of the shorezone beneath that side of the lake. This creates the artesian head that facilitates the formation of the more spectacular linear-trending tufa mounds. In contrast, the brine plume-freshwater interface lies near or directly below the shoreline around much of the rest of the lake. There the saline groundwater discharge zone is just below the playa surface and it contributes to development of saline mudflats and flat sandy beachrock/rubble atop recently exposed former lake beds in an area that lacks significant tufa pinnacles.

Simulations by Rogers and Driese (*op cit*) confirm that extensive faulting controls local permeability in the basin fill beneath the lake waters. Faulting increases vertical permeability and leads to focused or channelled regions of outflow and seepage in the lake floor. High permeability zones in the lake substrate on the western side means resurging less-saline groundwater can overcome the opposing force of the saline groundwater density plume and so can issue onto the lake floor where its degassing outflow is marked by linear belts of spectacular tufa precipitation, (Council and Bennett, 1993).

In the longer time frame of the Mono Lake's Quaternary hydrology, the redistribution of the basin's solutes between the lake and underlying saline groundwater body is today still driven by late Quaternary lake level changes (Figure 4.22b; Rogers and Driese, 1995b). At times of low lake levels in the Late Pleistocene, the higher concentration and density of lake waters caused solute loss via free convection (brine reflux). This probably occurred more rapidly and penetrated deeper into the sediment column along open faults or fractures. At higher lake levels, the shoreline discharge zone moved closer to the basin edge (e.g. the Lake Russell strandline; Figure 4.22b). The now-unrestrained saline groundwater mass subsided, drawing solutes from the lake waters into the basin sediments. Subsequent

falling lake levels again constricted the saline groundwater zone beneath the lake, driving saline water and their solutes back into the lake waters and once again increasing solute content of surface waters.

Sediment permeability below the lake is the major control on the solute transfer rate between the lake and its groundwater reservoir. Only the larger, longer-term lake level changes drive saline groundwater movement in the lake margin. Depending on permeability of the basin fill aquifer, the equilibration of the saline groundwater and lake solute content to lake water level requires hundreds to thousands of years. Rogers and Driese (1993a, b) suggest that current conditions, where a more saline Mono Lake brine pool (50,000-90,000 ppm) overlies less concentrated groundwater ($\approx 18,000$ ppm), reflects the still active impact of late Pleistocene lake high stands. In support of this they note that Mono Lake's historical salinity data have a large scatter, but suggest there was a 5% decrease in the lake's solute content over the last 50 years of drawdown; they suggest this indicates a diffusive solute flux into lacustrine sediments for this period. Their conclusions are the opposite of the commonly accepted view of Mono Lake drawdown automatically increasing the salinity of the lake waters.

Saline lakes of Turkey

Turkey, with its active compressional tectonics and semi-arid climate, is ideally situated to form permanent ponded bodies of somewhat saline water in mountainous endorheic depressions. It has some of the largest modern saline lacustrine systems in the Northern Hemisphere in subaqueous settings ranging from perennial water pools about the edges of ephemeral saline mudflat and pan systems like Tuz Golu and Aci Golu (Golu = lake), to large deep bodies of alkaline water, such as Lake Van which have extents comparable to Great Salt Lake and Lake Urmia (Figure 4.24). As in the Andes, ongoing plate to plate compression and associated volcanism throughout the Neogene of Turkey has created rich deposits of exploitable saline minerals, especially borates and zeolites, in the many Tertiary lacustrine depressions of Turkey, (Chapter 11).

Lake Van, Turkey

Van Gölü in eastern Turkey has an area of 3,574 km², a maximum water depth of 451 m, a volume of 576 km³ and a catchment of more than 15,000 km². It is the world's largest soda lake and the 4th largest closed-basin perennial lake in the world. It is the largest lake in Turkey and at its widest point it is some 119 km across (Figures 4.24, 4.25). The main water mass of the

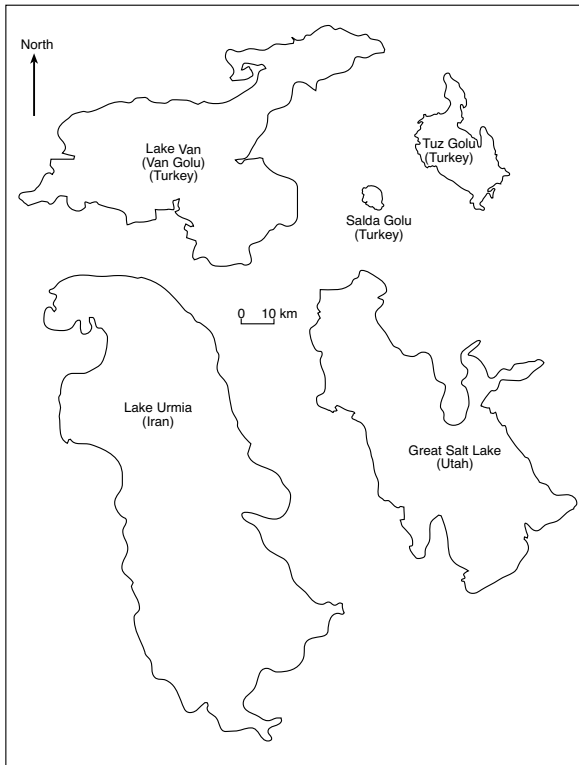

Figure 4.24. Same scale outlines of the various Turkish Salt lakes compared to Lake Urmia (Iran) and Great Salt Lake (Utah).

lake lies in its west, where waters are deeper than 400m. The lake sits in the lower part of a steep-walled, fault-controlled basin, once drained by the Murat River (Figure 4.25). During the mid Pleistocene, some 200 ka, a lava flow from the Nemrut

volcano extended some 60 km across the southwestern end of the basin, blocking westward drainage from the lake via the Murat River and thereby transforming the depression into an endorheic basin.

Climate in the drainage basin is highly continental with hot dry summers and long cold winters. Annual precipitation across the drainage basin is variable and ranges between 400 and 700 mm. Most detrital influx into the lake is in April to June, carried by snowmelt and spring rains. In summer the present day lake waters are thermally stratified and temperatures within the uppermost water column reach as high as 19-20°C (Figure 4.26). Below 50 m depth, water temperatures are less than 3°C and do not change much year round. In winter the shallower northern sections of the lake can freeze over, and the onset of lower surface water temperatures in the autumn drives an annual overturn of the lake waters.

Salinity is 22‰, pH hovers around 9.5 and can be as high as 9.8 making the lake waters highly alkaline (≈ 153 meq/l; Figure 4.26). Free oxygen is present throughout the water column, but drops to values <1 mg/l near the lake bottom. Calcium concentrations in the lake waters are low (≈ 4 mg/l; Thiel et al., 1997) The main cation in the lake waters, sodium, is not only balanced by chloride, but also to a near equivalent extent by high levels of carbonate and bicarbonate ions. As in Mono Lake, the high alkalinity reflects the preponderance of young volcanics in the drainage basin and ongoing hydrothermal circulation. This high alkalinity in the lake's hydrogeochemistry explains the onset of trona deposition when the lake dried out some 15 ka. Relatively high salinity and very high alkalinity means modern

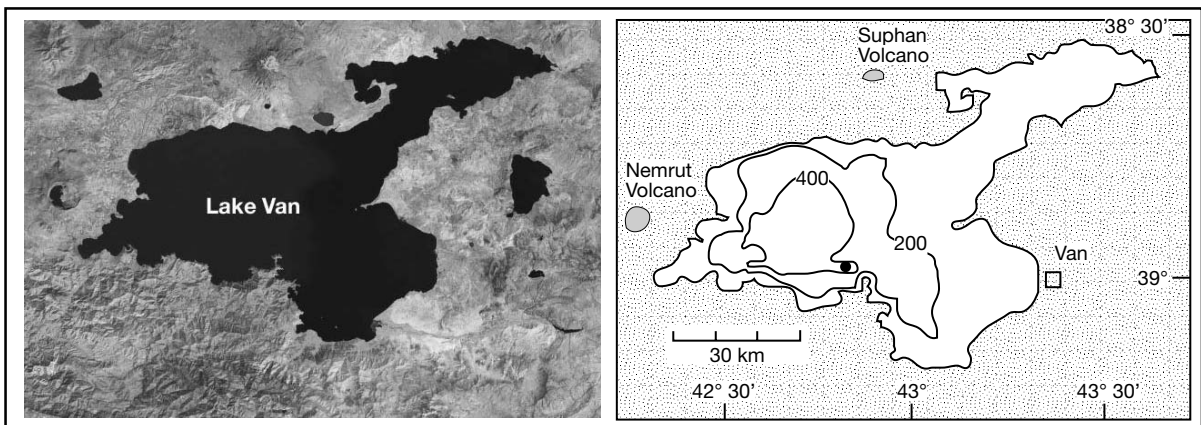

Figure 4.25. Lake Van, eastern Turkey, is the largest perennial saline lake in Turkey. Toward the top of the image are the Satak Mountains, Nemrut Lake, the crater lake of an active volcano, that last erupted in the year 1440 lies to the west. Ercek Lake can be seen to the east of Lake Van. To the north of Lake Van is the extinct Suphan Volcano, a circular volcanic maar with an elevation of 4061 metres. (Landsat image courtesy of NASA). Bathymetry is in metres and the black circle indicates the position of piston core K10, with its geology and chronology illustrated in Figure 4.28.

Figure 4.26. Temperature, oxygen and alkalinity profiles in the Lake Van water column (after Thiel et al., 1997).

lake waters host a low diversity, largely endemic phytoplankton population dominated by diatoms and cyanobacteria (primary producers). Copepods and ciliates are the main contributors to the zooplankton.

Today, the lake water level is around 1648m asl and fluctuates around 50 cm annually, being lowest during the winter months and rising after the spring thaw to reach its highest level each July (Figure 4.27a). Longer term lake levels over the

last few decades have been rising at rates as high as 2.6 m per decade, leading to major problems for agriculturalists working lands about the strandzone or lake floodplain. Millennial lake level changes are even more significant. Some 15 ka the lake had dried into a series of saline pans and the water level was more than 450 metres below that of today (Figure 4.27b; Landmann et al., 1996). A few thousand years earlier, at the height of the last glacial, some 18 ka, the water level in Lake Van was 72 m above its present position (Degens et al., 1984). The rapidity of natural water level changes are of the same magnitude as those currently occurring in the Dead Sea Basin (Figure 4.42).

Lake Van deep bottom sediments were collected by a series of piston cores in 1990 and the results published in Landmann et al. (1996) and Thiel et al. (1997). Their work, along with the results of an earlier piston core study by Kempe and Degens (1978), are summarised in the next few paragraphs and a key core (K10) is illustrated in Figure 4.28. Sediments accumulating on the deeper parts of the Lake Van floor are mainly dark-coloured carbonaceous siliceous carbonate laminites/mudstones, with layering that indicates annual deposition cycles and so are true varves. Varve counts imply core K10 recovered some 15,000 years of lake history (Figure 4.28). Lighter coloured laminae in each varve couplet are dominated by micritic carbonate and opaline silica. Darker laminae are characterised by higher amounts of organic material and high proportions of nonchemical detrital sediment matrix, which was carried into the lake by spring melt waters. Dolomite occurs in various

lamina, but is detrital, not authigenic, and comes from eroded Cretaceous dolomites.

Colours in the recovered core are mostly dark and range from dark brown to dark greyish green; they reflect largely anoxic deepwater conditions (Eh of 150 to -280 mV), which have prevailed on the subaqueous lake floor for the last 15 ka. Accordingly, organic contents in the bottom sediments are high, the organics are oil prone, and TOC ranges up to 5-6% (Thiel et al., 1997). The base of the laminite unit is at around 8.5 m in core K10 and is defined by a sandy layer, thought to indicate the drawdown stage in the deeper parts of the lake, some 15 ka (Figure 4.27b).

Material caught in sediment traps in the central parts of the lake show that most of the micritic carbonate in the cored laminite was annual, probably precipitated in the evaporative surface layer each summer to fall (Landmann et al., 1996). Aragonite/calcite ratios, determined by X-ray diffraction analysis on core K10, scatter between 2 and 9 in sediments younger than 3700 yr B.P., and from 1 to 4 in older sediments (Figure 4.28). The other main chemical component in the sediment traps is opaline silica, largely derived from phytoplanktonic diatom tests.

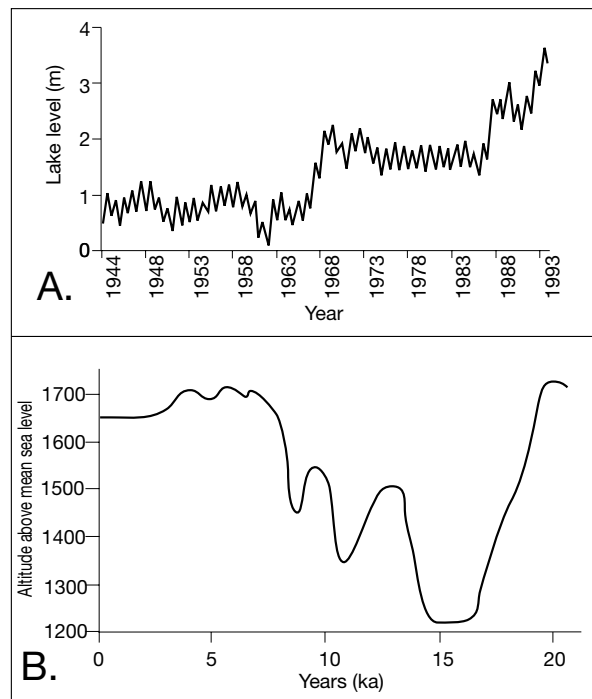

Figure 4.27. Water levels in Lake Van (Vangolu), Turkey. A) Water levels changes in the period 1944-1993 (after Kadioglu et al., 1997). B) Water level changes in the last 20,000 years (after Landmann et al., 1996).

Because present lake waters are supersaturated with respect to alkaline earth carbonates, carbonate precipitation is most obvious in the lake at positions of calcium input where fresher waters mix with more saline lake waters. This can be at the mouths of rivers, where whittings have been documented, or it can occur on the shallow lake floor down to depths of 120 metres, where the degassing of resurging calcium-rich groundwaters escaping into the lake waters creates tufa towers or pinnacles, up to 40m high. These structures constitute some of the largest active microbialite buildups in the world today (Kempe et al., 1991). Lake Van does suffer from severe winters, but these aragonite/calcite tufa samples described by Kempe et al. (1991) were collected in the summer. The possibility of primary ikaite was not considered. So, it not known if some of the initial tufa in Lake Van was once ikaite, which then converted to CaCO_3 . A textural comparison with similar structures in Mono Lake suggests this may be so, especially in older colder stages in the lake history.

The current condition of Vangolu is a useful analog for the Pleistocene freshwater stages in many of the world's soda lakes that are currently in a hypersaline (trona) stage and for many pre-Quaternary alkaline lakes. It serves as a useful analog for the laminites of High Magadi Beds of the Lake Magadi and Lake Natron and for the oil shales of the Eocene Green River Fm, USA.

Salda Lake, Turkey

Saldagolu is another highly alkaline ($\text{pH} > 9$) saline lake in southern Turkey, located in a collision belt at an elevation of 1139 m asl. It is bowl-shaped and occupies the lowest part of a fluvial and seepage-fed endorheic depression at the foot of the Esler Mountains. Lake waters are up to 184 metres deep and cover an area of 43.7 km^2 (Figure 4.29). Lake levels rise about 50-70 cm each spring, but longterm levels are falling and have been doing so for decades exposing widespread beach-rock like terraces and stromatolites of hydromagnesite and aragonite. Inflow waters to Salda Golu are enriched in magnesium and carbonate and when compared to Lake Van are much fresher, they are even capable of supporting the local livestock.

The lake drainage is rimmed on three sides by serpentinites (ophiolites) and on the fourth by a downfaulted block of Upper Cretaceous limestone. Hazburgite is the dominant country rock, though in places it has been metamorphosed to lizardite ($\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$) and subsidiary dunitite, all Mg-rich phases. All the rivers draining into the lake follow faults, flow across peridotites, and under the lowered water levels of today are losing streams. Waters typically seeping into fan deltas or into the lake surrounds before ever reaching the strandzone of Salda Golu (Russell et al., 1999).

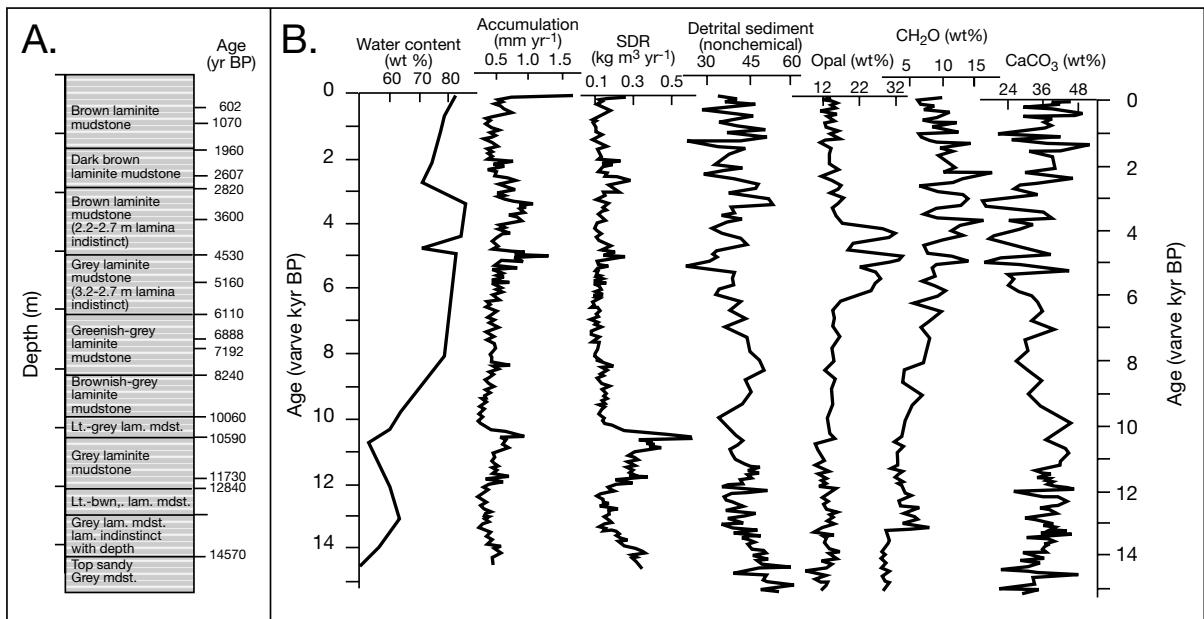

Figure 4.28. Lake Van Core K10 (see figure 4.25 for location). A) Laminites lithology plotted against depth and varve-determined ages. B) Core properties plotted against varve determined time. SDR = rate of sediment deposition. Opal is dominantly from diatom tests and CaCO_3 is mostly from aragonite with lesser calcite (after Landmann et al., 1996).

Magnesium concentration averages 60 ppm in wells and cold springs in the lake surrounds, temperatures range up to 12-15°C and pH lies in the range 8-10 (Braithwaite and Zedef, 1996). Sodium levels in the groundwaters of the lake surrounds are low (\approx 5 ppm) as are most other ions, with the exception of HCO_3^- . In contrast, lake waters contain 300 ppm of Mg and 200 ppm of Na down to a depth of 80 metres, with a pH around 9.1. Mg in the lake has increased by a factor of 6 compared to waters in the surrounding aquifers, while Na in lake water is more than 40 times that in the lake surrounds. Obviously, the bulk of the groundwater seeping into the lake edge gathers Mg as it seeps lakeward through older river mouth fan deltas, which contain abundant cobble of metastable Mg-rich ultramafics such as lizardite (Russell et al., 1999). Lakeward seeping groundwater outside the deltas also picks magnesium, relative to Ca, as it cannibalizes the older hydromagnesite-cemented gravelly strandlines/terraces that circumscribe the present lake. Subsequent hydromagnesite precipitation in the lake is probably related to an increase in pH in the lake waters, tied to HCO_3^- depletion (CO_2 depletion) as it enters the lake, perhaps indirectly brought about by the metabolic activities of microbialites.

Composite stromatolites, several metres high and composed largely of hydromagnesite, line significant portions of the current lake margin; they are best developed atop the now largely inactive fan deltas of the Salda River (Karakova Dere) in the SSW of the lake and the Yesilova delta in the ESE of the lake (Figures 1.6, 4.29). Outside of the fan deltas, smaller stromatolitic mounds of hydromagnesite occur along the lake's western strandzone. Most of the detrital sediment currently accumulating along the strandzone between reef mounds is created by the mechanical (wave-driven) breakdown of former carbonate terraces and hydromagnesite microbialites; it is not derived from longshore transport of fluvial sediment (Braithwaite and Zedef, 1994, 1996; Russell et al., 1999). Hydromagnesite precipitates, now exposed by falling water levels, give the present strandplain its bright white colour. Fine-grained hydromagnesite, reworked

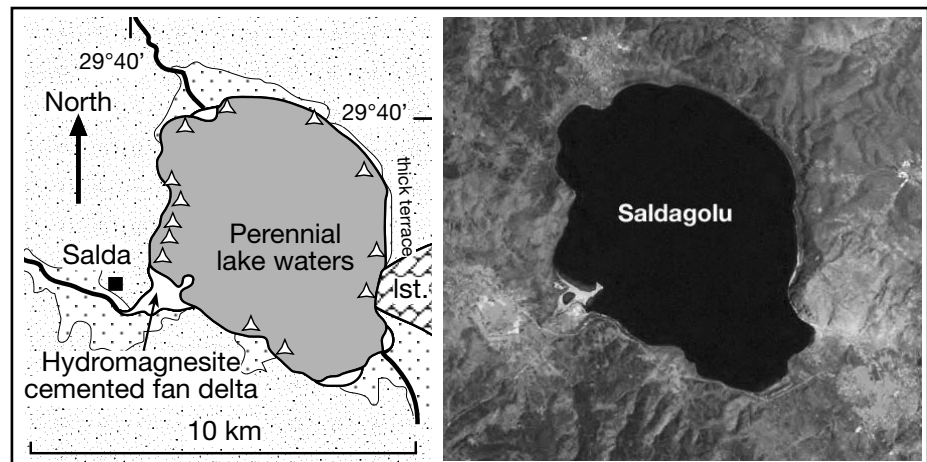

Figure 4.29. Saldalake, Turkey. A perennial carbonate precipitating lake, currently accumulating hydromagnesite and aragonite. The lake is best known for the subaqueous stromatolites accumulating basinward of hydromagnesite strandline terraces, with most prolific occurrences indicated by triangles (for detail on the stromatolites see Chapter 1).

from tufa shorelines and from the terraces, is suspended in the water column during storms and is probably redeposited as micritic turbidites alternating with laminites in the deeper part of the lake.

Further landward from the present strandline, the earlier hydromagnesite terraces preserve no obvious stromatolites, but include boulders and blocks of reworked hydromagnesite up to 0.5 m across. Many of these circum-lake terraces appear to be inorganic precipitates that started to form when lake levels were higher. It seems that stromatolitic morphologies do not survive long-term exposure and lithification as they quickly degenerate into a porous, coarse-grained poorly lithified floatstone, with the positions of former microbialites sometimes still recognisable as mounded outlines in intervening muds (Russell et al, 1999). Like the hydromagnesite stromatolites of the Coorong region, stromatolites in Saldalake have poor preservation potential.

Hydromagnesite precipitation and biofilm coating throughout the current lake is facilitated by the metabolic activities of a flourishing flora of diatoms and cyanobacteria. Biofilms cover the surface of the stromatolites and much of the littoral zone of the current lake. But precipitated crystals do not occur in direct contact with cell surface, implying CO_2 fluctuations may be driving precipitation rather than direct biomineralization. Interestingly, diatoms rather than cyanobacteria dominate the phytoplankton assemblage in the current surface waters of the lake and each year take up all the available silica (Russell et al., 1999). Silica averages 16 ppm in the wells and springs about the lake yet is below detection limit (1 ppm) in the lake

surface waters. Opaline diatom tests rapidly dissolve out of the consolidating stromatolites and are rarely found as body fossils in any of the exposed hydromagnesite cliffs about the lake edge, once again a similar situation to that found in the hydromagnesite-aragonite lakes of the Coorong.

Lake Tuz, Turkey (Tuz Gölü)

Lake Tuz (*tuz* = salt; aka Lake Sereflikochisar) has an elevation of 905 m asl and a water full area of 2,600 km². After Lake Van, it is the second largest lake in Turkey (Figure 4.24) and occupies the lowest part of a fault-defined (transtensional) endorheic depression in the arid Central Plateau. Unlike Vangolu, much of the current lake floor is a salt-crusted saline pan for at least six months a year, with a small area of perennial brine along its eastern higher-relief edge.

To the east of the lake lies a mountainous highland of metamorphics dominated by granites and gneisses. Highlands to the north are composed of sandstones and shales, andesitic and basaltic volcanics lie to the northwest, ophiolite hills lie to the west, and rhyolitic tuffs and andesites constitute the lower relief hills to the south and southeast. Flatter areas of the Konya drainage basin between these highlands are covered by gypsiferous lacustrine marls of various Neogene ages (Figure 4.30).

At some 350 mm/year the area receives the lowest annual precipitation in Turkey, while potential monthly evaporation ranges between 1175 and 1390 mm in a yearly cycle. Natural river inflow to the lake depression totals 88×10^6 m³/yr and comes from three main rivers (Peceneközü, Uluiрмаk and Insuyu). Each year a discharge from the artificial Konya drain releases around 75×10^6 m³ of wastewater into the lake.

Maximum brine depth in the lake is 1.5 m, attained in the spring when meltwaters reach the lake from the adjacent highlands. Evaporative evolution of the natural inflow brines shows a continuous trend from Ca-HCO₃ rich spring waters to Na-SO₄-Cl rich brines with considerable variations in ionic proportions in inflow brines related to lithologic variations in the drainage area. There were times in the Late Pleistocene (20-17 ka and 13 ka) when lake levels were 15 metres higher than today and the Tuzgolu depression was filled with permanent water up to 16 metres deep (Kashima, 2002). Older, but undated, Quaternary shoreline terraces occur some 100 metres above the present lake level (Erol, 1978).

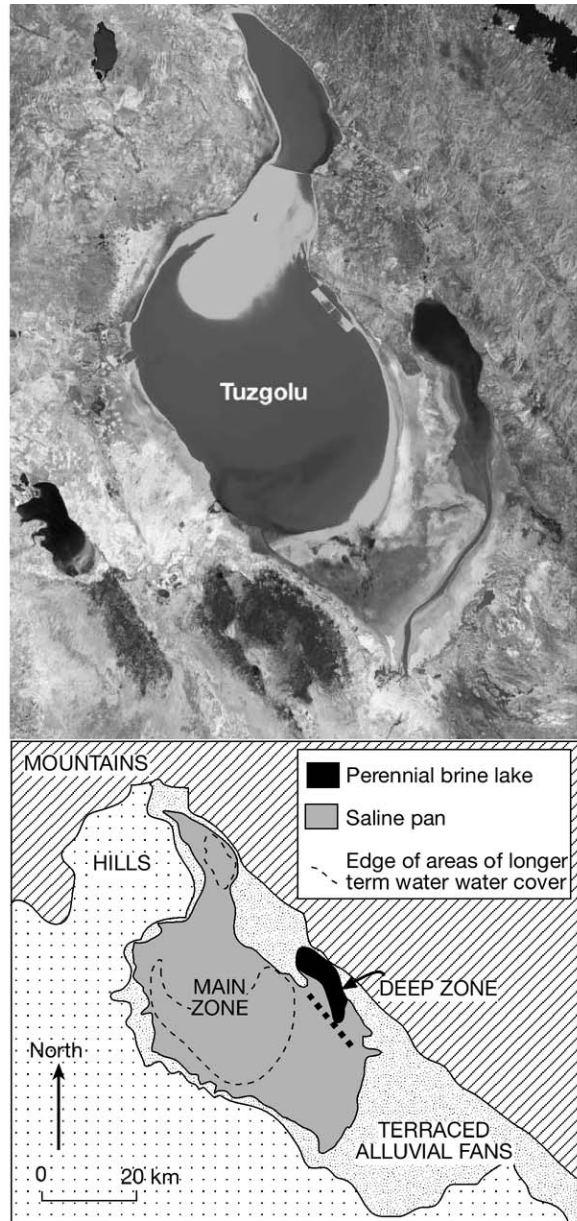

Figure 4.30. Tuz Golu, Turkey. Shows a partially desiccated stage in the lake when much of the saline pan is still water covered. The sill separating the main zone from the deep zone is clearly exposed. The manmade drainage channel and its waste plume cutting into the southwestern part of main zone is also visible. The obvious linear separation between the mountains to the northeast and the terraced alluvial plain reflects the transtensional fault-controlled origin of the Acigolu depression (image courtesy of NASA).

Each year, by mid summer most of the lake floor has dried up and only a few small areas retain permanent surface water in spring-fed seep ponds or brackish marshes (aka moat facies). The largest area of pooled perennial brine lies south of the town of Sereflikochisar, in the eastern part of the lake. It has a permanent brine-covered area of 35 km² called the “deep zone” and it expands with each snowmelt in the nearby mountains. It is separated from the “main” salt pan, which constitutes much of the rest of the lake surface, by a low salt crusted ridge (Figure 4.30).

Waters covering the “main” zone are \approx 70 cm deep in spring, but dry out in summer to early autumn and leave behind a 1-30cm thick halite crust over an area of 1200 ha, which is mined by a large saltworks on the lake shore (\approx 750,000 tonne/year) to provide 55% of Turkish salt needs. In contrast, waters in the deep zone are permanent, are not halite saturated and can be as deep as 1.5 metres in the spring.

Evaporite mineralogy in the seasonal salt crust in the “main zone”, especially in the northern arm studied by Camur and Mutlu (1996), consists of mixtures of halite, gypsum, aragonite and calcite. The unconsolidated sediment for 1-30 cm below the salt crust starts with a gypsum-, huntite- and magnesite bearing levels up to 25 cm thick, with polyhalite in the more central parts of the main zone. This is underlain by a layer up to 35 cm thick composed of gypsum, huntite, magnesite, illite and smectite-bearing sediments. Holocene dolomite was documented in shallow sediment cores from the central parts of the main zone (Irion, 1968) and minor anhydrite was noted along the northern edge of Tuzgolu by Camur and Mutlu, (1996). Each summer halite cumulates cover the chevrons of the salt pan crust and coarsely -crystalline lenticular and prismatic gypsum crystals (0.3 - 4 cm diameter) are commonplace in the sediment immediately beneath the salt crust (up to 50% by volume). They constitute a “desert rose” unit in a micritic matrix made up of varying proportions of magnesite, huntite and dolomite mixed with siliciclastic detritus.

The interaction of microbialites with the recycling salts in the “main” zone has produced disc-like structures in dried halite known as salt biscuits (Mueller and Irion, 1969). Biscuits are 2-7 mm thick crusts, with diameters between 3 and 8 cm. The upper surface tends to be smooth and covered with cumulates of small halite cubes (<2 mm diameter), the lower surface is made up of larger downward-aligned halite crystals up to a centimetre long. Irion and Mueller (1968) concluded that the biscuits are founded halite rafts with ongoing underside growth fed by ongoing capillary rise after surface waters had receded.

A constant freshened, but unnatural, inflow today reaches Tuzgolu via the 150 km long Konya drain (completed in 1974). It feeds a saline sump that drains agricultural wastewater from the Konya irrigation area to the south. In addition, all untreated sewage from Konya city and several hundred industries are periodically released into this drainage channel. This means that each year agricultural waste exuded from the channel into the lake includes the leached residues of more than 1105 tons of pesticides and 446 tons of fertilisers applied to the Konya basin. Industrial waste includes outflows from dairy farms, aluminium and copper plants, leather processing units and a LPG bottling plant. Large amounts of nitrogen, oil, phosphorous, sulphur and organic wastes, as well as heavy metals, including borax, zinc, iron, lead, arsenic, cadmium and mercury today reach the lake depression through the Konya channel. Yet the lake brine is recovered annually for salt manufacture in pans about the lake edge, which supply more than half of the domestic and industrial salt consumed in Turkey. Pumping of industrial and agricultural wastes into salt sumps is an environmental quandary, typical of many developed agricultural and industrial areas in semi arid areas across the world. Only in the last decade have the some of the required hydrological and groundwater studies begun to assess wastewater and salinization effects in such basins in Australia, Egypt, Israel, Mexico, Turkey and the USA.

Lake Aci, Turkey

Acigolu lies in the next major intermontane valley to the northeast of Salda Lake (Figure 4.31). It is a perennial brine lake surrounded by extensive saline pan and mudflat sediments. Like Tuzgolu, the lake is fed by two distinct water sources, less saline Mg-HCO₃ groundwater and local Na-SO₄ springs, while the final lake waters are Na-Cl-SO₄ brines (Mutlu et al., 1999). Differences in composition of the two inflow waters are attributed to different water cycles and different intensities of rock-water interactions.

Dry mudflats in Acigolu are composed of gypsum, calcite, dolomite and huntite, together with clastics. In contrast, wet or brine-soaked mudflats exist locally around saline Na-SO₄ springs and are characterised by efflorescences of halite, bloedite; thenardite and/or mirabilite. Laminated to structureless gel-like sediments composed of aragonite and organic matter typify the bottom sediments of areas of perennial lake brines along the fault controlled southwestern margin and are also zones where halobacteria flourish year-round (Mutlu et al., 1999).

Figure 4.31. Acigolu, SW Turkey. Older strandlines are visible in the north of the lake, while an area of shallow perennial brine (aragonite+organics) occupies the more southerly portion of the lake depression. Part of the fresher water Lake Burdur is discernible toward the bottom right of the image. Near the lower bottom centre of the image is the white salt crust of the now dry Yarash Lake. Numerous faults and lineaments are visible in the surrounding highlands and control the linear orientation of the southwest lake edge (Landsat image courtesy of NASA).

Lake Urmia, NW Iran

Lake Urmia, formerly Lake Rezaieyh, is a shallow perennial saline lake in the lowest part of an endorheic depression in Azerbaijan Province of northwest Iran. Surface waters have a current elevation of slightly more than 1,280 m asl and surface salinities range annually from 80 to 280‰. The lake is some 140 km long and 80 km wide, with an area of 4,700 - 6,000 km². It is the largest lake in Iran and, with a brine volume around 28 km³, it is also one of the world's largest perennial hypersaline lakes (Figures 4.24, 4.32a). Average water depth is around 5 metres, which deepens to 8 metres in the south, where the maximum water depth is 15 metres.

Lake Urmia lies at the bottom of an endorheic basin located further

along the same alpine collision suture as the Turkish lakes. It was created as the Turkish and Eurasian plates were squeezed sideways along very active strike-slip fault systems. Palaeozoic metamorphics crop out in the Zagros Mountains to the west of Lake Urmia. Infracambrian sediments lie to the south, while the northern and northeastern lake margins are characterised by outcrops and subcrops of the evaporitic Middle Miocene Fars Formation and underlying marine limestones of the Lower Miocene. Several Miocene salt domes pierce the surface of the lake's drainage basin.

Climatically, the lake lies in a semi-arid, almost desert environment, with precipitation averaging 30 cm per year. The climate is harsh with winter temperatures

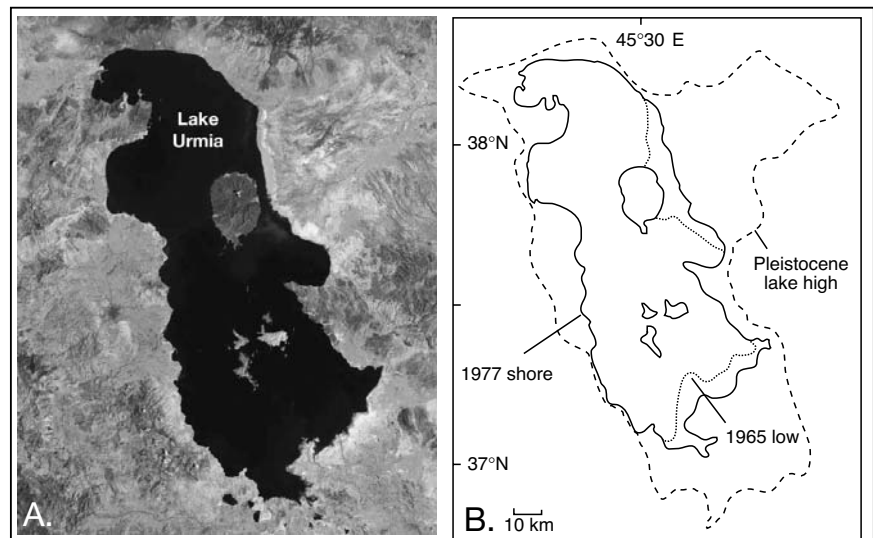

Figure 4.32. Lake Urmia, Iran. A) General distribution of lake sediments clearly showing the Talkerud alluvial braid plain and fan delta to the northwest of the lake and exposed strandline sediments along parts of the northwest and southeastern shores (Landsat image courtesy of NASA). B) Varying extent of Lake Urmia, northwest Iran, shows outline of the lake as defined by its 1977 AD water level, as well as the 1965 AD shoreline and the much more extensive freshened lake that formed during the Pleistocene (in part after Kelts and Sharabi, 1986).

down to -20°C and summers up to 40°C . Surface inflow from the $52,000\text{ km}^2$ drainage basin is strongly seasonal, driving an annual lake water level fluctuation of up to 1-2 metres, especially during the spring melt when the Talkkeh and Simineh Rivers discharge around $57\text{ m}^3/\text{s}$ into the lake (Figure 4.33). By summer the inflow drops to $1.7\text{--}3.7\text{ m}^3/\text{sec}$ and lake levels fall once more.

Figure 4.33. Water levels changes in Lake Urmia, Iran, for the period 1992-2004. (replotted from altimetry derived from TOPEX/POSEIDON and Jason-1 satellite passes by the USDA and last accessed on April 2, 2004 at <http://www.pecad.fas.usda.gov/cropexplorer/>).

Topographically, the surrounding region is either plateau or mountain. Mountains west of the lake have peaks that exceed 3350 metres making that side of the lakeshore somewhat steeper. Salt flats and the fan deltas characterise lake sediments along the southern and western shores. Slight changes in water level can drive drastic migrations of the strandline across the evaporitic mudflats of the lake. In 1977 the lake had a water level of 1284 m asl, while in 1965 the water level had hovered around 1278 m; the lake level had risen by 6 metres in a decade and the shoreline had migrated 5-10 km (Figure 4.32b). Similarly, there was a 5 metre fall in lake level from 1996 to 2003 (Figure 4.33).

Modern lake floor sediments are mostly aragonitic pelletal laminites/mudstones, near identical in appearance, depths of deposition and origin to those of Great Salt Lake, Utah. Laminites in both lakes result from the seasonal biologically-mediated precipitation of aragonite (Kelts and Shahrabi, 1986). When salinity and nutrient levels are suitable, Urmia's surface waters support an abundant summer flora of the green alga *Enteromorpha intestinalis* along with species of *Dunaliella* and *Tetraselmis*. Blooms can be so intense in some years that the water changes colour to a deep green and light penetration is measured in tens of centimetres. The algal bloom is followed quickly by a bloom of the brine shrimp *Artemia salina* (upto 4,000 individuals per litre), which graze the alga. While feeding, the shrimp also ingest particulate aragonite that is precipitating in the lake waters. Thus aragonite in the Urmia laminites occurs both as $10\text{ }\mu\text{m}$ long euhedral prisms in pelagic mud and as the major constituent in sand-sized faecal pellets from the brine shrimp. Both of types of aragonite are interlaminated with organic-rich laminae in a matrix dominated by terrigenous sediment brought to the lake by spring melt. The aragonite is sometimes sufficiently cemented to form cm-thick crusts on and beneath the lake floor. The precipitation of aragonite, rather than calcite, reflects the high Mg/Ca ratio of lake waters (molar ratio 28:1).

At some time earlier in the Quaternary the lake level was lower than today and portions of the lake floor became so saline that gypsum precipitated. At the northern end of the lake this gypsum bed is now some 1.5 metres below laminites of the current subaqueous lake floor. It was interpreted as a sabkha unit by Kelts and Shahrabi, (1986). In other parts of the lake dolomitic mudflats were time equivalents to this now buried gypsum. Oolites shoals formed at the northeast end of the lake but they too are now buried beneath 30 cm of putrid, black organic-rich mud.

The biota and the general spectrum of carbonate sediments found in Lake Urmia is near identical to that of Great Salt Lake, Utah. Like Great Salt Lake, sediments formed on the deeper floor of the perennial saline lake are pelletal aragonite laminates, while shallower sediments accumulated in ooid strandzones or as cemented crusts/beachrocks.

Lake Natron and Lake Magadi, East Africa

These two lakes are probably the most often cited saline alkaline lakes in the geological literature. Both are groundwater sumps, are small and lie just south of the equator in the eastern branch of the East African Rift, which extends for more than 3000 km from the Afar Triangle in the north to Mozambique in the south. Lake Natron, the larger of the two, is in northern Tanzania, at latitude $2^{\circ} 20' \text{ S}$, and longitude $36^{\circ} 10' \text{ E}$; it extends some 55 km N-S and 24 km E-W, with a total surface area of about 950 sq. km. Its northern shore touches the territorial boundary with Kenya. Lake Magadi lies within Kenya slightly to the north of Lake Natron at the bottom of a steep-sided valley, which is the lowest point in the eastern or Gregory Rift Valley (Figure 4.34a). It extends roughly 20 km N-S and is up to 6 km wide. Both lakes lie at an altitude of some 600 m above sea level and are surrounded by plateaus and active volcanoes reaching to more than 3,000 m asl (Figure 4.34b). With an area of only

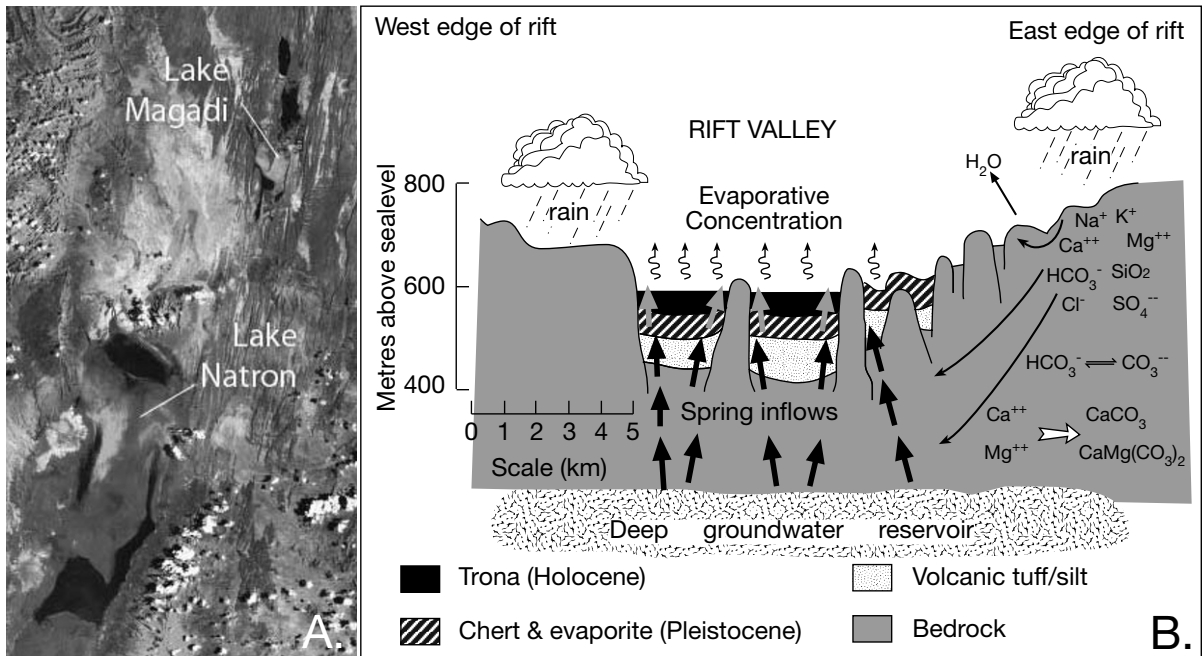

Figure 4.34. Lake Natron and Lake Magadi, East African Rift. A) Position in the East African (Gregory) rift showing adjacent and underlying volcanogenic basement (Landsat image courtesy of NASA). B) Scaled schematic of the distribution of evaporitic lacustrine sediment in the rift valley based on an east-west transect of Lake Magadi (after Jones et al., 1977).

90 km², Lake Magadi is one of the most saline, but also one of the smallest, alkaline lakes in the Rift Valley.

The eastern Rift Valley stretches from Ethiopia to Tanzania and contains numerous endorheic soda lakes of varying salinity. Some lakes are fresh, like Lake Naivasha, others are quite saline Na-CO₃-HCO₃ solute systems like Natron and Magadi. Salinities range from 5% in the more northerly lakes (Bogoria, Nakuru, Elementeria, Sonachi) to around 30% and halite/trona saturation (Magadi, Little Magadi and Natron) in the south of the valley. The pH of surface waters in all is typically above 9, with values ranging up to 11.5 in the more saline alkaline depressions. Hydrographic closure is provided either by location in a volcanic crater or by formation of lake depressions in block-faulted lavas and volcanoclastics. The Rift Valley is volcanically active, with ongoing outpourings of sodic lavas and numerous hot springs (some boiling) about the edges of many of the modern lakes, indicating active hydrothermal circulation. Spring outflows are typically less saline than the lakes they feed and form biological refugia during times of widespread drought.

Climate in the lowermost parts of the rift valley in the vicinity of lakes Natron and Magadi is arid, with high temperatures and an adiabatically reduced mean annual rainfall that is typically less

than 500 mm in non El Nino years. Most precipitation falls in a single rainy season from March to May. Potential evaporation on the rift valley floor exceeds rainfall for most of the year so that the hydrological balance in the drainage region about both lakes is clearly negative. This facilitates the precipitation of aragonite in perennial brine pools about the lake edges and trona in the more central saline pan areas. Air temperatures around the lake can reach 40°C in the dry season, while temperatures can be as high as 66-68°C in dark-coloured mudflat sediment that make up the edge of the moat facies and in the thin brine sheets in megapolygonal saucers in the trona areas.

Both lakes are surrounded by metamorphosed Precambrian basement rocks. Volcanism began in earnest with the Neogene opening of the rift and continues today, with active volcanoes in the vicinity of both lakes. A general rule for volcanoes of the rift valley near Magadi and Natron is: the younger the volcanism the higher the alkalinity. Ol Doi Nyongai, which is the youngest volcano in the vicinity of Lake Natron (≈20 km south of the lake), spews forth carbonatite lavas that are molten mixtures of sodium carbonate and calcium carbonate salts. Hydrothermal circulation, associated with the numerous active volcanoes and their feeder faults, supplies hot alkaline brines to the many hot springs situated about the edges of both lakes (Table 4.3). More than 20 warm, saline springs, with

temperatures between 32° and 52°C, and release rates between 30 and 300 litres/sec, discharge into Lake Natron from scree slopes adjacent to the salt pan. There is no perennial stream flow into Lake Magadi, but it too has numerous warm surface springs feeding saline brines to the perennial lagoon portions of the Magadi depression (Figure 4.36). Eugster (1970) argued that subterranean seepage from nearby Lake Naivasha contributes a solute load equivalent to that carried by all other saline groundwater springs in the Magadi depression.

Other than spring brines, the only other perennial water source to Lake Natron is the Ewaso Ngiro River, which drains into the north end of the lake. Yet today, no bedload sediment carried by the Ewaso Ngiro reaches Lake Natron. It is almost all deposited in an adjacent swamp created when the river was ponded and dammed behind a recently uplifted horst adjacent to the Shambole volcano. River blockage forced the river to dump its traction/suspended load into the waters of the burgeoning Ewaso Ngiro swamp. River water, minus any sediment load, now continually seeps out of the edge of the swamp into a perennial brine lake at the northern end of Lake Natron (Figure 4.35). The effect of uplift on bedload in Lake Natron implies that mineralogical changes in ancient lacustrine units are not always a response to climatic changes; mineralogy in a lake depression can change due to tectonics.

Brine chemistry

Interstitial groundwaters and hot spring waters come from parent waters with low levels of alkaline earths Mg and Ca, and high levels of Na, Cl and HCO₃ (Table 4.3). This chemistry is ideal for on-going trona precipitation at higher salinities (Figure 2.12). Rain falling in the drainage basin contains normal levels of Ca²⁺ and Mg²⁺ but on the way to the lake depression the same waters flow over and through highly alkaline and reactive volcanics. By the time these same waters flow out onto the lake as

springs and seeps they have gathered a four-fold dominance in bicarbonate over the alkaline earths (Ca + Mg). They have already passed the calcium carbonate chemical divide and left behind their calcium and magnesium in various pedogenic and phreatic carbonates to become path I brines (Figures 2.12, 4.34).

Chloride in brines in both lakes behaves conservatively, and so its concentration can be used as a brine evolution marker (Eugster, 1970). Chlorine levels show an 18,000 fold increase in concentration in the lake brine compared to river and spring inflow. Yet this is not sufficient to precipitate large volumes of halite within the Natron-Magadi depression, nor does the current warm climate favour the accumulation of natron over trona. Trona is the first Na-carbonate mineral to precipitate in equilibrium with concentrating lake brines. Natron could form as a coprecipitate if the surface brine temperature falls below 25°C (Figure 2.13). But, such low temperatures do not occur in either Lake Magadi or Lake Natron at the times trona precipitates.

As trona forms, there is a marked decrease in the bicarbonate proportion (relative to chloride) in the increasingly saline lake brine. As the brine continues to concentrate, lesser amounts of

	Ewaso Ngiro River	Hot Spring (Natron)	Interstitial brine (Natron)	Surface water (Natron)	Hot Spring (Magadi)	Salt pan brine (Magadi)	Moat brine (Magadi)	Surface water (Nakuru)

Table 4.3. Typical chemistry of waters and brines in saline East African rift valley lakes (ion contents in ppm, cited from various sources listed in text).

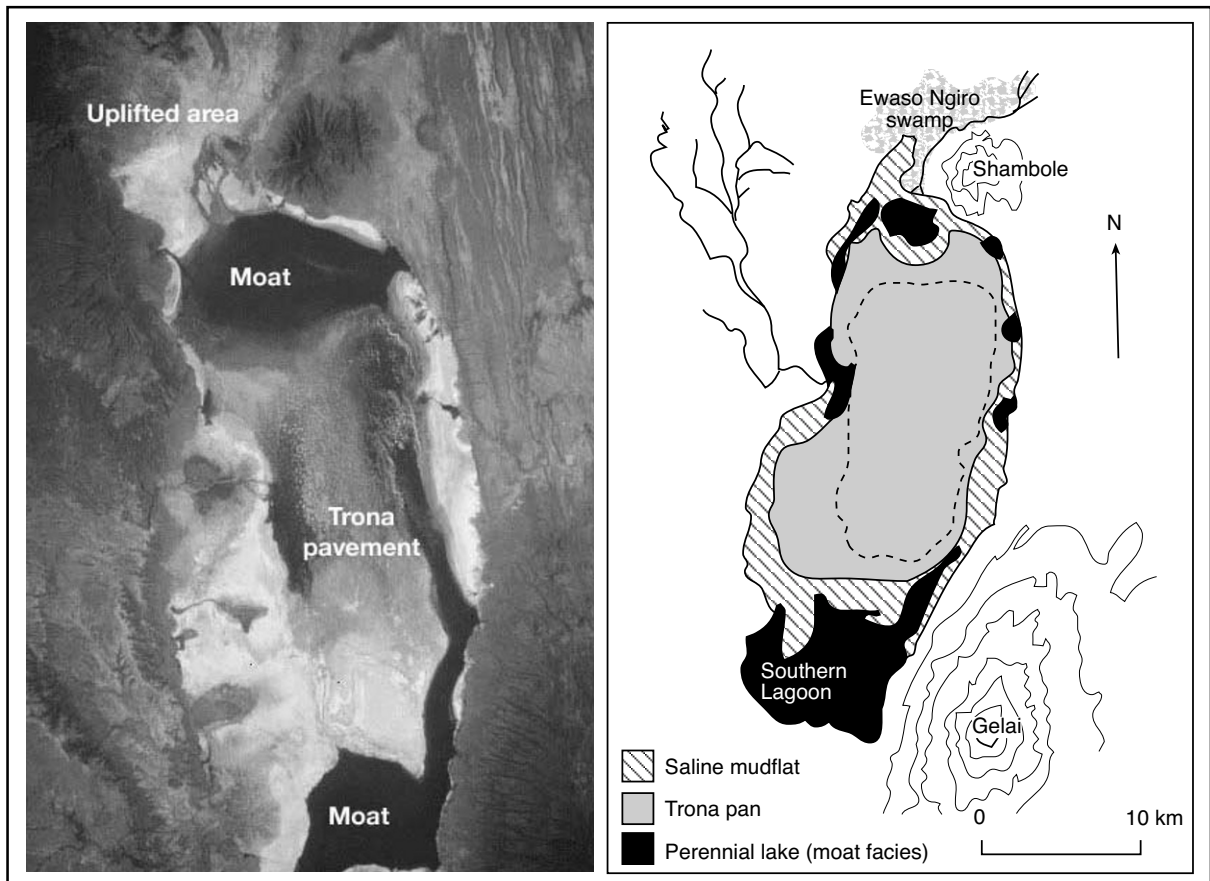

Figure 4.35. Lake Natron. A) Northerly looking view of Lake Natron showing moat facies about the lake edge and the more central trona platform, the water covered area appears pink due to a flourishing haloarchaeal population (Photo courtesy of NASA). B) Geological setting of Lake Natron.

trona precipitate and ultimately halite should crystallise. But, the high humidities maintained over the lake brines in the deep valley bottoms of Lake Magadi and Lake Natron mean surface waters can only rarely attain concentrations where halite can precipitate in large volumes (no more than 5-10% halite is preserved in the trona crusts in either lake). Higher temperatures at the time the various Na-carbonates precipitate from the lake brines means thermonatrite (not natron) is the other sodium carbonate accumulating in both lakes (Figure 2.13); only at rare to minor levels in Magadi, but it can locally constitute up to 30% of the trona pavement in Lake Natron.

Interestingly, the concurrent fluoride increase between inflow and the trona stage of the lake brine is only 7,200 times (compared to 18,000 in chloride in the same waters), indicating its removal as a sodium salt. A lack of Ca in lake brines prevents direct fluorite precipitation in this fluorine-rich hydrothermal province. Accordingly, fluoride concentrations in the interstitial

brines of the trona^{4.2} platform can be more than 1400 ppm. This, and the elevated Na levels in the concentrated lake brines, leads to the precipitation of sodium fluoride salts in the trona crust that include kogarkoite ($\text{Na}_3\text{SO}_4\text{F}$) and villiumite (NaF) (Darragi et al., 1983; Eugster, 1986). Prior to its documentation in a Lake Natron trona crust, kogarkoite had only been observed in hydrothermal deposits.

Holocene sediments

Spring and ephemeral stream-fed carbonate lagoons form permanent water-filled depressions that line the edges of the trona pan in both lakes. Unlike the more central trona depositing saline pan, the lagoons never dry up and are sometimes described as a “moat” to the lakes (Figures 4.35, 4.36). In Lake Natron, which

^{4.2} Use of fluoride-rich trona from Lake Natron as a food tenderiser has led to widespread dental fluorosis in the local population (Mabelya et al., 1997).

year-round contains more freestanding water than Magadi, the lagoon water depths during the wet season can be upwards of 10 m. These perennial brine lakes are floored by black micritic laminites, which are mostly composed of aragonite and dolomite peloids and can contain up to 16% TOC. The lagoon floor laminites and nearby pisolites and cemented crusts of the spring seeps, constitute a carbonate “moat” facies. Although located about the lake edge, this laminated carbonate unit is deposited in waters deeper than the ephemeral brine sheets forming the trona pavement lake centres. Less saline areas near spring seeps in the moat lagoons in both lakes can contain thriving populations of *Tilapia alcalica*, a small fish that survives at temperatures of 39°C and pH up to 10.5. Away from the spring-freshened areas, the lagoon bottom waters and pore waters in pavements become too saline and too anoxic to support vertebrates and a well-adapted halophilic microbial biota flourishes, including endemic alkaphilic archaea, (Chapter 9).

Trona accumulates in the central portions of both lakes as flat pavements composed of stacked saline pan crusts. Some 2,100 km² of the northeastern part of Lake Natron is covered by an impure trona bed averaging 1.5 metres thick (Figure 4.35). The Lake Magadi trona pan is some 74 km² in area and is 7 - 50 m thick, known locally as the “Evaporite Series” (Figure 4.36). It is made up of cm-scale stacked trona-detrital couplets (Baker, 1958). Light-coloured trona layers are composed of rosettes and splays of upward pointing, growth-aligned trona crystals. Thin bands of finer trona coloured by dark, mainly windblown dust separate the crust layers from each other. Even as it stacks and dissolves, each layer retains some porosity between interlocking growth aligned crystal splays.

During the wet season the trona pans in both lakes are covered by shallow brine sheets (<1 m

deep) and are subaerially exposed for the remainder of the year. When not covered by lake brines, the modern surface of both the Magadi and Natron trona pans are rock hard and occupy topographically higher positions compared to the water surface of the adjacent perennial lagoons. This “moat” geomorphology is used as a natural protection from predators by flamingoes that, once waters recede from the trona pan, nest in large numbers on the platform, especially in Lake Natron (see flamingo connection in Chapter 9).

Trona saturation is achieved when the shrinking brine sheets are 2-10 centimetres deep. At that stage the trona prisms grow upward from the pan surface as cm-scale aligned elongate blades and splays. Interlocking of the crystal splays give the accreting trona sheet an inherent strength that allows it to support expansion polygons or pressure ridges, with saucers up

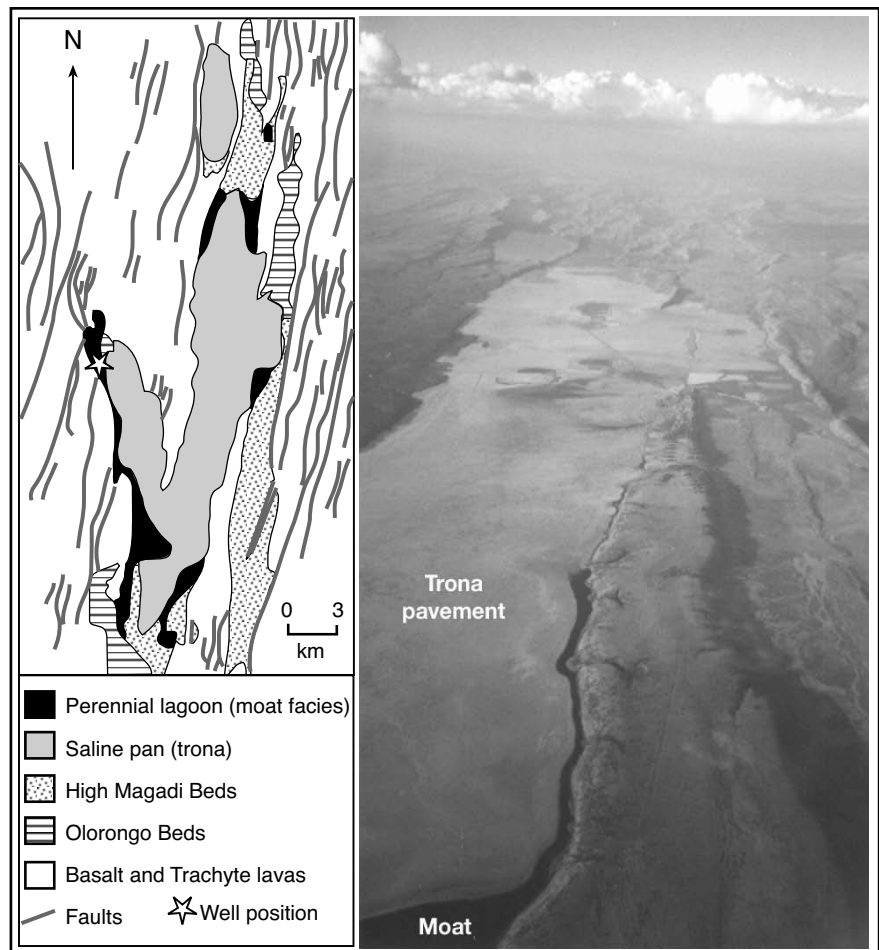

Figure 4.36. Depositional setting of Lake Magadi. Aerial view looks north and shows dark coloured moat facies of perennial lagoon defining lake edge. The well position locates the core in the High Magadi beds documented in Figure 4.37.

to several tens of metres wide and ridges up to a metre high. Ridging is the result of pavement overthrusting, driven by the sideways expansion of trona layers jostling for space in the various growing crystal pavement. The resultant cracking and thrusting of the layers cuts the trona pavement up into a series of overthrust-edged saucers, with small bright pink brine pools in the centre of each polygon; the colour is the result of a haloarchaeal bloom (see Chapter 9).

At the same time the ridges are forming, thin films or rafts float on the surface of the brine sheet. Trona rafts contribute only a minor amount to the total trona volume in the pavement unit, but are important in controlling mineralogy as they slow evaporation and raise the temperature of the underlying brine through a greenhouse effect. Temperatures of 60°-65°C can occur annually within thin brine sheets immediately below the trona rafts and so drive precipitation of thermonatrite (Figure 2.13). As brine level continues to fall, the upward-growing bottom-nucleated trona splays break through the floating rafts. Prior to complete drying, high winds can break up and flounder the rafts or blow them into heaps about the local strandzones of small brine pools.

Finally, the brine level falls below the surface of the newly formed trona crystal crust and the annual primary depositional cycle is complete. Small amounts of trona continues to crystallise as minor amounts of interstitial cement below the surface of the exposed pan. When the pan surface dries out, the brine level stays very close to the surface of the trona pavement. Even during exceptionally dry years it drops no more than 5 cm into the trona layer. Whenever the surface of the layer is exposed during the dry season it can be covered by a thin layer of windblown material.

With the next rainy season the water table rises as the pan is once again covered by water. Initially, these inflow waters are fresh and undersaturated with respect to the pore waters of the trona pavement. So they float above the top of the dense interstitial brines and any trona crystals poking up into these freshened waters start to dissolve. Last season's crystals are truncated by the influx of freshened waters. During this freshened stage, windblown clays and other detritus on the pavement surface can be retransported by waves. Then the wet-season rains cease and the trona precipitation cycle begins anew. Each season a trona layer 2 to 5 cm thick forms on the saline pan in both lakes but subsequent seasonal dissolution means the average Holocene accumulation rate for Lake Magadi trona is at most 0.4 cm/yr. The much thinner layer of Holocene trona preserved in Lake Natron, implies dissolution levels are even higher compared to Lake Magadi. The annual trona crop in Lake Magadi is around

1.5 million tonnes/year, but the bulk of this crop ($\approx 75\%$) is recycled by pan dissolution each wet season. Lake Magadi has been described as an "ephemeral saline lake at the peak of its trona productivity" (Eugster, 1980b). Trona in Lake Magadi has been extracted at various times from 1914 until today using dredging barges. Replenishment of trona in the lake is so rapid that at the rates the Magadi trona is mined (230,000 tonnes/year) it is a renewable resource (Chapter 11).

Late Pleistocene sediments

Aside from the Ewaso Ngiro River, two other rivers flow toward the shores of Lake Natron, the Peninj and Malambo Rivers. Today, these rivers are ephemeral and any surface water sinks into the riverine sediment fans well before it ever reaches the current lake strandline. Some 9,000 to 10,000 years ago during the last high water stage, these rivers, and the Ewaso Ngiro, deposited fan deltas along the edge of a much fresher and higher Lake Natron. Today, these sediments form "hung" delta lobes on the surrounding landscape located well back from the lake shoreline, some 10 to 60m above the present lake level. In earlier lake-full times the flood sands from these highstand deltas probably extended further out into the lake centre and so may now directly underlie the trona-hosting sediments of the lake centre and act as potential aquifers for fresher groundwaters that prevent the accumulation of thick trona units in Lake Natron.

At the time the fan deltas were active Lakes Magadi and Natron were both deeper, larger and fresher water bodies. At such times in the late Pleistocene the two lakes sometimes merged into a single pluvial lake (Hilaire-Marcel et al., 1987). Studies of stromatolites and tufa terraces from various high lake levels in the vicinity of both lakes show that the most recent high lake levels were part of a two-stepped climatic optimum that occurred some 12 to 11 ka (Williamson et al., 1993; Icole et al., 1990). The first humid period (between 12 and 11 ka) created a lacustrine highstand that topped the 635m-elevation barrier (msl) separating the Magadi and Natron depressions. Between 11 and 10.7 ka the lake level dropped below the barrier, once again separating the two lakes. A second maximal high stand occurred around 10 ka, possibly once again joining the lakes. Since that time, and throughout the Holocene, the lake levels have been consistently near their present levels and some 60 m below their former highstands.

The High Magadi Beds were deposited as diatomaceous mudstones when lake waters were more than 13 to 14 metres above the present level and relict shorelines from that time are

still mappable (Figure 4.36). Lake sediments of that time are mostly bedded volcanic muds and cherts, typically deposited as lakefloor laminates with abundant fish scales visible on partings. A 8.7m core taken from this highstand facies in the region of the Flamingo Nursery on the northern edge of Lake Magadi recovered High Magadi beds that were deposited from 40 to 9 ka (Figure 4.37; Damnati et al., 1995; Williamson et al., 1993). The lower (870–740 cm) and upper (295–6 cm) units in the core consist of laminated silts made up of alternating layers of magadiite (zeolite-rich) and organic-rich muds (TOC > 5% dry weight). The middle unit (295–740 cm) contains homogenous inorganic clay silts that are unlaminated, suggesting the lake was not stratified at that time. The upper laminated unit was deposited 12 to 9 ka, the middle unit \approx 23 ka, while the lower laminated unit contains sediments as old as 40 ka. Each unit is separated from the other by a thin sand that is thought to mark a hiatus in chemical sedimentation and to be a flood sand from the feeder deltas.

The laminae episodes in the core indicate times when a relatively deep lake was chemically and thermally stratified. Light laminae in the couplets are in turn comprised of couplets. Each light layer is made up of a microlayer rich in detrital elements (quartz and feldspar) and broken diatom frustules that is overlain by a microlayer of magadiite (Damnati et al., 1995). The dark lamina in each couplet is composed of a microlayer made up mostly of well preserved diatom frustules, covered by a layer of microspherules (probably microbial) associated with autochthonous organics generated in the lake waters. White lamina indicate a more humid season climate and dark laminae indicate drier climatic conditions in the lake depression. Variations in lamina thickness can be tied to year to year variations

Figure 4.37. Core in the High Magadi beds, Lake Magadi (see Figure 4.36 for location; after Damnati et al., 1995).

in monsoonal intensity and to ENSO years. These Pleistocene laminae are very similar to those accumulating in Lake Van today and the general lake hydrology and humid climates are probably comparable, although one forms in a transtensional tectonic regime and the other is part of a rift valley fill.

Two hundred kilometres north of Magadi is Lake Bogoria, a permanent freshwater lake, which today receives more fluvial inflow than either Magadi or Natron. Lake Bogoria is located in the lower part of what is locally an asymmetric rift valley with active fan deltas forming along the steeper gradient eastern side of the lake, Gilbert-style deltas typify Holocene deposits on the less steep western side and diatomaceous laminae are accumulating in the deep lake centre. It is probably a Holocene counterpart of the Late Pleistocene situation when the High Magadi beds were deposited.

An important general observation for saline systems, based on the African Rift valley lakes, is that perennial continental lakes

do not usually deposit bedded evaporites at the same time that they deposit thick fluviodeltaic successions. Nor do all lakes in a rift valley accumulate evaporites at the same time. Episodes of fluviodeltaic deposition and thick evaporite deposition are separate in time and space – a restriction inherent in the isolated lake hydrology needed to precipitate evaporites. That is, ancient lacustrine evaporite beds occurring in separate but adjacent basins are not necessarily time equivalent. And, it is almost impossible to form evaporites when the lake waters are diluted by fresh water carrying siliciclastics into deltas. However, the time intervals resolvable in the siliciclastic-to-evaporite transition in the African Rift Lakes are less than a few thousand years. In pre-Quaternary lacustrine deposits, such as the Eocene Green River Formation, the two sedimentation styles may appear syndepositional and are easily mis-correlated.

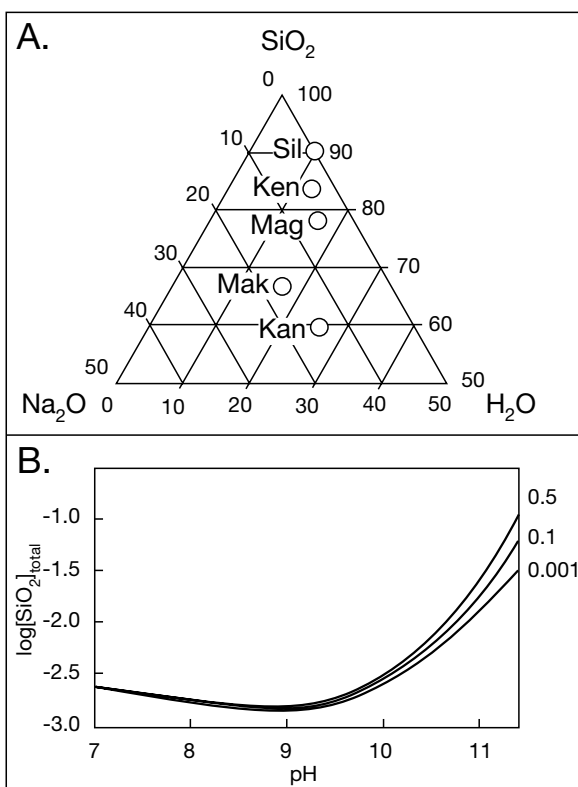

Figure 4.38. Magadiite chemistry. A) Sodium silicates minerals plotted in the upper part of the ternary diagram $\text{Na}_2\text{O}\pm\text{SiO}_2\pm\text{H}_2\text{O}$ showing the position of various hydrous sodium silicates related to varying proportion of the constituent water silica and sodic contents (Ken, kenyaite; Kan, kanemite; Mag, magadiite; Mak, makatite; Sil, silhyrite). B) Concentration of $[\text{SiO}_2]_{\text{total}}$ at equilibrium with magadiite as a function of pH at ionic strengths of 0.5, 0.1 and 0.001 at 0.001 mol Na^+ L^{-1} , 25 °C (after Dietzel and Leftofsky-Papst, 2002).

Diagenesis - magadiite and evaporitic chert

Neoformed sodium silicates (especially magadiite) accumulate in alkaline carbonate-rich hydrogeochemical environments, especially in organic-rich diatomaceous laminites of the freshened stages of soda lakes. Such sodium silicates were first documented in the High Magadi beds (Eugster, 1969, 1980b; Baker, 1958) and also occur in the High Natron beds. There are three sodium silicates in the High Magadi beds: magadiite - $\text{NaSi}_7\text{O}_{13}(\text{OH})_3\cdot\text{H}_2\text{O}$, kenyaite - $\text{NaSi}_{11}\text{O}_20.5(\text{OH})_3\cdot\text{H}_2\text{O}$, and makatite - $\text{NaSi}_2\text{O}_3(\text{OH})_3\cdot\text{H}_2\text{O}$ (Figure 4.38a). Of these, only magadiite occurs in substantial quantities, typically as beds, mounds and nodules. Kenyaite, never occurs as beds, but is not uncommon as nodules in the bedded magadiite laminites of Lake Magadi. Some magadiite nodules have kenyaite at their centres, perhaps implying kenyaite can be created by the weathering of magadiite.

To date, magadiite has been found only in Quaternary alkaline lacustrine settings. In addition to Lake Magadi, Quaternary magadiite has been found in Lake Bogoria, in Lake Chad in western central Africa, Alkali Valley playa in Wyoming, and Trinity County in California (Sebag et al., 2001). On a longer time scale, ancient Magadi-type (crocodile skin) chert has been found in many ancient lacustrine basins, in the Jurassic of Wyoming, the Proterozoic Callana Beds of the Adelaide geosyncline in South Australia, and in Precambrian banded iron formations in Western Australia (see also Table 7.11).

Conditions associated with the precipitation of magadiite from lake brines in Lake Chad, and probably most other soda lake occurrences including Lake Magadi are (Sebag et al., 2001); 1) elevated alkalinity (pH >9), 2) high concentrations of dissolved silica (up to 2700 ppm), 3) incorporation of sodium ions into the silica lattice that precipitates at the time of supersaturation. Depending on the concentrations of Na and Si in the brine, the various sodium silicates will precipitate (Figure 4.38).

Bedded magadiite is widespread in High Magadi laminites, it precipitated in the Pleistocene when Lake Magadi was deeper, fresher and density stratified. Most of this magadiite is an authigenic phase precipitated during shallow diagenesis via the interaction of alkaline brines with reactive siliceous materials such as volcanic glass and zeolites (Jones et al., 1967). Even today, hydro-sodium-aluminosilicate gels precipitate about the edge of Lake Magadi where saline spring waters first emerge. With shallow burial the gels convert to analcime, erionite, and magadiite.

Two mechanisms are thought to drive the precipitation of the sodium silicates. One is intense evaporation, so the resulting

sodium silicates are intimately associated with evaporite indicators, such as evaporite splays and dissolution breccias with evaporite pseudomorphs and moulds in the magadiite host. The other is the pH decrease that occurs when a brine comes into contact with more diluted or more acidic water as when two stratified water masses with differing chemistries mix (Figure 4.38b). Likewise, although the pH change may be as little as 0.5, a decrease in pH from 10.3 to 9.8 lowers amorphous silica saturation more than 500 ppm (Figure 7.58). In contrast to the modern occurrences, the pH and dilution changes needed to form the Pleistocene magadiite of the High Magadi laminites were probably related to the annual overturn of the stratified water mass.

Freshly precipitated, magadiite is a soft plastic white paste (Maglione, 1980), and remains so while bathed in alkaline pore brines. However, when exposed to drying and dehydration it quickly loses its plasticity, cracks and shrinks as it irreversibly hardens into chert. Shrinkage (25% volume change) of the hardening surface creates neoformed chert with a superficial crack network made up of small prisms separated by fissures, comparable to desiccation cracks (Figure 4.39; Icole and Perinet, 1984). It gives the surface of any resulting chert a characteristic “crocodile-skin” or cracked appearance. This is a texture used to support an alkaline lacustrine interpretation in ancient counterparts, such as the crocodile cherts in the Eocene Green River Formation (Figure 4.39). In Phanerozoic hosts, such nodules are readily distinguished from the much more commonplace and nondiagnostic smooth-walled chert nodule, which are widespread in both marine and nonmarine matrices.

Whenever a plastic magadiite horizon in the High Magadi beds is traced from depth (≈ 1 m) to the surface or from subcrop to outcrop, a conversion from magadiite to surface chert is always seen. In the perimeter sediments of Lake Magadi, Eugster (1969) described what he considered to be an impressive syndepositional result of this transformation, namely shrinkage megapolygons up to 50 m across in a bedded chert host with bounding upturned chert ridges up to 2 m high.

More recent work on the same structures by Behr and Röhrich (2000) has concluded the megapolygons do not indicate a response to mineralogical transformation, rather they are part of a suite of prelithification structures in soft siliceous lake sediment. The chert megapolygons are a soft sediment response to strong deformation and local-scale diapirism, as are the associated pillow-chert mounds, chert extrusives along dykes and fault ramps, horizontal liquefaction slides with breccias, slumps, petees, flows and shear-structures in the magadiite

Figure 4.39. Magadiite chert from Lake Magadi showing cauliflower surface texture, also known as crocodile skin.

beds (now all chert at outcrop). Collapse, liquefaction and extrusion of the pre-lithified siliceous matrix were caused by seismotectonic rift activity in the lake basin and it activated fault scarplets and large-scale dyke systems. Seismic activity led to liquefaction and other earthquake-induced intrasediment deformation, especially along fault ramps and on tilted blocks. The textures all indicate the chert megapolygons are a form of seismite and do not indicate volume changes in the transition from magadiite to chert. After liquefaction and extrusion, the exposed magadiite material solidified via spontaneous crystallisation in an environment that was characterised by highly variable pH and salinity.

Since the work of Eugster in the 1960s, three sets of diagenetic processes are now thought to be responsible for driving the conversion of magadiite to chert in Lake Magadi and other soda lakes:

(1) Leaching of sodium by dilute surface runoff during weathering of the High Magadi beds, as evidenced by tracing unweathered beds into outcrop and summarized in the chemical transformation (Eugster, 1969);

(2) Spontaneous release of sodium driving the conversion of magadiite to chert, whatever the nature of throughflushing solutions and environments. In this process sodium is expelled even in the presence of brines; it does not require the fresh water needed for process 1, and perhaps better explains the occurrence of calcite-filled trona casts in cherts and the presence of chert nodules in unweathered magadiite horizons in Lake Magadi (Hay, 1968, 1970).

(3) To this inorganic perspective on the transformation to form chert, Behr and Röhrlich (2000) added a biological one. Based on their field observations and microbiological studies of the cherts in Lake Magadi region, they argue that inorganic cherts are rare at the type locality of Magadi-style cherts. They go on to note that most of the cherts in the Magadi depression are older than the High Magadi Beds and developed from flat-topped calcareous bioherms of *Pleurocapsa*, *Gloecocapsa*, and other coccoid cyanobacteria, along with thinly bedded filamentous microbial mats, stromatolites, bacterial slimes, diatoms, *Dascladiacea* colonies and other organic matter accumulations. Silicification occurred from a silicasol via opal-A to opal-C with final recrystallisation to a chert of quartzine composition. They conclude that metabolic processes of cyanobacteria controlled the pH of the brine and strongly influenced the dissolution-precipitation mechanism that created the chert (Figure 7.58).

Dead Sea, Middle East

The Dead Sea water surface defines what is the deepest continental position (-415 m asl) on the earth's current terrestrial surface. It is our only modern example of bedded salts accumulating on the floor of a brine body where water depths are measured in hundreds of metres. This salt-encrusted depression is 80 km long and 20 km wide, has an area of 810 km², is covered by a brine volume of 147 km³ and occupies the lowest part of a drainage basin with a catchment area of 40,650 km² (Figure 4.40). However, falling water levels in the past few decades mean the permanent water mass now only occupies the northern part of the lake, while saline pans occupy the southern basin so that the current perennial "Sea" is now only some 50 km long. Rainfall in the region is 45 to 90 mm, evaporation around 1500 mm, and air temperatures between 11 and 21°C

in winter and 18 to 40°C in summer, with a recorded maximum of 51°C. The subsiding basin is surrounded by mountain ranges to the east and west, producing an orographic rain shadow that further emphasises the aridity of the adjacent desert (Figure 4.40).

So, until recently, the basin floor was physiographically divisible into two contiguous and permanent brine-covered water bodies, the Northern and Southern basins, largely separated by a diapir-cored shallow sill, the Lisan ridge and joined at the Lisan Straits. But continuing falling water levels means that today the North Basin is the only permanent natural water mass with waters some 320 m deep (Figure 4.42a). The Southern Basin is today a saline pan/mudflat, which would be a subaerially exposed plain, except that brine-filled saltworks now cover much of the former Southern Basin lake. Perennial brine sheets are artificially maintained in these pans by continually pumping of brines from the Northern Basin (Figure 11.10).

The basin floor beneath the waters of the Northern Basin is asymmetric, with the western slopes around 7° and the eastern slopes about 8°. The northern part of the Northern Basin is flatter and smoother than either its eastern and western slopes and is covered by deltaic clays of the Jordan River outfall (Figure 4.40a). Away from the northern slope the outflow zones of the various streams and

Figure 4.40. Dead Sea depression, Middle East. A) Dead Sea Valley. Image of the depression in the early 1990s, showing the Dead Sea separated into a deep Northern Basin separated by the Lisan Straits from the Southern Basin with its solar ponds. The Jordan River enters the Dead Sea at its northern end. Sea of Galilee is visible in the northern end of image (Image courtesy of NASA). B) Bathymetry of lake floor in metres below sea level, the basin shows E-W basin asymmetry with a somewhat steeper eastern margin.

B) Schematic cross section of lake geology showing the importance of subsidence, in relation to salt tectonics and strike-slip faults as controls on sediment distribution in the depression (in part after Zak, 1980).

wadis are defined by local clastic aprons or fan deltas, most of which are now “hung” in response to the lowered lake levels (Figure 4.49a).

Geological Setting

The Dead Sea depression is a large strike–slip basin located within the Dead Sea transform; a plate boundary separating the Arabian plate from the African plate and connecting the divergent plate boundary of the Red Sea to the convergent plate boundary of the Taurus Mountains in southern Turkey. Since it formed, 105 km of left-lateral horizontal movement has occurred along the transform. In places where crust is stretched or attenuated, plate stress is accommodated in several rapidly subsiding en-echelon rhomb-shaped grabens separated across west-stepping fault segments. The Dead Sea basin and the Gulf of Elat to its south are the largest of these graben depressions and are separated by the Yotvata Playa basin (Figure 3.31a). The Dead Sea basin fill is 110 km long, 16 km wide and 6–12 km deep and located in the offset between two longitudinal faults, the Arava Fault and the Western Boundary (Jericho) Fault (Figure 4.41a; Garfunkel et al., 1981; Garfunkel and Ben-Avraham, 1996).

Movement began 15 Ma in the Miocene with the opening of the Red Sea and is continuing today at a rate of 5 to 10 mm/yr. The Dead Sea basin floor is more strongly coupled to the western margin (Levantine plate) and is being left behind by the northward moving Arabian plate. Since the Miocene, depocentres in the Dead Sea region have moved 50 km northward along

the shear zone (Zak and Freund, 1981) to create the offlapping style of sedimentation in the Dead Sea–Arava Valley, with a basin geometry reminiscent of the Ridge Basin in California. Continued extensional movement has triggered halokinesis in the underlying Miocene evaporites so that diapirs subcrop along the Western Boundary Fault and its offshoots (Figure 4.41b; Neev and Hall, 1979). Salt in these structures is equivalent to the salt in the outcropping Mount Sedom diapir.

The Holocene to Miocene fill is 8 to 10 km thick beneath the Dead Sea, with at least 90 metres of Holocene fill beneath the Southern Basin. There have been three stages of deposition since the Miocene inception of the Dead Sea valley (Figure 4.41b; Garfunkel and Ben-Avraham, 1996). The bottom 2 to 3 km of fill is made up of continental conglomerates of the Hazeva (Lido) Formation. This represents the first stage of basin fill, during which deposition kept pace with subsidence of the rift. It ended in the late Miocene (8–10 Ma) when differential uplift along the transform edges and rapid subsidence of the basin led to a deep topographic trough. During this second stage (4–6 Ma) the trough was invaded by Mediterranean seawater through the Yizre’el Valley to create a highly restricted arm that was periodically cut off from the ocean and deposited the 2–3 km thick halite-rich evaporites of the Sedom Formation (also known as the Usdum Fm.). This 2 to 3 km-thick section is now halokinetic in the Dead Sea region. In its third stage, the basin was cut off from the Mediterranean seepage to become a closed continental basin. A series of large lakes formed during this time and 3–4 km of fluvial and lacustrine sediments of the Plio-Pleistocene Amora and Samra-Lisan formations were

Table 4.4. Major inputs to the Dead Sea and their solute compositions. Flow is in 10^6 m³/yr and concentrations in mg/l (compiled from data in Azmar and Ergenzinger, 2002; Abu-Jabar, 1998; Karcz, 1987).

deposited (Figure 4.41). The Pleistocene Amora Fm. in the region of the Dead Sea is a fluvio-lacustrine chalky marl with entrained gypsum, anhydrite, sands, conglomerates and thin halite layers. The overlying Lisan-Samra Fm. was deposited in the last large lake that filled the majority of the Dead Sea-Jordan Rift Valley during the later Pleistocene. It consists mostly of finely layered marls, laminites and chalks with gypsum in its more evaporitic portions.

Unlike the marine isotopic signatures of the salts in the Sedom Formation, isotopes in the evaporites of the various Pleistocene sequences indicate their precipitation from lacustral CaCl-rich connate brines. Groundwater inflow chemistries were created by rock-water interactions with an original connate seawater brines first trapped in sediments of the rift walls in "Sedom time" (Raab et al., 2000). After the final Pliocene disconnection from the sea and a lowering of the lake levels, these residual brines gradually seeped and leached back in to the Sedom basin. There was never a hydrographic connection of the Dead Sea to the Gulf of Aqaba in the south and all of the Pleistocene salts in the depression come from the evaporation of continental groundwaters, not from ongoing marine-fed seepage. Neogene parts of the intervening rift valley were always above sea level and even today the Arava Valley is characterised by ridges up to 200 metres above sea level in the Gulf of Aqaba.

The rapid accumulation of Amora and Samra sediments within a subsiding and extending valley, atop thick bedded evaporites of the Sedom Fm. initiated several salt diapirs along the valley floor, the best known being Mt. Sedom (Figure 4.41b; Larsen et al., 2002). The Mount Sedom diapir has pierced the surface atop a 200 m-high salt wall. Throughout the Holocene, salt has

been rising in Mt. Sedom at a rate of 6-7 mm a⁻¹ (Frumkin, 1996a).

Water level changes

The highest recorded level of the Dead Sea (-392 m asl) was reached in the 1920s (Figure 4.42a), since then the lake level has been decreasing and today is around -416 m asl and still falling. At the beginning of 1978 the falling waters reached a level of -399.6 m asl, which dried out the Lisan Straits and divided the water covered area of the Dead Sea into separate Northern and Southern basins (Figure 4.43a). Since 1977, the surface level of the Dead Sea has been falling at a rate ≈60 cm/year. The lake water surface reached -410 m (msl) in 1997 and from 1998 to 2002 the lowering rate reached 100 cm/year. Since the 1930s, the trend of water levels in the Dead Sea lake has been falling or "droughty" (Figure 4.42a). In a "droughty" year the total level rise in winter is smaller than the yearly drop, and in a "rainy" year-larger. For example, in the droughty period 1981-1988, the net level drop in water level in every single year is in the range 70-90 cm yr⁻¹ (Figure 4.42b; Anati, 1998; Yechieli et al., 1998; Gertman and Hecht, 2002). An exactly balanced year, which is the common situation in most of the world's perennial lakes in temperate climates, has never been recorded in the Dead Sea. Dead Sea water level changes underline the general observation that differences in the hydrological balance in a lacustrine setting are the dominant control on the various styles of lake fill and that evaporites only accumulate in underbalanced lacustrine settings (Figure 5.8).

It seems the rate of fall has been accelerating since the 1960s. This more rapid rate of fall is largely a response to the diversion

of river water from the Jordan and Yarmuch Rivers into irrigation projects in Syria, Israel and Jordan. As a result, the inflow of fresh water into the Dead Sea has diminished significantly in the past half century. In the 1950s, the yearly Jordan River input to the Dead Sea was estimated to have been 1,370 million m³, while present annual inflow is between 250 and 300 million m³. Moreover, Israel and Jordan are pumping Dead Sea waters from the northern basin into saltworks in the southern Basin, further contributing to the falling water levels. Streams other than the Jordan River supply surface runoff to the Dead Sea and include; Wadi Mujib, which discharges around 83 x 10⁶ m³, Wadi Karak, which discharges around 18 x 10⁶ m³; Wadi Hasra, which discharges about 34 x 10⁶ m³; and the Zerqa Ma'in Springs which discharge about 23 x 10⁶ m³. Small intervalley catchments provide an additional 30 x 10⁶ m³ (Table 4.4, Figure 4.40b; Abu-Jaber, 1998; Salameh and Bannayan, 1993).

Until the 1960s, the Jordan River, flowing south from the Sea of Galilee, provided 80% of the water received by the Dead Sea (Eugster and Hardie, 1978). Storm runoff provided around 8% and spring inflow the remainder. Historically, the bulk of the water and detrital sediment entering the Dead Sea Basin was carried by the Jordan River into the northern end of the lake. However, even before the current drastic lowering of the Jordan's flow to a quarter of previous levels, the bulk of the solutes forming chemical precipitates in the Dead Sea came from saline springs fed by dissolving Miocene salt and not from the Jordan inflow. Annual spring inflow is thought to be around 80 million cubic metres and up to 300 times more saline than the waters of the Jordan River. As in many other evaporite basins, hydrography and solute cycling in the Dead Sea are largely decoupled.

Figure 4.42. Changes in the Dead Sea water level at various time scales. A) Historical changes in the water level of the Dead Sea brine level since 1800, showing obvious acceleration in rate of fall since the 1960s and the “droughty” or falling trend since 1918. B) Detailed curve for the last three decades showing how rapid rises are tied to “wet” years and the consequent meromictic lake hydrology. C) Variations in the areas of the Northern and Southern Basins and the growing area of anthropogenic salt pans as it relates to changing brine levels. C) Changes in the Dead Sea level for the past 8,000 years (A and C replotted from Enzel et al., 2003; B replotted from Gertman and Hecht, 2002).

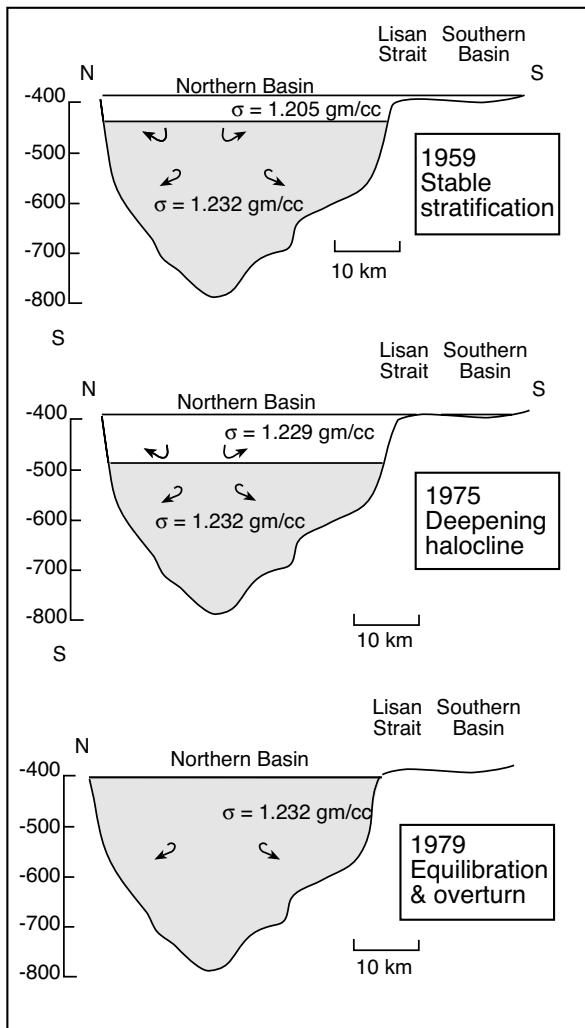

Figure 4.43. Evolution of Dead Sea stratification in the period 1959-1979 showing the loss of brine stratification via lessening of freshened inflow from Jordan River and entry of brine waste from south. This resulted in increased salinity of surface waters, a deepening of the halocline and final equalisation of densities of the two masses and their overturn in 1979.

Given the marked fall in brine level over the last 50 years, Yechieli et al. (1998) addressed the interesting quandary, “Will the Dead Sea ever dry up?” They argue it will not dry up completely as the rate of evaporation will continue to decrease as the salinity of the brine increases. The evaporation rate of fresh water under Dead Sea conditions is about 3.5 m/yr, while the evaporation rate of Dead Sea surface waters is about three times lower (Figure 2.3b). In 1944, when the surface salinity of the Dead Sea was about 280 g/l, the rate of evaporation was 1.7 m/yr. By 1960, it decreased to 1.5–1.6 m/yr at a salinity of

300 g/l, and in 1979–1980, the evaporation rate was 1.3–1.4 m/yr at a salinity of 330 g/l. An extremely low evaporation rate (1.05 m/yr) characterised the period 1983–1987. The present rate of evaporation is believed to be ~1.25 m/yr (range 1.1–1.4 m/yr).

Assuming water inflow remains at present levels, a new equilibrium between evaporation and water input will be reached in about 400 years (Yechieli et al. 1998). The brine surface will then be at –500m, more than 80 m below the present value. The surface area of the lake will be 526 km², and the water volume will have decreased by about one third from its present level. The remaining brine, in equilibrium with the air of 50% humidity, will contain about 380 g/l dissolved salts, and have a density of 1.27 kg/l (Krumgalz et al. 2000). Over longer time frames encompassing the Holocene, the current levels of the lake are not unusual, although the rate at which levels are changing may well be (Figure 4.42c). Similar lake level lows ~–500m asl characterised the Dead Sea some 2.5 and 4 ka (Enzel et al., 2003).

Density stratification: Holomixis versus meromixis

Until 1979 lake waters were meromictic or “permanently stratified” and had been so for 300 years (Stiller and Chung, 1984). In the 1950s there was a well-developed permanent pycnocline and thermocline at a depth of 50 m (Figure 4.43; Neev and Emery, 1967). The average temperature of the upper 50 m of the water body was between 16 and 36°C and density around 1.205 gm/cc, while at brine depths greater than 50 m, the temperature was a constant 21.5°C and the water density was 1.232 gm/cc. But in the 1960s and 70s the lessening inflow from the Jordan meant the surface water mass became increasingly saline and the permanent pycnocline deepened. In 1975 the pycnocline was some 100 metres below the lake surface and the upper water mass had a density of 1.229 gm/cc. In February 1979 the densities of the upper and lower water masses equalised and the lake overturned, whereby the lower water mass mixed with the upper water mass and the lake had become holomictic (Steinhorn, 1983). It was marked by a strong and persistent H₂S smell as bottom waters came into contact with the atmosphere for the first time in centuries. Prior to the 1979 overturn, the lake had been continually stratified (meromictic) since its last holomictic period some 300 years earlier. Overturn has occurred naturally a number of times in the lake’s Holocene history and these episodes are marked by beds of massive coarsely-crystalline deepwater halite.

After 1979 the lake entered a new phase in which its hydrological regime seesawed between holomictic and meromictic regimes, depending on the size of the storm runoff into the lake (Gertman and Hecht, 2002; Anati, 1998). The Dead Sea level rises, typically in winter, in an relatively unpredictable fashion driven by short events of varying intensity (runoff and sudden floods), and drops at a fairly constant rate for the rest of the year. The first holomictic period, 1979–1980, lasted for 2 months only. It was succeeded by a 4-year meromictic period (1980–1983). The second holomictic period lasted for 9 years (1983–1991; Figure 4.42b). Then, during an unusually wet winter in 1991–1992, some $1.5 \times 10^9 \text{ m}^3$ of meteoric water entered the lake. This caused the lake level to rise by 2 metres and formed a freshened stable upper water mass, which persisted until November, 1995 when stratification collapsed and the lake overturned once more (Anati et al., 1995). The upper layer with a relatively low salinity was restored and a new meromictic period began.

During each meromictic period, the hydrological regime of the Dead Sea is characterized by following long-term trends (Gertman and Hecht, 2002): the mixolimnion thickens as the depth of the summer thermocline increases from 12–15 to 25–30 m; the quasi-salinity^{4,3} of the upper layer, initially around 164 kg/m^3 , increases rapidly at a rate of about $16\text{--}18 \text{ kg/m}^3/\text{year}$; the quasi-salinity of the deep water, initially of about 235 kg/m^3 , decreases slowly at a rate of about $0.08\text{--}0.10 \text{ kg/m}^3/\text{year}$; and the winter minimal temperature of the upper layer, initially of about 16°C , increases rapidly at a rate of about $2^\circ\text{C}/\text{year}$. In November 1995, the latest meromictic period of the Dead Sea came to an end. In other words, even though the meromictic upper water mass persists for years, its physical properties not

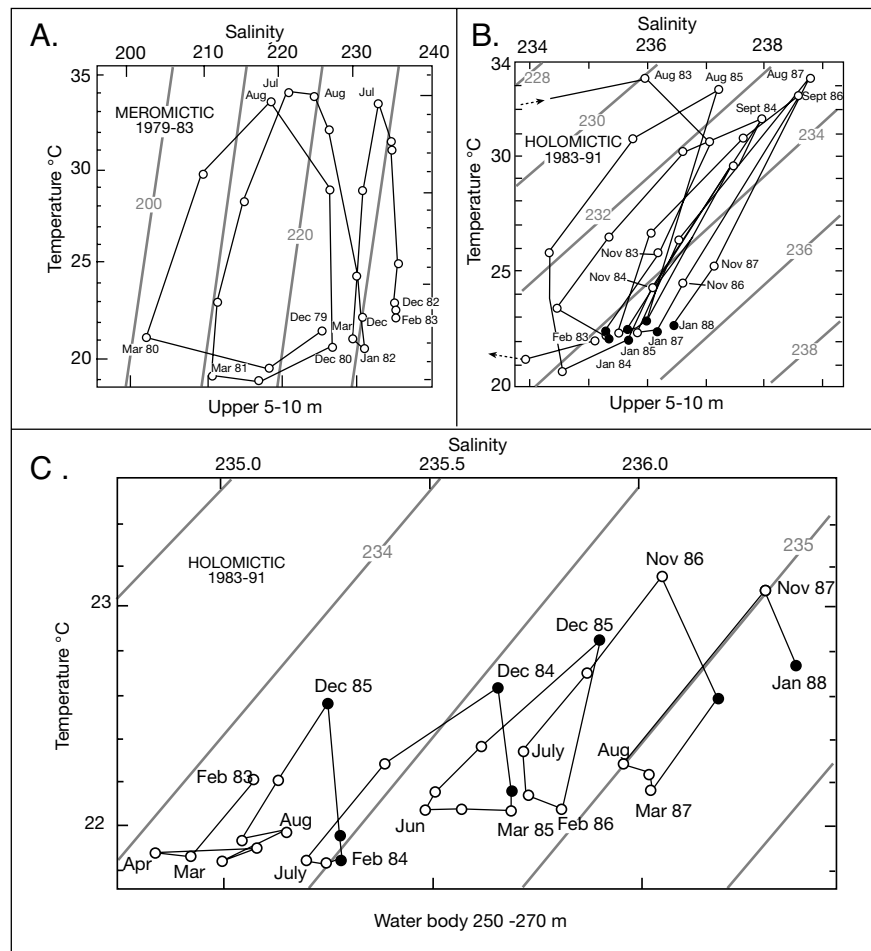

Figure 4.44. Dead Sea hydrological evolution in temperature-salinity space (T-S diagrams after Anati, 1998) A) Upper 5–10 m water trends in the meromictic period 1979–1983. B) Upper 5–10 m water trends in the holomictic period 1983–1991. C) Water trends in lower water mass at 250–270 m depth for much of the holomictic period 1983–1991.

only change annually, driven by seasonal changes in temperature and evaporation intensity, it also evolves from year to year as it becomes increasingly warmer, more saline and denser until its physical properties equal those of the underlying deep water

^{4,3}Solute proportions of the waters of the Dead Sea are relatively rich in calcium, magnesium, potassium and bromine, and relatively poor in sodium, sulphate and carbonate, thus are significantly different from those of modern seawater (Table 4.4). Strictly speaking, in view of the peculiar chemical composition of its waters, the accepted definition of “salinity” based on seawater proportions does not apply to the waters of the Dead Sea and it has been replaced by an “equivalent salinity” based on pycnometry (Anati, 1999; Gertman and Hecht, 2002) and referred to as “quasi-salinity.” Thus, quasi-salinity is defined as the Dead Sea water density anomaly from 1000 kg/m^3 at an arbitrary reference temperature of 25°C . For the sake of comparison, a quasi-salinity of 235 kg/m^3 is the equivalent of 280‰ .

Figure 4.45. Long term changes in quasi-salinity and temperature in the deep water body (below 100m) of the Dead Sea in a meromictic to holomictic period (after Gertman and Hecht, 2002 and replotted data from <http://isramar.ocean.org.il/DeadSea> (last accessed Sept 29, 2004).

mass and the lake waters overturn. This evolution can be clearly seen in maps of the time-based evolution of temperature-salinity space (Figure 4.44a; Anati, 1998).

During holomictic periods, as exemplified by the period 1996–2000, the hydrological regime of the Dead Sea *in toto* is also characterized by long-term trends (Figures 4.44b, c, 4.45; Gertman and Hecht, 2002; Anati, 1998): the quasi-salinity of the entire Dead Sea increased at a rate of about 0.5 kg/m³/year, with practically no decrease during the winters; the temperature of the deep water mass increased with a rate of about 0.25°C/year; and the period of vertical convection of the entire water column, initially about 3 months, increased at a rate of about 1 week/year. Moreover, the temperature and salinity of the bottom layer in the deepest part of the Dead Sea rose by about 0.5–0.6°C and 0.15–0.25 kg/m³ during each holomictic summer.

During holomictic years, a stratification builds during the summer months with a thermocline generally located between 15 and 30 m depth (Figure 4.46a). The density contrast at the base of the upper water mass is large enough to balance an ephemeral destabilizing halocline formed daily in the uppermost few metres as a result of intense evaporation. At night the same uppermost waters cool and mix with underlying waters above the major thermocline. This stable thermocline persists throughout the summer and into autumn when the overlying air mass cools, so driving a cooling of the whole upper water mass until temperature and densities equalise and overturn occurs, usually in November. A temporary dilution of the upper water layers may occur due to winter rain floods, but in a holomictic year it is destroyed by summer evaporation, so

preventing the year round stratification that characterises the lake in its meromictic stage.

Detailed work on the lower Dead Sea water mass by Gertman and Hecht (2002) shows an additional interesting stratification in the lowermost parts of the lower water mass (Figure 4.46b, c). Temperature profiles of the bottom layer exhibit a step-like feature indicating advection of saltier, warmer and denser water into the lowermost parts of the Dead Sea. The differences in the size of the steps indicate the changes in the intensity of the advection in this part of the column. There are three possible sources for such waters; 1) Endbrines pumped back into the Northern Basin from the Dead Sea Works at the southern end of the Dead Sea, 2) Subsurface hot springs similar to those documented by Niemi et al. (1997), 3) Slope convection of warm saline dense brines from the shallow edges of the Dead Sea. At this time there has been insufficient monitoring to determine which of the possibilities is the most likely, or if all can contribute to the bottom anomaly.

Deep water Halite

The transformation of the brine column in the last two decades has allowed substantial halite to accumulate on the deep water floor of the basin for the first time in 300 years. Halite first crystallised in the near surface lake brines in 1979, while massive halite began to crystallise from the entire brine column toward the end of 1982, when ropes suspended in the water would quickly accumulate cm-thick rinds of centripetal halite (Steinhorn and Gat, 1983; Stiller and Sigg, 1990; Stiller et al., 1998). The mass of halite that precipitated between 1976 and 1992 is estimated to be about 2,550 × 10⁶ tonnes (Gavrieli

1997). The result of this holomictic saturation of the Dead Sea is a layer of coarse crystalline halite accumulating rapidly on the deep lake bottom that today (20 years after it began) is already several tens of centimetres thick. For the period 1983 to 1989 the estimated annual accumulation rate for halite on the Dead Sea floor was 3 - 6 cm/year (Levy, 1991, 1992). This new bed of halite defines the end of several hundred years of longterm brine stratification (meromixis) when halite did not precipitate in the hydrologically isolated lower brine mass. Instead a pelagic/detrital carbonate laminite had accumulated (see next section). Previous episodes of nonstratification in the deep brine column (holomixis) are indicated by similar but now buried beds of widespread metre-thick massive halite beneath the lake floor (Levy, 1984).

Several crystal morphologies define the halites currently accumulating above and on the deep bottom of the Dead Sea (Gavrieli, 1997; Herut et al., 1998); a) Clear aggregates of sedimentary halite crystals forming interlocked aggregates and massive dm-thick bed on the lake floor that are made up of white to clear crystals up to 1 cm in diameter and typically interbedded with layers composed of fine grained (<1 mm diameter) halite crystals and brown mud, b) Individual clear idiomorphic cubes up to a cm long floating within brown mud layers and, c) Large interlocked clear centripetal halite crystals (0.5 - 2.0 cm long) growing on ropes suspended in the brine column. Much of the halite on the Dead Sea floor consists of intercalations of types a and b, with each constituting around 50% of the newly formed halite layer. Clay mud layers are

though to indicate wet years in the lake hydrology such as the period 1992-1993 (Gavrieli, 1997).

Finer-grained halite and gypsum layers are common in shallow waters (< 50 m) about the lake edge, particularly in the western and southern parts of the Northern Basin where they cover much of the lake floor and may well indicate the effects of brine outfall from saltworks in the Southern Basin. Coarser clear cm-scale halite crystals and layers are today common in the deeper waters of the Dead Sea. This is not entirely consistent with many of our current models arguing that pelagic

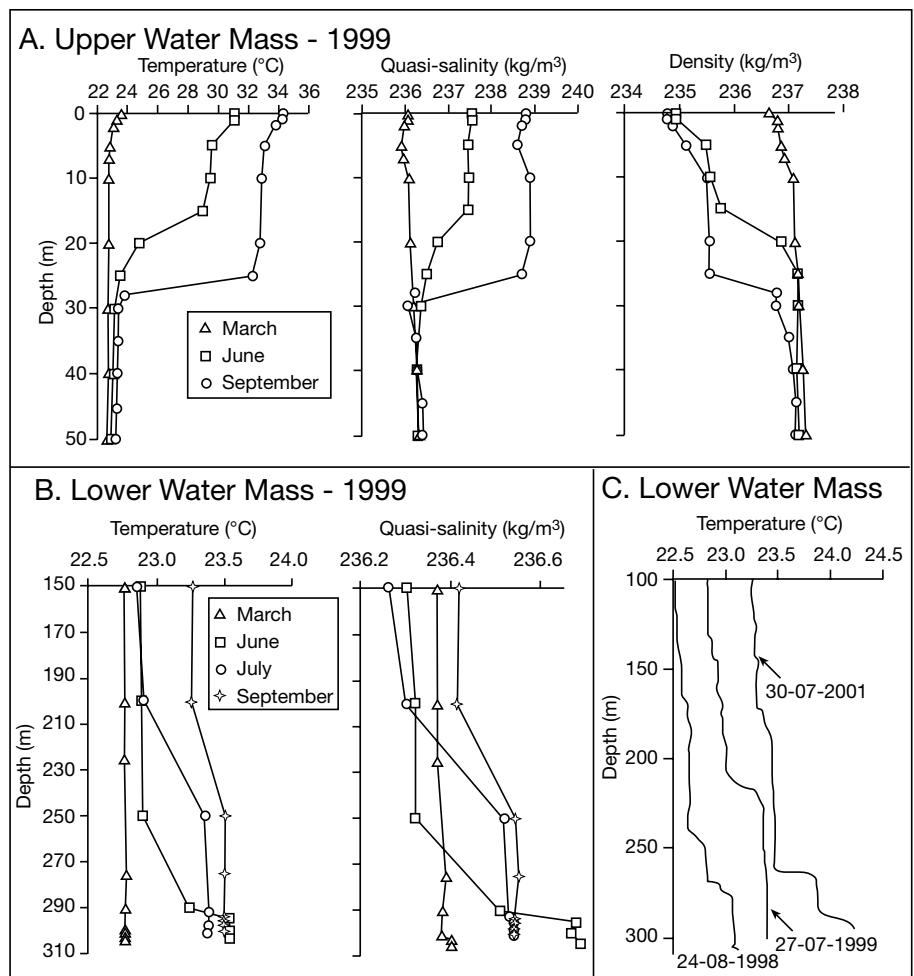

Figure 4.46. Stratification of the Dead Sea during holomictic years as illustrated by temperature, quasi-salinity and density profiles (after Gertman and Hecht, 2002). A) Stratification builds in the upper water mass at a depth of 20-30 m in the summer (June-September) and is destroyed by overturn in the autumn (March). Note the smaller daily increase in temperature and salinity/density in the uppermost 5 metres of the water mass due to intense daily evaporation. B) Temperature and salinity anomalies in the lower water column in September 1999. C) Temperature anomalies in the lowermost part of the lower water column. All profiles were measured at site EG320, its location is shown in Figure 4.40b.

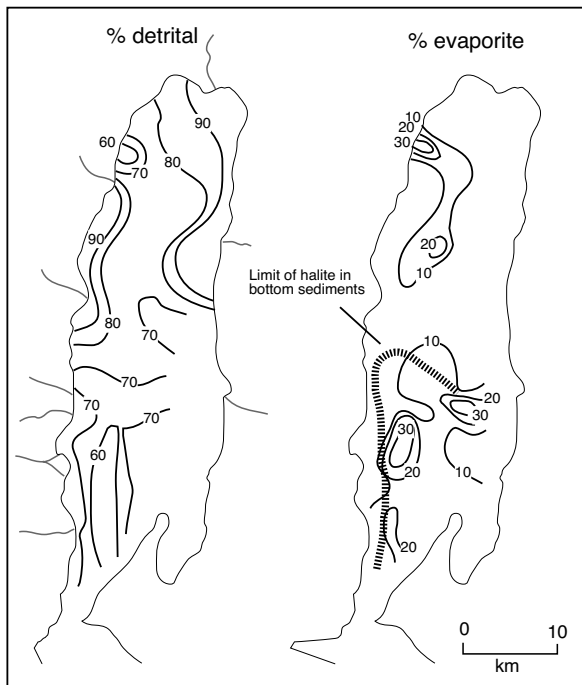

Figure 4.47. Bottom sediment distribution map of sediment mostly created prior to monomictic halite precipitation in 1979. The eastern or Jordanian parts of the Lake floor was not sampled (after Garber, Levy and Friedman, 1987).

deep water “salt and pepper” textured, finely-crystalline halite laminites indicate the deeper water parts of an evaporite basin fill (e.g. Schreiber and El Tabakh, 2000).

Some of the finer-grained salt layers in the Dead Sea are thought to precipitate via outsalting. Prior to 1979 this occurred where dense brine plumes, created in the areas of more intense evaporation about the lake edge sank into the deeper part of the basin. A similar hydrology is perhaps indicated by Figure 4.46c. Outsalting, via mixing between Dead Sea waters and the industrially concentrated end brines pumped into the Northern Basin from the solar operations of the Southern Basin is most obvious in the southern part of the Northern Basin (Figure 4.47; Epstein et al., 1975; Gavrieli, 1997). At 480 g/l these bottom hugging waste brines from potash manufacture are more concentrated than waters of the Northern Basin and have different relative proportions of the major ions. They are depleted in potassium and sodium and are enriched in magnesium and chloride relative to the Dead Sea waters, creating a situation ideal for saltout at the mixing zone between the two waters (Gavrieli, 1997; Yechieli et al., 1998). Saltout has probably occurred in the southern part of the Northern Basin for decades and is defined by bottom sediment areas where finer-grained halite occurs in 1-20 cm thick layers interbedded

with gypsiferous brown mud. Descending brine plumes probably allowed halite and coarse-grained gypsum to accumulate beneath zones of mixing, even prior to the 1979 turnover, as can be clearly seen in preholomictic maps of bottom sediments (Figure 4.47).

But mixing-induced saltout does not explain all of the halite currently accumulating across the floor of the Northern Basin. Another possible mechanism is the annual cooling of the uppermost brine layer in holomictic years (Gavrieli, 1997). Temperatures in summer in the upper water 30 metres in holomictic years are $\approx 34\text{--}36^\circ\text{C}$, while in winter they are $\approx 22\text{--}24^\circ\text{C}$ (Figure 4.46a). Although annual precipitation due to cooling of surface waters creates supersaturated chemistries, no unequivocal halite crystallisation driven by seasonal cooling has been observed in the Dead Sea. Yet, when saturated brines are collected and allowed to cool in the lab, halite precipitation as mm-scale crystals does occur spontaneously (Gavrieli, 1997).

Brine mixing and seasonal cooling explain the formation of finer-grained cumulate halites, but do not explain the formation of cm-scale crystal aggregates and layers. Yet such crystals can and do form in the current waters of the Dead Sea, as evidenced by coarse clusters in the current seafloor bed and large crystals hanging off anchor ropes. Gavrieli (1997) argues that these larger crystals in the bottom layers are authigenic and indicate slower ongoing authigenic growth in halite-saturated pore waters and brine columns situated at or just beneath the present day lake floor. Such saturated growth can only be maintained when the lake waters are holomictic. It seems that authigenic growth and recrystallisation is an ongoing process, as is seen in the pervasive recrystallisation and coarse crystalline overprint preserved in the 500 year old Dead Sea halite layer cored by Levy (1984).

Interestingly, cores taken twenty years earlier in the 1960s, below water depths of 40 m at the southern end of the Northern Basin, bottomed on a hard halite bed after passing through 10 to 80 cm of soft carbonate laminite (Neev and Emery, 1967). This halite was deposited some 300-500 or so years ago during a previous holomictic event. Likewise, four reflectors, so obvious in sediments of the deeper part of the Northern Basin, probably mark contacts between carbonate marls and beds of massive rock salt (Ben-Avraham et al., 1993). If the massive cm-scale inclusion-poor randomly-oriented crystals of the halite bed intercalated with finer-grained halite layers that are currently accumulating on the floor of the Dead are similar to textures in this buried deep water halite, then the notion that deepwater halite is solely a silt-sized “rain from heaven”

laminite is problematic. But, then again, the uniqueness, the small scale, and the continental transform setting of the Dead Sea means its utility as an analog for ancient marine-fed basinwide evaporites is also somewhat problematic.

Deep water laminites

Prior to overturn in 1979, away from the Jordan river delta, away from wadi aprons and away from the influence of end brine mixing, the deep bottom sediments were mostly carbonate laminites accumulating in water depths ranging from more than a few metres down to the deepest parts of the basin. These laminites are today being covered by halite, but prior to the onset of holomixis in 1979 carbonate laminites were the main sediment accumulating on the deep lake floor. Lamina in the mm-scale light-dark couplets are dominated by two time-separate pelagic components, namely terrigenous detritals and chemical precipitates (Garber, 1980; Garber et al., 1987). Light coloured lamina are dominated by chemical precipitates, mostly made up of stellate aragonite clusters precipitated in the upper water mass (Figure 4.48). Dark-coloured detrital layers in laminites contain limestone (calcite) grains, quartz, and silicate clays, along with minor feldspar and dolomite, all allochthonous components carried into the basin as bottom load, suspended load and air-borne detritus. The proportion of terrigenous material in the laminites increases toward the lake shoreline, especially toward river and stream mouths (Figure 4.47). Illite averages about 40% of the carbonate-free clay fraction of the laminites, smectite about 32%, and kaolinite about 28%. Locally, there are lesser and varying proportions of pelagic gypsum and coarser “in situ” gypsum roses within the carbonate/detrital laminites (Figure 4.49b).

Whitening events precipitating the aragonite occurred in the surface waters of the Dead Sea every few years prior to the onset of holomixis. For example, Neev and Emery (1967) sampled two summer “whitenings” of surface waters that occurred in 1959 and determined a gypsum to aragonite weight ratio of 3.14. Yet the aragonite in light lamina in the laminites on the bottom, hundreds of metres below, were almost 100% CaCO_3 . They had identified a chemical discrepancy that needed an explanation and attributed the alternation of aragonite in the lighter lamina and calcite in the darker lamina to the activities of sulphate-reducing bacteria acting on pelagic gypsum settling through the anoxic density stratified water column and converting it to bacterial calcite. Elsewhere, sulphate-reducing bacteria are known to destroy organic matter and gypsum, converting them to sulphides, energy, and H_2S with calcite as a byproduct (Figure 9.41a).

Subsequent isotopic work on the calcite lamina by Garber (1980) showed the calcite was detrital, not bacteriogenic. He also found that the laminites were not annual or “true” varves, only 15 to 20 lamina couplets had been deposited on the Dead Sea floor in the first 75 years of the last century. More recent work on CO_2 flux in the Dead Sea water during the meromictic period from February 1993 to December 1994 showed that summer whitenings are probably not the major source of aragonite in the laminites (Barkan et al., 2001). Rather aragonite precipitation occurs via mixing (salting out) in the upper water mass after a massive bicarbonate input from winter floods. This notion of precipitation resulting from winter flooding and brine mixing is contrary to the accepted notion of summer precipitation of aragonite in the uppermost surface waters of the historic Lake Lisan, the predecessor of the Dead Sea (see next section). But it better explains the lack of annual varving noted by Garber and means that either the origin of the aragonite laminites in the Lisan Fm should be re-evaluated, or the present Dead Sea should not be considered a direct hydrologic analog for the somewhat fresher and deeper waters of Lake Lisan.

Figure 4.48. Dead Sea deep water laminites in bottom core collected in Northern Basin in water depths of more than 200 m. It was collected in late 1970s when water mass was still stratified. Light coloured laminae are composed of stellate aragonite prisms precipitated as “whitenings”, while dark coloured laminae are dominated by detrital calcite. Scale bar on core is 5 cm (Images courtesy of Ray Garber).

Figure 4.49. Dead Sea. A) Ein Gedi, village located on a “hanging” fan delta of Late Pleistocene age and is evidence of higher lake levels at that time. B) Intrasediment gypsum rose growing in bottom sediment in brine depths of more than 200 metres. Brines may be supplied from brine plumes from dissolving salt diapir crests. C) Exposed unconsolidated laminite muds on the eastern margin of the Dead Sea. D) Trench in muds shown in C); Note the soft sediment deformation in some layers. (All photos courtesy of Ray Garber).

The dark coloured detrital-dominated mm-scale layers of the Dead Sea laminites lack a pervasive microfossil/diatom component, unlike laminites forming in less saline perennial lakes such as Lake Van. Diatom frustules do accumulate on the lake floor where diatoms flourish in areas of longterm freshened water. Their remains are common only in the detrital-rich prodelta laminites of the northern region of the Dead Sea. There, the Jordan River delta is building out into the lake and carries the remains of diatoms, along with abundant clays and silts. Surface waters over the rest of the Dead Sea are too saline to allow diatoms to live.

Prior to the onset of holomixis, intrasediment gypsum made up of individual crystal disks, constituted around 6% of the sediment volume in deep basinal laminites. In fact, contrary to the earlier findings of Neev and Emery (1967), Garber (1980) found gypsum in all cores recovered in the mid 1970s

from laminites in lake bottom settings ranging from shallow sea-marginal, through slope to deep basinal settings. Gypsum rarely formed in discrete laminae, small lenticular crystals were mostly disseminated through the terrigenous (dark) layers but larger crystals cut through both light and dark lamina. Garber (op cit.) concluded that gypsum in the deepwater laminites was probably present even during the studies of Neev and Emery. He argued that finely crystalline sand-sized gypsum was probably the settled-out remnants of gypsum precipitated in the surface waters, either as documented in the whittings by Neev and Emery (1967) or by brine mixing near the contact of the upper and lower water masses. Further gypsum crystal growth into desert-rose like displacive aggregates in the sediment (Figure 4.49b) was interpreted to indicate upward brine diffusion through the bottom sediments. Such upwelling brines were perhaps derived by the dissolution of nearby subcropping salt structures.

The absolute paucity of bedded salts during meromixis was the most surprising thing about the deepwater sediments accumulating in the Dead Sea in the three hundred years prior to 1979. Why were they absent on the bottom when the upper water mass was at gypsum saturation a number of times each summer and the lower water mass was at or near halite supersaturation year round? The answer lay in the permanence of the upper water mass, it prevented chemical change in the lower mass and hence, although the lower waters were supersaturated there was no concentration mechanism to allow it to accumulate salts. Only pelagics made it to the bottom until the brine column mixed and the Dead Sea became a holomictic system in direct contact with the atmosphere. Then large volumes of evaporitic halite could accumulate on the deep basin floor in areas covered by waters hundreds of metres deep. The Dead Sea clearly shows that halite and other salts can accumulate at the base of a brine column several hundred metres deep. But, they do so mostly as coarsely crystalline aggregates, not fine-grained laminites, and can only do so when the whole brine column is a well mixed (holomictic) water mass. When a brine column is

permanently stratified, no “in situ” bottom growth occurs. The dominant depositional style is a “rain-from-heaven” made up of less saline precipitates and siliciclastic fines, with chemical precipitates forming either at the mixing zone between the two water masses, or at the air-brine interface.

Basin margin sediments

Layers of siliciclastic and calcitic detritus in the deep water bottom sediments are generally tied to floods and wind borne dust sourced in the highlands about the basin margins. Fan delta lobes about the basin margin indicate positions where streams and wadis drain into a water-filled depression. In the Dead Sea they show two main styles; 1) Currently active deltas that reach down to the present lake shoreline (Figure 4.50) and, 2) Late Pleistocene fan deltas that are typically smaller in extent than their Holocene counterparts and form “hanging” deltas (Figure 4.49a; Sneh, 1979; Bookman et al., 2004). The more obvious hanging deltas were actively accumulating sediment

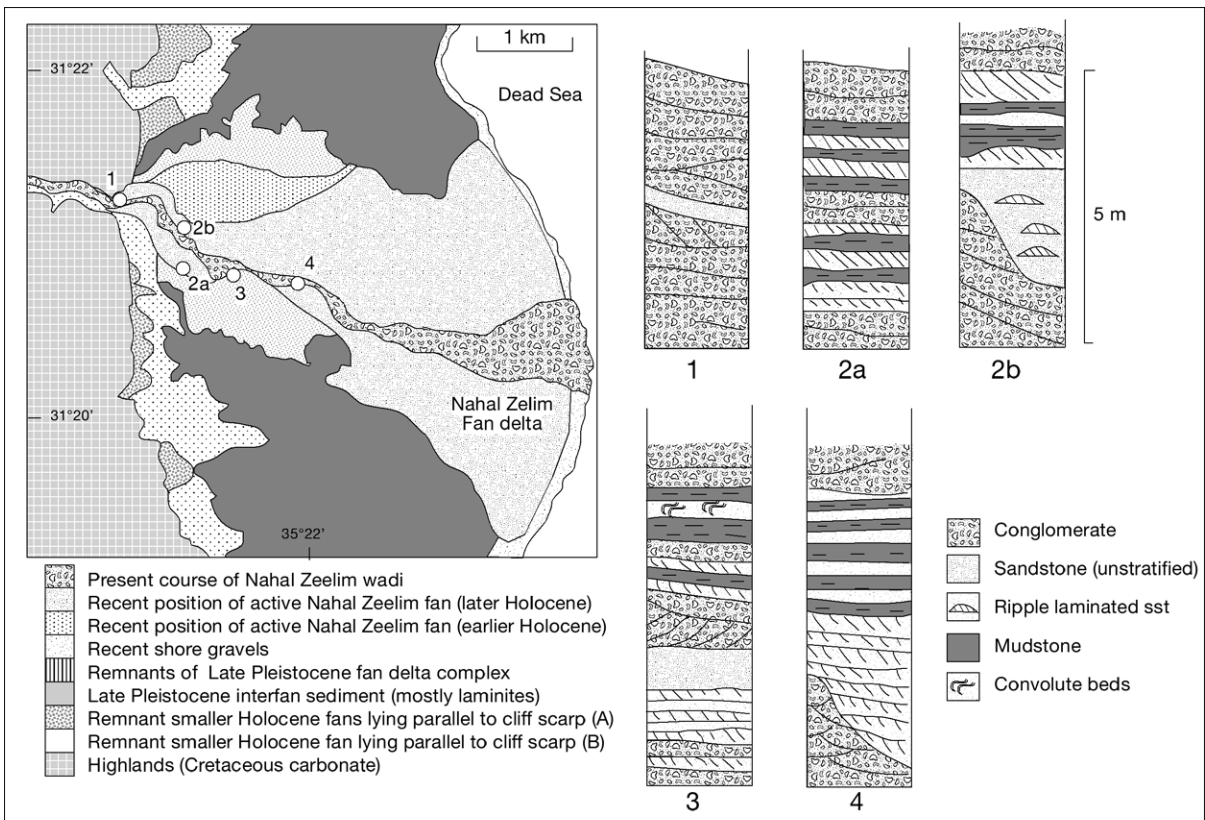

Figure 4.50. Nahal Zeelim fan delta, Dead Sea margin. Map shows multiple overprinted fan delta lobes from avulsion. Lobes of the Holocene delta lie below “hanging” late Pleistocene fan delta sediments deposited when the lake water level was 180 m above its present level. Vertical successions of five measured fan delta sections (1-4; localities shown on map) show a fining into the basin trend in average grain size (after Sneh, 1979).

in Lake Lisan time when lake waters were fresher and lake levels were up to 200 m higher. Size of the fan deltas vary, with the Nahal Zeelim delta being the largest of the active deltas located along the western margin of the depression (Sneh, 1979). In terms of the morphometry of fan deltas worldwide, Nahal Zeelim is relatively small ($\approx 6 \text{ km}^2$), its slope is steep (2.5°), and its catchment (235 km^2) is quite large for the size of the sediment lobe. Its morphometry reflects its arid setting, water supply is low and pulsed with resupply during times of short intense storm floods.

Each delta lobe is made up of several successive fan sequences, with facies changing from dominantly conglomerates at the head of the fan to sands and muds at the foot (Figure 4.50). In the proximal parts of a Dead Sea fan delta lobe, units of crudely stratified conglomerate alternate with coarse to medium sands that show cut and fill textures, along with abundant trough and planar cross beds. In the sand-dominated medial parts, structures range from unstratified or poorly layered sandy beds, through granule and mud-ball layers, into trough and planar crossbedded sands. Many of the finer sands in this zone preserve ripple

cross laminae. Further into the basin, the more distal parts of the fan lobes are composed of interlayered sand/mud facies intercalated with carbonate laminites. Alternations of coarse to medium sand with layers of very fine sand characterise distal fan sediments, as do thin 2-3 cm thick layers of mm-layered aragonitic laminite. Rapid deposition of fan sediments atop water-saturated laminites creates numerous examples of convolute bedding that formed as rapidly deposited sands loaded brine-soaked muds.

In strandzones away from the direct influence of active fan deltas, the grain size of sediments tend to indicate distance of the strandline from the base of the cliffed escarpment that defines the edge of the present Dead Sea basin. Where the present shoreline of the Dead Sea is a long distance from the fan-lined border escarpment, sediments tend to be muddy laminites, deposited during times of relatively higher water (meromictic) during the last few centuries and including blocks derived by reworking of Lisan marls (Figure 4.49c, d). In strandlines closer to the escarpment the shores are moderately steep with beaches and bars of sand and gravel

Figure 4.51. Geology of the Dead Sea basin showing the distribution of the various depositional settings in plan view and as a block diagram of the Northern Dead Sea basin. The River Jordan forms a fluviodeltaic wedge in the northern part of the basin. Active transension faulting and block rotation has exposed older lake deposits of the Lisan Formation at higher elevations as well as an apron of alluvial fan sediments with a number of "hung" fan deltas tied to older higher water levels in the lake. The saline pan in the southern basin is dominated by halite, artificial pans fed with deep brines have been constructed in this area to produce sylite and other potash products (see Chapter 11).

reworked from the base of the escarpment, especially where waves are eroding older bajada sediments. Where the shoreline is a cliff at the base of a border escarpment, the sediments tend to be reworked blocks and muddy slumps of Pleistocene Lisan Formation (Neev and Emery, 1967). Fluctuations in water levels throughout the Quaternary have created numerous terraces; more than 30 near-horizontal sandy shore terraces and gravel bars have been recognised behind the current lake strandline (Bookman et al., 2004).

The asymmetry of the tectonic setting of the Dead Sea depression is reflected in the granulometry of the fans. The eastern side of the Dead Sea is the more active transform escarpment, so slopes are somewhat steeper and fans are dominated by poorly-sorted debris flows, which often reach all the way to the modern strandline. On the western side of the depression the slopes are not as steep (Figure 4.40b). Based on comparisons with the rift lakes of Africa, there should be sand aprons created by widespread longshore reworking of fan delta sediments along this western side. But this is not happening in the Dead Sea, any clean sands created by wave action on the western side of the depression are swamped with sheets of muds derived by erosive reworking of Lisan Fm. laminites which blanket the depression. In terms of the Dead Sea's ability to act as a Holocene lacustrine analog for modelling reservoir sand distributions in ancient evaporite-sealed lacustrine counterparts, it suffers from the same problems as that other deep hole in the ground with evaporites - Death Valley, California. Both depressions are too deep, with sides simply too steep, to allow well-sorted sand bodies to accumulate in substantial volumes about the lake edge.

Much of the exposed margin of the Dead Sea between active fan delta lobes is made up of soft laminites and intercalated indurated beach-rock-like aragonitic crusts. These exposed recent laminites were deposited from meromictic lake waters and were deposited prior to 1979 (Figure 4.49c, d). Intercalated with the sea margin laminites are gravels and sands reworked from fan sediments and perhaps acting as aquifers or at least zones of high crossflows of waters into the lake margins. Exposed gravels and sands are sometimes cemented into beach rock sheets and have been coated with mm-scale laminated aragonite encrustations and stained with manganese (Garber et al., 1981; Garber and Friedman, 1983). Some of these aragonite precipitates are botryoidal, others are encrusting, yet others are oolitic/pisolitic, all are interpreted by Garber as largely inorganic precipitates. They are reminiscent of the microbial, stromatolitic and pisolitic crusts of the South Australian salinas and like them indicate strandzones and seeps in ancient counterparts.

In summary, surface sediment distribution in the Dead Sea region is a combination of Holocene accumulations and palimpsest Lisan Fm. derivatives (Figure 4.51). Today the lake is holomictic and a bed of coarsely-crystalline, inclusion-free halite is accumulating on the deep water floor of the lake. At the same time detrital accumulations fed from stream inputs, especially the Jordan River, dominate the northern parts of the lake. In the recent past (pre 1979) the lake was permanently stratified and deposition of carbonate laminite was the dominant depositional style on the deep lake floor.

Fluvial input to the fresher surface waters of the lake supplied both the detritals (calcite, aluminosilicate clays and siliciclastics) and drove the mixed water chemistry that created the aragonite rich portions of the laminite couplets. Dust storms also supply detritus to the deep lake bottom.

Lake Lisan, Jordan Valley

Beneath and surrounding the Holocene sediments of the Dead Sea are the sediments of the Quaternary Lisan (70 to 17 ka) and Damya (17 to 12 ka) formations (Bartov et al., 2002). The Lisan Formation forms a blanketing cover throughout the Jordan Valley (Figure 4.54a). *Lisan* is Arabic for tongue and describes the shape of the Lisan Peninsula where the type section was measured. Pleistocene Lake Lisan waters left behind dissected terraces of lacustrine sediment, consisting of laminated marls up to 40m thick, that extend from Lake Tiberias (Sea of Galilee) in the north to a boundary ridge some 35 km south of the Dead Sea (Figure 4.52). The highest outcrops of Lisan

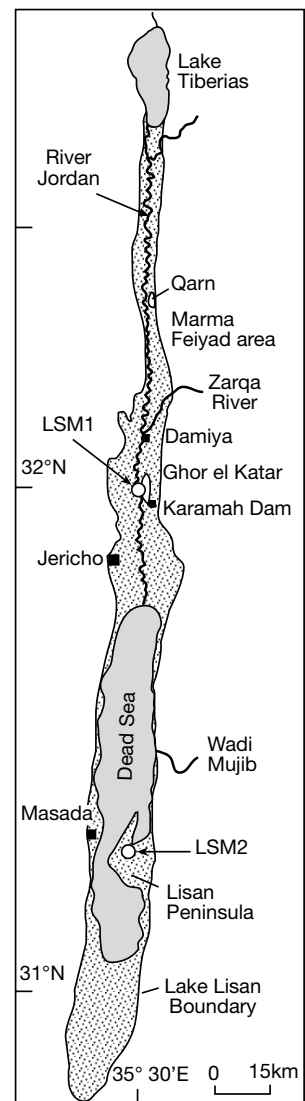

Figure 4.52. Extent of Pleistocene Lake Lisan in the Dead Sea transform. Positions of sites LSM1 and LSM2 are indicated (see figure 4.55 for detail).

Figure 4.53. Lake Lisan levels between 15,000 and 50,000 years ago.

laminites are found at -180 m asl, but there is morphological evidence for lake waters as high as -150m or even -130 m asl during Lisan time (Figure 4.53). During its highstand, Lake Lisan covered several subbasins in the Jordan Valley, it had a maximum area of some 2,000 km² and a drainage basin of 40,000 km². Pre-Holocene, but post-Lisan, sediments occur in fan delta regions near the current Dead Sea shore and in the vicinity of the city of Damya in Jordan, which is the type area for the Damya Formation.

Mineralogical variations in the Lisan Formation along the Jordan Valley show lake waters varied both in aerial extent and salinity. The lake was permanently stratified for much of its history. In its southern part, the sedimentary sequence consists mainly of laminated evaporites, and salinity is thought to have ranged between 100 and 300 g/l and lake water levels were probably lower. At the higher elevations that characterise Lisan outcrops in the north in the Kinarot basin, sediments of the Lisan Formation are very different, and the sequence is mainly diatomite. The change from south to north probably indicates inflow from the north and a freshening of surface waters during the highest stands of the lake. Salinities throughout Lisan time were hypersaline but probably less than those of the present Dead Sea (Abed and Yaghan, 2000).

Landmann et al. (2002) document two styles of couplet in the Lisan laminites; 1) detritus–aragonite (most common), and 2) detritus–aragonite–gypsum. Begin et al. (1974) documented the lithology and biota of the Lisan Formation along the Jordan Valley west of the Jordan River. They subdivided it into a lower Laminated Member and an upper gypsiferous White Cliff Member. Along the Jordan Valley they described three laminite facies; a gypsum facies in the Dead Sea region, and an aragonite facies north of the Dead Sea up to Marma Feiyad and a diatomite facies further north. Later work by Abed and Yaghan (2000) in the vicinity of Ghor el Katar and the nearby Karameh Dam reclassified the Lisan into three members; Lower Laminite, Middle Clay and Upper Laminite with the White Cliffs making up the upper part of the Upper Laminite. The contrast in gypsum content in laminites of the Lisan formation from the Ghor el Katar region (LSM1) compared with those of the Dead Sea region (LSM2) is clearly documented in the detailed mineralogy of two outcrop sections published by Landmann et al., (2002; Figures 4.52, 4.55).

The Lower Laminite is made up of thinly interlaminated calcareous silt and aragonite with subordinate sand layers. In the Ghor el Katar area (LSM1) the Lower Laminite is 15 m thick and the aragonite proportion is less than 30%. The Middle Clay is composed of massive black clays, and is around 9 metres thick. The clay matrix is mostly mixed layer illite/smectite with minor kaolinite. No gypsum or other evaporites occur in the Middle Clay and its organic content can be as high as 6%. The Upper Laminite is once again mostly interlayered aragonite and detrital silt (Figure 4.55). Thin sand and clay layers are not uncommon in this unit. Its uppermost 5-7 metres outcrops as a conspicuous white cliff that entrains layers with abundant gypsum. This upper portion in section LSM1 is equivalent to the White Cliff Member of Begin et al. (1974) as documented in section LSM2 (Figure 4.55). To the south of Ghor el Katar area, the White Cliff unit thickens until it is more than 25 m thick on the Lisan Peninsula (LSM2; Figure 4.55).

The Lower and Upper Laminated members are composed of very fine, varve-like white and dark laminae. White laminae are usually monomineralic and composed mainly of aragonite needles with diatom frustules. In the White Cliff unit the light-coloured laminae are composed almost entirely of gypsum or mixtures of aragonite and gypsum. Gypsum laminae are dominated by fine lenticular gypsum crystals (0.25 to 0.50 mm) with their long axes arranged parallel to the bedding. Dark laminae are predominantly detrital mud-sized calcite, the reworked remnants of microfossils, nannofossils and rock fragments. Quartz, dolomite, clay minerals (kaolinite, smectite,

Figure 4.54. Lisan Formation. A) View of Lisan Formation outcropping along the escarpment of the Dead Sea, B) Syndepositional slump in the Lisan Formation.

illite, and palygorskite), halite, and gypsum also occur in these detrital calcitic layers, much like in the laminites of the present Dead Sea floor.

In the vicinity of the modern Dead Sea the laminae in the Lisan Formation are sometimes crenulated and may contain sulphur concretions. Some layers display sediment slumps and overfolds, water escape structures, growth faults, and other evidence of soft sediment deformation (Figure 4.54b). The Lisan Formation was laid down as a water-saturated muddy succession; earthquakes kicked off multiple episodes of sediment movement both syndepositionally and in the shallow subsurface (Weidlich and Bernecker, 2004).

Some of the non-gypsiferous aragonitic couplets are interpreted as accumulating in lake-waters some 400-600 metres deep. But gypsum in some of the Lisan laminites in the White Cliff Member show evidence of much shallower deposition in the form of large vertically

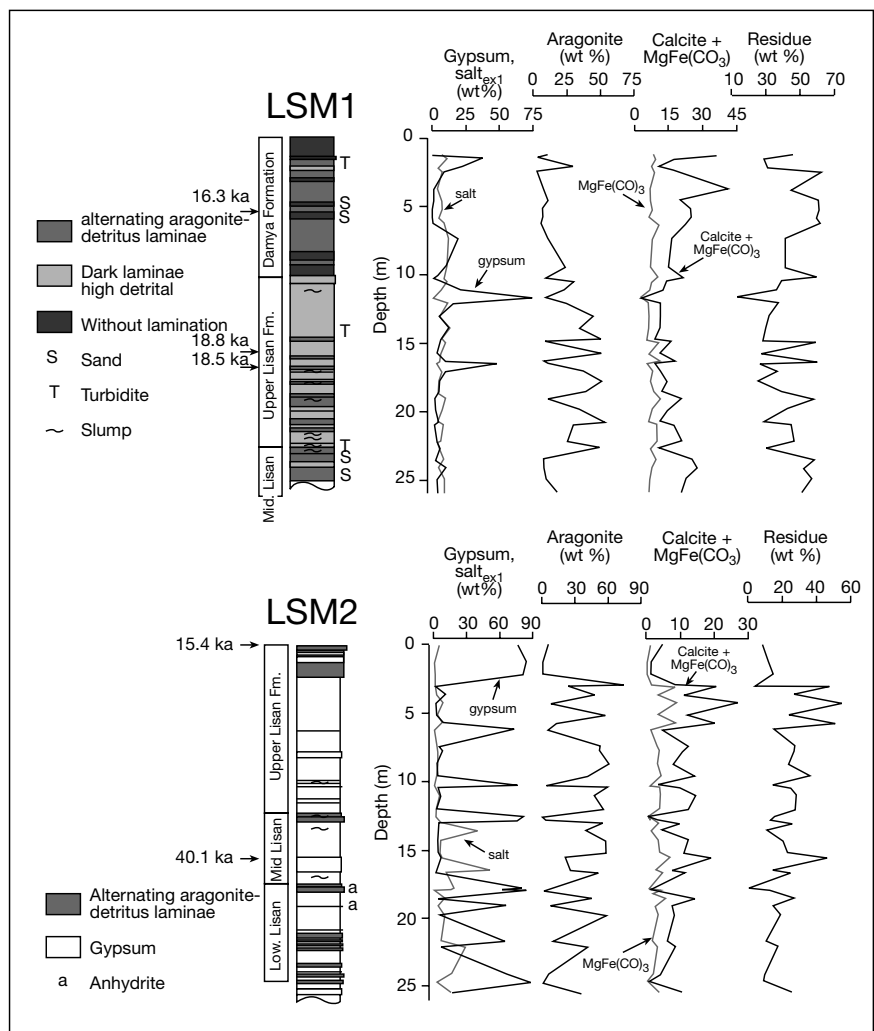

Figure 4.55. Stratigraphy and mineralogy of the Lisan and Damya formations in the Jordan Valley. Positions of the sections are shown in Figure 4.52 (after Landmann et al., 2002).

aligned gypsum crystals. These giant crystals fit better an earlier model of Lisan Formation deposition by Picard (1943) who described the coarsely crystalline gypsiferous parts of the Lisan Formation as being deposited in a combination of settings, a shallow lake, a large playa, and/or a giant sabkha. The presence or absence of gypsum perhaps indicates changing water levels in the Lisan Lake so that when bedded and growth-aligned gypsum is commonplace the Lisan water levels were lower..

Overlying the Lisan Formation is up to 14 m of clastics of the Damya Formation (equivalent to the "unnamed unit" of Begin et al., 1974). Damya sediments are mostly clays, silts and sands, some gravels and no evaporites (Abed and Yaghan, 2000). It was deposited in a freshwater to brackish lake stage with a water level of -160m at the onset of Lake Damya some 15-16 ka. According to Begin et al. (1985), the Lake Damya ended some 10-11 ka with a drop to -700 m asl, a fall in lake level of more than 800 metres in a few thousand years (Figure 4.53). If real, it means the driest period in Lake Lisan's history was immediately preceded by the wettest time in Damya climate. Clearly, waters levels in perennial saline lakes are subject to high frequency, high amplitude changes in water level with rates of change that can be 4 to 8 times greater than marine eustatic changes in an icehouse climatic mode (Chapter 5).

Lake Asal, Republic of Djibouti

Lake Asal, with a water surface some 155 m below sea level, is the lowest place in Africa (Figure 4.56). The lake is small (area 52 km²) and shallow, with a maximum depth of 30 metres and an average depth of 7.4 metres. The lake depression lies in the NW-SE oriented Asal - Ghoubbat al Kharab rift extending northeast into the Gulf of Aden. It is part of a tectonic system considered to be one of two examples where an oceanic ridge outcrops; the other being on the island of Iceland. This part of the rift extends southwest into the East African rift and is at the marine-fed end of what is our type example (Afar triangle) of a spreading centre (triple junction) in an arid part of world's rift systems. Locally, the ridge shows a spreading rate of 30-60 mm/year. Although small, Lake Asal is one of the few modern examples of a marine-fed rift basin that is actively accumulating bedded evaporites. As such, it is the only Quaternary analog for ancient marine-fed rifts including the numerous Mesozoic evaporitic lacustrine basins that underlie passive margins on either side of the Atlantic (Table 5.6).

The lake today is completely continental with no surface connection to the ocean. Yet the fact its -155m asl level has changed

little in the last few centuries argues it is fed a steady flow of seawater through the highly fractured 10 km wide volcanic ridge that separates oceanic water at Ghoubbat al Kharab from the hypersaline waters of Lake Asal. It constitutes an excellent example of a drawdown marine seepage basin fed through a volcanic ridge.

Many actively flowing springs, locally called manda, are dotted along the eastern strandzone of the lake. Their geochemical makeup is very close to seawater proportions (Sanjuan et al., 1990). Total marine inflow to the lake is estimated to be of the order of 60-80 m³ per second, with transit times for waters seeping from the ocean to the lake floor measured in less than tens of years, or at most two centuries (Demange et al., 1971; Fontes et al., 1980). Outflow is focused along shallow narrow fracture networks that cut the volcanic ridge (Mlynarski and Zlotnicki, 2001). There are also several hydrothermal springs and many fumaroles still active in the area and it is clear that the subsurface temperatures are still very high below the fracture meshworks carrying cooler seawater inflows to the lake depression.

Two deep wells were drilled in the Asal area in 1975, Asal-1 had a final depth of 1154 m and Asal-2, a final depth of 1554 m. These thermal test holes were drilled at the southwest edge of the geothermal area in a region where there is no direct inflow from the sea. Asal-1 produced 22 kg/sec of high salinity water with a measured temperature at 1040 m of 255°C prior to flow testing, and 260°C during a flow test in 1981. Water produced by Asal-1 had a very high solids concentration (128 g/l) and during the 1981 flow test, rapid incrustation in the casing had plugged the well in less than 3 months. The other well, Asal-2, was plugged inside the casing, possibly by drilling mud, and is no longer producing steam.

Lake brines reach salinities of 350 ‰ and, like their marine spring feeds have seawater like proportions, dominated by Cl, Na, K, SO₄ and Mg. Salts in the perennial standing body of lake brine are mostly gypsum, which is accumulating with mounded and bottom-nucleated aligned-layer textures identical to those that characterise the South Australian salinas. Gypsum precipitation dominates in this the southeastern part of the lake depression, located next to the seeps that bring seawater to the surface. Fractures also intersect the subaqueous lake floor and seawater can be seen to rise up along fractures cutting the lake bottom. Older layered and mounded gypsum beds crop out around the lake edge to as high as 55 metres above the present lake level (Stieltjes, 1973).

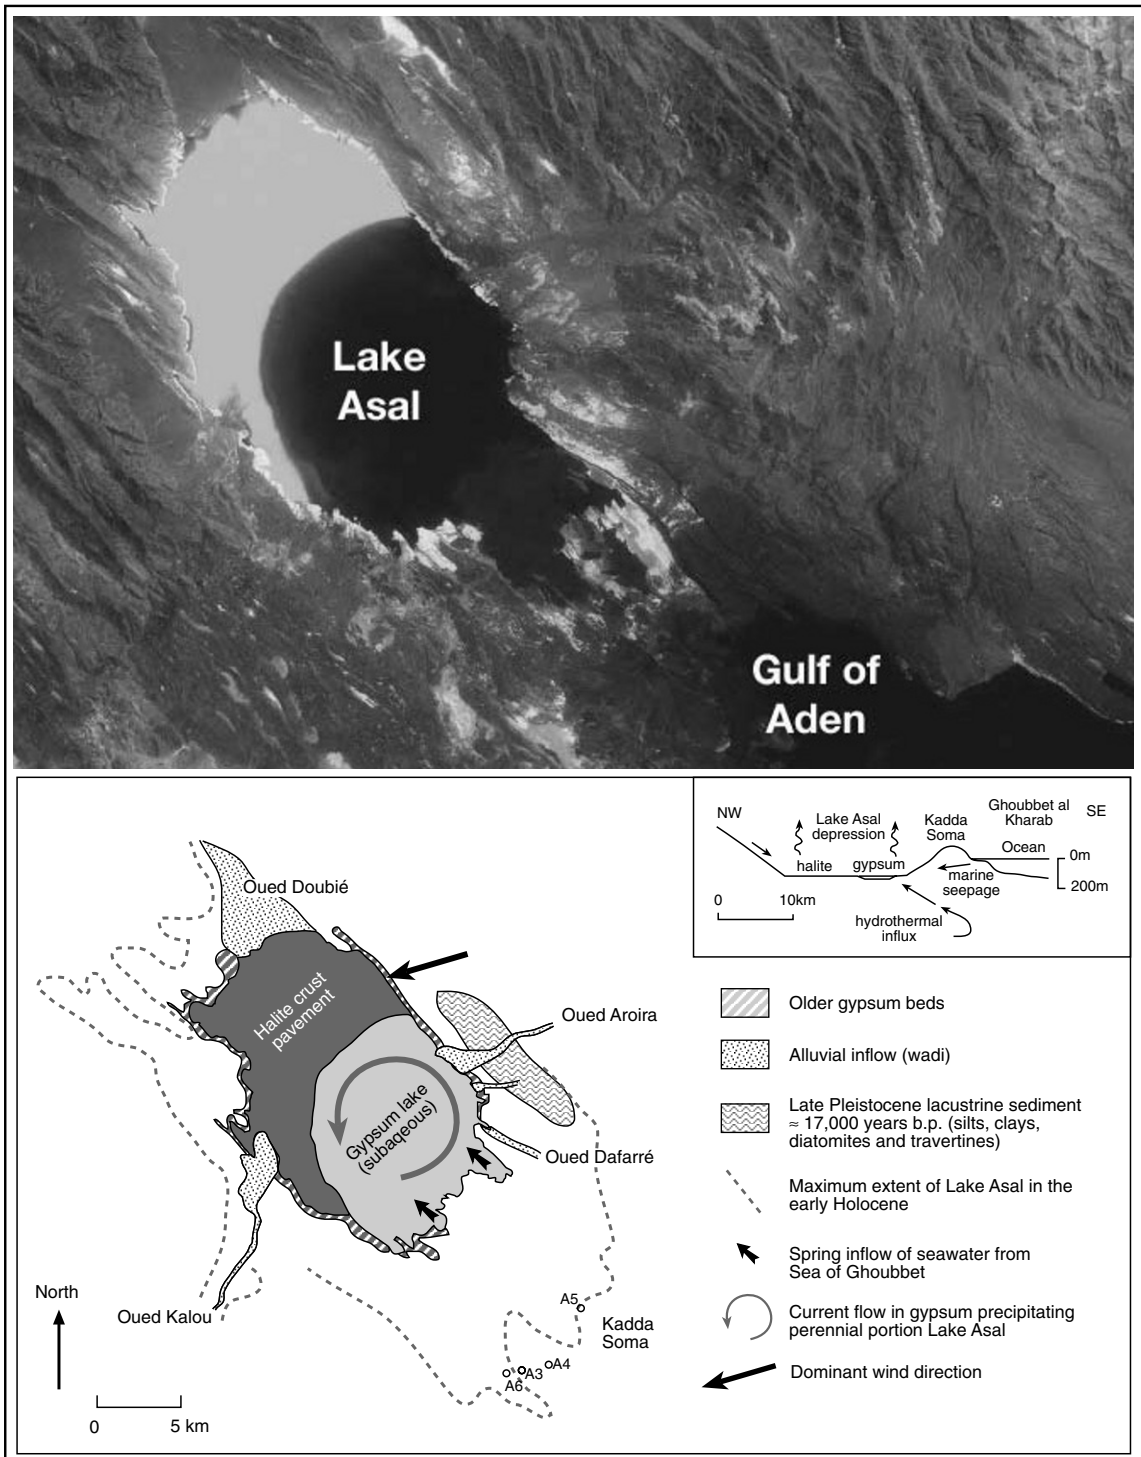

Figure 4.56. Holocene sediment distribution in Lake Asal, Republic of Djibouti (surface geology after Stieljes, 1973). Marine inflow is via fractured basalts of the Kadda Soma. A_{3,4,5,6} indicate positions of geothermal test wells - A₁ and A₂ lie further to the southwest. The inset is an idealised cross section from the ocean to the lake depression (Landsat image courtesy of NASA).

Hydrological compartment	Volume (1000 km ³)	Percent
Oceans	1,370,000	97.61
Glaciers, ice, snow	29,000	2.08
Subsurface	4,067	0.295
Freshwater lakes, rivers	126	0.009
Saline lakes	104	0.008
Atmosphere	14	0.001

Table 4.5. Water volumes in the global water compartments (after Wetzel, 1988).

Stacked halite crusts characterise the saline pan facies that covers much of the northeastern part of the lake where it forms a wide (≈ 60 km) and thick (20–80 metre) accumulation of pan halite. Prior to 1978 the top of this halite plain lay some 30 to 80 cm above the water surface of the perennial gypsum lake. Then in 1978 renewed volcano-tectonic activity in the region

reopened fractures and faults leading to an increased influx of waters from the Ghoubbat al Kharab and a rise of lake waters which partially submerged the top of the salt pan (Ruegg et al., 1979). Once again, as in most other basins accumulating bedded evaporites, the changes in hydrological base level in this depressed pan are in large part driven by tectonics, not marine eustacy (see Chapter 5). The separation between areas of subaqueous gypsum and pan halite clearly shows how two mineral phases cannot accumulate simultaneously in a single holomictic brine lake, but can be adjacent facies.

Are all modern saline lakes shallow?

Table 4.5 shows the relative importance of saline lakes in the total volume of the world's surface water. There is as much water caught up in the world's saline lakes as there is in freshwater lake systems. Tables 4.6 and 4.7 summarize the physiographic

	Area km ²	Brine surface	Hydrological setting (Brine source)	Tectonic Setting	Characteristics
Lake MacLeod, Australia (Logan, 1987)	2,500	≈ 1 m below sealevel	Evolved from stratified perennial to ephemeral during sediment infill (marine)	Passive margin	Holocene marine-fed coastal salina with 10m thick bottom-nucleated salt beds. Stable brine curtain maintains salt beds and marine-fed seepage margin. Salts have filled an interdunal depression to within a metre of ambient sealevel via seepage of mostly marine-fed groundwater.
Abu Dhabi mudflats (Evans et al., 1969)	≈ 300	≈ 1 m above sealevel (asl)	Ephemeral with water cover during marine flood stage (marine)	Ramp in foreland basin	Holocene marine-fed coastal mudflat with 1-2m thick displacive salts growing in detrital matrix of supratidal and intertidal units. Stable brine curtain is maintained by capillary evaporation and marine seepage.
Dead Sea, Middle East (Ben-Avraham et al., 1999)	1,000	-415 m asl	310 metre deep lake hypersaline lake with alternating longterm meromictic and holomictic brine columns (nonmarine)	Continental transform basin	Quaternary fluvial/seepage-fed deep perennial lake. Thick stable brine curtain bathes multiple stacked subaqueous beds. Beds in Northern Basin deposited in deep water, Southern Basin in saline pan/ salina settings. Much of the solute is fed to the lake from springs carrying dissolved Miocene (4-6 Ma) evaporites (diapirs also outcrop on lake floor).
Kara-Bogaz-Gol, Turkmenistan	13,000	28 m below sealevel	Endorheic basin joined by a narrow inlet to Caspian Sea (nonmarine)	Intramontane basin in a continent-continent collision belt	In the last 0.5 million years three separate Mg-Na-SO ₄ -rich salt layers have formed across the gulf, perhaps forming best in glacial episodes when the connection to the Caspian was reduced compared to today, and year round temperatures were much lower. Such glacial conditions favoured a perennial lake to pan mode of cryogenic mirabilite precipitation (Figure 11.56)
Lake Eyre, Australia (Magee et al., 1995)	9,300	-15 m asl	Ephemeral lake mudflats with up to 6 metres of freshwater cover emplaced during occasional storm flood (nonmarine)	Intracratonic sag atop Precambrian rift	Quaternary fluvial-seepage fed, has changed from fresh (100 ka) to the ephemeral salt lake of today, showing the decreasing effect of the monsoonal feed. Upwelling and throughflushing of freshened artesian waters beneath the lake destroys the brine curtain and so prevents more than 2-3m of halite accumulating beneath the lowermost parts of the lake floor.
Salar Uyuni, Bolivia (Risacher and Fritz, 2000)	10,600	+ 3653 m asl	Saline pan with peripheral mudflat (continental/hydrothermal)	Intramontane basin in a forearc collision belt	Largest salt pan in the world today. A 121m deep well intersected 12 saline-pan beds separated by 11 lacustrine mud beds, all bathed in a stable brine curtain. Mud layers thicken upwards, while the thickness of the salt beds decreases markedly from the base upward.

Table 4.6. Representative listing of variations in Quaternary evaporite deposits.

variety of some Quaternary perennial brine lakes. Admittedly, around 70% of the saline lake water volume listed in Table 4.5 comes from the Caspian Sea. This saline lake and the other saline lakes of western Asia (Kara-Bogaz-Gol, Lake Urmia, Lake Issyk-Kul and Lake Van) are all located in foreland basins created by Neogene collision tectonics and together contribute what appears to be an anomalously high proportion to the world's total volume of saline lake waters. Then again, over 40% of the listed freshwater volume comes from the combined volumes of Lake Baikal and the Great Lakes of the North Americas. Also, most saline water bodies are shallow, so the area of the world's surface covered by saline lakes is probably greater than that covered by freshwater lakes.

In terms of saline lake sediments associated with saline water bodies, the largest contiguous area of Quaternary bedded salt accumulating today is in Salar Uyuni, a continental lake (saline pan/mudflat) with a water level some thousands of metres above sea level. The Dead Sea, with a water surface more than 415 m below sealevel is our onHolocene example of a substantial deepwater evaporite basin currently accumulating halite. Its inflow is a combination of river and saline spring inflow. Our best example of an active marine-fed perennial saline lake, which is still accumulating bedded shoalwater gypsum and pan halite, is Lake Asal, a rift depression lake with a water surface some 155 metres below sea level. In area, it is exceeded by many of the marine seepage-fed Holocene coastal salinas of southern and western Australia. Unlike Lake Asal, the Australian coastal salinas have equilibrated within a metre of the height of their sea level source and are no longer actively accumulating subaqueous bedded salts. Active subsidence in a rift seems to allow a continental lake to maintain permanently subaqueous brines, as is the case in the Dead Sea. After Lake Asal, Death Valley at -86 m asl, is the next deepest hole on the world's surface that is occupied by a saline lacustrine system. In its current form it is a saline pan rather than a perennial halite accumulating lake, but in the Late Pleistocene it was a deep perennial system (Chapter 3). Although well studied, the volume of salts accumulating in Death Valley is relatively minor in terms of the total volume of salt in saline lacustrine settings of the world.

A plot of salinity versus brine depth in the world's perennial saline lakes shows that lakes accumulating salts more saline than calcite/aragonite/dolomite couplets (salinities > 70 ‰) tend to be shallow, with brines less than 10-20 metres deep (Figure 4.57a). In terms of total salts held in the lake waters the less saline lakes (Caspian, Aral Sea, Lake Urmia) dominate (Figure 4.57b). An obvious exception to the more saline

lakes being characterised by shallow to ephemeral surface waters is the current condition of the Dead Sea. The Dead Sea's physiography as a narrow rapidly subsiding basin in the deepest continental position on the world's surface makes it unique amongst the world's modern saline lakes. But the Dead Sea can accumulate halite in its deepest waters only when its longterm density stratification is destroyed (holomixis). The destruction of the halocline is not an annual event, as it is in some of the less saline lakes (e.g. Lake Van), but seems to occur every few hundred years.

All of the largest active perennial saline water bodies, which are depositing substantial volumes and areas of subaqueous salts over time frames measures longer than 10,000 years, are continental not marine depressions. All the largest perennial saline lakes occur in semi-arid rather than arid to hyperarid climates and all are located in tectonically active and subsiding (underfilled) basins such as in the Andes, the tectonic collision zones of Turkey and Iran, and the Basin and Range of USA.

Figure 4.57. Physiography of saline lakes of the world. A) Maximum salinity of saline lake waters versus maximum water depth in the lake (data plotted from Table 4.7). B) Mass of salt held in selected lake waters. Note logarithmic scale.

Table 4.7. Physical characteristics of some perennial saline lakes worldwide.

Tectonism facilitates steep topographic gradients, endorheic closure and subsidence within large intermontane depressions, all three factors seem to be needed in order to form a permanent brine body in Quaternary systems. Milder levels

of aridity allow waters to persist above the land surface and do not drive the conversion of the hydrology to sabkhas and evaporitic mudflats that characterise the more arid settings.

The other significant factor common to the formation of large perennial saline lakes is longterm climate change. Ephemeral flood-pan lacustrine systems, such as Lake Eyre and Lake Frome in Australia, which today are combinations of saline pans and evaporitic mudflats, were large perennial lakes in milder climatic episodes in the Late Pleistocene. These southern hemisphere “mega-lake” phases are tied to a more southerly influence of the monsoonal belt during these times. Even historical flooding events in the central Australian playas are frequently tied to La Nina phases in the El Nino-Southern Oscillations (ENS. Laminated Pleistocene (10-12 ka) lacustrine sediments from Lake Magadi also preserve evidence of ENSO changes in the variations of laminae thickness (Damnati and Taieb, 1995). Changes in Pleistocene climate also explain why many modern playas and pans in the Basin and Range were once perennial lakes; during pluvial episodes of the Late Pleistocene some were even freshwater lakes with waters more than 100 metres deep (Smoot and Lowenstein, 1991). Death Valley for example, changed from its modern saline pan/mudflat setting into a perennial saline lake in this time (Chapter 3). Perhaps one of the most impressive Late Pleistocene megalakes was Lake Chad some 8,000 to 10,000 years ago when its water-covered area was equivalent to that of the present Caspian Sea. Other lakes currently in their fresher saline stages (Lake Van and Lake Urmia) experienced times of shrinkage and desiccation in the Late Pleistocene.

To state everything we have discussed so far in its simplest terms: to accumulate bedded salts, you need a large, deep centrally-draining somewhat leaky hole in the ground (a groundwater sump). And, like Goldilocks, it

performs best in a climate that is not “too hot” and not “too cold” and not “too wet” and not “too dry.” If we use Quaternary examples of evaporites as strict uniformitarian analogues for ancient evaporite deposits then we must conclude that thick, laterally extensive salt beds are always continental lacustrine deposits, accumulating in tectonically-induced, rapidly-subsiding intermontane basins.

Marine seepage fed platform and basinwide evaporite settings do not exist today. But, the next chapter will show that most of the largest examples of ancient evaporites are actually marine-fed precipitates, deposited under eustatic and tectonic conditions for which there are no Quaternary counterparts.

Chapter 5: Ancient basins and stratigraphic evolution

Is the present the key to the past in evaporite studies? It's a question that has plagued geologists working with salts since the 17th century, when Werner's neptunist postulates explained world geology (including igneous strata) as layered precipitates from cooling oceanic waters. And like Werner's Scottish protagonists, we are still discussing the merits of strict uniformitarianism. In this chapter I am not questioning the fundamental principle of using present process to interpret the past. Nor am I questioning the utility of detailed studies of modern process to reliably interpret the past. Let me put it plainly for the creationist community and proponents of "intelligent design," all the geological evidence clearly shows the earth is not 8,000, but more than 4 billion years old, that biological evolution is fact, it interacts with and responds to the physical environment and has been in operation for at least the past 3.5 billion years. There is no need to invoke the supernatural to explain biological evolution and other earth processes, and there is no geological evidence for a worldwide biblical flood of epic proportions drowning mankind and covering all the land.

What I am questioning is strict actualistic approaches to sedimentological interpretation of evaporites, whether the depositional diversity we see in our current icehouse climate

mode and eustasy is sufficiently broad to explain the diversity of ancient evaporites (Table 5.1). If our present is the key in terms of all scales of deposition and climate, then why are there no marine platform evaporites forming today and why are there no evaporitic seaways? Chapters 3 and 4 show that the largest and thickest Quaternary evaporites are continental lacustrine deposits, not marine-fed systems. We shall shortly see that such lacustrine systems are directly and completely comparable with their ancient lacustrine counterparts in terms of facies, salt thicknesses and lateral extents. But the scale of lacustrine evaporite development, past and present, pales in comparison to some ancient marine-fed saline systems. There are no modern counterparts to such ancient marine-associated systems. Our inability to compare all aspects of evaporite deposition, past and present, reflects a present-day lack of both longterm shallow epeiric seas and of large drawdown basins fed by seawater seeps.

The Hith Anhydrite of the Middle East, the Zechstein salts of Europe and the Messinian evaporites of the Mediterranean have no modern same-scale counterparts. An understanding of the shortcomings inherent in applying strict uniformitarian models is tied to current styles of continent-scale tectonics and

	ICEHOUSE	GREENHOUSE
Age	Late Cenozoic, Late Carboniferous to Early Permian, Late Neoproterozoic	Cambrian to Middle Carboniferous, Middle Permian to Early Cenozoic
Tectonic style	Collision, telescoping	Stretching, rifting
Seafloor spreading	Slow	Rapid
Subduction/volcanism	Low	High
Marine margin basins	Narrow shelves, limited short-lived interior seaways with small aerial extent	Wide shallow shelves and large long-lived interior seaways (epeiric seas)
Marine eustasy	High amplitude ($\approx 100\text{m}$) change on 100,000 year times scale (4th order). World sealevel is low (caught up in longterm polar ice sheets)	Low amplitude ($>5\text{-}10\text{m}$) change on 100,000 year times scale (4th order). World sealevel is high (no polar ice sheets)
Ocean Basins	Cold, oxygenated	Warm, often anoxic
High latitude climates	Glaciers, taiga and tundra	Deciduous forest
Mid latitude climate	Deciduous forest, glacial advances and steppe	Tropical wet and stressed forest
Low latitude climate	Rainforest, savanna and desert	Desert
Erosion/weathering	Fast/mechanical	Slow, chemical
Depositional styles of large evaporite basins	Tectonically induced endorheic continental depressions (terrestrial lacustrine; no marine-seep platform and basinwide evaporites accumulating at present time; but basinwides can form in suitably isolated icehouse conditions, and did so most recently in the Middle and Late Miocene)	Tectonically and eustatically induced endorheic continental and marine margin depressions (terrestrial lacustrine, marine platform and marine-fed basinwide styles can be widespread whenever suitable combinations of tectonics and eustasy occur)

Table 5.1. Climatic and depositional contrasts between icehouse and greenhouse earth.

icehouse eustasy. Put simply, the rates and amplitudes of seafloor spreading, orogeny and eustasy are not constant across deep time. Widespread marine evaporites require particular tectonic and/or eustatic conditions to accumulate, conditions that are not present on the world's modern surface (Table 5.1). They will be in the future, and they have been many times in the past.

This chapter demonstrates the importance of differences between icehouse and greenhouse climate/eustasy as controls on evaporite style in marine platforms. It shows how particular tectonic and climatic settings are needed to form saline giants in isolated subsealevel drawdown depressions. It also shows how interpretations using sequence stratigraphic marine eustatic frameworks do not work as well in ancient basinwide saline giants as they do in interpreting evaporites laid down on ancient marine platforms. Even on an ancient continental shelf, we need to separate icehouse from greenhouse platforms in order to understand evaporite distribution.

By the end of this chapter, I hope it will be obvious that when trying to predict and model ancient evaporites it is much more

useful to consider tectonics and hydrologies of large evaporite basins as the fundamental controls of basin-scale evaporite geometries, mineralogies and bounding surfaces. One should not force marine-seepage-fed drawdown systems into a marine-eustatic icehouse model. Nor should our interpretations be driven by the hydrologically dubious notions of ongoing surface (hydrographic) connections between ocean waters and restricted basins at the time thick salts accumulate; and yet these assumptions still dominate many interpretations of ancient evaporite basins.

Linking present to past aridity

In order to understand possible linkages between present and past evaporites, we must first understand geological indications of past and present climate. After all, the preceding chapters clearly show it is climate that drives the accumulation of salts in the deserts, lakes and sea margin systems of today and that the same was true in saline giants of the past. Only with a sturdy palaeoclimate understanding can we reliably compare

Figure 5.1. Sea level change through the Phanerozoic. A) Relative sea level curve, based on sequence stratigraphy of Vail et al., 1978. Icehouse and greenhouse intervals are not well constrained. B) and C) show Tertiary and Quaternary oxygen isotope/palaeotemperature curve of high latitude seawater and are based on deep marine sediment cores in the Southern Ocean. Isotope scale on the Tertiary curve is relative to SMOW, the Quaternary curve is corrected to a zero mean (both curves are after Williams et al., 1993).

Quaternary to older depositional settings. Quaternary and late Neogene climatic systems, characterised by waxing and waning polar ice sheets, define the current “icehouse” climate mode. Today, some 10% of the world's surface is covered by ice, representing about 80% of surface freshwater, and a further 20% is affected by permafrost. Of these ice-covered lands, Antarctica has 86% by area and Greenland 11%. In the last glacial maximum (18-20 ka) a staggering 30% of the earth's surface was covered by ice.

The current icehouse mode evolved during the latter part of the Tertiary period and is characterised by glacially -driven oscillations in sealevel with amplitudes of more than a hundred metres, with repeat frequencies around 100,000 years (Figure 5.1). Marine-fed evaporite distribution associated with icehouse and its older counterparts at the end of the Palaeozoic and the Neoproterozoic are not the same as that of the “greenhouse” climate mode, which has dominated much of the earth's Phanerozoic history (Table 5.1).

Quaternary climate (icehouse), especially in semi-arid to temperate latitudes, is characterised by repeated rapid temperature swings from levels much like those of today (interglacial) to levels many degrees colder. Colder (glacial) times are associated with growth of huge km-thick circumpolar and high latitude/high elevation ice sheets and lowered sealevels. Ocean surface temperatures were up to a few degrees cooler at such times, while sealevels fell more than a hundred metres compared with its interglacial current level. On the land, mountain tree lines shifted to lower positions, grasslands replaced forests, continental ice- and periglacial-driven processes were more widespread and large volumes of dust and sand were blown about by cold, intense winds. During passage into the cooler climatic phases (glacials) of icehouse mode climate there were rapid pulses of sealevel fall, while in the passage to warmer (interglacial) periods the rates of sealevel rise were even more intense. There have been more than 15 glacial periods in the last 1.7 million years. It was in the latter part of this icehouse regime of rapid change and climatic stress that *Homo sapiens* first came to be some 100 ka.

This remarkable 1.8 Ma climatic period known as the Quaternary is the culmination of a slow and uneven climatic progression toward cooler conditions that typified much of the latter part of the Tertiary and a transition from greenhouse to icehouse earth. At the start of the Tertiary, Antarctica was ice-free. Oxygen isotope palaeotemperatures suggest that the nearby southern oceans were quite warm, perhaps 18°C at the surface and forests were flourishing even at very high latitudes (Figure 5.1; Williams et al., 1993, p 21).

The cooling of the world's oceans, as interpreted from $\delta^{18}\text{O}$ data by Zachos et al. (2001), started during the early Eocene climatic optimum (≈ 50 -52 Ma) when the measured $\delta^{18}\text{O}$ reached a minimum for the Cenozoic with equivalent deep ocean temperatures of +12°C. From ≈ 50 Ma until the early Oligocene the world's ocean seems to have steadily cooled. The reasons for this cooling and the onset of the current icehouse mode are a topic of ongoing debate. All agree the underlying cause was plate tectonics. Interpretations as to mechanism are split between proponents supporting changing oceanic circulation, driven by a widening Southern Ocean and a closing Tethys as the main driving mechanism, versus those arguing that falling CO_2 levels was the major driver, driven by the rising Himalayas and burial of significant quantities of terrestrial biomass. The post-Cretaceous lessening of oceanic ridge activity may be another contributing factor to gradual Cenozoic cooling.

Around 50 Ma Australia began to drift north, opening the Southern Ocean Seaway and so establishing the beginnings of the Antarctic Circumpolar Current (ACC). From that time the ACC completely encircled the Antarctic continent. It acted as a barrier that prevented warm currents of the lower latitudes ever reaching the Antarctic coast and reduced the transport of “sensible” heat to the higher latitudes, so contributing to the growing polar cold. The tropics were little effected and so the equator-pole temperature gradient began to increase, invigorating the intensity of worldscale atmospheric circulation.

Throughout the Paleocene and the Eocene it was still possible for the major equatorial ocean currents to encircle the globe, passages were still open between the Americas, between India and Europe, and between Australia and Indo-China. Worldwide climate was still generally warm. A powerful western equatorial drift passed through the open remnants of the Tethyan Ocean and allowed ongoing transfer of tropical heat to the polar regions. Closure of the Tethys, as India approached the Eurasian continent, ended circum-equatorial circulation and forced circulation south of Africa into the temperate zone. This early Eocene event is the first of four major steps that punctuate the longterm history of Cenozoic cooling (McGowran et al., 1992).

But even when the Tethyan connection closed, the initial effect on Antarctica's cool, but not frigid, climate was relatively minor. As the Eocene progressed, the Southern Ocean continued to widen but the ACC circulation did not develop to its present intensity because of shallow barriers or seafloor baffles between Australia and Antarctica (East Tasman Rise) and in the region of the Drake Passage between South America and Antarctica. Even so, high latitude cooling continued to increase, driven forward by the ongoing widening of the Southern Ocean.

At the end of the Eocene, around 34 Ma, there was a major cooling episode (Lawver and Gahagan, 2003). High latitude deep water temperatures in the Southern Ocean dropped 4–5°C, probably indicating the development of freezing conditions at sealevel around Antarctica and the first formation of sea ice. Land temperatures over high latitudes in both hemispheres probably dropped by 10°C. With the opening of the Drake Passage around 32 Ma to water depths greater than 2000 m, South America completely parted from Antarctica. This enhanced the intensity of the ACC, so producing further cooling and formation of greater volumes of ice on the Antarctic land mass (Lawver and Gahagan, 2003). The very rapid cooling of ocean temperatures at the end of the Eocene probably reflects a positive feedback between growing Antarctic ice and an increase in the world's albedo (increased reflection of sunlight).

The continuing widening of the Southern Ocean and the complete floundering of Drake Passage around 25 Ma allowed the ACC to begin to develop to its full intensity, including the set up of cold bottom water circulation, which effectively cut off Antarctica from any warming equatorial influences. By the Miocene, the ACC had attained levels of flow volume comparable to those of the Quaternary (Rack, 1993).

Widespread thick ice sheets covered Antarctica by the Middle Miocene and ice sheets moved out onto the continental shelf by the Late Miocene, as indicated by ice-rafted continental debris in deep oceanic sediments around much of Antarctica at that time (Lawver and Gahagan, 2003). It heralded the arrival of permanent thick glacial ice at sealevel, a circum-Antarctic condition that persists today. Significant cooling is seen in the oceanic paleotemperature curve at this time. It is still not well understood why it took until the Mid-Miocene for the Antarctic ice to reach extents similar to those of today, long after the development of the ACC in the early Miocene. But the associated effects on equatorial-pole temperature gradients are clear. The resulting strengthened winds intensified Mid-Miocene ocean water circulation, which in turn was associated with increased upwelling and biological activity in many of the world's oceans.

A further global cooling took place in the Late Miocene when world sealevel dropped a further 40–50 m (Kennet, 1982). This regression, in association with local tectonic activity, contributed to the isolation of the Mediterranean from the rest of the world's oceans. It perhaps helped deposit huge thicknesses of salt in giant shallow lakes across the lower parts of the former Mediterranean seafloor in an episode known as the Messinian salinity crisis. But this widely accepted correlation of an icesheet-induced major sealevel fall and widespread

evaporite deposition in the Mediterranean has been questioned by Hodell et al. (2001) who defined a Miocene glacial period that lasted from \approx 6.26 to 5.50 Ma. It consisted of 18 glacial-to-interglacial oscillations that were controlled by the 41-kyr cycle of obliquity. Although the intensification of polar glaciation at 6.26 Ma may have contributed to the restriction of the Mediterranean, it preceded the depositional onset of the lower Messinian evaporite unit at 5.96 Ma by some 300 kyr. It seems that the initiation of evaporite accumulation in the Mediterranean evaporite basin, the world's last "saline giant," was tectonic and not glacio-eustatic.

Whatever the ultimate cause of the Messinian isolation, the volume of oceanic salt deposited in the Mediterranean during the salinity crisis is 40 times that which would be deposited if the present Mediterranean evaporated to complete dryness, illustrating that there was a phreatic inflow of subsurface seawater brines into the drawdown Mediterranean depression. Removal of this volume of salt from the world's oceans lowered the salinity of the open ocean water by 6%. As less saline seawater freezes at a higher temperature, this in turn fed back into global climate by allowing yet more sea ice to develop in higher latitudes, so further reinforcing high latitude cooling.

After a slight warming in the early Pliocene, conditions cooled still further. As North and South America united across the Panama Isthmus, late Pliocene (around 3 Ma) climatic conditions in the Northern Hemisphere had cooled to where ice-rafted debris was being deposited in deep water sediments of the Northern Atlantic. By 2.4 Ma, near the beginning of the Quaternary, permanent moderate-sized ice sheets characterised the high latitude lands of the Northern Hemisphere. This marked the beginning of a climatic phase characterised by the repeated waxing and waning of polar ice sheets in the high latitudes of both the Southern and Northern Hemispheres, further enhancing high amplitude and high frequency changes in sealevel and further intensifying the alternation of warmer (interglacial) and cooler (glacial) climatic episodes.

During the early Quaternary (Matuyama magnetic chron 0.78–1.77Ma) the warm to cool climatic alternations follow a periodicity of 41 ka (Williams et al., 1993). This is equivalent to the repeating cyclicality in the obliquity of the earth's axis in terms of the plane of its ecliptic (21.8°–24.4°). From 0.8 Ma the amplitude of climatic fluctuations recorded in marine sediments seems to increase, reflected in the increased sizes of the cold phase ice sheets. The periodicity of climatic fluctuations in this time also appears to increase to a cycling time of 100 ka. This correlates to the eccentricity of the earth's orbit around the sun as it varies from nearly circular to somewhat elliptical. This 100

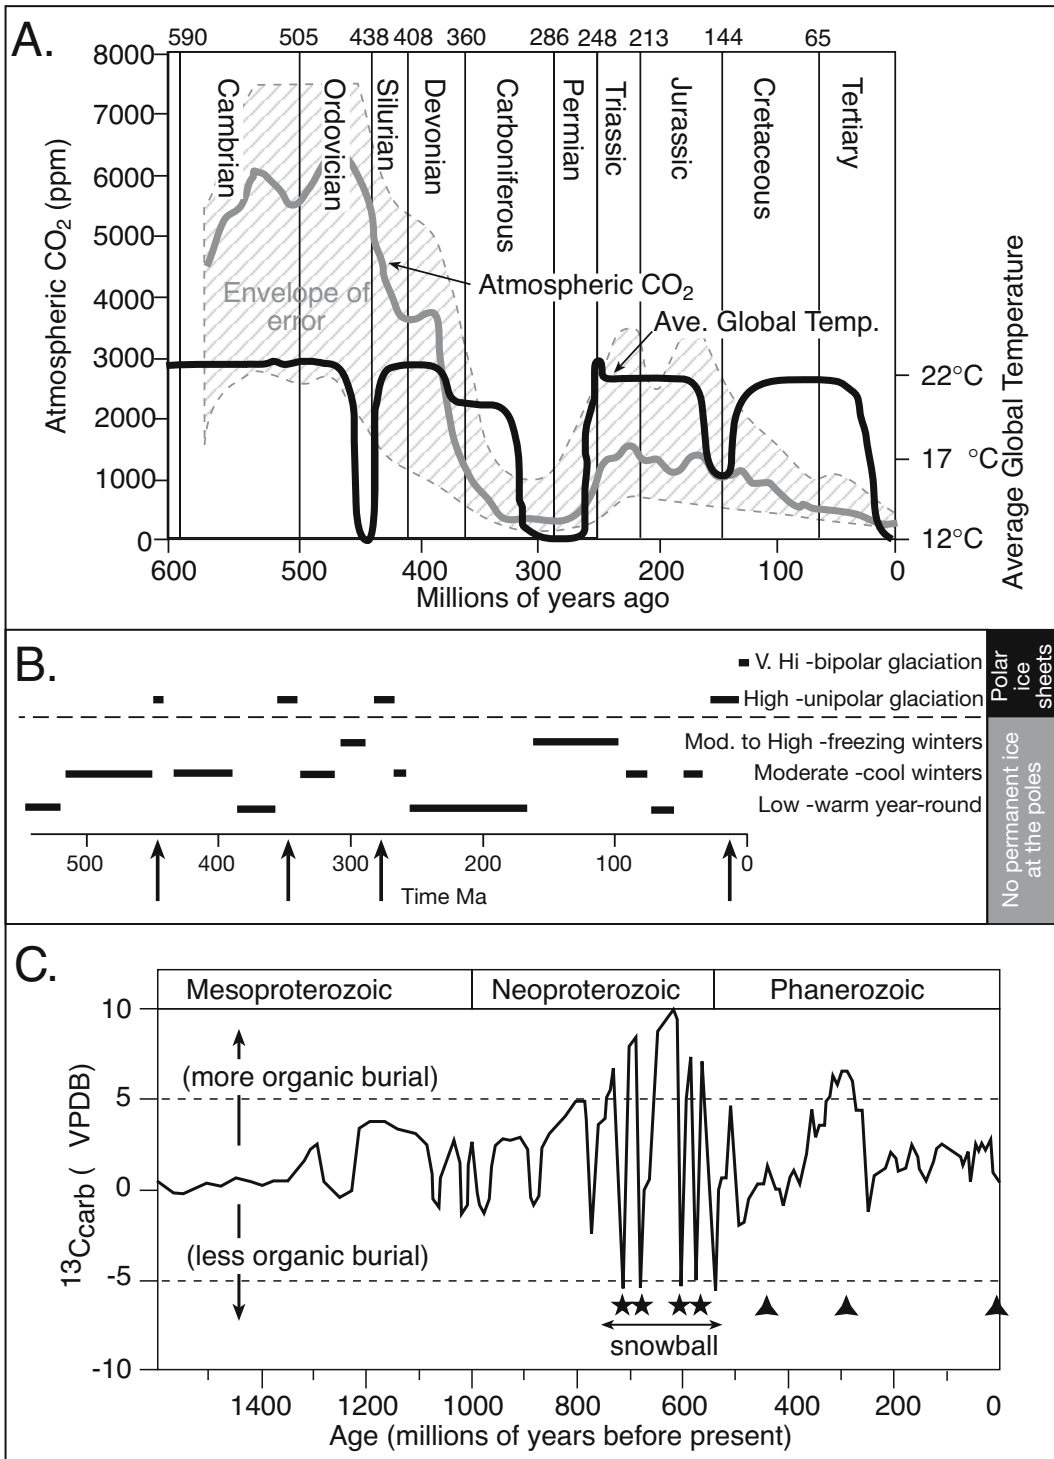

Figure 5.2. Climate change across geological time. A) Global temperature and atmospheric CO₂ change over time (after Berner, 1998). B) Pole to Equator climatic gradient through time, arrows indicate episodes of polar ice (replotted from data in Boucot and Gray, 2001) C) Secular variation in Carbon-13 content of shallow marine carbonates over the last 1600 million years - see also Figure 2.33 (after Kah et al., 2001).

ka periodicity, with sealevel amplitudes of more than 100 m, is especially dominant in the last 400 ka of world history, but superimposed on this are the 41 ka cycles and 23 ka precession cycles of the earth's equinoxes (Figure 5.1).

Rapid climatic change and high amplitude high frequency changes in sealevel are the hallmarks of the Quaternary, and probably most of late Neogene. Relative to the previous 200 million years of climatic history, the climatic fluctuations of the Quaternary were unprecedented in terms of their speed and amplitude. The mean annual temperature difference between the last glacial maximum (18 ± 3 ka) and the early Holocene climatic optimum (9 ± 3 ka) is around 10°C in many temperate land areas of the world (Williams et al., 1993; p. 223). This is roughly equivalent to the inferred longterm drop in temperatures between the early Eocene and early Pliocene in these same regions (Figure 5.1). The surface of the Southern Ocean cooled by $10\text{--}15^\circ\text{C}$ over this 40 million year period. Temperature drops of a similar magnitude occurred in eastern Australia over the 100,000 year time span that separates the last interglacial from the last glacial maximum in this region. Similar high frequency changes typify the Quaternary in many other parts of the world.

Prior to our present "icehouse" climate mode of the last 15-25 million years, the last time when there were widespread polar ice sheets, high amplitude-high frequency sealevel fluctuations, and a similar "ice house" climate was the Permo-Carboniferous some 270-315 Ma (Figure 5.2a, b). Prior to this we must go as far back as the Late Ordovician and then to the Neoproterozoic to see evidence of other worldwide "icehouse" conditions (Figure 5.2c). The late Ordovician glaciation (≈ 440 Ma) was unusual compared to the icehouse episodes that preceded and postdated it. Major glaciation was apparently confined to South America and Northwest Africa and nowhere else. Timewise, it is also the most contentious of the Phanerozoic icehouses. Brenchley et al. (1994) argue it was restricted to the Hirnantian and was some 0.5-1 m.y. long, rather than the 35 m.y. of earlier estimates. In terms of paleogeography, it probably defines the southern polar position of a uniting Gondwana. It was an Ordovician Antarctica equivalent, not associated with the breakdown of worldscale ocean circulation and it probably had no more than local climatic influence in a overall warming greenhouse world (Drury, 1999).

In fact, in the last 600 million years the late Carboniferous to the early Permian (315 -270 Ma) was the only time when atmospheric CO_2 and average global temperature were both as low as they are today. Even so, today's bipolar glaciation

appears to be a unique icehouse scenario compared to the rest of the Phanerozoic (Figure 5.2b). The obvious conclusion is that the last 20 ma, and certainly the last 2 Ma of the Quaternary experienced climate and eustatic styles that are simply not representative of non-icehouse conditions covering the majority of Phanerozoic time.

Prior to the Phanerozoic, preceding Proterozoic icehouse regimes consist of at least three and maybe up to five glacial pulses between 900 and 550 Ma (Figure 5.2c), the latter part of this episode encompasses the notion of a completely ice-covered "snowball earth" (Figure 2.33; Hoffman et al., 1998). If real, this was a cryogenic system far more intense than the bipolar system of today, with its own unique climatic and sedimentologic implications. Prior to this Neoproterozoic icehouse, there is evidence of earlier worldwide glacial (icehouse) conditions at 2200 Ma and possibly at 2500 Ma. If snowball conditions did encompass the Neoproterozoic earth with an ice envelope, and ultimately lead to the Phanerozoic explosion of life, then the only possible "evaporite" salts that could have accumulated in snowball episodes would have been hydrothermal anhydrite in the vicinity of volcanic vents and spreading ridges, or cryogenic hydrohalite precipitates and volumetrically minor slushes of mirabilite and hydrohalite created during the formation of widespread sea ice. Hydrohalite ($\text{NaCl}\cdot 2\text{H}_2\text{O}$) is the stable form of halite below temperatures of 0.1°C , it is anhydrous at higher temperatures, hydrohalite has four times the volume of mirabilite in modern sea ice (Richardson, 1976). The possibility of preservation of either mineral, other than as isolated pseudomorphs, along with ikaite in glacial meltwater deposits is zero.

The rapid melting of the global icesheets of snowball earth and the transition to widespread temperatures as hot as 50°C during the formation of successive cap dolomites, along with the likely encroachment of shallow epeiric seaways via the return of continental glacial waters to the sea, would have encouraged the formation of widespread platform evaporites in association with the cap carbonates. Widespread megapolygonal tepees and/or salt karst does outcrop in the appropriate stratigraphic position in the Neoproterozoic dolomite capstones in Oman (pers. obs.) and atop the Elatina Shale in the Flinders Ranges of Australia. Defining the worldwide timing of such Neoproterozoic evaporites and their dissolution residues may be an interesting test of the validity the "freeze and fry" climate conjectured for snowball earth. Some megapolygons beneath cementstone layers have been interpreted in a very nonuniformitarian fashion by snowball earth proponents. They are tepee-like with unbroken crests and not thought to be true tepees. Rather they are me-

chanically-formed chevron-like wave structures indicative of wave periods of 21-30 seconds and formed by consistent flow velocities of 20 m/sec in megawinds blowing across oceans with unlimited fetch (Allen and Hoffman, 2005).

Clearly, our present icehouse climatic regime does not represent climatic and sealevel regimes throughout much of geological time. As Charles Dickens once wrote on contemporary time, "It was the best of times, it was the worst of times." In terms of marine evaporite deposition, a lack of "strict uniformitarianism" leads to a paucity of Quaternary analogues for most large marine-fed evaporite deposits.

Varying extent of ancient evaporites

Nowhere in Quaternary depositional systems is there Holocene proof of a desiccated ocean basin, yet in the Late Miocene (Messinian) salinity crisis a series of subsealevel saline depressions on the Mediterranean floor filled the lowest parts of the Mediterranean with 2-km-thick sequences of halite and gypsum

in less than 300,000 years (e.g. Balearic Basin; Figure 5.3). These Messinian evaporites were laid down on the floors of a chain of shallow saline seas that were more than a thousand kilometres long, more than two hundred kilometres across, with brine surfaces more than 2,000 metres below ambient sealevel. They formed in the lowermost parts of a hyperarid to semiarid seafloor desert that extended from Spain to Israel and from northern Italy to Libya (Cita, 1983; Hsu et al., 1973).

Similarly, there is no Holocene proof of evaporitic brine-reflux dolomitisation and the associated salt seals, simply because there is no Holocene example of a whole carbonate platform being covered by an evaporite deposit. Yet in ancient evaporite basins, reflux dolomitization was a widespread and pervasive mechanism that yielded substantial intercrystalline porosity in platform carbonates beneath laterally continuous beds of platform evaporite salts (Chapter 10).

Many thick ancient salt accumulations are underlain or overlain, and sometimes intercalated, with thick widespread marine carbonate beds. A major dilemma facing geologists interpreting

such strata is the lack of Quaternary marine counterparts with comparable depositional scale and unit thickness (Figure 5.3a, b). All thick Quaternary salt deposits are medium-scale accumulations of continental lacustrine evaporites in tectonically active settings (Table 5.2; Chapters 3 and 4). The ancient evaporite record entrains much larger volumes of salts precipitated in platform or basinwide settings tied to a seawater feed (marine-fed evaporites), as well as ancient continental lacustrine deposits (continental evaporites) with similar thicknesses and extents to the Quaternary examples discussed in Chapters 3 and 4 (Figure 5.3).

The largest marine-fed Holocene subaqueous deposits fill coastal salinas with halite or gypsum beds up to 10 m thick along the semi-arid western and southern coasts of Australia (areas up to 2,500 km²). Preserved Pleistocene salt beds do not underlie these marine-fed Holocene coastal salinas. The term “marine-fed” refers to the dominant source of the inflowing groundwaters at the time the evaporites are deposited, not to the presence of a hydrographic connection to the ocean, which these deposits typically lack. Although they are excellent natural environments to study the textures of precipitation in relation to brine stability and permanence, and to document early alteration mechanisms, even the largest Holocene coastal deposits pale in size and volume when compared to ancient

marine-fed accumulations (Figure 5.3a). There is a similar lack of stacking and extent in the type area for modern marine-fed evaporitic mudflats, or sabkhas, in the Arabian Gulf (Warren and Kendall, 1985; Warren, 1991).

The largest accumulations of ancient marine-fed salts are basinwide deposits, which were laid down in hydrographically-isolated subsealevel depressions, created by divergent, convergent and intracratonic (intraplate) tectonics. Their sediment volumes are not evenly distributed across the Phanerozoic, with the period from the Permian through Jurassic generating the greatest Phanerozoic accumulations of both halite and total evaporites (Figure 5.4). This corresponds to the time of the assembly and disassembly of the Pangaeon supercontinent. A supercontinent is the culmination of a mega-longterm (300 – 600 million year duration) tectonic pattern of continental accretion and fragmentation, whereby a supercontinent gradually assembles then rifts and drifts apart prior to reassembling (e.g. Veevers, 2004). Basinwide evaporites are most likely to accumulate on the floors of isolated subsealevel depressions at times of close proximity of drifting landmasses. This occurs both during the building of the supercontinent and then during times of its early disassembling. Ongoing marine drawdown incursions into marine-fed arid-zone subsealevel basins takes place both as a supercontinent assembles (collision and fore-

land basins) and then as it unzips (rifts and intracratonic sag basins).

Marine platform evaporites are the other major type of ancient marine-fed salt accumulation. They formed on continental margins throughout much more of Phanerozoic time than basinwides. They are characterised by bedded units of calcium sulphates (with lesser halite), typically 10-50 m thick and interbedded with marine carbonates. Stacked platform sections with this style of accumulation encompass depositional time frames of $\approx 1-10$ my. Basinwide evaporite fills tend to be thicker (>100m), more halite prone and purer than platform evaporites and to accumulate rapidly across time frames of less than a million years. Platform evaporite occurrences are largely tied to times in earth history when climate was in greenhouse mode.

The wider extents, greater depositional and diagenetic diversity and greater thicknesses of Phanerozoic marine-fed evaporites reflects two sets conditions not actively influencing modern marine-fed evaporites:

- *Warmer climates of greenhouse earth* creating wider latitudinal distributions of reefs, shoal-rimmed platforms and epeiric seaways under styles of eustatic fluctuation that were more suited to extensive evaporite deposition in the isolated backreef and lagoon.

Figure 5.4. Changes in worldwide volumes of evaporites and of halite with time compared to earth climate mode and supercontinent cycles (base data for the sediment volumes from Land et al. (1988) and Zharkov (1981).

- *Set up of the correct tectonic and climatic conditions* for the hydrographic isolation of large subsealevel tracts in a tectonic depression where marine groundwater feed was the dominant source of solutes onto the arid basin floor.

Study of ancient marine evaporite deposits underscores limitations inherent in the strict actualistic application of the Law of Uniformitarianism. Processes and textures of deposition and early diagenesis can be studied in modern settings (as detailed in Chapters 1 through 4), but current climatic eustatic and tectonic interactions do not encompass all the levels of variation that have occurred in deep time.

Building blocks of ancient salt beds

Whatever an ancient evaporite basin's regional or tectonic setting, the depositional signature can be broken down into three main building blocks: mudflats (with sabkhas, salinas and saline pans), salterns and deeper water slope/basin deposits ((Figure 5.5; Table 5.3).

Evaporitic mudflats form laterally extensive units composed of stacked, shoaling-upward, matrix-dominated cycles (1 - 5 m thick). The whole unit is typically widespread and readily correlatable across scales of up to hundreds of kilometres, but individual beds or layers are not easily traced across the same

lateral extent. Salts accumulated as a mosaic of dry and saline mudflats (sabkhas) separated by local brine-filled depressions (salinas/salt pans) in both marine-fed and continental settings. Much of the matrix was deposited by storm-induced sheet floods feeding sediments and surface waters onto the mudflat, both from the land and from the lake or seaway. On its "seaward" side the matrix tended to be carbonate mud, but typically lacked stenohaline marine fossils. On its "landward side" beds are often interlayered with eolian or fluvial braidplain/sheetwash sediments (Figure 5.5a).

As the stormwaters began to dry up, windblown cm-thick evaporating brine sheets oozed and trickled back and forth atop the very flat mudflat surface. The vast extent of the mudflat, and resulting high humidity in the overlying air, greatly slowed the rate of evaporation so that halite and gypsum were the dominant precipitates. Large parts of these ancient mudflats were sabkhat accumulating displacive and replacive capillary salts. Hence, much of an ancient evaporitic mudflat mosaic is characterised by nodular and enterolithic CaSO_4 pseudomorphs after discoidal gypsum, and skeletal and chaotic halite.

Thin sheets of brine covered extensive areas for weeks or months after a storm or flood, depositing thin layers and stringers of pan gypsum or halite a few centimetres thick atop the freshly deposited silts and sands. Later, once the brine sheet had dried

	Evaporitic mudflat	Saltern	Slope and basin
Brine depth and stability	Ephemeral shallow brine sheet to subaerial	Longterm brine sheet to permanent shallow seaway	Permanent brine lake or sea deeper than 2-10 m
Dominant evaporative/ precipitation mechanism	Capillary evaporation, wind-blown thin brine sheets	Solar concentration of permanent brine, typically density stratified for part of its annual depositional cycle	Solar concentration with laminites in density stratified bodies, massive coarsely crystalline in unstratified brines
Textures	Displacive and replacive capillary salts, chicken wire and nodular textures, skeletal and pagoda halite, chaotic halite, haloturbation, Stokes surfaces, syndepositional micro-karst cements, eolian silt and sand ripples in evaporitic beds	Bottom nucleation, growth aligned laminar to chevron textures crosscut by dissolution. Mechanically reworked beds with ripples, cross beds, gypsolites/halolites. Syndepositional exposure with water table drawdown is not common, but does occur	Pelagic settling of cumulates and rafts, dense brine underflows, turbidity currents in density stratified brines. Massive beds of inclusion-free coarsely crystalline bottom growths at the base of unstratified saturated brine bodies
Holocene depositional analogs	Sabkhat, salt pan, salina	Salt pan, salina	Some aspects of deepwater brine lakes (esp. Dead Sea)
Lateral extent and wireline correlation	Whole unit is laterally continuous, but it exhibits strong lateral variability in proportions and distributions of internal salt masses. Tendency to be matrix-rich and show a "spiky" signature in conventional wireline logs. Conventional wireline not calibrated to core can be confused with reflux-generated evaporite cements	Good lateral continuity of whole bed. In a marine shelf this can extend over the whole extent of underlying platform. Good lateral continuity of various internal salt horizons within a saltern unit. Tendency to be evaporite-rich with little matrix and show "blocky" signatures in conventional wireline logs, which can be similar to slope and basin	Good lateral continuity of bed. Internal salt units tend to be laterally continuous in deeper parts of basin and individual layers in laminites can extend for 50-100 km. Slope units tend to show less lateral continuity. Tendency to be matrix-poor. Conventional wireline signature similar to saltern. FMI can be distinctive

Table 5.3. Characteristics of depositional systems that define ancient evaporites. deposits

up or was blown to another locality on the mudflat, it left behind a freshly deposited salt crust exposed to the vagaries of air, sun, wind, haloturbation and diagenesis. Ongoing exposure and deflation of the mudflat surface created Stokes surfaces, drove additional precipitation of intrasediment salts, exposed earlier carbonate crusts, altered gypsum to anhydrite, and meant the partial or complete dissolution of early brine sheet crusts. Throughout, the aggrading mudflat periodically captured influxes of eolian silt blown in from adjacent dry mudflats.

Somewhat longer-term ponding of brine sheets (months to years) occurred within local depressions to form small shallow brine lakes (salinas and pans) atop the mudflat. Water bodies were a few to tens of kilometres across and a few dm to metres deep (Figure 5.5a). Resulting salt crusts and subaqueous beds were purer and somewhat thicker (>1-2 metres) than time-equivalent intervals of capillary salts accumulating in the subaerial surrounds. Such purer units are resolvable in the vertical perspective of a conventional wireline log, especially in an image log, but are not readily correlated using logs from well to well. Overall the matrix-rich evaporite mudflat log is a distinguishable wireline signature. But, if it is not calibrated to core or to an image log, it is readily confused with units of open marine carbonate plugged by evaporite cements precipitated during brine reflux (see Chapter 10).

The term tidal-flat or peritidal evaporite is inappropriate in describing these gigantic epeiric/continental mudflats. Yet, marine-edge terminology is widely used by some sedimentologists in describing ancient evaporitic mudflats. They base its application on textural comparisons with the coastal sabkhas of Abu Dhabi. But as we saw in Chapter 3, nodular and displacive sabkha salts form in capillary settings ranging from continental lacustrine to coastal. Capillary salts, even in the classic sabkha, come mostly from resurging deeply-circulated groundwaters, a transport and emplacement mechanism that is independent of any possible tidal association in some of the matrix. Plus, the huge lateral extent of ancient mudflats, typically constituting the edges of huge interior seaways or shallow brine lakes, meant there was little or no tidal exchange with open ocean waters (Hallam, 1981; Warren, 1991). Strandplain or strandzone evaporite is apropos in describing the vast expanses of ephemeral water in ancient evaporitic mudflats.

Examples of evaporitic mudflat-dominated deposits include; Sequence 4 in the Upper Triassic Argilo-Gréseux Inferieur of the Berkine Basin, Algeria (Turner et al., 2001); the Minnelusa Formation in Wyoming (Achauer, 1982); the seal facies in the Permian Basal Seven Rivers Formation in Yates field, west Texas

(Warren, 1991); the northern regions of the Palo Duro Basin during deposition of the Upper San Andres Formation, Texas Panhandle (Hovorka, 1987); the more landward parts of the Lower Clear Fork Formation of Texas (Handford, 1981); the Cambrian Red Heart Dolomite of the Georgina Basin, Australia (Nicolaidis, 1995); the Archaean Wittenoorn Dolomite of the Hamersley Group, Western Australia (Kargel et al., 1996).

Saltern describes extensive shallow-subaqueous evaporite beds (5-50 m thick) deposited across hundreds of kilometres in the hypersaline portions of an ancient evaporite lake or seaway (Warren, 1991). Deposition took place in both marine-fed and continental settings (Figure 5.5b; Table 5.3). Unlike evaporite mudflats, units tend to lack matrix within the stacks of salt layers that constitute the unit. Internal textures range from aligned crystals layers, or their ghosts, which preserve little evidence of syndepositional exposure through to stacks of salt pan crusts separated by abundant dissolution surfaces.

Unlike the sabkha, pan and salina components of an evaporitic mudflat, there are no modern counterparts for salterns in terms of scale or location. Salterns formed in extensive salt-depositing seaways that covered former open marine platform carbonates or accumulated on 100 km+ wide evaporite shelves about the edges of giant deep brine seas (Figure 5.6). Even so, most saltern texture can be interpreted using analogous textures in subaqueous salt beds in Quaternary lakes (Chapters 1 and 4).

Individual beds were precipitated from meromictic perennial brine sheets that were a few tens of centimetres or more deep and were originally accumulations of growth aligned crystals, rafts, clusters and crusts. Horizontal laminae in calcium sulphate beds were often crosscut or interrupted by coarse-grained to giant, vertically aligned crystals of calcium sulphate or halite. Primary sulphate textures were altered and recrystallised syndepositionally or during burial into nodular and coarsely crystalline textures. Primary halite chevron textures tend to be retained as remnants in a variably recrystallised matrix of halite spar. The end result of saltern deposition is a number of superimposed shoaling-upward beds (parasequences) composed of one or two dominant minerals, usually halite or gypsum (now nodular anhydrite).

Smaller crystals can be reworked by storms into subaqueous traction deposits characterized by graded and reverse-graded beds, rippled and crossbedded layers, and algal rip-up structures. The graded beds and the rippled layers probably recorded waning storm-flood conditions (Hardie and Eugster, 1971). Reverse-graded mechanical beds recorded either episodes of

Figure 5.5. Depositional geometries of: A) evaporitic mudflat and B) saltern (after Warren, 1989, 1991). Both can occur in ramp or platform settings, the notation XYZ refers to the ramp subdivisions of Irwin (1965).

storm surging (increasing energy levels) across the saltern, or episodes of brine dilution that had slowed precipitation, so that coarser crystal overgrowths came to dominate the upper part of the lamina or layer.

Freshening of saltern waters to where salinities were undersaturated with respect to halite or gypsum created thin cm-dm mudstone to wackestone layers (calcite or dolomite) entraining intraclast breccias, tepees, pisolites, cross beds, crystalgalaminites, micritic domal stromatolites, often with numerous pellets coming from brine shrimp and ostracodes or other opportunistic halotolerant species. Mud interbeds can also preserve rare vertebrate tracks.

Using shallow-looking conventional wireline logs (e.g. PEF or MSFL), a saltern is typically resolvable into internal beds of relatively pure cyclic sets (parasequences). Core and image logs show cycles are typically shoaling cycles (e.g., domes passing up into laminites) with decimetre to metre scale layering that can be traced over large well to well distances. The relative purity (>95% salts), greater thickness of bed cycles and improved lateral continuity gives saltern beds a blocky wireline signature that frequently allows their distinction from evaporitic mudflats when using wirelines for subsurface correlation (Table 5.3). Mapping this distinction can be an important reservoir quality indicator (Figure 10.37).

Ancient examples of saltern deposits include the Cretaceous Ferry Lake Anhydrite in the northern Gulf of Mexico (Pittman, 1985), the ramp interior evaporite cycles of the Early Cretaceous of the Caohuila platform (Lehmann et al., 1998), the P_1 and P_2 evaporites of the San Andres Formation on the northwest shelf of the Permian Basin, the Lower San Andres Formation of the Texas Panhandle (Elliott and Warren, 1989), the upper Visean anhydrites of southern Belgium (De Putter et al.,

1994), and the Hith Anhydrite of the Middle East (Azer and Peebles, 1998).

Deepwater evaporites accumulated beneath deeper brines of lacustrine and basinwide evaporite successions and encompass the slope, rise and basin deposits (Figure 5.6). Fine-grained halite or gypsum laminites accumulated in the central deeper parts of a density-stratified basin, they were intercalated with less saline salts, as well as with carbonate or organic laminites. The fine layering reflects change in the saturation states of the surface brines or variations in the rate of sediment supply and grain size from the more marginward slope deposit feeds (Figure 5.6a). These “deepwater” laminites accumulated in two main ways; 1) as “rain from heaven” with crystallites first forming in the upper supersaturated metre or two of the brine column and then settling to the deep brine seafloor, 2) as the distal ends of evaporite turbidites and debris flows that characterise the slope and rise in basinwide deepwater settings. Slope deposits accumulate up-dip from the laminites of the basin floor and are mechanically reworked from saltern or mudflat parent. They are characterised by textural associations typical of deeper water in all sedimentary basins and include; turbidite fans, Bouma cycles, slumps and debris flows, sole marks, tool marks, scour and fill, ball and pillow structures. All are relatively high energy features intercalated with laminites deposited during times of quiet bottom settle-out.

Studies of basin-centre and slope evaporites in the Permian of the Delaware and Zechstein basins, the Visean evaporites of the Canadian Atlantic, and the Miocene of Red Sea rift in the Yemen Republic, the Messinian of Spain and the Apennines indicate these ancient deepwater sequences can be interpreted in much the same way that deepwater deposits are interpreted in carbonate and siliciclastic depositional systems (Anderson et al., 1972; Clark, 1980a, b; Richter-Bernburg, 1986; Schlager and Bolz,

1977; Schenk et al., 1994; El Anbaawy et al., 1992; Rouchy et al., 1995; Peryt, 2000; Orti et al., 2003; Roveri et al., 2001). The main difference when compared to other deepwater clastics relates to water depth and the relative importance of “rain from heaven” versus resedimented shelf deposits in depositing the fine laminites of the basin centre.

Interpreting an ancient evaporite as deep water is more difficult than separating subaqueous and subaerial depositional styles (Warren and Kendall, 1985; Warren 1985). A lack of a benthonic microfauna, similar conventional wireline signatures and varying degrees of drawdown during deposition of thick interlayered coarsely crystalline and laminated evaporite sequences, means water depth determinations are difficult in ancient slope and basin evaporites. Varying intensities of drawdown as evaporites accumulate in a basin centre plays havoc with the assumptions of rates of water level change that are inherent in estimating water depths in open marine deposits. Unlike marine basins where sealevel tends to fluctuate tens of metres above and below the shelf break, brine surfaces in basins accumulating evaporites in drawdown basin centres can be 2 km or more below sealevel and the position of the shelf break prior to basin isolation, and it can happen in the space of a few tens of thousands of years.

Using a deep “water full” basin model, Richter-Bernburg (1957) estimates water depths of more than 1000 metres for anhydrite laminites in the centre of the Permian Zechstein basin. Subsequent work by Schreiber (1988a) postulates a minimum relief of 100-200m for the shelf to base-of-slope transition during anhydrite deposition. Warren (1989, 1991) argues that determinations of deep versus shallow in a drawdown basin are difficult, but favours water depths of no more than 100-200m. Kendall (1992) argues deepwater evaporites typically form in water depths greater than 20-40 metres; but, like Warren (1985), notes that “deepwater” sulphate laminates can form in brines less than a few metres deep. The mechanism driving resedimentation

Figure 5.6. Depositional setting and characteristics of deep water evaporites. A) Depositional spectrum accumulating beneath deep and layered brines. B) Depositional spectrum accumulating beneath a deep holomictic and saturated brine column (see Chapter 4).

in “deepwater” salts is also contentious; Schlager and Bolz (1977) favour turbidity currents, while Clark (1980a) favours a control by storm surge instability (Figure 5.6a).

Unlike deepwater anhydritic laminites, resedimented ancient halites are not widely recognised and their interpretation in ancient salt beds typically stems from their entrained nonevaporite clasts, rather than from textures in any finely layered halites (Czapowski 1987). One of the better-documented examples of platform halite being redeposited into deeper water is the halite breccias and olistoliths in Middle Miocene evaporite in the Wieliczka and Stebnyk salt mines of Poland (Peryt and Kovalevich, 1997). There, the salt breccia is interpreted as a series of subaqueous fans, with redeposition of the originally shallow water halite into deep water, driven by vertical tectonic movements and the northward advance of the Carpathian Nappes. Water depths at the time of halite deposition are interpreted to have been between ten and tens of metres deep. Others have interpreted the same mine sequence to be halokinetic.

In understanding ancient deepwater evaporites and reliably tying down water depths, a significant problem is that there are only two Holocene settings, both continental lakes, where “deep water salts” are accumulating in waters deeper than 30 metres (Dead Sea halite and Canadian mirabilite). The deepwater sediments in almost all modern saline lakes are carbonate laminites. Modern deepwater analogues accumulate in small steep sided continental depressions, while deepwater ancient evaporites accumulated across the flat floors of broad drawdown marine basins with no modern counterpart. If we take the two Holocene examples as direct analogues they show the following: Massive beds made up of coarsely crystalline meshworks of sodium sulphate salts are accumulating beneath 30 m deep brine columns in small salt lakes in the interior of Canada (Chapter 11; Last, 1994). Finely-laminated bottom carbonates alternating with massive crystalline halite beds are accumulating on the floor of the Northern basin of the Dead Sea (≈ 300 m deep brine).

Using the current textures in the Dead Sea and Canada as a process analog we should add another style of deepwater evaporite; namely, beds made up of rapidly deposited, coarsely crystalline, meshworks of prisms. The prisms accumulate on stable bottoms and so show little upward crystal orientation with a characteristic lack of inclusion-rich layering in individual prisms. These beds indicate times when the deep brine column was holomictic and saturated with respect to the salt of interest (Figure 5.6b). From strandzone to deep basin floor, this coarsely crystalline halite is a lakewide time-synchronous holomictic unit.

Laminites probably indicate periods when deep bottom brines in the centres of many ancient evaporite basins were density-stratified, sediment starved and anoxic, or at best dysaerobic for long periods (Kirkland and Evans, 1981; Hite and Anders, 1991). The resulting cumulates often entrained significant volumes of pelagic organic matter and, with suitable burial, yielded hydrocarbons or ultimately were converted to graphitic schists. The bottom sediments in the deepwater gypsum of the Gibellina Basin contain up to 7% TOC, similar elevated levels occur in the mesohaline laminite of the Paradox basin. At present the organics entrained in the evaporitic carbonates of the Sicilian basins are still thermally immature, while those in the Paradox are mostly locked in place by pervasive diagenetic salt cements. The evaporite association of many of these deepwater meromictic pelagics means their potential to act as source rocks is limited to a few particular settings (Figure 9.3).

Evaporites: broad scale models

Saltern and mudflat beds, along with varying development of slope and basin deposits, occur in three interrelated regional depositional settings:

Platform evaporites: Stratiform beds typically <50 m thick and composed of stacked <1 to 5 m thick parasequences or cycles with a variably present restricted marine carbonate base. Salts were deposited as mixed evaporitic mudflat and saltern evaporites, sometimes with local accumulations of bitterns. Typically they were deposited across large marine platform areas that pass basinward into deeper water sediments (Figure 5.7a). In marine-margin epeiric settings, such as the Jurassic Arab/Hith and Permian Khuff cycles of the Middle East, these platform evaporites are intercalated with shoalwater marine-influenced carbonate shelf/ramp sediments, which in turn pass basinward across a subaerial sill into open marine carbonates. Landward they pass into arid zone continental siliciclastics or carbonate mudflats. Platform salts intercalated with open marine to restricted marine platform carbonates are termed marine-fed platform evaporites. The intimate association between potential reservoir (frequently reflux-dolomitised limestone) and seal (platform evaporites) in many marine platform evaporite settings has created many of the giant and supergiant Jurassic and Permian oil and gas fields in the Middle East and the Permian Basin of west Texas (Chapter 10). Platform evaporites, often without intercalated carbonate beds, also form shallower circum-basin belts around a deeper water basin-centre in basinwide/(saline giant) systems (Figure 5.7b; e.g. Werra Anhydrite in the Zechstein Basin).

Basinwide evaporites Thick, basinwide units > 50-100 m thick of deepwater/shallow water evaporites retain textural evidence of different but synchronous depositional settings, including mudflat, saltern, slope and basin (Figures 5.6, 5.7b). When evaporite deposition took place, the whole basin was evaporitic typically saturated with the same mineral phase across large areas of the basin (as when halite today forms halite chevrons on the pans and coarse inclusion-poor crystal meshworks on the deep basin floor of the Dead Sea). Bittern salts sometimes accumulate during the most isolated times in the basin's drawdown history, typically in depressions with minimal surface water influx, either in the lowest parts of the basin centre, or in platform depressions behind the shelf break (Chapter 11).

Continental playalacustrine deposits These are constructed of stratiform salt units, typically with the greater volume of gypsum and halite deposited in evaporitic mudflats and salt pans, rather

Figure 5.7. Ancient evaporite settings that have no modern analogues. A) Platform evaporites. B) Basinwide evaporites (see text for explanation).

than in perennial lakes (Figure 5.8). Total thicknesses range from metres to hundreds of metres, with lateral extents measured in tens to hundreds of kilometres (Figure 5.3). Such salt beds are separated and often surrounded by deposits of lacustrine muds, alluvial fans, ephemeral streams, sheet floods, eolian sands and redbeds. Typically the salts accumulated in endorheic or highly restricted discharge basins. Basins typically have a shallow water table in the saline mudflat area and a lowermost depression with ephemeral ponded brine pans. Perennial saline lakes formed during more humid periods in the same depression or in parts of the lake floor located below the regional water table (moat facies). Evaporite mineralogy was dependent on composition of inflowing waters; suitable settings accumulated thick sequences of trona, glauberite and thenardite as well as more typical sequences of halite and anhydrite. High water stage perennial sediments tend to be carbonate-rich or silica-rich (diatomaceous) laminites. Ancient examples include the Eocene Green River Formation of Wyoming and the Permian Pingdiqian Formation of the Junggar Basin, China.

Let us now look in a little more detail at sedimentological characteristics that allow a determination of depositional setting of these three ancient evaporite groupings.

Lacustrine evaporites

According to the degree of accommodation space, all ancient lacustrine deposits can be subdivided into 3 types: underfilled, balanced and overfilled (Figure 5.8; Bohacs et al., 2000). Accommodation is the space available for sediment accumulation

below the basins outlet or spill-point. The type of lake is defined by how much of that space is filled by some combination of sediment + plus water over a particular time span. Hence climate (≈ sediment supply + water depth and permanence) and tectonics/inherited topography (≈ potential accommodation) exert coequal controls on the nature and distribution of the various lacustrine deposits. Changes in climate or tectonic subsidence means ancient lacustrine basin fill can evolve from one lake type to another a number of times in the infill history of the basin (Lambiase, 1990).

The fluvial-lacustrine facies association that occurs in overfilled (humid) lakes is composed of marlstone, argillaceous coquina and bioclastic grainstone, along with widespread sandstones, carbonaceous mudstones and coals with a freshwater fauna. Beds retain mixtures of aquatic and terrigenous organic matter and most sedimentary textures are physical, not biogenic (Figure 5.8; Bohacs et al., 2000). The fluctuating-profundal lacustrine facies association is common in balanced lakes and is made up of a complex of interbeds of heterogenous lithologies including carbonates, siliciclastics, argillaceous and organic rich mudstones, with a fresh to saline water biota. Dominantly aquatic organic matter is found in beds and bedsets, while sedimentary structures are typified by a combination of physical and biogenic features.

Evaporitic lacustrine facies typically accumulate in underfilled basins, with lithologies ranging across clastic sandstone and carbonate grainstones, kerogenites (oil shales) and evaporites. Widespread shoalwater evaporites typically fill the lowermost parts of the basin during the most arid or underfilled times in the lake history. Halophilic organic matter can accumulate in moat facies at that time, or halotolerant organic remains can accumulate across larger parts of the lake floor when water levels are somewhat higher and fresher (Chapters 4 and 9). Sedimentary structures include both physical and biogenic structures, as well as textures indicating periodic desiccation (mudcracks) and crystallization (cumulate, growth-aligned and displacive textures).

Lake type & lacustrine facies association	Stratigraphy	Lithologies	Sedimentology	Organic matter	Kerogen-hydrocarbon characteristics
OVERFILLED  Fluvial-lacustrine facies association	Maximum progradation:  • parasequences related to lateral progradation (relatively stable) • maximum fluvial input	Terrigenous sediment dominant • mudstone, marls • sandstone • coal, coaly shale • coquina (isolated highs in basin)	Physical sedimentation dominant: • ripples, dunes, flat bed • root casts • burrows (infaunal and epifaunal)	• freshwater biota charophytic and aquatic alga OM • low to moderate TOC • terrigenous and algal biomarkers	• mixed type I-III kerogen • both oil and gas generative • very waxy, low sulphur oils
BALANCED FILL  Fluctuating-profundal facies association	Mixed progradation & aggradation  • distinct shoaling cycles common • fluvial input variable	Mixed chemical and terrigenous sediment: • marl, mudstone • siltstone, sandstone • carbonate, grainstone, wackestone, micrite • kerogenite	Physical & biogenic sedimentation: • flat beds, • current, wave and wind ripples • stromatolites, pisolites and oncolites • mudcracks • burrows (epifaunal)	• saline tolerant biota aquatic algal OM minimal land plant • moderate to high TOC • algal biomarkers	• predominantly type I kerogen, type I-III mixtures near flooding surfaces • mostly oil generative • paraffinic but relatively nonwaxy oils, low sulphur
UNDERFILLED  Evaporitic facies association	Maximum aggradation minimum progradation  • high-frequency wet-dry cycles • minimum fluvial input • maximum evaporite input	Chemical sediments dominant: • mudstone, kerogenite • evaporite • siltstone, sandstone • grainstone, boundstone wackestone, micrite • flat-pebble conglomerate	Chemical, biogenic & physical sedimentation: • cumulative textures • disjunctive fabrics • stromatolites, pisolites and oncolites • climbing ripples • flat beds • eolian cross beds	• low diversity halotolerant to halophilic biota • algal-bacterial OM • low TOC in oxidised margins • high to very high TOC oil shale in basin centre • "hypersaline" biomarkers	• type I kerogen • mostly oil generative • paraffinic oils, moderate to high sulphur

Figure 5.8. Attributes of the three major styles of lacustrine basins (after Bohacs et al., 2000).

Studies of sizes of modern lakes of all three types, their water depths and the character and thickness of ancient counterparts typically do not correlate with measured or inferred climatic humidity (Bohacs et al., 2000). Interestingly, the drainage basins of the world's largest rivers contain no large lakes, only a few relatively small ones (e.g., Amazon, Congo, Orinoco and Mississippi River basins). Ancient lake systems show a similar lack of correlation between lake size, climate and fluvial volumes (Carroll and Bohacs, 1999). Of the three types of ancient lakes, the focus for the remainder of this section is on the underfilled or evaporitic lakes. For further discussion of the sedimentology of other two lacustrine associations, the interested reader is referred to the excellent review paper by Bohacs et al. (2000) and the references therein.

Ancient saline lacustrine deposits range in age from Neogene to Precambrian (Table 5.4). Facies patterns and distributions in saline lakes are different from marine carbonate or siliciclastic-filled basins as; 1) the depositional base level changes much more rapidly in lakes and with much higher amplitudes, 2) salinity is not constant. As was documented in the various saline lake/playas discussed in chapters 3 and 4, water/brine depth and lake salinity can change hundred of metres in less than a few thousand years, from a highstand deep perennial fresher lake accumulating deepwater chemical laminites, along with lake-plain and highstand deltas, to a shallow or ephemeral lake made up of small saline pans on broad salt flats and mudflats. In Lake Van, Turkey, there was a change of 600 m

in 2-3 thousand years, Lake Malawi in the East African rift dropped as much as 140 m in just 340 years (Owen et al., 1990) and the lake level in the Dead Sea is currently falling at similar rates. Changes are related to local climate and uplift and, unlike the base level changes in marine eustacy, do not show time synchronous change tied to worldwide climate mode (icehouse versus greenhouse). Facies analyses tied to dated

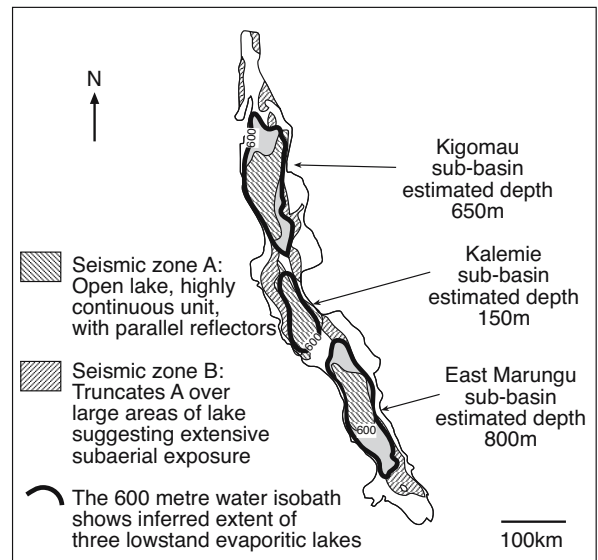

Figure 5.9. Subdivision of Lake Tanganyika into three separate sub-basins during a mid- to late-Pleistocene lowstand (after Tiercelin and Mondeguer, 1991).

cores in Lake Tanganyika, Africa, show the current lake was made up of three separate saline lakes when water levels were lower in the mid to late Pleistocene (Figure 5.9). Compared to Lake Tanganyika, Lake Magadi and Salar Uyuni show the

opposite effects in terms of timing of late Quaternary high water in that their current salt pan surfaces are some tens of metres below what were the much higher lake water surfaces in the late Pleistocene.

Table 5.4 continued. Some representative examples of Pre-Quaternary saline lake deposits (underbalanced systems).

Vertical changes in facies and lithologies are abrupt in many ancient saline lake systems, a reflection of these rapid high amplitude changes in water levels. Large falls in lake water level lead to “hanging” deltas and terraces along with deep incisions through highstand Pleistocene deposits. In arid lowstand lakes, newly exposed lake floor sediments can be overprinted by subaerial weathering and the processes of soil formation. Exposed lake floor laminites can be sabkharized, as is happening today in Salt Flat Playa, west Texas (Hussain and Warren, 1989).

Intuitively, many sedimentologists assume that climate is the major control on water depth and salinity in a saline lake basin. That is, larger deeper lakes with thicker lake sediment packages should accumulate in wet or humid climatic periods, while drier saline periods should be characterised by saline deposits with lesser aerial extents. But the hydrology of all lake basins, including endorheic basins, is never truly closed and varying degrees of reflux and leakage play significant roles in the final salt distribution (Chapter 2). Concurrent saline lakes in Turkey or the African Rift Valley can range from hypersaline to brackish in intermontane valleys located only a few tens of kilometres apart. Assuming all ancient lakes in an area are arid or humid at the same time is not a valid approach to correlation of salt beds in adjacent saline lake basins.

Eocene Lake Gosuite, USA

Lacustrine sediments deposited in Eocene Lake Gosuite are preserved in the Green River Formation, which has several

members corresponding to major lake high- and low-stands, each of which probably lasted several hundred thousand years or more. Saline lacustrine phases of the Green River Formation, such as the Wilkins Peak Member, have two main modes. Lake high-stands are marked by oil shales (laminated dolomitic kerogenites). Lowstands, when water covered areas of the lake contracted and salinity increased, are indicated by salt beds of saltern/pan trona or halite deposited atop the oil shale layers. Dolomitic mudstones were deposited during lowstands as subaerial evaporitic mudflats across over the dried and exposed lake floor. These strandzone to shoalwater carbonates are made up of structureless to laminated muds, algal dolomudstones algal boundstones, oolitic pisolitic grainstones and ostracode grainstones, which a comparison to the massive unit in the Holocene Coorong lakes show are mostly ephemeral to strandzone indicators. Sandstone and siltstone line the basin edge and may be present as thin interbeds in the kerogenites. Roehler (1993) identified 77 depositional cycles of mudflat/kerogenite in cores from the Wilkins Peak Member. Based on an estimated duration of 1.6 My for the member, he calculated an average period of 21 kyr for the cycles and suggested they were probably caused by the earth’s precession, which has periodicities of 19 and 23 kyr.

The oil shales (kerogenites) are composed of mm-scale alternations of amorphous algal organic matter (kerogen) and slightly thicker laminae of carbonate (mostly dolomite) and clay. TOC content can exceed 25%. Comparisons to laminites accumulating in the various Quaternary saline lakes detailed in Chapter 4 means most authors now agree the Eocene kerogenites of the

Green River Basin indicate highstand conditions (Figure 5.10). But the definition of “deep” for the water depths accumulating kerogenite varies from author to author. The thickest beds of oil shale tend to occur toward the basin centre and some oil shale intervals are laterally extensive, perhaps indicating deposition at the bottom of a substantial body of perennial lake waters. Toward the basin margin the oil shales change to marlstones, kerogen-rich marlstones and lean oil shales (Hite and Anders, 1991). Basin centre oil shale accumulations can also contain diagenetic dawsonite, halite and nacholite (Dyner, 1981). They may also entrain mud-cracked horizons and solution breccia beds. To interpret the shales, some authors focus on the large lateral extent of the finely-laminated kerogenites and infer deposition at the bottom of a deep stratified water mass with density-stratified permanent waters more than tens of metres deep (Bradley and Eugster, 1969; Desborough, 1978; Dyner, 1981). Others focus on the intercalation of the oil shales with evaporites and subaerial indicators, along with the dolomitic nature of the matrix and propose a shallow lake/saline pan

depositional model for the widespread kerogenites (Eugster and Surdam, 1973; Smoot, 1983).

Changes in Lake Gosuite water levels may mean the highstand sediments of kerogenite have a somewhat greater areal extent than the salts (Figure 5.10a), but their deposition on the floor of a perennial body of water does not mean they also show greater thicknesses. The freshest “lake-full” organic-enriched sediments of the Green River Formation in Wyoming are actually the thinnest and least aerially extensive of the various members of the Green River Formation (e.g. Luman Tongue). In contrast, the Tipton and Laney members, which accumulated as varved oil shales beneath more saline meromictic lake waters have greater extents and thicknesses (Figure 5.10b; Hite and Anders, 1991).

Within the saline lake phase, those sediments deposited when the lake was at its driest (the Wilkins Peak Member), were deposited much more rapidly than the perennial saline lake

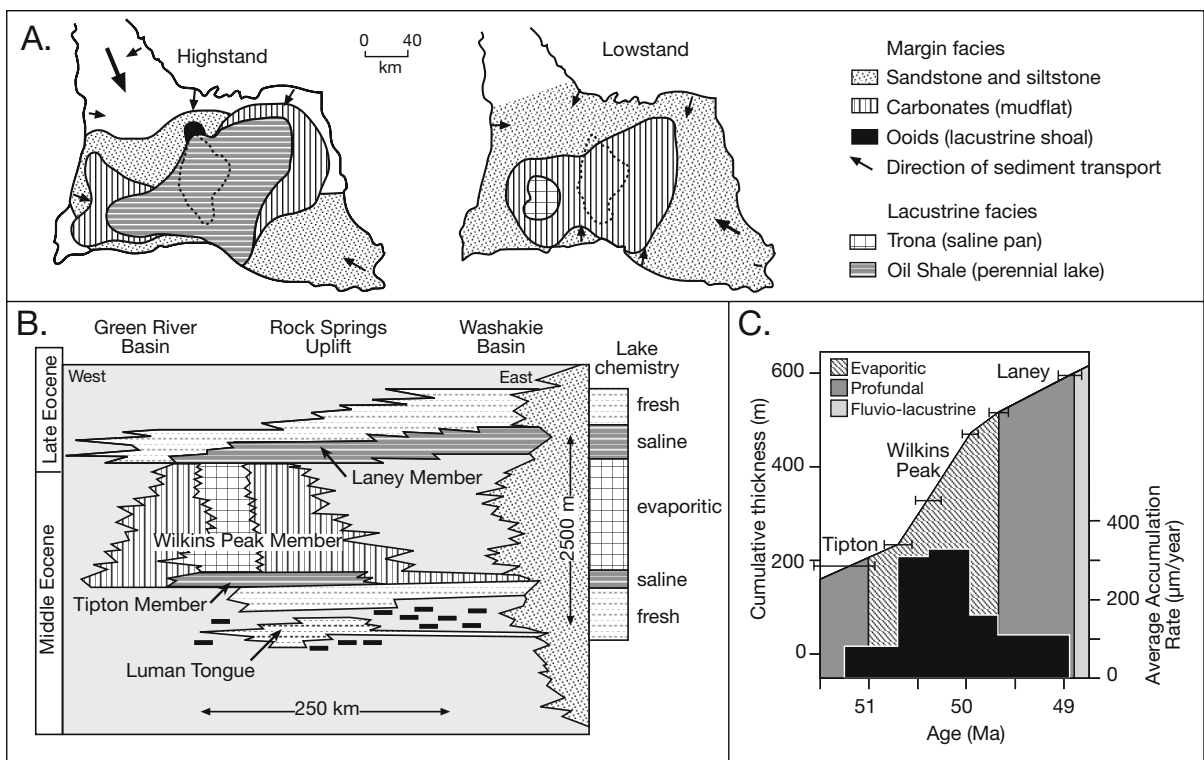

Figure 5.10. Lithofacies distribution of Eocene Lake Gosuite as preserved in the Green River Formation, Wyoming. A) Wilkins Peak time showing highstand conditions with extensive accumulations of oil shale beneath the salinity-stratified waters of a perennial lake versus lowstand conditions when carbonate mudflats dominated and trona was precipitated beneath very shallow to ephemeral waters of a hypersaline brine lake (after Surdam and Wolfbauer, 1975). Dashed line outlines the approximate position of the Rock Springs Uplift. B) Schematic E-W cross section showing lateral extents and thicknesses of various lacustrine units (after Bohacs et al., 2000). C) Average sediment-accumulation rates for the Green River Formation based on a reference section in the southern Greater Green River Basin (after Smith et al., 2003).

laminites either of the Tipton or Laney members. $^{40}\text{Ar}/^{39}\text{Ar}$ based accumulation rates of Smith et al. (2003) are direct measurements of accumulation rates and do not rely on lamina counts being annual varves (Figure 5.10c). For a reference section near the southern Green River Basin depocentre they calculated accumulation rates of 88 ± 34 and $104 \pm 18 \mu\text{m}/\text{yr}$ for the Tipton and Laney members; both values are consistent with an annual origin for the laminae. A much faster accumulation rate emerges from the Wilkins Peak Member. In the same reference section they calculated a net average rate of $327 \pm 85 \mu\text{m}/\text{yr}$, which is three times as fast as for the Tipton or Laney Members.

Their observation of faster accumulation rates is in accord with U-series disequilibrium-based results from Quaternary playa-lake evaporites. Ku et al. (1998) found that accumulation rates in a core from Death Valley were much higher for the salt-pan evaporite facies than for perennial lake muds, and Bobst et al. (2001) noted that accumulation rates during dry phases of the Salar de Atacama were up to three times as high as during wet periods (see Chapter 3). Net accumulation rates in these cases range between 0.5 and 1.8 mm/yr, which are up to five to six times faster than deposition of the Wilkins Peak Member. However, higher rates of Wilkins Peak Member evaporite accumulation may have occurred in the basin's subsurface depocentre, which lies to the west of the reference section (Smith et al., 2003).

Evaporitic sediments of Wilkins Peak Member, which accumulated at a time when the lake's waters were at their shallowest (perennial saline lake) and saltiest (pan/mudflat), are stratigraphically the thickest member of the Green River Formation (Smoot, 1983). This more saline lacustrine phase separating the kerogenites is enriched in sodium bicarbonate minerals such as trona and nacholite in layers and is discussed in more detail in Chapter 11.

The alternation of playa and perennial lake modes explains accumulations of hydrogen-prone organics as oil shales in many saline lacustrine systems (Table 9.1). Boyer (1982) argues that hydrogen-rich oil shales in the Green River Basin accumulated beneath an anoxic lower brine layer in a density-stratified meromictic and relatively shallow saline lake. It was created and maintained by ongoing dissolution of underlying pan evaporites, especially trona/halite. He named this evaporite-induced stratification, ectogenic meromixis. If true, then accumulations of very thick oil shales in the Laney Member of the Bridger-Washakie basins and the Mahogany Bed of the Uinta-Piceance Creek basins are also a likely response

to shallow subsurface dissolution lake evaporites. The lack of similar underlying soluble beds in fresher water lacustrine oil shale basins (as in Honyanchi Fm. of China and the Rundle oil shale of Australia) may help explain why the trona-associated oil shales of the Green River Fm. are unique in their very high oil content. It also explains why virtually the entire Green River fish fauna, so famous for its high quality of preservation, is made up of pelagic freshwater taxa, which flourished in the freshened upper water mass (Grande, 1980). The permanent saline anoxic bottom layer was too nasty to support anything but well adapted microbes (see Chapter 9).

Oligo-Miocene lake, Calatayud Basin, Spain

The Oligocene-Miocene Calatayud basin of Spain is a foreland basin formed by the uplift of the Pyrenean chain to the north and is bounded to the southeast by the Catalanian Coastal Range and the Iberian range to the southwest (Figure 5.11a). Thick beds of lacustrine salts accumulated in the endorheic lower parts of the basin. These deposits entrain a combination of carbonate and sulphate lacustrine environments, fed a combination of Pyrenean waters via resurging groundwaters and alluvial systems. Deposits show strong similarities in distribution patterns and textures with the lacustrine evaporites and clastic aprons of the adjacent Ebro Basin (Figure 8.10; Salvany and Orti, 1994; Arenas and Pardo, 1999).

Miocene climate fluctuated from arid to more humid, but more importantly the mountains to the North of the lake depression were composed of Triassic evaporites and Mesozoic marine carbonates. As they weathered they supplied ions for the salts accumulating in residual brines within the topographically lowest parts of the lake floor. The nearby Ebro Basin is well known for its economic accumulations of lacustrine glauberite that, as in the Calatayud Basin, largely occur in the central part of the basin (Figure 11.53b). Two distinct lake styles alternated through time: a) High lake levels associated with a single body of dilute carbonate water, where massive biogenic carbonate facies proliferated. These lakes had wide palustrine vegetated margins, where bioturbated facies dominated the depositional signature. b) Low lake levels of a playa-lake with extensive development of saline pans and mudflats surrounding a more permanent gypsum-saturated brine body.

In the drawdown or playa stage a subaerial basin floor sloped gently down from a northern marginal mudflat zone to a central saline complex. Gypsum accumulated across the lake depression as both primary beds of mechanically reworked and 'in situ' gypsarenite, as well as early diagenetic precipitates of

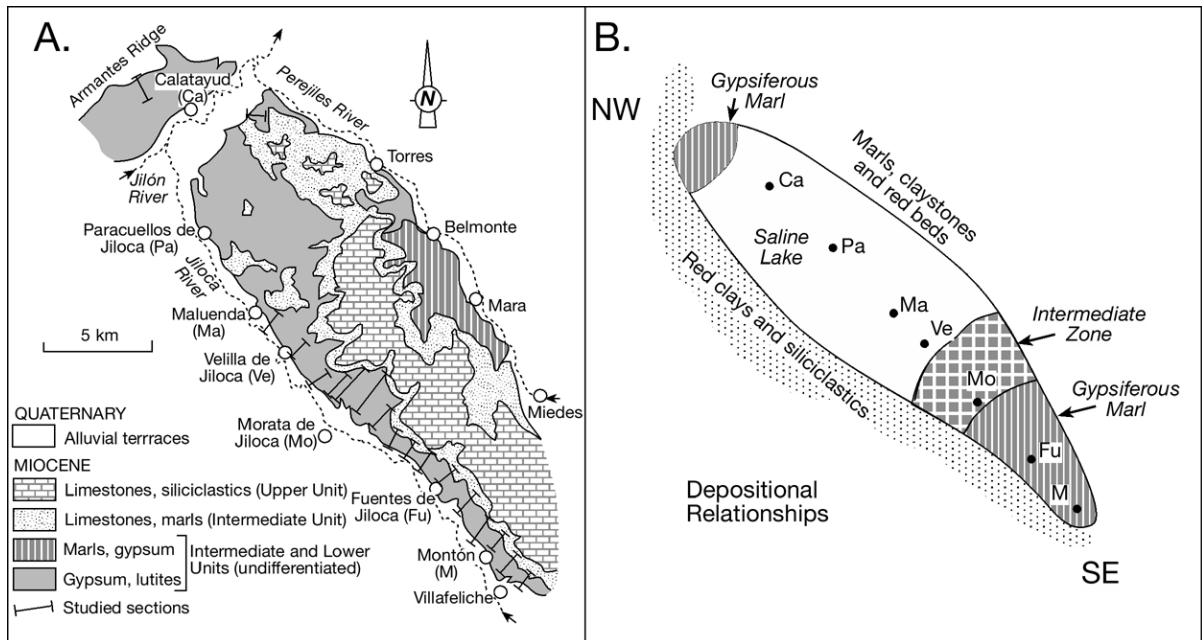

Figure 5.11. Lacustrine sediment distribution in Cataluyud Basin, Spain. lenticular anhydrite (Figure 5.11a). Surface runoff from nearby highlands constructed a bajada along the southern margin of the lake depression. But the transport of the greater volume of solute into the basin was from the north and largely subsurface, via groundwater flow through an extensive karst systems in the evaporitic Mesozoic limestones. Shallow groundwaters seeping south down the hydrologic gradient supplied increasingly fractionated and saline brines to lakes and pans all the way from the basin margin to the basin centre (Figure 5.11b; Salvany and Orti, 1994; Salvany et al., 1994; Orti and Rosell, 2000).

Calcium carbonate and gypsum precipitated in the fan edges and in marginal palustrine marshes and ponds, while substantial beds of dolomite and charophyte residues accumulated over large parts of the lake floor during more humid climatic episodes (Figure 5.11a). Many of the laminated gypsarenite beds are bioturbated, indicating periodic episodes of freshening and exposure, even as the gypsum was accumulating (Figure 5.12a; Rodriguez-Aranda and Calvo, 1998; Figure 1.23). Margin mudflats, marshes and ponds acted as preconcentrators for the shallow groundwaters seeping slowly toward the central sump of the lake centre. By the time these fractionating brines reached the central

sump, they were highly concentrated and capable of precipitating thick beds of gypsum, halite and glauberite. Much of the glauberite and polyhalite, along with some of the gypsum, was an early diagenetic interstitial precipitate, created by capillary evaporation of cross-seeping brines. The halite beds were predominantly primary saline pan units, composed of hoppers and chevrons interbedded with laminated primary gypsum (Figures 5.12a, 11.53b).

The whole Oligocene Miocene lacustrine succession in the Cataluyud Basin is made up of six 100-200 m thick cycles. The lower part of each cycle commences with beds of saline lake salts (including glauberite) that show typical playa mudflat/pan textures and have the greatest lateral extent (Figure 5.12b; Orti and Rosell, 2000; Salvany and Orti, 1994; Arenas and Pardo, 1999). Saline facies then shrink toward the basin centre as the lakes evolve into a freshened palustrine stage, until the top of each cycle is dominated fine-grained siliciclastics and alluvial fan sediments, which reflect progressive progradation of alluvial fans into the lake centre. The tops of some cycles are composed entirely of clays and fine-grained clastics. Depocentres of successive cycles shift toward the north over time, suggesting the ultimate control on the cyclicity was tectonic, not climatic.

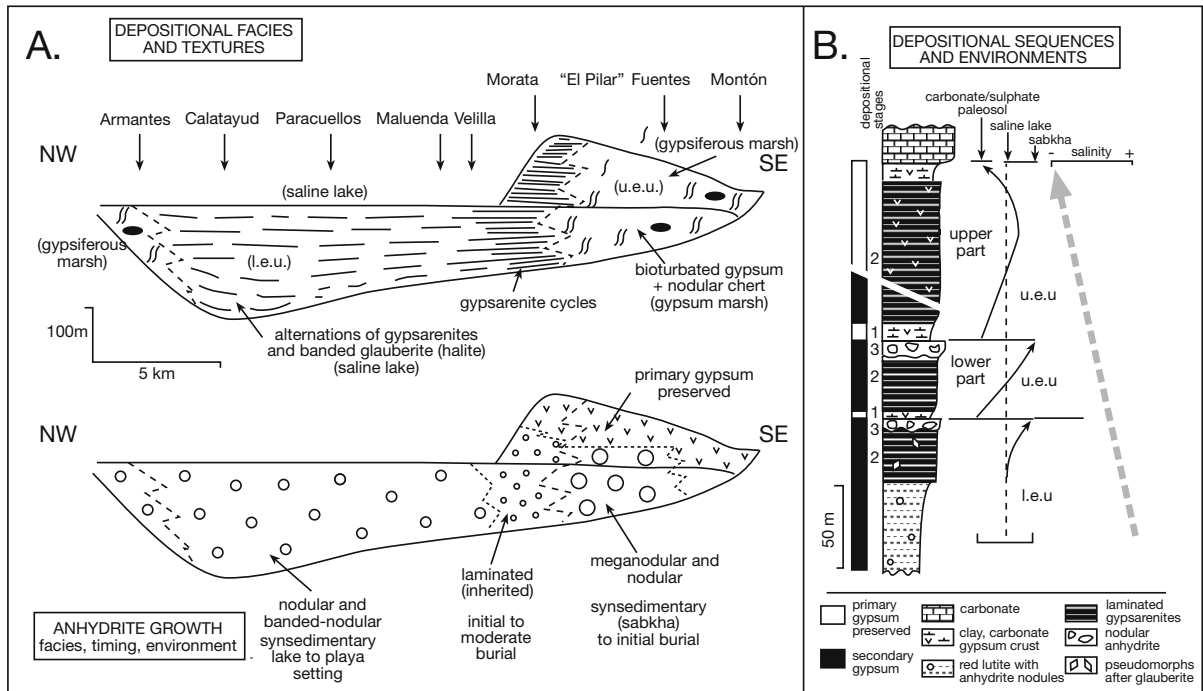

Figure 5.12. Lacustrine evaporites in the Calatayud Basin, Spain. **A)** Depositional facies distribution and their differential conversion to anhydrite: l.e.u., lower evaporite unit; u.e.u., upper evaporite unit (See Figure 5.11 for location of sections and Figure 11.53b for depositional style). **B)** Depositional sequences and evaporite units in the area of the village of Morata. Salinity arrow indicates a decrease in the ionic concentration of the parent brines with time. The lower part of the upper evaporite unit shows a complete depositional cycle with associated salinity increase. Depositional stages: (1) dilution stage: gypsiferous-calcareous horizon (carbonate-sulphate palaeosol); (2) concentration stage: laminated gypsarenite (saline lake); (3) subaerial, hypersaline stage: nodular anhydrite (sabkha) (after Orti and Rosell, 2000).

Much of the Miocene evaporitic sediment in the Calatayud Basin outcrops or subcrops along the southwestern part of the basin where it is liable to rapid karstification and collapse. The proximity to groundwater crossflow throughout the late Tertiary period means many primary evaporite textures in the basin have been diagenetically overprinted at various times in its burial and uplift history (Orti and Rosell, 2000). In the gypsiferous marsh facies, the dominant, massive, bioturbated gypsum was partly replaced very early in the sediment history by syndepositionary chert nodules and siliceous crusts (Figure 5.12a). In the saline lake facies, a replacement of portions of the laminated glauberite by anhydrite also occurred early. Episodes of subaerial exposure and pedogenic/capillary alteration are represented by: 1) pedogenic carbonates (with nodular magnesite) and gypsiferous crusts composed of poikilitic crystals; and 2) nodular anhydrite, which probably formed in the capillary zone of a lacustrine sabkha or mudflat. Additionally, a somewhat later pervasive meganodular secondary anhydrite texture overprints much of the laminated lake gypsum, presumably driven by heating of ascending, highly saline groundwaters. The timing of anhydritization was mainly controlled by the salinity of the

pore solutions, and ongoing from the onset of deposition to moderate burial (Orti and Rosell, 2000). The basin's diagenetic history indicates the complexity of evaporite textural evolution, even in strata that are undeformed and have undergone no more than shallow burial (Figures 7.36, 7.44).

Permian lacustrine redbeds, Kansas

The mid-Permian (Leonardian) Nippewalla Group of Kansas and the Opeche Shale of North Dakota are part of an extensive redbed succession deposited in an arid continental interior sag basin on the Pangaeon megacontinent (Figure 5.13a; Benison and Goldstein, 2000, 2001). Characteristic lithologies comprise bedded pan evaporites, red-bed siliciclastics and grey siliciclastics, all laid down in a series of continental playas (Figure 5.13b, c). Most evaporite deposition took place in a series of halite-dominated ephemeral saline lakes surrounded by saline and dry mudflats, sandflats and sand dunes. It was an environment characterised by acid groundwaters with hydrologies not unlike those of southeastern interior Australia and exemplified by the redbed lacustrine associations forming

today in and around Lake Tyrell, Victoria and the salt lake landscape of southwest Western Australia (Benison and Goldstein 2002; Figure 2.20). Permian climate alternated between arid, when red siltstones and bedded evaporites dominated the various saline lake centres, and more humid when grey siltstones and palustral carbonates were widespread.

Bedded evaporites were deposited as saltpan and chaotic halites, or as less widespread bedded units containing calcium sulphate salts. Like the acid drainage basins of Australia, the system lacked widespread carbonates. These evaporite-depositing depressions were surrounded by extensive redbed mudflats and sandflats. Lithologies and sedimentary features indicate lacustrine and eolian deposition, subaerial exposure and palaeosol formation. Grey siliciclastic mudstones represent a freshwater-brackish perennial lake facies and are characterized by planar and convolute laminations, ostracods, peloids and plant material. Water levels were higher and the climate more humid when the grey siltstones were deposited. Bedded anhydrites containing gypsum-crystal pseudomorphs, clastic anhydrite grains, along with grey mud drapes and partings, all suggest deposition in saline lake depressions. Bedded halites consist of chevron and cumulate crystals, dissolution surfaces and pipes, and mudcracked microcrystalline salt crusts. They were deposited in saline pans subject to flooding, evaporative concentration and desiccation. Chaotic halite, composed of red-bed mudstone and siltstone with displacive halite crystals, formed in saline mudflats surrounding the salt pans. Red-bed mudstone and siltstone with little or no displacive halite, but with abundant cracking, root and plant features were deposited in dry mudflats in areas where water throughputs were less saline and waters were sufficiently fresh to allow halophytes to grow. Red-bed sandstone, composed of well-sorted, well-rounded quartz

grains cemented with halite, indicate eolian and rare shallow-water deposition.

Evaporation, desiccation, flooding and wind reworking played significant roles in this environment (Benison and Goldstein, *op. cit.*). The Nippewalla Group/Opeche Shale siliciclastics and evaporites represent an evolution from a perennial lacustrine system to a nonmarine, acidic saline pan system in the mid-continent of North America. Inclusion data from primary chevrons in the pan halite preserve temperature fluctuations at the seasonal scale and act as first-rate proxies for Permian climate in an

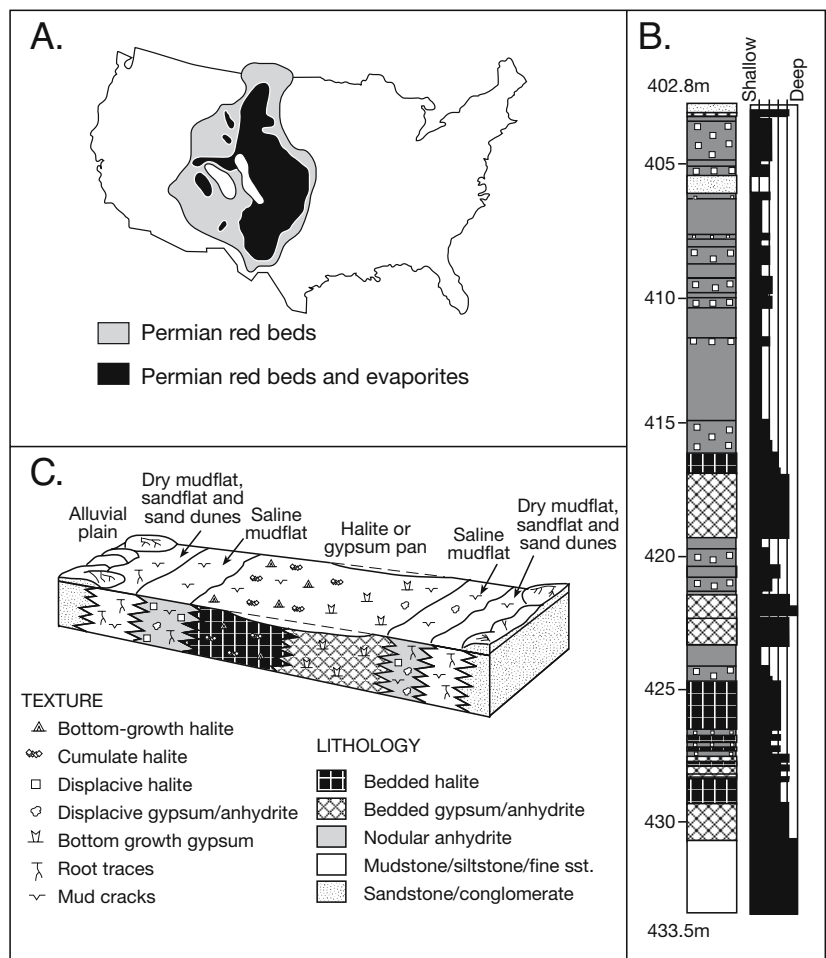

Figure 5.13. Permian redbeds of interior USA. A) Distribution of Permian red beds and evaporites in the USA. B) Lithological description and relative depths of depositional environments of the Nippewalla Group from the subsurface of western Kansas; Anadarko-Davis No. 1 core, Seward County, Kansas. Deeper probably indicates a wetter climate and so this core seems to represent a transition from a wetter to a drier climate. C) Inland playa associations that controlled sediment patterns in red beds of both the Opeche Shale and Nippewalla Group. (after Benison and Goldstein, 2000, 2001).

arid megadesert created by the formation of Pangaea (Figure 2.28). To the south, time equivalent evaporitic sediment in the San Andres and Clear Fork formations of the Palo Duro Basin, show an increasing marine influence in the form of intercalated carbonates. There widespread pan halites and bedded gypsums are intercalated with oolitic, restricted-marine platform carbonates, cryptogalaminites become significant contributors to the sediment volume, and bioturbation from marine burrowers are locally important in some of the carbonate units (Handford, 1981; Hovorka, 1987). Halite pseudomorphs after bedded coarse-grained gypsum is an important early diagenetic fabric in some of these sediments.

This passage to more marine-influenced saline pans and salterns in the south illustrates a correlation problem common to many ancient evaporites deposited atop cratonic landmasses. Namely, what defines an evaporite bed as marine or marine seepage-fed versus continental lacustrine in what where highly restricted settings where even marine-fed depressions had no surface connection to the ocean. This paradox is discussed in more detail later in this chapter.

Other Lacustrine Red Bed Associations

In a number of underfilled lacustrine basins the supply of water may be insufficient to maintain a shallow water table or a perennial lake in the drainage basin sump. In this situation the basin dries to where much of the sediment is reworked by wind action and little evidence of bedded lacustrine evaporites remains. Much of the basin fill is wind-reworked silt and loess. This is the situation in the present day Lake Eyre drainage basin of Central Australia and was also the case in the Triassic across much of northwest Europe (Figure 5.14; Talbot et al., 1994; Reinhardt and Ricken, 2000). This was when the Mercia Mudstone Group was deposited in Great Britain and the Kueper in Germany. Deposition was dominated by a characteristic assemblage of fine-grained facies, the most widespread of which is a variably dolomitic red mudstone. It is typically massive and unfossiliferous except for occasional vague horizontal laminae and irregularly distributed wispy sand

patches (e.g. Brookfield, 2003). Desiccation features are common, as are blocky weathering patterns. Nodular beds of gypsum/anhydrite and celestine are associated with the mudstone, along with gypsum-filled desiccation cracks and pseudomorphs after displacive halite and suggestions of haloturbation. Locally there are also 10-30 cm thick dolomite and limestone beds. These thin beds range from micritic mudstones to ooid grainstones and packstones with freshwater algal remains (charophytes and *Botryococcus*). These local freshwater intervals are interpreted as areas of ponded floodwaters brought to the basin after exceptional rains (Talbot et al., 1994). As for the rest of the lithotypes, they too have their counterparts in times of freshened lacustrine sedimentation tied to flooding of the Quaternary Lake Eyre Basin (Chapter 3).

Details of other saltpan and perennial lacustrine deposits, where the bedded salts are an exploited resource or a intimately associated with an exploited resource, are discussed in Chapter 11 (borates, lithium, magnesites, nitrates, potash, sodium carbonate, sodium sulphate, zeolites).

Platform evaporites on epeiric shelves

Platform evaporites accumulated in epicontinental (epeiric) or pericontinental settings and constitute the salt layers in many stacked shoaling marine platform cycles, where 5-10 m

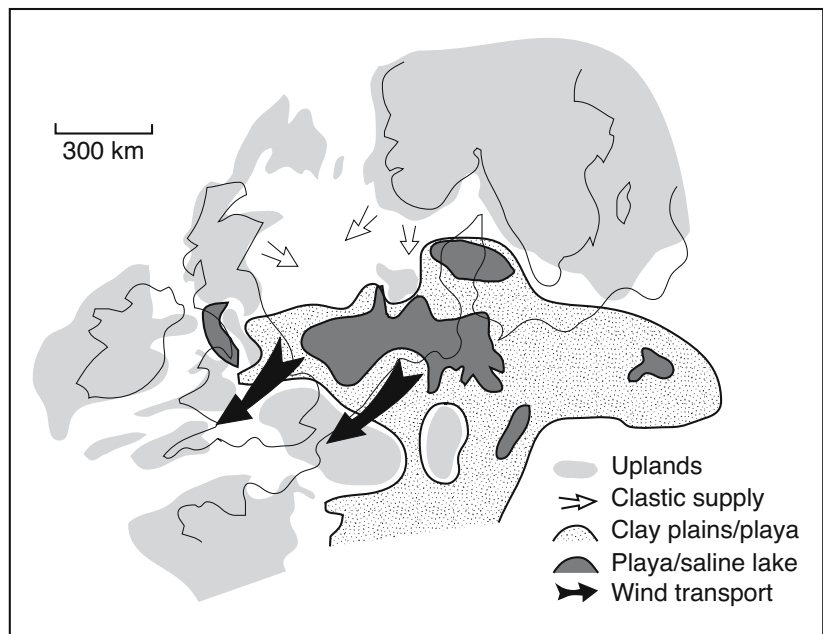

Figure 5.14. Late Triassic palaeogeography of northwest Europe showing how deposition was predominantly in an endorheic basin and wind was blowing dust from mudflats about large discharge playas (after Talbot et al., 1994).

thick evaporite units (typically anhydrite with lesser halite) are repeatedly interbedded with open-marine shoalwater carbonates or continental siliciclastics. Epeiric seaways were huge very shallow shelf and interior seas, up to thousands of kilometres across, that typically held waters no more than tens of metres deep and were usually much shallower during the hydrographically-isolated bedded salt phases (Figure 5.15). Epeiric seaways require large areas of continent to be covered by water and so are commonplace at times when world sealevels are high, as exemplified by greenhouse climate modes. In the world's current icehouse mode, sealevels are low as much of this water is caught up in polar icesheets and so there only are few Quaternary examples of epeiric carbonate seaways; they are all open marine systems (e.g. Gulf of Carpentaria, northern Australia, with its patchy but widespread *Halimeda* mounds and the Yucatan Shelf of Mexico with its well developed strandline of calcareous eolianite).

When an epeiric basin is cut off from a surface connection to the open ocean (hydrographically isolated), deposition occurs in widespread evaporitic mudflats surrounded by desert dunes and wadi plains. Or deposition occurs beneath sluggish, slowly circulating perennial sheets of marine-fed brine that cover the lower parts of the basin, especially near zones of marine seepage. There the surface waters can become holomictic and attain sufficient salinity to precipitate and stack widespread salts beds into units as much as 5-10 metres thick. Subaerial evaporitic carbonate mudflats and sandplains typically separated the brine sheets from the open ocean.

At other times, when the same areas on the epeiric platform had a surface connection to the adjacent ocean (hydrographic connection), they were covered by shallow seawater. It could concentrate into the mesohaline range, especially in more restricted parts away from areas of marine resupply, but could not reach sufficient concentration to produce bedded salts. The greater volume of the platform sediments at times of surface connection were muddy marine carbonates, mostly peloid wackestones and mudstones. Skeletal and peloidal (oolitic)

Figure 5.15. Epeiric (epicontinental) seaways covered large areas of the continental interior with shallow marine waters, while pericontinental seaways formed as very wide shelf edges. They have no modern counterparts but were commonplace in greenhouse earth when the continental freeboard was much larger than it is today. Waters were very shallow over areas that were hundreds to thousands of kilometres across. With hydrographic isolation these restricted marine seaways quickly became salterns or evaporitic mudflats (after Heckel, 1974).

grainstone shoals built up in areas where current energies from waves, or possibly tides along the marine edge, were sufficient to winnow lime mud but not grains. This created sand flat islands or shoals with long axes subparallel to the direction of dominant current transport, encased in peloids or muds. These beds constitute the reservoir sands in many mudflat and saltern sealed epeiric sequences, such as the Arab D and Khuff carbonates in the Middle East (Figure 10.9). Repetitive and characteristic shoaling-upward stacks or parasequences accumulated on the platform as the various types of marine sediments aggraded and prograded in this carbonate milieu. The extensive flat arid areas circumscribing the seawater-covered areas of the open seaway were typically huge evaporitic mudflats. Salinities along the low-relief strandzones of these huge shallow seaways were sufficiently elevated that the only fossil evidence of life was the occasional stromatolite in a mass of microbial laminites.

Mudflat edges of these isolated seaways and the marine-fed platform salterns generated dense seaward-flowing seeps of residual reflux liquor. Such brines cycled through and across the underlying platform sediment to create reflux dolomites (Figure 2.49). The fluxes were sometimes sufficiently voluminous to supply longterm chemosynthetic seeps on the open sea floor of the adjacent open marine platform. At times of hydrographic connection, brines escaping from an adjacent mudflat into the seaway would become bottom-hugging waters, which trickled and seeped into local brine sumps on the marine platform floor.

Figure 5.16. Evaporite depositional styles - ramp and shelf. A) Gently deepening ramp with restriction created by exposed zone Y shoal. B) Rimmed shelf with restriction supplied by exposed reef/shoal that defines the platform margin. C) Rimmed shelf with deep rim and restriction supplied by exposed mid-shelf shoal (Warren, 1999).

Ultimately, these denser, bottom waters formed areas characterised by long-term dense anoxic bottom water beneath a column of normal platform seawater. These areas were intraplatform or intrashelf basins that were local, slightly deeper, warmer (heliothermic) depressions on the seaway floor. They could be up to hundreds of kilometres across, but water columns were no more than 10-30 m deep. By the time the mudflat-derived bottom brines finally ponded in the deeper parts of such intraplatform lows, salinities may have been diluted, via mixing, to where they were no more than a few ‰ higher than normal seawater. This was sufficient to maintain a density/thermal stratification, so that the bottom waters were dysaerobic to anoxic. A number of organic-rich oil-prone carbonate laminites and marls (source rocks) accumulated in these lows, such as the Jurassic Hanifa Formation a significant source rock of the Arabian Platform (Figures 9.3, 9.4). At times of hydrographic connection between the epeiric platform and the world's oceans, the platform areas surrounding these intraplatform depressions were shallow and

more oxygenated than the depression floor, with largely normal marine salinities and water depths typically less than 10 metres. This encouraged the local accumulation of reef mounds and sandy shoals.

Hydrographic connection between the open ocean and the epeiric seaway could be lost for a number of reasons; a sand shoal buildup at the platform rim, a slight fall in sealevel, or tectonic tilting. Once portions of epeiric or pericontinental seaways lost their hydrographic connection to the open ocean, bedded marine-fed saltern and mudflat evaporites were laid down. This occurred within one of two carbonate platform settings; either on a *carbonate ramp* or on a *carbonate shelf* (Figures 5.7, 5.16). Carbonate ramps have slopes of less than 1° , the wave agitated zone is typically close to the seashore, and there is no high relief shelf break located some distance seaward from shoreline (Ahr, 1973). Slopes in ancient epeiric ramps in greenhouse times and in intracratonic seas were as low as 1 in 50,000, compared to modern ramp gradients of between 1 in 500 and 1 in 2500 (Burchette and Wright, 1992; Warren 1991). In

contrast, carbonate shelves are shallow water, land-coupled platforms with a pronounced break in slope into deeper water (Figure 5.16b). The break in slope is typically a wave agitated to high-energy feature, it may be composed of a reef rim or a series of mechanically-reworked sand shoals and islands. The slope, seaward of the platform edge, is typically measured in degrees of inclination. In modern reef-rimmed platforms the seaward slope ranges from 30° to vertical.

Evaporitic epeiric ramps

Ahr's original ramp model envisaged a uniform slope from the shoreline into the basin, later termed a homoclinal ramp by Read (1985). However all modern ramps, and some ancient ramps appear to have a subaqueous slope break into deeper water and are termed distally-steepened ramps. The inclination of the slope

is still flat (<1-2°) and never approaches that of a carbonate shelf. Modern ramps characterise the tropical carbonate coasts of the southern Arabian Gulf, the Gulf of Carpentaria and the Yucatan shelf. All these modern ramps face directly into the open ocean and have never shallowed sufficiently to isolate large portions of their lagoons and so lack widespread salt beds. The only well documented example of a modern carbonate ramp with some evaporite deposition is the Trucial Coast of the southern Arabian (Persian) Gulf (Purser and Evans, 1973). But, it is a poor analog for any epeiric or pericontinental counterpart as it is not supplied solute from a seawater source, its evaporite belt is supratidal, less than 10-15 km wide, matrix-rich and less than a metre thick (Chapter 3).

Unlike most modern carbonate ramps, which are tens to a few hundred kilometres wide, ancient epeiric ramps were hundreds to thousands of kilometres across and formed huge evaporitic seaways at the edges of continents (pericontinental seaways;

Figure 5.15) or extended as near-land-locked interior seaways that spread out across large areas of various continental cratons (epicontinental seaways). The Permian red beds discussed in the lacustrine section are the landward end of one such interior evaporitic lake or seaway (a saltern). The world's last development of such a huge interior seaway was in the Eocene in evaporitic platform carbonates of the Middle East (Table 5.5). But these platform evaporites (Radhuma, Rus and Damman formations) are perhaps better considered as basinwide back-bulge or intracratonic sag salts, deposited in a response to flexural sag and basin isolation behind the migrating forebulge of the Zagros Orogeny (Alavi, 2004). If so, this makes the world's most recent episode of marine platform evaporite as old as the Paleocene or the Cretaceous (Table 5.5, Figure 10.29).

The transition into an icehouse climatic mode in the Tertiary, the capture of large volumes of ocean water in oscillating ice caps, and a slowing in the rate of seafloor spreading, meant

Table 5.5 continued. Representative examples of Paleozoic evaporitic platforms. In some, the former evaporite beds are now represented by laterally extensive solution breccia horizons. Some examples are also the margins to tectonically-induced basinwide evaporite fills.

large evaporite seaways, so conspicuous on the Late Permian and Mesozoic platforms, had disappeared from the face of the earth by the mid Tertiary. A lack of modern analogues means we cannot directly observe the influence that epeiric seaways had on the depositional styles of ramp evaporites. We are forced to scale up sediment patterns in Quaternary coastal evaporites in the knowledge that the high amplitude, high frequency, eustasy of today is not the hydrological or eustatic equivalent of the sea-margin ramps of greenhouse earth.

Epeiric ramps were first modeled by Shaw (1964) and Irwin (1965), they both concluded that the huge areas of restricted stagnant circulation on the backsides of these seaways were capable of periodically accumulating extensive beds of evaporites. Irwin's epicontinental-sea model proposed there were three zones of varying hydraulic energy on ancient platform ramps (Figures 5.16a):

- *Zone X* was a wide low-energy region situated below wavebase on the open-marine side of the platform, so that sediments were mainly bioturbated marine mudstones and wackestones. It was often hundreds of kilometres wide and locally characterized by limited water circulation with occasional stagnation. Now and then, this led to the deposition of organic-rich laminated sediments.
- *Zone Y* was a narrow, intermediate to high-energy belt beginning where waves first bottomed on the seafloor and extending landward to the limit of any tidal action. Sediments in this zone included sand and grainstone shoals, mud banks, reef mounds and patch reefs. These sediments could build elongate shoals that restricted and at times prevented the surface entry of seawater into the adjacent zone Z.
- *Zone Z* was an extremely shallow, restricted low-energy region on the landward side of zone Y. In arid settings, wherever zone Z was hydrographically isolated from zone X, extensive saltern and mudflat evaporites were deposited. At times when zone Z and zone X had a surface connection through zone Y, the seaward portion of zone Z was covered by restricted-marine mostly muddy sediments with local sandier carbonates. The more distal portions on its continental side were evaporitic mudflats.

Marine wave energy was dissipated some distance basinward from zone Z as it spent itself against the seaward side of the shoals, bars, and reefs of zone Y. Shallow wave-agitated facies of zone Y passed down the slope into deeper-water subtidal open-marine facies of zone X without a rapid change in slope angle. Behind the zone Y shoal, bottom slopes in zone Z were even less than on the open marine ramp and had maximum

bottom angles of only a few seconds of arc ($\approx 1:50,000$). Thus, huge areas of zone Z were covered by extremely shallow water sheets, much of it only tens of centimetres deep. This is a setting replicated at a much smaller scale in the modern khors of the United Arab Emirates. During times of widespread evaporite deposition across zone Z there was no hydrographic connection to the ocean and so tidal effects were negligible. Depositional textures were largely akin to those formed in modern saline pans and sabkhas although perennial seaways depositing salterns were a distinct possibility in zones with more relief behind Zone Y.

Zone Z water levels fluctuated most rapidly during intense storms or hurricanes, as sheets of sediment-laden seawater could be washed landward over zone Y into zone Z, or during exceptional episodes of flash-flooding generated by torrential rainstorms in the continental hinterland. Both marine and meteoric influx freshened the surface and nearsurface brines of Zone Z as sheets of water migrated tens of kilometres across the strandplain. At the same time a new pulse of marine or continental clastic sediment matrix was delivered. Evaporite-forming areas in zone Z were up to hundreds of kilometres wide, far wider than any evaporitic area on the modern land surface.

On any evaporitic ramp there was some degree of topographic relief about zone Y, and restriction of water flow across it. When salts were accumulating in Zone Z there were no perennial surface channels connecting it to the waters of Zone X (see later discussion and Figure 5.28). Vertical sequences of evaporites deposited in zone Z were very much dependent on the relative physiography of zone Y. If zone Y was a well developed low-relief shoreline with extensive washover flats behind, then much of zone Z was an evaporitic mudflat; a mosaic of sabkhas and salinas. Or, if zone Y was a higher-relief shoal, it would be backed by a marine seepage-fed evaporite lagoon, and zone Z would consist of saltern evaporites with an increasing proportion of subaerial mudflat indicators (desiccation cracks, karst, erosion features, displacement textures) toward the top of the unit and toward the landward and seaward strandplains (Figure 5.5).

Units P₁ and P₂ of the San Andres Formation in the northwestern platform of the Permian Basin and the Palo Duro Basin illustrate the saltern-ramp end member (Figure 10.22; Elliott and Warren, 1989). Similar saltern signatures dominated the San Andres and Clear Fork formations in the Palo Duro Basin (Figure 5.17). Correlatable units of saltern anhydrite or halite in the Palo Duro Basin have areas of more than 26,000 km². At times of widespread evaporite deposition on the Palo Duro Basin and the northwestern shelf of west Texas, one could

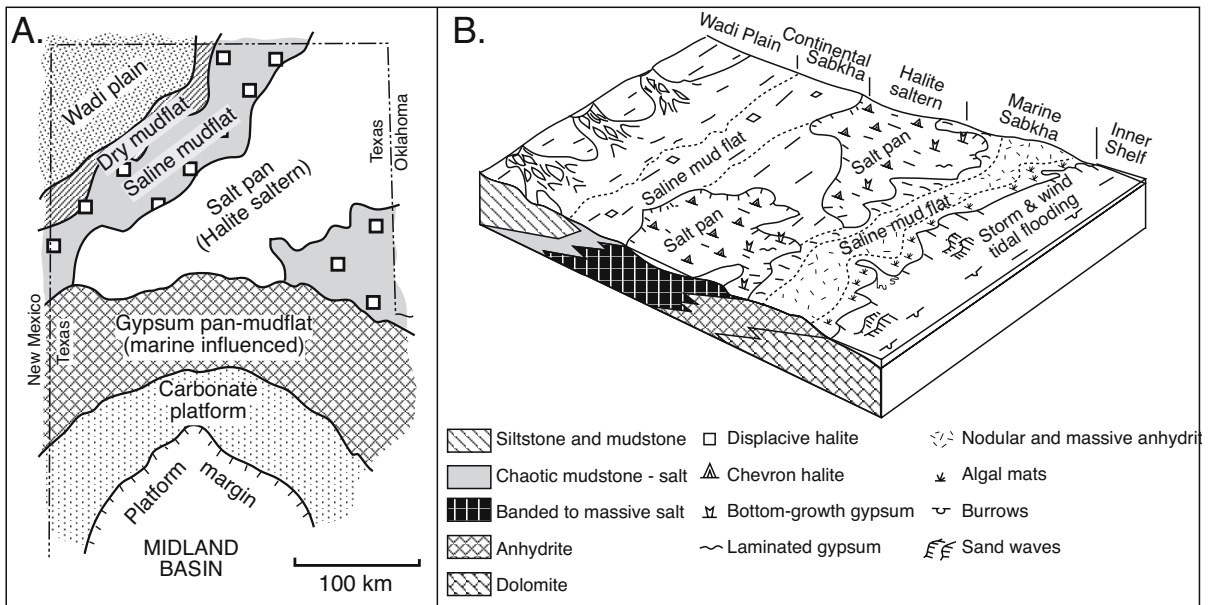

Figure 5.17. Lithofacies and paleogeography of the early Permian Lower Clear Fork Formation, an evaporitic ramp at the northern end of the Midland Basin in the Texas Panhandle. A) Plan View. B) Schematic of depositional relationships between main evaporitic facies (after Handford, 1981).

have travelled 50 to 150 km south and seaward from the strandplain of the brine sheet and never crossed through water that was much more than a few metres deep, nor less saline than gypsum-saturated.

The northern portions of the Lower Clear Fork Formation of the Palo Duro Basin illustrate the evaporitic mudflat-ramp end member where extensive “dirty” halite beds are intercalated with fine-grained siliciclastics (Figure 5.17a; Handford, 1981, 1991). Deposition took place in an evaporitic mudflat and pan complex that passed further northward into the large continental desert made up of salt pans, wadis and dunes documented by Benison and Goldstein, (2001). Southward, the Clear Fork ramp passed from highly continental mudflats into marine-fed saltern deposits and then across the restriction of the Zone Y phylloid buildups into open-marine carbonates of zone X (Figure 5.17b; Ramage, 1987). Deciding where to place a line separating marine from nonmarine brines is near impossible; although it is generally true in this and in most other arid successions passing from the marine into huge interior redbed deserts that the thicker bedded salt accumulations are more likely on the marine side of the system.

Thick evaporitic carbonates and intercalated anhydrites of the Khuff Formation define a huge evaporitic platform (≈ 255 Ma) in the Arabian Gulf, with an upper section that straddles the Permo-Triassic boundary (Figure 5.18; Al-Jallal 1995,

Dasgupta et al., 2002). In eastern Saudi Arabia, the Khuff Formation is divided into five units or members designated as Khuff A through E. However, throughout the Gulf region the Khuff may comprise as many as seven designated mappable subsurface units or members (Al-Jallal, 1995). Most of the Khuff Formation is composed of carbonates and evaporites; major siliciclastic facies increase towards the west and toward the base of the sequence, especially in Saudi Arabia. As many as four of the five units are capable of acting as hydrocarbon reservoirs and correspond to four depositional carbonate-anhydrite cycles where transgressive marine carbonates are capped by regressive anhydrites.

The Khuff Formation thickens from about 260 m in southwestern Saudi Arabia to more than 915 m in the central Rub ‘al Khali Basin, 1,220 m in Oman, and 1,520 m in Iran. Typical thickness for the Khuff ranges between 370 m and 490 m over most of central and eastern Arabia (Al-Jallal, 1995). The basal Khuff section consists mostly of siliciclastics throughout southern Arabia. The “basal Khuff clastics” in Saudi Arabia are made up of shale, carbonaceous shale, limestone streaks, and incised channel-fill sandstones. Individual channel-fill sandstone units of the basal Khuff clastics are as much as 18 m in thickness and can cut deeply into the underlying Unayzah Formation. In the Hazmiyah field of central Saudi Arabia, the reservoir occurs entirely within these channel sandstones in the basal Khuff (Senalp and Al-Duaiji, 1995). The Unayzah and

basal Khuff sandstones form the principal reservoirs in central Saudi Arabia; however, widespread reservoir quality variations occur in these sandstone reservoirs owing to heterogeneous sedimentary facies and variable diagenetic intensity (Aktas and Cocker, 1995; Polkowski, 1997).

Over most of the rest of Saudi Arabia and west into Oman and the UAE the Khuff is more than a 1 km thick and composed of numerous 2-10 m thick shoaling stacked dolomitized carbonate cycles or parasequences. These Late Permian dolomites are major gas reservoirs along the offshore in the Arabian Gulf north and west of Qatar. In contrast, the regionally extensive anhydrite, shale, and tight (low-permeability) carbonates of the Khuff Formation form the major regional seal for Pre-Khuff hydrocarbon accumulations in central and eastern Saudi Arabia (Al-Jallal, 1995; Wender and others, 1998).

Deposition of this thick carbonate succession was initiated as a ramp in the late Khazanian or early Tatarian and had evolved into a reef-rimmed evaporitic platform by the later Permian to early Triassic (Figure 5.18). Most of the cycles in the upper part of the Khuff are capable of producing gas and are variably dolomitised oolite-peloid successions that typically grade upward into fine-grained laminites and nodular mudflat/pan anhydrite. Carbonate cycles atop siliciclastics in the lower part of the Khuff tend to be more dominated by coarsening-upward shoreface/shoal cycles with lesser mudflat laminites.

All the Khuff beds and markers pass westward via a belt of mixed detrital carbonate and siliciclastics onto the palaeohigh of the Arabian Shield. Correlations and definitions of time-equivalence in adjacent wells or outcrops in this belt is problematic due to a lack of appropriate fossils and similarity in wadi/dune depositional styles throughout large passages of Palaeozoic and Mesozoic time in the circum-Arabian Shield area.

The succession is punctuated by numerous intervals of subaqueous and pan anhydrite (after gypsum) with local development of evaporitic mudflat facies atop shoals (pers. obs.). In the middle of the Khuff succession is a

thick saltern sulphate bed called the Middle Anhydrite. It is a regional marker bed originally deposited as a thick sequence of bottom-nucleated subaqueous gypsum. This marker defines a time when the whole of the Khuff platform was converted to a saltern rather than the more typical combinations of evaporitic mudflats and pans (Chapter 10).

The Jurassic section atop the Khuff in Saudi Arabia and the Emirates is another evaporitic platform succession. It constitutes the most significant source-reservoir-seal association for hydrocarbons anywhere in the world (see detailed discussion of Hanifa, Arab D and Hith Anhydrite in Chapters 9 and 10). Both the Arab and the Khuff formations accumulated at different times along the southern shore of the Neo-Tethyan Ocean when sediment accretion atop an original Hercynian horst and block terrain periodically isolated large parts of the platform interior (Figure 10.9). This led to the punctuation of the carbonate platform record with evaporite beds throughout much of the Mesozoic.

Regionally, the Mesozoic in the Middle East was a period of tectonic activity centred around the opening and closing of the Tethys. The Late Permian ocean backed onto the huge land-

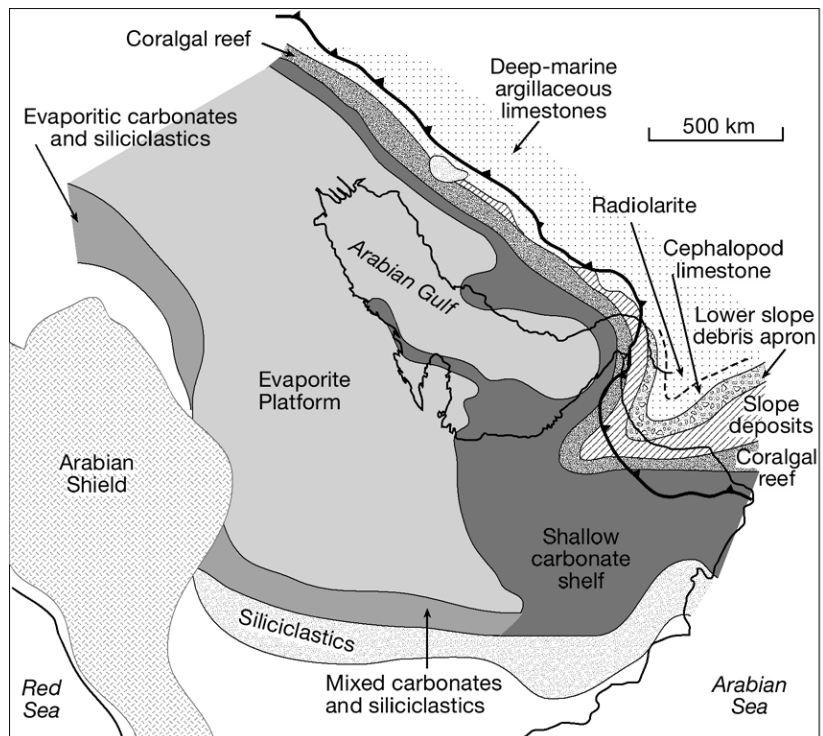

Figure 5.18. Major facies belts and their interrelationships in the Permian Khuff Formation of the Middle East (after Al-Jallal, 1995).

Figure 5.19. Phanerozoic distribution of reefs (black shading), reef mounds (dashed line), major extinctions and the dominant reef formers through time (after Kiessling et al., 1999) versus the worldwide volume of evaporites (after Hite and Anders, 1991).

masses of Pangaea and in both opening and closing stages of the supercontinent the ocean created large subsealevel marine margin areas where epeiric carbonate seas formed that were periodically isolated as intracratonic sags and then filled to hydrologic base level with bedded salts. Similar evaporite entraining epeiric carbonate ramps also characterised the Infracambrian of the Middle East, the lower Palaeozoic of North America and Australia, the late Palaeozoic of America and Russia, and the Triassic and Jurassic of Europe (Table 5.5).

Evaporites atop rimmed epeiric shelves

Ancient rimmed-shelves were shallow-water carbonate platforms with an outer wave-agitated edge marked by biogenically induced buildups or highs and a pronounced increase in slope that was typically a few degrees, less often more than 60° , into deep water (Read, 1985). Platform evaporites can be found behind such rims throughout the Phanerozoic (Table 5.4a, b). Subsurface examples of this style of carbonate deposition, as opposed to ramps, are readily identified seismically using obvious clinofolds and reflection discontinuities that define the shelf edge or shelf break. Many modern reef-rimmed shelves are constructed by combinations of corals and coralline algae, but different organisms have occupied the framebuilder niche in the past; stromatolites in the Proterozoic, stromatoporoids

in the Devonian and rudistids in the Cretaceous. When Phanerozoic reef occurrences are plotted in time against evaporite volumes there is little or no correlation implying reef-rimmed platforms are not the dominant mechanism driving times of widespread evaporites. It implies tectonic isolation during times of continental make-up or break-up, and not eustasy, created the depressions and the drawdown hydrologies that precipitated the greater volumes of world's ancient evaporites (Figure 5.19).

Areas behind platform rims in arid settings are typically made up of seepage-fed evaporitic carbonate flats that pass landward into salterns and then into mudflat evaporites or arid zone siliciclastics (Figures 5.7a and 5.16b, c; Warren, 1991). The platform rim in greenhouse times was continuous to semicontinuous during times of open marine carbonate growth, characterized by high-energy reefs and reef mounds with intervening grainstone shoals and flats. Rimmed shelves require biogenic binding and cementation to maintain an elevated rim, they cannot form on siliciclastic platforms (high turbidity), nor can they flourish if they are connected at the surface to hinterland areas where extensive evaporites are accumulating. Both these scenarios set up inimical seaward-flushing waters; in one the reef-formers are killed off by detrital plugging, in the other by elevated salinity.

The change in the major reef formers through time does create some interesting variations in the degree of proximity of the living reef formers to the evaporite accumulating areas. Precambrian stromatolitic platform-edge reefs could grow in close proximity to an evaporitic mudflat; some stromatolitic horizons are repeatedly intercalated and even penetrate saltern beds in the Neoproterozoic Ara salt of Oman. Cambrian archeocyathids were much more fragile. For example, in the well-exposed reef outcrops of the Flinders Ranges in South Australia the archeocyathids never outcrop in close proximity to evaporitic mudflats. There are always debris aprons and unconformities separating bioherms from overlying evaporite dissolution breccias. Stromatoporoids in lagoonal bioherms in the Alberta Basin appear to have better tolerated exposure to mesohaline waters, at least for short periods. But with no

modern analog it is difficult to define why this is so (e.g. were stromatoporoids related more to calcareous sponges or to cyanobacterial plexi?). Phanerozoic corals (rugose, tabulate and scleractinian) consistently show a poor tolerance to salinity change (stenohaline fauna) and living communities were never able to tolerate salinity changes for more than a few hours. Rudists appear to have been more robust in their salinity tolerance. In core from the subsurface of Texas I have seen small *in situ* buildups forming units adjacent to both oyster bioherms (estuarine) and the least saline portions of ancient evaporitic mudflats. This ability to survive changed salinities is probably related to their molluscan pedigree. When conditions became too saline, too hot or too fresh they could retract their filtering apparatus, pull down their opercular caps and wait out the adverse conditions, at least for a day or two. Even today, chemosynthetic molluscs can survive in close proximity to deep seafloor brine lakes (Figure 9.40).

The degree of restriction in the evaporite-depositing lagoon area behind the platform edge is controlled by the continuity of the rimming shoal. To form a saltern or an evaporitic mudflat in an ancient lagoonal depression requires the rim crest to be at or above sealevel, with any channels cutting across the rim and its sandflat to be choked with sediment (Lucia, 1972). This prevents freshening via the free exchange of marine and back-rim waters. Otherwise, like the carbonate platforms of today, conditions behind the shelf rim or shoal can never become saline enough to deposit widespread evaporites and, at best, restricted marine carbonates are deposited.

The Cretaceous Ferry Lake Anhydrite formed behind a rimmed platform as a 90 m-thick unit extending from east Texas to Alabama (Figure 5.20). It is made up of metres-thick alternating units of carbonate and anhydrite deposited in the lagoonal area of

a broad, shallow reef/shoal-rimmed carbonate platform. Using wireline signatures, individual sulphate beds can be traced over distances of more than 160 km ((Figure 5.20a; Pittman, 1985). Where it subcrops toward its present landward extent the anhydrites have been dissolved by meteoric waters. At the time of deposition they passed further landward into alluvial plain conglomerates and redbeds. Detailed core study in the J. B. Kitchens No. 1 well (Henderson Co, Texas) showed the anhydrite beds are mostly composed of vertical- to near vertical-aligned nodules separated by fine mm-laminated anhydrite (Loucks and Longman, 1982). These structures are diagenetic “ghosts” after original bottom-nucleated gypsum. Throughout much of its subsurface extent the wirelines signature of the correlated anhydrites show a clean blocky appearance with neutron-density crossplots indicating high levels of sulphate purity, making it a saltern deposit (Warren, 1991). Sabkha mudflat signatures in

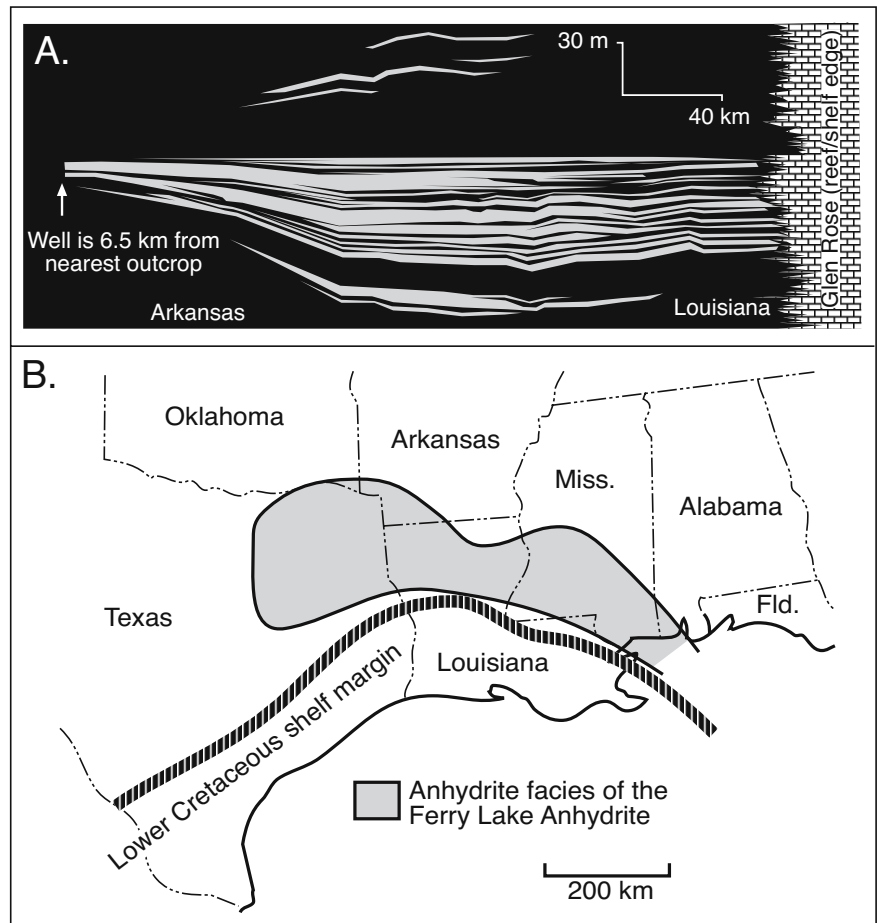

Figure 5.20. Lower Cretaceous Ferry Lake Anhydrite, northern Gulf of Mexico. A) N-S cross section showing distribution of main anhydrite beds from wireline logs (after Pittman, 1985). B) Distribution of anhydrite saltern on the platform behind the rudistid shelf margin shoal (after Loucks and Longman, 1982).

the anhydrites are rare. The saltern/lagoon was up to 260 km (160 miles) wide and was separated from open marine waters by shelf-margin bank or shoals dominated by rudistid debris of the Glen Rose Formation (Figure 5.20b). The position of the shoal was possibly controlled by down-to-the-basin faulting. This in turn was controlled by into-the-basin salt flow and associated growth faulting, driven by halokinetic movement of the underlying Jurassic Louann Salt (Chapter 6).

The anhydrite beds are up to 7 m thick and contain thin mudstone layers with entrained anhydrite rip-up clasts. The thicker carbonate beds, which separate the anhydrites, are near-normal-marine lagoonal bioclastic/oolitic wackestones indicating times of hydrographic connection through the rim facies to the open ocean. The entrained fauna includes ostracodes and molluscs, several units contain *Orbitulina* and echinoid fragments, indicating that normal marine waters were present either during highstands or in times of storm-induced marine floods.

Loucks and Longman's original 1982 interpretation was that the marine carbonate beds were deposited during periodic storm flooding of a restricted carbonate lagoon by marine waters. They also postulated that a single perennial evaporite lagoon was capable of depositing gypsum on its seaward side and halite on its landward side. Given a lack of widespread halite and what we now know about saltern hydrology this surface-connected scenario of marine on one side of a lagoon and halite on the other is somewhat unlikely. To deposit a widespread subaqueous evaporite unit requires total or near total isolation from a surface connection to the ocean in a system where a single perennial brine is at saturation with a single mineral phase (see later hydrological discussion in this chapter). A more likely scenario is that the Ferry Lake Anhydrites were precipitated simultaneously across a gypsum-saturated seaway during times of complete surface isolation from the ocean, and halite was perhaps forming stacked crusts in isolated pan depressions within subaerial mudflats in the most landward parts of the basin (as in Lake Asal today). On the seaward side of the saltern the crests of the rudistid shoals and reefs were subaerially exposed, while the underlying shoal sediment was an unconfined aquifer facilitating the phreatic supply of marine water into the drawdown saltern filled with gypsum-saturated brine sheets up to a few metres deep.

An even more thoroughly documented example of a rimmed evaporitic platform is the Permian margin of the Delaware Basin in west Texas and New Mexico, USA (Figures 5.21a, 7.9). The margin is exposed in the Guadalupe Mountains, while its

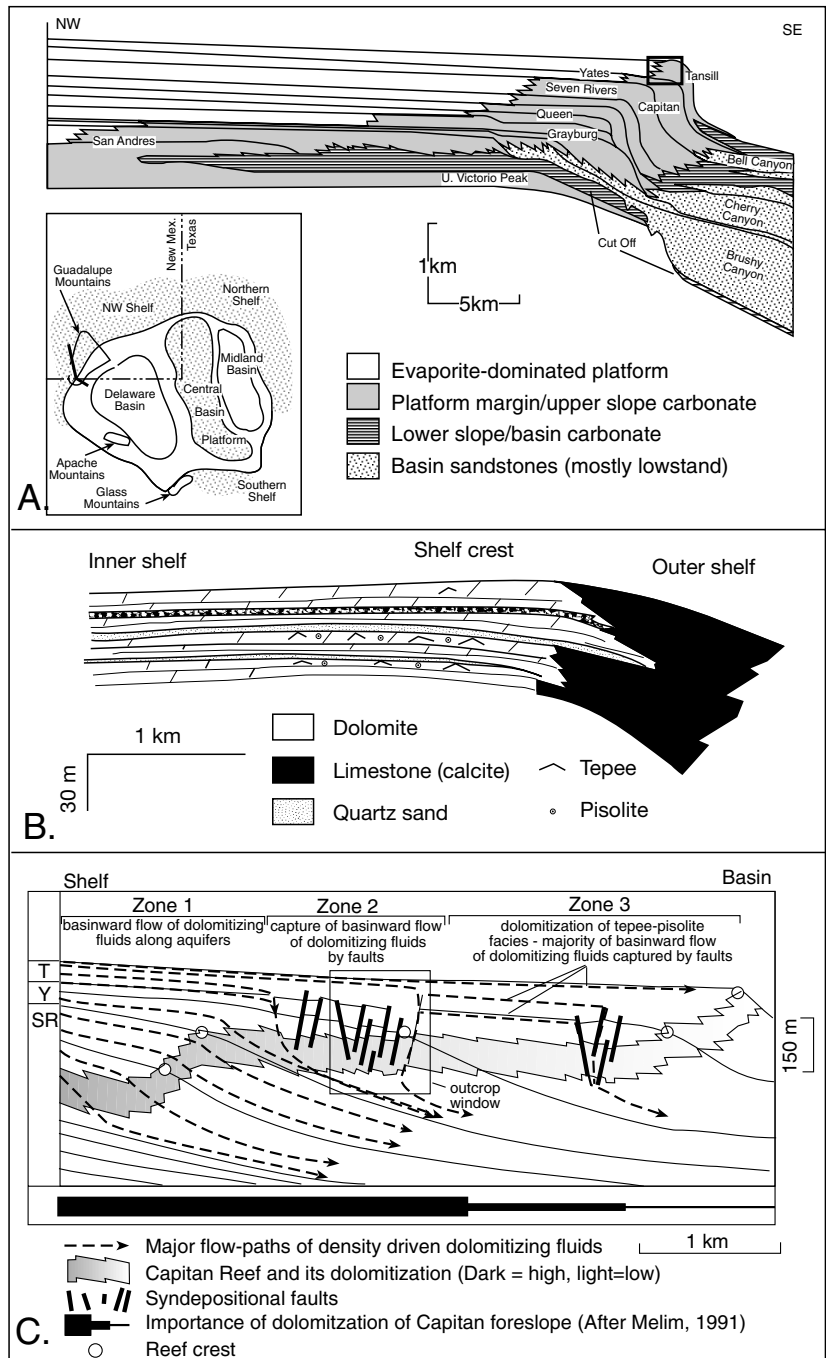

dolomitised, evaporite-sealed, subsurface lagoonal counterparts form the most productive reservoir intervals from the NW shelf into the Central Basin Platform. The Permian Basin of west Texas covers an area of more than 100,000 km² and is almost completely encircled by the reef-rim sediments of the Goat Seep and Capitan formations. Some distance landward of the reef is a 13 km wide belt of highly cyclic platform carbonates made up of widely correlatable stacks of dolomite mudstone and wackestone, capped by anhydritic laminites, which Sarg (1981, 2001) interprets as subaqueous. Even further landward are thick belts of saltern evaporites, which have been largely dissolved from their outcrop expressions in the Guadalupe Mountains.

Seaward of the cyclic platform dolomites, in a position somewhat closer to the reef mass proper, is an 0.8 to 3 km wide belt of carbonate sands and pisolitic rudstones. These were deposited as mostly coarsening-upward, cyclic stacks, which culminate in tepee-overprinted pisolite beds with subaerial exposure or truncation surfaces. These evaporitic carbonates constitute the tepee-overprinted pisolitic strandzone and barrier island shoal facies of the Guadalupe platform (Esteban and Pray, 1983) and were described in some detail in Chapter 1. Evaporite-sealed counterparts to the dolomitized pisolitic cycles also constitute high quality subsurface reservoirs (Chapter 10).

During deposition the pisolite facies constituted a series of shoals that are considered by many to have been the topographically highest part of the platform (Esteban and Pray, 1983; Mutti and Simo, 1993). Located landward of the reef, the island shoal facies distinguishes this style of platform from the more usual reef-rimmed reconstruction, where the reef mass and its sand flat occupy the topographically highest position on the platform profile (Figures 5.16b, 5.21b). The pisolitic high of the Guadalupe region is the type area for what is called a distally-steepened reef rim or deep reef-rimmed shelf. This platform profile occurs in other shelf margins characterised by platform salterns (Figure 5.16c). A little further basinward of the pisolites and tepees are the reef masses of the Goat seep and Capitan formations. Separating the pisolitic shoal zone from the reef rim proper was a narrow belt of carbonate wackestones, typified by a low diversity marine fauna.

The basal part of the reef mass is pervasively cemented by cm-scale aragonite botryoids (now calcite), which can constitute up to 90% of the reef matrix. This zone of intense cementation passes upward into prolific biogenic masses of sponges, bryozoa, brachiopods and *Tubiphytes*, all bound by calcareous algae and marine cements. Some of the calcareous algae are coelobites,

Figure 5.21. Permian reef complex of the Guadalupe Mountains, west Texas. A) Schematic cross section of the Permian carbonate platform based on outcrops in the Guadalupe Mountains of Texas and New Mexico. Note the initial strongly progradational ramp-like profile in the San Andres Formation and its evolution to a reef-rimmed shelf with a well defined slope break, along with steep shelf margin that was several hundred metres high. The platform interior is dominated by saltern evaporites (white) that pass seaward through pisolitic island shoal/strandzone facies into the deep-rim reef of the Capitan Formation (after Kerans et al., 1993; Kerans and Fitchen, 1996). The basinward slope of the evaporite sequence is based on the current configuration of the basin margin and probably does not reflect the original slope. It is created by post depositional regional tilting. Map inset shows major physiographic provinces of the Permian Basin in west Texas and New Mexico. B) Detailed facies and dolomitisation relationships based on measured sections in the Yates/Tansill Formation showing the position of the shelf crest landward of the reefs of the Capitan limestone (after Mutti and Simo, 1993). C) Dolomitisation of the Capitan shelf strata and reef by dense mesohaline fluids that originated in the near back reef evaporitic shelf-lagoon (Hunt et al., 2002). Basinward flow of the dolomitising fluids was along aquifer units within the shelf—the sandstones resting on sequence boundaries. The basinward tilting of the back reef strata between the shelf crest and the Capitan may have helped promote a basinward flow of the dolomitising fluids, but the main hydrological gradient came from natural brine reflux. In areas updip of the faults (zone 1, the basinward flow of the dolomitising fluids would have primarily been along aquifers and downward through the reef and foreereef (both areas here are extensively dolomitised). The flow of fluids through the foreereef followed bedding, and dolomitisation decreases downward through these strata (Melim and Scholle, 2002). Further downdip in the cross-section (zone 2), much of the basinward flow of the dolomitising fluids would have been captured by the syndepositional faults and related fracture systems that reach high into the platform stratigraphy. Here, the sandstone-dominated fill of the faults and fractures provided vertical conduits for the dense dolomitising fluids through the platform. Capture of the flow of the dolomitising fluids by the fault zones in updip locations (zone 2) may have acted to inhibit the extensive dolomitisation of the middle and upper Capitan reef further downdip (zone 3). Here, dolomitisation is mostly limited to tepee–pisolite facies. Hunt et al.’s model is a logical extension of that developed by Melim (1991) and they argue dolomitisation was likely a discontinuous process typical of TST and HST times, while fracture-controlled dissolution prevailed during lowstands.

a

which flourished in dark aragonite-cemented fractures in the growing reef. The reef mass is largely undolomitised and internally shows no evidence of subaerial exposure, implying aragonite cementation was early and that the reef was never capable of growing to sealevel.

It may well be that the stenohaline biota of the reef rim could never grow to sealevel, nor form closer to the pisolitic shoreline, because of the debilitating effect of increased salinities. Dense brines, created by evaporative drawdown on the landward side of the island shoal, refluxed seaward via sandstone aquifers and growth faults beneath the unconfined marine phreatic lens to seep back to the seafloor just seaward of the basin shoreline to create a facies belt characterised by a low diversity, halotolerant biota. Brines mixed freely with seawater in this near coastal seafloor zone and so were dissipated into the huge reservoir of open ocean water that occupied the Delaware Basin (Figure 5.22a). If the deep reef rim grew up toward the sea surface it would create greater restriction immediately behind the reef rim allowing the escaping reflux brines to gather and increase the salinity of the back reef waters. As these more saline waters spilt and washed over the still subaqueous reef rim it would slow the growth of the reef until subsidence allowed freshening of the lagoon once again (Figure 5.22b). Hence the reef could never grow to approach the sea surface in front of a huge area of widespread evaporites and refluxing dolomitising brines. Whenever it did so, it shot itself in the back before it ever reached the sea surface.

Seaward of the reef rim is a 2 km wide belt of carbonate slope and rise sediments, which also defines the shelf break. It is made up of massive to thinly bedded limestones with intercalated slumps of shelf material, breccias and debris flows (Melim and Scholle, 2002). Small downslope buildups are found on the shallower parts of some slopes. Portions of the deepwater carbonate sands and the deeper parts of the shelf margins of the Delaware Basin are dolomitised to lesser degrees than the platform. Even so, the distribution of dolomite in these sediments reflect the influence of widespread evaporite deposition and brine reflux in the hinterland and the more seaward focusing action of syndepositional growth faults (Figure 5.21c; Hunt et al., 2002).

Further out, widespread siliciclastic sand sheets dominate the basin floor. These form a channelised deepwater belt at the foot of the carbonate slope in a zone some 6 km wide and up to 35 m thick. The sand sheets were fed by desert dune sands from the hinterland, which largely bypassed the shelf margin via canyons transecting the reef. Some of these basinal channelised sands are unusual compared to typical deepwater sand channels in that they contain drape muds on the channel floor and a rather homogenous set of sedimentary structures. They are interpreted either as density flows created by bottom-hugging saline brine flows, which originated in the platform salterns (Williamson, 1978) or as settle-out muds and silts carried out over the seaway by intense winds from an adjacent sand sea (erg), much in the same way that silt and mud is carried out into the Atlantic off the Saharan coast of north Africa today (Fischer and Sarnthein, 1988).

Figure 5.22. Effect of a deep reef-rim growth in a saltern-backed platform.

Saline platform sequences have been recognised as far back as the Archean (Figure 5.23). A number of impure dolomitic limestone beds in the latest Archean (≈ 2.5 Ga) Wittenoom and Carawine dolomites of the Hamersley Group in Western Australia contain features such as mud cracks and evaporite pseudomorphs that indicate shallow water with local evaporitic mudflats (Kargel et al., 1996). The system extended across what was possibly the original extent of the Hamesley Basin as defined by Trendall (1983) in his evaporite-basin model for initial banded iron precipitation. In the barred platform model of initial iron precipitation published by Morris (1993) it also corresponded to what was interpreted to be a broad carbonate platform passing

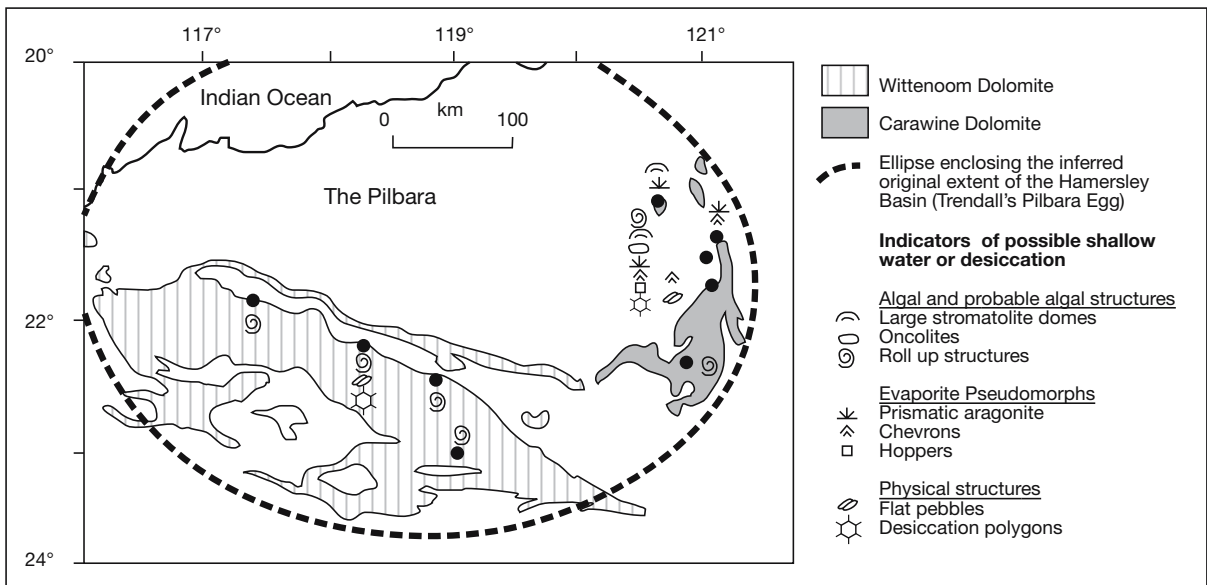

Figure 5.23. Sketch map showing the distribution of sedimentological features that indicate shallow water and evaporitic conditions in the Archean Wittenoom and Carawine dolomites in the Pilbara of Western Australia (after Kargel et al., 1996) and used as evidence to indicate that the widespread banded iron ores in this region first precipitated as saline precipitates in a barred marine platform basin.

into deeper marine waters to the south. In either case, during the accumulation of the Wittenoom and Carawine dolomites the depositional setting was a carbonate platform that at times was evaporitic.

These evaporitic dolomites underlie the world-scale banded iron ores (BIFs) of the Hamersley Basin, deposits that contain 10% of the world's known iron ore reserves. As in all models of ore deposits of this age, explanations for the formation of the banded iron ores are contentious. Trendall (1983) favours an evaporitic basin to explain the precipitation of the ore, Morris (1985) favours supergene enrichment beneath a Paleoproterozoic weathering surface, Li et al. (1993) favour a hypogene origin, while Powell et al. (1999) argue for synorogenic Paleoproterozoic hydrothermal fluids squeezed northward away from the Ophthalmian fold belt.

Marine versus nonmarine stages in epeiric seaways

Correlations across the Clear Fork ramp passing into the siliciclastics of the Opeche Shale or the Khuff Formation anhydrites passing laterally into basin rim continental siliciclastics derived from the Arabian Shield, or Guadalupe salterns passing landward into wadi and dune deposits are all problematic. They underline the everyday problem of reliably tying facies to time horizons in many ancient mixed siliciclastic/evaporite/carbonate platforms. Fossil-lean but

extensive areas of saltern evaporites typically backed onto, and were surrounded by, evaporitic mudflats and fossil-lean sand-sheets with numerous internal unconformities that are Stokes surfaces. The problem is worse in ramps, which lack well developed clinoforms that can be used seismically to define the seaward side of a subsurface carbonate platform. Something as simple as determining whether the platform had a marine or nonmarine brine feed is problematic in many subsurface salterns. Little if any open-marine carbonate matrix was ever transported into the highly isolated parts of the hinterland, even during intense hurricane events. For much of the time the water conditions in the saltern/lagoon were too saline for most marine or carbonate-secreting organisms with the possible exception of cyanobacteria and halophilic mats. When the base of a saltern evaporite cycle is made up of carbonates, they usually retain some evidence of a marine biota so that it is likely that the overlying salt beds were fed by marine seepage. But, if the intrasalt beds are dominantly mud, with no fossils, what was the original depositional setting?

This problem beleaguers depositional interpretations of the Permian (Leonardian) Nippewalla Group of Kansas, a lateral time equivalent succession to the Clear Fork Formation of the Palo Duro Basin. As mentioned earlier, Benison and Goldstein (2001) argue the Nippewalla Group siliciclastics and evaporites represent an evolution from a lacustrine system to a nonmarine, acidic saline pan system in the mid-continent

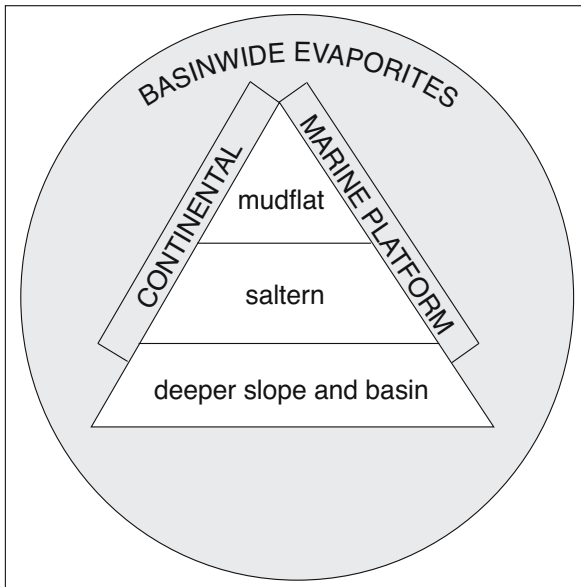

Figure 5.24. Venn plot showing the diversity of environmental settings possible in basinwide evaporites.

of North America. Most evaporite deposition took place in halite-dominated ephemeral saline lakes surrounded by saline and dry mudflats, sandflats and sand dunes. The key to their continental interpretation comes, not from the textures in the nodular anhydrite or the halite and chaotic halite beds, which

are equivocal, but from a volumetrically unimportant grey mudstone facies. This they interpret as a perennial lake deposit akin to the acid redbed lakes in parts of modern Australia. It is a grey siliciclastic mudstone characterized by planar and convolute laminations, ostracodes, peloids and plant material laid down in a freshwater-brackish perennial lake.

More reliable interpretations of a salt bed as marine or nonmarine are usually best done by studying the less saline intrasalt beds. In fact, it is the first feature on the list of four criteria noted by Hardie (1984) as most useful in separating marine and nonmarine evaporites. He listed; 1) sedimentology of the associated non-saline facies, 2) kinds of fossils, 3) kinds and associations of primary evaporite minerals and, 4) geochemical characteristics of evaporite minerals.

Basinwide evaporites

Basinwide evaporites are thick basin-filling evaporite units, often described as “saline giants” or “mega-evaporites.” Salt sequences typically extend across large areas of the central parts of a sedimentary basin and contain textural evidence of a variety of depositional settings ranging from deepwater to saltern to mudflat (Figures 5.7b, 5.24; Table 5.6). Basinwide evaporites are not accumulating anywhere on the surface of the world today as the necessary interactions between tectonics,

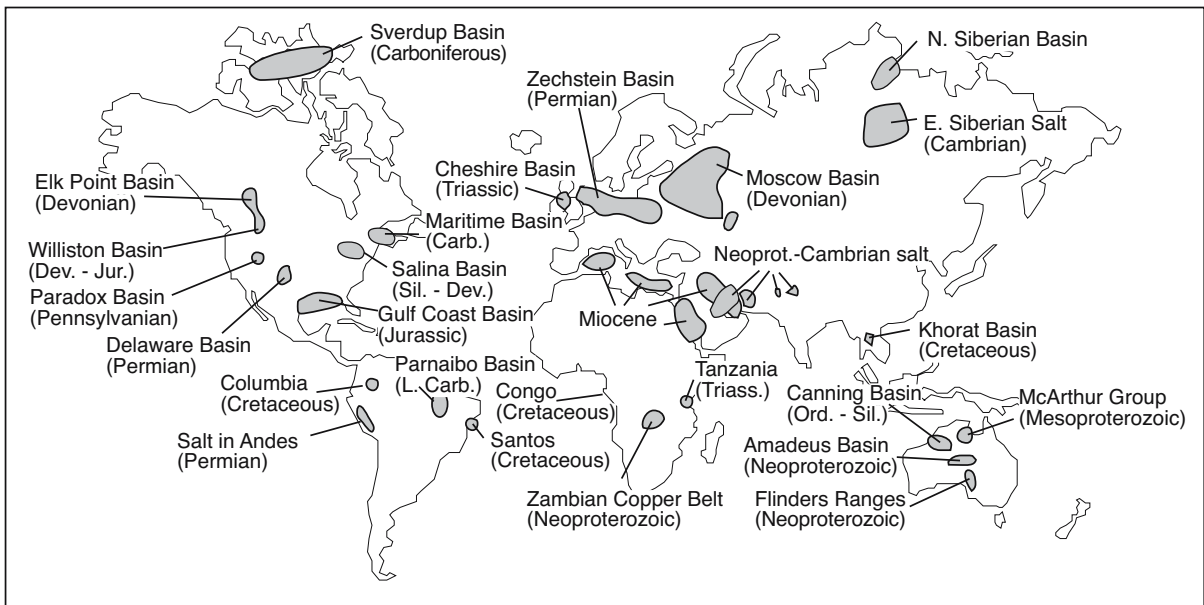

Figure 5.25. Map showing location and age of some of major basinwide evaporite deposits. All of the Proterozoic examples, except the Amadeus Basin of Australia and the Fahud Salt Basin of Oman, are characterised by dissolution breccias and pseudomorphs, not the actual salts. Owing to the small size of the map, basins are drawn for visual clarity not to exact scale.

Table 5.6 continued. Representative examples of basinwide evaporites (also called saline giants and basin centre evaporites). In some the former evaporite beds are now represented by laterally extensive solution breccia horizons.

hydrology and climate do not exist. Basin-central evaporite is another term to describe this grouping of ancient deposits (Kendall, 1992). I prefer the term basinwide as the evaporite sequence can fill the basin centre and then climb out over the old basin margin (e.g. the transition from Castile to Salado formations in the Delaware Basin).

Basinwide evaporites can constitute large proportions of sediment fill in many ancient evaporitic basins, such as the Delaware Basin of west Texas, the Zechstein Basin of Europe, the Louann Salt Basins in the Gulf of Mexico, the Hormuz Salt Basins in the Arabian Gulf and the Late Miocene Messinian sub-basins in the Mediterranean (Figure 5.25). The total evaporite fill in such basins is often hundreds to thousands of metres thick and composed of numerous stacked “brining upward” evaporite cycles tens to hundreds of metres thick (e.g. the Z1-Z4 of the Permian Zechstein of northwest Europe). Rather than the anhydrite that dominates the mineralogy of many marine platform evaporites, basinwides typically contain thick halite beds that can source halokinetic structures.

Saltern textures (salt pan and salina) dominate basinwide deposits, although basin and slope deposits can also occur, especially in the early stages of each depositional cycle. Sometimes, especially in the gypsum/anhydrite stages of an evaporite fill the saltern constructs a “platform” area in the basin with deeper water sulphate laminites accumulating in the central part of the basin (Figures 5.7a, 5.26a). At other times the basin centre had filled and shallowed to where a saltern extended across the entire depositional area of the basin (Figure 5.26b, c). Stacking of a number of saltern cycles into a thick basinwide sequence indicates the basin did not fill in a single depositional episode, but as a number of brining-upward and/or shoaling-upward depositional cycles typically composed of even finer scale parasequences. Compared with saltern deposits in marine-margin platform evaporites, the salterns in many basinwide evaporite basins tend to accumulate as much thicker units (>100m), and bedded salts are not restricted to the shoalwater/lagoonal portions of any underlying carbonate platform. Rather, they tend to cover and encase underlying carbonate reef rims and pinnacles.

Depositional styles

Basinwide evaporites can be classified into three settings (Figure 5.26; Warren, 1989; Kendall, 1992):

- Deeper water–deep basin
- Shallower water–deep basin
- Shallow water–shallow basin

Deeper water–deep basin evaporites have basin centres dominated by “deepwater” evaporites composed mostly of finely laminated salts (mostly sulphates) or coarsely crystalline inclusion-free halite meshworks. Individual laminar groupings in the basin-centre laminites can be correlated over wide areas (Figure 5.26a). This style of deposition dominates a hydrographically isolated marine-fed basin that reaches hydrologic equilibrium (water inflow = loss) at a time when a relatively deep water mass still covers the basin centre. The contentious part of this model lies in what water depth defines a deepwater brine in the basin centre, is it 30m, 100m or >1000m? Basin slopes at times when the basin water column is meromictic are dominated by reworked saltern evaporites deposited as slumps and turbidites, while pelagic laminites dominate the basin centre (Figure 5.6a). At times when water levels are somewhat lower and the water mass is holomictic then coarsely crystalline evaporites (either gypsum or halite) are deposited across the basin floor (Figure 5.6b).

Seawater flows into the basin as a perennial seepage; if the basin remains hydrographically isolated, evaporites can fill the basin to a water level just below that of the supplying ocean (Figure 5.38). Consequently, the evaporite unit “in toto” is a shallowing upward succession, often composed of smaller shallowing-upward cycles (parasequences). The basin fill starts off dominated by deeper water laminated and resedimented salts that pass up section into shallow-water salterns, pans, mudflats, or continental playas. But it can also preserve coarser crystalline units indicating holomictic but still “deep” episodes in the basin fill.

The Permian Castile Formation and the transition into the overlying Salado Formation in the Delaware Basin in west Texas is a good example of this passage from predominantly deep to predominantly shallow (Figure 1.24). The basin-centre started off relatively deep with the deposition of the varved sediments of the Castile Formation, and with time filled and shallowed into the shoalwater/playa deposits of the Salado Formation. Any sediments that immediately postdate the evaporites of this overall shallowing sequence will also be shoal water or saline mudflat deposits. This is the case with the shoalwater/mudflat deposits of Rustler Dolomite where it overlies the Salado Formation in the Permian Basin, west Texas. Other examples of deeper water deposition occur in the basin-centre deposits of the north and south Zechstein basins of NW Europe and the deeper parts of the marginal basins in the Messinian of the Italian Apennines.

Figure 5.26. Basinwide evaporite settings, see Figure 5.6 for more detail on 5.26a, which only represents the meromictic stage (modified from Warren, 1989; Kendall, 1992).

The *shallower water–deep basin* sequence is dominated by shallow water evaporites deposited as stacked saltern to mudflat cycles in a basin with a hydrological base level hundreds to thousands of metres below sealevel. This type of basin is supplied by evaporative drawdown, pulling seawater into the basin as a series of marginward seeps perhaps interrupted by the occasional waterfall (Figure 5.26b). It characterises the more drawdown stages of evaporite deposition in both soft suture collision belts and some intracontinental rifts. This style of evaporite fill is often intimately related to the deeper water–deep basin style of deposits and indicates a more arid period in the same depositional basin. That is, its hydrological equilibrium is reached when much shallower waters cover the basin centre and there are many topographically deep evaporite basins where deeper fills alternate with shallower fills.

In the collision setting the underlying basin-centre succession is typically a deep marine sediment, often a pelagic carbonate

that passes upward across a disconformity or unconformity into alternating stacked saltern and deeper water evaporites. Normal marine pelagics were deposited before the basin depression was hydrographically isolated from the ocean and can return to dominate the basin fill if a hydrographic connection is re-established. The transition from a deeper marine basin to evaporitic can be marked by organic-rich restricted marine-influenced deposits (Figures 9.3,9.24). Basin margin regions can contain reefal deposits from the preceding marine phase.

Shallower water–deep basin fills dominate the evaporite fill in many marine-fed rift successions, such as the Aptian South Atlantic Salt Basin. Thick salts precipitated atop an endorheic rift valley floor that was hundreds of metres below sealevel (Szatmari, 2000). Unlike the relatively small volumes of marine-fed salts being deposited in today’s best example of a shallow water–deep basin marine-fed rift (Lake Asal depression; Figure 4.56), the volumes of salt deposited in ancient rift sags could be huge. Consider the wedge-shaped body of Upper Aptian salt that was deposited in the South Atlantic Salt Basin as Africa separated from South America about a rotational pole in NE Brazil (Szatmari, 2000). The salt basin was more than 2000 km long, some 400 km wide at its southern end in the Santos Basin and tapered northward to less than 100 km wide in the Sergipe-Alagoas Basin. Prior to halokinesis, the original salt thickness in the various sub-basins was around 2 km. Most of the salt was deposited as halite in a series of saline lakes/salters within a pre-existing continental rift depression, with a floor some 2 km below sealevel. Marine flooding ended the depression’s isolation from the sea in the late Aptian. It required nearly one million cubic kilometres of water to fill the depression to sealevel, an event that would have caused a geologically instantaneous drop of 3 m in global sealevel (Szatmari, 2000).

The *shallower water–shallow basin* association forms under conditions of ongoing subsidence where the rate of evaporite aggradation keeps pace with tectonic subsidence (Figure 5.26c). The basin depositional setting starts off shallow and remains shallow throughout the deposition of the evaporite sequence.

Sedimentary signatures are dominated by interfingering saltern, saline pan and mudflat successions often crosscut by karstic erosional surfaces. There is little or no evidence of deeper water evaporites. Shallow water–shallow basin evaporites are typical of intracratonic sag fills such as in the Williston Basin in the USA and the Silurian–Ordovician Canning Basin in Australia. Salt beds in intracratonic fills are typically intercalated with shallow-water open-marine carbonates and siliciclastics and tend to form stacked cyclic units with thicknesses between 10m and 100 m, unlike the thick rift and collision successions (>100-1000 m thick). Using data from one or two wells it can be very difficult to distinguish intracratonic basinwide evaporites from marine-margin platform evaporites. The distinction requires a thorough knowledge of the basin’s tectonic history and architecture and is often best resolved using regional seismic and well data. This style of deposition also dominates the later stages of basin infill in what were previously deep hydrographically-isolated evaporite basins, as described in the other two members of this classification.

In reality, interpreting basin-filling evaporites is never as simple nor as predictable as a three-end-member classification suggests. Changes in brine level, subsidence rates or climate, play havoc with a simple tripartite breakdown of evaporite basins. Water depths in an evaporite basin are never constant, they rise and fall in response to intensity of tectonism, climate, sealevel change, playa capture and associated changes in the degree of seepage, evaporation intensity and surface runoff in the inflow zones. Basinwide provinces such as the Mediterranean Basin during the Late Miocene, or the Permian Basins of Texas and northern Europe in the Late Permian, are actually composed of a series of large sub-basins. Each sub-basin in an evaporitic province responds in its own fashion, depending on the local topography, tectonics, and climate and the total fill can contain examples of all three end members.

Tectonic styles

Throughout earth history, basinwides tend to accumulate in three tectonic settings: 1) Areas of rifting continental plates; 2) Areas of converging continental plates (collision belts); 3) Areas of intracontinental or intraplate sags, which are often the result of farfield plate stress induced by continental orogeny acting on zones of pre-existing crustal weakness such as an old rift belt or foreland depression (Table 5.6; Figure 5.27). Evaporating brines in

most basinwide lows tend to be maintained by a continuous inflow of marine groundwaters into tectonic depressions (marine-fed hydrological systems). This hydrology is created in an arid setting wherever tectonically-driven subsidence moves the basin floor to sub-sealevel elevations without allowing a surface connection to the open ocean.

Basinwide evaporite style changes as continents accrete and suture. The various salt-filled basins, that together make up the Pangaeian peak in the salt volume curve, were created mostly by plate tectonic mechanisms within what were tectonically-induced arid to hyperarid climatic zones of the latest Palaeozoic to Mesozoic earth (Figure 5.4). Volumes of salts caught up in this association dwarf all Quaternary salt volumes. Zharkov (1981) recognized 95 Permian evaporite basins with a total volume of $1.5 \times 10^6 \text{ km}^3$ (37 were halite-dominated and 48 sulphate-dominated). The basinwides that make up the Pangaeian peak came into being as the continents collided to construct the Pangaeian supercontinent and then as it rifted and sagged during its breakup.

Carboniferous basinwide evaporites were precipitated in the Williston Basin and northern Ellesmere region in North America, in northern Brazil, North Africa, the East-European Platform, and Kazakhstan (Trappe, 2000). Early Permian evaporite basins form a broad belt along western Pangaea, but also in northeastern

Figure 5.27. Tectonic settings of basinwide evaporite deposition in the past (no current counterparts) and Quaternary setting of large continental evaporite basins in the framework of the Wilson cycle (stages A-G). Strike-slip basins are associated with local readjustments to stresses created by plates moving past each other. Evaporites can only form in hydrographically isolated (typically endorheic) environments and so do not form in open marine stages C or D. Evaporites are shaded black.

North America and eastern Greenland, as well as in northern South America (including western Brazil). Large salt deposits of the same age are found in central Europe including portions of the East-European Platform and the Urals. The largest Early Permian deposit fills the East European Basin from the Caspian to the Black Sea with some $500 \times 10^3 \text{ km}^3$ of halite and $100 \times 10^3 \text{ km}^3$ of anhydrite (Magaritz 1987). Late Permian evaporites include major deposits in the Zechstein Basin of northwestern Europe and the evaporites of west Texas. Together these basins define a broad band of equatorial aridity extending from about 50°N to about 30°S palaeolatitude, with basinwide salt deposition ranging in time and world climate across Carboniferous icehouse to Permian greenhouse.

Permian halite volumes are in their turn dwarfed by those of the Triassic, which account for 22% of all Phanerozoic halite,

while Permian and Triassic halite together make up 35% of the world's halite (Figure 5.4). During the Early Triassic, evaporite formation intensified as huge evaporite pans associated with redbeds developed in southeastern and western USA, western Canada, northwestern Africa, western and southeastern Europe, central South America, south-central Africa and eastern Greenland (Tables 5.6, 5.7). Large evaporite platforms were established in northern Arabia, Iraq, Kazakhstan, and northern China. The increased salt volume reflects intensified rift activity in low latitude regions during the Triassic breakup of Pangaea. Extension, followed by cooling and sagging, established a number of large isolated subsealevel rifts and intracratonic sags, which acted as the preeminent salt accumulators.

Thus, the plethora of Pangaeen basinwide evaporites is associated with three time-plate tectonic associations (Table

5.7; Figure 5.27): 1) Pennsylvanian to Permian accretion of the Pangaeian supercontinent, as mostly marine-fed collision basin evaporites were deposited along the soft collision belt of the irregularly embayed margins of Gondwana, Laurussia and Siberia; 2) Intraplate extensional depressions created during the subsequent Mesozoic breakup of Pangaea into Gondwana/Laurasia; salt beds deposited in these widening marine-fed rift basins, including the continental salts of the Newark Basin (Triassic), the marine salts of the Gulf of Mexico (Jurassic), the Campos Basin (Cretaceous) and the various mostly marine-fed salt basins of offshore west Africa (Evans, 1978); and 3) Associated intracratonic sag salt accumulations in basins that typically sit atop the failed arms of earlier more sharply-defined fault-bound rift successions (Youssef, 1998) or in the hinterland or foreland of orogenic belts created by farfield stresses driven by interplate collision (Pysklywec and Mitrovica, 2000). The intracratonic-sag basins in the Pangaeian association are especially obvious in the various Triassic and Jurassic salt basins of Northern Africa, which formed isolated subsealevel marine-fed depressions as Pangaea unzipped along its Tethyan and Atlantic axes.

Large intracratonic sags also typify many other subsealevel isolated marine-seep fed saline giants outside of the time of the Pangaeian supercontinent (e.g. the Devonian Elk Point Basin, the Palaeozoic Williston Basin, the Silurian Michigan Basin and Ordovician Canning Basin), as do other rift (e.g. Frasnian of Dnieper-Denets of eastern Europe) and collision (Miocene of the alpine Mediterranean and the Zagros foreland) associations (Table 5.7).

Creation and destruction of the Gondwana supercontinent in the Neoproterozoic-Early Cambrian (≈ 550 Ma) defines an earlier, but not as well documented, peak in the evaporite distribution curve shown in Figure 5.4. Thick layers of preserved rock salt (halite) are widespread in the latest Ediacarian to the Early Cambrian. Indeed, these strata contain some of the world's thickest successions of rock salt (Table 5.5). They include the Hormuz Salt of Iran and the Arabian Gulf, the Ara Salt of Oman (both thought to be latest Ediacarian), the Salt Range salt of Pakistan (Atdabanian-Botoman), and the Usolka and equivalent salts of Siberia (Tommotian-Atdabanian). The assembly Gondwana, took place during the Ediacarian to Early Cambrian. It involved the amalgamation of the separate crustal blocks of Avalonia, Europa, Arabia, Africa, Madagascar, South America, and Antarctica (together forming West Gondwana) and resulted in the compressional Pan-African orogeny, which culminated between 560 and 530 Ma. East Gondwana (India,

South China, North China and Australia) collided with West Gondwana along the Mozambique suture between ca. 600 and 550 Ma. The development of thick salts in the Ara Formation, once thought to be rift deposits of Tommotian age, now appear to be foreland basin deposits of late Ediacarian age. Even older (Neoproterozoic) thick halite beds such as the Bitter Springs Fm. in the Amadeus and the halites of the Browne and Madley Fms. in the Officer Basin of Central Australia, as well as the widespread dissolution breccia after Callana Fm. halites in the Flinders Ranges and the Duruchaus Fm. in Namibia and its equivalents in the Katangan copper Belt are perhaps related to the breakup some 850 Ma of the Mesoproterozoic supercontinent known as Rodinia or Kanatia.

Volumes of salt deposited in saline giants can be huge, with individual deposits accumulating over geologically short time frames of no more than a few million years. For example, the deposition of the Jurassic Louann Salt in the Gulf of Mexico some 175 Ma, sequestered approximately 8% of world-ocean NaCl (Land et al., 1988), while the Messinian evaporites of the Mediterranean were deposited in less than 300,000 years, yet lowered oceanic salinities by 6‰. Unlike platform evaporites, which can be tied to climate and eustasy on greenhouse epeiric platforms, the formation of basinwide deposits is not related to icehouse or greenhouse episodes in earth history. Rather, the formation of saline giants can be related to particular plate tectonic stages (A-H) in the Wilson cycle (Figure 5.27). Named in honour of J. Tuzo Wilson, the Wilson cycle encapsulates the notion that as new ocean basins open via the formation of new seafloor, others must close driven by the process of subduction and ultimately by collision (Wilson, 1966).

The requirement that the basin must be hydrographically isolated and that there must be a huge source of brine available to supply the required ions means; 1) all large thick volumes of salts (basinwides) must come from seawater and the only mechanism capable of supplying this volume is seepage into an isolated subsealevel depression, and 2) the isolation of huge tectonic depressions capable of accumulating evaporites must be systems with high continentality. Thus there are only some stages in the plate tectonic cycle where basinwides can form. One is when the incipient ocean basin is first extending and subsiding to become an evaporite-capped seafloor. The salt accumulating basin is floored by continental sediments and basalts and surrounded by continental crust; it is a hydrographically isolated subsealevel incipient ocean depression (Stage B passing into early Stage C in Figure 5.27; north Atlantic margin in Jurassic, South Atlantic Margin in the Cretaceous and possibly

the Hormuz Basin in the Neoproterozoic/Cambrian). Another is as two continental land masses come together along a soft or irregular suture belt to create subsealevel remnant ocean basins and foreland basins (Late Stage E and F in Figure 5.27 as in the Late Miocene in the Mediterranean; Middle Miocene in Poland). Somewhat smaller endorheic accumulations are currently accumulating in Quaternary tectonic depressions with a nonmarine brine feed. Such continental salts characterise the Dead Sea in the Middle East, the various suprasedlevel lacustrine deposits of the Andes (salars) and the various saline lakes of the African rift (see Chapters 3 and 4). A third is where farfield tectonic flexure creates intracratonic sags.

Importance of hydrographic isolation

Modern continental lacustrine evaporites all accumulate in underfilled endorheic or hydrographically closed basins (Chapter 2). Likewise, marine-fed evaporite basins require complete hydrographic isolation from the ocean and a subsealevel water surface in order to maintain the required throughput/seepage of brine (Chapters 3 and 4). Both basinwide and platform evaporites are a response to underfilled marine-seepage hydrologies. I use the term hydrographic isolation as distinct from the groundwater connection, which dominates in all evaporite-accumulating depressions. Lucia (1972) studied the interrelationship between

maximum salinity in a modern evaporite basin and the basin's water balance (water loss versus gain). He showed that for marine-fed halite to precipitate any surface inlet from the ocean must be at least one hundred million times smaller in cross-sectional area than the surface area of the basin; for gypsum it must be at least a million times smaller (Figure 5.28). That is, any basin accumulating thick beds of evaporites effectively lacks a continuous surface connection to the ocean or other standing body of brackish water.

Maiklem (1971) in a study of evaporative drawdown in the Elk Point Basin of Canada showed that, once it was hydrographically isolated from the ocean, the Devonian Pesqu'ile barrier it did not have sufficient transmissivity to prevent evaporative drawdown, even with permeability of 73 darcies. Kendall (1989) recalculated Maiklem's figures using more realistic values of 0.9-2.7 darcies for permeability in the barrier and concluded that evaporative losses were as much as 200-800 times greater than the rate of supply. Any saline giant precipitating bedded salts is subject to evaporative drawdown and seepage influx of marine-fed phreatic waters. A corollary is that at the time of thick evaporite precipitation there is a correlative unconformity or hiatus forming in the adjacent nonevaporite lithologies that make up the surrounds of the hydrographically isolated depression.

Figure 5.28. Relationship between the ratios of the cross-sectional area of a surface inlet (A_i) and the surface area of the associated hypersaline basin (A_o) plotted against salinity in the basin, with examples from several modern evaporitic depressions. Note that Quaternary examples that are accumulating substantial evaporite beds have no surface connection and are fed either by continental inflow or by marine seepage (modified from Lucia, 1972; Handford, 1991).

An evaporite basin capable of accumulating thick salt beds is always located in a large isolated depression where at the onset of drawdown more water is being lost by evaporation than entering as seepage inflow and runoff. The water level in the basin is drawn down until the volume of water lost equals the volume of inflow (hydrologic equilibrium). A potentiometric gradient (elevation head) then exists between the level of water in the basin and its surrounds, so that by definition an evaporite basin must be an underfilled basin. Such large deep holes in the landsurface attract not just marine seepage, but also ground and formation water seepage from beneath areas adjacent to the hole. In a drawdown saline-giant basin, with a predominantly marine source, the seawater enters mostly as resurging brines through springs in the basin floor. In a saline lake fed by nonmarine water, the water enters by a combination of occasional storm runoff and rainfall, as well as by groundwater and hydrothermal springs (Chapter 4).

Water ponded in an evaporitic depression must remain at the surface or reside just below the land surface in the realm of capillary evaporation. Otherwise, thick sequences of bedded salt could not accumulate, parent waters would seep away before attaining salinities high enough to precipitate salts. In a hydrological setting where the saline water table is rising into a previously vadose environment, the first salts typically precipitate as a capillary cement in previously nonevaporitic sediments of the basin floor. This is the typical situation in marine transgressions and it characterises evaporite accumulation in marine-fed Holocene coastal salinas without a hydrographic connection to the ocean. It is also the hydrology of their larger scale counterparts in subsiding rifts and intracratonic sags where rising relative sealevels force a marine-fed seepage hydrology into a previously continental depression. It also characterises Quaternary continental lacustrine transitions from a dry mudflat or sandflat into a saline pan or perennial saline lake and can be driven by a change to a more humid climate in an arid nonmarine basin.

In a hydrological situation where a previously marine basin becomes a marine-fed depression, the basin waterlevel falls. It is drawdown once the basin-centre or platform lagoon becomes hydrographically isolated from the ocean. Now the water level falls and surface water concentration increases to where dense saline brines begin to sink into the underlying succession. The water level will fall until the volume of water lost from the basin by a combination of evaporation and reflux leakage equals the volume entering by influx seepage of marine and continental waters. Hydrological equilibration in some basins occurs at gypsum saturation, in others at halite saturation. In some basins

it occurs when the water level is a water surface and subaqueous evaporites accumulate. In other basins it does not occur until the water level falls below the surface of the sediments and evaporitic mudflat deposition dominates. Hydrographic isolation drives the formation of marine-fed platform evaporites where a fourth order sealevel fall occurs during a 3rd order rise (Figure 5.37). It also dominates in basinwide evaporite deposits formed in soft-collision continent-continent suture belts (Figure 5.27). It also occurs in continental lakes undergoing a transition from fresher high-waterlevel systems into saline lower-waterlevel lakes. In this purely continental scenario the transition in lake style can be a climatically-driven change from humid to arid, or it can be a tectonically-driven change in the amount of fresh water entering the lake depression (Chapter 4).

In all situations of holomictic subaqueous and salt pan evaporites, the necessary hydrology creates a cone of refluxing brine. This leaky plume of dense brine bathes the accumulating evaporites in saturated and supersaturated water as the plume sinks, spreads and diffuses into the underlying regional hydrology. I call this zone of sinking waters associated with the accumulation of bedded salts the brine curtain (Figure 5.29). The process is brine reflux, the geometry outlined by salt-saturated pore waters defines the brine curtain. Rates of brine escape or brine residence time within the plume of the brine curtain control many of the backreactions discussed in Chapter 2 (e.g. halite pseudomorphs after subaqueous gypsum - Hovorka, 1992; carnallite in Lake Qaidam - Casas et al., 1992; and the mineralogy of the Holocene Coorong Lakes - Warren, 1990).

Once the brine curtain (reflux plume) is established and actively cycling hypersaline groundwaters, it is not easily displaced by short-term inflows of less-dense marine or meteoric groundwaters. The curtain creates an autochthonous hydrology of stable hypersaline pore waters where evaporites can continue to accumulate as secondary cements and alteration haloes (Figure 5.29). It is a plume of dense pore waters with wedgelike margins that force less-saline groundwaters to enter the basin as a series of seeps and springs about the edge of the curtain. Upon burial the evaporite cements associated with the base of the curtain are typically the first part of the evaporite sequence to be dissolved by resurging basinal and compactional waters.

Locally, the brine curtain may be breached atop areas of exceptionally strong upwelling or artesian outflow, which can be situated well out into the salt-saturated parts of the basin. Where resurging artesian waters break through the brine curtain to the

Figure 5.29. Schematic of a brine curtain in a marine-fed and a meteoric-fed evaporitic setting ($V:H \approx 10:1$). Once established the brine curtain is actively maintained by ongoing evaporation and reflux, as well as by the relatively impervious nature of the salt bed (highly effective aquitard). It is difficult to displace the curtain via influx from the margin of less-dense marine or meteoric waters. These tend to float out over the saline water table atop the denser waters of the curtain and move into the salt-filled depression via groundwater wedges that feed spring seeps about its edges. Short-term high-volume runoff or floods of fresher waters tend to form a floating brine sheet across the brine body, which disappears once it is concentrated to where its salinity and density equals that of the underlying brine body. Focused outflow of confined artesian water can locally displace the brine plume. Longer term fluctuations in the volume of all types of freshened inflow can cause changes in the mineral equilibrium that is depositing salts across the perennial brine covered floor. It can lead either to a freshening or a salinity increase in the waters of the brine curtain. Such longterm changes in flow volume favour dissolution, alteration or backreaction of pre-existing mineral phases, as can complete drying of the brine body, which may follow a longterm lowering of the regional water table.

landsurface, as along the fault lines that cut across Lake Frome, they feed prominent lines of spring mounds on the lake floor. In some ancient drawdown basins a localised freshened upflow occurred through zones of exposed pinnacle reefs and were associated with haloes of less saline mineralogies in a sea of halite. Unlike the hydrologies of most ancient basinwide evaporites, the brine curtain in many Quaternary continental lakes in central Australia fades at depths not far below the surface of the lake sediments. In lakes such as Lake Eyre and Lake Amadeus, or the sabkhas of the Abu Dhabi coast, the brine curtain is destroyed at depths of a few metres by dilution from resurging artesian waters. This brackish to mesohaline upwelling of regional groundwater, coupled with periodic surface floods, continually recycles salts into nearsurface sediments. There they are deflated or washed away, so preventing stacking of thick bedded salts within the playa or sabkha depressions. The only bedded salt to accumulate in such settings is a continually recycling pan crust that is never more than a metre thick. Its hydrogeochemistry is largely decoupled from the mineralogies of the underlying sediments (Chapters 2 and 3).

Logan (1987) and Kendall (1992) use the term “hydroseal” to describe the lowermost salt layer in any evaporite sequence. They interpret it, and not the formative reflux hydrology, as the fundamental cause of evaporite accumulation and the varying mineralogies in the basin. The notion of a “hydroseal” is not strictly correct, as secondary or capillary salts precipitated in any zone of refluxing brine must be by definition forming in an aquitard and not an aquiclude. It leaks, to varying degrees, across the whole of the salt-covered basin floor. Even when a salt bed becomes cemented it still dissolves from its underside and becomes a supplier of brines to the base of a more deeply buried brine curtain (Chapter 8). As pore waters making up the brine plume slowly seep and sink, they ultimately mix with underlying compactional and basinal crossflows, as well as any more marginward meteoric or marine inflows. This mixing drives diagenetic reactions that include the precipitation of quartz overgrowths and dolomite cements in units located further away from the brine curtain (Ceriani et al., 2002; Morrow et al., 2002).

Thus, the term “seal” is not appropriate to any reflux situation and the notion of the base of an evaporite bed as a total seal, which is not subject to dissolution or alteration, is one of the reasons why the significance of basal anhydrites and other diagenetic deposits, such as some of the Rote/Faule Kupferschiefer ores, were not attributed to an inherent evaporite dissolution hydrology (Figure 9.46; Warren, 1999, 2000b).

Problems in correlation *sans* hydrology

The need for hydrographic isolation means thick salts are not simultaneous with marine carbonates. Likewise, there are fundamental hydrological problems with the notion that evaporite beds pass laterally below the same sheet of water into contiguous synchronous carbonates and clastic beds. This requires longterm maintenance of subvertical density interfaces in a fluid, which is a physical impossibility. Put simply, if you ignore the unique hydrology needed to deposit a thick evaporite bed, the correlation will fail. Thick evaporites must correlate to unconformities in their surrounds and subaqueous evaporite deposition in a single brine-filled water body (basin) must be a simultaneous holomictic event.

Shaw (1977) in a landmark paper was one of the first geologists to recognise that the classic silled-basin model, with evaporites accumulating in the basin centre and a restricted surface connection to the ocean defined by growing reefs, is hydrostatically unsound. He went on to demonstrate that in such a scenario deepwater evaporites cannot accumulate. Kendall (1988) further develops his arguments by integrating his conclusions with the work of Lucia (1972) to illustrate that when an evaporite basin is depositing widespread salts it must be totally isolated from a surface supply of seawater. Deepwater evaporites are possible in such isolated nonstratified basins (see discussion of the Dead Sea halite in Chapter 4).

Deepwater halite accumulating simultaneously with platform gypsum and basin entry carbonate in a single water mass is not possible, yet it is commonly invoked in models of many ancient evaporite basins. In order to deposit gypsum in a shallow area of a brine body and halite in a deeper area of the same brine body requires an inclined halocline. The required fluid system cannot exist over the longterm in a single brine body. Any body made up of liquids of two different densities cannot support shear. The inclined halocline required by this model will spontaneously collapse in order

to regain its gravitational equilibrium. Once it has restratified to a horizontal interface the precipitation of salts in the deeper brine body ceases until the salinities of the upper and lower brine bodies are equalised by the concentration of the upper less saline water body (Chapters 2 and 4). There never has been and there never will be a brine lake or seaway with a permanently non-horizontal halocline.

In terms of stratigraphy, this means a thick subaqueous bedded halite intersection in one well is an unlikely time correlative of a thick subaqueous anhydrite/gypsum bed in an adjacent well a few kilometres away. The only exception is if they were deposited in nonconnected water bodies in two separate sub-basins or if one or both units were capillary salts not bottom growths. Monomineralogic subaqueous evaporite beds are perhaps one of the few examples of true “layer cake” stratigraphy. Many of the supposed correlations and basin reconstructions in the literature, which propose that a deep subaqueous halite in the basin-centre is time-equivalent to a shallower subaqueous basin marginward anhydrite and to a biologically restricted, but growing, reef carbonate in the seawater inflow area are wrong as they ignore the fundamental principles of physics and hydrology. By implication, the geological interpretations and correlations in the same regions will be marked by the nonrecognition of the significance of erosion surfaces, hiati or dissolution horizons in adjacent wells or in the carbonates or other marine strata that occupy the basin margin. A time of evaporite deposition corresponds to a time of exposure and the creation of a subaerial unconformity in adjacent carbonate sills.

FIGURE 5.30. DISSOLUTION OF EVAPORITES ABOUT THE MARGIN OF A BASIN CAN CREATE AN APPARENT OFFLAPPING STRATIGRAPHY FROM AN ONLAP SITUATION (AFTER KENDALL, 1988).

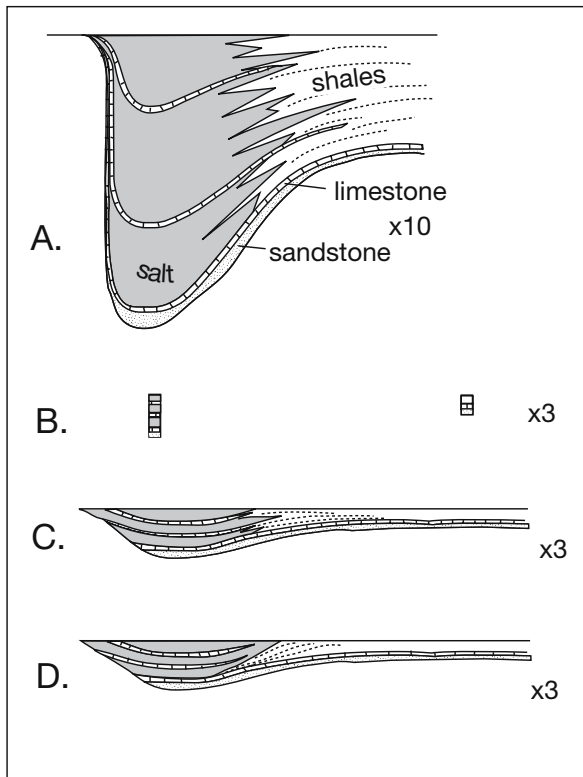

Figure 5.31. Effect of vertical exaggeration on correlation between thick evaporite sequences and marginal clastics or carbonates (after Busson, 1980; Kendall, 1988). A) Conventional correlation with significant vertical exaggeration showing lateral equivalency of evaporites and marginward clastics or carbonates. B) Original data drawn with less vertical exaggeration. C) Conventional correlation with less vertical exaggeration (hydrologically unlikely in an evaporite basin accumulating thick salt beds). D) Alternative correlation, which assumes drawdown is required and so there is no equivalency between salt beds and marginward clastics or carbonates (hydrologically likely in drawdown basin). Alternative D) is reasonable to most geologists when not suffering from a psychological need to draw near-horizontal correlation lines. It implies times of thick salt accumulation were distinct from times of carbonate deposition.

Kendall (1988) lists five factors that should be addressed when correlating evaporite units or applying the principles of sequence stratigraphy to evaporite basins:

1. *A lack of stratigraphic control*; evaporite depositing areas tend to be populated by halotolerant organisms that have low biostratigraphic potential. This means that biostratigraphic faunal analysis can be used to bracket the evaporite group (using fossils in nonevaporite strata above and below the unit of interest); but intra-evaporite biostratigraphic subdivision is near impossible.

2. *The rapidity of evaporite deposition*; evaporites accumulate at some of the most rapid sedimentation rates known. Even if fossils are present in intrasalt units that separate a number of evaporite beds, the very short time required to deposit thick evaporite sequences means the biota are incapable of evolving fast enough to be used for biostratigraphic control of the evaporites.

3. *Complexity of stratigraphic relationships*; stratigraphic relationships between the surrounding nonevaporite lithologies and the evaporites are typically dynamic and problematic. Their hydrology and rapid rate of deposition mean evaporites accumulate so rapidly that lateral correlatives to the evaporite deposit are at best thin, or more typically, are surfaces of erosion or nondeposition.

4. *Early dissolution about basin edge*; A high likelihood of partial to complete subsurface dissolution, especially of the more soluble salts, almost from the time the salts accumulate (Figure 5.30). This means most ancient evaporite deposits show clear evidence of thinning, especially about the edges of a thick evaporite succession where flushing by meteoric and basal waters is most likely to occur. As we shall see in Chapter 7, a salt bed or halokinetic salt mass shrinks like a block or ice, inwards from its edges. If the evaporite dissolves completely, remnants may be missed (such as layers of insolubles or thin dissolution breccias), and a whole episode of basin history and structural evolution ignored. Even when evaporites remain in the basin, a greater degree of dissolution in zones of freshening about the basin edge means the current distribution of mineralogies may bear no relation to their original distribution in a basin (Figure 5.30). Removal of the marginal portion of a halite layer that had overstepped an earlier anhydrite unit will convert an onlapping situation to an apparent offlapping situation in a seismic section in an area without well control. Likewise many apparent “bull’s-eye” basins may be the result of marginward dissolution of the more soluble evaporite layers.

5. *Inappropriate scaling*; We tend as a profession to use vertically exaggerated cross sections to make relationships more obvious in what are natural systems with thin relative to width ratios (Figure 5.31a). Their training makes most geologists reluctant to draw steeply inclined bed-to-bed correlations when more horizontal possibilities are available (Kendall, 1988; Busson, 1980). A propensity for large vertical exaggeration in basin cross-sections leads to a tendency to draw correlation lines that show transitional facies between the evaporite beds and the surrounding nonevaporites, and to impose age equivalence of evaporites and nonevaporites (Figure 5.31b, c). But the inherent hydrological constraints required to form a platform

or basinwide evaporite fill means salt beds tend to accumulate rapidly in isolated depressions on the land's surface. Times of evaporite deposition correlate to times of isolation and so to times of nondeposition or gaps (unconformities) in adjacent nonevaporite strata. In such situations we should be quite happy to draw inclined correlation lines showing that at the time of evaporite deposition there was little or no deposition taking place in the adjacent nonevaporite strata (Figure 5.31d).

Dolomite aprons in a drawdown basin

Requirements of hydrographic isolation for basinwide evaporites also have consequences for reflux dolomites. In contrast to well documented reflux dolomite geometries and distributions in platform evaporite associations (Figures 2.50, 10.24), outputs from dolomitising hydrologies in saline giants are a little more complicated (Figure 5.32). Brine plume and seawater seepage inflow in a drawdown basinwide evaporite

depression is driven by piezometric head between sealevel and the brine -air interface, which can be of hundreds to thousands of metres below sealevel (Figure 5.7b). With no modern counterpart, one can only infer, not observe, the hydrological and diagenetic character of such basinwide systems by studying the more accessible outcrop examples of platform and basinwide evaporites, as in the Messinian evaporite/dolomite associations of the circum-Mediterranean (Sun and Esteban, 1994; Lu and Meyers, 1998), the Permian Zechsteinkalk dolomites associated with basinwide evaporites of NW Europe (Clark, 1980a; Peryt and Scholle, 1996) and the Devonian basinwide evaporites and associated dolomites of the Keg River- Pine Point Presqu'ile of Canada (Maiklem, 1971; Kendall, 1989).

Maiklem (1971), Cercone (1988) and Kendall (1989) pointed out the potential for widespread dolomitisation via seawater seepage beneath subaerially exposed carbonate slopes about a drawdown basin margin is largely independent of marine

Figure 5.32. Evaporative drawdown dolomitization. A) Hydrology of basin showing seepage facies and halite in basin centre. Note the potential for the mixing of seawater seepage with refluxing brines both about the margin of the drawdown basin and beneath the reflux curtain across much of the basin floor. Diagram is not drawn to any consistent lateral scale. B) Close-up of facies pattern associated with seepage outflow zones and the potential positions of marine/meteoric and marine/hypersaline mixing zones (in part after Warren, 2000a and Kendall, 1989).

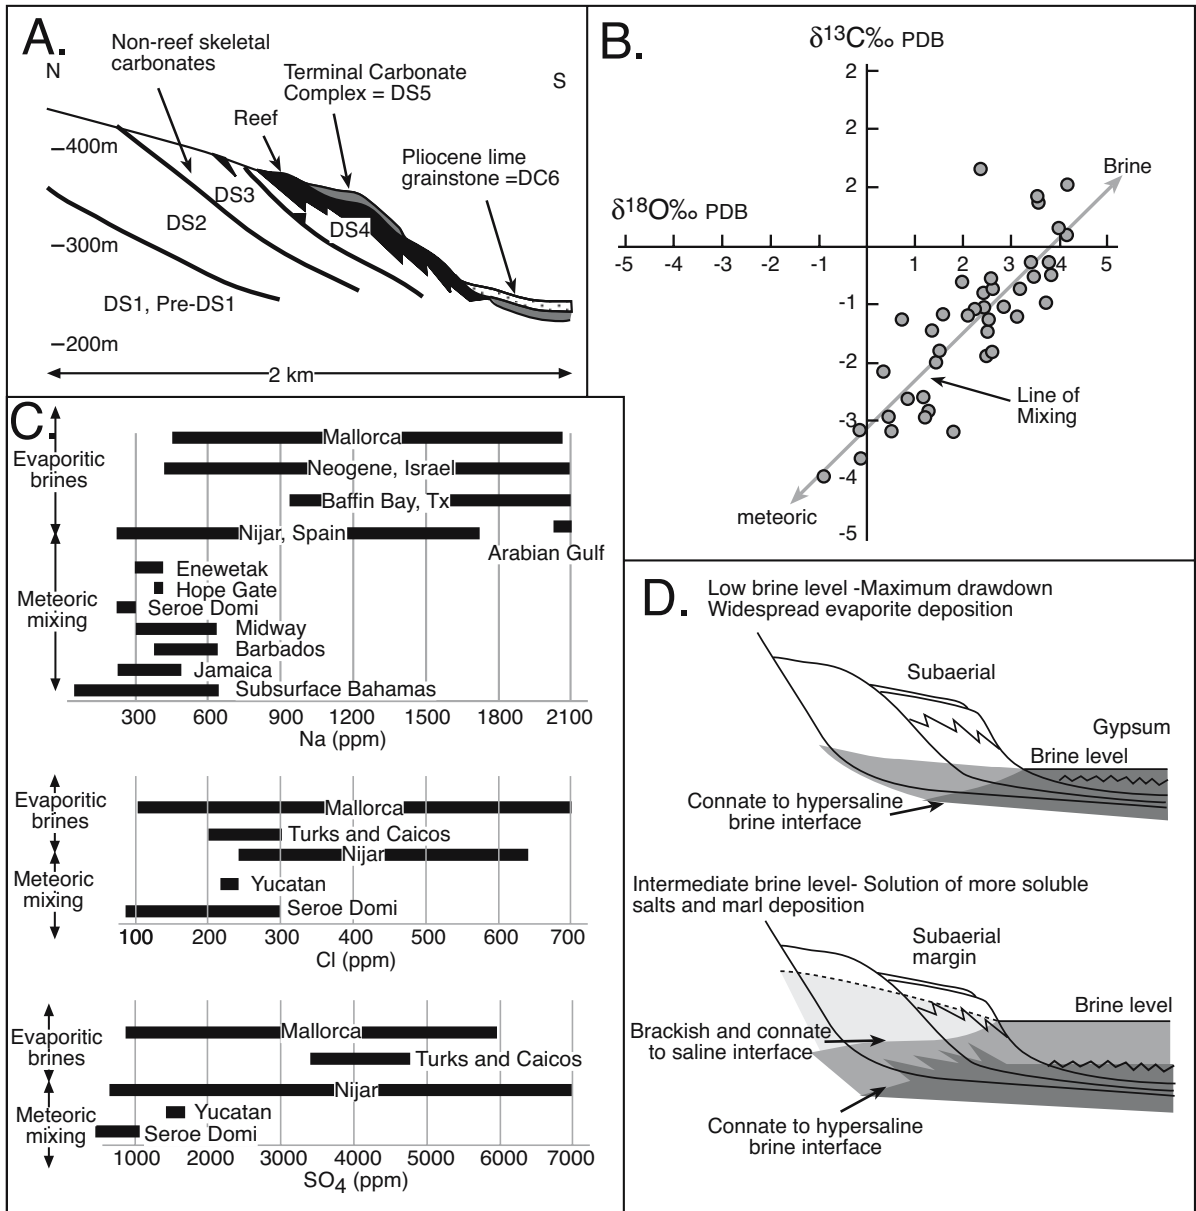

Figure 5.33. Nijar dolomites in the Messinian of Spain. A) Composite stratigraphic cross section of the Tortonian-Messinian carbonate platform at Nijar. DS = depositional sequence. B) Oxygen and carbon isotopes of the Nijar dolomites C) Na, Cl and SO₄ contents of Nijar dolomites compared to other Tertiary and modern dolomites formed in mixing zone, seawater and evaporative brines. D) Model of migration of mixing interfaces between hypersaline brine, connate seawater and meteoric brackish waters. Their position within the carbonate margin is controlled by fluctuation in brine level in the basin (after Meyers et al., 1997; Lu and Myers, 1998; Lu et al., 2002).

eustasy (Figure 5.32). Drawdown basins have the potential to flush huge volumes of phreatic seawater through the basin edge. As the groundwater heads in such systems are measured not in metres but hundreds of metres, and if one accepts that seawater flushing has the potential to dolomitise marine limestone, then the potential for dolomitisation is huge within

carbonate aquifers about the margin of an evaporite drawdown basin. "Mixing" zone dolomites are also likely, but not in a classic seawater-freshwater Ghyben Herzberg interface on the marine side. Rather dolomite will form in rapidly fluctuating and flushed interfaces and outflows in and about the now isolated and exposed carbonate slope and rise shown in Figure 5.32.

The schematic is drawn assuming an unconfined aquifer in the interval separating the marine from the seepage zone. The reality is much more likely to be a combination of confined and unconfined aquifers feeding predominantly seawater into the basin margin. This zone of mixing and seawater spring outflows will move to and fro over the exposed basin edge as the brine level in the basin responds to changes in tectonics and climate.

Outflow points of these predominantly seawater brines develop a characteristic set of pisolitic/tepee cementstone lithologies - the strandline/seepage facies described in Chapter 1. Kendall (1992) showed how such a carbonate seepage facies can be used to define hydrologies in the Devonian Keg River Basin where these spring-aprons were mostly located about exposed former shelf slopes and pinnacle reefs (Figure 5.32b). When part of an inactive pinnacle reef or other aerially exposed bioherm, these permeable carbonates can act as confined aquifer outflow zones capable of breaching the active reflux curtain on the basin floor, much like the modern spring mounds of Lake Eyre and Lake Frome (Figure 5.32a). Slightly down dip of the seepage facies were evaporitic mudflats dominated by anhydrite and in the lowermost sections of the basin floor were widespread areas of perennial surface brine (the halite seaways of the Keg River Basin). Away from seawater and meteoric discharge seeps, the downward reflux associated with the brine curtain moved Mg-rich waters into underlying sediments driving reflux dolomitization and evaporite plugging. This water ultimately mixed with deeply circulating seawater seepage fluids and other subsurface waters (Figure 5.32a).

Such a basinwide hydrology creates both reflux and mixing zone chemistries, which have the potential to dolomitise any limestone host in contact with the outer parts of the brine curtain. Detail of such drawdown mechanisms can be inferred in dolomite distribution within Neogene evaporitic sub-basins of the Mediterranean. For example, Meyers et al. (1997) and Lu and Meyers (1998) have documented pervasive dolomites that cut across intra-Miocene sequence boundaries in the Nijar Platform and also occur in the youngest Messinian reef/oolitic units (Figure 5.33a). The dolomites do not transect the Miocene-Pliocene unconformity, although they do occur as clasts in overlying basal Pliocene lime grainstones. This constrains the dolomitization as being latest Miocene and pre-Pliocene, suggesting this widespread dolomitization occurred within 600,000 years and possibly in less than 200,000 years. It is an excellent indication of the large volumes of phreatic seawater that can be cycled through the rock pores in short times in drawdown hydrologies.

Carbon and oxygen isotopes of Nijar dolomites show marked positive covariation, with most values ranging from +5.4 to -1.2‰ $\delta^{18}\text{O}_{\text{PDB}}$ and +2.5 to -4.3‰ $\delta^{13}\text{C}_{\text{PDB}}$ (Figure 5.33b; Meyers et al., 1997). The highest $\delta^{18}\text{O}$ values are heavier than reasonable estimates of Messinian normal-salinity seawater dolomites, suggesting the involvement of evaporative brines in the dolomitisation process. Calculations of covariations of O and C isotopes during water-rock interaction and fluid-fluid mixing argue against recrystallisation of Nijar dolomites, an interpretation also supported by their Ca richness (49-57 mol %). Mixing calculations show that four-fifths of Nijar data are consistent with dolomitization via mixtures of freshwater and a few tens of per cent of marine-derived evaporative brine, while one-fifth are consistent with mixtures of freshwater and normal-salinity seawater. Modelling of covariations of $^{87}\text{Sr}/^{86}\text{Sr}$ and Sr/Ca ratios that developed during mixing, further supports involvement of evaporative brine, and suggests that any freshwaters involved in the dolomitization had low Sr/Ca ratios and relatively high Sr and Ca concentrations. Na, Cl, and SO_4 concentrations in Nijar dolomites (200-1700 ppm, 300-600 ppm, and 600-6500 ppm, respectively) also argue for involvement of evaporative brines, and for mixtures of brine with freshwater and/or seawater (Figure 5.33c).

Meyers et al. (1997) and Lu and Meyers (1998) proposed that most dolomitization occurred after Messinian reef formation during multiple relative sealevel/brine level changes associated with evaporative drawdown. Marine carbonate deposition of the Nijar shelf occurred during high sealevels, and evaporite deposition during lowered basin water levels associated with evaporative drawdown. During drawdown, basin brines with 5x- to 6x-seawater concentrations (gypsum precipitating) developed on the floor of the Nijar Basin. Brines mixed with freshwater and seawater mainly in a groundwater setting about the basin margin as fluctuating base levels of the brine curtain drove before it a zone of freshened/meteoric water seepages (Figure 5.33d).

Similar drawdown dolomites can be found in the Zechstein of NW Europe where dolomitized algal-bryozoal reefs, oolites and intertidal to shallow subtidal skeletal grainstones to mudstones occur adjacent to the margin of the Zechstein salts. They are interlayered with the platform portion of basinwide evaporite beds composed of anhydrite and halite (see later in this chapter). Evaporite salts were deposited during the complete isolation and drawdown of the Zechstein Basin. It was at this time of drawdown that reflux dolomites replaced the adjacent and underlying Zechstein limestones (Clark, 1980a). At the same time the regression of facies associated with the drawdown of

the brine base level caused the encroachment and displacement of formerly marine to hypersaline porewaters by meteoric waters in the dolomites of the Magnesian Limestone (Kaldi and Gidman, 1982).

Sequence stratigraphy in evaporite basins?

Sequence stratigraphy is the study of ancient rock relationships within a chronostratigraphic framework of repetitive, genetically related strata, bound by surfaces of erosion or nondeposition or their correlative conformities (Posamentier and James, 1993). Stratigraphic sequences are deposited during a single cycle of relative sealevel change and the rise and subsequent fall of sealevel within the shallow marine setting generates a characteristic sedimentary wedge with a specific geometry and vertical stacking pattern. Sequences are conformable successions constructed by genetically related strata, bound at the top and bottom by unconformities and their correlative

conformities (Figure 5.34; Van Wagoner et al., 1988, 1990; Tucker, 1993). Unconformities bounding sedimentary wedges may represent a significant time gap and may die out in more basinward positions where sealevel oscillations do not expose the sedimentation surface.

In classic sequence stratigraphic interpretations of marine sequences the major control on depositional extent and geometry is assumed to be relative sealevel change, determined by rates of eustatic sealevel variation and tectonic subsidence. Depositional sequences are generated by a single cycle of relative sea-level change, and a complete depositional sequence, bounded by unconformities, consists of, from oldest to youngest, lowstand, transgressive, and highstand components (= systems tracts). This evolution creates the characteristic transgressive-regressive pattern of sedimentary facies within a depositional sequence with the outline of a sigmoidal wedge or prism (Figure 5.35); lowstand systems tract (LST), transgressive systems tract (TST) and highstand systems tract (HST)). A seismically resolvable depositional sigmoid typically has a thickness of 10-100 m,

extends laterally for 10-100's km, and represents a depositional episode of 1-5 million years in duration. According to Haq et al. (1987), it is a response to 3rd order sealevel changes (Table 5.8). Internally depositional sequences are constructed of sub-seismic-resolution parasequences (metre- to decametre-scale 4th and 5th order depositional cycles). Parasequences are typically bound by local scale unconformities and disconformities.

Chronostratigraphic correlation is an important application of sequence stratigraphy. It is tied to the notion that sediment wedges form in response to worldwide sealevel cycles of rise and fall. If so, then seismic geometries can be used to extract a global sealevel cycle chart (aka Vail or Exxon sealevel curves). This then leads to the construction of age models for given stratigraphic successions that are based on the correlation of a local stratigraphic sigmoid to this global sealevel curve (Posamentier and James, 1993). Different orders of sealevel change are recognised based on the time interval

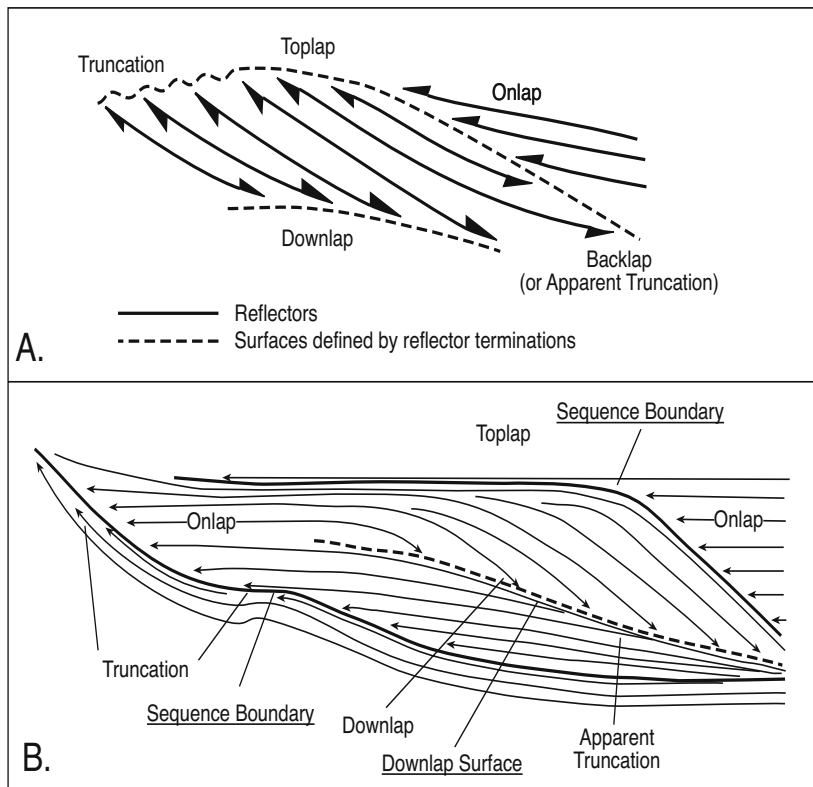

Figure 5.34. Fundamentals of seismic sequence interpretation. A) Terminology used in defining sequence interpretation of seismic reflectors. B) Sequence boundaries define a depositional package.

encapsulated in the sealevel cycle (Table 5.8). The use of sequence stratigraphic principles to construct age-eustatic (chronostratigraphic) models is based on the assumption that stratigraphic successions are a function primarily of eustatic rather than local tectonic fluctuations or that the effect of tectonics can be removed to allow sealevel fitting.

First and second order changes in world sealevel are a response to changes in the volume of the ocean basins caused by continental dispersal and collision. High rates of seafloor spreading during continental dispersal reduce ocean basin volume, leading to high sealevel. Third order changes have durations of 1 to 10 m.y. and are typically about 2.5 m.y. in length. The cause of third order cycles is controversial as they are too short to attribute to most world scale tectonic events affecting the volume of the ocean basins, but too long to attribute to glacio-eustatic responses. Other more local tectonic events, such as changes in plate stress and regional tectonism, are of the correct duration, but do not appear to be capable of generating sufficient change in water depth to account for the magnitude of world scale third order cycles. Fourth order (500 ky - 200 ky) and fifth order (200 ky - 10 ky) cycles are widely documented in marine sediments (outcrop and core based parasequences) in many periods of the Phanerozoic in both shallow marine and pelagic strata. These cycles are possibly the result of changes in global climate driven by cycles in the Earth's orbital parameters and tilt, collectively referred to as Milankovitch Cycles.

Figure 5.35. The familiar sigmoidal or "slug" model of a marine carbonate depositional sequence used by sequence stratigraphers with the black shaded areas representing carbonate shoal/reef sediments. A single depositional sequence consists of lowstand, transgressive and highstand systems tracts (after Van Wagoner et al., 1988 and other sources). In terms of associated evaporite deposition each sequence boundary (unconformity) may be time equivalent to a thick sequence of basinwide evaporite fill, which accumulated further out in the basin. Saltern evaporites tend to accumulate on the platform landward of the reefs within transgressive system tract sediment packages when higher order sea sealevel falls expose reef crests and isolate lagoons from a surface connection to the ocean.

There is still much debate in the literature as to controls on the magnitude and frequency of the various sealevel changes that could facilitate a correlation of sedimentation packages worldwide; especially at the third order world scale cycles where seismic and rock based interpretations overlap. At that scale, some authors well versed in outcrop and core study go further and question the reality and the scientific basis for the construction of world scale age correlations based on seismic-based third-order eustatic age curves in almost all sedimentary basins (e.g. Miall, 1997).

For evaporites, there is also the problem of different depositional rates inside and outside a hydrographically isolated groundwater

Order	Years	Tectono-eustatic	Rifting and thermal subsidence	Global eustatic	In-plane stress	Glacioeustatic, tectonic, sedimentary	Basinwide Evaporites Time to deposit 1-2 km of fill
1st	10 ⁸	↕	↕	↕	↕	↕	SEISMIC SIGMOIDS ↕ PARASEQUENCES
2nd	10 ⁷						
3rd	10 ⁶	SEISMIC SIGMOIDS		↕	↕		
4th	10 ⁵	↕					
5th	10 ⁴	← -- Typical limit of seismic resolution in siliciclastics and carbonates -- →				↕	
6th	10 ³	PARASEQUENCES					

Table 5.8. Orders of sealevel change and likely driving mechanisms (in part after Tucker, 1993).

sump. Rates of evaporite deposition, especially in basinwide settings, are an order of magnitude higher than that of marine shelf carbonates or siliciclastics (1-2 km in 300,000 to 500,000 years are typical). Seismic geometries resolvable in evaporite fills are typically 4th and 5th order, with parasequence sets resolving time frames of the order of a thousand years (6th order). Comparing seismic stratigraphies inside and outside a basinwide evaporite basin and attempting, based on the evaporites, to relate the eustatic interpretation to the global curve is difficult if not impossible. We are not resolving depositional evolution at the same time scale (Table 5.8).

More generally accepted than worldwide chronostratigraphic correlation is the application of seismic sequence stratigraphy to lithology prediction based on interpretation of depositional geometries and basin architecture using a combination of seismic, wireline, core and outcrop data. For example, the favoured sites for major porosity development in carbonate-dominated depositional sequences include large, isolated buildups within the transgressive phase, massive grainstone aprons located immediately landward of the shelf-margin facies within the regressive phase, and karst-affected platform interior facies immediately beneath the sequence-bounding inter-regional unconformities (Figure 5.35).

There are numerous volumes and papers now published that deal with high resolution sequence stratigraphy of arid zone carbonate shelves and ramps and how they differ from siliciclastic sequences in their response to sealevel changes (Figure 5.35; Read et al., 1995; Budd et al., 1995; Loucks and Sarg, 1993; Tucker, 1993; Posamentier et al., 1993; James and Kendall, 1992). The details will not be repeated here and the interested reader should refer to these volumes. There are only a few published papers that deal specifically with the sequence stratigraphy of evaporite systems; key papers include, Tucker, 1991; Goodall et al., 1992; Strohmenger et al., 1996a, b; Sarg, 2001. The results are contentious and most concentrate on the carbonate (marine-connected?) stage of the evaporite basin. This is understandable as it is in these carbonate units that potential hydrocarbon reservoir facies are to be found, often beneath or adjacent to the evaporite seal.

Does sealevel control salt sequences?

When attempting to interpret eustatic effects (global sealevel) in evaporite basins, a requirement of no effective hydrographic connection to the open ocean during times of extensive evaporite accumulation plays havoc with the fundamental marine eustatic paradigms of sequence stratigraphy. Documented brine level

changes in lacustrine and marine basinwide settings are ≈ 1 km in a few thousand years and there is no simple relationship between sealevel changes going on outside the basin and the geometry of the evaporite body in the isolated evaporite-accumulating basin (Kendall, 1992).

All evaporite basins with a marine-seepage feed have a brine level that is below sealevel. It is, after all, drawdown that drives brine influx in ancient marine-fed basins. The relative difference in water level across the isolating barrier may be no more than a few to tens of metres, as it was in the platform evaporites of Guadalupian backshoal strata in west Texas, or it may be thousands of metres as it was in the late Miocene salinity crisis in the Mediterranean, the Cretaceous evaporites of the southern Atlantic and the early stages of the Permian salinity crisis in the Zechstein Basin of NW Europe. Brine salinities and the rate of salinity change in a brine-filled depression, as well as the absolute brine level in an isolated basin, are controlled by the local climate, the rate of brine leakage through the underlying brine curtain and the rate of seepage replenishment of the inflow waters and brines about the depression's margin. With most ancient saline giants the creation of a depression capable of accumulating and preserving thick lacustrine and basinwide evaporite fill is a response to tectonics, not eustacy (Figure 5.27).

Marine-fed platform evaporites must be distinguished from basinwide evaporites if one wishes to apply the marine eustatic concepts. At our present level of understanding we can probably fit marine-margin platform evaporites and some intracratonic saltern fills (epeiric seaways) into a global eustatic context. In the absence of tectonic tilting in these two settings, the precipitation of large volumes of platform salts is largely dependent on marine phreatic seepage through a carbonate barrier. It requires platform isolation brought about by a slight fall in sealevel, perhaps a 4th order fall on a 3rd order rise in greenhouse mode (Figure 5.7a). The evaporites can fill the depression behind the barrier; but cannot, as they are seepage fed, rise any higher than sealevel. The isolating barriers in turn have geometries and distributions across the platform that are controlled by sealevel changes (Read et al., 1995; Loucks and Sarg, 1993).

In contrast, tectonically-formed subsealevel basinwide evaporite units, with their much lower hydrological base level, are more problematic in terms of using the effects of sealevel fluctuations to understand and predict evaporite geometries and mineralogies. The problem will remain until the hydrologies of large-scale drawdown systems are better understood. Formation

of basinwide evaporite sequences are largely tied to a suitable juxtaposition of tectonics and climate. In such a scenario the decametre sealevel fluctuations on the marine side of the isolating barrier are largely irrelevant to evaporite depositional styles within the lowermost portions of an isolated basin experiencing a drawdown that is up to 1,500 - 2,000 metres below sealevel. Likewise continental lacustrine evaporites are not directly tied to the world sealevel curve. In both basinwide and continental lacustrine scenarios the application of sequence stratigraphic modelling is most useful in a genetic rather than an age (world sealevel) context.

Icehouse and greenhouse eustacy

Sequences in seismic stratigraphy are unconformity-bound packages generated by high amplitude sealevel changes with bounding surfaces typically produced during relative sealevel falls (Tucker, 1993). High amplitude sealevel changes producing regional sequence boundaries can occur on several time scales depending on the presence or absence of polar ice caps. At times of no polar ice cap (greenhouse earth) the high amplitude changes that produce sealevel oscillations of several tens of metres are a response to second and third order processes, while fourth/fifth order processes produce only metre-scale relative sealevel changes and associated parasequences (Figure 5.36). In contrast, when there are polar ice caps (icehouse earth) the high amplitude sealevel changes (typically greater than 100 metres) are brought about by fourth-/fifth order processes. The driving force for these high amplitude/high frequency oscillations is change in polar ice volume driven by Milankovitch rhythms (Figures 5.1, 5.2). During icehouse times the same longer term second-/third-order fluctuations in sealevel that dominate the greenhouse style still occur, but they now have a lower amplitude and longer period than the glacially driven changes. Thus the glacially-driven eustatic cycles swamp these longer term effects, so that in icehouse times fourth-order sequences are produced and are arranged into sequence sets (Tucker, 1993). Greenhouse periods produce third order sequences constructed by fourth-/fifth order parasequences and show a much more prevalent cyclicality in lagoonal parasequences.

Figure 5.36. Relationship between icehouse and greenhouse conditions, eustacy and global CO₂ (after Read and Horbury, 1993; see Figure 5.2 for more detail and refinement of curves/climate). Upper half of figure shows palaeolatitudinal extent of continental ice-raftered deposits (crosshatched) and marine ice-raftered debris (dots). The curve beneath plots net forcing of climate due to variations in CO₂ and solar luminosity. Inferred times of general icehouse and greenhouse earth are shown on the horizontal axis (icehouse times are narrower if defined on a basis of presence of polar ice, as in Figure 5.2b). Lower half of diagram shows first order Vail sealevel curve in upper part. Bottom diagram shows typical third order sealevel curve with 1-10 my period. Schematic 4th order with superimposed 5th order sealevel curves are drawn for icehouse and greenhouse conditions.

The Neogene sedimentary marine record is an icehouse record, where fourth-order sequences dominate the continental margin as unconformity-bound, relatively thin (5-30 m thick), stratal packages. Other older icehouse intervals include the late Precambrian and the Permo-Carboniferous (Figures 5.2, 5.36). In contrast in greenhouse times (Late Cambrian to Middle Ordovician, Silurian to Early Devonian, Late Permian to

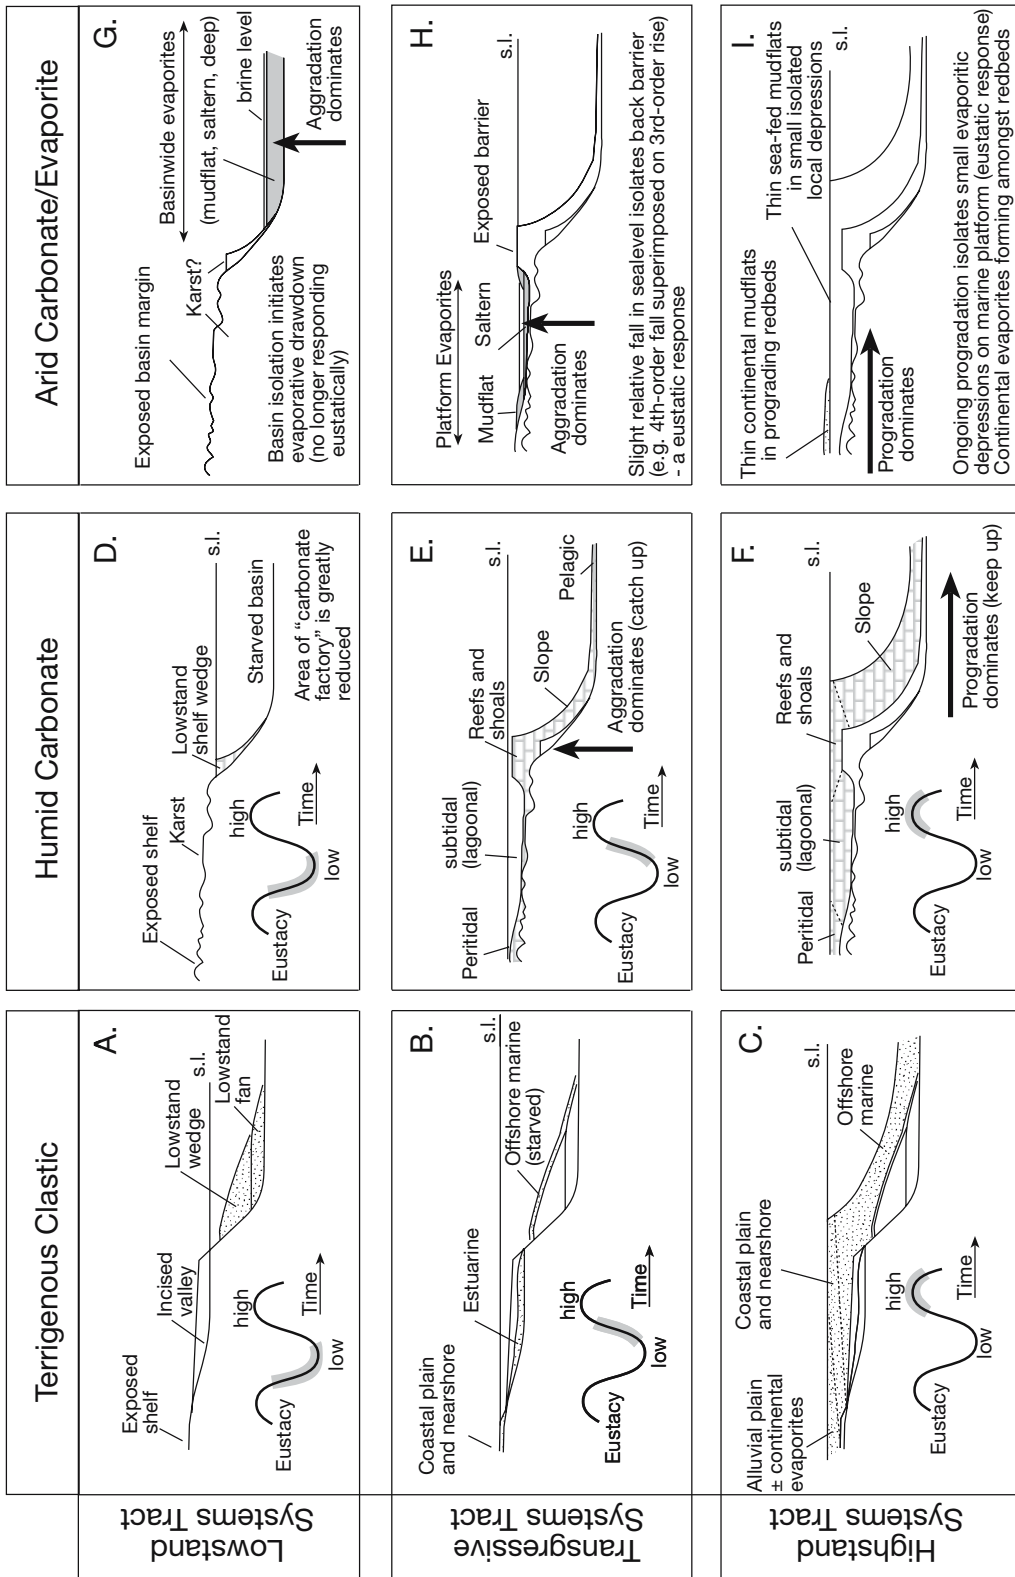

Figure 5.37. Sequence stratigraphic models for terrigenous clastic, humid carbonate and arid carbonate platform systems. Note there are significant differences. In a lowstand systems tract there are substantial volumes of terrigenous sediment deposited at the foot-of-slope, but relatively minor carbonate deposition if sealevel is below the shelf break (lowstand shelf wedge). In an isolated evaporite basin large volumes of basinwide evaporites can accumulate as a lowstand systems tract. In a transgressive systems tract carbonate sedimentation in a humid setting reaches its highest growth potential. If a transgressive systems tract is also subject to a higher order fall that isolates a seepage depression on the shelf, then thick sequences of platform evaporites can form. In a highstand systems tract only thin mudflat evaporite units can form, while thick sequences of platform clastics and carbonates can accumulate. See text for full discussion of this figure.

Oligocene), marine stratal packages consist of much thicker unconformity-bound sequences (50 m to hundreds of metres thick) deposited as third order cycles made up of fourth-fifth order parasequences that are 1 to 10 metres thick.

Marine-margin platform evaporites

Marine carbonate platform systems show a different set of depositional responses to sealevel change compared with siliciclastics (Figure 5.37). This is because almost all marine carbonate is ultimately biogenic. Unlike siliciclastic shelves (Figure 5.37a-c), carbonate shelves most actively aggrade and then prograde both seaward and landward during times when the continental margin and interior is covered by shallow seas. That is, those most rapidly growing parts of any epicontinental platform, usually the reef crest and associated grainstone belts, aggrade most rapidly when part of a transgressive systems tract (Figure 5.37e). In contrast, the marine carbonate platform progrades most rapidly when part of a highstand systems tract (Figure 5.37f). When part of a lowstand systems tract, the much more restricted area of the “carbonate factory” means little or no growth can take place in either deep or shallow water, karstification of exposed platform sediments dominates at the sequence boundary on the platform (Figure 5.37d).

Unlike siliciclastics, carbonate sedimentation rates cannot be assumed to be near-constant across a platform. The variation in unit thickness reflects the strong environmental controls imposed on biogenic sedimentation rates. Thus, changes in geometric stacking patterns in carbonates do not necessarily directly reflect changes in the rates of relative sealevel rise as environmental changes are not always directly linked to changes in sealevel, but may reflect differing rates of deposition due to differing biotal growth rates across the platform (James and Kendall, 1992; Hunt and Tucker, 1992).

In a marine carbonate system the TST is the time when the maximum growth potential of the carbonate platform is realised and the parts of the open marine platform with the greatest growth potential typically aggrade to sealevel and then begin to prograde both seaward and into the lagoon (Figure 5.37e). In contrast, evaporite deposition occurs on a marine platform when a back-reef or lagoonal depression is isolated from a surface connection with the sea (Figure 5.37h). On a ramp, the barrier is usually a buildup of some sort of continuous zone Y shoal, on a rimmed shelf it is typically the reef belt or the associated grainstone/pisolite flat that have built up to sealevel.

Hydrographic isolation across the barrier crest and the onset of thick platform evaporites are usually initiated by a slight fall

in sealevel, following a time of vertical aggradation (catch up) in the more rapidly growing parts of the carbonate platform; e.g. a fourth order fall superimposed on a third order rise in greenhouse mode. Thick platform evaporites are most likely to form as part of a transgressive systems tract (third order) in a greenhouse earth. Any slight fall in sealevel will be marked by an unconformity across the topographic high (rim/shoal), which isolates the marine from the evaporite-depositing areas (Figure 5.37h). Thinner evaporative mudflat (sabkha/salina) units may form as part of a highstand systems tract where ongoing progradation of the shelf (keep up) isolates small depressions further landward (Figure 5.37i).

When platform evaporites were deposited, the subaerial isolation either of the rim/grainstone buildups on a rimmed shelf or of the zone Y shoal facies on a ramp were responsible for the restriction of the lagoon to the point where evaporites could accumulate (Figure 5.28; Lucia, 1972). Otherwise, like the carbonate shoals and reefs on platforms of today, subaqueous conditions behind the shelf rim or shoal would have never become saline enough to deposit subaqueous evaporites and only thin capillary zone sabkha caps (< 1m thick) could prograde across the landward feather edge of marine lagoon sediments. Prior to hydrographic isolation, normal marine to restricted marine sediments had been accumulating in the lagoon, so that in a vertical profile normal marine bioturbated shelf wackestones and mudstones typically underlie bedded platform evaporites. In sequence stratigraphic terms, episodes when platform evaporites accumulate correlate to karstic exposure surfaces or bounding surfaces on the platform crest. But, as it occurs in greenhouse eustasy, 4th-order sealevel did not fall more than a few metres, so it is a type 2 sequence boundary. In contrast all basinwide deposits are defined by type 1 sequence boundaries (in truth, applying marine seashore terminology to a hydrographically isolated and drawdown basin is probably wrong usage, or at least inappropriate).

Once an evaporite lagoon on the platform is hydrographically isolated from the open ocean, two end members can be deposited behind the rim; either saltern sequences or mudflat-dominated successions (Figure 5.7). The dominance of one or the other reflects the response of evaporite drawdown hydrology to changes in relative sealevel on the platform. An evaporitic mudflat mosaic forms when there is intense evaporation and relatively slow rates of marine seepage recharge and longterm surface brine cover is relatively rare. Mudflat fills dominate if there is little difference in elevation between the sealevel on the other side of the exposed barrier crest and the floor of evaporitic depression. Sediments of the rim /shoal (oolite/grainstone/pisolite/boundstone) pass directly upward into thin

intercalated sabkha/salina units or stacked sabkha cycles and back to shoal facies that make up the base of the next cycle, with no intervening saltern sequences.

Saltern fills tend to dominate evaporites of the lagoon fill when evaporation is less intense and/or there is a greater rate of seepage replenishment through the isolating barrier. Salterns are more common if there is a greater potentiometric head across the barrier between ambient sealevel and the water surface in the lagoon. This tends to occur when the platform lagoon was deeper at the time of its isolation. This happens during a transgression in settings where the rim/shoal aggrades relatively rapidly, while the backshoal platform does not keep pace with the same rise in sealevel. Early shoalwater carbonates deposited on the lagoonal side of the rim are not all that different from those on the seaward side of the rim. This is especially true where the rim is incipiently drowned at the onset of the transgression. While the rim was growing and catching up to a new, higher sealevel the waters in the lagoon could freely exchange with the open ocean and so a diverse open-marine biota flourished within the lagoon.

When a rim reef or shoal catches up to the new higher sealevel and coalesces into an isolating barrier, conditions in the carbonate-accumulating epeiric lagoon become more restricted. As the exchange with open ocean waters is reduced; sediments are now deposited as restricted-marine carbonates. With complete restriction across the rim or shoal, the lagoonal waters become sufficiently saline to deposit evaporites and fill the drawdown lagoon with a shoaling-upward saltern cycle, perhaps capped by a mudflat sequence. The saltern evaporite unit is as thick as the lagoon was deep at the inception of evaporite deposition (Figures 5.7a, 5.37h).

Such subaqueous saltern beds tend to be widespread across the evaporite lagoon and so are easily correlated from well to well as metre- to decametre-thick clean evaporites. The ten or so subaqueous cycles of the Cretaceous Ferry Lake Anhydrite in the northern Gulf of Mexico region (Figure 5.20a; Pittman, 1985) and the Permian San Andres cycles on the northern margin of the Delaware Basin (Elliott and Warren, 1989) are examples of stacked saltern beds, while the base of the Late Permian Seven Rivers Formation atop Yates Field on the Central Basin Platform in west Texas is an example of the stacked mudflat mosaic (Figure 10.38). The geology and reservoir/seal properties of these units is detailed in Chapter 10.

Unlike bedded carbonates and siliciclastics, the effects of syndepositional and later evaporite dissolution can greatly complicate any attempt at high-resolution stratigraphic in-

terpretation in an evaporitic platform. Dissolution typically occurs as the subsiding platform evaporite passes from an active phreatic hypersaline hydrology into a compactional or thermobaric regime. This creates thin dissolution breccias and residue layers that extend over large portions of the platform (Chapter 7). Such breccias can be confused with subaerial exposure surfaces and humid/temperate phreatic karst. Unless the significance of evaporite dissolution breccias and the timing of dissolution in relation to burial is recognised, whole episodes of platform isolation may be miscorrelated. Many published outcrop-based studies of high-resolution stratigraphy in carbonate-evaporite platforms are problematic because dissolution breccias, which tend to be thin and recessive, are largely unrecognised or, if recognised, misinterpreted as marine flooding surfaces. And yet, a one-metre thick breccia may mark the position of a former 100m thick salt bed. This is especially true in Precambrian platforms where biostratigraphic checks on correlation are not possible.

Platform evaporites in a greenhouse earth?

The high amplitude rapid to-and-fro of the icehouse sea across Neogene platforms has discouraged the deposition of extensive shallow water platform evaporites. The most recent time of extensive platform evaporites is perhaps the Eocene in the Middle East, centred on Iraq and Iran or the Paleocene of North Africa (Table 5.5). Platform evaporites tend to form under greenhouse earth conditions characterised by lower amplitude sealevel fluctuations and higher world sealevel with marine waters over large parts of the continental masses (epeiric seaways). The high-amplitude high-frequency sealevel changes of icehouse earth encourage local high-relief “catch-up” reefs and banks due to ongoing rapid flooding and exposure of the platform, along with substantial unconformities and pervasive meteoric diagenesis deep in the reefs. Hence icehouse carbonate facies show considerable lateral thickness variations (Read and Horbury, 1993). Throughout the Quaternary there has never been sufficient time for shelf edge reefs and sand belts to grow and accrete into a single continuous shelf margin facies belt similar to those that characterise greenhouse time. Before it can happen, icehouse sealevel falls off the shelf edge every 100,000 years or so.

Thus, platform reefs and shoals typically do not develop into laterally continuous strike-parallel belts under an icehouse scenario. Converting large areas of periplatform lagoons into isolated depressions with marine-seepage hydrologies suitable for precipitating evaporites simply does not happen. The only place where marine-fed isolated seepage depressions can occur

in today's icehouse scenario is in narrow sea-marginal highstand bands, as evidenced by numerous small scale sabkhas and salinas along the marine coasts of many arid areas (Chapters 3 and 4). Sealevel repeatedly falls off the platform in icehouse earth mode (>100m fall; type 1 boundaries) and so any local areas of sea-marginal peritidal or seepage evaporites that may have formed in a highstand are subject to widespread dissolution via vadose flushing, as is seen in the worldwide lack of well preserved Pleistocene marine sabkhat and salinas (Warren, 1991). Even in the hyperarid coastal zone of the Red Sea, only small isolated remnants of marine-fed evaporites from the last 100 ka sealevel high remain and none remain from the previous 200 ka high (Figure 4.15). Thus, modern highstand marine-edge evaporites are small in scale and have little or no longterm preservation potential.

In contrast, the low amplitude low frequency sealevel oscillations that characterise epeiric seaways and shelves in greenhouse earth intervals favour the formation of stable, large, highly restricted, at times evaporitic, depressions on the inner shelf portions of many marine platforms. Sea levels were high and covered more of the craton. Carbonate platform rims had growth potentials that could more than keep pace with the low amplitude fourth order sealevel fluctuations. Wide, flat carbonate platforms with huge back-platform lagoons were commonplace (epeiric seas). A slight fall in sealevel meant seepage waters easily ponded in isolated large shallow shelf depressions behind continuous, now subaerially exposed reef or shoal rims. In areas where epeiric seaways covered large inland portions of the continental interior, the formation of a tectonic or shelf rim barrier followed by a fall in sealevel meant that the entire platform interiors and intracratonic sag basins could become evaporitic.

Thus, stacked platform evaporites tend to form in epeiric and pericontinental seas in greenhouse times as rapidly deposited, but extensive, saltern and mudflat beds precipitated atop marine lagoon sediments. They were part of an overall TST, but only precipitated during short intervals characterised by higher-order low amplitude falls in sealevel. At such times the platform crest was subaerial and much of the platform was brine saturated. Today there are no substantial epeiric seaways and the isolating effects of slight sealevel falls, as well as any possibility of accreting an ongoing laterally continuous carbonate platform rim, are swamped by the overriding influence of rapid, high-amplitude, icesheet-induced 4th order sealevel changes moving across relatively narrow and steeper continental shelves. Conditions suitable for the formation of platform evaporites simply do not exist under today's icehouse eustatic regime.

Basinwide evaporites

Thick basin-filling evaporites (more than 500-1,000 m thick and hundreds of kilometres across) accumulated in both greenhouse and icehouse periods. They did so, not because of fluctuations in sealevel, but as a result of tectonic isolation of large parts of the earth's surface from the direct surface influx of the world's ocean waters. Fills tend to be autocyclic and tectonically induced, although subsequent fluctuations in sealevel may have aided erosional breaching and refilling of the depression by seawater episodes (Table 5.6; Figure 5.27). Once isolated, changes in sealevel outside the basin rim may change potentiometric head with respect to the free brine surface in the basin and so drive changes in the rate of supply of brine. A relatively high sealevel outside of the basin will create a steeper potentiometric gradient and hence encourage more rapid replenishment of brine and a greater volume of brine seeping through the permeable barriers that separate the brine depression from the open ocean (e.g. Kendall, 1992). When relative sealevel is lower, this decreases the potentiometric gradient and slows the rate of brine flow. A fall in sealevel also causes the sea coast to retreat from the isolated depression, which further decreases sea water supply.

But autocyclic mechanisms, including the vagaries of climate, tectonics and adiabatic effects, along with the rate of formation and efficiency of intrabasin brine curtains or hydroseals, all interact to swamp the influence of sealevel changes to the hydrology of the evaporite basin (Chapter 2). For example, the aggradational infill of a tectonic depression by salt beds that create their own underlying aquitard or brine curtain has the same effect as the change in sealevel on potentiometric gradient of the inflow. As the sequence aggrades it decreases the potentiometric gradient and so slows the rate of marine recharge independent of changes in absolute sealevel.

The effect was noted by Warren (1982b) and used to explain the changes in the infill cycle textures in Holocene gypsum-filled salinas in coastal southern Australia. Logan (1987) discusses similar hydrological transitions in controlling vertical sequences and the transition from halite to gypsum with aggradation in Holocene Lake MacLeod, Western Australia. Kendall (1989) used such Holocene analogues to interpret the upward transition from anhydrites to carbonates in the Middle Devonian of northern Alberta (Muskeg and Sulphur Point Formations). Previously the transition was interpreted as reflecting a sealevel rise, but Kendall argued it would more likely reflect a transition related to sealevel fall outside of the basin and a decreasing volume of marine inflow into a marine-

fed basin with no surface connection to the ocean. His model better explains the terminal nonmarine bed that makes up the overlying Watt Mountain unit.

In summary, unless a rise in sealevel breaches the tectonic sill and converts the basin once more to a restricted mesohaline sea-way, decametre-scale sealevel fluctuations outside the isolated basin exert a relatively minor influence on basinwide hydrology and hence on the detailed stratigraphy of a basinwide evaporite unit. While the basin is isolated much of the fill is autocyclic, it reflects changes in the hydrological base level that have more to do with fluctuations in tectonics and climate as they effect inflow/seepage hydrology. In the larger saline giants, such as the Messinian sequences of the Mediterranean and the Zechstein of NW Europe, any changes in relative sealevel that occurred outside the drawdown evaporite basin and probably across a barrier that was hundreds of kilometres from the drawdown strandline were largely irrelevant to the style and geometries of evaporite deposition in the basin.

Basinwide sequence stratigraphy?

Given our rudimentary understanding of hydrology and isolation in basinwide settings, let us now look at some of the implications in terms of high-resolution stratigraphic analysis in basinwide evaporite deposits. Documented examples are few and far between, and tend to concentrate on patterns in the mesohaline to marine carbonate facies. High resolution interpretation of any intercalated thick salt beds is more challenging because:

- Outcrop studies of geometries of evaporite units are near useless as most of the evaporite is dissolved well before it approaches the land surface - differential collapse and flow during dissolution means detailed internal relationships and depositional geometries are lost not just at outcrop but also in the shallow subsurface,
- Seismic analysis tied to well data in bedded saline giants is rarely undertaken because very few oil companies wish to characterise the internal stratigraphy of what is an undeniable seal facies,
- Deeply buried thick basinwide salt sequences are subject to flow into diapiric and other structures - this largely destroys the stratigraphic integrity of internal reflectors in halokinetic parts of the basin and the onset of flow can be very early, even synprecipitational (see Chapter 6).

All authors working on basinwide systems (aka basin-centre and saline giants) agree that they are lowstand deposits (Kendall, 1988; Strohmenger et al, 1996a, b; Tucker 1991;

Warren, 1999; Sarg, 2001). Kendall (1988) and Warren (1999) attempt to address the principles of sequence stratigraphy in terms of the isolated hydrological framework and the need to precipitate widespread and thick salt sequences. Others consider that basinwides require a reduced connection to the world's oceans, yet others allow intrabasinal marine carbonates to be possible syndepositional sediments with basinwide evaporites. The latter expresses a blissful ignorance of the fundamentals of hydrology and hydrography seen in sediment textures and distributions in all modern evaporite basins.

Tucker derives two end member models to interpret the evaporite carbonate relationships in saline giants: Model 1, incomplete drawdown with marginal gypsum wedges and basinal laminated gypsum; and Model 2, complete drawdown with halite basin-fills. However, his hydrological constraints are not clearly stated and his hydrological assumption that marginal gypsum wedges typically form in relation to a lowered sealevel without isolation (his Figure 2) is probably not correct (see Goodall et al., 1992).

Figure 5.38 assimilates some of the concepts of Tucker (1991) as well as the work of Kendall (1988) and my own work. It is a preliminary attempt to place basinwide evaporite geometries and overall basin fills into a sequence stratigraphic context. Unlike Tucker (1991) it is based on the notion that in an isolated basin the drawdown hydrology is largely independent of decametre scale sealevel fluctuations that are going on outside the basin. Most of the internal decametre-scale evaporite geometries in a saline giant are autocyclic, while larger scale geometries reflect ongoing interactions between tectonics and climate. Only if and when the basin is connected at the surface to the world's oceans do the geometries of the carbonate units reflect a marine eustatic control and by then basinwide evaporites are not accumulating.

In the time prior to the onset of hydrographic isolation the basin has a surface connection to the world's ocean (Figure 5.38a). The depositional response at this time is a classic marine carbonate response and the only widespread evaporites that precipitate are typical marine-margin saltern/mudflat evaporites that are intercalated with normal marine platform sediments (see Figures 5.7a and 5.37 for interpretations of this style). Pinnacle reefs and mud mounds may grow on the shelf foreslope during the marine TST (e.g. right-hand part of Figure 5.38a). In the basin centre, thin (condensed) pelagic deepwater carbonates and hemipelagic mudrocks will be deposited, mostly as thin finely-laminated units that pass laterally into slope deposits about the basin edge.

Once sealevel falls below the sill height —either through a eustatic change in sealevel or, more likely, through regional tectonic movement that cuts off the basin from a surface connection with the world’s oceans— evaporative drawdown will

quickly lower the brine level in the evaporite basin to where it is well below the old carbonate shelf break (Figure 5.38b). Under an arid climate, water within the now isolated basin will rapidly become hypersaline. Seawater, along with formation,

Figure 5.38. Sequence stratigraphic model for basinwide evaporite deposition in a basin undergoing complete isolation from a surface connection to the world’s oceans and subsequent drawdown.

continental, and hydrothermal waters, now seeps into the depression. It enters through permeable, now subaerially exposed, formerly deepwater carbonate slopes and former pinnacle reefs. These outflow zones generate spring and tufa deposits with characteristic textures such as pisolites, tepees, tufas and stromatolites. In the relatively deep subaqueous basin centre, organic-rich mesohaline carbonate laminites typically mark the onset of basin isolation and continue to form until the basin is hydrographically isolated and equilibrium is reached.

If hydrological equilibrium is reached at gypsum saturation then gypsum has the potential to accumulate across the whole basin. When the water column is meromictic coarsely crystalline zig-zag or laminated gypsum forms best in the “chemical factory” of the shallow basin edge while detrital and pelagic laminites accumulate in the basin centre (Figure 5.38b). If the basin does not subside greatly as it becomes isolated, the level of this new gypsum wedge (platform) will first form atop old slope carbonates and below the old carbonate shelf break. With respect to sealevel outside the isolated basin this is a lowstand deposit associated with the creation of a karstic type 1 boundary on the old carbonate shelf prism in areas about the basin edge not covered by brine. But, with respect to the subsequent drawdown hydrology of the basin, it is a highstand system tract.

Resedimentation of the saltern/mudflat sediments of the gypsum wedge into deeper density-stratified waters by storms, slope failures, debris flows and turbidity currents will deposit graded beds, slumps and breccias as gypsum slope deposits and fine-grained “rain-from-heaven” gypsum laminites in the basin centre. At times when the brine column is holomictic, coarse-crystalline gypsum can perhaps accumulate across the deeper basin floor (there are no Holocene analogs for deepwater gypsum, but there are for halite and mirabilite).

If this situation of gypsum saturation is hydrologically stable, that is hydrological inflow balances outflow at gypsum-precipitating salinities, and the situation is maintained for time frames $\approx 10^5$ years or more, the whole basin evaporite fill may be composed of gypsum. Such was the case during precipitation of large portions of the Permian Castile Formation of Texas (Chapter 1). Metre-scale sedimentary cycles (parasequences) will be developed within the prograding gypsum wedge reflecting higher-frequency low-amplitude (5th-6th-order, i.e. $10^4/10^3$ year) autocyclic brine-level changes within the basin (Figure 1.24).

If hydrological equilibrium is still not maintained in the basin, and brine losses continue to exceed inflows, the brine level

will continue to be drawn down and the salinity of the residual brine will increase. Saltern gypsum will begin to precipitate in the basin centre if the brine depth drops below 10-30 m. If a hydrological balance is still not reached and the brine level continues to fall, the brine body next reaches halite saturation (Figure 5.38c). Based on most Holocene analogues (except the current Dead Sea) water depths at the onset of halite deposition are less than a few tens-of-metres to metres and saltern or pan halite will be deposited across the whole basin floor. If the waters are density stratified then locally there may be deeper-water depressions on the basin floor that fill with fine-grained laminated “salt-and-pepper-textured” deepwater halite cumulates lacking any evidence of subaerial exposure (this requires brine depths of 2 metres or more, if Lake MacLeod and the artificial halite pans of the southern Dead Sea Basin are used as textural analogues; Warren, 1991). If the brine column is holomictic then beds of coarsely-crystalline randomly-oriented inclusion-free halite meshworks will accumulate, rather than fine-grained halite or gypsum cumulates. This stage of the sedimentation is still a lowstand with respect to sealevel outside the basin, and is now a lowstand systems tract with respect to the basin hydrology. If the analog of the deep water fill of the Dead Sea is used as an analog then the deeper parts of an ancient basinwide evaporite fill will be composed of beds of coarse-crystalline halite meshworks interlayered with carbonate-gypsum or halite laminites.

Once thick pan halite units begin to accumulate across the basin floor, the degree of permeability loss in salts below the precipitation surface increases drastically, reflecting a near complete loss of porosity in metre-decametre thick halite beds. The brine curtain and its cement aquitard can now support a permanent halite-saturated brine body. This can maintain a near permanent position atop the primary crystallisation surface with only occasional episodes of complete desiccation or flood-induced surface freshening. Thus the halite body begins to aggrade as a series of subaqueous metre-thick autocyclic parasequences, with each metres-thick cycle deposited in time frames of 10^2 - 10^3 years. The maintenance of this aggrading hydrology allows the basin to fill with predominantly saltern halite (Figure 5.38d).

With respect to sealevel outside the isolated basin it is still a lowstand system, but in terms of the intrabasin geometries it is a transgressive systems tract. But it is a transgressive systems tract that has no parallel in the marine realm. It is an autocyclic transgression that aggrades as it maintains and grows its own near impervious base soaked in a saturated brine curtain that is maintained by slowly refluxing brines. There is no suitable eustatic term in the classic sequence stratigraphic literature to

describe this, as there is no concept of autocyclic transgression where the sedimentation surface creates the stabilising hydrology that in turn facilitates the rise of the sedimentation surface. Tucker (1991) terms this unit the lowstand basin-fill-halite; I am more comfortable calling it an intrabasinal transgressive systems tract halite.

As the halite fill continues to aggrade it climbs over the old gypsum wedge and, if the basin is subsiding but still isolated, it can also climb over the old gypsum and then the carbonate shelf margin (Figure 5.38e). As the fill tops an older platform margin it reaches a vast flat karst-etched plain. Before being retained the permanent basin waters must now spread over a much wider area of an older platform top. I call this the “fill and spill” stage of the basin’s sedimentation and hydrology. It is still a lowstand systems tract with respect to external sealevel and the marine groundwater feed, but a transgressive systems tract with respect to intrabasin geometries. It is typically a mudflat system, although salterns may still occur. The fill and spill point horizon is often marked by a change in mineralogy, which indicates a change in depositional hydrology.

In a semi-arid system this spill point is often defined by beds of less saline evaporite minerals such as gypsum or lacustrine carbonates. Rainfall and meteoric influx are an increasingly important part of the ponded surface water volume as they spread outside the former less aerially extensive depression. In contrast, if fill and spill occurs in a very arid setting, the effect of meteoric freshening is minimal and as the piezometric head is less than at the onset of evaporite deposition in the drawdown basin. Surface brines are less diluted and the hydrology may pass into bittern saturation so that syndepositional bittern or potash salts are possible precipitates. A hydrological transition to “fill and spill” under a hyperarid scenario explains why the potash cycles in the Salado Formation of the Delaware Basin are largely confined to regions in the vicinity of the old carbonate platform margin (Figure 11.18a).

Once again the transition is autocyclic and dependent on climate within the basin. The system is still a lowstand with respect to sealevel outside the basin. In terms of the intrabasin geometry it is a transgressive systems tract either atop the older HST gypsum wedge or atop the former HST of the older carbonate margin. Tucker (1991) also recognises this TST (his early TST gypsum or TST retrogradational sabkha evaporite lagoons), but he only allows for a CaSO_4 mineralogy and he relates it to a surface reconnection with the world’s oceans. Unlike Tucker (1991), I feel that this widespread thin unit is deposited subsealevel in a still isolated basin where surface reconnection to the ocean

has yet to occur. I also emphasise that this TST is not always gypsum/anhydrite, it can be composed of a multiplicity of mineralogies depending on the degree of climatic restriction in the basin. Kendall (1992; his Figure 40) also recognises this stage, but he relates the mineralogical transition to less saline minerals to a transgression beyond a hydroseal or basal aquitard, that allows greater volumes of brine to be lost from the system, and so average salinities in the surface brines are lowered. This is a valid concept, but it is not complete as it does not explain why some basins are actually precipitating more hypersaline minerals and bittern salts in the upper parts of the halite basin fill.

Once the basin is reconnected to the open ocean, the formerly exposed carbonate platforms are reflooded and a carbonate TST re-established. In this scenario any subsequent platform evaporite deposits can be considered equivalent to the marine marginal platform evaporites discussed in the preceding section and their internal geometries behind the isolating platform rim or shoal may well once again reflect eustatic controls (Figure 5.38f). Because the aggraded evaporite surface is a flat plain at the time of marine reflooding, the onset of marine carbonate deposition is typically characterised by ramp deposits. If the carbonate biota also contain appropriate binders and reef formers the profile quickly evolves into a rimmed carbonate shelf. The transition to a rimmed shelf in many ancient basins undergoing regional extension is typically focused by halokinetically induced shallowing of the seafloor driven by flow of the thick underlying halite (Chapter 6).

Basinwide examples

Three of the better documented areas where high resolution sequence analysis has been attempted on bedded basinwide evaporites are; 1) gypsum-halite evaporites of Messinian age in the marginal basins of the Mediterranean, 2) the basinwide anhydrite-halite evaporites of Permian Zechstein in NW Europe, and 3) the halite-dominated salt beds of the Silurian Salt of the Michigan Basin.

Messinian evaporites of the Mediterranean

In the icehouse world of Messinian evaporites in the Mediterranean, there are two styles of marine-fed evaporite deposition. One is characterised by high level, marginward circum-Mediterranean deposits, the other by a number of much larger, thicker, basin-centre deposits that now lie below more than 2,000 m of water and Plio-Pleistocene overburden (Hsu et al., 1973). There are excellent onshore exposures of the marginward Messinian

Figure 5.39. Distribution of basinwide Messinian evaporites, both onshore and offshore.

basins in Sicily, Spain and Cyprus (Figure 5.39, 5.40a). In contrast, in the various sub-basins in the deeper parts of the Mediterranean Sea, where seismic lines show thick sequences of salts deposited during times of maximum drawdown, there has been little core sampling and so there is little reliable facies interpretation based on rock samples. DSDP (Deep Sea Drilling Project) wells that did manage to recover salts sampled a combination of salt pan halite and sabkha anhydrite, showing that the salts accumulated on a basin bottom that was covered with brine lakes, which at times dried up to accumulate pan halite (Hsu et al., 1973). While not questioning the hydrographic isolation of the Mediterranean during the Messinian, Hardie and Lowenstein (2004) have questioned the notion of complete desiccation and rather argue for a sub-wave subaqueous origin to much of the evaporite recovered in the DSDP cores.

Aside from this textural evidence for drawdown precipitation in the few deepsea cores recovered from more basin-centre positions in the Mediterranean, there is also evidence for Late Miocene drawdown in the strata and unconformities surrounding the main salt beds. Drawdown to an erosional base level, that at times in the Messinian was 1-2 km below sealevel, created the widespread “M” reflector, a seismic indicator of subaerial exposure about much of the Mediterranean margin. Drawdown also deepened the thalwegs of many major rivers draining into the Late Miocene Mediterranean depression. Wells in the Nile Delta at the eastern end of the Mediterranean, which are more than 300m (1000 feet) deep and enter Messinian strata, do not reach the bottom of Nile canyon (Aal et al., 2001). Said (1993) shows the Messinian incision of the Nile thalweg reached a depth of 170 m at Aswan, 800 m at Assuit and more than 2500 m immediately north of Cairo. Similar deep Late Miocene channels occur at the western end of the Mediterranean in Libya, Algeria, Israel and Syria (Griffin, 2002). Likewise the thalweg

of the northern end of the Rhone River gorge was cut deeply into its granite basement in the Late Miocene and is now filled with marine sediments. For the same reason, some of the deepest karst in the world formed in Yugoslavian (Montenegrin) carbonate hosts during this time of maximum drawdown, with some caves now more than 900 metres deep.

Assuming a surface marine connection to the Atlantic immediately prior to the time of evaporite precipitation, Krijgsman et al. (1999, 2002) argued

that the onset of the Messinian salinity crisis was synchronous over the entire Mediterranean basin, dated at 5.96 +/- 0.02 million years ago (Figure 5.40a). They argue that isolation from the Atlantic Ocean was established between 5.59 and 5.33 million years ago, causing a large fall in Mediterranean water level, followed by circum-Mediterranean erosion and basinwide evaporites (5.59-5.50 million years ago) and in turn followed by deposition (5.50-5.33 million years ago) of nonmarine sediments in a large ‘Lago Mare’ (Lake Sea) basin immediately prior to surface reconnection with the world’s ocean (a likely example of “fill and spill” sedimentation).

Once hydrographically isolated, the cyclic evaporite deposition in the various Messinian basins can be almost entirely related to circum-Mediterranean climate changes driven by changes in the earth’s precession, and not to obliquity-induced glacio-eustatic sealevel changes. Krijgsman et al. argue in favour of a dominantly tectonic origin for the Messinian salinity crisis, although its exact timing of some of its parasequence boundaries may well have been controlled by the \approx 40-kyr component of the Earth’s eccentricity.

Others argue for a somewhat later onset of the salinity crisis (\approx 5.6 Ma) and that rather than a time synchronous deposition of Messinian evaporites throughout the Mediterranean there were two time-separate styles of evaporite deposition (Figure 5.40a): 1) marginward areas around the periphery of the Mediterranean, versus 2) more basinal or central regions (Clauzon et al., 1996; Butler et al., 1995). Yet others argue that within a framework of basin isolation the exact time of onset of evaporite accumulation in the various marginal sub-basins may not be time synchronous around the margin of the Mediterranean and that evaporite sequences in some marginal basins may postdate the main unconformity (Riding et al., 1999).

Figure 5.40. Messinian salinity crisis in the Mediterranean. A) Plot of $\delta^{18}\text{O}$ of equatorial Pacific tied to magnetostratigraphy, Messinian stratigraphy and modeled January insolation for that time frame (modified after Clauzon et al. (1996) and Butler et al. (1995)). Note the difference in interpretation of the upper evaporite in Sicily. B) Schematic times sequence showing mode of formation of marginal and basinwide evaporites in the Mediterranean. Note that the interpretation of Butler et al. (1995) requires a time 5.

The diachroneity between the basin margin and basin centre Messinian evaporites can be deduced from the stratigraphic relationships linking the evaporites in the marginal basins to the major Messinian erosional surface (M-reflector) that surrounds the basin centre evaporites. During the first phase of isolation and local drawdown (from 5.75 to 5.60 Ma), the deposition of evaporites took place in Spain and Sicily and other marginward areas in response to a modest sealevel fall in various tectonically isolated (compressional fold belts)

subsealevel basins. In the second interval (from 5.60 to 5.33 Ma), more central parts of the Mediterranean basin became isolated and deposition largely ceased in the marginal basins (Figure 5.40b; Clauzon et al., 1996).

The stratigraphy in marginal basins of the Mediterranean Ridges, Sicily and some of the other Messinian basins, such as Crete and Cyprus, was defined by mineralogies evolving separately in a series of rising “piggy-back” foreland basins,

Figure 5.41. Schematic shows tectonism related distribution of continental, marine margin and basin centre lacustrine evaporites around the time of closure of the Mediterranean basin and the Late Miocene salinity crisis. Schematic is constructed based on geology of the Mediterranean Ridges, Sicily and the Italian Peninsula (in part after Westbrook and Reston, 2002).

created during thrusting-related uplift that was active in the Messinian and continues today (Figure 5.41; Westbrook and Reston, 2002). In many marginal basins, such as in Cyprus, the changes in the level of drawdown were related to ongoing transcurrent faulting and rifting. Much of the tectonic drive creating the evaporite fill in the various marginal basins, prior to the main drawdown, was a result of the collision of Africa with Eurasia, which ultimately drove the closure of the surface connection to the Atlantic and ultimately caused the whole Late Miocene Mediterranean deep basin floor to become isolated and evaporitic.

According to Clauzon et al. (1996) the first major evaporite-depositing episode (5.75-5.60 Ma) took place during a cooling period associated with a weak global sealevel fall that isolated numerous tectonically induced circum-Mediterranean marginal basins in Spain, Libya, Morocco, the Apennines, Sicily, and Cyprus. Isolation of these marginal basins occurred while the adjacent Mediterranean Sea still retained a direct surface connection with the Atlantic (Time 2; Figure 5.40b). The next period of evaporite deposition (5.60-5.33 Ma) occurred when the whole Mediterranean was isolated and basinwide evaporites were deposited in a series of giant evaporite sub-basins (hundreds to thousands of kilometres across) and now located beneath the present deep Mediterranean floor (Time 3; Figure 5.40b). Away from halokinetic areas, none of these

areas outcrop and only their uppermost portions have been sampled by a few wells in the DSDP programme. At the time they formed there was a huge drop of some 1500-2000 metres in water level, and widespread basin-centre marine-fed brine lakes of the Mediterranean were completely isolated from any surface connection with adjacent Atlantic or Tethyan remnants. The isolation was driven by the ongoing collision tectonics as Africa collided with Eurasia. At the time of the complete isolation of the Mediterranean Basin there was a worldwide warming trend and a likely global sealevel high, but tectonic isolation completely negated the effects of eustasy within the Mediterranean.

Even so, the onset of evaporite deposition in marginal basins was driven by a combination of eustasy and tectonics. The evaporite phase of the marginal basins was typically preceded by cyclic Late Miocene carbonate ramp or reef cycles; which are readily interpreted using the principles of high-resolution carbonate sequence stratigraphy (e.g. in Spain and Italy- Martin et al., 1996; Esteban, 1996; in Morocco- Benson et al., 1997; Cunningham et al., 1997). Post reef growth, the typical response of the marginward basins to isolation and the onset of basin drawdown was the accumulation of an evaporitic carbonate rim (aragonite/dolomite) about a drawdown bedded-gypsum saltern, with marine-fed bitterns accumulating in the most isolated portions of these subsealevel depressions. Such a

situation outcrops today as the Calcare di Base rim facies circumscribing the bedded salts of the dominantly gypsum saltern fill in the Sicilian Basin (Figure 5.42a). The Calcare di Base indicates the drawdown basin possessed a marine seepage connection to the Mediterranean Sea. The “in situ” occurrences of this dolomitic seepage unit are restricted to the margin of the Sicilian Basin and it has an isotopic signature that becomes increasingly heavy toward the sites of gypsum and halite precipitation (Figure 5.42b: Decima et al., 1988). Once any circum-Mediterranean marginward basin was isolated from a surface connection to the ocean, ongoing tectonics and autocyclic mechanisms controlled the chemistry, cyclicity and textural styles in the various evaporite basins. Stratigraphic relationships between reefs that define the edges of the basin and consequent subaqueous carbonate/gypsum/ halite that then filled these marginal basins are clearly time separate events (Figure 5.42b).

The depocentres of the marginal basins in Sicily are in synclines related to underlying thrust structures of the frontal part of the Maghreian chain (Figure 5.43; Butler et al., 1995). Prior to hydrographic isolation from the Mediterranean seawater, these basins were hydrodynamically linked through the thrust foredeeps to world sealevel. Thus Late Miocene reef and ramp precursors in the various Sicilian basins were linked eustatically. Initial isolation and drawdown of the Mediterranean base level is marked across the thrust belt by first cycle evaporitic carbonates and evaporites on the structural highs and lows, respectively. Vast accumulations of halite and potassium salts (up to 1200 m thick) are restricted to growing thrust synclines. Salts were deposited once the subsealevel depressions were hydrographically isolated. At that time the different evaporite signatures were related to different water conditions, reflecting various continental and marine seepage plumes and circulations across various sub-basins (Butler et al., 1995). Internal cyclicity (parasequence scale) reflect high-frequency autocyclic

variations in brine level, and are not tied to marine eustacy. Thrusting provided accommodation space for evaporites and also controlled the groundwater pathways into the desiccating basins. In similar fashion Messinian sediments of the northern Marcean Apennines form part of a syn-orogenic foreland basin succession. They underwent shortening by thrust-related folding soon after deposition (Mazzoli, 1994).

For the same reasons, that is, varying times of restriction and loss of surface connection, the onset of hypersaline conditions in the various Sicilian basin occurred diachronously. Even the Tripoli Formation began to accumulate locally at various times well before the onset of deposition of the main evaporites (Bellanca et al., 2001). Mesohaline sediments first occur in

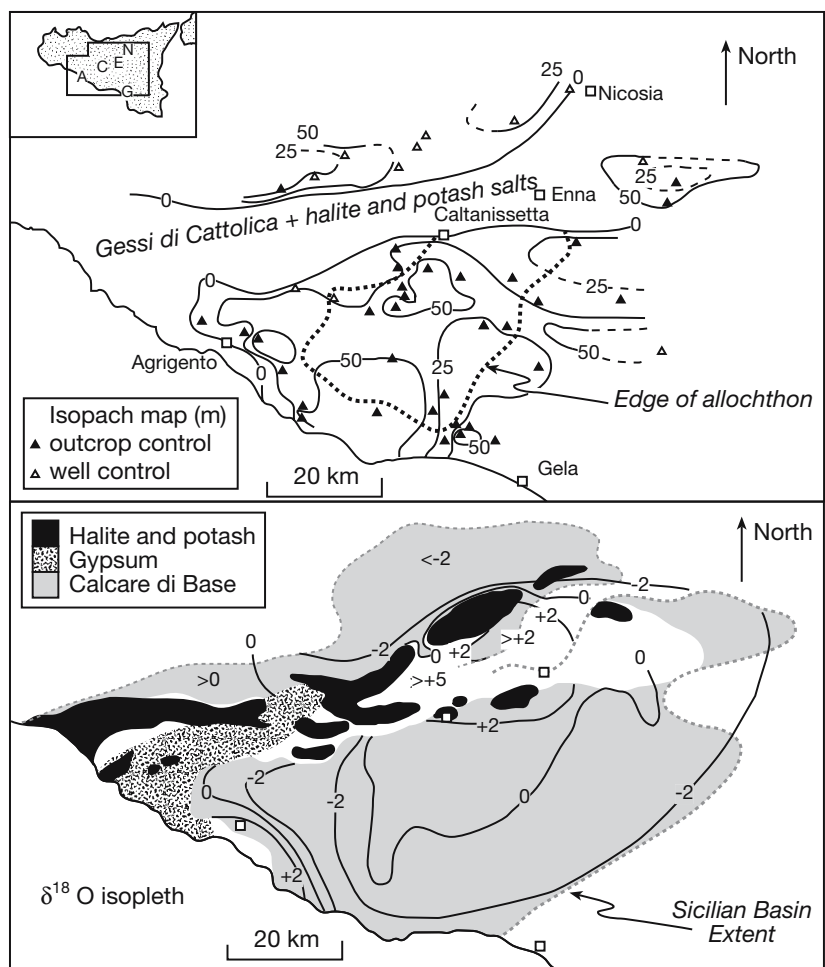

Figure 5.42. Calcare di Base, Sicilian Basin (after Decima et al., 1988) A) Isopach (in metres) and breakdown into an “in situ” unit and an allochthon block that was thrust over the evaporite salts. B) Oxygen isotope distribution in the in situ unit showing depletion in parts of Calcare di Base deposited further from areas of contemporaneous salt deposition (gypsum, halite and potash).

Figure 5.43. Marginal thrust top evaporites in Sicily (modified after Butler et al., 1995). A) Regional model for stratigraphy across different thrust top basins during deposition of the Lower Evaporites (see Figure 5.41). Note the evaporite forming basins are isolated from a surface connection with the Mediterranean, but have a seepage connection. Restricted surface marine circulation facilitates deposition of the Tripoli Formation. Progressive thrusting leads to progressive reduction of import of marine inflow and finally to deposition of potash evaporites under conditions of hyperaridity and predominantly continental recharge. B) A relative chronostratigraphic model for Messinian and Lower Pliocene deposits of Sicily and their correlation with basinwide deposits of the central Mediterranean sub-basins. Note that deposition of basinwide evaporites on the floor of the Mediterranean corresponds to an unconformity (sequence boundary) that separates the Lower and Upper Evaporites. This interpretation contrasts with that of Clauzon et al. (1996).

cycle 34 (6.32 Ma) at Serra Pirciata, cycle 42 (6.15 Ma) at Torrente Vaccarizzo, and cycle 44 (6.12 Ma) at Marianopoli.

These changes represent the hydrological and sedimentary response to the thrust induced fragmentation of a larger marine

Tripoli basin into different sub-basins, which ended in the more or less in complete endorheic closure as recorded by the deposition of the overlying evaporite-rich Calcare di Base Formation (true onset of the evaporitic event).

Clauzon et al. (1996) group the deposition of the Upper and Lower Evaporites of Sicily into a single period from 5.75 to 5.60 Ma. The initial eustatically-induced marginward isolation was then followed by complete isolation and drawdown of the whole Mediterranean (Figure 5.43a). In contrast, and although they use only relative time, Butler et al. recognise a major sequence boundary between the Upper and Lower Evaporites of the Sicilian Basin (also called the First and Second cycles). They interpret this sequence boundary as corresponding to the major drawdown of the whole Mediterranean and the formation of a major regional unconformity, which now surrounds all these basinwide deposits (M reflector; see Lofi et al., 2005). They go on to interpret the Upper Evaporite (Second Cycle - mostly saltern gypsum, not halite or bitterns) as being deposited in the isolated marginal seepage basins of Sicily once the Mediterranean was again flooded by seawater entering via a newly re-established surface connection (Figure 5.43b). The contact with the upper evaporites and the overlying deepwater marine Trubi Formation is a maximum flooding surface in both scenarios.

There is also a degree of chronostratigraphic confusion in relating the evaporite fills of many of the marginward basins of Spain to the main Mediterranean drawdown event. The Sorbas basin, Spain, is a good illustration of this. Depending on the author, the main saltern unit (Yesares gypsum) is considered to be time equivalent to the Lower Evaporite unit of the main Mediterranean drawdown event, or it postdates it or predates it (Figure 5.44a). The key

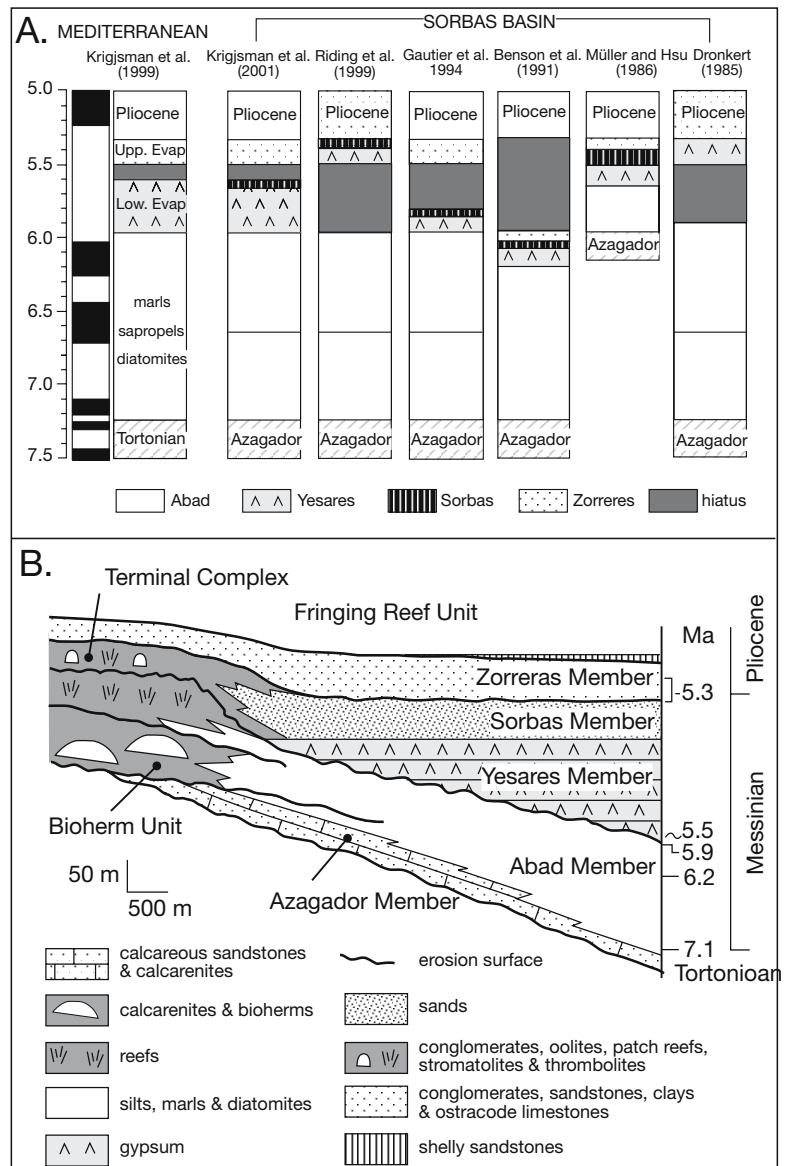

Figure 5.44. Messinian lithofacies, Sorbas Basin, Spain. A) Overview of different chronostratigraphic models for the marginal Sorbas basin showing the large controversies in timing and duration of the various stratigraphic members in relation to the recently established Messinian Mediterranean astrochronology (Krijgsman et al., 2001). The models of Dronkert (1985) and Riding et al. (1998) are based on a correlation of the Yesares Member to the 'Upper Evaporites' of the Mediterranean. The models of Müller and Hsu (1987) and Gautier et al. (1994) are plotted along with the timing by various cited authors of Yesares Member to the 'Lower Evaporites' and the Zorreras to the 'Upper Evaporites'. B) The Messinian-Pliocene succession in the Sorbas Basin. According to Riding et al. (1998) the "Salinity Crisis" sealevel fall occurred within the interval 5.9–5.5 Ma, and the resulting drawdown-driven erosion surface is below the Yesares Gypsum Member, and atop the Fringing Reef Unit. Note the marginal onlap of the Sorbas-Terminal Complex.

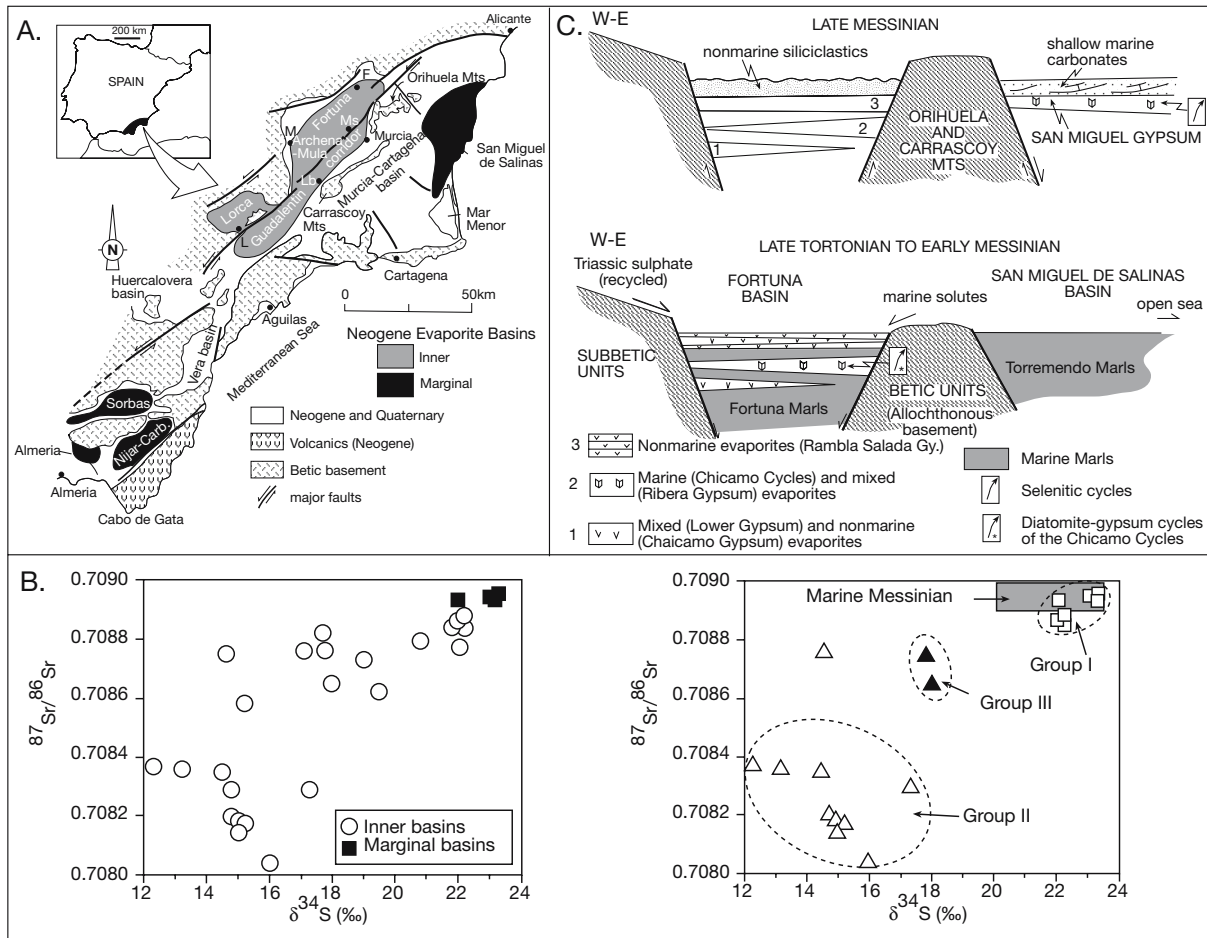

Figure 5.45. Neogene evaporites, Spain (after Playa et al., 2000). A) Location of the Neogene inner and marginal basins in the Eastern Betics. Towns: F: Fortuna; L: Lorca; Lb: Librilla; M: Mula; Ms: Molina de Segura. Ridges: LT: La Tercia Mts. B) Isotopic composition ($^{87}\text{Sr}/^{86}\text{Sr}$ ratio, and $\delta^{34}\text{S}$) of gypsum lithofacies. Plot on left shows primary and secondary gypsum (undifferentiated) samples in the inner and marginal basins. Marine-fed gypsum in the sea-marginal basins shows a much tighter clustering of values reflecting its near isochemical seawater parent. Plot on the right shows primary gypsum samples. Group I: selenites (aligned coarsely crystalline gypsum of the sea-marginal basins). Groups II and III: gypsum lithofacies of the inner more continental basins. The areal distribution of the Messinian marine sulphates from the Mediterranean region is shown shaded in grey. C) Schematic showing the distribution of Neogene evaporite sediments from more continental basins in the west (inner basins such as the Fortuna basin) to the east (sea-marginal basins such as the San Miguel de Salinas basin) in the easternmost part of the Betics (Murcia–Alicante region).

to where it is positioned in the stratigraphy relates to where the equivalent to the main erosion surface (M-equivalent) is placed. Riding et al., (1999) place a regional erosion surface and unconformity (300,000 years exposure) at the base of the Yesares Formation, making the Yesares equivalent to the Upper Evaporite, while Krijgsman et al., (2001) argue any discontinuities at the base of this unit are not regional but reflect no more than local slumping. The debate continues and is yet to be resolved.

The Sorbas Basin is one of a number of marginward basins formed in a complex system of transcurrent faults, with both transpressive and transtensional characteristics. Tectonics controlled depositional geometries in the evaporite fill of the marginal basins of the Betic Cordillera of SE Spain, not sealevel changes outside the hydrographically isolated depression (Figure 5.45a; Playa et al., 2000; Michalzik, 1996). They are seepage basins and there is no evidence for any catacratic-like connection of any of these basins before and during the

formation of Messinian evaporites. Nor is there evidence for a “mega-Niagara Falls,” ending the salinity crisis, as first suggested by Hsu et al. (1973).

The most frequently occurring gypsum lithofacies in all the Spanish basins formed in shallow-water depositional environments and include: crystalline selenitic gypsum (‘grasslike gypsum’), laminated gypsum and crossbedded gypsarenite. Sabkha-type chickenwire alabastrine gypsum are rare in the Spanish sea marginal basins (Michalzik, 1996). Evenly laminated gypsum units interbedded with graded gypsarenites (turbidites), gypsrudites (debrites) and slumps occur in basins or parts of basins with considerable palaeoslopes. Evidence for early diagenetic overprinting includes the formation of giant gypsum twin crystals, ‘super cones’ and alabastrine nodular gypsum. The accumulation of Messinian evaporites in SE Spain was perhaps instigated by a third-order sealevel lowstand that isolated these marginal tectonic basins from the Mediterranean Sea. But all the smaller-scale evaporite units (parasequences) in the various marginal basins, at the scale of shoaling decametre-cycles, are fourth- to sixth-order cyclic and rhythmic responses. They are clearly related to basin dynamics or to autogenetic processes of the local facies (facies dynamics). None are related to high-frequency marine eustacy (Michalzik, 1996).

Inland from the marine fed sea-marginal Messinian basins of Spain are large saline lacustrine basins fed both by seawater seeps and continental waters from the Pyrenees with a substantial solute component coming from the dissolution of Triassic sulphate salts. The saline fills of these largely continental depressions started earlier in the Miocene than the sea-marginal marine-fed depressions (Tortonian versus Messinian) with both their surface and groundwater feeds showing a more continental provenance (Figure 5.45a). For example, in the inner basins of the Murcia-Alicante region, a number of continental-influenced evaporite units were differentiated by Playa et al. (2000). The more continental saltern gypsum lithofacies have the following characteristics (Figure 5.45b): 1) Variable strontium contents, with mean values (primary gypsum) between 1,121 and 2,380 ppm; 2) Isotopic compositions of sulphur ($\delta^{34}\text{S}$) ranging from those characteristic of the Tertiary marine water (+20.3 to +25.5 ‰) to those characteristic of the Triassic sulphates (+8.0 to +16.0 ‰), the latter suggesting recycling of the sulphate anion in meteoric waters; intermediate values (+17.4 to +19.6 ‰) are attributed to mixed mother brines; and, 3) Strontium ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) between 0.70804 and 0.70888; these values range from those of the Tertiary marine water to those exceeding the Triassic sulphates, suggesting additional continental contribu-

tions (from both dissolving country rocks and hydrothermal solutions). The comparison between the sulphur and strontium isotopic compositions of the sulphates, together with the study of the biota present in the marls associated with the gypsum, distinguishes marine, continental, and mixed units (Playa et al., 2000).

In the marine-fed sea marginal basins of the Eastern Betics, where single evaporite units characterized by selenitic gypsum prevail: (1) the strontium contents are more homogeneous, with mean values (primary gypsum) between 493 and 625 ppm; (2) the isotopic compositions of oxygen ($\delta^{18}\text{O}$) and sulphur ($\delta^{34}\text{S}$) between +12.2 and +14.8 ‰, and between +22.0 and +23.5 ‰, respectively; and (3) the strontium ratios ($^{87}\text{Sr}/^{86}\text{Sr}$) varying from 0.70890 to 0.70895. The clear separation between properties of the two gypsum-entraining foreland depressions (Fortuna Basin versus San Miguel de salinas Basin) illustrate that, although gypsum deposition occurred in two side-by-side basins, some units on the continental side started to accumulate bedded gypsum earlier than the Messinian and with signatures that reflect a mixed continental-marine parentage (Figure 5.45c).

At the other end of the Mediterranean in Cyprus, Messinian gypsum units accumulated in a series of semi-isolated tectonically-induced small marginward piggyback basins. They contained landlocked brine sheets (gypsum salterns) located not far below ambient sealevel (Robertson et al., 1995). Evaporites in south Cyprus (Maroni Basin) formed in elongate marginal basins between compressional lineaments instigated by Early Miocene thrusting in a tectonic situation similar to that described for Sicily. In the sub-basins of west, southwest and south Cyprus, large scale slumping of saltern gypsum into deeper water formed megarudite debris flows, which are thought to have been triggered by one or several phases of extensional faulting. The Pissouri and Polemi basins of south Cyprus also preserve sediments of late Messinian-Early Pliocene “Lago Mare” sediments (Figure 5.41).

All the Messinian-Pliocene transitions that define the end of the salinity crisis in Cyprus and in approximately equivalent basinward sediments in the Mediterranean on the edge of the Erathostenes Seamount are marked by a very rapid environmental change, as indicated by sharp variations in lithology, sedimentology, microfaunal assemblages and stable isotope composition (Rouchy et al., 2001). The latest Messinian interval in both regions is known as ‘Lago-Mare’ and is dominated by transitional sediments deposited in mostly oligo-mesohaline conditions. The most striking feature in the Pissouri Basin is the intercalation between the uppermost gypsum bed and the

base of the Zanclean (Early Pliocene) deposits of four main horizons of palaeosols interbedded with carbonates and conglomerates. Palaeosols indicate periods of subaerial exposure in the marginward basins of Cyprus that were long enough to permit pedogenesis during the transition to less evaporitic conditions. Intercalated conglomerates indicate intense erosion of the Troodos Massif and its sedimentary cover. In contrast, shallow oligohaline conditions persisted in the deeper parts of the Mediterranean basin, as indicated at ODP Site 968. Both in the Pissouri Basin of Cyprus and on the flank of the Erathostenes Seamount in the Mediterranean the late Messinian sediments are directly overlain by the lowermost Pliocene sediments deposited in well-oxygenated deep marine conditions. This drastic change of water depth that typifies the basinwide end to the salinity crisis shows that as in the earlier evaporite stages, water levels of the latest Messinian “Lago Mare” were still far below that of the world ocean, by at least more than several hundred metres.

Moreover, the study of the Polemi sections shows that oligohaline conditions had already started during the deposition of the upper gypsum sub-unit. Typical brackish and fresh water assemblages are present in the last two gypsum layers and intergypsum beds (Rouchy et al., 2001). This indicates that freshwater dilution, i.e. the Lago-Mare conditions, resulted from a progressive change of the hydrological budget, which had started during deposition of the upper evaporites and climaxed after the deposition of the uppermost gypsum layer (classic Lago-Mare facies). This basinwide evolution is interpreted as

Figure 5.46. Evolution of the Vena del Gesso basin, Italian Apennines, from the Tortonion to the late Miocene with respect to facies and the evolving thrust basin topography indicated by the Forli Line (after Roveri et al., 2003).

being due both to the severance from the marine brine feed and to the increasing contribution of the runoff-precipitation versus marine inputs in the hydrological budget of the Mediterranean toward the end of the salinity crisis, immediately prior to the re-establishment of open marine conditions. In my opinion it reflects a transition into a fill and spill mode of deposition in a relatively humid setting and is not the first time of basin isolation argued by Krijgsman, rather it is the last stage of basin isolation and immediately predates the return to a surface connection to the world ocean.

Further complicating the resolution of a marine eustatic history for cycles in sediments deposited in the Messinian salinity crisis is the ongoing likelihood of gravity tectonics moving large blocks of shallow water evaporites into deeper water settings. Such olistoliths characterise many continent-to-continent collision belts and such a gravity slump system controlled the distribution of Messinian sediments about the Riolo anticline in the Italian Apennines (Roveri et al., 2003; Manzi et al., 2005). Primary, shallow-water evaporites (growth-aligned selenitic saltern gypsum) only occur to the west of the Forli line in Vena del Gesso basin (Figure 5.46a-d). The abrupt vertical facies changes in the region from the euxinic shales to the overlying shallow-water evaporites implies a dramatic relative sealevel fall, on the order of several hundreds of metres, occurring in a very short time span.

But lateral and vertical facies changes within the underlying deepmarine turbidites of the Marnoso-Arenacea Formation show Messinian evaporite precipitation occurred in a thrust-top basin (Vena del Gesso basin), bound to the north and to the east by the thrust-related Riolo anticline, which had been actively growing since the late Tortonian (Figure 5.46a-b). Both gypsum deposition and its subsequent deformation were strongly controlled by evolving palaeobathymetry driven by gravity tectonics.

Primary growth-aligned gypsum accumulated in a shallow, silled marginal basin (Vena del Gesso basin) that lay to the east of the growing Riolo anticline, while organic-rich shales were deposited in the adjacent deeper and larger foredeep basin to the west (Figure 5.46c). These gypsum deposits underwent severe postdepositional deformation related to large-scale gravitational collapse, tied to regional uplift events. Deformation was also coincident with the end of the evaporitic phase in the marginal thrust-top basin. Along the inner, shallower-dipping limb of the anticline bounding the basin, large-scale, weakly deformed gypsum slabs slid downslope along a detachment surface devel-

oped at the contact with the underlying euxinic shales, forming both extensional and compressional features and showing an overall southwestern vergence (Figure 5.46d).

The identification of a south-southwest-dipping palaeoslope by Roveri et al. (2003) suggests that the deformational features affecting the gypsum unit were probably driven by gravity and not by deformation tied to active thrust planes (Figure 5.46d). The steeper frontal limb of the anticline promoted the transformation of gypsum slides into debris flows and turbidite currents that deposited their load in the adjacent deeper basin to the west. This gravitational deformation was sealed by postevaporitic upper Messinian Lago Mare deposits.

The sedimentary history of the Vena del Gesso basin, as documented by Roveri et al. (2003) and Manzi et al. (2005), suggests that the Messinian salinity crisis in the Apennine foredeep, as well as in the Balearic, Tyrrhenian, Sicily, and Eastern Mediterranean Basins, was tightly linked to intrabasinal tectonic processes not worldwide eustasy. The large-scale, postdepositional gravity collapse of primary evaporitic deposits into the deeper parts of adjacent foreland basins is a widespread feature in the Mediterranean basins, and it may have altered the original stratigraphic relationships in some places. It means the amplitude of any waterlevel fall cannot be easily determined in some marginal basins as some beds are allochthonous.

Outside of the Mediterranean there are other complications for notions of world-scale eustasy controlling basinwide evaporite deposition. Work in the Neogene sediments in the Red Sea and the Gulf of Suez has shown that the concept of maximum regional aridity corresponding to times of maximum evaporite accumulation and minimal clastic accumulation is not that simple. Studies of the Miocene/Plio-Pleistocene succession in the Gulf of Suez and the Red Sea have shown that the Messinian (Zeit Formation and equivalent) sediments were deposited at rates greater than other units of the Miocene/Plio-Pleistocene (Griffin, 1999). The Zeit Formation contains a significantly higher clastic content than the underlying evaporitic South Gharib Formation indicating that the Messinian in this region adjacent to the main Mediterranean basin was a time of high rainfall and high sediment yield rates. This period, named the Zeit Wet Phase, stands in marked contrast to the arid conditions of the preceding Tortonian Stage when halite-bearing South Gharib Formation and its equivalents were precipitated in the Gulf of Suez and Red Sea (Griffin, *op cit*). It suggests that the Zeit Wet Phase was marked by high monsoonal activity and that this wet phase peaked in the late Messinian. This was the

time of the lowstand maximum in the Mediterranean driving the Messinian Salinity Crisis.

The preceding discussion of the inherent, and still not fully resolved, largely tectonically controlled climatic and hydrologic complexities in the Messinian of the Mediterranean is based on more than three decades of detailed scientific work, mostly in exposed marginal basin stratigraphies, where the evaporites are still largely preserved as primary gypsum. With the possible exception of an initial third order fall in worldwide sealevel cutting off the basin, all these deposits were isolated via active tectonism. Their finer stratigraphic geometries are not reflective of eustasy but of tectonically induced drawdown and autocyclicality. Much larger volumes of basinwide evaporites are preserved beneath the present deepwater centres of the various Mediterranean basins. These bedded sections currently lie beneath hundreds of metres of Pliocene and Pleistocene sediment; only halokinetic intervals lie within a few tens of metres of the modern deep seafloor. With the exception of a few DSDP holes that intersected the uppermost few metres of bedded salts, the internal stratigraphies of these saline giants are largely unsampled and uninterpreted. And yet we know deposition of 1-2 km-thick basinwide salts took place in less than 300,000-400,000 years. By definition, the total 1+ km package of the Messinian sequence must be a fourth order sequence (Table 5.8). It implies that internal reflectors and cycles seen in seismic sections through thick basinwide evaporites, must reflect fifth and sixth order time frames.

Any eustatic curves, based on seismic that encapsulates the very high accumulation rates of basinwide evaporites in large basin-centre positions in the Mediterranean, will outline very high frequency responses. Even if we ignore the fact that ancient basinwide evaporites are depositional systems with internal responses not related to sealevel changes, comparison of eustatic curves derived from internal geometries of basinwide evaporites with lower order eustatic curves derived from the worldwide study of various marine carbonate or siliciclastic sequences is simply not possible. The internal reflectors and responses that we can resolve seismically within a basinwide evaporite unit are responding to water level changes that are far too short-term to be compared with the eustatic information captured in classic Vail or Exxon-style sealevel curves. We cannot correlate the various eustatic peaks and troughs outlined by the depositional tracts in either system, they are responding to different time-based waterlevel frequencies. The highest seismically resolvable frequencies in a marine sequence are third, and perhaps the occasional fourth, order response. In basinwide evaporite sequence we are looking at

seismically resolvable bounding surfaces that are responses to fifth or sixth order cycles.

Errors arise if intrabasinal correlations attempt to tie thick basinwide evaporite deposits to what are mistakenly considered time-equivalent eustatic curves based on studies of seismic sections through marine carbonates either within or outside the basin. What it most clearly shows is that, using the most recent example we have of a saline giant, the deposition of the one km-plus evaporite units in the various basin centres corresponds to a two dimensional bounding surface or centripetal unconformity (M-marker) immediately outside of the evaporite depositing areas. This should be the starting point for any seismic-based correlation of the evaporites (or subsequent dissolution breccias) with adjacent normal marine sediments.

So, is it also a questionable approach to attempt a sequence stratigraphic age comparison between the marine sediments and deposits sandwiched between the various salt beds of a marine-fed saline giant? Unless we clearly define all sequence boundaries and realise that thick beds of evaporites equate with regional unconformities in surrounding sediments, we may be comparing chalk and cheese. And yet some authors have been courageous enough to attempt internal sequence stratigraphy of ancient saline giants based on various eustatic scales. We shall now look at such a set of studies in the Zechstein evaporites.

Sequence stratigraphy in the Zechstein

During the Late Permian an area of approximately 600,000 km² in northern Europe was covered by the waters of the epicontinental Zechstein Sea (Figure 5.47). The sea was relatively shallow; its maximum basin-centre depth is estimated to have been \approx 300 metres in the early mesohaline stage prior to complete isolation and drawdown (Brongersma-Sanders, 1972). The basin was subdivided into two main east-west oriented basins, called the Northern and Southern Permian Basins, which were separated by a sequence of palaeo-highs, the Mid-North Sea and Ringkøbing-Fyn Highs. Lithostratigraphic similarities between the evaporitic fill of the two basins suggest that the highs did not prevent the free surface exchange of brine between the north and south regions of the Zechstein depression.

During the Late Permian, this part of northern Europe lay at a palaeolatitude of \approx 25°N and within the Pangaeon supercontinent. This, coupled with the restricted and at times marine-fed seepage supply of seawater from the Boreal Ocean to the North and the Tethys Ocean to the Southeast, resulted in deposition of thick sequences of bedded sulphate and halite

evaporites, along with minor volumes of bittern salts. Prior to the onset of marine-fed seepage, the basin accumulated terrigenous sediment known as the Rotliegend/Wiessliedend Formation, in an arid continental playa/eolian/wadi setting in a subsealevel depression created by the final stages of the Variscan Orogeny (Carboniferous-Early Permian). The region at that time was characterised by the development of pull-apart rift basins that evolved into passive margins by the Middle Permian-Triassic period.

This time frame encompasses the main stage of basin subsidence and is characterised by aridity and periodic widespread evaporite deposition including Zechstein evaporites in the Late Permian, followed by Muschelkalk salts in the Middle Triassic and Keuper salts in the Late Triassic (Figure 5.48a). The Mesozoic of NW Europe was also characterised by ongoing metasomatic and hydrothermal activity, as evident from multiphase, cross-cutting, intraformational veinlets. The following Rhaetian through Lower Cretaceous period was marked by intensive faulting, rifting, and the initiation through much of the basin of large-scale halokinesis, sourced in the Zechstein halites.

The Zechstein encompassed the last 5-7 million years of the Permian (Figure 5.48a; Menning, 1995). Most drill intersections and most sequence stratigraphic interpretations have been completed in the southern basin. This is the region associated

with onshore hydrocarbons in the Zechstein of the Netherlands and northern Germany and is also a region where halite and potash salts have been mined for centuries (Chapters 6 and 11). Late Permian fill in the southern Zechstein Basin constitutes a classic basinwide deposit, with circumbasinal transitions from an evaporite platform about the basin edge into a deeper-water centre dominated by laminites (Figures 5.47, 5.48b).

Traditionally, the Zechstein Group is divided by its mineralogy into evaporitic cycles that reflect progressive evaporation from less saline to more saline salts. This method defined four main evaporite cycles (Z1-Z4) and rudimentary fifth and sixth cycles (Z1-Z6; Figure 5.48a). An ideal Zechstein cycle starts with a transgressive nonevaporitic “shale,” followed by carbonates and culminates in thick evaporites (mostly halite/anhydrite). Since most of the classic formation boundaries are picked at what are now considered by sequence stratigraphers to be maximum flooding surfaces (at base Z1: Coppershale or Kupferschiefer Member; base Z3: Grey Salt Clay Member; base Z4: Red Salt Clay Member), the lithostratigraphy of the Zechstein Group closely approaches that of units broken out using the concepts of genetic sequence stratigraphy (Figure 5.48b; Geluk, 2000). It means these basal transgressive units (mfs) provide a base for correlation of the main lithostratigraphic units. The lower three Zechstein evaporite cycles (Z1-Z3) are marine-fed basinwides. They contain evaporitic carbonates in their basal parts that

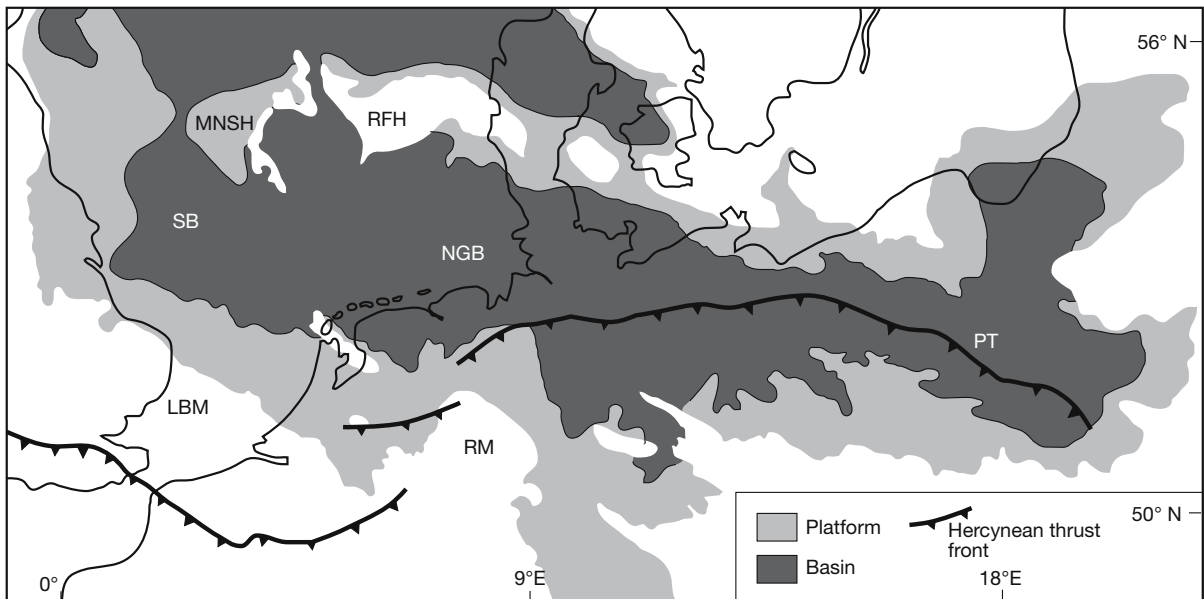

Figure 5.47. Facies distribution in the southern Zechstein Basin (after Geluk, 2000). The basin is bordered to the north by the Mid North Sea High and Ringkøbing-Fyn High and the London-Brabant Massif and Rhenish Massif in the south. The solid black line represents the location of the Variscan Thrust Front. MNSH: Mid North Sea High; RFH: Ringkøbing-Fyn High; SB: Silverpit Basin, LBM: London-Brabant Massif; RM: Rhenish Massif; NGB: North German Basin; PT: Polish Trough.

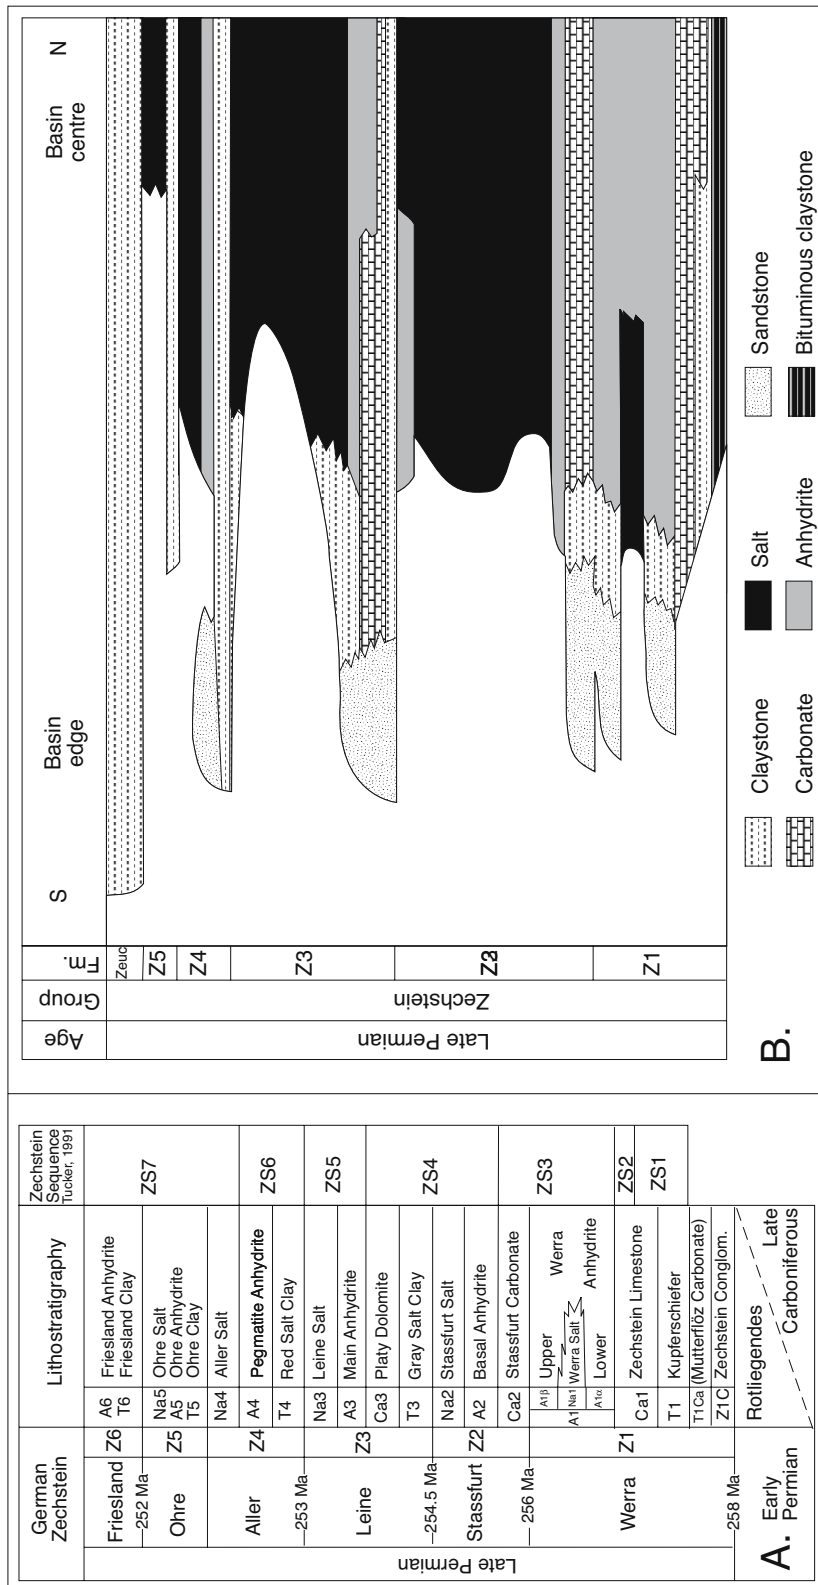

Figure 5.48. Zechstein Stratigraphy. A) Stratigraphy of the Zechstein Series in Germany (after Strohmenger et al. 1996a, b, and sources therein). Shown are the classic Zechstein cycles (Z1-Z6) and the Zechstein sequences (ZS1-ZS7) as proposed by Tucker (1991). B) Classic lithostratigraphic subdivisions from the basin fringe to the basin centre (after Geluk, 2000).

indicate initial precipitation from brines with near normal marine salinities (Taylor, 1990; Leyrer et al., 2001). The overlying anhydrites and salts in these cycles reflect the progressive evaporation of marine-fed salterns and deeper water brine lakes.

Classic transgressive/regressive cycles interpreted in the Z1 and Z2 cycles have been related to glacio-eustatic sealevel fluctuations by Strohmenger et al. (1996a, b) and Leyrer et al. (2001). Earlier, Tucker (1991) published an alternative to the classic Zechstein stratigraphy based on what he interpreted as third order sequences (ZS1-ZS7). In it he correlates evaporites with sealevel lowstands (LSTs) and carbonates with sealevel highstands (TSTs and HSTs). Tucker's approach, in tying evaporites to lowstands, is opposite to that of the classic stratigraphic approach in the basin (pre-sequence stratigraphy) that tied evaporite deposits to highstands, but his approach is more realistic in terms of evaporite hydrology. His classification was criticised firstly by Goodall et al. (1992) on the basis he assumed external sealevel exerted a one-for-one control on evaporite mineralogy and position, and then by Strohmenger et al. (1996a) as his classification did not respect exposure surfaces and stratal geometries.

Strohmenger et al. (1996a, b) and Leyrer et al. (2001) went on to refine a sequence

stratigraphic approach for the basal Zechstein (Z1 and Z2) using facies analysis, geometric relationships, stacking patterns and forward modelling based on core and seismic from the subsurface of northern Germany (Figure 5.49). However, Strohmenger et al. (op. cit.) found that due to the poor quality of internal reflectors in the Zechstein sequence they could not use the usual approach of interpreting the major depositional units from seismic, then establishing a seismic stratigraphic model and then tying well data to seismic. Rather they had to first establish a geological model based on detailed stratigraphic analysis of core and outcrop. Then they developed a sequence stratigraphic framework and then interpreted and forward modeled the intra-Zechstein reflectors. Their analysis (Figure 5.49) shows that reworked sandstones of the Weissliegende and/or the Zechstein conglomerate (Z1C) record the initial transgression of the Zechstein sea and overlie the Zechstein sequence boundary (ZSB1). Transgressive systems tract (TST) deposits of the first Zechstein sequence (ZS1) are also represented by deeper marine carbonates of the Mutterflöz (T1Ca). The overlying Kupferschiefer is interpreted as a condensed section (CS) indicating maximum flooding (mfs) of the first Zechstein sequence. The bulk of the shallow water Zechstein limestone (Ca1) is interpreted as a highstand systems tract (HST). It is separated from the thin uppermost part of the Zechstein Limestone by a karst horizon corresponding to an erosive sequence boundary (ZSB2).

Correlatable shallow water carbonates (oncolites and stromatolites) indicate lowstand systems tracts (LST) of the second Zechstein sequence (ZS2; Figure 4.50). The uppermost part of the Zechstein Limestone represents the transgressive systems tract of the second Zechstein sequence (ZS2). According to Strohmenger et al. (1996a, b) there is no indication of a sequence boundary at the top of the Ca-1 platform carbonates (contrasts with Tucker 1991). They argue Ca1

carbonates, in a basal position, show a deepening upward tendency toward the superimposed deposits of the A1 sulphates. They place the maximum flooding surface (mfs) of the second Zechstein sequence at the top of the Ca1 platform carbonates. The overlying anhydrites of the A-1 sulphate platform (Werra Anhydrite) are interpreted as predominantly highstand systems tract deposits displaying an erosive sequence boundary (ZSB3) at its top. This is in direct contradiction with Tucker (1991) and according to Strohmenger et al. (1996a, b) it is only in the slope and basal environments that the A1 also represents lowstand wedge deposits of the third Zechstein sequence (ZS3).

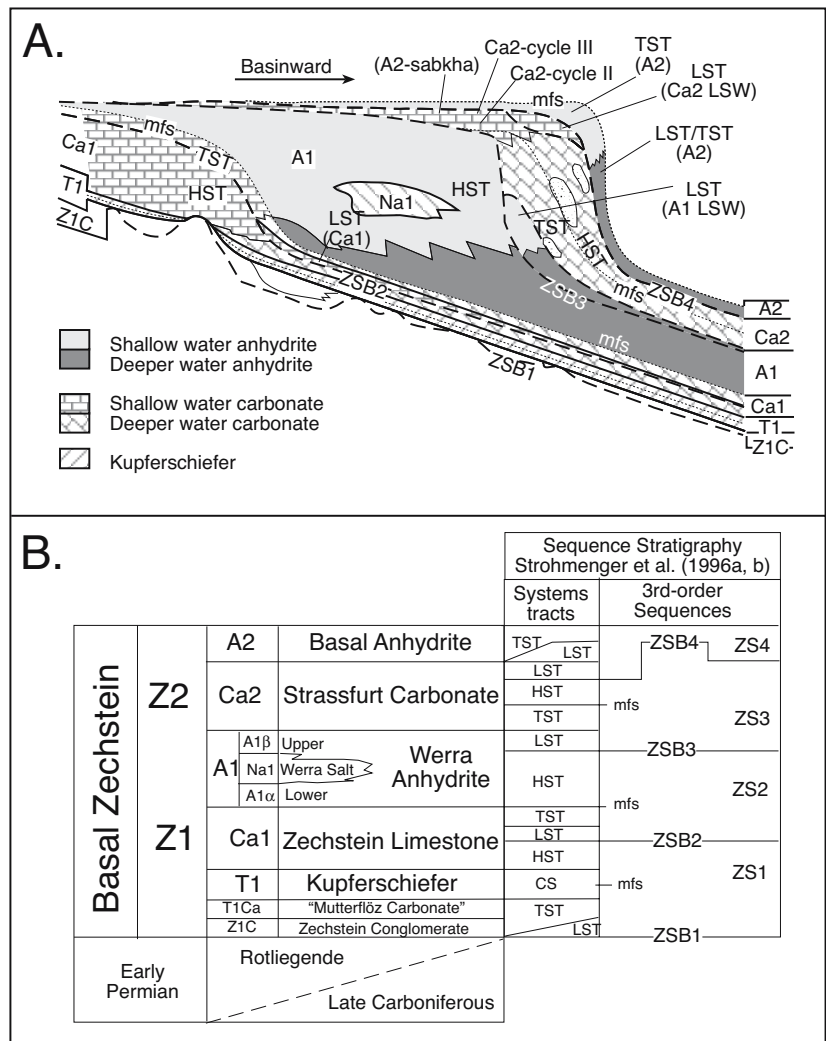

Figure 5.49. Zechstein evaporites of northwestern Germany (after Strohmenger et al., 1996a, b and sources therein). A) Schematic of basal Zechstein relationships on the southern margin of the Zechstein Basin. B) Lithostratigraphy of basal Zechstein showing classic subdivision (Z1-Z2) and Strohmenger et al. (1996a) subdivision (ZS1-ZS4). ZSB = Zechstein sequence boundary.

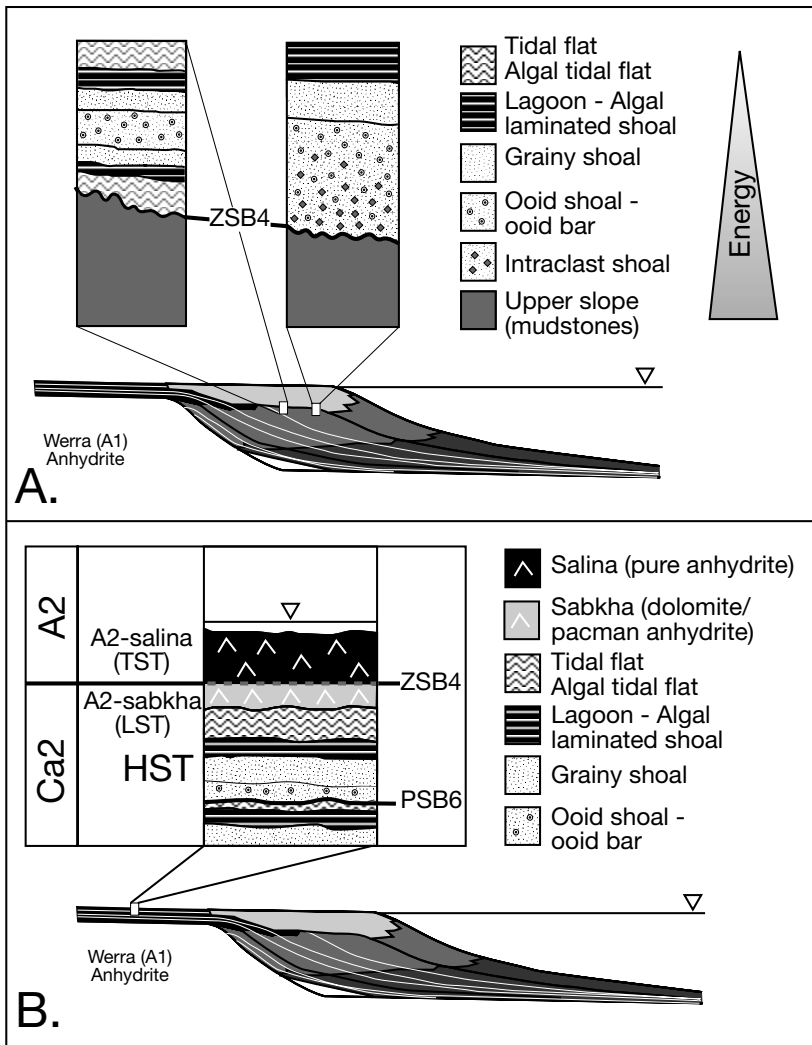

Figure 5.50. Facies associations in Ca₂ carbonate platform, Zechstein Basin, northwest Germany (after Leyrer et al., 2001). A) Slope position (HST of ZS3 to TST of ZS4). B) Platform position (HST of ZS3 to TST of ZS4).

In reality, each of the evaporite cycles is made up of a highly complicated stack of parasequences that sequence stratigraphers argue represent higher order sea-level fluctuations. In my opinion, climate-related intrabasinal autocyclicality is a more likely driving mechanism at the scale of the parasequences. The contradiction underlies the difficulties in sequence stratigraphic analysis of evaporite deposits using models derived from geometries and 3rd order eustatic responses of marine systems. The terms highstand systems tract and lowstand systems tract are largely defined by whether the shelf of the basin that is under consideration is covered by water. There is no concept as yet in the sequence stratigraphic literature that an aggrading

evaporite bed causes its overlying brine level to rise (autocyclic hydrologic feedback).

Most Zechstein interpretations assume a surface connection to the ocean at all times and that there were direct marine eustatic responses in brine base level. We have already discussed the likely errors inherent in this assumption. In the marine realm we are talking about eustatic sealevel amplitudes of no more than a hundred or so metres in icehouse periods and less than decametres in greenhouse periods. There is an inherent assumption in classic sequence stratigraphy that in greenhouse and icehouse times the prime locus of sedimentation is near a shoreline, either on the shelf or just basinward of the shelf break (Type 2 and Type 1 boundaries). In an evaporite basin that is undergoing drawdown we are discussing an initial hydrographic isolation (mesohaline carbonates are considered to indicate the mfs by the sequence stratigraphers) quickly followed by a water level fall of more than 500-1,000 metres and the onset of widespread evaporite precipitation. Any strandline in the system will likely have migrated hundreds of kilometres and be situated well out on the old continental slope at the onset of evaporite accumulation. Once again, marine eustatic models do not apply.

At hydrologic equilibrium (inflow=loss) the whole marine highstand shelf and slope, as well as part of the basin floor, is exposed. Water levels even in the deepest parts of the basin are mostly less than a few tens of metres and no more than one or two hundred metres. In this scenario the locus of maximum deposition is not tied to sediment supply from outside the basin (siliciclastics) or to any need for shallow waters atop a carbonate platform. The maximum locus of evaporite deposition is in the lowest part of the isolated depression in many drawdown basins with no surface connection to the ocean. This area is assumed to be deep water by sequence stratigraphers, but textures from the salts accumulating there are typically saltern or salt pan with local deeper water cumulates.

Defining the stratigraphic significance of sequence boundaries, such as the ZSB2, are more problematic in such hydrographically isolated drawdown scenario (Figure 5.49). Strohmenger argues that the Ca1 carbonates, in basinal position, show a deepening upward tendency toward the superimposed deposits of the A1 sulphates. What he is observing is a gradational transition. The term deepening is probably too categorical in this scenario. If the basin is isolated so that thick gypsum/anhydrite can accumulate, then the brine level in the basin must be lowered with respect to the old shelf. The A1 profile above the ZSB2 sequence boundary is most likely subaqueous throughout, and is a “brining upward” profile. The sequence does not deepen upward, it is continuously subaqueous but brines upward as the regional water level is lowered. That is, the average annual salinity of the brine body is increasing up section and ongoing lowering of the brine level does not stop until an effective brine curtain/inflow equilibrium is established. The brine level is not reflecting marine eustasy but a hydrological/climatic balance.

Stacking patterns laid down in such scenarios are not well understood, but should not be forced to fit the classic paradigms of marine sequence stratigraphy. We are looking at an evaporite system that probably was at any time deeper or shallower depending on the vagaries of climate and tectonics and largely independent of eustasy. All we can say in terms of the A1-sulphates is that at no time during the deposition of the sulphate phase was the water deeper than a few hundred metres and probably was mostly less than tens of metres deep (Warren, 1989; Kendall, 1992). During the preceding carbonate platform phase the water body was obviously less saline and probably deeper on average than during sulphate deposition and tended toward meromictic rather than holomictic conditions.

Even in the carbonate horizons separating the main evaporite phases, thought by many to be marine, the drastic changes in intrabasinal base level create problems in creating a reliable sequence stratigraphic interpretation if interpreters have assumed a hydrographically connected sealevel in the basin. The Zechstein 2 Carbonate (Ca2) overlies the A1-Sulphate (Werra Anhydrite) and according to Strohmenger et al. (1996a, b) and Leyrer et al. (2001) encompasses transgressive systems tract as well as highstand systems tract deposits of Zechstein sequence ZS3. The maximum flooding of the Ca2 is correlated with the flooding of the A1-sulphate platform. Therefore, Ca2-platform carbonates (Main Dolomite) are dominated by shallow-water highstand deposits of the third Zechstein sequence (ZS3). Deposits of the Ca2 transgressive systems tract

are coated-grain and composite-grain packstones/grainstones that contain reworked anhydrite clasts of the underlying A1. Leyrer et al. (2001) clearly demonstrate that the depositional facies, and hence the porosity distribution of the gas-bearing Ca-2 carbonates in the subsurface of northern Germany, are in large part controlled by high energy positions that reflect a shallow “sea” superimposed on the underlying evaporite topography. This topography was created prior to carbonate deposition by saltern to basin transitions in the underlying Werra (A1) Anhydrite.

An upper contact of the Ca2 carbonate is defined by the transition of shallow-water Ca2 carbonates into the overlying anhydrites of the A2 (Strohmenger et al., 1996a, b; Leyrer et al., 2001). The stratigraphic limit between the Ca2 and A2 is highly arbitrary and conventionally drawn in wells by the last up-section occurrence of bedded dolomite, but is gradational. Carbonates near the contact show typical Ca2 facies (e.g. algal-laminated coated-grain and composite-grain wackestones/ packstones and algal bindstones) and are often intercalated with bedded anhydrites of the A2 (Figure 5.50). Furthermore, according to Strohmenger et al. (op. cit.), the platform anhydrites of the A2 at this contact can display ghost structures of Ca2 facies. Leyrer (pers comm.) appropriately describes this as “Pacman” anhydrite, although it is perhaps more widely known as anhydritization. It indicates that the lower part of the A2 can be interpreted as sabkha/pan deposits (A2-sabkha) cannibalising the Ca2 carbonate and indicating the emergence of the Ca2 platform at the end of Ca2 time (Figure 5.50b). Alternately, the widespread evaporites within and replacing A2 carbonates could be a form of reflux-driven cementation/replacement created during deposition of the overlying saltern anhydrite. In my opinion this contact is perhaps tied to the time when the ooid/grainstone shoal along the basin edge became sufficiently well developed to isolate the platform lagoon and so it converted to an evaporitic mudflat or saltern.

According to Strohmenger et al. (1996a, b) the fourth sequence boundary of the Basal Zechstein (ZSB4) occurs not on top of the Ca2 shallow-water carbonates, but somewhere within the A2-platform deposits, once again in contrast to the model of Tucker, 1991. The lower part of the A2 (anhydritised or Pacman-style Ca2 facies) is interpreted as the time equivalent of shallow-water Ca2 carbonates that overlie deeper-marine upper slope carbonates in a basinward position, corresponding to the lowstand systems tract (lowstand wedge) of the fourth Zechstein sequence (ZS4; Figure 5.50a). The uppermost part of the A2 (pure salina-type anhydrites on top of pacman

anhydrites showing ghost structures of Ca₂-platform facies) is thought to represent the transgressive systems tract of the fourth Zechstein sequence (ZS4; Figure 5.50b). The relatively thick anhydrite accumulations of the A2 (approx. 100 m), which occur basinward of the Ca₂ slope, are thought to represent both lowstand systems tract as well as transgressive systems tract deposits of the fourth Zechstein sequence (ZS4).

According to Strohmenger et al. (1996a, b) the basinward progradation of the third-order Basal Zechstein depositional sequences is forced by the tectono-eustatic, first- and second-order sealevel lowstand of the latest Permian. The cyclicities observed within the different systems tracts are thought to be caused by higher order sealevel fluctuations with durations of 0.08-0.5 Ma (fourth-order cycles), 0.03-0.08 Ma (fifth-order cycles) or 0.01-0.03 Ma (sixth-order cycles and related to orbitally controlled Milankovitch cycles (Leyrer et al., 2001). Strohmenger et al. (1996a, b) go on to argue that the 0.1 and/or 0.4 Ma Milankovitch cycles indicate to high-amplitude sealevel fluctuations throughout the Late Permian. They draw analogies to small-scale sequences as described from the Yates Formation (United States, Permian Basin) by Borer and Harris (1991) and from the Wegener Halvø Formation (Jameson Land Basin, East Greenland) by Scholle et al. (1993).

In my opinion, there is a problem in comparing eustatic sealevel models, derived from platform evaporites of the Permian of Greenland and west Texas, to the basinwide drawdown platform evaporites of the Zechstein. Work by Strohmenger et al., (1996a, b) and Steinhoff and Strohmenger (1999) provide excellent core-based facies breakdowns of the evaporite stratigraphy and mapping of water level changes and hence predictors of porosity in units such as the Ca-2 carbonates, which are the major onshore gas reservoir in northern Germany (Leyrer et al., 2001). Where I have a problem is accepting the leap of faith in applying marine-derived Vail-curve age models (timing of cycle orders) to the brine level fluctuations that controlled the shelf to basin geometries of the Basal Zechstein. This approach ignores the need for complete lack of a surface connection with the ocean to deposit thick evaporite sequences. Furthermore, if we look to analogies in the marine-fed saline giants sub-basins of the Messinian, then sedimentation rates used by Strohmenger et al. for sealevel ties to evaporite packages, such as the A1 sulphates, are much too slow. Thick basin-centre evaporites require particular conditions of tectonic isolation to form, when this does occur the evaporites are laid down very rapidly (5th and 6th order cycles), as they were in the Mediterranean.

Sequence stratigraphy in the Silurian Salina Group of the Michigan Basin

The Michigan basin in the Late Silurian was a roughly circular intracratonic sag basin, approximately 400 km in diameter and fringed by reef pinnacles passing updip into an extensive rimmed platform (Figure 5.51a; Brennan and Lowenstein, 2002). The reefs are encased in salts of the Salina Group. When Salina Group evaporite deposition commenced some 423 Ma the palaeolatitude was approximately 26°S, and approximately 20°S at 417 Ma, when Salina Group deposition ended (Brennan and Lowenstein, 2002). Prior to its hydrographic isolation, marine waters entered from the southern Kokomo Sea, via the Clinton Inlet, and from the northern Moose River Basin via the Georgian Inlet (Briggs et al., 1980). A relative sealevel drop in the late Wenlockian produced restriction and isolated the Michigan Basin from the Silurian ocean; throughout, the earth was in greenhouse climate mode (Dellwig, 1955; Dellwig and Evans, 1969). The deep-water A-0 unit (calcite–anhydrite–halite), the first deposit associated with this sealevel drop, is conformably overlain by the A-1 Evaporite and defines the transition into mesohaline conditions as the surface connection to the open ocean was lost (Figure 5.52; Dellwig, 1955; Nurmi and Friedman, 1977; Gill, 1977; Briggs et al., 1980; Cercone, 1988; Leibold and Howell, 1991).

Middle Silurian pinnacle reef reservoirs in the Michigan Basin are isolated stromatoporoid/coral-crinoid buildups, which are encased and sealed by a combination of Upper Silurian halite, anhydrite and fine-grained carbonate (Figures 5.51, 5.52). Reef pinnacles form two hydrocarbon belts some 16 to 24 km (10 to 15 miles) wide that extend basinward from the steep inner face of an extensive, but nonproductive, barrier reef (Figure 10.32). The basinal equivalent of the reefs is a thin carbonate some 18 to 24 m (60 to 80 ft) thick. The reef/bank rimmed platform is dolomitised, as are most of the pinnacles, although a few of the more basinal pinnacles are still limestone (Sears and Lucia, 1979, 1980). Pinnacles are capped by an erosional unconformity and reef growth had ceased well before the basinwide drawdown events that deposited the encasing evaporite cycles (Figure 5.51a; Gill, 1985). Drawdown created the karst horizon that caps the marine reef sediments of the Guelph Formation and immediately underlies the stromatolitic capstones formed during deposition of the A-1 evaporitic carbonates (Mesolella et al., 1974). During drawdown the pinnacles formed topographic highs and were sites of marine groundwater escape (pisolitic/stromatolitic seepage facies) until they were enveloped in aggrading salts of the A-2 cycle.

Figure 5.51. Silurian evaporites in the Michigan Basin, USA. A) Location of Salina Group, the evaporite-filled central Michigan Basin is identified by the dotted oval, and the evaporite-sealed northern and southern pinnacle reef trends are shown by the larger dots. Also shown is the position of the JEM Petroleum Corporation Bruggers well, Missaukee County, Michigan. B) Stratigraphic chart of Silurian formations in the Michigan Basin (after Gill, 1979).

The sealing evaporites of the Lower Salina Group were some of the first thick sequences of salt to be interpreted as containing textures of more than one depositional setting. The earliest depositional interpretations of these salts were as deepwater deposits (Dellwig, 1955; Dellwig and Evans, 1969). Nurmi and Friedman (1977) challenged many of Dellwig’s conclusions. They interpreted much of the halite as having formed as stacked halite crusts precipitated beneath shallow brine sheets subject to periodic drying. The arguments of Nurmi and Friedman were rooted strongly in processes observed in Holocene salt crusts.

A shallow to ephemeral water model came to dominate subsequent interpretations and have been reinforced by subsequent detailed geochemical studies (Figure 5.52; Brennan and Lowenstein, 2002).

Thus, the evaporites imply episodes of evaporative drawdown and that there was subaerial exposure of the reef crests prior to their encasement in salt, via a process of “fill and spill.” The complex rapid rise and fall of the brine level over vertical distance of several tens of metres during the accumulation of the Salina Group drove ongoing alteration, dolomitisation and evaporite plugging, not just of the Salina Group but also in the Niagaran, especially in those pinnacles sitting below zones where thick sequences of evaporites were accumulating.

Detailed stratigraphic analysis of the evaporites and evaporitic carbonates in the vicinity of producing pinnacles clearly define the complexity of sequences accumulating under a system of basinwide evaporitic drawdown. Using more than 350 wells and numerous cores, Leibold (1992) and Howell and Leibold (1992), defined four composite sequences: Niagaran, A-1 Unit, A-2 Unit, and the B Unit (Figure 5.52). The Niagara Group carbonates comprise a dominantly intrabasinal highstand composite sequence that was deposited on a preexisting carbonate ramp and was interrupted by at least one major drawdown event. Numerous Type 1 unconformities on the carbonate platform margin were recognised by Leibold (op. cit.) and related to evaporative drawdown events. Thus, the Niagaran is a composite sequence made up of two sequences separated by an unconformity. The lower sequence consists of three parasequence sets: aggradational (“White Niagaran” ramp), transgressive (“Gray Niagaran”), and progradational (“Brown Niagaran”). The Brown Niagaran includes a distinct stromatoporoid shelf-bank margin and a zone of pinnacle

reef growth. Biostratigraphic, lithostratigraphic and isotopic evidence indicates Upper Niagaran water depths in the basin exceeded 250 metres prior to drawdown. The Brown Niagaran parasequence set is interrupted by a drawdown unconformity, represented by the subaerial exposure surface mentioned earlier. It extends below the shelf margin into the inter-pinnacle reef areas and defines a type 1 boundary (Figure 5.52).

A second drawdown event ended Niagaran deposition and initiated the A-1 Unit as a thick (140 m) lowstand evaporite wedge in the basin (Figure 5.52, 5.53). Deposition of the halite-dominated A-1 Evaporite occurred in an initially somewhat deeper brine that progressively shallowed. The JEM Bruggers 3–7 core, Missaukee County, Michigan completely cored the A-1 evaporite (Figure 5.52; Leibold, 1992). The basal 10 m of the A-1 Evaporite is composed of alternating layers of coarse, clear halite (50–150 mm thick) and anhydrite (30–100

mm thick). It was interpreted as a possibly deeper water unit showing widespread halite recrystallisation, but models of meshwork halite (Dead Sea holomictic/meromictic analog) were not available in the early 1990s. This unit is overlain by 25 m of chevron-rich halite, the upper 5 m contains bedding planes dipping up to 40°, which have been interpreted by Leibold (op cit.) as buckled pressure-ridged pan halite crusts, formed during subaerial exposure (Leibold, 1992). This is overlain by the “mid-basin potash facies”, which is up to 60 m thick and composed of halite and sylvite elsewhere in the Michigan Basin (Leibold, 1992). The potash facies in the JEM Bruggers core does not contain bedded sylvite; however, primary fluid inclusions in the halite do contain daughter crystals of sylvite, carnallite, and tachyhydrite (Leibold, 1992). These potash facies also contain borate nodules and buckled salt crust polygons indicating saline-pan deposition with periodic basin desiccation. The mid-basin potash facies is overlain by halite that has been pervasively recrystallized (Leibold, 1992).

pervasively recrystallized (Leibold, 1992).

Leibold (1992) and Raup and Hite (1993) analysed bromide from bulk halite samples in the JEM Bruggers 3–7 core and showed that coarse halite and chevron-rich facies at the bottom of the A-1 Evaporite display a systematic upsection increase in Br concentration, ranging from 25 to 200 ppm. This type of bromine profile, along with the upward increase in the density of chevrons, and buckled crust polygons towards the top of the chevron-rich facies indicate that this lowermost section of the A-1 halite formed by the progressive evaporation of a large shallow body of brine, which dried out at the top of the unit. In contrast, halite from the mid-basin potash facies does not exhibit any systematic increase in the Br concentrations. Instead, the Br is relatively high (210 ppm) throughout, which suggests these halites did not form strictly by the progressive evaporation of a large body of Silurian seawater (Figure 5.52).

The A-1 Evaporite is overlain by the A-1 Carbonate, which signifies

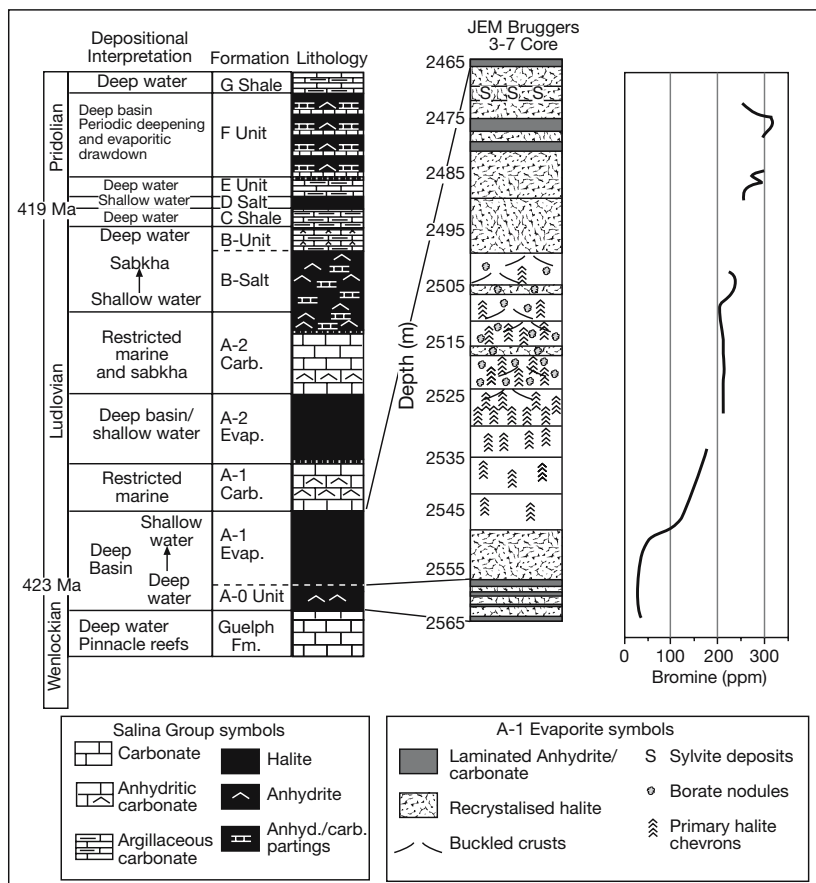

Figure 5.52. Stratigraphy of the Salina Group (left column) and detailed facies of A-0 and A-1 Evaporites in Bruggers 3–7 core (right column), Michigan Basin (Upper Silurian). The thicknesses of the Salina Group Formations are not to scale. The depositional interpretations of the Salina Group are primarily from Leibold (1992). (after Brennan and Lowenstein, 2002).

Figure 5.53. Schematic showing facies relationships of a shelf to basin profile in the Silurian of the southern Michigan Basin (in part after Sarg, 2001).

a higher volume of marine brine in the Michigan Basin, this could indicate a more humid climate or a possible renewed surface connection to the Silurian ocean. The A-1 Carbonate is overlain by the A-2 Evaporite, which indicates a second period of increased aridity or the return to isolation of the Michigan Basin from the Silurian ocean. The A-2 carbonate, a gray, nonfossiliferous mudstone, conformably overlies the A-2 Evaporite. The B Evaporite conformably overlies the A-2 Carbonate and is composed of two units, the B-Salt and the overlying B Unit. The B-Salt deposits consist of halite interbedded with anhydrite and dolomite partings (Leibold, 1992), which likely formed within a shallow isolated central basin. The B-Unit is interpreted by Leibold (op. cit.) as a deep-water, anhydrite-rich, argillaceous carbonate, which marks the beginning of a regional transgression. The C Shale, D-Salt, and the E-Unit possibly indicate alternating incursions of seawater and isolation and concentration of the basin waters (Droste and Shaver, 1985) or more likely they are responses to climatically induced transitions from meromictic to holomictic basin waters.

The mid-Pridolian F-Unit is the uppermost evaporite formation of the Salina Group and comprises six separate halite units, F-1 to F-6, that are separated by shales, dolomites, and anhydrites (Sonnenfeld and Al-Asam, 1991). The lowermost F-1-Salt is composed of continuous beds of chevron-rich halite separated by anhydrite partings (Dellwig and Evans, 1969) and resembles similar facies in the A-1 Evaporite. Bromide concentrations increase systematically upsection in the halites of the F-1-Salt (Das et al., 1990), consistent with the profile expected for evaporation of a large body of seawater-fed brine. Sulphur and strontium isotopic analyses of the anhydrite in the F-1 salt are also consistent with Silurian seawater values (Das et al., 1990).

The thickness, orientation and mineralogical zonation of marginal evaporite wedges in the basal A-1 Evaporite overlying the Niagaran sequence required initial minimum brine depths of 20 metres and so imply wind and water currents influenced evaporite deposition (Sarg, 2001). Overlying lower A-1 Evaporite salts were deposited in shallower brines, less than a metre or two deep, as indicated by chevron-rich growth-aligned halite pan textures. Middle and upper A-1 evaporite lithofacies contain evidence of alternating very shallow brine and subaerial depositional conditions (Leibold, 1992). The Middle A-1 lithofacies are sylvite- and borate-rich, with sylvite beds present only in the central Michigan Basin (Figure 5.51a). Upper A-1 evaporite lithofacies, which Sarg (2001) calls transgressive (I prefer fill and spill), are dominated by stacked, saltpan morphologies. The brine level at this time was well below sealevel and the basin had no surface connection to the open ocean.

Periodic seawater flooding or climatically-induced freshening then renewed carbonate deposition as the A-1 carbonate was deposited across the basin and platform region (Leibold, op. cit.). The A-1 composite sequence was terminated by further drawdown, resulting in a second thick lowstand evaporite wedge (A-2 halite). Reflooding and/or climatically induced freshening initiated multiple stacked A-2 carbonate aggradational sequences, separated by several drawdown unconformities. The B Unit is a composite of carbonate/evaporite sequences, each consisting of an aggradational carbonate parasequence and a lowstand evaporite wedge. These sequences mark the final filling of the basinal depression created during Niagaran carbonate deposition. Thus the A-1 and A-2 units of the Salina Group each comprise a lowstand relative to external sealevel, with each evaporite sequence set overlain by a relative highstand carbonate sequence set. Both composite sequences are punc-

tuated by several, widely-correlatable drawdown events. The B-Evaporite is dominantly a “lowstand” composite sequence consisting of stacked, shallowing-upward evaporite cycles.

Sequence stratigraphic interpretation in the Michigan Basin sequence underscores the difficulties in interpreting an isolated intracratonic basin using unconformity/bounding-surface terminology tied to a set of marine sealevel implications. It is very hard to do this reliably in a basin that lacked a marine connection for most of its evaporite history and in a hydrological situation where intrabasinal water level fluctuations were not necessarily related to extrabasinal eustatic changes. Recognising regional unconformities in core and seismic is the key to any reliable sequence stratigraphic interpretations in this situation. Unfortunately unconformities are numerous in drawdown sequences and correlations of supposed regional unconformities from basin edge to basin centre are difficult. Often it is done based on marine eustatic assumptions and this of course leads to circular arguments in interpretations of eustasy based on a sequence stratigraphic interpretation.

Sarg (2001; his Table 1) lists the Michigan Basin as a type example of a third-order basin centre fill (10-100 m thick) with an onlap basin margin and he places it in the same classification category as the Z1-Z4 units in the Zechstein Basin. A fact to remember when attempting unconformity-based correlation and sequence stratigraphic interpretation is that evaporite aggradation rates are so rapid in a basinwide systems that the basin fill quickly aggrades to the intrabasin hydrological equilibrium (time frames of up to 1-2 km of fill in a few hundred thousand years). It means that in the 1-7 million year long history of any evaporite-filled basin there were long periods, post the attainment of hydrological equilibrium, when not much was happening depositionally. That is, based on the hydrologies detailed in Chapters 2 through 4 and the chronology of the Messinian in the Mediterranean, we know that evaporite basins fill rapidly with stacks of 5th and 6th order cycles. Using salt thickness to divide evaporite successions into second order (100-1000 m) versus third order (10-100 m) cycles is an irrelevancy that comes from applying assumptions inherent in a marine eustatic terminology.

Thick-bedded marine-fed evaporites are intrabasinal responses to hydrological evolution and should not be tied to any marine eustatic implication. Marine-fed and the associated concept of hydrological equilibrium (drawdown) are not the same as assuming marine salts fill the basin to sealevel. When 1-2 km thick halite beds were accumulating in the Messinian in Mediterranean basin, the saltpan surface never came within a kilometre of sealevel in the adjacent Atlantic.

Sarg (2001) also argues that the coral-crinoid growth occurred in Michigan Basin pinnacles in a marine reconnection episode, following the A1 evaporite drawdown stage. He equates subsequent coral-crinoid growth to ongoing growth in the Niagaran Platform via a set of regional unconformities. Others have difficulty with this correlation and see stenohaline crinoid-coral deposition ceasing throughout the basin at the end of the Niagaran with subsequent mud mound growth occurring in mesohaline marine-seepage fed conditions. This group of workers choose a different set of unconformity correlations. They see the euryhaline stromatolite/stromatoporoid biomes as the major contributors to mound growth once the Michigan Basin lost its surface connection to the ocean.

This debate of a possible marine surface connection post-A1 carbonate and a definition of the A-0 carbonate, first detailed by Mesolella et al. (1974) in three models of pinnacle-evaporite inter-relationships, continues today. What we have learnt since the early 1970s is that all of the salts in the Michigan basin were deposited in shallow drawdown waters. At the time of evaporite deposition the basin's shelf margin and the crests of the pinnacle reefs were subaerially exposed, the tops of the inactive pinnacles acted as spring mound feeds to the surrounding lows characterised by a halo of anhydritic mudflats passing further out in to halite pans. Anhydrite is present both as a sabkha nodules and as widespread diagenetic cements within marine carbonate hosts. The possibility of widespread early burial anhydrite in Niagaran carbonate is something largely ignored by sequence stratigraphers working in pinnacles in the Michigan Basin, who tend to see anhydrite as a mostly marine mudflat facies not a seepage facies. With the possible exception of the pinnacle crests, no widespread open marine sediments accumulated in the Central Michigan Basin, even at times of freshened (but still evaporitic) carbonate accumulation, such as the A1 and A2 carbonates.

Summary

Modern and ancient evaporite basins can deposit kilometre-thick sequences in less than 300,000 years. Such infills only occur at times of complete basin isolation when there is no surface connection to the world's oceans. Once we realize that thick evaporite accumulations require a stable longterm brine curtain ($\approx 10^5$ - 10^6 years) to accumulate to substantial thicknesses and lateral extents, we reach an understanding of why the present is not a good time to study the scale and diversity of possible evaporite settings. High amplitude, high frequency 4th-order sealevel oscillations of our current “icehouse” climate do not

allow the set up of stable brine curtains in present-day continental platforms. Nor are there suitable rift or collision belts where conditions are suitable for the creation of marine-fed basinwide drawdown deposits. The last such basinwide event occurred in the Mediterranean some 5.5 Ma. Thick stable brine curtains are today only found in continental settings.

Sequence stratigraphic analysis must be tied to a subdivision of ancient evaporites into three depositional styles, continental lacustrine, marine platform and marine basinwide. All three are suitable for high-frequency seismic interpretation and the unique nature of salt mean it is easily recognised and traced in a seismic section. The hydrology needed to form a salt bed also makes it a close approximation to a time line in the basin architecture. But, of the three styles, a marine eustatic interpretation tied to sealevel is only possible in a marine platform evaporite succession.

Chapter 6: Salt tectonics

Introduction

Flowing salt produces some of the most complex and visually impressive low-temperature geological deformation to be seen on the earth's surface. In Iran, flowing glaciers of salt (namakiers) rise up to 1000 metres above the surrounding Zagros landscape. Diapiric salt also outcrops in the Andes, the Canadian Arctic, in Cardona in Spain, and subcrops near Hallestat/Dachstein in Austria and along the banks of the Nam Theun River in Laos. It also is an important mechanism in controlling the formation of many complex traps for hydrocarbons and base metals (Warren, 2000b).

That rising salt can maintain units of highly soluble near-pure halite near the earth's surface is why Neolithic salt exploitation in Europe was inland and centred on mines at Cardona and Hallestat, as opposed to sites of seasonal coastal evaporation on the coastal plain. Some diapiric salt masses even have religious significance; Lot's wife on the edge of the Dead Sea is a 12m-high column of salt lying at the foot of the much larger Mt Sedom (Usdum). It is a dissolutional remnant from a gypsum-capped outcropping diapir composed of Miocene salt, which also makes up Mount Sedom. It was noted by Fulcher of Chartres (Chaplain to King Baldwin) who accompanied the crusader Baldwin I across the Dead Sea valley in December 1100 AD. But Sedom's description as a mountain is somewhat of a

misnomer, it is certainly 8 km across, but only rises a hundred metres or so above the floor of the Dead Sea Valley.

Salt tectonics (syn. halotectonics and halokinesis) is a general term that encompasses notions of lateral and vertical salt flow, trans-stratal salt movement, salt pillowing and diapirism, it refers to tectonic deformation involving halite or other evaporites as a substratum or source layer (Figure 6.1). Concepts of salt tectonics have undergone a major revision in the last fifteen years, due mainly to advances in 3D seismic acquisition and processing, especially 3D prestack depth imaging, and the realisation that salt tectonics is best modeled by considering a salt bed as a pressurized fluid layer overlain by brittle sediment (Hodgkins and O'Brien, 1994; Ratcliff and Weber, 1997).

Salt tectonics can be summarised in two simple geological principles. First, differential loading drives salt tectonics; this make halokinesis a much more passive process than had been believed. Second, salt is a very weak and incompetent layer in the subsurface; its lateral flow and sliding carries along its overburden in extension and acts as a décollement in compression. Salt sheets, tongues, and allochthonous nappes are major subhorizontal components of the salt tectonic realm (Figure 6.1). Like any less competent layer in extension it undergoes boudinage and drives fracturing in its more brittle overburden.

Figure 6.1. Interpreted seismic profile through allochthonous salt sheets that build the Sigsbee Escarpment (to southeast), base of continental slope off Louisiana, Gulf of Mexico (after Wu, 1993; Jackson and Vendeville, 1994). Note how supra-allochthonous faults have initiated diapiric upwelling at 1, 2 and 3. The allochthon is underlain by shortened strata of the Mississippi Fan Foldbelt. BS = base of Jurassic Louann Salt; TS = Top of salt; MCFS = Middle Cretaceous flooding surface equivalent; MO = Middle Oligocene; LM = Lower Miocene; MM1 = Lower Middle Miocene; MM2 = Middle Miocene; MM3 = Upper Middle Miocene; UM = Upper Miocene; PLI = Pliocene. Note how Jurassic salt has climbed the stratigraphy and now overlies and seals Neogene deepwater sediment.

The word diapir originally comes from the Greek *diaperin*, meaning “to thrust-through” and was coined by L. Marzic in 1902 to describe salt features of the Romanian Alps at a time when diapir emplacement was considered to be a forceful intrusive process capable of pushing aside kilometres of overburden. Today, salt diapirs are defined as salt flow features showing discordant contacts with the encasing sedimentary strata. This definition does not uncritically encompass notions of active piercement and the shouldering aside of thick overburden. Where feasible salt constituting a diapir should be further classified as either allochthonous or autochthonous.

Allochthonous salt structurally overlies parts of its (stratigraphically younger) overburden and is often no longer connected to the primary salt bed (mother salt level). For example, spectacular allochthonous salt sheets in the northern Gulf of Mexico form a line of five or so huge asymmetric tongues of Jurassic salt that now overlie and seal Pliocene to Pleistocene sediments. They coalesce behind the Sigsbee Scarp to form a salt tongue canopy and can be considered analogous to gravitational nappes in orogenic belts (Figure 6.1; Worrall and Snelson, 1989). Allochthonous salt bodies climb the stratigraphy via a series of tiers or canopies, leaving evidence of passage as thin salt pods, dissolution residues and alteration aprons along salt welds or overburden touchdowns, much like a garden slug leaves behind a slime trail. Autochthonous salt structures are those still firmly rooted in the stratigraphic level of the primary salt bed. Prior to the application of current seismic imaging and processing techniques most diapiric structures were interpreted as autochthonous thumb-like appendages connected at the level of primary weld.

A whole new realm of salt/sediment configurations and oil exploration plays have opened up in the last two decades with the realization that; a) salt sheets can be allochthonous and subhorizontal over large areas in a sedimentary basin, and b) structures in the salt allochthon overburden are tied either to the trailing edge of the allochthon where salt is evacuating/withdrawing, or the leading edge where salt is flowing at or near the surface. A range of potential subsalt hydrocarbon traps have now been successfully drilled in the Americas, where the move into deeper water revitalised what were considered mature exploration provinces (Montgomery and Moore, 1997; Meisling et al., 2001).

This chapter will concentrate on salt structures; halokinetic breccias that remain after the salt has dissolved will be discussed in Chapter 7, hydrocarbon associations are discussed in Chapter 10 and exploitable diapiric salts in Chapter 11. Diapirs do not just form in salt, they can occur in any geological material

with markedly different pressure and strength compared to its overburden. Some of the principles and concepts developed in describing salt diapirism as newtonian fluid responses can be successfully applied to overpressured shales, serpentinites and even molten granites rising through the mantle (Talbot, 1992a).

Physics of salt systems

Even with our greatly improved ability to seismically outline salt features, the comments made by Richter-Bernburg, more than two decades ago, still hold true today. In a 1980 review he noted that our geological understanding of the world's various salt structures is still very much like that of a sculptor to the human body; the whole figure can be perfectly described, especially using 3D seismic and forward modelling, but the anatomy, the inner organs and the complicated inner structures remain largely disregarded. So before we look at the various geometries sculpted by salt, let us look internally at the properties of salt that drive salt flow and at the internal textures indicative of this flow.

Density, viscosity, strength & buoyancy

After it loses effective porosity by 100-200m burial, halite's density of 2.2 gm/cc remains near constant throughout the diagenetic realm and it is near incompressible to depths of 6-8 km (Figure 6.2a). With entry into greenschist depths, deeply buried halite can experience massive recrystallisation and dissolution, along with a slight decrease in density due to thermal expansion (Figures 6.2a, 8.19; Lewis and Holness, 1996). In contrast, burial compaction in shales and most other sediments is defined by a progressive loss of porosity, with an associated increase in density and strength until it exceeds that of the salt below. This means that salt has positive buoyancy when buried beneath nonevaporitic overburden to depths in excess of a kilometre. With a muddy overburden, the depth of density crossover, sometimes called the level of neutral buoyancy, is typically shallower than 1300 to 1500 metres. It can be much shallower beneath reefs and other cemented carbonates, which can have densities equal to, or greater than, salt almost from the time of deposition. This can lead to rapid foundering and brecciation of reef materials, especially in areas of overburden extension and allochthon spreading.

Few other rocks are as thermally conductive or as close to truly viscous as natural rock salt (Figure 6.2b, c). Viscosity is a measure of a fluid's resistance to flow or its internal fric-

tion and is measured by the ratio of shear stress to the rate of shear strain. Laboratory measurements show wet carnallite can have a viscosity as low as 10^8 Pa.s, while dry halite has a viscosity around 10^{18} Pa.s (for comparison, honey at 14°C has a viscosity ≈ 60 Pa.s; window putty $\approx 10^5$ Pa.s; and road tar $\approx 10^7$ Pa.s; $1 \text{ Pa.s} = 10 \text{ poise}$). The viscosity of salt in the Gulf of Mexico is 10^{13} to 10^{16} Pa.s, depending on moisture content and temperature. The adjacent overburden of clays and sands is less viscous by four to five orders of magnitude. Davison et al. (1996a) estimates the ratio, sedimentary rock: evaporite rock viscosity, ranges from 50 to 10^4 . As different parts of a diapir deform at different rates and by different mechanisms, the effective subsurface viscosity values for diapiric salt vary with position in the diapir, the water content of the salt and time. Due to its much higher moisture content (from meteoric waters), diapiric salt is much less viscous when it reaches the surface as a tongue of extruded salt than at depth.

Over geological time frames, finer-grained wet salt approaches^{6.1} Newtonian viscous behaviour, unless it is atypically coarse grained. And like any fluid it cannot support shear so a mound of wet salt emplaced on the earth's surface will spread under its own weight. Using a viscous fluid model, salt diapirism and its relationship to its overburden can be likened to Rayleigh-Taylor instability with a viscous substratum (salt) and an overlying denser viscous fluid (overburden; e.g. discussions in Koyi, 1991; Talbot, 1992a,b). Under such a fluid-fluid model, diapirism is spontaneously initiated by small irregularities in the fluid-fluid interface that then amplify with time and buoyancy contrast. Diapirs rise continuously and inevitably until the less dense salt overlies its overburden. The only requirement for Rayleigh-Taylor instability in a fluid-fluid system is density inversion; diapirism modeled in such a way does not require any external trigger such as regional extension or differential loading. Under this fluid-fluid scenario, any regional extension thins the fluid overburden and the source layer, so reducing the overall thickness. The resulting diapirs are smaller, more

^{6.1}Newtonian (or viscous) flow occurs when the rate of shear stress is directly proportional to the shear strain.

Figure 6.2. Physical properties of rock salt compared to other lithologies. A) Density changes with burial. B) Thermal conductivity (see also Figure 8.19a). C) Viscosity.

closely spaced, and more slowly rising than those in unthinned counterparts (Koyi, 1991).

Rather than model the salt's overburden as a viscous fluid, proponents of the "brittle school" tend to model salt as a pressurized pseudo-fluid at subsurface flow rates, and consider its sedimentary overburden liable to show brittle responses to stress (e.g. Jackson and Vendeville, 1994). In most subsurface situations it means that relative density as a trigger and a subsequent control to halokinesis, is a less important consideration than relative strength of salt and its overburden. This style of modelling is better supported by the geological observations that; diapirs rise episodically rather than continuously, that salt flows when loaded (much like toothpaste is squeezed out of its tube) and that faulting, rather than folding, characterises much of the early deformation in the overburden. In reality, the strength response of a buried salt bed and its overburden will depend on the strain rate and the rate of deformation in the overburden. Salt can fracture and fault at high strain rates (brittle response), but the required strain rate is much higher than experienced in many typical subsurface situations (Jackson and Talbot, 1994).

Subsurface nonevaporitic sediments, including indurated shales, show time-independent, pressure-dependent brittle behaviour under stress and deform most readily by frictional slip along faults. In contrast, bedded salt under stress tends to flow and

deform. Most adherents of the brittle school contend that varying combinations of regional extension, differential loading and gravity sliding, will localise, initiate and promote diapirism of salt and shale. The conclusions of the “brittle” school are supported by studies showing virtually all sediments at shallow crustal depths (<8-10 km) deform as faulted brittle masses, rather than by the creep and folding that typifies deforming evaporite salts. This depth range encompasses much of the realm of salt tectonics in sedimentary basins.

Evaporite salts are unique in their tendency to flow in the diagenetic realm. Representative strain rates and speeds of salt deformation are listed in Table 6.1. A strain value of 10^{-15} s⁻¹ indicates that a rock stretches at a rate of 10^{-15} of its length per second and is representative of the slow strain rates encountered in rock deformation rates in active orogenic belts. A value of 10^{-9} is 1 million times faster and represents strain rates in active (wet) salt glaciers in Iran (1.6×10^{-13} to 1.8×10^{-8} per second; Wenkert, 1979) and equates to an annual rate of rise of ≈ 2 m/year in the salt stem. But the rate of salt supply and surface flow is not constant; salt glaciers (namakiers) in Iran always flow faster after a rain; the Dashti glacier at Kuh-e-Namak flows at upto 0.5 m/day during the few weeks of the annual wet season, but flows little if any during the dry season when the glacier expands and contracts diurnally in response to changes in surface temperature. But what do these observed rates of deformation mean in terms of driving mechanism and how does flow occur at the crystalline scale?

Cataclastic or brittle responses to deformation involve microfracturing and sliding of grains and grain fragments (grain crushing) and are important in non-evaporite indurated sediments at low temperatures and confining pressures (Talbot and Jackson, 1987). The same brittle responses are also seen in salt mines in areas where deformation failure of salt pillars has occurred. In contrast, any fluid responses to deformation result in kinking of crystal lattices by various combinations

of slip, glide or dislocations of grains, known collectively as dislocation creep.

Based on naturally and artificially deformed salt samples, Carter et al. (1983) concluded dislocation creep occurs at temperatures and pressures relevant to subsurface salt deformation. They found that short-term, high stress flow properties of dry salt can be reasonably encapsulated in an empirical power-law equation (Figure 6.3a). This power law explains the rates of creep and differential stress fields interpreted in shallow diapiric salt. It does not explain the much higher strain rates of 10^{-8} to 10^{-11} measured in salt allochthons and salt glaciers (extruded wet salt) at stress differentials estimated to be around 0.5 MPa and at ambient surface temperatures (Talbot and Jackson, 1987a). Nor do their stress/strain triaxial experiments duplicate the elongate recrystallised textures of naturally deformed salt; such textures imply some sort of diffusional flow (Urai et al., 1986).

Classic hard-rock diffusional flow mechanisms allow strain by diffusion of ions along grain boundaries (Coble creep) or through the crystal lattice (Nabarro-Herring creep). In dry salt experiments these mechanisms are largely irrelevant in the low temperature fields that characterise salt deformation in the diagenetic realm. In wet salt, a diffusion mechanism can operate at much lower temperatures and differential stresses (Urai et al., 1986). The high solubility of chloride salts means solution transfer creep (aka solution precipitation creep and pressure solution creep) is the prevalent deformation mechanism in flowing salt in the diagenetic realm (Figure 6.3b). Triaxial deformation experiments by Urai et al., (1986) using carnallite, sylvite and rock salt showed that flow laws based on short-term high-stress experiments conducted on dry salt should not be extrapolated to salt deforming under lower strain rates and nondilatant conditions. They found that both dry salt (≈ 0.05 wt% inherent water) and wet (brine-saturated) salt both deformed by power law creep with $n > 5$ at strain rates faster than 10^{-7} s⁻¹, as found by Carter and Hansen (1983). However, the same rocks

deformed by power law creep with $n \approx 2$ (dry) or $n \approx 1$ (wet) when samples were stained more slowly by suppressing the rate of dilatancy (either by increasing confining pressure to between 5 to 10 MPa, or adding brine under dilatant conditions.

Type of flow	Strain rate (s ⁻¹)	Speed (mm a ⁻¹)	Speed
Lava flow (faster when hotter)	10^{-5} to 10^{-4}	5×10^{11} to 3×10^{13}	1 to 60 km hr ⁻¹
Ice glacier (surges with increased temperature)	10^{-10} to 5×10^{-8}	3×10^5 to 2×10^7	1 to 60 m day ⁻¹
Salt glacier (surges after a rainstorm)	10^{-11} to 2×10^{-9}	2×10^3 to 2×10^6	10 to 100 km Ma ⁻¹
Mantle currents (temperature and pressure controlled)	10^{-15} to 10^{-14}	10 to 10^3	2 m a ⁻¹ to 5 m day ⁻¹
Spreading salt tongue (<30km wide)	8×10^{-15} to 10^{-11}	2 to 20	2 to 20 km Ma ⁻¹
Spreading salt tongue (>30km wide)	3×10^{-16} to 10^{-15}	0.5 to 3	0.5 to 3 km Ma ⁻¹
Rising diapiric salt (increases with water content)	2×10^{-16} to 8×10^{-11}	1×10^2 to 2	10 m to 2 km Ma ⁻¹

Table 6.1. Representative strain and flow rates (after Jackson and Vendeville, 1994).

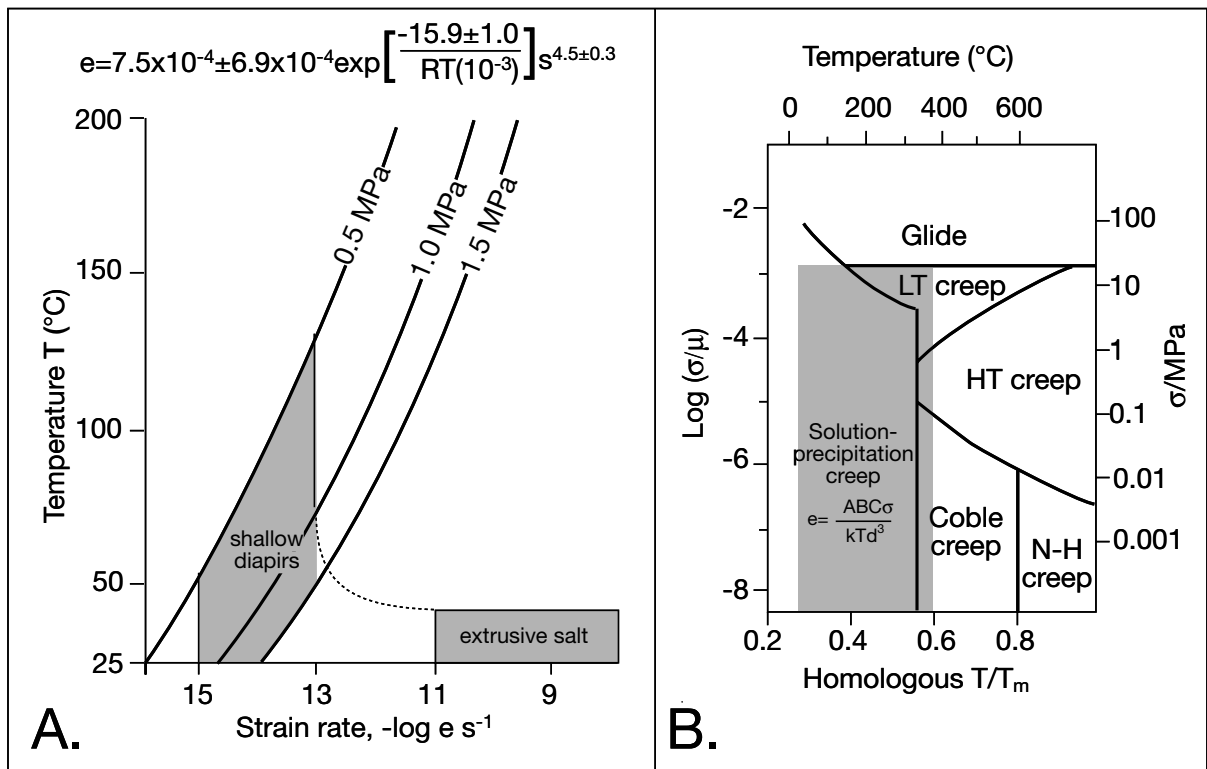

Figure 6.3. Conditions of temperature and strain where salt tends to flow rather than fracture (after Talbot and Jackson, 1987a; Carter and Hansen, 1983). A) Power law behaviour of dry rock salt where the relation between steady-state strain rate (e) and differential stress (σ in MPa) is highly nonlinear (stress exponent, $n = 4.5$). This power law does explain deformation in salt diapirs but not the much higher strain rates of extruded salt/salt glaciers. There much of the flow is periodic and facilitated by the presence of water. R is universal gas constant and T the absolute temperature. B) Deformation mechanism map for damp rock salt showing dominant deformation mechanisms for different temperatures and stresses. Shaded area shows the dominant field for most natural salt flow, which lies mainly in the solution-transfer field (solutant diffusivity term; C = grain boundary structure parameter; k = Boltzmann constant; d = grain size. T_m = melting point of halite; LT and HT is low and high temperature; N-H is Nabarro Herring (after Urai et al., 1986).

They also found that samples deformed under these more geologically realistic conditions had completely recrystallised with flattened fabrics very similar to those of naturally deformed salt. This process of solution transfer creep in the salt produces new gneiss-like crystal textures made up of amoeboid-like strain-free flattened salt grains (a flow parallel fabric). Solution-transfer creep or pressure solution creep occurs in regimes of differential stress as halite grains dissolve in regions of high stress and reprecipitate in regions of low stress. The basic processes involved are the migration of existing grain boundaries and the formation of new high angle grain boundaries (Drury and Urai, 1990). New crystals are less substructured and replace older more substructured grains as migrating crystal grain boundaries consume and sweep through the older milky inclusion-rich portions of the salt. Crystals in an area swept by grain boundary migration tend to be inclusion-free, with fluid inclusions now focused along the grain boundaries and so providing conditions

suitable for pressure-solution induced creep of the salt mass (Urai et al., 1986; Spiers et al., 1990). Much of this new salt is clear and sparry rather than milky.

Grain boundary migration in deforming wet salt typically leads to grain growth during recrystallization, but can also lead to grain size reduction if new grain boundaries are formed at grain boundary bulges or as a result of grain dissection by migrating boundaries (Ter Heege et al., 2005). New grain boundaries may also form from subgrain boundaries, by progressive misorientation of subgrains or by migration of a sub-boundary through an area of cumulative lattice rotation. This is called rotation recrystallization. The relative importance of migration and rotation recrystallization is dependent on the deformation conditions (i.e. temperature, strain rate and stress). The mean grain size D of dynamically recrystallized materials has been found to be related to the steady state flow stress σ by a general

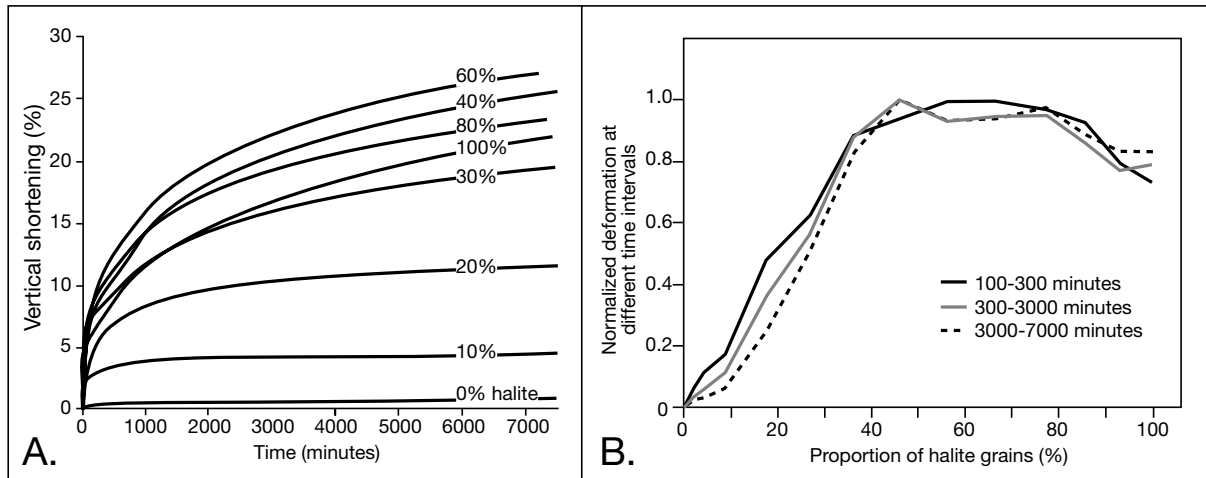

Figure 6.4. Effect of impurities on salt compression, cementation and pressure solution. A) Result of drained compaction experiments. Compaction curves $E(t) = (x_0 - x(t))/x_0$ for different samples show that the total amount of compaction after 7000 min (roughly 5 days) depends on the relative proportion of halite and calcite grains. The highest finite compaction (vertical shortening) does not occur in a sample composed of 100% halite grains. B) Effect of the mineralogical composition on the amount of vertical shortening on a halite-calcite aggregate. The three curves are normalized to the average maximum deformation of the tested samples at the given elapsed time and they show the same trend, within experimental errors. The mixtures with halite contents between 0 to about 40% do not exhibit this behavior. The rate of deformation goes down during progressive deformation for halite proportions ranging between 10% and 40% (after Zubtsov et al., 2004).

theoretical relation of the type $D = K\sigma^p$, a power law, where K and p are material and mechanism specific constants (see also Figure 6.11 and discussion). Ter Heege et al., (2005) have now experimentally modelled the specific deformation of wet salt and concluded that the equation is of the form:

$$(D/\beta) = 10^{-1.55 \pm 0.24} (\sigma/\mu)^{-1.85 \pm 0.23} \exp(14.2 \pm 2.8/RT)$$

with D denoting mean recrystallized grain size, Burgers vector $\beta = 3.99 \times 10^{-4}$ μm and the shear modulus $\mu = 1.5 \times 10^4$ MPa.

The intensity of salt flow and recrystallisation (re-annealing) can in part depend on levels of impurities in deforming and compressing salt. Various lab-created mixtures of crushed halite aggregate and calcite crystals show an interesting set of responses under triaxial compression with free drainage of fluid products (Zubtsov et al., 2004). A 100% halite sample, or an 80:20 halite-calcite mixture, are both less susceptible to compressional shortening than halite-calcite mixtures of between 40% and 60% halite (Figure 6.4a). This is true at all time ranges in the experiment, which ran for periods of up to 5 days (Figure 6.4b). Mixtures with <30% halite show less shortening than all samples with higher proportions of halite in the mix. These responses indicates two mechanisms competing at the grain-to-grain scale: 1) intergranular pressure solution at grain contacts, which facilitates compression, especially across boundaries with different chemical potential

as typically occurs at contacts between grains with different mineralogy, and, 2) grain boundary healing (re-annealing), as occurs between halite-halite grains and studied in pure halites by Urai et al. (1986). It drives the ongoing annealing that then hinders further compaction. As the halite content in the mixture increases, more and more halite-halite grain contacts can heal and so act to resist compression. Volume loss by draining of pressure solution fluids becomes less efficient in such healed or partially healed contacts (Zubtsov et al., 2004). This is another illustration of pure salt's ability to act as an effective seal, it shows that even when faulted salt will quickly anneal itself, unless impurities can enter the fault plane.

When the creep and frictional strengths of wet and dry salt are compared with equivalent strengths of other sedimentary rocks, using a representative strain rate of 10^{-14} s^{-1} , it can be seen that even dry salt is much weaker than any overburden sediment, except perhaps for extremely shallow water-saturated muds less than a few hundred metres deep where water contents can be in excess 50% (Figure 6.5). Damp salt, which deforms by solution-transfer creep is hundreds of times weaker than dry salt, which deforms by dislocation creep, which the movement by slippage along lattice defects (Urai et al., 1986).

The minute quantities of brine caught up as inclusions and intergranular films in confined natural salt have a profound effect on strength. Damp salt does not even require external

water to act as a newtonian fluid (Urai et al., 1986). Water in a deforming salt unit need not come from an external source as its brine-filled inclusions contain sufficient water (up to 4-5% by volume) to allow salt to flow naturally at the earth surface conditions. In other words, salt can flow spontaneously by solution transfer creep, once extruded at the surface it will collapse or spread under its own weight (gravity collapse).

Deforming salt has almost no shear strength at most geological time scales of applied stress; it is a pseudo-fluid (Figure 6.5; Weijermars et al., 1993). The extreme weakness of natural wet salt at the surface is seen in seismic onlap patterns of allochthonous salt sheets deforming by gravity gliding in the Gulf of Mexico. The salt sills are emplaced into low density water-saturated shales at depths of less than 250-300m beneath the sediment-water interface, with a mean depth of 150m (Figure 6.6; Nelson and Fairchild, 1989; Nelson, 1991). Shales deeper than that were too strong to be laterally intruded by a salt sheet. Were density contrast rather than relative strength the controlling factor, then salt sheets would have spread out at depths \approx 1400 metres, which is the level of neutral buoyancy beneath this part of the Gulf of Mexico (Nelson, 1991). Salt weakness, or lack of strength, is thus more significant than buoyancy contrast in controlling the position of flowing allochthonous salt sheets in earth-space.

The weakness of salt at geologic strain rates means the viscous forces in flowing salt cannot easily drag or stretch the overburden. Rather, thick flow-susceptible salt sheets acts as a pressurized layer of lubricant that effectively decouples the overburden from the basement. A thick salt bed tends to act as a ductile "crack stopper" whereby it hinders faults and dykes propagating into higher or lower levels of the stratigraphy. A thick salt layer segments basin sediments into suprasalt and infrasalt layers that can deform independently or even by different processes. The impervious but fluid nature of salt focuses and entraps petroleum and mineralising fluids against a salt seal at the tops of subsalt faults, even if the faulting postdates the subsalt and suprasalt layers (Chapter 10).

Salt layers act as a lubricant in deforming sediment masses. The lubricious effects of salt layers are seen in the widths, taper angles, and internal structures of dynamic wedges at both converging and diverging plate boundaries. By lubricating regional décollements, even thin layers of salt influence how huge areas shorten or extend during gravity gliding. It leads to the complexities of raft tectonics, where rapidly opening ocean basins generate floundering blocks of brittle sediments (tens of kilometres across and kilometres thick) that glide down into the widening basin atop a layer of lubricating salt. For the same reason fold thrust belts in converging plate margins that are deforming over salt layers are much wider, with taper angles

Figure 6.5. Comparison of creep and frictional strength of dry salt with equivalent strengths of dry and wet sedimentary rocks and sediments (after Jackson and Vendeville, 1994). Creep strength is the deviatoric stress required to drive salt flow at a representative strain rate of 10^{-14} s^{-1} . Pore pressure coefficient (λ) is the ratio of pore pressure to lithostatic pressure: $\lambda=0$ for dry rocks, $\lambda=0.46$ for hydrostatically pressured rocks and $\lambda = 0.86$ for overpressured rocks. In contrast wet salt is so weak (strength of 0.01 MPa at this strain rate) that its creep curve plots virtually on the central axis.

Figure 6.6. Salt allochthon, northern Gulf of Mexico (after Nelson, 1991). Onlap of frontal reflectors above a thin roof, averaging only 100m thick (arrows on left hand edge of salt tongue), indicates shallow emplacement of the allochthonous salt tongue.

$<2^\circ$; while those deforming over more competent décollement layers are narrower, with taper angles nearing 8° (Davis and Engelder, 1987).

In reality, a simple division into brittle versus viscous fluid response models is an oversimplification as salt and the adjacent sediments can, depending on the circumstances, exhibit either brittle or viscous responses (Davison et al., 1996a; Poliakov et al., 1996). Salt at the surface is brittle enough to fault or shear, and such displacements are not uncommon in salt mines or in faults cutting across the surfaces of some dry salars of South America (Figure 3.47). Likewise the overburden can show evidence of viscous behaviour. Sediments atop allochthonous salt sheets in the Mexican fold ridges in the Gulf of Mexico are mostly folded not faulted. Seismic also shows many diapirs have sedimentary margins with smooth drag profiles known as shale sheaths, rather than brittle faulted margins adjacent to fluid salt.

Pressure effects

The realisation that density inversion is not the major force driving the onset of salt diapirism led to an improved understanding of the significance of pressure differences once salt flow has begun. Like all buried sediments, a salt source layer is pressurised by its own weight, along with that of the overburden, to create a pressure head (Ψ). The typical subsurface situation prior to diapirism is where a unit of pressured salt underlies a more competent sedimentary sequence. As hydrostatic fluid

pressures build within the accumulating overburden it fails, typically under extension. Failure is often activated by externally applied stress such as; continental slope/pull-apart, seismic triggering, gravity sliding, or the onset of inversion tectonics. Pressure is released in the overburden via brittle failure and pressurised salt flows in to take up the dilating space. As this occurs the fractured blocks of the more competent overburden simultaneously pull apart and sink into the rising salt.

Flowing salt moves laterally or is dragged into developing gaps, with a speed dependant on the relative rates of overburden sinking and extension, which in turn reflects on the fluidity of the salt. If overburden mostly sinks as blocks into a fluid salt layer, then salt filling the space between the blocks rises relative to the surface of the sinking overburden and so can spill and spread over the surface of the sinking overburden block (see allochthon discussion). However if the salt layer is relatively strong or if separation dominates, then the salt diapir may never rise very high at all and never spill and flow at the surface. If extension continues once the salt has risen to the maximum level dictated by the pressure field, then the salt diapir crest will collapse as the gap between adjacent overburden blocks increases. A graben will develop atop the salt crest, depositing sediments in the top levels of the dilating supra-diapir space (see discussion of falling diapirs).

Active piercing of a brittle sediment overburden can occur wherever the pressure head (Ψ) exerted by the fluid salt creates a buoyancy force that exceeds the strength of the overburden.

Figure 6.7 illustrates pressure head for three situations where the fluid salt layer is rising through its brittle overburden (Jackson and Vendeville, 1994). In all, any net upward force in the salt is resisted by the strength of the overburden roof, which depends on roof thickness. Thin roofs are weak and easily pierced, whereas thick roofs are too strong to be pierced by pressurised salt alone and require regional extension to be diapirically breached. The thickness of sediment that can maintain sufficient strength to hold back a buoyant (pressurised) salt bed defines the piercement threshold layer. If sediment thickness is less than the piercement threshold, then a salt diapir can actively pierce or shoulder aside its overburden (shown by the arrow in Figure 6.7a). Active piercement can occur where the floor of an erosional valley, or sag-focused erosion, thins the overburden layer to such a degree that the trough floor lies below the piercement threshold (Figure 6.7b). This is the mechanism driving salt diapirism in the Canyonlands National Monument, USA, with a diapir formed in a area thinned beyond the piercement threshold by the erosive activity of the Colorado River (Schulz-Ela and Walsh, 2002). Active piercement can also occur in situations where the suprasalt roof is thinned by extension, a commonplace feature in actively spreading rift systems (Figure 6.7c).

Jackson and Vendeville (1994) noted that, the taller or wider the salt ridge or plug, the more easily it pierces its overburden. Likewise, the thinner the roof, the more easily it is pierced. Structures with linear planforms (ridges or troughs) are more easily pierced than those with circular planforms (plugs or cavities). Pressure forces below a surface trough or cavity are set up by the density ratio between overburden and air or water (typical ratios around 2 or higher). Conversely, pressure forces above salt ridges or

plugs reflect the lower density ratio between overburden and salt, typically around 1.1 to 1.2.

Salt's fluidity and ability to reanneal make it a highly effective low permeability barrier to fluids escaping from the underlying

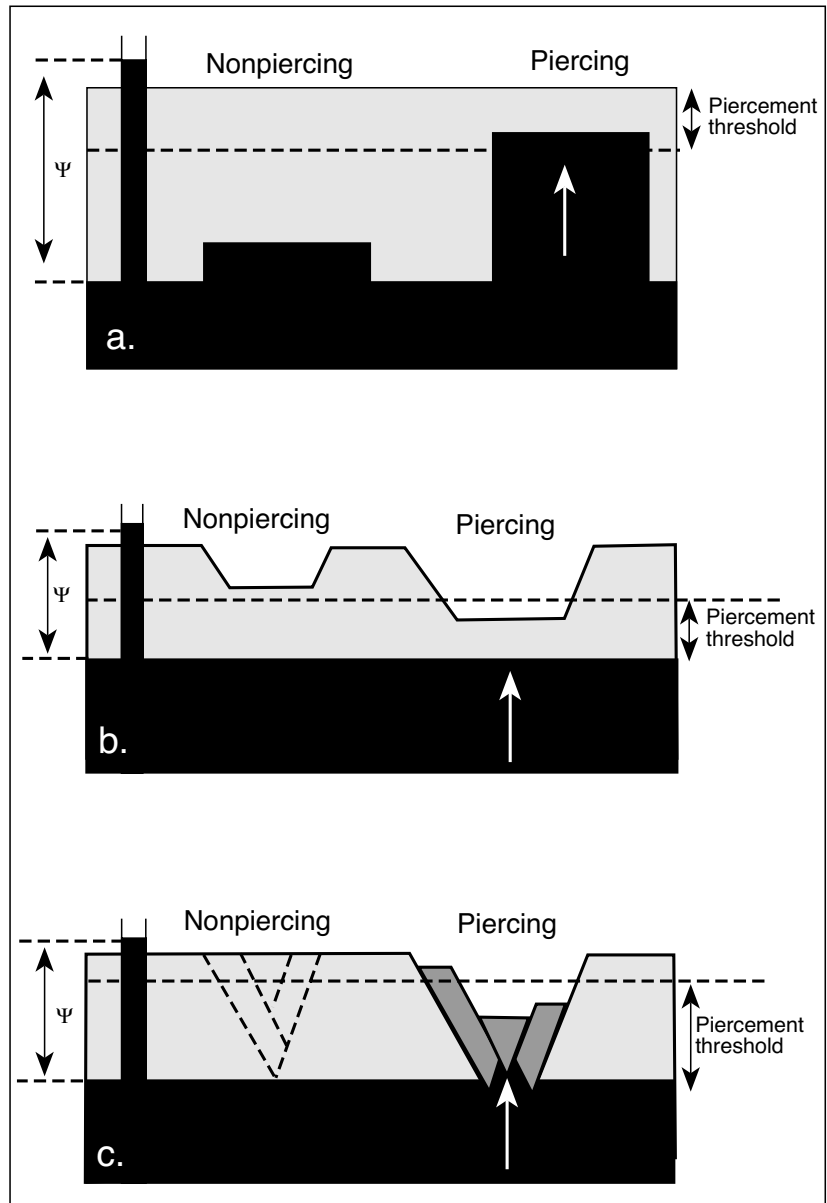

Figure 6.7. Conditions for active piercement of salt (black) overlain by rigid brittle overburden (grey). Where the overburden is thinner than the piercement threshold, the salt can break through (white arrows) under nonextensional conditions above salt ridges (a) or below topographic troughs (b). In (c) the non-stretched salt roof is too thick to permit diapirism but where it is thinned by extension to below the critical thickness a diapir can break through. Ψ is the pressure head of salt (after Jackson and Vendeville, 1994).

sediments. As sediment is deposited atop an impervious but fluid salt layer, pressure beneath it builds as it acts as a pressure blanket. A layer of salt in a subsiding basin exaggerates overpressures in the section beneath the salt and mitigates transfer of overpressure to the section overlying the salt. If there are no breaches in the salt layer this can result in a tremendous increase of overpressure across the lower salt boundary (Figure 8.14). Even thin salt sills can be highly efficient fluid seals. As a result, extremely overpressured sediments can be intersected immediately under a salt sill, creating a drilling hazard. Whenever or wherever a salt sheet is breached by salt dissolution or salt evacuation, a highly pressured pulse of subsalt fluids moves up through the breach. In many situations the sole of a growth fault marks the breach and the extending fault becomes a conduit for the escape of hot basinal fluids, along with their elevated metal contents (Warren, 2000b).

Thermal effects

In addition to pressure/strength interactions, variations in burial temperature gradients can also have an effect on salt flow. In terms of its thermal properties halite is an unusual mineral; as well as being one of the most thermally conductive sediments (at 43°C the thermal conductivity of halite is 5.13 W/m-K, while a typical shale at the same temperature is 1.76 W/m-K), its volumetrics also respond differentially to heating. At a depth of 5 km, under a geothermal gradient of 30°C/km, halite expands 2% due to heat and contracts 0.5% due to pressure (Jackson and Talbot, 1994). Under such a scenario (assuming zero porosity at either depth) the base of a thick salt unit becomes slightly less dense with the increased temperatures associated with burial and so creates a temperature-induced density inversion. Thermally induced convective flow is theoretically possible in a salt layer thicker than 2.9 km under a geothermal gradient of 30°C per km (assuming a viscosity of $<10^{16}$ Pa.s). This mechanism may trigger diapirism in salt-filled rifts characterised by elevated nearsurface temperatures and high geothermal gradients (Talbot, 1978). The volcano-shaped salt mounds associated with hot springs in Ethiopia's Danakil Depression may be located above the tops of thermally convecting plumes of salt, as may the diapiric features on Europa, a moon of Jupiter (Pappalardo and Barr, 2004) and the layered ice diapirs on Triton a moon of Neptune (Schenk and Jackson, 1993).

Gussow (1968) argued that outcropping Iranian salt glaciers were catastrophic extrusives emplaced hot, in a similar way to a lava flow. He thought that heated salt was intrusive and that the salt glaciers have now cooled and are no longer flowing. He was strongly influenced by early experimental work on disloca-

tion creep using coarse-grained dry salt that had indicated salt could only flow at temperatures above 200°C. We now know that most confined salt in the sedimentary realm is wet and capable of flow at earth surface temperatures (see above). Later work on the Iranian glaciers by Kent (1979, 1987) and Talbot (1979) indicated that the salt is still flowing today and that hot intrusion was not a major mechanism of salt emplacement in this or in other sedimentary basins. Temperature triggers, as first noted by Gussow (1968), do become an important consideration that can create intrusive sills and dykes once bedded salt enters greenschist facies conditions, as is perhaps seen in intrusive Neoproterozoic salt remnants in the thrust belt of the Damara Orogen in Namibia and in the Ugandan copper belt (Warren, 1999; Chapter 6 for discussion).

Flow textures and rates

Salt structures are zones where salt has thickened relative to its original stratigraphic thickness and by definition, salt must have flowed into this thickened structure. In salt pillows the sense of flow thickening is mainly horizontal, while in diapirs there is a much greater component of vertical flow. In Zechstein "pillows" the predominantly horizontal flow of halite is indicated by a gross morphology with a gentle nonpiercement style of thickening, but coring shows thickening of the salt structure was driven by stacked large scale flow-folds with near horizontal axial planes, as seen in the Anloo pillow in the Netherlands (Figure 6.8a; Geluk, 1998). In the late "pillow" stage, the flow direction changes from predominantly horizontal to an even less predictable system as the salt starts to pierce its overburden.

By the diapir stage the morphology of a salt structure shows that the sense of salt movement is predominantly vertical and that salt breaks through its cover. Diapiric salt is often mined, so its internal structures have been mapped. By this stage vertical fold axes (curtain folds) have been superimposed on the horizontal fold axes. Frictional interactions between the edges of the diapiric salt and adjacent strata drives even more complex fold patterns as flow vortices are created by irregularities in the thickness of the diapir neck. An analogy for this style flow folding is that created when a handkerchief is poked up and through a napkin ring. Once the salt is at the surface it spreads as a series of salt glaciers (namakiers) and allochthons rolling and advancing over the surrounding landscape, much in the same way as a military tank rolls forward on its track.

In many diapiric structures the central part of the salt neck contains salt from the older (lower) part of the salt stratig-

raphy and the margins are made up of younger units. This is true for the diapirs of Dasht-i-Kavir (Figure 6.8b) and many Zechstein diapirs such as Bente, Reidel, Winschoten and Zuidwending diapirs (Figure 6.9a). But, as noted by Geluk (1998), this is a generalisation for there are many Zechstein diapirs where the reverse is true (e.g. Gorleben, Hänigsen and Pieterburen diapirs).

Richter-Bernburg (1980) argues for high levels of structural complexity in all salt deposits and that even our expectations of internally consistent layering in a sequence of stratiform salt beds may not be true. He cites the Silurian Salina Salt in the Wiskey Mine near Cleveland in Michigan where apparent isoclinal folds with horizontal axial planes are exposed on a 3 m-tall mine face in an area of the Canadian Shield where typical formation dips are less than 5°. An underground visit in 1984 by Professor Bernburg and me to another nearby mine in the Salina Salt with similar features lead to a discussion of whether these features were actually isoclinal folds or stacked and backfilled syndepositional erosional channels. However, in other salt basins with structures showing external geometries of pillowing or diapirism, the complexity of the internal structures that form in halokinetic salt is indisputable (Balk, 1953; Talbot and Jackson, 1987a).

Internal complexity is especially obvious in Zechstein diapirs where potash layers have been mapped as part of the extraction and ore control process (Figure 6.9). Characteristic flow folding and shearing is outlined by halite beds swimming or floating in isoclinally-folded carnallite beds, as in diapirs in Miocene potash of Sicily and Poland and Zechstein of Germany. In all these examples, areas of high strain are largely accommodated by the least competent layer, typically potassium salt or purer finer-grained rock salt units (Figure 6.9b). Some halite layers between these high strain intervals can remain relatively undeformed and even retain remnants of primary fabrics, such as megapolygons and microkarst pits. As the structure

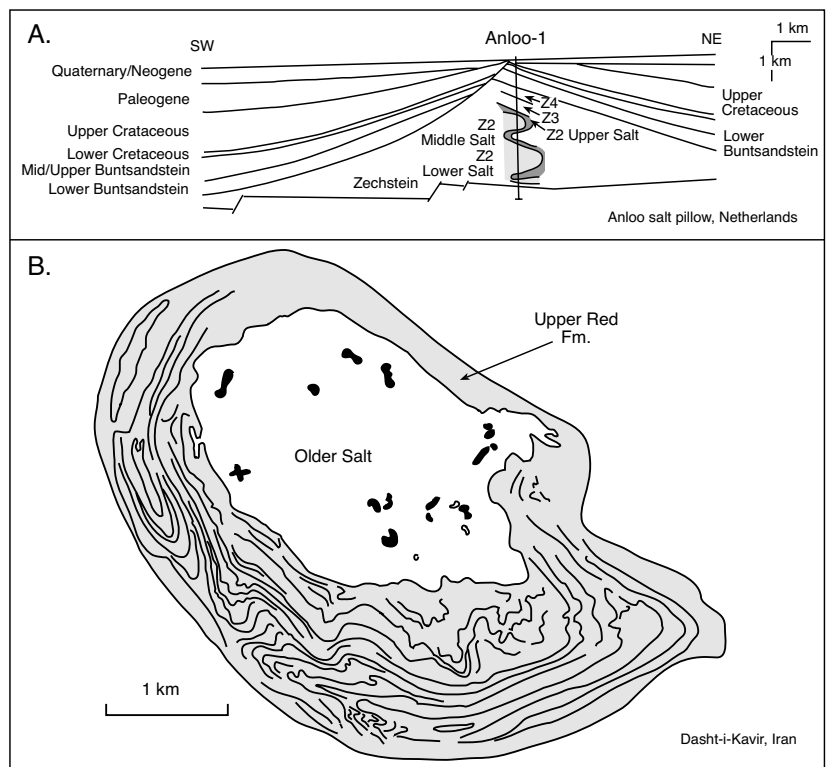

Figure 6.8. Internal fabrics of salt structures. A) Interpreted folded internal structure of the Anloo salt pillow (Permian Zechstein salt) based on regional seismic and fabrics observed in the Anloo-1 Well (after Geluk, 1998). B) Outcropping salt structure (Dome 20 in the Dasht-i-Kavir, Iran). Its central portion is made up of Older Salt (Eocene), which is composed of relatively pure halite. Surrounding this, and making up the outer part of the dome, is the Miocene Upper Red Formation, which entrains alternations of clay, anhydrite and halite. These layers clearly outline the complex folding styles that characterises salt flow (after Jackson et al., 1990 - see also Figure 3.62).

continues to deform these more competent layers also begin to brecciate or stretch into boudins. Finally, these halite layers pervasively recrystallise via pressure solution creep and no primary texture remains.

The internal complexity of salt structures is such that the near-surface portions of salt diapirs may be divided into a number of zones showing differential movement and separated by shear zones. This was first demonstrated by Balk (1953) in a classic paper mapping the internal complexities and shears in mined salt diapirs in the Gulf coast. Subsequent work by Kupfer (1976) on the same structures further refined notions of internal shear in diapirs. A shear forms where adjacent parts of a salt structure rise at different rates. This differential rise at the crest of a structure typically creates an active topographic high and a lack of thick caprock atop a rising spine, as is the case at Jefferson Island salt dome (Balk, 1953, Kupfer, 1976). The

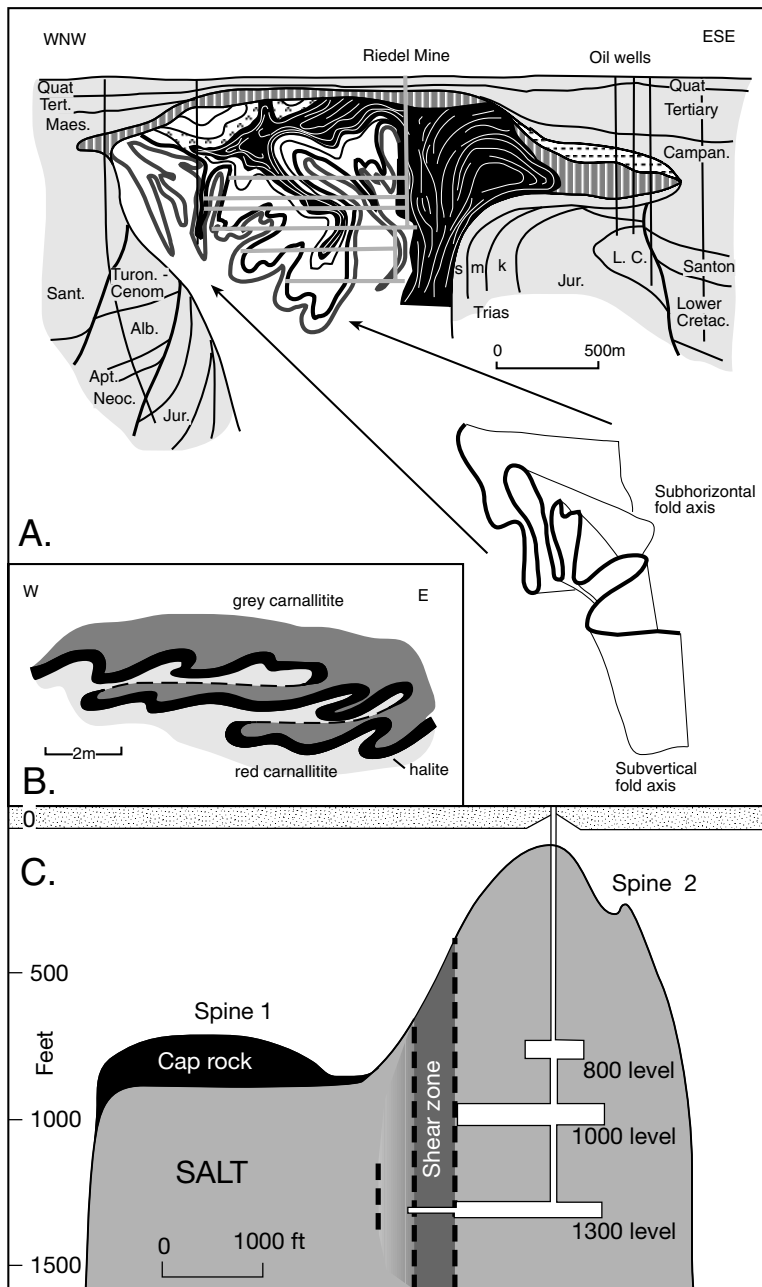

Figure 6.9. Internal structures of salt diapirs, A) Riedel diapir, Germany. The stratigraphically older part of the diapir (grey) of the structure sits atop the younger salt (white). Inset is a three dimensional diagram of the folds outlined by potash beds (ore horizon) in younger salt showing how axes of folds pass from a vertical orientation to a subhorizontal with depth. B) Halite bed (black) defines sheath folds and shear planes floating in deformed carnallitic matrix in a potassic ore zone in the Krügershall Mine near Halle/Saale, Germany (after Richter-Bernburg, 1980). C) Cross section through the Jefferson Island Salt dome, Louisiana, showing a wide boundary shear separating an active salt spine from a less active caprock-capped part of the structural crest. North is to the left and the 800, 1000 and 1300 ft working levels of the mine are shown (after Kupfer, 1976).

younger part of this salt stock is now 250 m (800 ft) higher than the adjacent flat-topped mass, which is also overlain by a cap rock (Figure 6.9c). The boundary separating the spine from the less active portion of the crest is finer-grained and shale rich and it formed a limit to the former salt mining of the pure salt within the spine. Shale-rich shear zones at the edges of active spines are sometimes called “black salt” by the miners and can show a greater propensity to leak water into a mine. The spine and its boundary shear are also seen in the Jefferson landscape, with a solution lake defining the zone of shallower salt created by the active spine. Shear zones within diapirs are potential problem zones if the crestal portions of domes are utilised for any type of fluid storage without an understanding of the significance of “black salt” (Figure 12.26).

In a benchmark paper on the internal complexity of salt structures in Europe Richter-Bernburg (1980) made a number of interesting observations:

- Salt deposits are not, or have not always been, in mechanical equilibrium with their ambient environment and deformations caused by salt flow have to be expected in all subsurface situations
- Isoclinal and overturned folds can occur in simple salt ridges so that stratigraphically older members of a formation can dip into the local area from above a particular horizon.
- By the diapir stage, possibilities are open for building folds of all imaginable - or even unimaginable - features and shapes (including migmatitic and boudinage styles). Axes of curtain folds in a diapir are not simply vertical, they may be inclined in all - mathematically! - possible directions.

He concludes that any prognosis about the interior structure of a halokinetic salt body -even if it is scarcely diapiric- is not possible without seeing it from the inside.

This mesoscale complexity reflects deformation textures that are occurring on the

microscale. As a salt crystal migrates in an actively flowing salt, it recrystallises via pressure solution creep. As it re-anneals, its outline stretches and deforms, leaving behind a strain memory of the stress regime in the various structures and crystal fabrics preserved in the diapir (Raymer and Kendall, 1998; Talbot, 1992a; Zak and Freund, 1980). Like many other crystalline rocks in structurally complex lithologies, such as migmatites and mylonites, the grains in flowing salt have such short strain memories that they rarely strain beyond length to width ratios of 4 or 5 before new crystals are created by the effects of pressure solution creep (Figure 6.10a). Hence, fine-scale grain-shape fabrics in confined flowing salt can record only the later stages of the strain history. Actual strains, resulting from superimposed deformations, are recorded by larger strain markers—primary layering or bedding, nodules, inclusions, and veins—all of which have much longer strain memories than individual halite crystals (Talbot and Jackson, 1987a,b).

Constant readjustments and recrystallisation to the variable stress field experienced during flow does indicate the ambient stress field in a diapir. Most halokinetic salt crystals have long axes that are a few cm long and are steeply inclined to subvertical within a salt stem or wall (Figure 6.10a). Between the elongate crystals are subgrain crystals with diameters that are a response to stress and can be approximated by an experimental power law equation noted by Carter et al., 1993 (see also Figure 6.3):

$$D(\mu\text{m}) = 214\sigma^{-1.15} \text{ (MPa)}$$

where D is the average subgrain size in microns and σ is differential stress in MPa.

A subgrain is a volume of crystalline material surrounded by subgrain walls composed of planar arrays of dislocations (Looft, 2000). The subgrain walls separate crystalline material of the same composition with slightly misoriented crystal lattices (usually less than 1°). Creep proceeds at stresses above a critical shear stress by glide and the multiplication of dislocations (Carter, 1976). Dislocations are linear defects in the crystal lattice that divide slipped regions in the crystal from unslipped regions, allowing localized slip to occur and spread consecutively. With increasing deformation, dislocation density increases and work hardening occurs as the dislocations tangle and interfere with each other, limiting mobility. Recovery occurs by the diffusion of vacancies that allow dislocations to climb normal to their slip planes to avoid obstacles, and form stable subgrain walls. Steady-state creep constitutes the bulk of the creep strain in naturally deformed deeper diapiric salt and occurs when the salt recovers at the same rate that it hardens,

Figure 6.10. Micro and macro scale flow texturing. A) Digitised outline of flow textured halite crystals in a thin section of diapiric salt, no primary texture remains. B) Schematic velocity fields in a flowing diapir derived from physical models. The deformed outlines of originally vertical markers are shown, as well as bed facing directions (after Davison et al., 1996a).

so that large creep strains can be achieved at constant stress and strain-rate (Carter, 1976; Carter et al., 1993).

A detailed analysis of subgrain size immediately below the two-spined crest of the Weeks Island salt dome in Louisiana found differential stresses vary from 0.87 to 2.33 MPa at the 1000 ft level (Figure 6.11; Looft, 2000). More actively moving salt is indicated by higher stress levels and smaller subgrains. Such textures are generally associated with areas of salt spine beneath regions of higher surface topographic relief and lows with zones of coarser-grained, recrystallized salt.

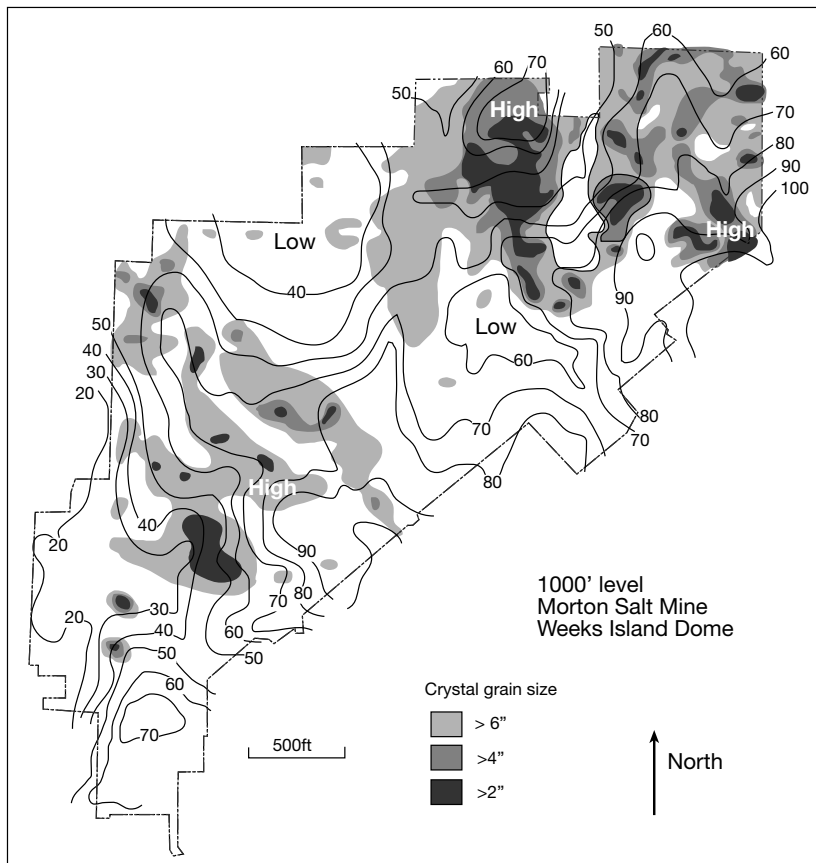

Figure 6.11. Comparison of the salt grain size in the 1000 ft level of the Morton Salt Mine, Weeks Island Louisiana, with surface topography over the mine. The finer-grained salt is generally associated with topographic high areas, while topographic depressions are associated with coarser-grained salt (after Loeff, 2000).

Detailed mapping of internal mesoscale strain markers along with modelling experiments have clearly shown internal flow in deforming salt away from shear zone is also not homogeneous (Kupfer, 1976; Zak and Freund, 1980; Burliga, 1996; Davison et al., 1996a; Sans et al., 1996a, b; Smith, 1996; Talbot and Alavi, 1996; Geluk, 1998). Foliations in deformed salt in a diapir are often axial to folds that develop in the primary layering and to the flow folds that map local gradients in flow rates along internal stream lines and surfaces in the moving salt (Figure 6.10b; Talbot, 1979, 1992b). If these layers approach mechanical passivity then the flowing viscous salt “fluid” picks up internal flow folds wherever the salt slows and thickens to pass obstructions. Beyond the obstruction the flow accelerates and internal folds tighten and almost disappear in the narrowing flow before they refold at the next obstruction. If the internal markers are strain active, the slow (competent) layers fold, while fast (incompetent) layers mullion as they shorten

within the slowing flow. Shears zones forming in a deforming salt body first grow in the least competent (usually potassic) horizons within the flowing salt mass. Between the shear zones, less deformed halite layers are carried laterally and upward into the diapir stem.

Davison et al. (1996a) show that fold wavelengths in Zechstein salt the North Sea (Figure 6.41) are of the order of 20–30 km in layers with an original thickness of more than one kilometre and an overburden that is now more than one kilometre thick. The spacing of the folds controls the amount of salt that drains into any particular structure. With a circular drainage envelope of 10 km radius a 1.5 km-thick salt layer can supply of the order of 470 km³ of salt to a single diapir. This is much greater than the volume of salt held in a typical North Sea diapir, which is around 25–75 km³. It means there has been substantial salt loss by allochthon escape and crestral dissolution. The rate of salt supply is not constant throughout the drainage area as the rate of radial flow increases closer to the diapir. According to Davison et al. (1996a) the constriction associated

with flow into the diapir neck creates strain within the neck up to 80 times greater than in the surrounding source layer. Thus, vertical flow in the centre of a diapiric neck produces extreme prolate strain textures that are in turn nullified at the top of the diapir where vertical flattening takes place via recrystallisation (Figure 6.10b).

Various combinations of pressure solution creep and dislocation creep create the deformed, aligned and recrystallised halite textures seen in cores recovered from salt flows (Figure 6.10a). Average halite grain size in cores from deformed recrystallised salt ranges between 5 and 10 mm in Zechstein salt in the North Sea and in Miocene salt in Mt Sedom in Israel and from 15 to 20 mm in Gulf Coast salt; all with L/S ratios typically greater than 1.5 (Davison et al., 1996a; Zak and Freund, 1980; Talbot and Jackson, 1987a).

Any interbedded sediment within the salt source layer strengthens a salt unit; it initially creates drag zones within the flowing salt, and so induces anisotropic strength and strain effects in the source layer as it moves toward the salt stem. This drag is often sufficient to generate small wavelength sheath folds. Once diapirism is more advanced, intrasalt beds (up to 40m thick) in the mother salt are brecciated or boudinaged. Salt can then flow across former intervening layers, carrying along fragmented and fractured layer remnants, with the whole region then behaving like a pure salt mass. Thus, once the system attains diapiric status, the strength and resistance to flow created by more competent intrasalt beds is drastically reduced by boudinage and breakup. Once the intrasalt beds are broken, diapiric salt can develop internal vortices like a billowing cloud of smoke, which trap, encapsulate and lift the fractured blocks of intrasalt beds. These fragments, usually dolomite anhydrite or dolerite, are referred to as “rafts” although they are not truly floating in the salt mass. Their density is typically higher than that of the salt. Rather, they are being swept upwards on a very slow rising plume. They can be porous and contain gas (including H₂S), oil or water and may create zones of unexpected overpressure when drilling salt. Once salt flow slows or ceases, blocks previously buoyed and caught up in the flowing salt mass of the diapir stem can sink back toward the base of the salt stem (Figure 8.15; Koyi, 2001). The style of intrasalt boudinage depends on the degree of induration of the entrained sedimentary layers. Where the sediments are well indurated the breakup of intrasalt beds tends to create angular clasts, where less consolidated the beds tend to stream, streak and flow plastically, like the adjacent salt. Boudinaged and aligned angular clasts and blocks are a substantial component in any later halokinetic dissolution breccia (Figures 7.22, 7.23).

Triggers, drivers and outcomes of salt flow

We have seen that density inversion does not bring about salt flow; so what is the trigger? From our preceding discussion we can state unequivocally that pure salt is extremely weak compared to its surrounds. Wet salt at the surface collapses under its own weight (gravity spreading) and so behaves like a Newtonian fluid across most geological time scales. In contrast any overlying or adjacent sediment responds brittlely to the same stress field. Salt structures in extensional basins that are accumulating sediment are triggered and driven by two main mechanisms; extension and differential loading. Both are derived from externally applied forces. Later in this chapter we

shall look at salt flow in relation to compressional forces, but we will now focus on extensional systems.

Salt flow can be triggered syndepositionally with the accumulation and gravity-driven extension of overburden or by an episode of regional extension long after bedded salt was first deposited and buried (Vendeville, 2005a,b). Syndepositional movement was the case with the numerous early allochthons and minibasins in the Jurassic of the northern Gulf of Mexico and the Cretaceous of Santos Basin of Brazil. Initial halokinetic-sediment feedback began in the Mesozoic, yet further out in both basins flow continues today as allochthons of Mesozoic salt are emplaced atop Neogene deep-sea floor sediment. Later flow, triggered by regional extension, was the case in the Zechstein salt (Late Permian) over much of the current North Sea; flow was mostly Mesozoic and did not begin until tens of millions of years after salt deposition had ceased. There was yet another episode of salt flow in the Zechstein salt in the North Sea. It took place in the late Mesozoic to Tertiary and was triggered by compression tied to the Alpine orogeny.

Studies of halokinesis conducted in the 1980s tended to place more significance on the triggering and driving effects of differential loading (Trusheim, 1960; Dailly, 1976; Seni and Jackson, 1983a,b; Jackson and Talbot, 1986, 1991; Worrall and Snelson, 1989; Nelson, 1991). Studies in the early 1990s tended to emphasise the role of regional extension (Duval et al., 1992; Vendeville and Jackson, 1992a,b; Demercian et al., 1993; Jackson and Vendeville, 1994). By the late 1990s, differential loading was physically modeled in the same way as extension had been and shown to be an equally valid mechanism for both triggering and driving salt flow in basins accumulating substantial volumes of sediment (Ge et al., 1997).

Now after more than two decades of detailed analysis of salt structuring in active halokinetic regions of the Gulf of Mexico, the Santos Basin and offshore West Africa, we know that both mechanisms can work concurrently from the first onset of salt flow. Waltham (1997) argued that apparent differences in triggers are two end members of a response continuum, depending in large part on the thickness of the salt and the rate of deformation (Figure 6.12).

Diapirs and extension

During regional extension diapirs can “pierce” the overburden in three related ways: reactively, actively and passively (Figure 6.13; Jackson et al., 1994 a, b). A reactive diapir pierces by filling the space created by divergence of faulted overburden

Figure 6.12. Shaded interval shows the overburden velocity field where drag (largely a brittle response in the overburden) dominates over buoyancy contrast as a trigger of salt flow (viscosity is 1×10^{18} Pa.s). The dashed curve shows the overburden velocity field at which drag dominates over buoyancy if the viscosity is 10 times higher (i.e. 1×10^{19} Pa.s). The crossline shows the salt thickness corresponding to an overburden velocity of 1 m/ka (after Waltham, 1997).

blocks. Reactive diapirism occurs during regional extension as salt approaches the surface beneath a subsiding graben in the thinned overburden. This surface graben is matched by development of an “inverse graben” at the underlying salt-sediment interface (isostatic balance). Salt fills the expanding space in the inverse graben and forms a reactive diapir that is triangular in cross section with flanking growth faults that become younger toward the diapir crest. If regional extension ceases before the onset of active diapirism, so does diapirism. Extension typically reflects a more regional set of tectonic processes such as gravity spreading or gliding of shelf and rise sediments in opening rifts. Diapiric salt at the reactive stage is not forcing aside overburden sediment, it merely reacts to regional stretching as it moves into space created by extension.

Extensional faulting is an effective mechanism for initiating diapirism in many situations, regardless of the prior overburden thickness, lithology or density (Figure 6.13; Vendeville and Jackson, 1992a, b). In such settings there is always a low ratio between salt pressure (Ψ) and brittle strength of the overburden. Reactive structures can be found either beneath newly-deposited thin overburden just starting to extend, or atop deeply buried salt beds in regions newly undergoing extension (Figure 6.7).

An active diapir, by definition, lifts and shoves aside its overburden. Unlike reactive diapirism, this style of salt emplacement must deal with a “room” problem. It requires forceful intrusion to remove the roof of sediment atop the salt. It is possible only if the overburden is relatively thin, whereby salt pressure exceeds

the brittle strength of the overburden (Figure 6.13). The roof must be thin enough for the pressure differential to lift it (Figure 6.7). For this to happen the roof is typically less than 20% of the entire thickness of the overburden flanking the diapir (Jackson et al., 1994b). However, once initiated, a diapir can actively pierce each new increment of sediment that buries it. Repetition of active piercement events sheds successive episodes of thin cover sediment into a debris belt around the growing diapir. Over time, an active diapir can pierce large cumulative thicknesses of sediment and create successive stacked unconformities about the diapir stem, which fade away with passage into areas above the withdrawal sink (rim syncline).

Each unconformity defines an episode of active piercement. Fractures formed during shedding of crestal sediment in active diapirism are extensional, often filled with infiltrated sediment and typically show little displacement of sedimentary layering on either side of the fracture (as is the case in fractured Lisan Fm. laminites atop actively flowing Sedom salt in the Dead Sea depression; Marco et al., 2002).

Once a diapir or salt wall emerges and flows onto the earth's surface it becomes a passive diapir, typically rimmed by salt allochthons; its edges spread and collapse under the weight of the extruded salt mass (Newtonian flow). A passive diapir crest maintains its position near the surface, while the adjacent sediment lows, along with the source salt layer they cover, subside. This is called downbuilding and rim syncline maintenance and was first documented by Barton (1933). A passive diapir cannot continue to rise without ongoing sedimentation to load areas adjacent to the at-surface salt, but the area of the salt mound can widen and if extension continues will ultimately subside (falling diapir stage). A thin skin of sediment can form atop the salt high but it is continually breached, pierced and fragmented. Its remnants are erosively shed from the diapir crest, or carried away “conveyor belt style” by divergent lateral flow of the underlying salt allochthon. Thus sediment does not accumulate atop the crest of a passive diapir and most adjustments in the thickness of accumulating sediment in the adjacent subsiding basin is a response to the evacuation or withdrawal of salt at deeper levels below the accumulating sediment pile.

A lack of vertical constraint to the rising salt at the passive stage means there is no “room” problem; flanking strata need not be rotated, faulted or pushed aside as they must be during active diapirism. Faulting and folding are negligible in the sediments adjacent to passive diapirs, apart from a narrow drag zone along the salt-sediment contact (Figure 6.13; Jackson et al., 1994a, b; Schultz-Ela, 2003). Once the source layer is depleted, the diapir ceases to grow and is buried by further sedimentation. Shapes of passive diapirs are primarily a function of the ratio of salt flow rates to sedimentation rates. When balanced, the diapir stem grows vertically; when sedimentation rate is relatively slow, the salt leaks out over its surrounds to give flanges to the diapir and a more mushroom-like allochthonous aspect.

The sequence reactive --> active --> passive can be altered by changes in rates of extension, depletion of the source layer or changes in sedimentation rate, and so various evolutionary paths are possible (Jackson et al., 1994a):

- Although a diapir may appear to be initiated passively it most likely was reactive or active during its earliest stages. If the overburden was thin and unevenly deposited the reactive and active stages are very brief, and the strata faulted during these very early stages can be too thin to be resolved seismically.
- A diapir that appears to have been passive may have passed through numerous cycles. Each cycle could have comprised an episode of passive growth during slow sedimentation, followed by burial during a period of rapid sedimentation and be terminated by a brief active salt breakout. Each active stage removes the overburden roof by doming, local

extension, entrainment, slumping, dissolution collapse and the creation of local unconformities.

- An active diapir can partially break through its roof, but never emerge, as: 1) the salt source layer may become depleted, 2) the salt source may be channelled off (pirated) by an emergent segment of an adjacent salt wall, or 3) without erosion or differential loading an active diapir only partially penetrates all but the thinnest roofs before reaching equilibrium (Schultz-Ela et al., 1993).

If a passive pluglike stock is later stretched during ongoing regional extension, the adjacent country rocks may also stretch, creating normal faults next to the diapir. But more typically the stretching is taken up in the much weaker salt body, so that passive elongated salt walls under extension are widened via ductile flow of salt. The much stronger flanking overburden may remain grossly intact and virtually devoid of normal faults at the scale of seismic resolution. An apparent absence of normal faults in sediments adjacent to a passive diapir wall means that even large amounts of regional extension may remain hidden within the expanding and deforming salt wall. This cryptic extension can be inferred by accurate reconstruction of cross sections backward in time. But this process is far from straightforward and requires additional constraints, such as independent data on the original length of the section or original thickness of salt (Schultz-Ela, 1992).

Diapirism and differential loading

In a series of scaled physical models Ge et al. (1997) demonstrated the importance of progradation as a trigger for salt

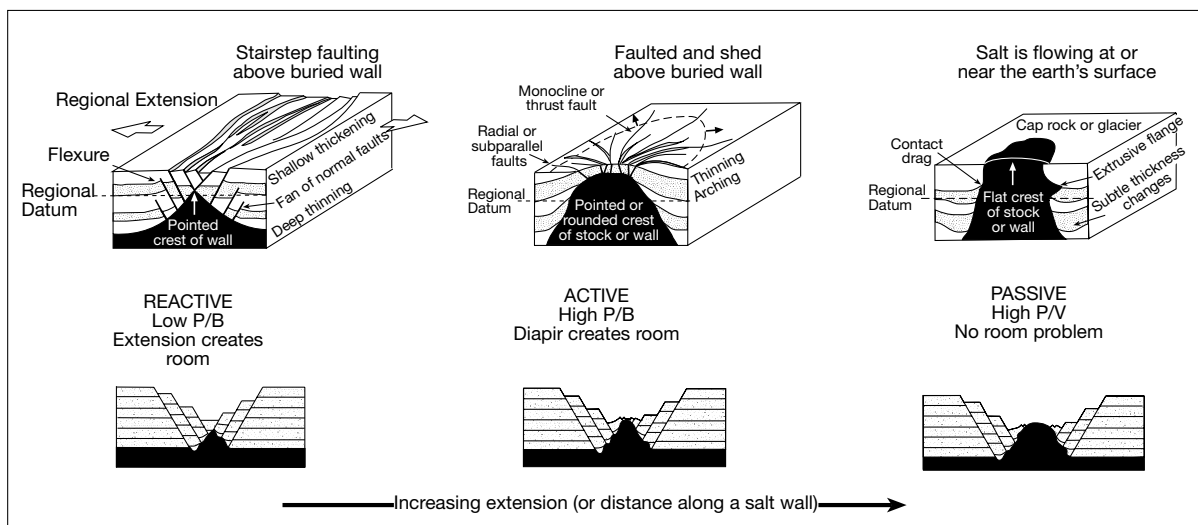

Figure 6.13. Three piercement modes for diapirs (salt is black) and their characteristic structures. Regional datum (dashed line) is the base of the stippled layer. P, V and B refer to stresses due to salt pressure, salt viscosity and overburden brittle strength, respectively. Extension is accommodated by both graben-related faulting and diapir widening (in part after Vendeville and Jackson, 1992a; Jackson et al., 1994a).

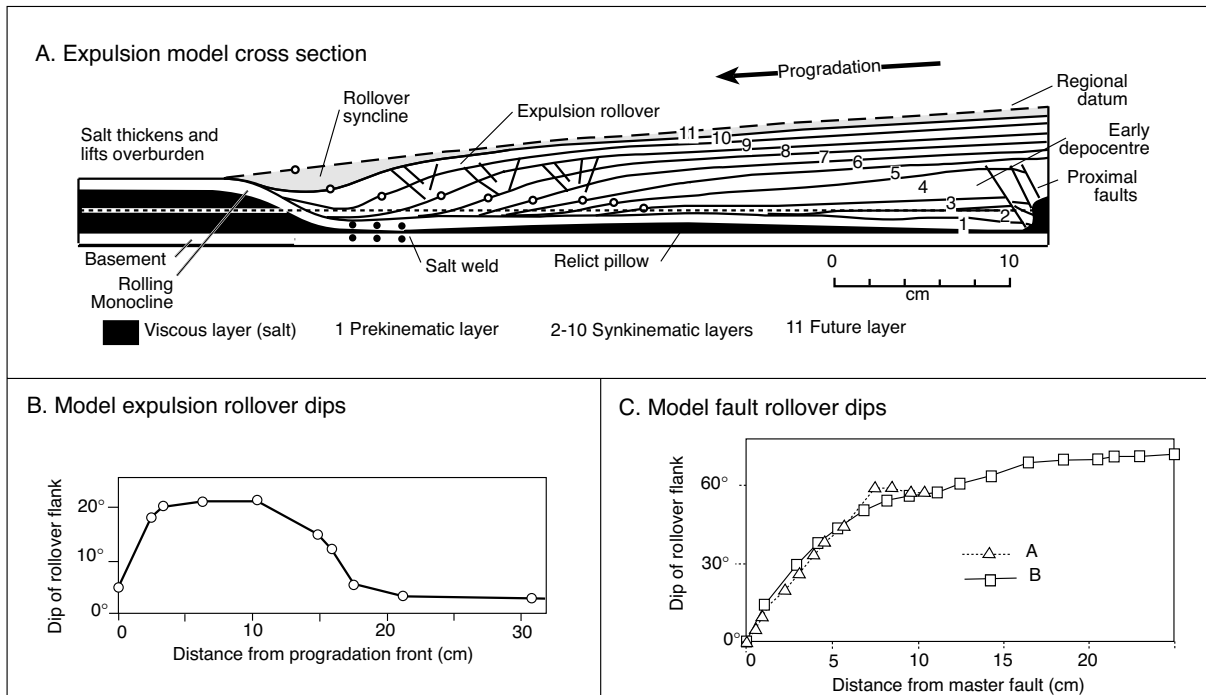

Figure 6.14. Expulsion rolover characteristics. A) Regional cross section with rolling monocline, rolover syncline, and expulsion rolover all migrating basinward with the basinward progression of the progradation front. Dashed horizontal line represents the top on an initially tabular salt body. Open black circles show positions of data points plotted in Figure 6.14b. B) Rollover plots of maximum dip associated with model illustrated in 6.14a. C) Rollover plot of model experiments: result A is from experiment model 188 listed in Ge et al. (1997), result B is from experiment E30 in McClay (1990) (modified from Ge et al., 1997).

tectonics and formation of allochthonous sheets. They considered two end members. One group of experiments modeled salt with an underlying flat top to the basament (Figure 6.14), while another group considered a basament with a stepped top, as would occur in a block faulted basament terrain (Figure 6.15). Regional extension and contraction were excluded in their models.

The prograding wedges above a tabular, buoyant salt layer that was underlain by a flat basament top, expelled the salt basinward in a predictable sequence of structures. From proximal to distal they were: a) sigmoidally distorted initially planar wedges, b) relict salt pillows and salt welds, c) basinward-dipping expulsion rolover and crestal graben, d) rolover syncline, e) landward-facing salt-cored monocline, and f) distal inflated salt layer (Figure 6.14a). This deformation zone amplified and advanced basinward together with the prograding sediment front. Complete evacuation of the salt left a basin-propagating salt weld below the prograding sediment wedge; incomplete evacuation left salt pillows as residual highs, but no diapiric salt structures were formed.

In contrast, progradation over a buoyant salt layer that was underlain by landward-facing basament steps or fault escarpments (Figure 6.15a), initially formed a broad anticline where the salt flow was focused across each basament step (Figure 6.15b). Early on, differential loading by the prograding wedge expelled the salt basinward in an identical fashion to that which occurs in a basin with no basament steps. Then the lateral escape of the salt was altered as it was slowed across the friction point created by the basament step. The salt backed up to form a broad asymmetric salt-cored anticline. Distal aggradation continued to pin the anticline and enhance differential loading. Next the anticline actively pierced its crest, which in the real world may have been thinned by faulting and erosion (Figure 6.15c). Thereafter the diapir grew passively, locally sourcing allochthonous salt sheets. This deformation cycle repeated over each basament step so that the age, amplitude, complexity and maturity of salt-related structures decreased basinward (Figure 6.15d-f).

As each allochthonous salt sheet was buried and evacuated by sediment loading, arcuate peripheral normal faults formed along the sheet's trailing edge, detached wrench faults formed

along its lateral edges, and active piercement at its leading edge allowed the sheet to break out and climb stratigraphic levels. This process formed a multi-tiered complex of salt sheets that migrated basinward with time. Ge et al.'s (1997) modelling clearly shows that immense landward-dipping (counter-regional) pseudofaults can arise entirely by salt expulsion rather than regional extension. Their physical model clearly shows that progradation alone can generate salt anticlines that mature into salt walls, stocks, glaciers or linked, multi-tiered complexes

of evacuated sheets and salt welds. The prograding sediment wedge expels salt basinward regardless of density relationships. In such situations there is a relationship between underlying basement discontinuities and the location of salt diapirs and allochthons. A result that is not obvious in purely extensional regimes where the zones of diapirism tend to begin in zones of overburden thinning that can bear no relationship to subsalt discontinuities.

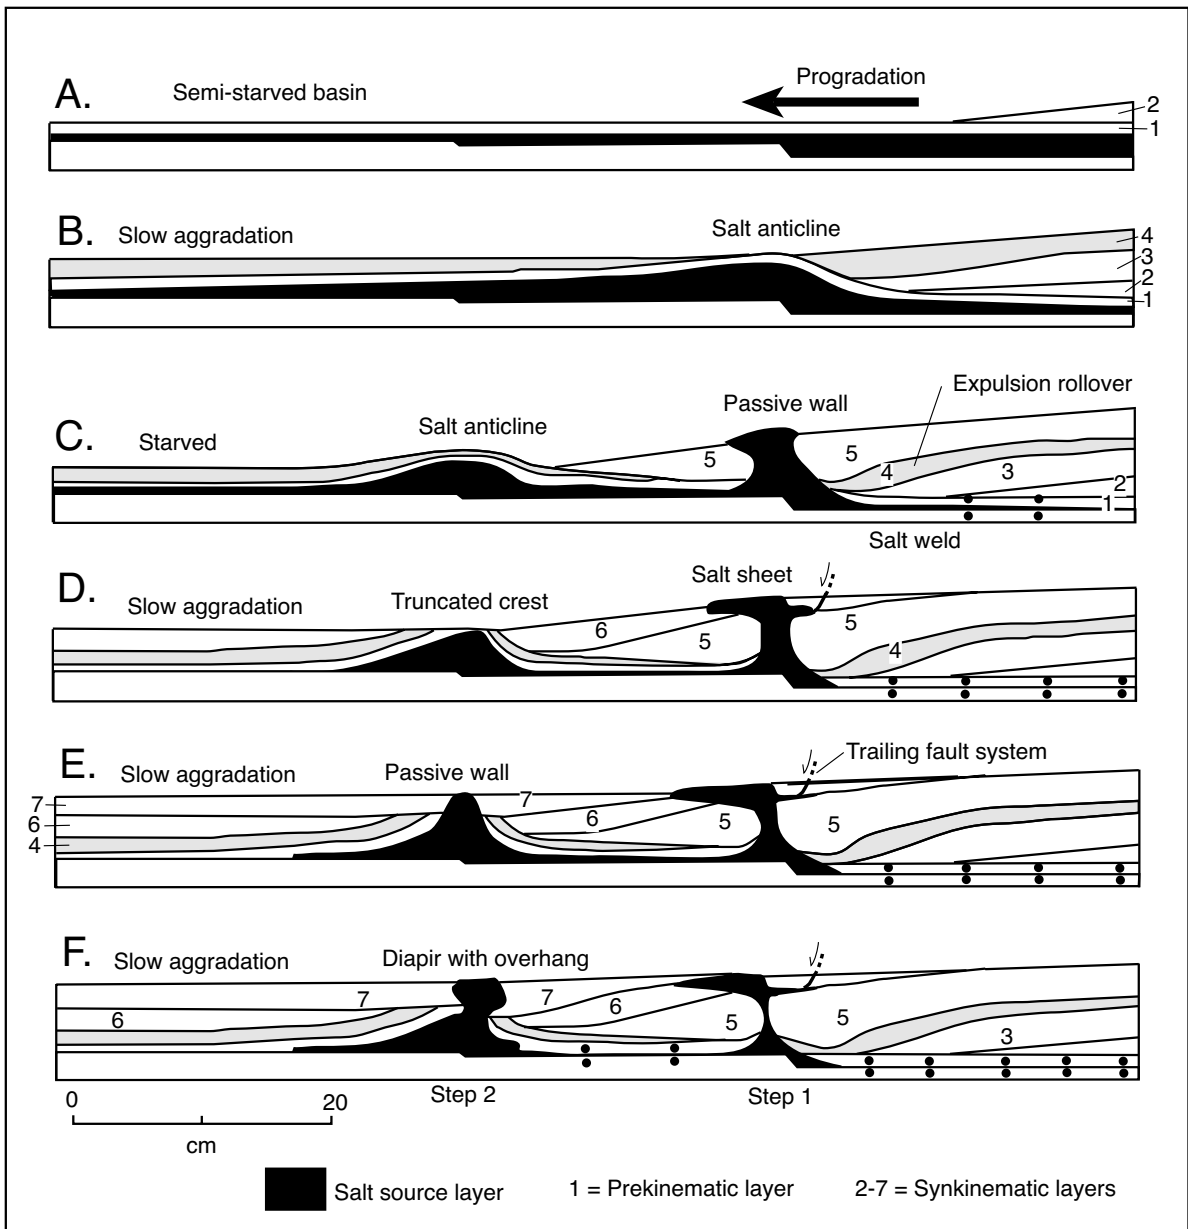

Figure 6.15. Evolution of salt structures during progradation atop a salt basin that is underlain by a stepped basement (modified from Ge et al., 1997).

Salt flows under both regional extension and progradation. Both are typically present and interacting in a sedimentary basin where extension drives the subsidence that in turn creates accommodation space, which is then filled by sediment. Extension is probably the dominant mechanism for triggering diapirism in deeply buried salt bodies, while progradation is a commonplace driving mechanism whenever salt is near the surface. Salt's propensity to flow means that diapirs, initially formed by early progradation of a wedge of continental shelf or platform sediment, can be later reactivated or overprinted during extensional or compressional regimes.

This leads to an obvious problem in distinguishing between expulsion rollover generated by progradation and a fault rollover in the hanging wall of a listric growth fault generated during extension. Ge et al. (1997) clearly show how dip analysis of the rollover plot can be used to help differentiate the two styles (Figure 6.14b, c). They plot the maximum dip of each sediment wedge in the expulsion rollover (open circles in 6.14a, b) versus distance from the present progradation front. Maximum dip was measured on the basinward-dipping flank in the rollover syncline. The rollover plot is shaped like an asymmetric hill with dips increasing rapidly away from the front to a maximum and then decreasing less rapidly. The maximum dip corresponds to where the thickest salt was expelled. The oldest wedges preserved the initial depositional slope (5° in modeled system) and planar shapes, even though they were folded and then unfolded by the passage of the structural monocline that rolled through them as the salt evacuation front passed by. The plot of a fault rollover in the hanging wall of a simple listric fault is quite different and shows no decrease in dip away from the present progradation front (Figure 6.14c). Dips of the hanging wall cut off abruptly and then gradually increase to reach a maximum value away from the surface trace of the listric fault. The constant maximum dip away from the fault corresponds to flattening of the underlying fault. This type of analysis can only be carried out on synkinematic strata, which are distinguished from prekinematic strata as they show local lateral variations in thickness. If a listric fault has multiple flats and ramps, the prekinematic strata generate a tail of data points that are not diagnostic and should not be used. See Ge et al. (1997) for a full explanation of this methodology and its application.

More recent publications subdivide the effects of sediment loading on salt flow into 1) systems with linear progradation fronts moving out over a salt mass (Vendeville, 2005) versus, 2) more lobate styles of sediment loading (Gauillier and Vendeville,

2005). The former are appropriate to linearly-loaded continental margins, as along much of the Atlantic slope-and-rise of South America and the Gulf of Mexico, while the latter models are more appropriate to lobate loaded margins, such as the Gulf of Lions and the Nile Cone.

Sedimentation rate controls diapir shape

The interaction of upwelling salt and accumulating sediment on the diapir's flanks controls the geometry of a passive or downbuilding diapir. If the rate of salt rise is less than the sediment accumulation rate, then a passive diapir narrows upward as onlapping sediments encroach onto the diapir ($R/A < 1$; Figure 6.16a, b). When a large volume of salt is supplied to the growing structure, the diapir rises faster than the surrounding sediment can aggrade. The resulting laterally unsupported salt ridge repeatedly overflows its unsupported margins, thus creating a salt tongue that widens upward over time ($R/A > 1$; Figure 6.16a, b). Eventually, all diapirs are buried by the slowing and eventual cessation of the salt supply. This typically happens once the mother salt (source layer) is thinned or depleted by salt withdrawal and overburden touchdown.

The gross flow rate of salt in passive diapirs reflects the balance between driving forces, retarding forces and salt supply (Jackson et al., 1994a). Any changes in sedimentation rate versus rate of salt supply controls the overall planform (at-surface shape) of a passive diapir. Within a single ovoid or elongate salt structure a diapir's rate of salt flux increases with increasing width. At the diapir's widest part, salt flow rates are high relative to sedimentation rates. Conversely, contact drag at the structure's extremities affects the narrower ends of an elliptical diapir more than at its wider parts. This slows the rate of rise at either end so creating relatively high aggradation rates. Thus salt spreads at the widest part of a diapir and retreats from its elliptical ends. Accordingly, an originally elongate salt wall evolves toward a string of pluglike passive stocks rising from the deeply buried reactive salt ridge. The number of exposed plugs atop a wall declines as they exhaust their salt supply and become buried.

If, during extension, the sedimentation rate is high compared to the rate of regional extension, a reactive diapir evolves into a squat deeply buried salt roller bounded by a listric (upward steepening) fault. Conversely, if the sedimentation rate is low compared to the rate of regional extension, a reactive diapiric ridge evolves into a tall salt wall or a number of adjacent salt

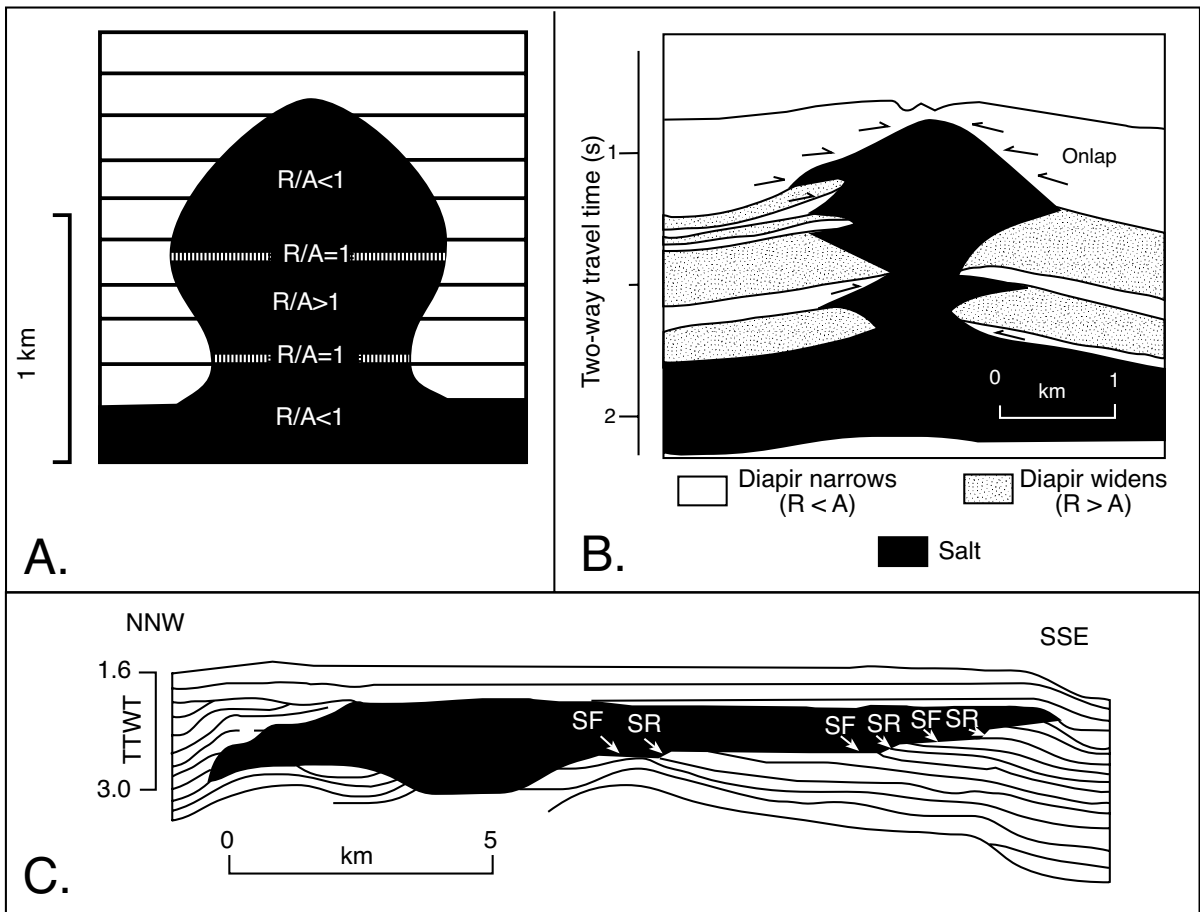

Figure 6.16. Passive diapirs with extrusive flanges onlapped by overburden. A) The shape of a diapir is controlled by the ratio of net diapiric rise R (incorporating the effects of dissolution), to aggradation rate (vertical accumulation of sediment). B) A typical North Sea Diapir with allochthonous salt wings (after Jenyon, 1986). C) The stepped base of Mica (aka Mitchell dome) Garden Banks, offshore Louisiana, shows it was emplaced as an allochthon not a sill; high R/A causes salt flats (SF), low R/A causes salt ramps (SR) (after Vendeville and Jackson, 1993).

plugs that show steep or overhanging discordant contacts and shallowly buried crests (Vendeville and Jackson, 1992a). Likewise sedimentation rate also controls the form of advance of an allochthonous salt sheet (Figure 6.16c). Salt flats indicate times of low sedimentation, while salt ramps indicate higher rates of sedimentation. Salt ramps are the remnants of an allochthon which was an active glacier moving across the seafloor. When the salt is completely evacuated the former ramp becomes a salt weld. Observation in seismic lines collected in the late 1980s across buried salt allochthons of the Gulf of Mexico showed a stepped base of salt (ramps and flats), rather than the older flat or planform interpretations. It changed the notion of salt allochthon emplacement from that of a salt sill injected into marine muds a few hundred metres or more below the seafloor into one of salt glaciers marching out over the seafloor.

As a salt glacier is extruded onto the seafloor it can flow in any direction, depending on the local slope (gravity spreading); it can even flow landward into the depression atop an adjoining rollover syncline (rim syncline). Over time the breakout sites, where the salt climbs the section and breaches to the surface, will ultimately shift basinward as salt is squeezed by the prograding basin fill (Figure 6.15). Regionally, the depocentre of active diapirism in the Gulf of Mexico has been shifting basinward since the Jurassic when the mother salt bed, the Louann Salt, first breached the surface. As each newly emplaced salt sheet is loaded by the prograding sediment pile, it carries its overburden basinward by gravity spreading. Thus, while a sheet evacuates into a new stratigraphic level it also generates halokinetic profiles atop it.

Extension, falling diapirs and turtles

Salt-lubricated extension can initiate and maintain diapirism throughout the reactive, active and passive stages. While connected to an adequate salt supply, passive diapirs can widen between separating blocks of overburden while still maintaining their crest at or near the surface (Vendeville and Jackson, 1992b). That is, once it attains its maximum height, a reactive/passive diapir can continue to widen by viscous flow. Salt inflow fills an ever-widening gap between the faulted extending blocks of overburden that are gliding apart on the salt source layer (Figure 6.17a, b). Eventually the salt supply becomes restricted and ultimately depleted so that the diapir crest sags or falls into a characteristic two-horned profile, even as the diapir body continues to widen (Figure 6.17c).

Turtle-structure anticlines, with crestal keystone grabens, form adjacent to falling diapirs and are another response to source-layer depletion. Historically, these anticlines were attributed to the evolution of a salt pillow as it contracted into a diapir (see Warren 1989 for discussion), but it is now known that they form during the falling diapir stage in an extending basin (Figure 6.17c-e). Once the salt supply to a diapir is restricted, more and more salt from the surrounds is withdrawn into the falling diapir (Figure 6.17c). As this occurs the region of overburden touchdown forms and then widens beneath the rim syncline sediments. Over time, the ongoing widening of this zone of salt withdrawal and touchdown causes the sediments of the rim syncline to invert into a turtle structure anticline, often with a keystone graben in the anticlinal crest (Figure 6.17d). The touchdown and inversion of the rim syncline sediment pile can create a topographic high on the seafloor. Sediments deposited atop the anticlinal crest may be higher energy sands and carbonate buildups, as has occurred in the reefal carbonate reservoirs that characterise buildups in the James Limestone in the Gulf of Mexico (Figure 10.46). Such positionally enhanced potential reservoir intervals can be thought of as self-reservoiring, self-closing and self-draining.

As the diapir crest continues to sag, the crest inverts from a topographic bulge into a subsiding depotrough or graben, which is rapidly filled with sediment. This creates a sediment thick atop the diapir (Figure 6.17c). Slippage along the bounding faults of this deepening graben continues, but no new faults generally form within the graben. Such a crestal graben lacks the stair-step faults that characterise the smaller and shallower crestal graben of a reactive diapir. Adjoining the indentation are hornlike cusps of salt below each bounding fault of the graben.

If extension continues after all salt supply to a passive stage diapir is cutoff, overburden touchdown occurs in the position of the former passive diapir. The falling diapir overburden segments into two flanking triangular relics flanked by glide blocks composed of older overburden (Figure 6.17e). The diapiric relics are now separated by deep, wide depocentres filled with younger sediments. If extension continues, the flanks of these diapiric relics subside until they too touchdown. Thus, ongoing extension and salt depletion causes even the young depocentre to subside until it too eventually inverts into a crestally faulted arch, called a mock-turtle anticline.

But what about the third dimension along the strike of a salt wall or diapir crest? In many diapiric settings, such as the North Sea and the Gulf of Mexico, salt walls can pass along strike from a section of the wall at the passive stage to a falling section of the wall marked by a thickening crestal graben. In other words, stages a-e in Figure 6.17 and a-d in Figure 6.18, can occur along strike within a single salt wall (joined by dashed lines in figures). Where subsidence is accommodating regional extension, salt tends to move into the rising (reactive-passive) sections of the wall and away from subsiding depressions below the crestal grabens. As salt flows into the intervening culminations along the wall they evolve into increasingly pluglike, rounded diapirs. If extension continues, these rising diapirs, which are commonly emergent, continue to widen and accommodate the regional extension without faulting. With sufficient extension, these diapirs ultimately exhaust their salt supply so that they too must subside and also become buried.

Prior to the work of Vendeville and Jackson (1992b) on falling diapirs, many of the crestal structures produced by diapir fall were attributed to salt dissolution or forceful active intrusion at the crest; all three possibilities should be evaluated in any areas of crestal grabens or remnant salt cusps/rollers. A long-standing bias toward salt dissolution causing crestal grabens is partly because criteria for interpreting the origin of crestal grabens are usually neither clearly stated nor consistently applied.

Falling diapirs and raft tectonics

In some areas of falling diapirs the overburden becomes stretched to two or three times its original length by normal faulting, but the sub-salt basement is not involved. This prodigious extension of the overburden over a non-deforming basement is enabled by a weak intervening ductile layer or décollement of salt. This style of overburden deformation is called raft tectonics and defines

an extreme form of thin-skinned^{6.2} extension or gravity sliding where rigid sediment blocks slip downslope atop a décollement layer of evaporite or shale (Spathopoulos, 1996; Cramez and Jackson, 2000; Fort et al., 2004). Raft tectonics characterises areas of large-scale extension where the hanging wall of an extensional salt-soled fault separates completely from the footwall, creating a fault weld via coherent slippage along the salt detachment surface (Figure 6.18a; Duval et al., 1992). In other words these rafts are allochthonous fault-defined overburden blocks that have slipped down-dip to become so far apart they are no longer in mutual contact across the growing fault that once separated them. Rafts characterise extensional geometries beneath the modern shelf and rise of Brazil in South America, Angola in central West Africa and the Gulf of Mexico (Figure 6.18a; Anderson et al., 2000). Similar large rafts characterise blocks of Zechstein sediment in the NW Permian Basin of the North Sea (Clark et al., 1998). In this case, the blocks of sediment are composed of platform anhydrite, which slid into the basin atop a halite lubricated sole.

With less extension the fault blocks are called pre-rafts as they remain in mutual contact across the fault and parts of the hanging wall still rests on its original footwall. Rafting movement produces listric faults and sediment-filled grabens atop a deflating salt mass. These sediment-filled grabens can be substantial structures; the Quenguela Graben in the Kwanza Basin measures 20 km wide and 90 km long, the nearby Gaivota Graben is 15-20 km wide and 225 km long (Figure 6.18b; Cramez and Jackson 2000).

With initial extension between two overburden blocks, a salt wall first rises passively to fill the increasing gap (Figure

Figure 6.17. Rise and fall of diapirs during synkinematic sedimentation and extension. The dashed line implies the various stages are not necessarily separate in time, but can be found along a single salt wall (after Vendeville and Jackson, 1992b).

6.18b; time 1). Once the supply of salt can no longer keep up with demand, the diapir starts to fall. The crest of the sagging diapir becomes a subsiding trough that fills rapidly with sediment (Figure 6.18b - time 3). While stretching and décollement are active the thickness of the evaporite layer is reduced both by downslope gravity drainage of the salt and ongoing dissolution. Once most of the salt is removed from under the sliding blocks, they ground or weld on the presalt layers and the downslope movement of the blocks stop (Figure 6.18b - time 4). Stretching or extension that drives raft tectonics can usually be attributed to gravity gliding. Gravity gliding is the translation of fault blocks down a gentle slope, driven by the downslope shear stress component of gravity on a tilted mass atop a mobile layer.

Regionally, salt basins characterised by raft tectonics can usually be divided into two different stress regimes (Figure 6.34a; Spathopoulos, 1996; Cramez and Jackson, 2000): an updip

^{6.2}Thin-skin tectonics describes a situation where most of the deformation occurs in sediments above a regional décollement and structures in the basement below the décollement are different to those above. Sometimes called a "no basement" structural interpretation.

Figure 6.18. Raft Tectonics, Angola. A) NE-SW section through the Block 4 region of the Lower Congo Basin (Anderson et al., 2000). West-dipping listric faults affect the late Cretaceous sediments in the east of the block. Further west, Miocene extensional faults and associated grabens separate an isolated Cretaceous fault block (raft) from the equivalent Cretaceous sediments on the shelf. A similar structural style, characterised by thin-skinned faults, exists to the west but with relatively simple Cretaceous roll-over anticlines. Each of these isolated fault blocks is separated from neighbouring fault blocks by Miocene grabens (Eastern and Western grabens). The Miocene faults flatten downwards onto a salt detachment in the Loeme Formation. B) Restoration model of a falling diapir in the zone of raft tectonics of the Kwanza Basin, Angola (after Schultz-Ela, 1992 and based on a seismic line in Duval et al., 1992).

extensional regime located under the shelf and upper slope where salt décollement has facilitated the breakup of overlying sediments into raft blocks, and a downdip compressional or contractional regime typically under the lower continental slope where the up dip extension is taken up in a fold or thrust province. Raft tectonics requires the creation of substantial lateral space into which the overburden can expand during stretching. Downdip space is generated by: 1) formation of a downdip fold or thrust belt, 2) down dip displacement of autochthonous salt into allochthonous salt sheets that climb the stratigraphy, and 3) generation of new oceanic crust by a spreading ridge with allochthonous salt allowing overlying blocks to slide (Duval et al., 1992). This downdip compressional terrain is discussed in more detail later in the chapter.

Salt allochthons (salt breakout)

Allochthonous salt sheets are flowing salt masses that have been moved by low temperature tectonic processes so that the front edge of the salt flow overlies younger strata and it is typically

no longer connected with the mother salt bed. Allochthons have areas measured in hundreds of square kilometres and thicknesses ranging up to several kilometres. They typically indicate into-the-basin translation of the salt mass and its overburden. When actively inflating with salt they lie at or very near the surface (Figure 6.19). Some authors draw a distinction between an allochthon and a namakier (salt glacier; *namak* is Farsi for salt), using namakier to describe the structure created by the extrusion of allochthonous salt at the surface. Others use the terms salt allochthon and namakier interchangeably.

In contrast to an allochthon, an autochthonous salt structure extends continuously down to the primary source layer and may not have experienced substantial lateral translation (Rowan et al., 1999). Allochthonous salt sheets characterise the present day continental margins of offshore Brazil, the Gulf of Mexico, West Africa, the North Sea and the Red Sea and outcrop as namakiers or their remnants in Iran, Algeria, Yemen, Mexico and Australia (Figure 6.19). Their recognition in the last two decades as potential traps in deepwater petroleum provinces

has opened up possibilities of prodigious subsalt hydrocarbon reservoirs, particularly in continental slope and rise sediments in the various circum-Atlantic salt basins (Chapter 10).

Proposed emplacement mechanisms for salt allochthons include: recumbent folding, deep intrusion, shallow intrusion and surface extrusion (Figure 6.19; Schultz-Ela and Jackson, 1996). In all categories, a massive basinward flow of salt is a major part of the emplacement process in both subaerial and submarine settings. Ewing and Antoine (1966) envisaged the allochthonous Sigsbee Scarp was the basinward flowing edge of an autochthonous diapir (Figure 6.19a). We now know their original interpretation, limited by the state of the seismic art at that time, was not correct in terms of its vertical connectivity to the mother salt bed (Figure 6.1). Amery (1969) discovered that the Sigsbee Scarp was the leading tip of a wedge of allochthonous salt.

Jackson and Cornelius (1987) modeled allochthonous salt sheets as flowing salt bodies ramping up to the nearsurface from a buried sub-salt step. The suprasalt wedge then spread rapidly under gravity as a recumbent fold anticline. They argued the whole system had advanced like a tank track rolling out over itself, with a core of allochthonous salt and a laterally sliding deformed sedimentary overburden (Figure 6.19b). As an allochthon rolls out over the seafloor it carries with it the veneer of accumulating and deforming sediment so that, when later buried and drilled, the sediments atop a salt sheet may be older than those below. This is case in the Vermilion #356 well drilled through a Gulf of Mexico salt sheet by Amoco in 1988. The highly overpressured section beneath the salt sheet is younger than the condensed suprasalt section in the same well (Figure 6.22; Harrison and Patton, 1995).

D'Onfro (1988) modeled allochthonous salt sheets as dykes and sills that were intruded in areas of local compression, such as the toe regions of growth faults (Figure 6.19c). Podladchikov et al. (1993) modeled asymmetric salt sheets as intruding laterally from a diapiric salt mass at depths of approximately 1 km depth. This level, according to the authors, lies just above an abrupt

thousand-fold downward increase in the viscosity in what otherwise are uniformly viscous sediments (Figure 6.19d). Amery (1969,1978) envisaged shallow allochthonous intrusion of the spreading salt layer as occurring beneath a thin sediment roof that was no more than 200 - 300 m thick. He visualised the salt as coming from an autochthonous diapir source. Nelson (1991) stated that most salt sheets in the Gulf of Mexico had been emplaced shallow at depths of around 100m and never

Figure 6.19. Hypotheses for the origin of allochthonous salt sheets. See text for explanation (modified from Schultz-Ela and Jackson, 1996).

more than 300m (Figures 6.6, 6.19e). Talbot (1993) pointed out the resemblance of salt sheet profiles to viscous fountains spreading laterally into unconsolidated surface muds (Figure 6.19f). The stepped base to many salt allochthons attest to their emplacement as surface rather than shallow subsurface features (Figure 6.16c).

Humphris (1978) was the first to postulate extrusion at the front of the vast Gulf of Mexico thrust nappe, which was riding basinward as an allochthonous salt sheet (Figures 6.1, 6.27). Jackson and Cornelius (1987) hypothesised that extrusion was possible if progradation was slow. Vendeville and Jackson (1992a) first modeled allochthonous salt sheets as forming under little or no roof. The concept of extrusive salt sheets on the sea floor under little or no sediment cover is now the most widely accepted mechanism for allochthon emplacement (Figure 6.19b, f; Fletcher et al., 1995; McGuinness and Hossack, 1993; Schultz-Ela and Jackson, 1996; Schuster, 1995). Salt sheets form by the geologically rapid widening of the crest of passive diapirs (Jackson et al., 1994b; Fletcher et al., 1995; Ge et al., 1997). As sediments are deposited around an extruding salt sheet, the salt glacier climbs up across the newly deposited

sediment. Thus a salt allochthon climbs over progressively younger sediment as it moves away from its feeder. The slope at the base of the salt sheet (ramp versus flat) is thus a function of the relative rate of sedimentation (Figure 6.16).

During times of active extrusion a salt sheet forms a bathymetric high with up to several hundred metres of relief above the surrounding seafloor (Fletcher et al., 1995). A feedback occurs between the rate at which salt is pumped to the surface and the rate at which seawater dissolves the salt. The rate of salt pumping is thought to be many times greater than the sedimentation rate during peak growth periods of the allochthon. Expanding salt sheets are protected from dissolution by a combination of: 1) sedimentary veneer, 2) an insoluble residue (or caprock) of anhydrite/gypsum, and 3) an overlying layer of saturated pore brines where circulation of sea water is locally restricted. If continuously deposited, a low-permeability sedimentary roof, alone, can protect underlying salt, even if the roof is continuously breached by deformation and erosion.

Historically, the ancient equivalents of salt glaciers were not widely recognised in the rock record. Now, with our improving

understanding of salt tectonics and the significance of widespread salt evacuation, ancient counterparts are now well documented in Kazakhstan, Algeria, Tunisia, Yemen, the Flinders Ranges and Mexico (Volozh et al., 1994; Vila et al., 1994, 2002; Davison et al., 1996; Dyson, 1998; Giles and Lawton, 1999, respectively). As any salt glacier or allochthon sheet spreads out over the surrounding landscape or seafloor they also laterally transport and deform any roof and can induce drag folds in subsalt sediments to ultimately create transition zones known as basal shears. With the exception of the namakiers of Iran, most areas where allochthons outcrop are no longer characterised by salt actively flowing at the surface. Rather, the former presence of thick flowing sheets of salt are indicated by dissolution breccias and welds and associated deformation in the surrounds of the former sheet (Figures 6.20a, b, 7.23, 7.24, 7.27).

Figure 6.20. Cross sections through outcropping salt allochthon terrains. A) Recumbent folding and thrusting are the main deformation features observed in the siltstones and gypsum layers of the overburden at the Jabal Al Milh diapir, Yemen (after Davison et al., 1996b). B) The Jebel Frikitia allochthon, Algeria, shows how breakout of salt into the next allochthon tier typically evolves into a gravitational collapse 'thrust' off the original salt wall. This thrust is a gravitational adjustment to "down to the basin" extension in the overburden. Breakout occurs in areas where pressurized salt rises faster than extension and sedimentation can accommodate.

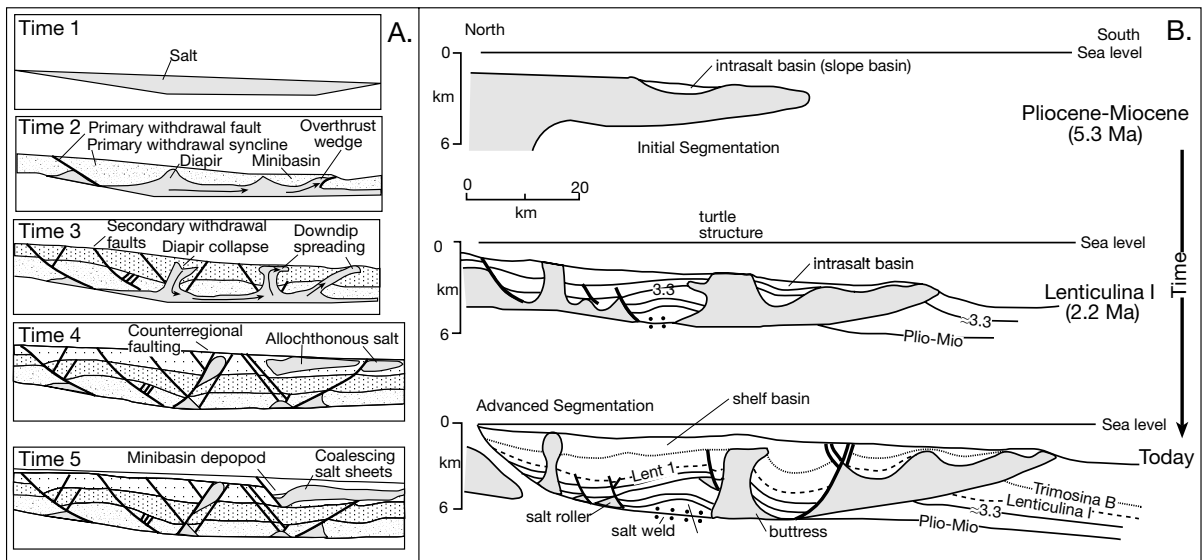

Figure 6.21. Salt allochthon evolution. A) Evolutionary model of the creation of allochthonous salt sheets in the Gulf of Mexico (after Montgomery and Moore, 1997). B) Schematic of evolution of eastern Green Canyon, Gulf of Mexico. At 5.3 Ma the salt sheet was extruded. From 6.3 to 3.3 Ma the ongoing basinward extension of the sheet promoted differential loading within half grabens. From 3.3 to 2.2 Ma the largest intrasalt basin displaced all the salt below it to create a salt weld and a structural inversion that was created by a turtle structure. Subsequently the sheet was further deformed as it continued to flow basinward and climb the stratigraphy (modified from Seni and Jackson, 1992).

Sheets, welds and basal (subsalt) shear zones

There are two major phases of allochthon emplacement (Montgomery and Moore, 1997): 1) initial inflation and loading of a salt mass, which generates zones of salt withdrawal and diapir formation (Figure 6.21a; times 1-3); and 2) subsequent suprasalt loading, which creates complex growth faults classified as regional and counter-regional faults (Figure 6.21a; times 3-5). This second stage occurs in levels of the stratigraphy that lie well above the primary salt level. Emplacement at all stages involves both syndepositional salt dissolution and shearing at the allochthon contacts. It can be associated with the spreading and/or coalescence of a number of salt sheets to form a salt canopy, which is in turn evacuated by later sediment loading (Figure 6.21b). Once emplaced, an allochthonous salt sheet is segmented into smaller second-generation structures. The top and bottom contacts of the initial salt sheet come closer and closer together until touchdown occurs and it becomes a salt weld (e.g. the Fraktia thrust weld in Figure 6.20b).

A salt weld forms when the salt sheet or primary bed is so thinned by withdrawal that salt is no longer resolvable on seismic profiles. The weld can still retain some salt or consist of faulted and brecciated sediment and insoluble residues. Salt welds are also called overburden touchdowns, or simply

touchdowns. A salt weld is usually, but not always, marked by a structural discordance. Another distinctive feature is the common presence of a structural inversion above the salt weld, which often defines some sort of broad anticlinal structure (e.g. turtle and mock-turtle structures; Figure 6.17).

Better-documented examples of weld textures do not come from the subsurface but from salt basin outcrops in regions such as the Flinders Ranges and the Zagros fold belt. One of the best examples is in the La Popa basin, near Monterey, Mexico, where a subvertical salt weld is exposed for 25 km along its strike (Figure 6.59; Rowan et al., 2003). Traverses across the weld indicate significant strike-parallel variability in both weld structure and the geometry of adjacent strata. In some places the weld is a 2 to 4 metre wide fault zone with brecciated and sheared siliciclastics, no remnant evaporites, and evidence of extensive fluid alteration. In other places, the weld contains up to 30 m of remnant gypsum, either massive or sheared, that locally contains inclusions of meta-igneous rocks or Jurassic dolostones that were carried up in the diapir. The La Popa weld ends in the west at an outcrop of gypsum several hundred metres in diameter that represents a remnant salt stock; in contrast, the weld trace is truncated in the south-east by an intra-Maastrichtian unconformity (see later in this chapter for geological detail).

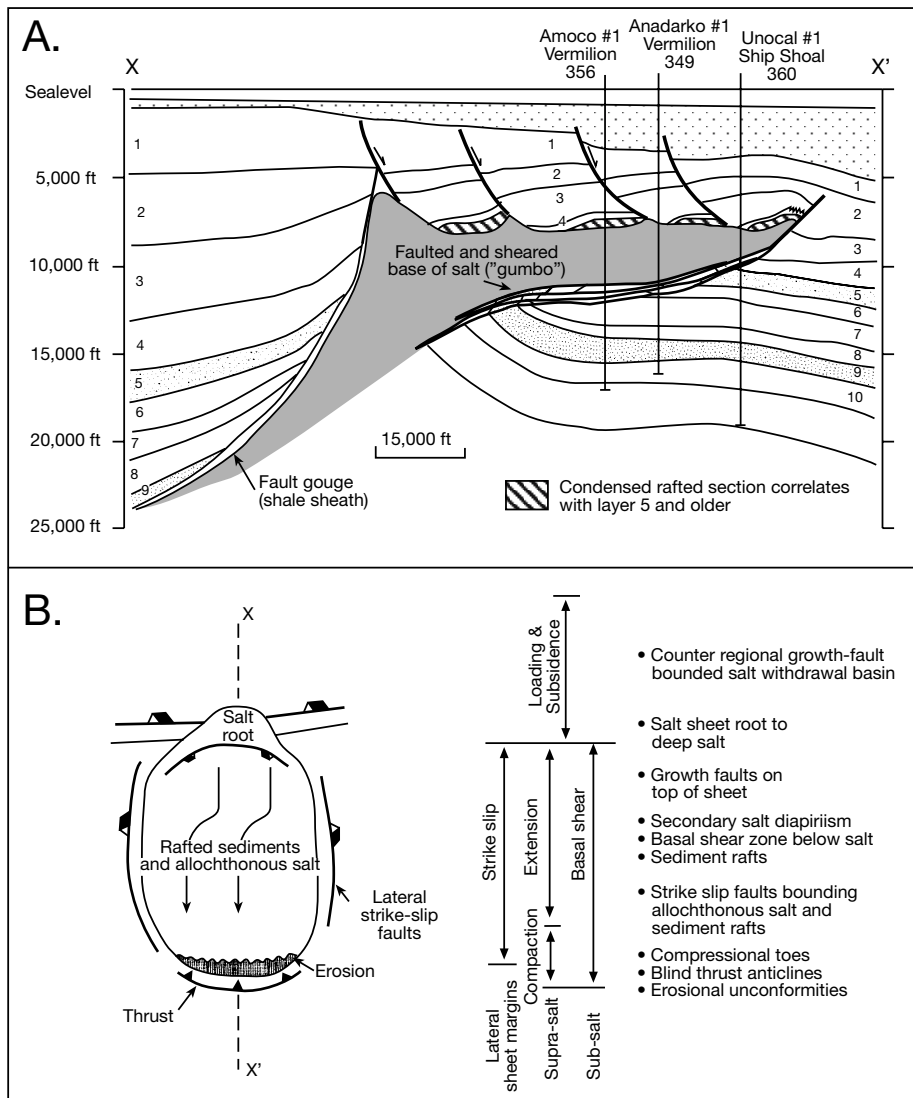

Figure 6.22. Basal shear model (after Harrison and Patton, 1995). A) Cross section view with a thrust fault defining the rising compressional nose of the salt sheet. Relevant Gulf of Mexico wells are placed schematically on this section. B). Map view. Down-to-the-basin translation of the composite salt/sediment glacier forms strike slip shears at the depopod margins. The compressional toe is a complex combination of normal fault and eroded blind-thrust anticlines (see later).

A primary weld joins strata originally separated by gently dipping autochthonous bedded salt. Secondary welds join minibasin or depopod strata originally separated by steep sided salt diapirs (walls or stocks). Tertiary welds join strata originally separated by gently dipping allochthonous salt sheets (Jackson and Cramez, 1989). Each side of the weld can slip relative to the other, as it can in a more steeply inclined fault that is lubricated by salt. The latter structure is termed a fault weld although all welds are tied to some sort of translation or shearing of strata above and below the salt sheet (Figure 6.21a, b). A fault weld

is simply a recognisable fault surface or fault zone joining strata originally separated by autochthonous or allochthonous salt. Thus a fault weld can be a salt weld along which there has been obvious faulting or shearing.

Shearing associated with the margins of salt diapirs has long been recognised as creating shale sheaths and as explaining shear-defined cylinders of differential salt movement within down-building subvertical diapirs (Hanna, 1953). This is especially obvious in subvertical salt structures that have been mined or crop out (Balk, 1953; Kupfer, 1976; Talbot and Jackson, 1987a; Zak and Freund, 1980). What differentiates classic subvertical diapir models and the lateral flow emphasis of allochthon models is the development of minibasins and listric faults in supra-allochthon sediments (Figures 6.21). A minibasin is an suprasalt depositional basin underlain and surrounded by allochthonous salt. The term intrasalt basin is sometimes used to described salt-floored minibasins or depopods. In

my opinion this is confusing as intra means within, these basins are never within, they are initially atop and laterally restrained by salt. Then in more mature extensional and compressional terrains where most of the salt in a former salt wall has been largely squeezed from the system the remaining adjacent depopods can be in lateral contact across a salt weld and floored by a salt weld (e.g. Figure 6.25). I use the term intrasalt to describe features completely encased in salt.

Once an allochthonous salt sheet is detached from its source layer, pods of condensed sediment are deposited as a roof carapace (e.g. palaeontological equivalent of unit 5 in Figure 6.22a). This suprasalt region loads and splits into a number of growth-fault defined suprasalt depopods (layers 1-4 in Figure 6.22a). Sediment accommodation space is created at the up dip end of this expanding minibasin via growth faulting, while thrusting and erosion is occurring at the same time at the downdip end (Figures 6.21 and 6.22b). The rotation of the suprasalt sediment prism as it accumulates is facilitated by the lateral migration of salt. Internal shear in the advancing salt sheet is greatest in the basal shear zone.

Sediments beneath the base of subhorizontal allochthon sheets or the subsequent welds typically preserve shear features that encompass both external and internal shear zones. They include; evidence of sediment pressurization, entrainment of country rock within the salt body and structurally induced drag folds (Figure 6.22a; Harrison and Patton, 1995; Alsop et al., 1996). Basal shear zones of allochthons are also called transition zones, gumbo zones, unconsolidated rubble zones, and can be considered as a subhorizontal type of shale sheath.

The basal shear zone is a response to thrusting along and within the base of the salt allochthon as it is emplaced at or near the sea floor (Harrison and Patterson, 1995). Consequent sediment loading atop the sheet drives further salt withdrawal and suprasalt sediment deformation (Figure 6.22a). Salt flow within the salt sheet occurs via internal shear and pressure solution creep. A pure salt sheet remains impermeable as it experiences no brittle response to flow deformation as it rolls out over its substrate (Figure 6.5). As the sediment carapace thickens over the salt sheet, overpressures develop in the subsalt transition zone. The resulting anomalously high pore fluid pressures facilitate simple shear beneath the sheet by reducing the effective normal stress, thereby allowing lateral movement of the sheet and its sediment carapace (gravity gliding; Baud and Haglund, 1996). Whether shearing occurs within the salt sheet or in the subsalt sediment is determined by which interval has the lower shear strength. Baud and Haglund (op. cit.) believe post first-emplacment shearing occurs within the salt sheet at least until anomalously high pore pressures develop in sediments below the sheet.

Measured pore pressures in the basal shear zone of Gulf of Mexico allochthons can be much higher than regional pore pressures and approach fracture-inducing pressures in some subsalt shales. Measured gradients as high as 0.88 psi/ft or balanced mud weights of 17 ppg characterise Gulf of Mexico drilling

(Table 8.3; Harrison and Patton, 1995). Field evidence cited in House and Pritchett (1995) indicates that the hyper-pressured interval below a salt sheet is typically 300 to 600 m (1000-2000 ft) thick and its upper part is likely to entrain a lithologically distinct “gumbo” or transition zone. In the Gulf of Mexico, a “gumbo” zone has been encountered beneath salt sheets emplaced into Pliocene, upper Miocene and middle Miocene age sections, but hyper-pressurised cells in the “gumbo” have been documented only below allochthons emplaced into Pliocene and upper Miocene sections (House and Pritchett, 1995). This may indicate that hyper-pressures are a geologically transient allochthon phenomenon and that with sufficient time a pressure equilibrium gradually re-establishes itself.

On passing through the salt allochthon the Amoco #1 well, Vermilion Block 356, immediately intersected such a pressured disturbed transition or “gumbo” zone. Cuttings from the gumbo zone documented a change with increasing depth below base of salt from a grey soft shale with pyrite traces into a firmer, medium to dark shale. Deep resistivities were less than 0.2 ohm.m in the shale in the first 120 m (400 ft) below the salt and increased to 0.4 ohm.m in the next 180 m (600 ft) possibly indicating decreasing pore water salinities or increasing organic content. The lowest resistivity zone corresponds to a wireline density ≈ 2.10 gm/cc that increases to 2.25 gm/cc by 300 m below base of salt. RFT measured pressures in thin sands in the disturbed (gumbo) zone were some 16.7 ppg equivalent, while measured pressures several thousand feet below the gumbo in the same well were 16.1 ppg equivalent.

The South Marsh Island Block 169 Amoco #1 well in a transition zone immediately below its salt sheet intersected pressure gradients of 17.4 ppg equivalent. This pressure level is only 0.3 ppg less than the calculated fracture gradient for the matrix (House and Pritchett, 1995). Below the “gumbo”, pressure gradients decrease to more typical regional values of 16.5 ppg equivalent. Pressure data divide this well into a high-pressure zone (hyper-pressure cell) some 335 m (1100 ft) thick immediately below the salt sheet and an underlying pressure transition zone some 245 m (800 ft) thick. Pressures below the transition zone are equivalent to regional overpressures.

Abnormally high pressures in transition zones (gumbo) typically indicate hydrologic isolation of this shale-rich section and a lack of hydraulic continuity (these shales do not readily dewater). Wireline image data show soft sediment deformation features, with higher levels of contortion in proximity to the allochthon contact. A similar style of disturbance outcrops in the transition zone of Jabal Al Milnh diapir, Yemen (Figure 6.20a) and in

subsalt thrust folds that define the Upper Cretaceous section of the Jebel Fraktia allochthon (Figure 6.20b). A basal shear zone in most active allochthon provinces is best considered as a potentially thick, highly pressured, faulted and folded interval. Fluids in this deformed zone may migrate along fault planes but typically not within the blocks of disturbed sediment matrix, which like the overlying salt, acts as vertical barriers to fluid flow. Pressure build-ups within the shales probably lead to periodic matrix fracturing and bleed-off of elevated pressures (seismic pumping).

Hence, the transition zone (gumbo zone) that characterises the lower contact of most active allochthon sheets is outlined by abnormal pressure and temperature gradients. Differential translation is concentrated at and immediately below the base of the salt sheet. Salt-lubricated slivers line up as sub-parallel thrust planes along the pressurised base of the allochthon, as do repeat sections and recumbent subsalt folds (Figure 6.22a; Harrison and Patton, 1995). A lack of fluid movement in a disturbed zone can also lead to anomalously low temperature gradients in this interval with a low thermal gradient halo typically characterising the interval immediately below the thick, thermally conductive salt sheet. Thermal gradients in this halo gradually increase downward until a more normal regional gradient is achieved. The low temperature, high-pressure interval that occurs below most allochthon sheets is a potential problem zone for the drilling engineer (Chapter 8).

Jackson and Hudec (2004) have expanded on Harrison and Patton's notion of basal thrusting (Figure 6.22a) by arguing that as salt allochthons continue to advance over the seafloor they act much in the same way as a glacial ice sheet advances and ploughs over glacial till. As allochthonous salt rides up over its underburden it pushes, deforms and thrusts portions of its water-saturated substrate. This in turn creates thrust ramps and duplexes in subsalt "gumbo" sediments immediately beneath the salt sheet.

When pressurised, the base of salt or gumbo zone tends to act as a permeability barrier to rising basinal fluids, as does the overlying salt (House and Pritchett, 1995). When rising fluids impinge on this zone they are forced to flow laterally, subparallel to the base of salt and through the gumbo until they encounter a breach point or the feather edge of the salt sheet (Chapter 8). But not all "gumbo" transitions are anomalously pressured and pressure character is not easily predicted ahead of drilling. For example, instead of being impervious, extra permeability can be created in a gumbo or transition zone via periodic salt evacuation from salt feeder stocks below an allochthon canopy.

Depending upon its local character, a gumbo zone can be a seal, it can be a path for hydrocarbon migration, or a potential reservoir. When pressurised a gumbo zone provides a potential trapping mechanism, much like a pressure-sealing fault. Hydrocarbons migrating laterally through a highly-pressured transition zone can be injected into low-pressured underlying sands and trapped due to the pressure differential. Or a transition zone can trap hydrocarbons migrating upward through subsalt sands as overpressures in the transition zone prohibit fluid invasion. If not overpressured, a fracture-susceptible gumbo zone can provide a permeability pathway for hydrocarbons migrating upward along base of a salt feeder as buoyant fluids move through the transition zone. Hydrocarbons can also migrate upward through suballochthon sands and then leak into the transition zone wherever the sand and transition zone contact one another. Lastly, subsalt transition zones could prove to be reservoirs themselves, as widespread leakage of hydrocarbons from below, or lateral migration of fluids through the gumbo, can saturate them. But most subsalt transition or "gumbo" zones are probably not of reservoir quality, observed log character shows most are disturbed and shale prone (LeBlanc, 1994). Fluid modelling based on allochthon-focused sub-salt flow has implications for the pulse-like mineralisation episodes and the development of footwall alteration haloes in many Proterozoic base metal deposits (Warren, 2000b).

Near-diapir suprasalt shear (drag zones)

Deformation in the suprasalt sediments immediately adjacent to a growing subvertical diapir or an inflating allochthon edge creates an external shear or drag zone. Drag zones form as beds in the overburden are rotated into steeply dipping attitudes

Figure 6.23. Dimensions and parameters of the diapir drag zone (after Davison et al., 2000b).

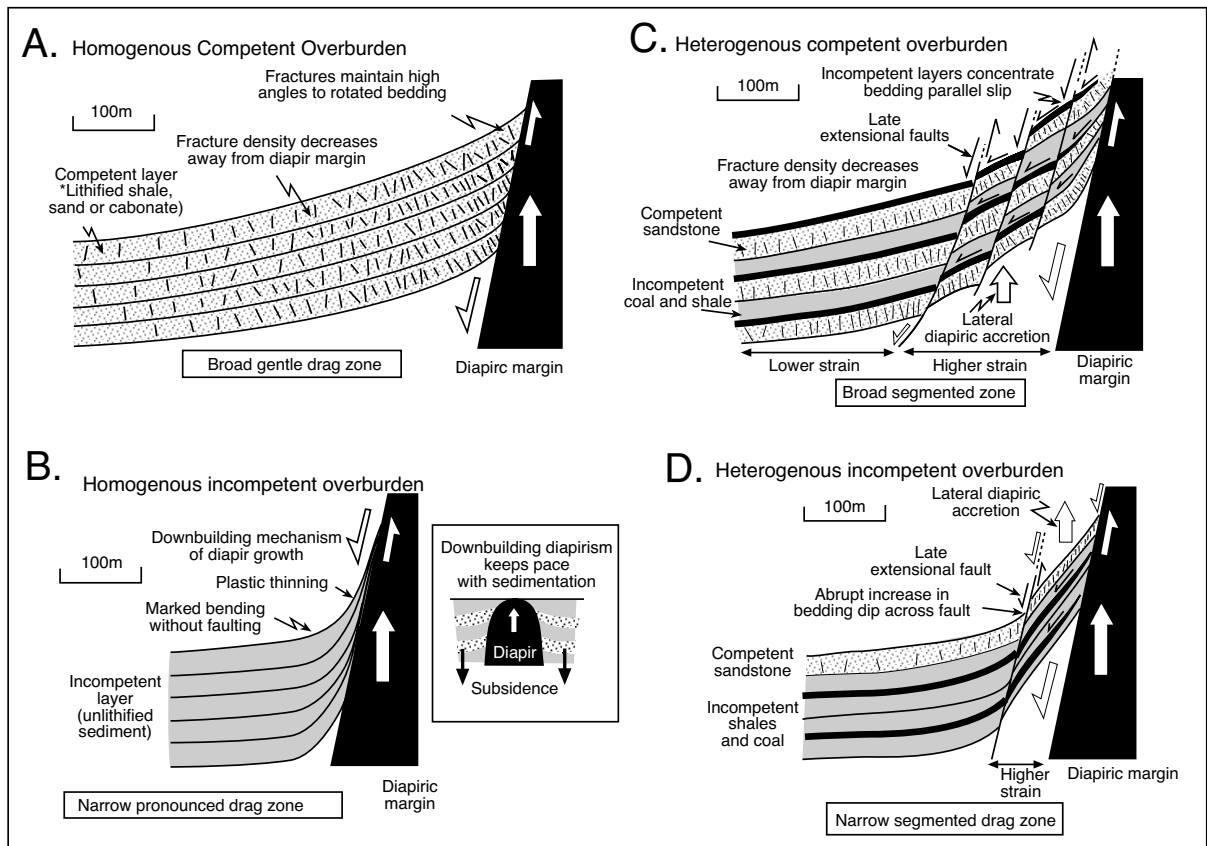

Figure 6.24. Schematic profiles of diapir drag zones (after Alsop et al., 2000). A) Broad drag zone within homogenous competent overburden. B) narrow drag zone with incompetent inhomogeneous overburden. C) Broad segmented drag zone within homogenous incompetent overburden. D) narrow segmented drag zone within heterogeneous incompetent overburden with marked internal competency contrasts. C) and D) also illustrate the process of lateral diapiric accretion where fault-bound material moves upward with the flanks of the diapir relative to sediments further out in the rim syncline.

that lie subparallel to the walls of the salt diapir (Schultz-Ela, 2003; Alsop et al., 2000). Rotations can be as steep as 90° and can even overturn beds. Deformation is driven by a variety of processes including downbuilding, differential compaction, grain boundary sliding, microfracturing, larger-scale faulting and pressure solution. The abutment of an inclined drag zone against a near-diapir fault can form a large number of stacked and compartmentalised oil and gas reservoir sands (Figure 10.45a).

Drag zones develop sequentially; initial salt pillow uplift creates broad gentle overburden flexure that increases in intensity as the structure evolves into a diapir (Figure 6.23). By the diapir stage the width of a drag zone is approximately equivalent to the width of the diapir at the diapiric base and decreases to 25% of the diapir width toward the diapir crest. Vertical relief of the upturn in a bed also decreases upward (Figure 6.23; Davison et al., 2000b). Vertical relief is some 5% of the diapir

height near the crest and increases to 30% near the diapir base, a consequence of the greater relative movement across the pre-movement and early syn-movement layers situated near the base of the diapir stem. The width of the drag zone increases proportionally with increasing diapir size and diapir height, while the total amount of bed upturn increases proportionally with the width of the drag zone.

In one of the few outcrop studies of the characteristics of diapir drag zones Alsop et al. (2000) relate variation across the zone to overburden competence (Figure 6.24). Their work focused on an outcropping diapiric province in Cape Breton Island, Nova Scotia, where five Viséan-age salt diapirs penetrate Upper Carboniferous (Namurian-Stephanian) conglomerates, sandstones, shales and coal seams. The width of diapiric drag zones varies from 70 metres up to 500 metres. Narrow drag zones are a response to the low mean competence of shales and siltstones, which were probably shallowly buried and poorly

lithified at the onset of diapirism (Figure 6.24b). Broader drag zones are dissected by two sets of extensional fractures, together with major faults, suggesting that the overburden was semi-lithified and displayed greater flexural rigidity at the time of salt flow (the beam effect; Figure 6.24a). Overburdens with high internal competency contrasts (e.g. interbedded sand-shale) generated strain localization and partitioning, with pervasive granulation seams and minor faults developed in the more competent sandstones and bedding-parallel shears in the coal and shale horizons. The various drag zones are segmented by steep outward-dipping faults associated with decametric, asymmetric drag profiles (Figure 6.24c, d). These faults facilitate the upward movement of material and effectively enlarge the diapiric process into the adjacent overburden a process they call lateral diapiric accretion.

In the subsurface, seismic of varying quality is usually all that is available to interpret drag zone geometries. Steep dips and irregularities in the distribution and density of adjacent salt means that the shape and extent of the diapiric drag zone is poorly defined in the inner shear zone area, especially when the diapir is bulbous. The width of the upturned zone caused solely by frictional drag is difficult to estimate, as a large section of the upturned interval can be due to the salt pedestal effect (Vendeville and Nilsen 1995). The increased permeability around zones of fracture adjacent to diapirs means that drag zones can act as preferential conduits for fluids escaping from deeper levels. Pervasive fracturing in broader drag zones formed by more competent beds helps explain the pervasive entry of ferroan brines into adjacent carbonates and fracture defining haloes as is seen in the outcropping Proterozoic diapiric province of the McArthur Basin, Australia (Warren, 1999). There the salt has long gone and only siderite/brunnerite haloes remain around fault welds and salt welds.

With prekinematic overburden, substantial drag-induced folds only form in exceedingly weak rock (Schultz-Ela, 2003). Even then, most folding develops by nearsurface upward and outward rotation. Protrusions of overburden into a diapir, where the contact dips shallowly outward, are most susceptible to folding due to frictional drag created by the crossflow of salt. Based on modelling experiments Schultz-Ela (op. cit.) argues synkinematic sedimentation is much more likely to engender large and broad folds in the drag zone because onlapping wedges may be continually produced during downbuilding. These syndepositional folds can even form in strong layers. He argues folding of onlaps over rising salt is really drape folding, so “drag” fold is actually a misnomer. Local gravity fold is perhaps a better descriptor of this style of deformation. Episodically deposited layers further enhance the potential for onlap folding.

For the same average aggradation rate, pulsed deposition of thick layers generates larger folds than do continuously deposited thin layers. Variation in thickness and timing of deposition increases the likelihood of multiple wide onlaps that evolve into substantial folds. Older layers tend to form the broadest and tallest folds because those layers prograded farthest across the diapir crest. As the salt contact steepens, the folded zone narrows as younger layers onlap onto older folds or the salt. Onlap folds can only form for a limited range of relative salt rise and deposition rates. Deposition much faster than the net rate of salt rise buries the diapir. Deposition that is too slow creates steep contacts or salt spilling onto the sediment surface, both of which result in little “drag” folding.

In three dimensions, outcrop and 3D seismic studies have shown that both radial and concentric faults occur in drag/drape zones around diapirs, and that the fault patterns are lithologically dependent (Davison et al., 2000). This pattern can facilitate the creation of a hydrocarbon-bearing column adjacent to a diapir that is more than a km tall. Many fault patterns are approximately sub-radial due to the intersection of multiple fault trends and many faults curve to become roughly tangential to the diapir face to produce cusped salt outlines in plan view (Figure 6.21; Chapter 10).

Welds, loading detachments and growth faults

Many regional growth faults in salt allochthon provinces sole out onto residual fault welds, which can be many tens of kilometres in length (Figure 6.21b). With time and ongoing salt evacuation, the basal shear zones and gumbos depressurize and evolve into normally pressured regions across the salt or fault weld. The link between growth faults and salt welds is an inherited relationship whereby one evolves or passes into the other (Jackson et al., 1994b; Fletcher et al., 1995). A thick salt sheet that was present before welding decouples faulted zones above and below it. This decoupling means most large faults sole out into the level of the former sheet.

Burial of an evacuating salt allochthon beneath loading sediment typically occurs after pinch-off from the feeder diapir (Fletcher et al., 1995). This allows the former sea floor high created by the glacier to relax (deflate), especially at the updip end of the sheet. Sediment can then prograde across the sheet beginning at its updip end (Figure 6.22a, 6.25). Even during burial of its updip end, an evacuating salt sheet typically retains several hundred metres of relief on the downdip end. Thus the downdip sheet continues to advance as a composite salt-sediment glacier. Sediments atop the allochthon are deformed, along with the flowing salt, as the gliding movement creates extensional breakaway zones at the updip end. In turn this

Figure 6.25. Efficiency of evacuation is reflected in the suprasalt structuring. A) With inefficient salt evacuation a fault segmented (Roho^{6,3}) system forms. B) With efficient evacuation a counter-regional system is created. C) Shows how the two systems can be created by the same salt body. Circles show position of salt weld. See text for explanation, black circles define salt welds (in part after Jackson and Vendeville, 1994b; Rowan, 1995).

initiates fault-bound minibasins at the updip end of actively flowing salt sheets (Figure 6.22). Ongoing slippage creates a growth fault rollover anticline as salt continues to extrude at the downdip or compressional end.

The same salt mass can recycle multiple times as tiers ascending into ever higher stratigraphic levels (Figure 6.25). Each time salt activity is transferred to a higher level, a largely welded smear of salt with vestigial salt structures is left behind at the lower levels. Substantial volumes of salt are lost via dissolution each time the salt approaches the seafloor or is bathed in less saline pore fluids. Thus, the ascending salt mass cannot recycle indefinitely and the driving mechanism is lost once a salt weld or overburden touchdown is created beneath the minibasins.

^{6,3}The detachment surface for these into-the-basin “Roho” growth-faults is inefficiently evacuated salt. With 1960s and 1970s vintage seismic data, it was not possible to image below the salt evacuation surface. An early seismic stratigrapher in Shell, Chuck Roripaugh, after being instructed to map to the Moho below areas of salt, jokingly labelled his map of the salt evacuation as “Roripaugh’s Moho” which was later contracted to Roho. This in-house joke has since escaped into the public literature.

A salt sheet that is isolated from its feeder stock can advance further only by cannibalising its trailing edge (Figure 6.21b; Fletcher et al., 1995; Schuster, 1995; Jackson and Vendeville, 1994b). If the salt is inefficiently withdrawn from the trailing edge, the salt becomes progressively sequestered into residual smaller bodies and the overall structure is called a fault-segmented sheet. In the Gulf of Mexico this is also called a “Roho” system or a listric weld (Figure 6.25a). Roho systems are characterised by major, listric, down-to-the-basin growth faults, which in the Gulf of Mexico sole into salt evacuation surfaces known as tertiary salt welds (as opposed to primary and secondary salt welds - see earlier). During shelf progradation over a salt sheet or salt “wing,” the rear (landward) margin of the salt sheet gradually segments and deep withdrawal structures are enhanced. At shallower levels, vestigial salt forms a train of sequestered salt walls formed by the partitioning of a formerly continuous sheet of salt. Each residual salt structure is typically in the footwall of a normal fault or is separated from its neighbour by a syncline. Each residual wall is generally overlain by a splay of extensional faults, which are commonly listric.

If salt is more efficiently withdrawn from the deflating trailing margin shelf progradation then a stepped counter-regional

system results (Figure 6.25b). Strata above the deflating salt sheet subside to form a shallow flat step along the weld of vanished salt. The step resembles a landward dipping growth fault. However, the step can be merely a pseudo-fault, like the contiguous deeper step created by upward evacuation of the original diapir. In three dimensions the shallow step fault is the axis of a partly evacuated sheet that is shaped like a tongue with curled up lateral margins (Figure 6.22b). Along the deepest axis of the tongue lies the deepest, most evacuated part of the salt sheet below the thickest overburden.

These two structures — the fault-segmented sheet (Roho) and the stepped counter-regional system — are end members of a load-induced evacuation series where the counter-regional systems define welds where salt has been completely evacuated and a Roho system defines less efficient evacuation. It is possible that as the salt climbs the stratigraphy the same salt body can create both Roho and counter-regional systems or welds depending on the efficiency of evacuation (Figure 6.25c).

Minibasins floors become welds

Differential loading, created by the emplacement of a depositional lobe atop a salt allochthon, induces a differential fluid pressure in the salt below. Salt squeezes laterally into flanking areas and a bathymetric high, which dams the accumulating sediment, forms a rim adjacent to the sediment accumulating in the growing minibasin (Figure 6.22). A feedback process is created as the sediment-loaded minibasin floor subsides by pushing salt aside, so allowing the basin to receive additional sediment (Figure 6.26a). The process continues until the minibasin floor touches down on the subsalt strata to form a salt weld. At that time, minibasin subsidence ceases. Once the minibasin touches down, subsidence shifts from the centre of the minibasin to the flanks, which are still underlain by salt. Both flanks subside, creating an anticlinal turtle structure. Subsequent depocentres form on both sides of the early depocentre (Figure 6.17).

Figure 6.26. Evolution of minibasins atop salt allochthons based on the northern Gulf of Mexico (as in Figure 6.21). A) Evolution of a minibasin as sediment loads a salt allochthon (after McBride et al., 1998a). B) Types of minibasins (after Koch et al., 1998).

Intrasalt minibasins that form above tabular salt allochthons typically entrain a sediment fill that indicates an evolution from slope basins to shelf basins (Figure 10.52). They are typically bound by arcuate growth faults formed largely by downslope salt withdrawal rather than by extension. Initially, the allochthon acts as a deflating cushion that accommodates sediment deposited in minibasins. After time, loading or extension, the original salt sheet transforms into thin but broad welds, which then act as major subhorizontal detachments for deep growth faults whose slip creates space for further sedimentation. Ultimately, the sheet itself is segmented into discrete salt structures separated by salt welds and fault welds. Second or third cycle tiers of salt structures can rise from these deformed sheets.

Substantial thicknesses of sediment can accumulate in minibasins; in the Green Canyon region of the Gulf of Mexico the intrasalt basins contain more than 5 km of Neogene and

Quaternary sediment fill (Figure 6.21b). Minibasins in the northern Gulf of Mexico are divisible into 5 types based on the relationship of the fill to the presence or absence of a salt weld (Figure 6.26b; Koch et al., 1998):

- Ramp (atop counter-regional)
- Salt-floored minibasin
- Welded minibasin
- Welded Listric minibasin (Roho)
- Primary basin (seaward of the allochthon)

Ramp basins predominate on the slope in Garden Banks and Green Canyon of the Gulf of Mexico. They are characterized by a south-bounding, north-dipping salt ramp (Figure 6.21b). Most ramp basins have young thick depocentres adjacent to the counter regional ramp. Ramp basins tend to be asymmetric and larger in areal extent. Welded basins were previously underlain by allochthonous salt that has been fully or partially evacuated. In the northern Gulf of Mexico they increase in frequency southward into the Walker Ridge and Keathley Canyon protraction areas (Figure 10.51).

Welded listric (Roho) basins in the northern Gulf of Mexico have south-dipping arcuate faults that sole into the evacuating salt. Welded basins have a multitude of internal fault patterns and sediment fills, some are symmetrical with bowl-shaped fills, others have multiple depositional axes and bidirectional stratal fills. Primary basins in the Gulf of Mexico show no evidence of allochthonous salt and display continuous sedimentary fill from Cretaceous to Recent. Salt-floored basins are underlain by continuous allochthonous salt, which typically shields them from the underlying petroleum kitchens. Salt-floored basins occur along the down dip edge of allochthonous salt near the Sigsbee escarpment and above very young salt sheets in Garden Banks and Green Canyon (Figures 6.1, 6.27).

As basin fill changes through geologic time, each of the five types of basin has a differing capability to receive and internally distribute the hydrocarbons it receives via a complex plumbing system from sources at greater depths below the basin (Koch et al., 1998). In

general, hydrocarbon entry points to basin strata in the Gulf of Mexico salt basins are controlled through time by salt movement and geometry. Koch et al (op. cit.) argue ramp basins have attractive plumbing for hydrocarbons as well as an enhanced trapping focus (Chapter 10). Welded and welded-listric basins are dependent on the evacuation of the salt floor for any hydrocarbon charge to occur, therefore the age and areal extent of the weld are factors in assigning prospectivity. Primary basins appear to have access to underlying sources but may lack effective migration pathways and trapping geometries. Salt-floored basins are the lowest ranked basins due to separation from source. Within the four areas studied by Koch et al. (1998), most discoveries have been in ramp and welded minibasins (about 1 BBOE in each basin type). Primary and salt floored minibasins show minor discoveries and none of significant size. The feedback between allochthon style, deposition of potential reservoirs units and hydrocarbon maturation is discussed in detail later in this chapter and in Chapter 10.

At broader scales than minibasin sags, salt sheets can spread laterally as they deform until they eventually coalesce with neighbouring salt sheets. Collectively they create a salt canopy, a feature that dominates much of the foot of slope in the

Figure 6.27. Salt canopy along the continental slope of rise of the Northern Gulf of Mexico. Image shows a series of salt-floored minibasin depressions atop a salt canopy (Image courtesy of Martin Jackson).

Figure 6.28. Comparison of structures produced by A) coalescence of unconfined salt glaciers, B) coalescence of confined, buried salt sheets, and C) segmentation of salt sheets by loading suprasalt minibasins (Jackson et al., 1994b).

northeastern Gulf of Mexico (Figure 6.27; Talbot, 1993; Wu, 1993). There individual lobate sheets coalesce westward into an extensive salt canopy whose leading edge is the Sigsbee Scarp. Adjoining sheets merge into canopies along salt sutures. The formation of a more or less continuous salt canopy must entail the upward and lateral movement of vast quantities of salt carrying with it an expanding overburden made up of minibasins actively accumulating sediments.

When the canopy roof is thin, the adjoining sheets are salt glaciers. In contrast, when a thicker roof of sediment confines the edges of adjacent sheets, the roof contracts into a cusped sediment-filled syncline associated with small thrust faults and kinks (Figure 6.28; Jackson et al., 1994b). This depositional syncline between suturing salt sheets is different from the depositional synclines created by depositional loading in suprasalt minibasins. Both contain thrusts, but minibasin thrusts are the result of slumping driven by the steepening sides of the subsiding

minibasin. They steepen over time but unlike canopy synclines do not contract laterally. The two types of syncline also differ in plan view, being cusped above salt sutures and bowl-shaped in minibasins atop segmenting salt sheets.

Fault families in allochthons

In the past decade our understanding of gravity gliding and salt flow in the Gulf of Mexico, the Santos Basin of offshore Brazil, the Kwanza Basin of offshore Angola has improved to where linkages between faults and anticlines in allochthon provinces can be predicted. Linkages between anticlines and extensional faults predominate, but links to contractional faults and strike-slip faults can also be predicted within a prograding sediment prism (Figures 6.29, 6.30, 6.31).

The observed diversity of structuration reflects the linked nature of gravity-driven deformation in zones where sedimentary overburden spreads under its own weight and slides basinward atop salt detachments (Rowan et al., 1999). Linked gravitational systems can range in scale from small, isolated, allochthonous salt sheets to the entire continental margin as it detaches and slides above autochthonous salt. Extension characterizes the landward and middle parts of salt-linked continental margin systems, while contraction usually occurs near the basinward

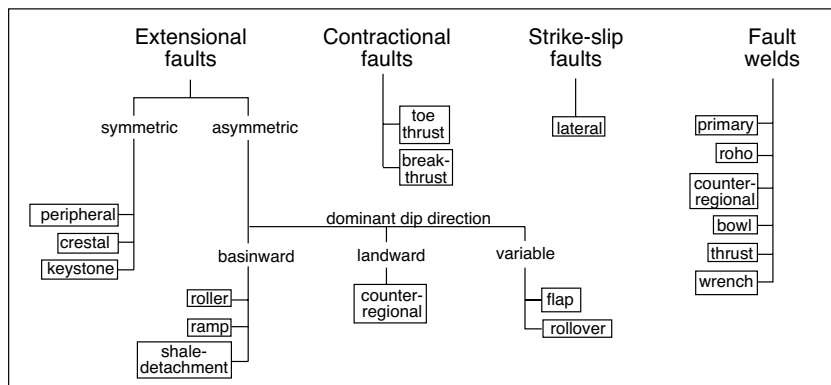

Figure 6.29. Classification system based on fault families and fault welds observed in the northern Gulf of Mexico (after Rowan et al., 1999).

limits of allochthonous salt (Figures 6.30, 6.31). Strike-slip deformation frequently connects these two domains. Where frontal contraction is not observed, downslope translation is usually accommodated by extrusion of allochthonous salt tongues.

Using a synthesis of existing seismic, Rowan et al (1999) reclassified the salt-associated faulting and welding in the Gulf of Mexico into related families (Figure 6.29). The classification is strictly geometric, without reference to kinematics, dynamics, or genesis. But the different families are connected in linked fault systems (inheritance), which, in turn, are associated with different types of salt systems. The transition from one fault family into another is typically related to position of the allochthon within the continental margin sediment prism (Figure 6.29). Each fault family is an array of faults having similar three-dimensional form and geometric relationships with deformed strata and associated salt. A fault family can include not only a dominant style (e.g., a basinward-dipping, listric, growth geometry), but also smaller faults that accommodate the strains and displacements induced by the primary faults. These subsidiary elements include antithetic faults, whose dip is opposite to that of the primary faults, and faults at high angles to the dominant trend. The various fault families and fault welds are tied to five varieties of salt systems: autochthonous salt, salt-tongue systems (both stepped counter-regional and Roho evacuation styles), salt-stock canopies, and salt nappes (Figures 6.30, 6.31).

Autochthonous salt tectonics: Autochthonous salt flow in the Gulf of Mexico is driven by two related mechanisms: gravity gliding and gravity spreading (Rowan et al., 1999). Early salt flow is dominated by gravity gliding (Figure 6.30). Oceanic spreading in the Gulf of Mexico began around the same time the Louann Salt accumulated during the Callovian. Subsequent cooling of the lithosphere probably tilted the continental margin basinward, causing gravity gliding of the thin overburden above autochthonous

Figure 6.30. Fault families in areas of salt flow centred on the primary salt level (autochthonous salt), which evacuates to leave behind the primary weld (after Rowan et al., 1999).

salt. Increased clastic input along the continental margin created a depocentre that flexed the underlying crust. This flexure probably reversed the basinward tilt of the autochthonous salt below the continental slope, thereby ending gravity gliding at this level in the stratigraphy; however, the continental margin remained gravitationally unstable and spread under its own weight, especially during Cenozoic clastic progradation. Thus, some of the structures established during early gravity gliding probably were reactivated during subsequent gravity spreading related to ongoing sediment loading. As a squeezed salt mass climbs the stratigraphy it separates from the primary salt level to become allochthonous salt. Ongoing allochthon loading and flowage forms the same spectrum of faults seen in autochthonous structures but now at levels well above those of the mother salt bed (Figure 6.30). Peripheral and roller fault families accommodate basinward extension at the landward margin of the basin and throughout the salt basin, respectively. Early reactive diapirism can create crestal fault families in this extensional zone. The extension is balanced by a combination of distributed salt extrusion and contractional deformation at the basinward limit of salt. Salt extrudes mainly from basinward-leaning salt diapirs (overlain by counter-regional fault families), but also from more vertical salt stocks. Contraction at the toe of the system creates detachment folds and break-thrust fault families. Folding, whether due to slip on extensional roller faults, collapse of seaward-leaning feeder diapirs, or contraction, generates a combination of rollover and keystone faults. Lateral fault families segment extensional

Figure 6.31. Fault families in salt allochthon provinces, based on the Gulf of Mexico (after Rowan et al., 1999). A) Typical assemblage of fault families and salt or fault welds in a stepped counter-regional allochthonous salt system. Roller faults are less common than the other types. B) Typical assemblage of fault families and fault welds in a Roho allochthonous salt system. C) Typical assemblage of fault families and salt or fault welds in an allochthonous salt-stock canopy. The frontal section shows a partially evacuated salt stock; the back cutout shows two coalesced stocks that have been completely evacuated. D) Typical assemblage of fault families in a salt nappe advancing over the abyssal plain. The basinward area shows an immature stage of evolution; the more landward area shows more highly evolved structures.

regimes, possibly controlled by the geometry of faults in the rifted basement (e.g., Watkins et al., 1995; Rowan, 1997). Remnant salt or primary welds provide the common link in autochthonous salt systems.

In a landward to basinward traverse, allochthonous fault associations break down into four interrelated fault families, which are shown in basinward order in Figure 6.31a-d.

Stepped Counter-regional Salt System: Salt-tongue systems comprise subhorizontal salt sheets fed by one or more basinward-leaning feeder diapirs (Rowan et al., 1999). These systems can evolve as stepped counter-regional systems (Schuster, 1995), consisting of a deep feeder weld, an intervening evacu-

ated salt sheet, and higher level basinward-leaning diapirs and landward-dipping salt welds. The linked fault system associated with this counter-regional weld is relatively simple (Figures 6.25b, 6.31a). It is dominated by a counter-regional fault family and associated rollover and keystone fault families. Additionally, a second counter-regional fault family may overlie the deep feeder (not shown), or there may be a roller fault family detaching on the secondary weld if there were any basinward translation during evacuation of the sheet.

Roho Salt System: Salt-tongue systems can also evolve as Roho systems (Schuster, 1995). These are generally longer in the downdip direction than are stepped counter-regional systems. The extra length creates a greater elevation for

the salt and thus more gravity spreading. The result is a linked fault system dominated by a roller fault family (Figures 6.25a, 6.31b). In places, shale-detachment fault families merge into the landward or lateral edges of the salt layer or weld. The extension on the combination of roller and shale-detachment faults is accommodated by salt extrusion or shortening along a to thrust fault family. Extension and contraction are linked by lateral fault families and a Roho weld. Minor structures include rollover fault families in the hanging walls of the roller faults and keystone fault families in the crests of contractional folds.

Salt-Stock Canopy System: Salt-stock canopies can be true or apparent depending on whether amalgamation occurred during stock growth or stock evacuation, respectively (Rowan et al., 1999). In both, a complex linked fault system can develop with the link provided by remnant allochthonous salt and bowl welds (Figure 6.31c). Partly or fully evacuated stocks can have ramp fault families at the landward margins, flap fault families at the basinward margins, and older roller fault families in the central areas. Where the canopy feeds a subhorizontal salt tongue, reactive diapirs and crestal fault families can form at the stretched hinge between the stock and tongue. Translation above the tongue can create roller and to thrust fault families linked by lateral fault families.

Salt-Nappe System: Salt nappes are large allochthonous salt bodies that advance tens to hundreds of kilometres basinward over long periods of time (Worrall and Snelson, 1989; Rowan, 1997). The front of a salt nappe is an arcuate lobe of salt covered by a generally landward-thickening clastic skin. In its most immature, distal regions, the structure is dominated by circular to elliptical minibasins up to 40 km wide. They subside into the salt and are separated by reactive diapirs formed during radial gravity spreading of the salt nappe (Jackson and Vendeville, 1995). Thus, the linked fault system is dominated by a polygonal pattern of crestal fault families (Figures 6.27, 6.31d). Toe thrusts can occur at the front of the nappe. Landward, the regular polygonal pattern degrades as

minibasins coalesce. Interaction between salt deformation and sedimentary loading may result in various fault families (e.g., counter-regional, roller, flap, lateral) and welds; however, the three-dimensional geometry of fault families in mature salt nappes is unknown because mature examples have not yet been identified.

Linking allochthons at the basin scale

Clearly, salt flow in a loading and extending sedimentary basin creates a number of predictable geometries, rollovers and fault patterns that are related by variations in rates of extension and loading as prograding suprasalt sediments evolve into ramps and welded basins (Figure 6.30, 6.31). In the Gulf of Mexico it is important to distinguish between the more landward intervals of salt flow, which are sourced in autochthonous salt and by definition are still linked to the primary salt level, and the more basinward flows sourced in allochthonous salt where the salt slug is no longer connected to the primary weld (Rowan

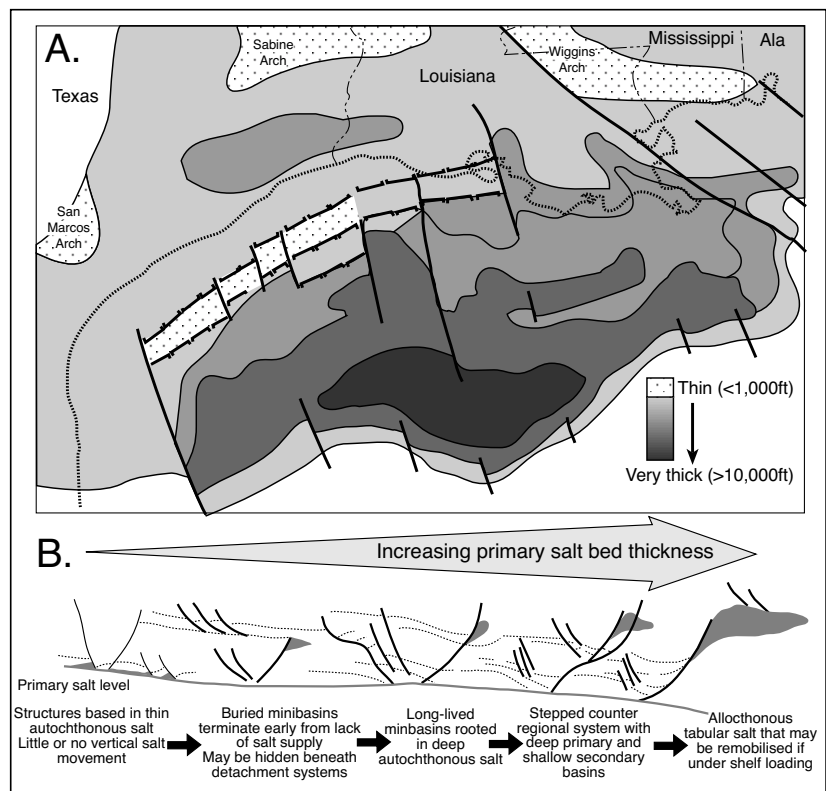

Figure 6.32. Salt tectonic style is controlled by original thickness of the primary salt layer. A) Approximate salt thickness at the time of deposition of the Jurassic Louann Salt. B) Schematic showing that autochthonous salt deformation tends to occur in zones of thinner primary salt, whereas allochthonous salt deformation is favoured by areas of thicker primary salt (after Karlo and Shoup, 2000).

et al., 2001). At the broadest scale of flow, Karlo and Shoup (2000) argue that the thickness of the primary salt bed (Jurassic Louann Salt) is what separates regions of autochthonous and allochthonous salt flow in the Gulf of Mexico. Allochthonous salt tends to be sourced in the thickest portions of the primary salt, while autochthonous flow tends to be sourced in the thinner areas of the primary source bed (Figure 6.32).

The resulting salt features and associated withdrawal basins make up an ordered but gradational sequence of structural styles across the shelf and slope (Figure 6.32; Karlo and Shoup, 2000). The sequence progresses from updip autochthonous basins with static diapirs that aborted and were buried, to the most downdip withdrawal basins that have been active at various levels in the stratigraphy since the Mesozoic and are related to an amalgamated and fully allochthonous salt canopy. They argue that differences in depositional thicknesses of the Louann Salt mean the thicker eastern half of the Gulf of Mexico basin has a full progression of salt-related structural styles, while the western half of the basin has a wide area lacking major salt structures that then abruptly juxtapose against tabular salt. The gravity slide detachments characteristic of the western half of the basin are superimposed over salt related structures where original salt thickness was insufficient to maintain structural growth at higher levels.

The work of Karlo and Shoup (op cit.) is supported by the results of Hall (2002) who found that most of the deep-water region of the northern Gulf of Mexico was underlain by an inflated mother salt layer during the Cretaceous to middle Miocene. The southern edge of this mega-pillow was either the depositional edge of the salt or a basement structure. Partial deflation of this mega-pillow during Late Miocene-Pleistocene sedimentation resulted in the formation of large structures overlying the mother salt. The process of 'deep' structuring was synchronous with progressive emplacement of shallow (allochthonous) salt to form the Sigsbee canopy in the southern part of the present-day deep-water area.

Compressional salt tectonics

Contractional or tectonically shortened salt basins are numerous and can be loosely classified into three conceptually shingled compressional styles (Figure 6.33; Letouzey et al., 1995):

- Zones of shortening at the toe of prograding and gravity-gliding systems (thin-skinned; Figure 6.34a),
- Thin-skinned deformation in fold and thrust belts (Figure 6.34b),

- Intracratonic inverted^{6.4} basins with or without wrench components - thick-skinned^{6.5} with basement involved in the compression (Figure 6.34c).

Contractional salt tectonism is produced either by convergent (including transpressive) plate tectonics, or is restricted to the seaward portions of divergent continental margins, where downslope gravity-sliding stacks and thrusts overburden blocks against each other as they slide basinward atop a salt décollement. Contractional salt tectonics require either the minimum principal stress (s_3) to be vertical (so creating shortening) or the intermediate principal stress (s_2) to be vertical (resulting in transpression; Jackson and Talbot, 1994). Compression in a salt-entraining basin tends to thicken both salt and its overburden units. This increases overburden strength and laterally squeezes the feeding stem of any existing diapir, while the increased overburden strength tends to impede piercement. Shortening or squeezing of diapirs, that earlier formed in extension, is an under-recognized process in gently shortened basins and a later section is allocated to this topic.

Shortening with gravity gliding

Belts of upslope extension are paired or linked to downslope compression on rapidly prograding shelf-slope systems on salt-cored passive continental margins. Overburden sediment slides downslope atop a lubricating salt layer, with the translation largely driven by the increasing weight of sediment accumulating atop the salt (Figure 6.34a). Shortening and compressional structures typify the toes of such systems, while extensional features and welds occur in the upslope position. Areas of extreme extension in the upslope regions evolve into regions of raft tectonics. In the zone between areas of extension and compression some large plates of sediment (up to tens of kilometres across and a kilometre or more thick) can shift or translate downslope with little intraplate evidence of migration until the downslope edge starts to experience compression and pop-up structures, such as squeezed diapirs, form.

The compressional toes of such regions of into-the-basin translation are characterized by rising growth folds and active thrusts. Compressional foot of slope systems lubricated by salt décollement include: the Perdido and Mississippi Fan

^{6.4} Inversion tectonics describes situations where older faults are reactivated and normal faults become compressional.

^{6.5} Thick-skin tectonics describes situations where the basement is involved and so tends to be dominated by higher angle faults compared to thin-skinned deformation.

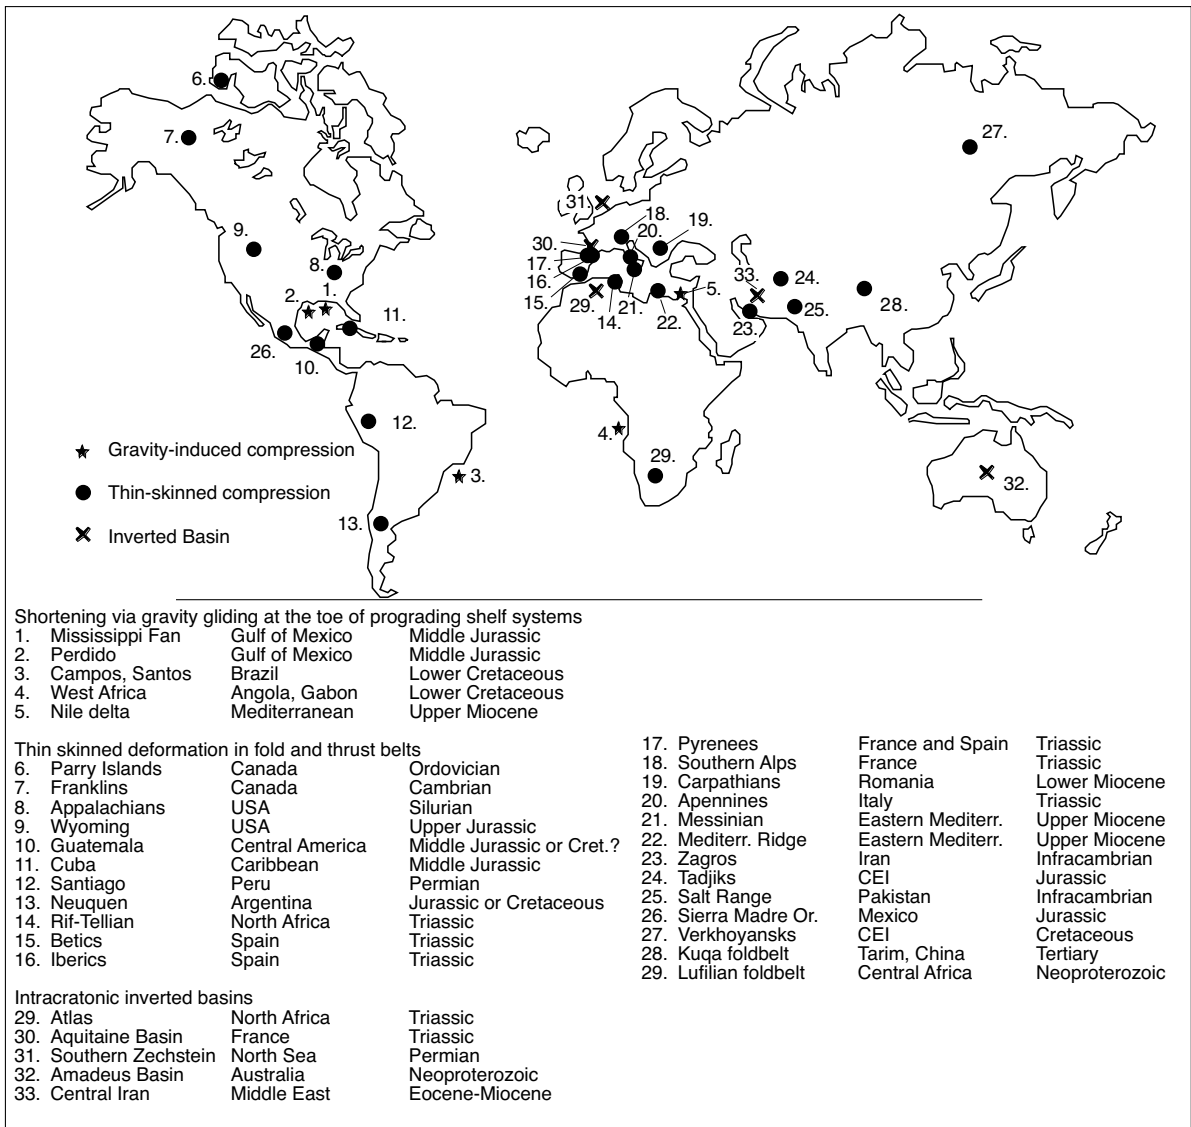

Figure 6.33. Worldwide occurrences of compressive deformation that involves salt sequences (in part after Letouzey et al., 1995; Davis and Engelder, 1985).

foldbelts in the Gulf of Mexico (Schuster, 1995), the deep Campos and Santos Basins of offshore Brazil (Cobbold et al., 1995, 2001), offshore west Africa (Duval et al., 1992; Cramez and Jackson, 2000; Brun and Fort, 2004), the eastern Mediterranean adjacent to the Nile Deep Sea fan (Sage and Letouzey, 1990), and offshore Yemen (Heaton et al., 1995). The salt in all the areas, with the exception of the Mediterranean, was precipitated in early post-rift time with consequent thermal subsidence generating a basinward tilt of the continental margin (typically > 1°-3°). The tilt was an early contributing factor to the décollement and gravity gliding, but was not the triggering

mechanism. That was supplied largely by differential loading tied to the rapid progradation of the up-dip shelf margin sediments. Compressional toe-thrust and diapiric systems are not the sole province of salt-floored systems, but also occur along the deepwater edges of mud-rich evaporite-free continental margins such as the Neogene fluvio-deltaic wedge of Brunei and the Niger Delta of Africa.

Because the extensional domain tends to lie in a more proximal shallower water position within such sedimentary basins they are, to date, better studied than the associated downdip com-

Figure 6.34. Compression tectonics. A) Gravity glide shortening at the toe of the continental slope. The basement is not involved in the deformation. B) Thin skinned deformation in front of the fold and thrust belt where subduction is the driving mechanism in the inner fold belt. C) Intracratonic inverted basin. Driving mechanism is regional contraction, which is orthogonal or oblique to the preexisting graben. Basement, salt and overburden are all shortened together (after Letouzey et al., 1995).

pressional terrain. This is the result of widespread hydrocarbon exploration and development in shelf and upper slope sediments. Structures characteristic of the salt-floored extensional domain include: salt rollers in the footwalls of listric normal growth faults, salt walls with triangular cross sections lying between intersecting conjugate normal faults, turtle anticlines and salt welds (see earlier in this chapter). Contractional or compressional domains tend to lie in deeper water further out into the basin at the foot of a continental slope or a prograding delta front. Many of these offshore compressional areas are covered by waters that are still too deep to be exploited with current drilling technology.

Shortening in gravity-glide salt belts is usually accommodated in salt-cored compressional foldbelts with growth-folds near the toe of the salt layer or at the base of the continental slope (Figure 6.34a). Contractional growth folds are the nearsurface subseafloor expression of a ramping thrust fault at the downdip end of an inflating salt allochthon. If the crest of a salt-cored fold is eroded or weakened enough by crestal faulting, salt may burst through as an active diapir. Once it reaches the surface, it can continue to grow as a passive diapir instigating a new allochthon-floored stratigraphic level of into-the-basin gliding.

The Mississippi Fan Fold Belt lies 200 km SSE of New Orleans and is defined by a such a series of ENE trending thrust-associated anticlines down dip of the current allochthon salt sheet

Figure 6.35. Thrust folding in downslope compressional belt, northern Gulf of Mexico (after Rowan, 1997). A) Map showing the location of presumed salt-cored anticlinal structures in the Mississippi Fan fold belt and locations of interpreted sections. B) Interpreted seismic section profile X-X' through a salt-cored anticline showing an asymmetric faulted detachment fold. C) Interpreted seismic section profile Y-Y' further along strike through the same structure, showing a symmetric faulted detachment fold. UMR = Upper Mexican Ridges; MMR = Middle Mexican Ridges.

canopy of the Jurassic Louann Salt (Figure 6.35). The fold belt probably defines the Jurassic limit of the original bedded

Louann Salt (Rowan, 1997). Today it is a zone of compressional response to updip loading and associated gravity spreading/sliding along a salt detachment, linked to updip normal faults (Figure 10.51b). Faults and folds are dominantly south vergent, although symmetric box folds and backthrusts exist. Updip, the shallow allochthonous salt sheets of the Sigsbee Nappe have over-ridden the landward portions of this same fold belt to create a number of hydrocarbon targets. Thickness variations in sediments above the Top MMR and a lack of such variations in more recent sediments of the Mississippi Fan unit suggest structures actively grew near the seafloor prior to the current episode of Tertiary-age shortening (Figure 6.35; Rowan, 1997).

Profile X-X' shows a seismic interpretation of one such asymmetric faulted detachment fold cored by the Louann Salt (Figure 6.35). Data from the Shell 471-1 Atwater well constrain the interpretation in the upper part of the section. The frontlimb of the fold is cut through by a major thrust fault, which is truncated up section by unconformable units of the Upper Mexican Ridges. A back thrust cuts through the backlimb and terminates against the main fault. Both thrusts are characterized by fault to fold transfer, although the displacement of individual units may vary up section. The overall geometry, fold-fault relationship, and the nature of the stratigraphic section, which consists primarily of alternating shales, chalk, marls, and turbidites, are all suggestive of an asymmetric faulted detachment fold (Mitra, 2002). The upper part of the Upper Mexican Ridges consists of growth units, which are strongly thinned and eroded on the crest of the structure, suggesting that the folds formed primarily during the deposition of these units (growth-fold deposition). The growth units thin onto the crest of the structure on both limbs and also are truncated on the backlimb. The salt cored structure shown in profile Y-Y' is located further east along the same ridge (Figure 6.35). It has a more symmetric pop-up geometry with a relatively flatter fold crest. Thrust faults on both limbs terminate upward within the Upper Mexican Ridges and downward within the Louann Salt. The thrust fault on the southern limb has a larger displacement; however, the difference in displacement on the two thrusts is smaller than in profile X-X'. Once again thickness changes in the upper part of the Upper Mexican

Ridges unit show it is also a growth fold, with fold-related seafloor topography controlling depositional patterns on the seafloor. The structural characteristics of this part of the fold ridge are suggestive of the symmetric faulted detachment fold model of Mitra (2002), with thrust faults propagating through rotated segments on both limbs.

Regionally, the style of compression across a salt-lubricated toe of the slope system is largely controlled by the extent of the salt layer (Letouzey et al., 1995). If the mother salt layer extends well out into the basin and beyond the zone of significant compression, the system tends to form a fold belt dominated by salt-cored buckle folds with little or no evidence of thrusting. If, on the other hand, the salt layer pinches out near the toe of the slope, the friction coefficient at the base of the contracting sediment pile is greatly increased and forms a narrower thrust-faulted zone (Figure 6.36).

The degree of shortening in such compressional thrust terrains can be substantial. In the deep water Santos Basin, Brazil, the downdip section is shortened by up to 50% of its original length as the seaward margin of the salt belt flows out over the backstop basalts of oceanic basement (Figure 6.37). Many of these thrust blocks show typical contractional salt thrust assemblages of sediment wedges in their footwall and chronologically older (Aptian) salt in their hanging walls. Interestingly, the giant oilfields of the Campos Basin and the fields of the Santos Basin only occur atop salt breakout windows on the inboard side of the belt of continuous salt or atop the zone of salt welds. This

Figure 6.36. Location of basinward pinchout of the salt layer controls the style of contractional/compressional structures. A) Where the salt layer does not extend out far past the foot of the continental slope, the frictional resistance increases at the base of the sedimentary pile and interferes with further basinward movement. This can create an imbricate thrust zone on the updip side of the salt pinchout. B) Where the salt layer extends across the basin and well out from the foot of the continental slope, the contraction is taken up in a series of buckle folds with crests that tend to lack thrust zones (after Letouzey et al., 1995).

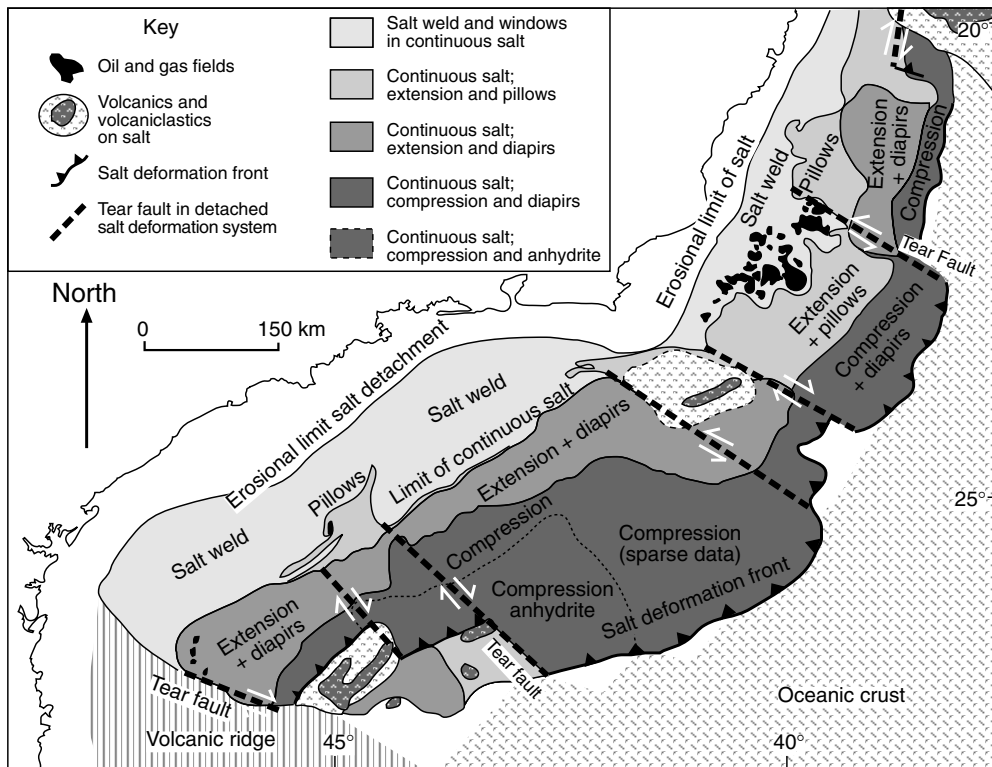

Figure 6.37. Map showing relationships between the various salt-detached basins in the Santos and Campos basins of offshore Brazil. Oil and gas fields only occur updip of the limit of continuous salt in suprasalt turbidite reservoirs that are sourced from sub salt lacustrine sediments (after Meisling et al., 2001).

reflects the high seal integrity of continuous salt sheets, which prevent hydrocarbons generated in the mature subsalt salt source from reaching the suprasalt turbidite reservoirs (Meisling et al., 2001). It is a very positive indicator of the possible presence of large subsalt traps some distance further offshore where halokinetic salt sheets constitute more continuous layers.

At the broad scale of salt flow in passive margin sediments along the edge of a widening ocean basin there is also the process of increasing shelf edge to ridge distance to be considered. Over time this will create an increasingly broad compressional zone in the zone of transitional crust at the foot of the continental slope. This is clearly illustrated in the expanding compressional belt down dip of the zone of raft tectonic in the seaward margin of the Kwanza Basin, Angola (Figure 6.37; Fort et al., 2004). A thick sequence of Cretaceous (Aptian) salt was laid down atop lacustrine sediments in the opening rift, followed by a transition into marine sediments the passive margin. Three groups of sediments make up this marine wedge; The Pinda Group (Albian to Late Cretaceous), consists of a carbonate platform followed by sedimentation increasingly dominated by marls and clays. The Iabe-Landana Group (Late Cretaceous to Eocene)

consists of dominantly siliciclastic sediments, with locally significant carbonates. Most of these deposits are located on the current platform, pinching out seaward into condensed sections, indicating a long-term highstand during the Late Cretaceous. The Malembo Group (Oligocene to the present day) corresponds to a large, prograding clastic wedge. The salt has acted as a décollement allowing updip extension and downdip compression.

The extensional domain is characterised by oceanward-sealed tectonic blocks, rollovers and diapirs, while the downdip compressional terrain is characterised by growth folds, squeezed diapirs and thrusts (Figure 6.38).

The compressional zone is divisible into; 1) an inner more upslope subdomain characterised by formation of contractional diapirs by the compression of former extensional diapirs (squeezed diapirs) and 2) an outer more downdip subdomain characterised by growth folds and thrusts. The upper subdomain indicates the expansion of the compressional domain in a more upslope direction as formerly extensional suprasalt sediments slides and piles at the foot of slope. The ductile diapir salt is trapped and pinched in anticlinal cores, leading to the formation of contractional diapirs that typically do not necessarily extrude at the surface but are stopped and sealed by further sedimentation. This type of updip extension and downdip compression indicates an initial salt geometry that wedged or thinned in both seaward and landward directions at the end of the margin-rifting stage (Aptian; Figure 6.38a). Postrifting cooling of the lithosphere then induced a seaward tilt in the margin and the development of gravitational instability, creating a seaward spreading-gliding system with an extensional upper end and a

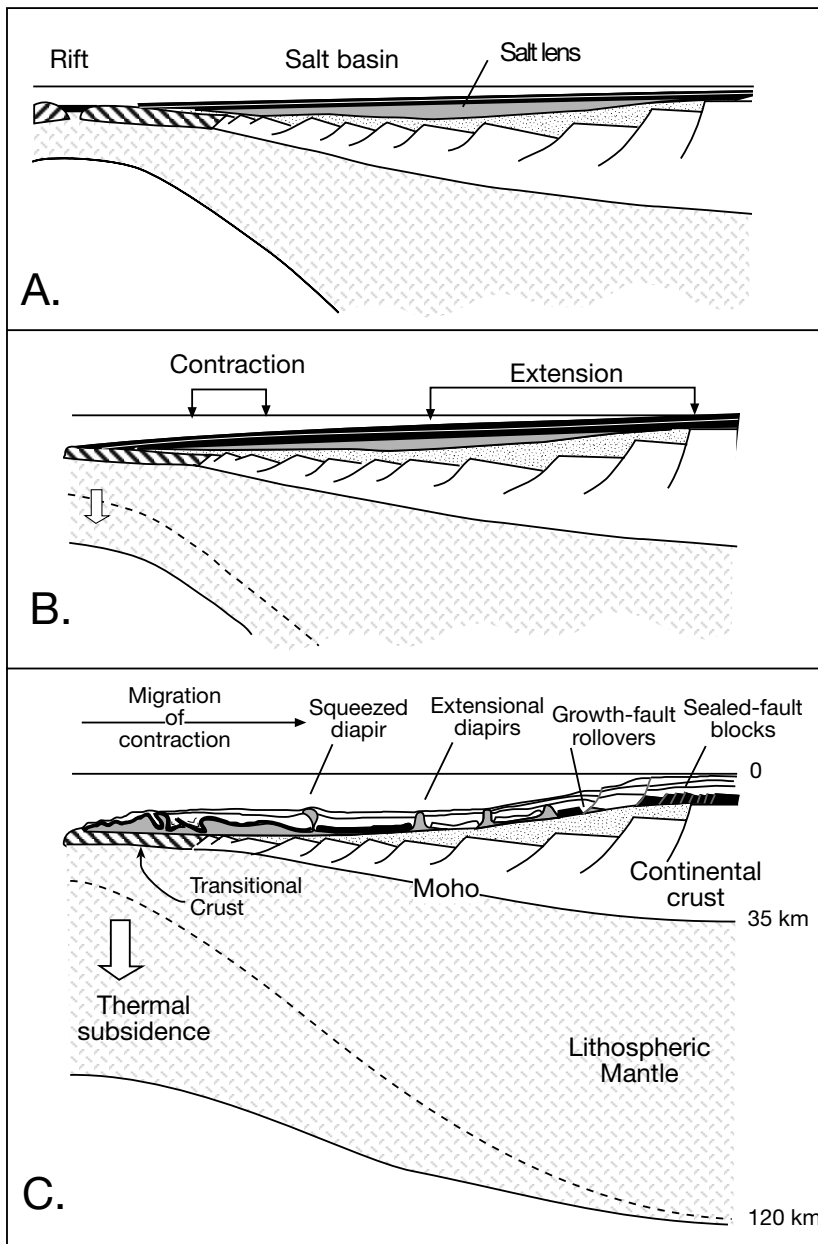

Figure 6.38. Evolutionary model of gravity spreading above salt in a passive-margin tectonic setting, at lithospheric scale based on the offshore region of Angola, central Africa. A) Initial stage following continental breakup. The salt basin is entirely covered by sediments that overlie oceanic crust. B) Synchronous initiation of contraction downslope and extension upslope. The compressional domain initiates at some distance from the salt wedge toe. C) Major displacement of extensional and compression domains during spreading. Compression migrates both downslope and upslope. Downslope migration reaches the salt toe. Upslope migration reaches the downslope part of the extensional domain, thus inducing diapir squeezing. Slope increases during spreading as a consequence of lithospheric cooling and subsequent subsidence. (Fort et al., 2004).

compressional downdip end (Figure 6.38b passing to 6.38c). The increasing into the basin tilt due to thermal subsidence drives an updip migration of the zone of compression or contraction (Figure 6.38c). Over time diapirs that formed by extensional processes become squeezed and take on the structural and trap morphologies of diapiric structures indicative of this compression (Figure 6.47).

Thin-skinned fold and thrust belts

Widening salt-floored rift basins are subject to later closure (Wilson cycle; Figure 5.27), so compressional deformation is often superimposed on originally extensional halokinetic margin (Figure 6.34b) or its aulocogen counterpart in the continental interior (Figure 6.34c). Allochthonous salt acts as a lubricant to any consequent thrust sheet as it pushes landward. Thin-skinned fold and thrust belts form in mountain chains where the basement is not involved in the deformation and evaporite layers are preferred detachment horizons (Letouzey et al., 1995). Resultant structures are predominantly oriented parallel to the intermediate stress direction and perpendicular to the maximum shortening. Examples of thin-skinned fold and thrust belt include: the Parry Islands Foldbelt in Arctic Canada (Harrison, 1995), the European Jura (Philippe, 1994), the Spanish Alps (Flinch et al., 1996), the Lufilian fold belt of Central Africa (Figure 7.27; Jackson et al., 2003), the Adelaidean foldbelt of southern Australia (Marshak and Flottmann, 1996), the Kuqa foldbelt of Tarim Basin of NW China (Liang Je Tang et al. (2004) and the Zagros Foldbelt of Iraq and Iran (Talbot and Alavi, 1996).

Figure 6.39. Characteristics of thrust propagation and taper angle in a salt cored and nonsalt cored thrust A) Salt lubricates thrust sheets. B) No salt to lubricate thrust sheet. Salt cored thrusts are wider, show more extensive thrust propagation, thinner thrust cross section and taper angles $<2^\circ$; while those deforming over other rock layers are narrower, with taper angles nearing 8° (after Davis and Engelder, 1985, 1987).

The style of deformation is dependent largely on the friction coefficient acting along the detachment level(s). The lower the basal friction level, the further the thrusts propagate out and so the wider the thrust belt, the thinner the cross section of deformation and the lower the taper angle (Figure 6.38: Davis and Engelder, 1985, 1987). A salt décollement in a compressional thrust terrain also enhances the development of major backthrusts and greater outward migration of the deformation front (Luján et al., 2003; Velaj et al., 1999). Preexisting faults and salt welds in a halokinetic prism on a passive margin can be a major zone of weakness in the development of subsequent compressional structures. Hence the very close association between preexisting faults and the current elongated salt structures of the southern North Sea (Figure 6.42).

A fundamental consequence of salt weakness in many salt-detached thrust foldbelts is an absence of a preferred direction of thrust transport (Figure 6.39; Davis and Engelder, 1987; Harrison, 1995; Bahroudi and Koyi, 2003; Luján et al., 2003). The geometry of individual thrusts and anticlines reveals little or nothing about the location of the tectonic hinterland without some independent understanding of the regional geol-

ogy. Angular folds (box folds, chevron folds and mitre folds) predominate in a buckling thin-skinned salt-cored thrust belt, reflecting internal deformation of anisotropic multilayers above the thin, ductile salt substratum. If the deforming salt substratum is thicker, the multilayers tend to buckle as a single unit into large sinusoidal folds, with consequent loss of fold angularity. Mixtures of forethrusts and backthrusts are common even in individual salt-cored anticlines.

An active example of this style of thin-skinned thrust, lubricated by salt, is found in the Salt Range region of Pakistan (Figure 6.40). The Salt Range and Potwar Plateau are the external and most recent expression of Himalayan shortening. This thin-skinned fold-and-thrust belt is detached upon thick Lower Cambrian evaporites of the Salt Range Formation. This basin-wide evaporite unit underlies the Potwar Basin and is roughly equivalent in age to the Hormuz Formation in the Zagros Belt of the Arabian Gulf. The presence of thick salt facilitated rapid thrust propagation of the basal detachment before the main fault plane rose to form the Salt Range thrust above a basement frontal ramp at the southern termination of the basin.

A dextral wrench zone defines the western limit of the Salt Range and corresponds to the edge of the halokinetic Infracambrian evaporite (Cotton and Koyi, 2000). There are three main zones of deformation across the Salt Range and Potwar Plateau: from north to south, these are the Northern Potwar deformation zone, the Soan syncline, and the Salt Range (Figure 6.40). Deformation in the Northern Potwar deformation zone is characterized by the development of an imbricate duplex in the footwall of the Main Boundary thrust of the Himalayas. Deformation of the overlying Main Boundary thrust sequence constrains development of the Northern Potwar deformation zone to younger than 10 Ma. The northern limb of the Soan syncline marks the southernmost limit of uplift in the Northern Potwar deformation zone. The northern limb of the Soan syncline is steeply upturned, forming a monocline. A sequence of salt cored pop-up structures and broad anticlinal swells accommodated shortening formed to the south of the Soan syncline axis. The contrast in deformation styles between the Northern Potwar deformation zone and the Soan syncline, seen in Figure 6.40, is attributed to the lubricating effect of the Infracambrian evaporite sequence (Salt Range Formation).

The Salt Range today forms an approximate east-west hanging wall in a thrust that accommodates ~25–30 km of shortening (Baker et al., 1988). The majority of deformation was accommodated within the hanging wall with some minor imbrication of the footwall. Deformation in the Salt Range area is considered to have occurred in two pulses, commencing ca. 5 Ma with a later pulse at 2 Ma. Lag time between pulses is attributed to breakback thrust development in the northern limb of the Soan syncline. The anomalous thickness of salt that has accumulated beneath the hanging wall of the Salt Range thrust is a result of differential loading by a prograding basin fill and

deformation front moving south from the growing Himalayas. This combination of sedimentary and tectonic loading caused a southward migration of the Salt Range Formation (like squeezing toothpaste). This thickening has been assisted in the central Salt Range by the buttressing effect of a major basement fault in front of the southward-migrating salt (Figure 6.40).

Another well-documented example with more than 200 km of salt-lubricated translation characterises the Triassic section of the external domain of the Betic Cordillera, near Gibraltar in the Mediterranean, where the thrust block is rootless and allochthonous (Flinch et al., 1996; Luján et al., 2003). The frontal accretionary wedge of the Guadalquivir allochthon consists of Triassic evaporites and red beds that form a gypsum-cemented melange mixed with Upper Cretaceous-Palaeogene deepwater sedimentary rocks. Throughout the unit, Jurassic rocks are absent. The widespread Triassic evaporites of the Guadalquivir allochthon were originally emplaced as gravitational allochthonous masses or salt sheets at the foot of the Betic continental slope. This occurred originally in a passive-margin gravity glide setting, much like the present day emplacement of allochthonous sheets of Jurassic salt atop Neogene sediments in the Texas-Louisiana Gulf Coast or the Santos Basin of Brazil. Later, during Neogene formation of the Gibraltar Arc, these evaporites were overthrust as an accretionary wedge to form the Guadalquivir allochthon. This explains the lack of Jurassic sediments within the melange of Guadalquivir allochthon. Triassic halokinetically pierced strata were thrust back up onto the former passive Betic margin, a lateral distance of some 200 km, from an area that lacked Jurassic deposits. Thus the Guadalquivir allochthon ended up atop sediment that was originally located well landward of the Guadalquivir prism.

Figure 6.40. North-South cross section in Pakistan across the Northern Potwar deformation zone (NPDZ), Soan syncline, and Salt Range (after Cotton and Koyi, 2000). Three deformation zones can be seen: an imbricate stack (NPDZ) forming a wedge at the rear northern part; a zone of broad anticlines and synclines with pop-up and/or pop-down structures in the middle; and a zone of thickened allochthonous salt (Salt Range) in the south.

Inverted basins

Varying degrees of inversion are common in many intracratonic basins, which tend to evolve into a compressional regime some time after subsidence of the initial extensional rift/sag has ceased (Figures 6.34c, 6.41). Salt-floored inverted basins typically pass laterally into a thin-skinned thrust terrain. By the time inversion occurs much of the sediment atop the primary salt interval is indurated and the basin is laterally confined. Examples of salt-entraining inverted basins include the relatively mild effects of Tertiary shortening of Palaeozoic and Mesozoic sediments in the southern and central North Sea Basins (Hooper et al., 1995; Stewart and Coward, 1995; Eggink et al., 1996) through to more extreme basin overprints as seen in the Cretaceous shortening of Triassic basins in the Atlas fold belt of north Africa (Vially et al., 1994), the Palaeozoic shortening of Neoproterozoic basins in the Flinders Ranges and the Amadeus Basin in central Australia (Stewart et al., 1991), and the Eocene-Miocene shortening of Palaeozoic and Mesozoic basins in the Zagros of central Iran (Jackson et al., 1990). Under a regional shortening event that is orthogonal or oblique to preexisting structures, the inversion typically squeezes hanging wall blocks upward, as the original extensional normal faults become compressional (Figure 6.41). Basement, salt and overlying sediments are all shortened with pre-existing salt structures (pillows, diapirs and walls) frequently taking up much of the initial compression.

Where the horizontal compressive stresses are near orthogonal to preexisting extensional structures and where these are bound by high angle normal faults, much of the inversion above the salt layer is accommodated by forced folding rather than slip along the former faults (Letouzey et al., 1990). New low-angle reverse faults are firmly rooted in the décollement salt and typically

Figure 6.41. Structural evolution of an inverted basement graben varies according to structures present in preexisting graben (salt is grey). A) Folds and short-cut faults develop in homogeneous strata above inverted basement faults. Fold hinges in the graben are perpendicular to the regional compression. B) Thrusts and folds are localised by preexisting salt structures. C) Thrusts and folds are localised by reactivation of basement faults (after Letouzey et al., 1995).

originate at the crest of the upthrown basement block, and so passively transport the former high-angle normal fault planes (Figure 6.41). This initiates short-cut thrust geometries. If the horizontal compression is oblique to the former normal fault, a strike-slip component is induced that can reactivate former high angle normal faults. In addition to conventional inversion features, such as forced folds and short cuts over basement faults, strike slip will also form *en echelon* synthetic faults in

the hanging walls of preexisting basement faults (Letouzey et al., 1995). Such *en echelon* systems define the basin edge of the Sahara flexure in Algeria (Vially et al., 1994).

Lateral pressures on a fluid salt décollement horizon undergoing compression promotes decoupling of the overburden and so create the following associations:

- Folding is more common than thrusting,
- Folds and thrusts lack consistent vergences, being commonly expressed as box folds and backthrusts;
- The cross sectional taper is typically low angle, which results in extremely broad fold and thrust belts;
- Complex three-dimensional edge effects form at the lateral boundary of the salt substratum.

Mild shortening in tectonically confined basins

Salt flow occurs within basins confined on either edge and subject to varying degrees of compression. Pre-existing basement structure is an obvious broad scale control on the development

and location of the various salt features in these basins while formerly extension diapirs experience compressional shortening. Salt walls and ridges of Permian salt in the southern North Sea Basin are type examples of extension followed by basin shortening and inversion. Many ridges tend to follow well-defined trends that parallel reactivated basement faults (Figure 6.41c, 6.42; Remmelts, 1995; Stewart et al., 1997). In other words, present suprasalt patterns in much of the southern North Sea Basin are not decoupled from subsalt structure, unlike the current gravity glide systems of the Gulf of Mexico. North Sea salt structures tend to first develop as extensional features atop the high of the upthrown basement block and are slightly offset but parallel to the controlling basement fault. At the same time salt was rising into these features, into-the-basin flow of salt was also creating downslope compressional buckles. Both these features typically first formed in the early Mesozoic, many millions of years after the Zechstein salt deposition had ceased (Mohr et al., 2004). Many such extensional diapirs were

then further altered during subsequent late Mesozoic compression and inversion.

There are three salt domains (defined by parallel salt ridges) in the southern North Sea (Figure 6.42; Remmelts, 1995). The first, in the north, are elongate salt structures oriented north to northeast in a province that runs from the Central North Sea Graben to northern Germany. The second encompasses the region from English waters to onshore Netherlands where the salt structures are elongated northwest and made up of both pillows and walls. The third encompasses onshore southern Germany where an eastward trend is more obvious and encompasses both pillows and low salt walls. Small structures, with no preferred orientations, separate the three domains. The domains defined by the various salt ridges correspond to the structural grain in the basement.

Triassic extensional faults strike north to north-northeast in the northern part of the basin where they form the boundary of the

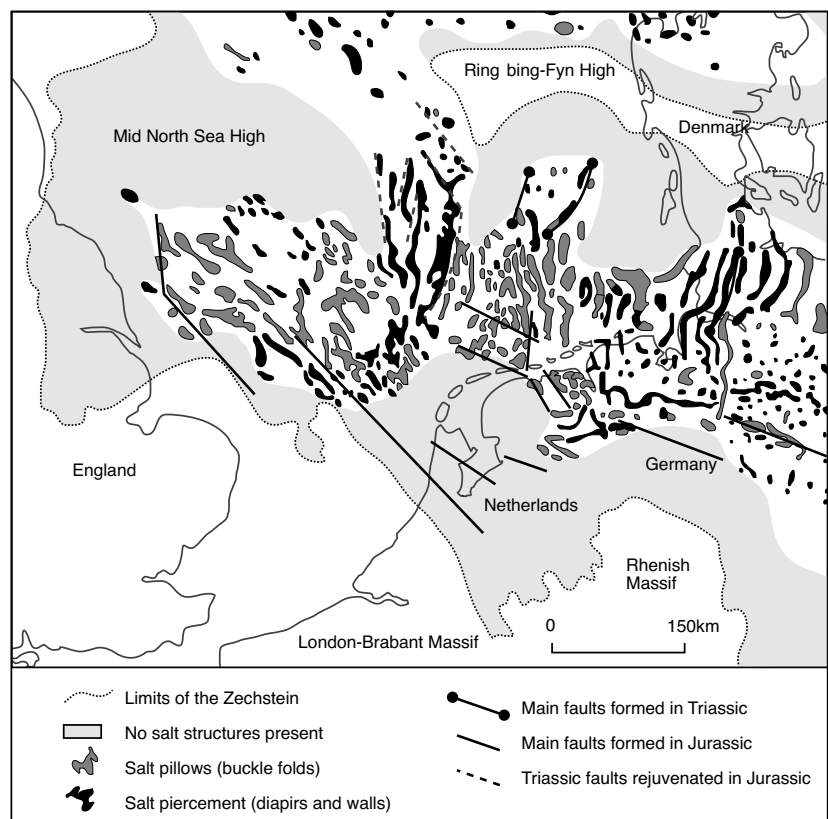

Figure 6.42. Salt structures in the southern North Sea showing that salt flow tends to be restricted to the basin centre. The various structures show a regularity of ridge spacing and there is an association with the major fault directions in the basin (after Remmelts, 1995).

Figure 6.43. Driving mechanisms for the evolution of suprasalt features atop the Zechstein salt in the western part of the southern North Sea Basin. All listed mechanisms, except thick-skinned extension, played a role. Salt structures evolved as the basin tectonics evolved from extension (upper diagram) to compression (lower diagram) and there is always an element of detachment tectonics, such as buckle folding, in the current distribution of the salt layer (after Coward and Stewart, 1995).

Central North Sea Graben, the Horn Graben and the Glückstadt Graben, while in onshore Germany this same orientation defines the Ens Low and the Weser Depression. Further south, extension was accommodated by transtensional slip in a northwest direction. Not only are the orientation of salt ridges and fault trends related across the domains, but so is the timing of salt movement and faulting. Salt piercement and basement fault movement is dominantly Triassic in the northern part of North Germany, while in the south a Jurassic age prevails. Piercement is mostly Late Jurassic in the Central North Sea Graben, as is the main tectonic phase.

Many diapirs in the southern North Sea Basin were initiated along extensional faults that defined half-graben edges in Triassic to Jurassic times (Figures 6.43, 6.44a). The lack of primary rim synclines indicates that many of the structures became diapiric without going through a pillow phase immediately atop the Zechstein salt. In extension the diapirs grew mainly by asymmetric downbuilding with salt rise focused on the upthrown block adjacent to the fault, probably with sporadic periods of bathymetric relief created at diapir crests (Figure 6.43, 6.44a). The associated hanging wall tilt drove gravity gliding of the post-salt section, with resultant low-angle extensional faulting upslope and salt-cored buckling downslope

with structural trends following basement grain (Thomas and Coward, 1996).

Many extensional half-grabens were subsequently tightened or compressed by a phase of thin-skinned inversion, associated with back-steepening of the margin fault system and a resulting reactivation of the extensional detachment system. The effects of this inversion have been noted in many parts of the northern North Sea so that post Early Cretaceous and Tertiary history of the southern North Sea Basin is compressional, not extensional. This is expressed as changes in basin tilt and in reverse slip on individual faults so that parts of the North Sea basin now tilt to the northeast, a reversal of the original Jurassic tilt direction in the UK section of the southern North Sea Basin (Figure 6.43; Stewart and Coward, 1995). This is especially obvious in thrust faults and structures that fringe the Broad Forties basin (Hayward and Graham, 1989 but is seen across the North Sea Graben (Thomas and Coward, 1996) and much of the southern North Sea Basin (Remmelts, 1996; Stewart et al., 1997). Within the South Viking Graben, shortening estimates vary between 14 and 18% and are expressed on seismic data by localized hanging wall folds and the back-steepening of faults along the fault complex of the western margin of the graben, together with out-of-graben thrusting up the hanging wall dip-slope.

In order to fully explain the elongate salt walls and pillows of the southern North Sea Basin the effects of both extension and inversion must be considered in the final analysis of the salt structure geometry. Recognition of significant inversion can change the interpretation of some elongate salt-cored anticlines from salt pillows/swells to compressional buckle folds and squeezing of earlier extensional structures (Figure 6.47). Clearly, any precontractual salt tectonics strongly influences the location of subsequent thrusts and folds (Figure 6.41; Letouzey et al., 1995).

During contraction and inversion, folds and thrusts are initiated where thickness variations in the salt were already present in the overburden (Figure 6.44a; Vendeville and Jackson, 1992a,b; Nalpas and Brun, 1993). Erosional thinning of the overburden over salt ridges or salt walls also localises thrusts and folds, even when they are not related to basement normal faults (Figure 6.44b). Décollement atop the compressed salt also induces normal-fault offsets on the top of salt that then localise thrusting and facilitate subsequent reactive diapirism (Figure 6.44b).

Figure 6.44. Extension and conversion structures, North Sea. A) Evolution of the Step Graben in the North Sea. Triassic extension focused the formation of salt structures atop normal faults in Sub-Zechstein basement. Early block faulting and accompanying rotation causes bedding plane parallel salt flow and pillowing atop the fault plane. This is followed by compression (shortening and inversion), tied to the Cretaceous unconformity and deposition of overlying sealing shales. Shortening drove oversteepening and flow reactivation during the Cretaceous-Tertiary inversion (after Remmelts, 1996). B) Buckle fold evolution with crestal erosion culminating in diapirism (after Coward and Stewart, 1995). See also Figure 6.47.

Can extrusion indicate extreme shortening?

With enough time, a sedimentary basin evolves from extensional to compressional or re-activated diapirs (Wilson Cycle), or a gentle salt anticline can evolve from a pillow created by gravity-driven downslope compressional folding (with an upslope extensional regime) into a compressional buckle fold via inversion (Figure 10.47). Salt can breakout out from anticlinal crests in either scenario and if it escapes onto the landsurface or seafloor it can initiate a new phase of passive diapirism.

Lateral shortening via buckling encourages thickening of salt in the anticlinal core, while the associated folding and crestal erosion can create the structural relief necessary for buoyancy and possible salt emergence, as can pinch-off from the mother salt layer. Such buckled salt-cored anticlines constitute the source to salt in the active namakiers of the Zagros Fold Belt of Iran (Figure 6.45). Once salt is extruded the original salt-cored anticline is subject to collapse and erosion (Figure 7.14).

But physical modelling of salt under compression creates a quandary as to whether the buckling and the thickening of a salt anticline alone can build sufficient pressure to initiate active diapirism, especially if the salt in the buckle-fold core is still connected to the mother salt layer. Physical models of a buckling compressional system using brittle overburden and a viscous salt-analogue silicone gel layer do not show breakout at the thickening anticlinal crests (Vendeville and Jackson, 1992b; Letouzey et al., 1995; Koyi, 1998). The silicone gel initially thickens in the rising anticlinal cores, then is squeezed out back down into the mother salt layer (the squeezed salt/gel takes the path of least resistance compared with breaking through the brittle overburden), or the gel is dragged along thrust planes. In all cases it stays in normal stratigraphic contact with the overlying thrust sheet. Only when there is a pre-existing diapir stem, or there is crestal erosion, or if the salt core is pinched off from the original mother salt level, is salt extruded. Extrusion in physical models with brittle overburden tends to occur whenever the stem is cut off from the mother bed and then the extrusion event is short lived (aka "popping the pimple").

Yet, 300-metre high glaciers of Neoproterozoic salt are flowing today across the landscape in the eastern foldbelt of the Zagros Mountains, Iran. The ubiquity of salt glaciers (namakiers) in this part of the Zagros foldbelt clearly shows salt can breach anticlines within regionally compressed terrains (Figures 6.45a, b, 6.46a). Zagros folds in this area are elongated symmetric whalebacks or box-shaped anticlines trending in a generally NW-SE direction, with the main thrust detachment at the level

Figure 6.45. Namakiers of Iran. A) Salt glaciers (dark blebs) of Hormuz Salt flowing across the landscape of Iran north and east of the coastal town of Bandar Abbas, offshore islands are also cored by salt diapir and with now inactive glacier residues at surface. B) Later view looking east across the Gach - Shoor region (Images courtesy of NASA, NASA/GSFC/METI/ERSDAC/JAROS, and the U.S./Japan ASTER Science Team; see <http://asterweb.jpl.nasa.gov/gallery>; accessed Dec 7, 2004).

of the Precambrian Hormuz salt (Alavi, 2004). Hundreds of kilometres to the northeast from the Hormozgan district, in the hydrocarbon rich section of foreland fold belt in the Fars district, the Miocene evaporites of the Fars/Gachsaran Formation can act as a secondary detachment level whereby pairs of shallow thrusts are rooted with opposite vergences toward the crest of the anticline (Figure 10.56). Besides gently dipping overthrusts, many salt-cored folds in the Hormozgan region are dissected by subvertical normal and wrench faults (Talbot and Alavi, 1996). The Zagros fold system in this region is

overthrust along, and cut off by, the Zandan Thrust, a branch of the Zagros Main Thrust, approximately 75 km east of Bandar Abbas. Salt breakout in the salt-cored anticline does not occur unless the crest of the anticline is faulted or eroded (Figures 6.44b, 6.46b). Clearly salt undergoing compression in a natural foldbelt does not easily pierce thick brittle overburden, as in the analogue models.

Bosak et al. (1999) and Fürst (1976) note that outcropping salt plugs and associated namakiers are mostly associated with sigmoidal bends in fold axes (the circular plugs of Fürst 1976) or occur near terminations of anticlines (plunge turnovers). Many flows are sourced on anticlinal flanks and not in axial crests (Figure 6.45b). This observation implies that zones of fault-induced extensional shear are more important in controlling the site of salt emergence rather than the zone of extension across the culmination of anticlinal crests (salt leaks out of the sides of sliced structures; we are slicing bladders, not popping pimples!). A few of the salt plugs on the anticlinal flanks lie closer to the synclinal axis than to the anticlinal axis. But in some of the less active namakiers the site of the original emergence can be difficult to define as extruded salt always rolls downslope. If it is cut off from its source, it will end up occupying flanks and synclinal axes. Even so, the following generalizations can be made; most salt plugs outcrop in bends

or faulted displaced offsets of the anticlinal axes, salt typically does not breakout in areas of straight (unfaulted) anticlinal axes. This led Talbot and Alavi (1996) to argue that Hormuz salt emerges as namakiers where the salt cored anticlinal crests are cut by faults, such as in the Kazerun and Mangarak fault zones (Figures 6.46b). A similar system of extensional tear faults across salt-cored compressional anticlines also explains emergent salt in Miocene salt diapirs of the Alborz region of Iran and Triassic salt in the Atlas ranges of Algeria (Figure 6.46c; Talbot and Aftabi, 2004; Vially et al., 1994).

Other than faulted and eroded anticlinal buckle folds, most other salt- or salt breccia-defined outcrops in compressional situations are along salt-lubricating thrust planes. Examples include Miocene salts in the Carpathians of Romania (Figures 10.58, 10.59), Triassic salts in alpine thrust belts in southern France and Spain, the Neoproterozoic Roan breccias of the Lufilian fold belt of Central Africa (Figure 7.27) and the Callana Formation breccias of the Flinders Ranges of South Australia (Figure 7.23). Modelling by Vendeville and Jackson (1993) showed that thrusting and strike-slip faulting can initiate asymmetric diapirism and salt allochthons in a compressional setting, but do so much less effectively than in extensional terrains.

Because compression driven emergence is occurring today as spectacular 1,000 m high salt glaciers in the Zagros mountain chain of Iran, allochthons as compressional features tied to later tectonic inversion are perhaps afforded a greater significance in salt tectonic modelling than the much larger but not so visible, compressional allochthons that typify the continental slope and rise positions of salt floored passive margins, as exemplified by the various the Atlantic basins. Interestingly, the Triassic thrust belts of southern Europe examples have now been reconstructed using balanced section techniques and the spectacular salt-cored thrust belts are seen to be centred on reactivated diapirs, first formed in an earlier extensional phase that was then

caught up in the thrust belt (Dardeau and Graciansky, 1990). How widespread the inheritance of salt diapirs and walls from extension into compressional thrust planes is still under debate although the early stages of the expression of the compressive belt are occurring in offshore Angola at a time well before any episode of continent-to-continent collision (Figure 6.38c). There is now widespread agreement that salt plays a fundamental role in controlling the amount of shortening in thin-skinned salt-entraining thrust provinces and outcomes range from mild inversion of an previously extensional system (such as pillow structures of the North Sea; Stewart and Coward, 1995) to fully developed salt-cored detached fold-and-thrust belts in the various alpine chains of Europe, North Africa, southwest Asia and central Australia.

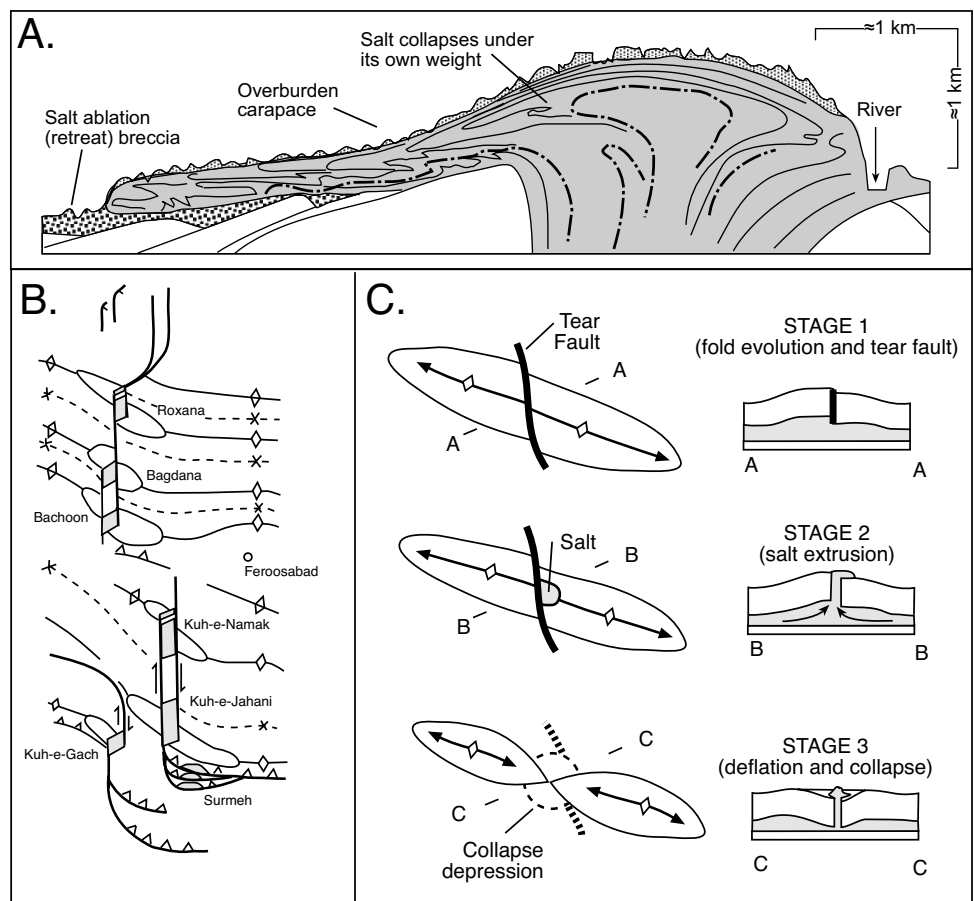

Figure 6.46. The importance of faulting as a control on salt extrusion in compressional buckling regimes. A) Cross section of Kun-e-Namak diapir, Iran. Internal folds show how salt flows over the landscape like the rolling track of a military tank (after Talbot, 1979). B) Current kinematics of Mangarak fault zone, Iran, showing the location of extrusions (grey) in zones where fault zone crosses salt-cored anticlinal culminations, shown as elliptical areas (after Talbot and Alavi, 1996). C) Schematic based on Algerian examples showing how salt extrusions occur where tear faults intersect salt-cored anticlinal culminations (modified from Letouzey et al., 1995). See Figure 6.45 for location of Iranian diapirs.

Criteria	Downbuilding	Rejuvenation driven by compression
Stratal thickness	Thick beds on the flanks thin over the salt, consistent with the syngrowth sedimentation patterns of Trusheim (1960) and Seni and Jackson (1983).	Uniform bed thickness over crest when not tectonically thinned. Large thickness of overburden folded above crest. High angle onlap onto pre-inversion unconformity.
Lithological variation	Thick beds on the flanks thin over the salt, consistent with the syngrowth sedimentation patterns of Trusheim (1960) and Seni and Jackson (1983).	Less concentric lithological variation produced when diapir inactive before inversion period.
Layer parallel shear	Normal sense of movement away from crest, caused by material sliding off crest.	Reverse sense of movement toward the crest.
Faulting	Small displacement normal faults on diapir shoulders, dipping away from the diapir. Crestal graben. Large listric growth faults along part of the salt contact.	Convex upward thrusts in the overburden on the shoulder of the diapir. Crestal horst as well as graben. Normal faults, strike-slip faults and thrust faults directly above the diapir e.g. Withjack and Scheiner (1982).
Drag zone geometry	Narrow and high relief.	Broad and lower relief.
Regional deformation	Regional extension faults.	Regional folds and thrusts and inverted extension structures in the cover.
Fold geometry of concordant overburden	Geometry moulds to the diapir.	Broad at top or, fold shapes unrelated to the underlying diapir shape.
Withdrawal basin	Primary and or secondary rim syncline sometimes present.	Absent when diapir is growing by compression. Diapir continues to grow even when source is severed by welding.

Table 6.2 Criteria for separating downbuilt diapirs from diapirs which have been reactivated by regional compression (after Davison et al., 2000b; Vendeville and Nilsen, 1995).

Distinguishing downbuilt and reactivated (mildly squeezed) diapirs

The preceding discussion of salt in compressional terrains shows that many extensional diapirs suffer later horizontal shortening (squeezed diapirs). Examples are found in all three compressional terrains, namely; a) thin-skinned fold and thrust belts at the toe of gravity-spreading systems on divergent margins, as in the South Atlantic, b) thin-skinned fold and thrust belts driven by plate convergence, as in the foreland fold belt of the Zagros Mountains, and c) inverted, thick-skinned extensional basins, such as the North Sea. Styles range from salt structures that merely acted as foci of mild compression induced folding and faulting to diapirs that underwent considerable rise of salt or reactivation.

Shortening squeezes salt in the diapir stem and so contributes to a short-term increase in salt supply. But this increase is temporary and decreases sharply once shortening closes and empties the feeding stem of the diapir. During shortening diapirs act as stress concentration zones where new folds/thrusts may form and propagate (Koyi, 1998). Thrusts can propagate from the salt pedestal and so cut the feeding stem of the diapir. These diapirs sag with time arguing that some of the inactive diapirs in the Zagros mountain belt may have their feeding stems cut-off during the Zagros orogeny. If breached, these diapirs can form large dissolution craters on the surface outlining the

region where the salt in their dynamic bulge has dissolved (e.g. Figure 6.46c).

In the relatively undeformed autochthonous salt region of the southern North Sea, the importance of Tertiary compression after Mesozoic extension was largely ignored until the early 1990s. Many diapirs cutting through the Tertiary section of the Central Graben, North Sea and the onshore basins of Germany, are now known to be rejuvenated diapirs with later episodes of salt flow driven by compression (Davison et al., 2000a, 2000b; Scheck et al., 2003; Mohr et al., 2004). Similar sets of rejuvenated diapirs can be also found nearby in the southwestern Nordkapp Basin (Henriksen and Vorren, 1996). In all these basins diapirs first formed in Triassic extension and were rejuvenated during Late Cretaceous to Middle Tertiary shortening. It was an event that formed the many Danian chalk reservoirs of the North Sea basin region offshore from Norway and Denmark.

Diapirs reactivated in compressional settings typically show common set of features (Table 6.2 Figure 6.47; Vendeville and Nilsen, 1995; Davison et al., 2000b); 1) Growth was episodic rather than continuous, allowing thick sets of strata to be deposited flat and horizontal as a thick roof atop the diapir crest during periods of diapiric quiescence, 2) Reactivated and compressed diapirs tend to have narrow or pinched-off stems, 3) Strata adjacent to the diapir are little deformed as most of the

deformation is taken up in the diapir salt, 4) Many reactivated and squeezed diapirs show a triangular-shaped basal pedestal. A lack of primary rim synclines around these diapirs during times of tectonic quiescence indicates that the structures went diapiric without necessarily going through a pillow phase.

Most rejuvenated structures grew by localised downbuilding associated with crestal extension and near-crestal gravity sliding with sporadic periods of bathymetric relief at the active diapir crest. For example, salt-cored sea-bed relief controlled the deposition of Palaeocene and Eocene turbidite sandstones in the North Sea, which today thicken away from the compressional re-activated diapir crests to form potential reservoir sands from 0 to 300 m thick (Figure 6.53). The effects of compression on autochthonous salt structures in the North Sea tend to be most obvious around the diapirs and not in the interdiapir areas. Compression in the Central Graben was driven by downslope sliding of overburden above the Zechstein salt on the Eastern Platform area during late Palaeocene, and by regional Alpine shortening across the whole of the Central Graben during middle Miocene times. The various re-activated diapirs of the North Sea are much less deformed than those described in the Triassic-salt cored décollements of Spain and the French Maritime Alps (Roca et al., 1996; Dardeau and Graciansky, 1990) or the Cegonha and similar compressional structures in offshore Angola (Duval et al., 1992; Fort et al., 2004).

Specific features in the overburden atop a North Sea diapir, which may help in determining whether a diapir was rejuvenated by late compression after a phase of downbuilding, are illustrated in Figure 6.47a (see also Letouzey et al., 1995; Vendeville and Nilsen, 1995; Guglielmo et al., 2000). Sediments atop rejuvenated North Sea diapirs exhibit some or all of the following characteristics: (a) localised unconformities with high angles of onlap above the unconformity; (b) thick lid

Figure 6.47. Rejuvenated diapirs and suprasalt deformation. A) Typical diapir crest showing deformation style in fractured chalks and Palaeocene sandstones (after Davison et al., 2000a). B) Seismic scale geometry of diapirs affected by late compression with (a) compressional fold in overburden, (b) reverse layer-parallel slip, (c) wide drag zone, (d) thrust faults on shoulders, (e) lack of rim synclines (f) localised unconformities and high angle of onlap above unconformity restricted to immediate diapir vicinity, and (g) thick updomed strata above the diapir (after Davison et al., 2000b).

of overburden strata (>300 m) updomed above the diapir; (c) reverse layer-parallel slip or concentric thrust faults localised at the diapir shoulders; (d) central horst block uplifted above diapir; (e) continued upward movement of the diapir even when pinched off from the source. The presence of layer parallel reverse slip and concentric reverse faults may not occur together. In experiments on active diapirs Schultz-Ela et al. (1993) showed that layer parallel slip occurs in overburden, which is anisotropic, and thrust faults at diapir shoulders occur in isotropic overburden. Crestal collapse graben also occur above some rejuvenated diapirs, but crestal horst structures have only ever been produced in physical models of upbuilt diapirs (Davison et al., 1993). The significance of the various fault patterns associated with the inversion of the diapir is discussed further in terms of hydrocarbons in Chapter 10.

Suprasalt doming influenced the distribution of chalk and sandstone overburden in the North Sea via crestal thinning associated with intense extensional faulting, tensile fracturing, gravity sliding and pressure solution (Figure 6.47b; Davison et al., 2000a). Salt buoyancy created topographic relief about the flanks of the thinned chalk layers, resulting in semi-indurated chalk sliding off the crests of the diapirs as shown by soft-sediment slump folding and bedding-parallel shear zones in the chalk in most producing offshore fields. Debris flows in the Kyle field carry clasts of caprock anhydrite indicating that the salt crest was exposed or was near the seafloor. Lithified angular clasts in the same debris flows indicate that chalk was already indurated and cemented at the time of extrusion, but nevertheless the diapir was able to actively break through and shed this lithified material. Topographic relief of several tens to hundreds of metres above the surrounding seafloor had developed atop reactivated diapir crests during the Late Cretaceous to Palaeocene period.

An associated flow of squeezed pore fluids through the chalk reservoirs in Banff, Machar, Kyle and North Pierce fields in the North Sea resulted in interconnected vuggy fractures filled with calcite. This calcite was probably derived from pressure solution, but much of the dissolved chalk atop the Machar diapir has since been removed from the system, with dissolution waters possibly escaping directly into the sea along major faults. A combination of all the rejuvenation effects produces what is an apparently intrusive single-event geometry. In reality, the overburden was tectonically thinned episodically and removed by gravity sliding, rather than actively pushed aside by rising salt in one event. Typical deformation patterns observed in chalks above a reactivated diapir are summarised in Figure 6.45b.

Palaeocene sands overlie chalks in many diapiric fields in the Central Graben. Bedding-plane slip surfaces, with at least 10 m of displacement, are common in the Palaeocene siliciclastic rocks from South Pierce field in the North Sea (Figure 6.47b; Davison et al., 2000a). Like the chalks, these overlying clastic sediments slid away from the diapir crest to accumulate on the diapir flanks as stacked and slumped deepwater sandstones. Sliding and shedding preferentially took place along mudstones, which preserve commonplace slump folds and polished faulted surfaces. Similar soft-sediment folds are not always present in the sandstones, which rode on the muddy slides and some coherent sandy blocks were translated large distances without any internal deformation. Thicknesses of the Tertiary sandstone packets increase from zero near the crest to 300 m on the flanks and indicate a combination off-crest channel stacking/ponding and crest-induced slumping. Davison et al. (2000a) argue that build-ups of tens of metres of supracrestal sediment were followed by up-doming of the salt diapir crest, which was accompanied by faulting and rotation of the strata until a critical angle was reached and then overburden slid off the diapir. Hence, as for their chalky precursors, these episodically active compressional diapirs were close to or at the seafloor during the Palaeocene to Eocene period, producing bathymetric highs that periodically shed their siliciclastic sediment cover (Figure 6.53).

Sediments and flowing salt

It is not just sediment patterns about reactivated diapirs that respond to salt-induced topography. Wherever flowing salt approaches the land surface in both continental and offshore positions it creates topographic relief in the landscape and so influences the style and pattern of deposition (Table 6.3). Historically, sedimentological studies of this phenomena focused on predicting suprasalt deposition and its utility in predicting associated porosity trends (see summary in Warren, 1989). Conclusions as to the position of sands, reefs and porosity belts in relation to salt structure highs in the landscape are still valid, but our understanding of mechanisms driving salt flow have substantially changed. With increasing recognition of the importance of lateral flow in allochthonous salt, the sedimentology of subsalt systems has become as important to model and predict.

Reactive diapirism typically forms a graben or low atop the diapir crest. Active diapirism, passive diapirism and compressional growth folds are all marked by topographic highs about the crest of the salt body. Salt flow rates are in turn influenced

by loading (sedimentation rates) and tectonics (rates of extension or compression). Interaction creates feedback whereby the geometry of a growing salt body is influenced by, and feeds back into, the depositional rate/water depth of the adjacent sedimentation setting. Once rising salt is sufficiently close to the surface to influence its topography, sedimentary feedback typifies all styles of halokinesis. At the scale of seismic resolution this is recorded in changes in bed thickness (e.g. formation of suprasalt/intersalt basins or minibasins, thickness changes approaching active diapirs ridges and growth folds), as well as varying onlap and offlap relationships, and changes in bed attitude as the salt body is approached. At the lithofacies scale, it is recorded in changing styles of shallowing or deepening of the sequence (sanding or shaling upward parasequences), the development or the drowning of reefs and shoals, syndepositional bed disturbance, slumping and faulting, as well as the formation of local unconformities and karsting.

At the broad scale of seismically resolvable sediment geometries, the style of sedimentation can be broken down into three groupings: prekinematic, synkinematic and postkinematic (Figure 6.48; Jackson and Talbot, 1994). The prekinematic layer records sedimentation before salt movement or any other deformation. A prekinematic sediment layer is an interval of strata where initial stratigraphic thickness is constant above a salt structure or its adjacent rim. That is, the prekinematic sediment layer is isopachous or its depositional thickness varies only as much as would be typical for the same sedimentation style in a region where no salt was present.

In contrast, the synkinematic layers record sediment thickness and facies changes related to salt-cored highs and crestal sloughing. Synkinematic layers thicken above withdrawal basins or locally thin against rapidly rising structures. For example,

in the East Texas Basin in the Gulf Coast, the percentage of stratigraphic or seismic-stratigraphic thinning of synkinematic strata ranges from 10 to 100% in units influenced by the flow of Jurassic Louann Salt (Seni and Jackson, 1983a,b). Changes in bed thickness are frequently recorded by onlap or truncation at all levels of the synkinematic layer (Figures 6.48, 6.49).

The postkinematic layer is the interval of strata deposited by sedimentation after salt flow, or any other deformation, has ceased. Basal postkinematic strata can onlap an underlying, uneven deformed surface but show no thickness changes that can be directly ascribed to deformation induced by local salt-flow. The postkinematic layer typically overlies the synkinematic layer.

Truncations (unconformities) are particularly useful in distinguishing the three packages. Removal and termination of dipping deformed strata by subaerial or subaqueous erosion forms a truncation or sequence boundary. Truncations cutting across anticlines or fault blocks indicate that the structures had surface relief at the time of erosion (Figure 6.48). Undeformed truncations mark the base of the postkinematic layer. Where a truncation is itself folded or faulted, it marks an episode of deformation of the synkinematic layer.

Various terms have also been coined to describe syn-kinematic basins that fill with sediment as they load and subside adjacent to or atop relatively thick allochthonous or autochthonous salt, which ultimately evacuates to leave behind weld and ramp basins (Figure 6.26). An older term for such sediment-filled basin atop a salt allochthon is a depotrough. In its strictest definition depotrough describes a basin filled with deepwater, mass flow or turbiditic deposits that uplap a diapir margin (Spindler, 1977). The term depotrough is used by some as equivalent to

a depopod. But a depopod can also be a basin filled with shallow water deltaic deposits draping over or against a flanking salt diapir. In many prograding shelf situations a depotrough passes upward into a depopod. A better term to describe sedimentary basins created by the coming and going of flowing salt is minibasin. It has no genetic implications. And without drilling there should be no assumption of predominant water depth or lithology accumulating during the fill of a minibasin. In much of the current literature there is a strong bias toward Gulf of Mexico models of sediment fill by deeper water siliciclastics passing up into fluviodeltaics. This bias reflects the excellent, but geographically localised, work that has been widely published on the slope and rise allochthons of offshore Gulf of Mexico. It has led some authors to discuss suprasalt reservoirs solely in terms of siliciclastic models. Outside of the Gulf of Mexico, modern and ancient minibasins are filled by other facies; such as chalks in the North Sea, or by shallow water lagoonal mudstones, grainstone shoals and reefs, as well as Mesozoic sabkhas and salterns in the Middle East (e.g. Davison et al., 1996b).

Sediments and evolving salt structures

The crestal positions of shallow salt structures in extensional regimes are intimately associated with faulting in the first two of the three evolutionary stages of diapirism (reactive and active versus passive). The reactive diapir is triggered by faulting in the extending brittle overburden whereby the hanging wall of an initial fault sinks into the source layer until resisted by increasing pressure forces in the salt source layer and the bending resistance of the overburden (Jackson and Vendeville, 1994a). Continuing expansion is accommodated by subsidence as new faults form repeatedly along the expanding axis of the graben. The central fault block sinks and dwindles, while the diapir rises below it, regardless of overburden density. Progressively smaller fault blocks are supported by fluid pressure of the salt at progressively higher levels flanking the triangular diapir. Syndiapir sedimentation keeps diapirs in the reactive phase longer by continually filling the graben floor with new layers of sediment (Figure 6.50). Reactive diapirism is controlled by the rate of regional extension; whenever regional extension ceases, a reactive diapir stops growing. In contrast both active and passive diapirs are strongly influenced by sedimentation rates and the deposition of sediment wedges (Ge et al., 1997).

Figure 6.48. Sedimentary record of salt flow during extension (upper panel) or shortening (lower panel). The prekinematic layer was deposited before salt movement began. The synkinematic layer was deposited during salt flow and includes many internal onlap or truncation surfaces. The postkinematic layer was deposited after salt flow ceased. Its base may onlap or truncate originally exposed surfaces in the synkinematic layer (after Jackson and Talbot, 1994).

Figure 6.49. Schematic of two episodes of structural inversion caused by subsidence and renewed uplift of a diapir. The inversions are recorded by changes in bed thickness and onlap directions indicated by barbed arrows (after Jackson and Talbot, 1994; Nelson, 1991).

At the time a reactive diapir is forming there is an active depression or graben atop the extending structure (Figure 6.50). There are three depositional settings that can supply sediment to that depression: continental, marine shelf, and deepwater slope to basin. If the extensional graben or depression atop the reactive diapir is in a continental situation, then any surface waters, lakes or rivers will tend to occupy that depression. In hydrologically open settings, the deposits of a series of stacked fluvial channels may infill the lower parts of the depression. In more restricted to hydrographically closed scenarios the graben fills with deposits from a series of elongate saline lakes and mudflats. If the graben depression forms in a marine shelf setting it may fill with deeper water lagoonal muds while shoal water sediments and reefs occupy the very shallow waters atop the edges of the faulted graben margin. If the reactive stage creates a graben depression in deeper waters on the upper part of the continental slope, then a series of growth faults amid thickened deltaic sand traps may occur and help load the system. Conversely the graben may create a deep seafloor depression that stacks successive episodes of submarine channel and fan sands.

Once a reactive diapir becomes sufficiently tall and its roof sufficiently thin, then pressure at the diapir crest impels the system into the active stage. The diapir lifts its roof, as it rotates, breaks through and shoulders aside its overburden. Crestal erosion and near-crest sloughing then disperses the fragmented roof materials as a series of monomict debris aprons composed of sediments that formerly overlay the diapir crest. Throughout this time, and during the following passive stage, the area above and about the diapir or salt wall is a topographic high that does not accumulate sediment. In the continental realm,

fluvial channel sands may stack into the depression created by any adjacent salt withdrawal sink. In the marine realm, the high often lifts the sea floor above wavebase and into shallow euphotic waters suitable for carbonate growth. The higher energy realm about a high on the open marine shelf means the muds are winnowed to leave behind sands and gravels. In the transitional continental marine setting, the high energy shorezone tends to lap up onto the edge of the high and wave action reworks and winnows the debris apron of the active stage into well sorted shorezone sands. Later in the passive stage the shorezone also picks up and redeposits exotic blocks derived by the dissolution of extruded salt to create polymict breccias and conglomerates.

Once salt is emergent at the land surface or on the seafloor the diapir has evolved into its passive stage (Figure 6.50). At this stage the salt is extrusive and any thin sediment roof that may periodically develop atop the salt has little mechanical influence and is destroyed by ongoing active breakout. Dissolution of the salt sheet on the seafloor creates anhydrite/gypsum carapaces and may also supply a cap of exotic blocks that have been dragged up from greater depths. In some Neoproterozoic salt allochthons in Northern Australia the transition from active to passive can be seen in a change of the debris apron constituents from monomict to polymict breccias. The increase in the variety of clasts is driven by dissolution of namakier salt, leaving behind a much broader range of clasts (pers. obs.). If the breccias are not recognised as salt allochthon-generated, such units are easily misidentified as the outcome of long distance transport driven by tectonic uplift. In Proterozoic and Archaean salt allochthons the salt carrier has typically dissolved, even in the feeders to many of these breccias. All that remains are

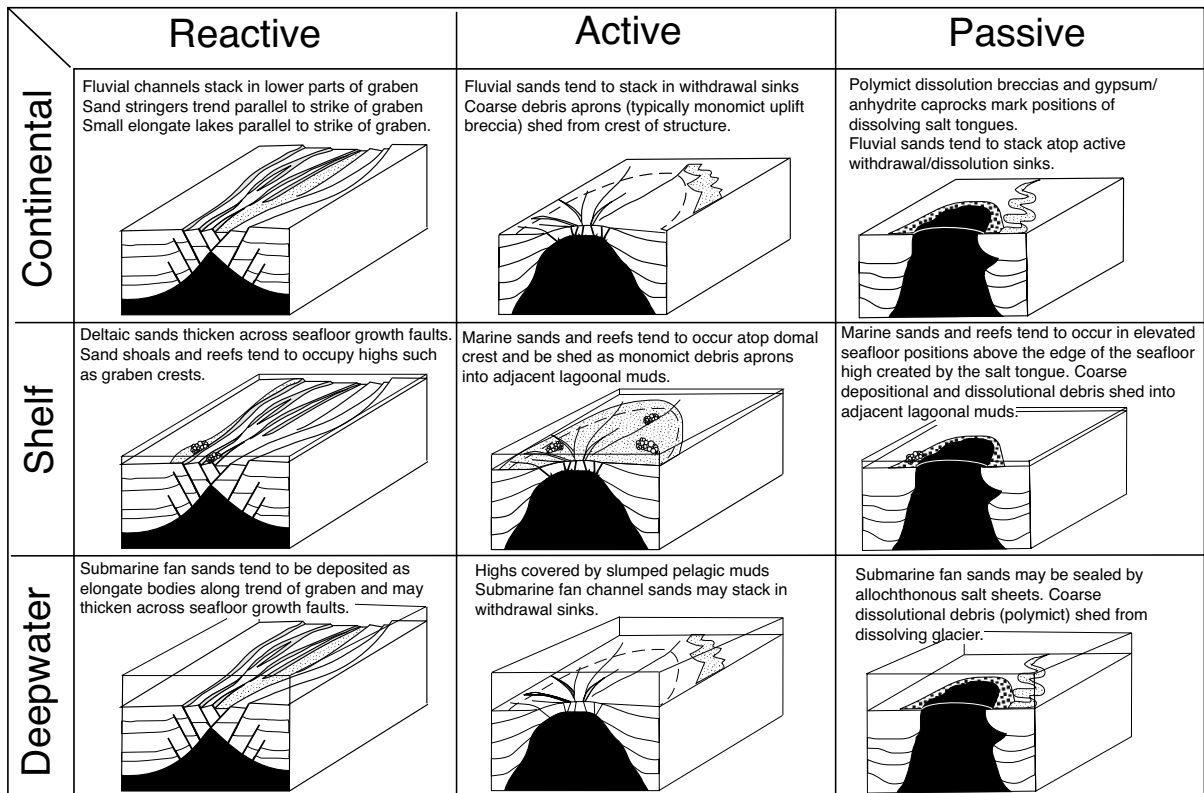

Figure 6.50. Schematic cross sections showing the control exerted by shallow salt (topographic high) on the distribution of sands and reefs in synkinematic sediments. Sand distribution changes with the stage of salt structure and water depth in the depositional setting (modified in part from Warren, 1999). This sequence of schematics is drawn using a diapir outline, but similar depth-related sediment patterns also form about the seafloor highs created by nearsurface salt allochthons or atop turtle structure anticlines in interdiapir areas.

characteristic alteration haloes around salt and fault welds and indicators of the former presence of salt in the matrix of the breccia itself (Chapter 7). This has significance to many base metal deposits and exploration models (Warren, 2000b). For example, in sedex exploration it is the difference between a predictive layered brine pool model as the control on prepared ground for subsequent mineralisation versus no discernable control other than fault proximity.

A salt-induced high on the seafloor can develop substantial relief over the surrounding region. A rich biota of bioherms and associated grainstone flats can form in shoalwater tropical seafloor settings. In the deeper water settings of the allochthons in the Gulf of Mexico the areas atop extrusive salt tongues have a relief measured in hundreds of metres above the surrounding seafloor (Fletcher et al., 1995). Such deep seafloor highs tend to channel turbiditic sands into the relative lows along the allochthon edge. While the salt is replenished (salt fountain), the region about the salt remains a topographic high. The maintenance of the salt at or near the sedimentation surface

by periodic overburden shedding means that both the active and the passive stages are characterised by many unconformities, debris aprons and thinning of strata in the vicinity of the diapir crest.

Three-thousand-year-old coral reefs that now lie some 18 m above sea level along the onshore portion of the active Al Salif diapir, Yemen (Davison et al., 1995, 1996b). This active stage diapir has lifted its roof and continues to do so today. The nearby Jabal al Milh diapir is the much-reduced remnant of a formerly active extrusive structure on a Pleistocene carbonate shelf (Figure 6.20a). In both, the highs atop the structures strongly influence the facies distribution of nearby carbonate and evaporite sediments. Offshore from this region are a number of depositionally similar islands and grainstone shoals that likely indicate sea floor shoaling atop other diapirs and salt walls in the same Miocene salt.

Topographic lows form above peripheral sinks created atop areas of salt withdrawal. These are often areas of preferential

sedimentation, that is, sediment thicks. Loading associated with accumulation of sediment in the sinks drives further salt flow. The lows persist until the salt is completely evacuated and a salt weld forms. Salt-flow induced highs and lows in the sedimentation surface persist until the diapiric ridge or crest is cut off from its supply by the formation of welds or touchdowns. Then the diapir and allochthon crests are buried by sediment that continues to aggrade until its thickness exceeds the piercement potential and the structure is no longer active.

Even though coal is not a sediment typically associated with evaporites the ongoing low created during the formation of suprasalt minibasins lows has preferentially accumulated a thick coal succession in the Pennsylvanian Joggins Formation, in the Cumberland Group of Nova Scotia (Waldron and Rygel., 2005). This 1.5-km-thick coal-bearing unit is famous for upright fossil lycopsid trees, and is preferentially preserved in the Athol syncline in the western Cumberland basin. Seismic profiles show that the Athol syncline sits atop a salt weld and that the Joggins Formation thins on the flanks of adjacent evaporite-cored anticlines. During deposition of the Joggins Formation, at least 1 km of syndepositional subsidence was facilitated by flow of underlying salt into the adjacent anticlines.

Both subaerial and submarine glaciers are topographic highs at the time of salt emplacement so the syndepositional surface adjacent to a glacier is subject to slumping and mass wasting. Like a glacier of ice, a salt allochthon or namakier can spread out over its own moraine, so that the lower contact of a preserved allochthon is disturbed even while the salt rolls out over its own lower surface (Figures 6.22a, 6.46a). It seems that the preservation potential of salt wings and allochthons are higher if emplaced as a submarine glacier compared to a subaerial glacier (Peel et al., 1995). Submarine salt glaciers form in passive margin settings and are protected from pervasive dissolution by a thin membrane of supersaturated salt mud, which maintains its suprasalt position as the salt sheet is loaded and minibasins form in the relative quiescence of the sub-wavebase seafloor. Subaerial glaciers tend to form in compressive continental terrains where the salt source is more limited and their carapaces are exposed to the continuous rigours of subaerial weathering and rainfall dissolution. Caprocks atop glaciers in both settings can form either as biological precipitates or as accumulations of insoluble weathering products.

Siliciclastic patterns

When a diapir crest is near the surface in a continental deltaic or fluvial setting it is a topographic high that focuses sand deposition into a series of stacked channels in the interdiapir area.

Even in a mature salt province, such as the modern siliciclastic Texas Gulf coast, salt structures are capable of maintaining a degree of topographic relief at the land surface and so act as a focus for off-structure fluvial sand accumulations (Figure 6.51) and as a focus for sand distributions further out on the modern siliciclastic dominated shelf (Morton and Suter, 1996).

Through time, the crest's position in earth space is maintained by the withdrawal of salt from an adjacent rim syncline, with the creation of a topographic low in the landscape atop the sediment-accumulating rim syncline. The effect of this topographic differential explains the 10-100% syndepositional thinning of lower Cretaceous Paluxy sands over the Van and Hawkins salt pillows and the Hainesville diapir in east Texas and the associated stacking of fluvial sands in the interdiapir areas (Seni and Jackson, 1983a). A net sandstone map shows that crestal areas contain between 5 and 20% less sand and that Cretaceous Paluxy sands were focused into withdrawal sinks between highs in the landscape created by the growing autochthonous salt structures (Figure 6.52a). Sand pinchout and lateral passage into floodplain muds atop the various salt structures clearly shows that the thinning of the Paluxy sands onto the various salt structure crests is depositional, rather than a response to active piercement. Likewise, sand body distribution in the Paleocene-Eocene Wilcox Group around Bethel and Oakwood domes in the southern East Texas Basin indicate the effects of dome induced topography on coeval fluvio-deltaic sedimentation in this Tertiary landscape (Figure 6.52b; Seni and Jackson, 1983a). For example, there are four stacked channel-fill sands, each more than 15 metres thick, in the rim syncline immediately east of the Bethel Dome. In contrast, there is only one sand body more than 15 metres thick in the strata over the Bethel Dome, yet the percentage of sand in thinned crestal succession is only slightly lower than in the stacked sands. Paluxy sands in the East Texas Basin were deposited around the basin margin as part of the Lower Cretaceous Trinity Group. At the same time, but further out in the basin, shelfal sediments were

Figure 6.52. Interaction of fluviodeltaic sedimentation and diapirism. **A)** Decreased thickness and sand percentage over Van, Hainesville and Hawkins salt structures in East Texas Basin indicate that fluvial systems bypassed topographic swells over salt structures during Paluxy deposition. **B)** Cross section across top of Bethel diapir and a percentage sandstone map showing how stacked fluviodeltaic sands of the Eocene Wilcox Group in the southern part of the East Texas Basin pinch out over the crest of the structure (after Seni and Jackson, 1983a).

dominantly carbonates of the James Limestone and the Glen Rose Formation. There seafloor highs atop salt structures and turtle structures controlled local patterns of carbonate reef and shoal sedimentation (Figure 10.46).

When a reactivated or squeezed diapir crest is near the deep seafloor of the continental slope it creates a syndepositional high, which then influences deepwater sand patterns (Figures 6.47, 6.53). A squeezed diapir's shape and its freeboard height above its surrounds affect the flow direction, speed, and thickness of turbidite sands accumulating in the various fan lobes atop withdrawal sinks adjacent to the squeezed diapir high. This was the case in the Eocene of the North Sea during the deposition of the deepwater Tay sand, which now forms the reservoir in the various Gannet fields (Figure 6.53a; Armstrong et al., 1987). Reservoir sands are broken down into three units; the lower, middle and upper sands, all deposited in a shoaling submarine fan complex. The area is underlain by various squeezed diapirs and some, like the Gannet North diapir, have exerted a major control on sand thickness and sand distribution. The seafloor

highs, generated by areas of shallow reactivated Zechstein salt structures, created sand pinchouts as salt-cored highs deflected dense turbidity flows away from their edges (Figure 6.53b). This minibasin system shows a classic vertical transition from stacked sheet to channel-levee geometries.

Carbonate patterns

The multiplicity of depositional settings above and around reactivated salt-cored highs in the Arabian Gulf gives an insight into the geometries of carbonate sands and porosity distribution in squeezed salt structures that are no longer extruding salt (Figure 6.54; Warren, 1989). Salt-cored seafloor highs surrounded by deeper gulf waters do not show the effects of widespread current reworking. These structures simply shed shallower water sediments centripetally into deep sub-wave base depths (Figure 6.55). Facies patterns tend to form concentric rings, with the best-sorted sediments at or near the crest of the now buried structure. Sediment patterns tend to become more elongate and stream in the direction of current transport once

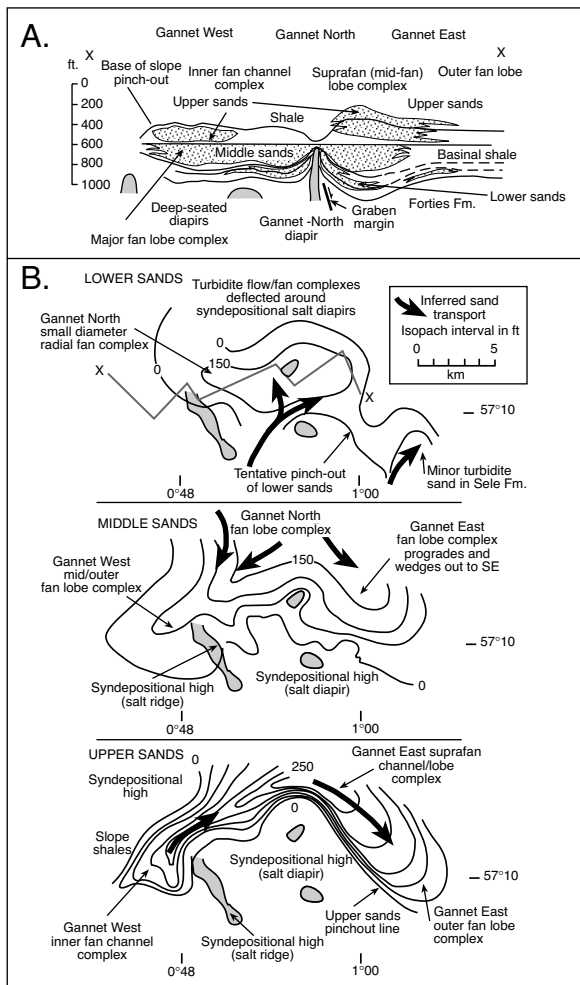

Figure 6.53. Eocene Tay Sands of the Gannet area of the North Sea. the depositional surface lies above wave base. In the case of the various grainstone and rudstone shoals of the Great Pearl Bank this largely reflects waves driven by the Shamal (Figure 6.54). When exploring for porosity in an ancient counterpart one would drill on or near the crest of the structure, as identified in seismic. Intermediate water depth highs in the Arabian Gulf are surrounded by waters of moderate to shallow depths. Sediment shed from the carbonate high is reworked by tides and other currents, both across the high and into the shoal water areas surrounding the high. Often, this type of structure generates a down current sediment tail, creating a strong asymmetry to

any reef or sand buildup on the structure itself. The sediment tails can be quite thick; off Dalma Island in the Arabian Gulf the modern downwind grainstone tail attains thicknesses of 20 m (Figure 6.54). Exploring for relict primary porosity on the ancient equivalent of this type of marine platform structure involves drilling both on or near the crest of the structure, as well as expecting and drilling sand trends that cut across the structural crest (Lomando et al., 1984; Lomando, 1999).

The observation that sediment tails about Arabian Gulf salt structures tend to trend in the same direction as the prevailing winds of the region is a useful predictive tool. Once the position and trend of any ancient grainstone shoal is established about an individual salt structure, likely grainstone orientation and position of potential reservoirs about other time equivalent diapirs in the region can be predicted as likely to occur in the same quadrant. In the case of the Great Pearl Bank the region about the salt structure highs with the highest probability of sand occurrence lies south to southeast of the salt-cored seafloor high (Figures 6.54, 6.55).

In near coastal settings in the southern Arabian Gulf the wind-wave sediment trend is often modified by coastal parallel (longshore) transport processes. Leeward sediment tails often extend from the high to the shoreline, generating a progressive shallowing between the high and the mainland that ultimately create a tombolo. Studies of the peritidal sand tail that extends from Yas Island onto the mainland at Jebel Dhanna show that shallowing increases the velocity of tidal currents. This causes the sequence to shoal upward from bioclastic grainstones and wackestones into oolite shoals that trend at an oblique angle to the trend of the sediment tail (Figure 6.56; Warren, 1989). The Jebel Dhanna diapir-cored high also controls the seaward extension of Holocene sabkha in the coastal plain behind the headland.

In the modern Gulf of Mexico, a reef system is actively accumulating coarse biogenic sediment atop a salt cored high in the Flower Gardens Bank. Upper-slope siliciclastic deepwater muds completely surround the reef-capped high. Carbonate buildups top the Flower Garden Bank because of the shoaling effects of salt just below the seafloor. A brine lake occupies the central part of East Flower Garden Bank (Rezak and Bright, 1981). Collapse foundering over the crest of the structure generated the graben that houses the lake, while ongoing salt dissolution and the focused escape of basinal brines maintain the dense waters of the lake. Healthy growing corals surround the lake, except where a canyon cuts a brine lip across the bank to the deep open seafloor. Halokinesis beneath the Flower Garden

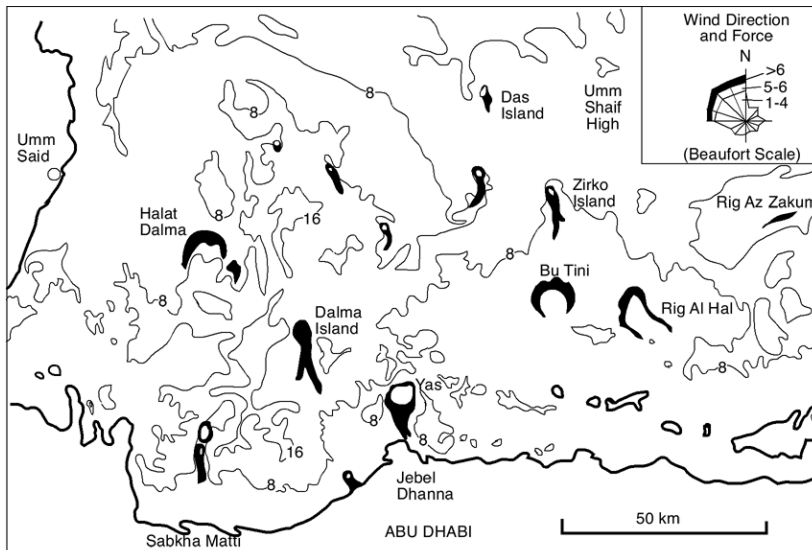

Figure 6.54. Relationship between wind direction and orientation of Holocene sediment tails (black) in shallow waters of the Great Pearl Bank, southern Arabian Gulf. Bathymetry in fathoms (after Purser, 1973; Warren, 1989).

Banks has converted an otherwise muddy siliciclastic platform into a region suitable for carbonate reef growth. Shoaling lifted the seafloor into a clear, well-lit environment and has created a carbonate buildup in what is otherwise a muddy, siliciclastic province. Brine seeps atop salt allochthons, located in much deeper waters at the foot of the continental slope, have allowed chemosynthetic mussel communities (biostromes) to flourish at water depths that are a kilometre or more below the base of

glacigenic units, thereby placing reef growth within the upper Cryogenian. A reef core facies of cumulate stromatolite domes first formed as mounds, which interfingered with the surrounding sediments, then as reefs, which stood well above the sea floor. Many mounds formed preferentially atop large debris blocks carried to the surface by diapiric salt.

the euphotic zone (Figure 9.33).

Ancient counterparts to the salt-cored islands in carbonate seaways, where carbonate sedimentation patterns are controlled by seafloor shoaling, occur in numerous diapir provinces ranging in age from Proterozoic to Neogene. Hydrocarbons and base metals have accumulated in brine lake laminites associated with some of these buildups (Warren, 2000b). For example, a series of Neoproterozoic stromatolite reefs fringe the western edge of the Enorama Diapir in the central Flinders Ranges (Figures 6.57, 7.23; Lemon, 2000). The enclosing stratigraphic unit, the Enorama Shale, is the locally-named interglacial succession, lying between the Sturtian and Marinoan (Varanger equivalent)

The Enorama diapir breccia blocks are typical of many diapir remnants (stems and welds) in the Central Flinders Ranges (Lemon, 2000). The breccias atop former salt stems and their surrounding debris aprons are made up of red and grey shales, sandstone blocks with halite casts, yellow dolomites with chert pseudomorphs of gypsum and anhydrite, and large blocks of amygdaloidal basalt and dolerite. All these blocks were carried up the stratigraphy by allochthonous - autochthonous salt source in the mother salt bed in the Callanna Group. Interaction with the surrounding sediments and inclusion of breccia fragments in the reefs and mounds shows continual movement and exposure of the diapir occurred throughout the deposition of the lower two thirds of the Enorama

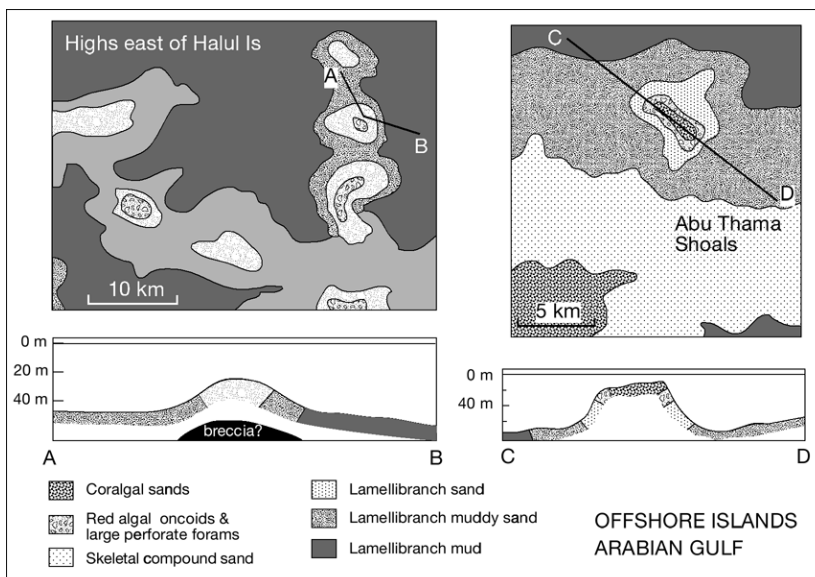

Figure 6.55. Sediment distribution on sea floor shoals atop buried salt structures on the floor of the Arabian Gulf (after Purser, 1973). See also Figure 7.22.

Shale. Lenses of diapir-derived polymict conglomerate are common along the flanks of the Enorama diapir and many of these show extensive evidence of shorezone reworking. Pebbles of conglomerate in cobbles of conglomerate within boulders indicate several phases of deposition followed uplift and erosion. The conglomerates commonly have a dolomicrite matrix which cements very early to allow the reworking to be recorded. Thickening of the Enorama Shale towards the Enorama Diapir is particularly evident in the stacked halokinetic sequences at the northern end of the diapir. Associated stacked conglomerate lenses that thicken toward the diapir stem, show this was an area of ongoing aggradation and syndepositional growth of the diapir stem as it fed salt into various allochthon sheets (aka christmas-tree diapirs; Dyson, 1998).

Not all mounds progressed to reefs, as the edge of the active diapir was unstable at times. The maximum size of a mound plus reef at Enorama is ≈ 50 m high and 200 m across the base. Syndepositional diapir activity is indicated by tilting of the surrounding sediments and by inclusion of insoluble debris shed from the diapiric island. Progressive movement is shown by cannibalisation and reworking of coarse shoreline conglomerates (Figure 6.57). Diapir movement continued after deposition of the reefs ceased so that the entire succession in the drag zone close to the diapir is tilted up to near vertical in what would be called the shale-sheath position in a siliciclastic interval.

Enorama reefs interfinger with both shallow water limestones of the Etina Formation and deep water siltstones of the Enorama Shale. The base to the middle of the Enorama Shale is a transgressive systems tract, deposited during a steady rise in sea level. Onlap onto the diapiric island is marked by backstepping of each reef higher in the section (Figure 6.57). Backstepping occurred as a number of pulses, each marked by channels of conglomerate shed from the diapir and by progressive convergence of local angular unconformity surfaces. Small pulses of salt uplift caused reefs to recolonise on higher ground, sometimes on previous reef growths, sometimes establishing a new mound. The reefs drowned as the sea floor next to the diapir subsided into the peripheral sink that flanked the diapir. On a mesoscale, the reefs are composed of a series of stromatolite mounds up to 6m high and 15m long. Lamination within the mounds is wrinkled and quite unlike nearby isopachous stromatolites characterised by smooth laminated micrite. The latter grew in the shallow water as Etina limestones and are interbedded with the older parts of the widespread reef complex. The microscale wrinkly structure of the reefs show a distinct clotted texture with filamentous linkages, reminiscent of calcareous alga like Epiphyton or Renalcis. The entire reef complex has been completely dolomitised, probably by solutions emanating from the diapir. Early dolomite cement has allowed mimetic preservation of sedimentary textures and some minor porosity.

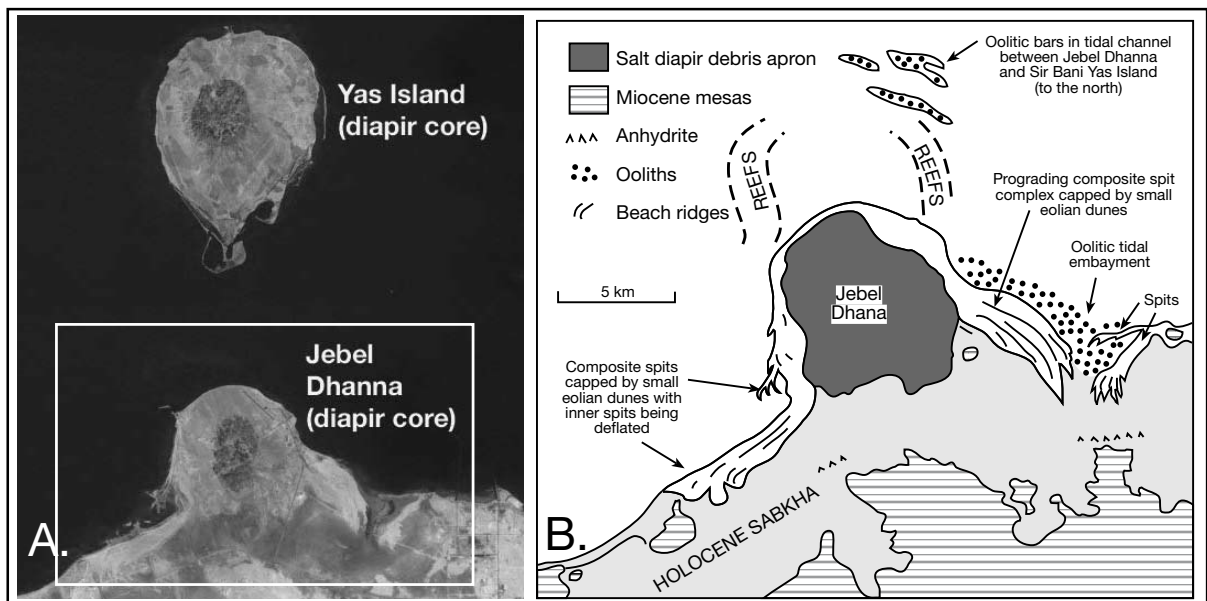

Figure 6.56. Sediment distribution controlled by the near coastal and coastal shoals created by Jebel Dhanna and Yas Island diapirs, coastal Abu Dhabi, see Figure 6.54 for location. A) Landsat image of coastal zone clearly shows diapir breccias forming cores to both diapiric outcrops (Image courtesy of NASA). B) Holocene sediment coastal patterns and tails in the vicinity of Jebel Dhanna (in part after Kirkham, 1997). Note that seaward extension of active reefs and offshore oolite bar thickens both controlled by the position of the diapir.

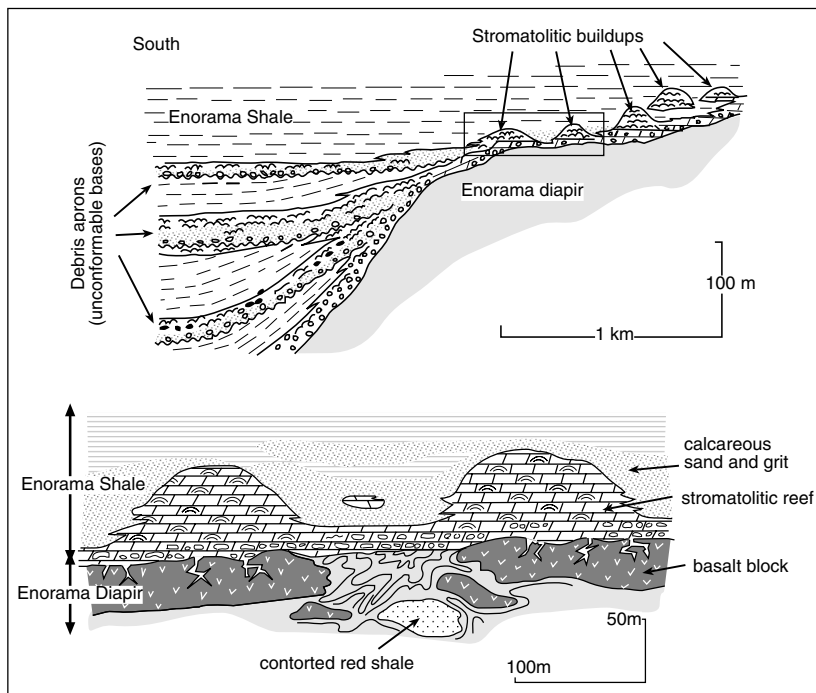

Figure 6.57. Palimpsestic reconstruction of part of the western Neoproterozoic margin of the Enorama diapir, Flinders Ranges, Australia. Lower figure shows detail of contact of reef with diapiric breccia. (after Lemon, 2000).

In summary, the reefs grew during a time of sea level rise and show a close relationship with rises in the Enorama Diapir, with each deepening upward reef succession being a response to a pulse of diapir growth. The diapir provided an area of shallow water around an island at a time when deeper water shale was being deposited in the rest of the basin. The mound to reef transition shows ‘catch up’ and ‘keep up’ growth habit but the sudden demise of each individual reef appears related to a subsequent pulse of salt movement on the diapir, not to broader eustacy.

Sediments tied to salt basin evolution

Suprasalt clastic sedimentation

Alexander and Flemings (1995) documented the spatial and temporal distribution of siliciclastic sand within an evolving Pliocene-Pleistocene salt-withdrawal shelf minibasin in the Gulf of Mexico; the Eugene Island Block 330 field. Part of it is a giant oil and gas field in offshore Louisiana and is located immediately landward of the deeper water Green Canyon area. The minibasin evolved through three phases: prodelta, proximal deltaic, and fluvial (Figures 6.58, 8.16). In the prodelta phase, bathyal and outer neritic shales and turbidites loaded and mobi-

lised the underlying salt sheet (Figure 6.58a). During the proximal deltaic phase, salt continued to withdraw from beneath the minibasin, and lowstand shelf margin deltas remained focused at a regional growth fault zone on the northern margin of the minibasin (Figure 6.58b). Sediment accumulation and fault slip rates were high, as thick sequences of deltaic sands were deposited adjacent to the fault system. During the final fluvial phase, salt withdrawal waned; consequently, the creation of accommodation space within the minibasin ceased (Figure 6.58c). The basin filled and, during lowstands, deltaic systems prograded southward. Unconformities developed in the minibasin during these lowstands. During transgressions, thick packages of shallow-water deltaic and fluvial sands (capped by shales) were deposited on top of the unconformities.

On a salt-floored continental margin that is being loaded by fluvio-deltaic wedges, the transition from deep water, when the floor of the minibasin first begins to subside as it is loaded, into a shelf and deltaic system is a natural evolution. The sedimentation model documented by Alexander and Flemings (1995) has a wider application to other salt-floored passive margins. Some authors in the Gulf of Mexico prefer to divide minibasin sedimentation into shelf-loaded and slope-load subcategories, but recognise it is all part of a feedback between basinward salt flow of the allochthon sheet and sediment loading (Figures 6.31, 10.52). Once the salt is evacuated from beneath a minibasin the basin can no longer subside and the depositional locus shifts basinward into the next minibasin atop the next tier of the allochthon. In the case of the Eugene Island minibasin this did not occur until the basin was filling with shelf sediments. In other basins this can happen while turbidites are still accumulating in the withdrawal sink. In this case the basin no longer accumulates turbidites, which now bypass the basin on their way downslope to the next active depopod.

Turbidite fill in Gulf of Mexico minibasins of the northern Green Canyon and Ewing Bank areas has been modeled by Rowan and Weimer (1998). They found that at the highest

order of scale, external factors dictated the volume and type of systemwide clastic input. Regional factors, such as nearby salt structures and the position of deltas, then controlled the dispersal of the clastics to the continental slope. Local factors, such as the thickness of underlying salt, influenced minibasin-specific evolution. In the deepwater slope setting these factors interact at three scales: (1) a broad transition from sand-rich ponded settings to shale-dominated bypass settings during the Pliocene-Pleistocene, (2) fluctuations over periods encapsulating several sequences creating highly variable stratigraphic stacking patterns, and (3) a progression from ponded to bypass facies within individual sea level cycles. The most sand-rich gravity flows in an ideal sequence are deposited in the minibasin at the beginning of a sea level cycle (i.e. during the lowstand) giving rise to sheet-like geometries. A transition to more mud-rich gravity flows leads to the formation of a channel levee system, where flows tend to be channelised and more organised. The gradual decrease of sediment volume within individual gravity flows during a sea level cycle increases the hemipelagic content (mixed pelagic and gravity flows) and eventually passes into a condensed section typified by pelagic mud-rich sediments or foraminiferal-rich oozes.

The idealised fining upward succession is complicated by varying rates of salt withdrawal from the minibasin, which influences the volume of accommodation space within the minibasin. The distribution of accommodation space can be further complicated if the crest of a diapir undergoes dissolution to create a potential zone for further sediment accumulation. Slides and slumps can occur anywhere within a sequence; they can originate from local slope failures or from oversteepened delta fronts and can be triggered by salt movement, dissolution or can be seismically induced.

Figure 6.58. Schematic of three-phase depositional evolution of intrasalt basin fill in the 330 Block, Gulf of Mexico (Alexander and Flemings, 1995). Evolution began prior to 2.8 Ma and continues today.

Suprasalt carbonate sedimentation

La Popa Basin, Nuevo Leon, Mexico, is a salt influenced foreland basin near Monterey in Mexico, with excellent exposures of halokinetically influenced sedimentation around three salt stems (La Popa, El Papalote and El Gordo diapirs) and along the 25 km La Popa salt weld/wall (Figure 6.59; Giles and Lawton, 1999; Giles and Goldhammer, 2002). As in the Flinders Ranges, reef growth is a halokinetic response to pulses of diapir growth. A number of thick (<600m) coral, sponge, red algal reefs, exposed as a series of carbonate lentils, are the most obvious sediments associated with halokinetic seafloor shoaling. These carbonate buildups, the La Popa, San Jose, El Toro and El Gordo lentils, developed as shoals atop significant seafloor highs created by the passive rise of salt diapirs during

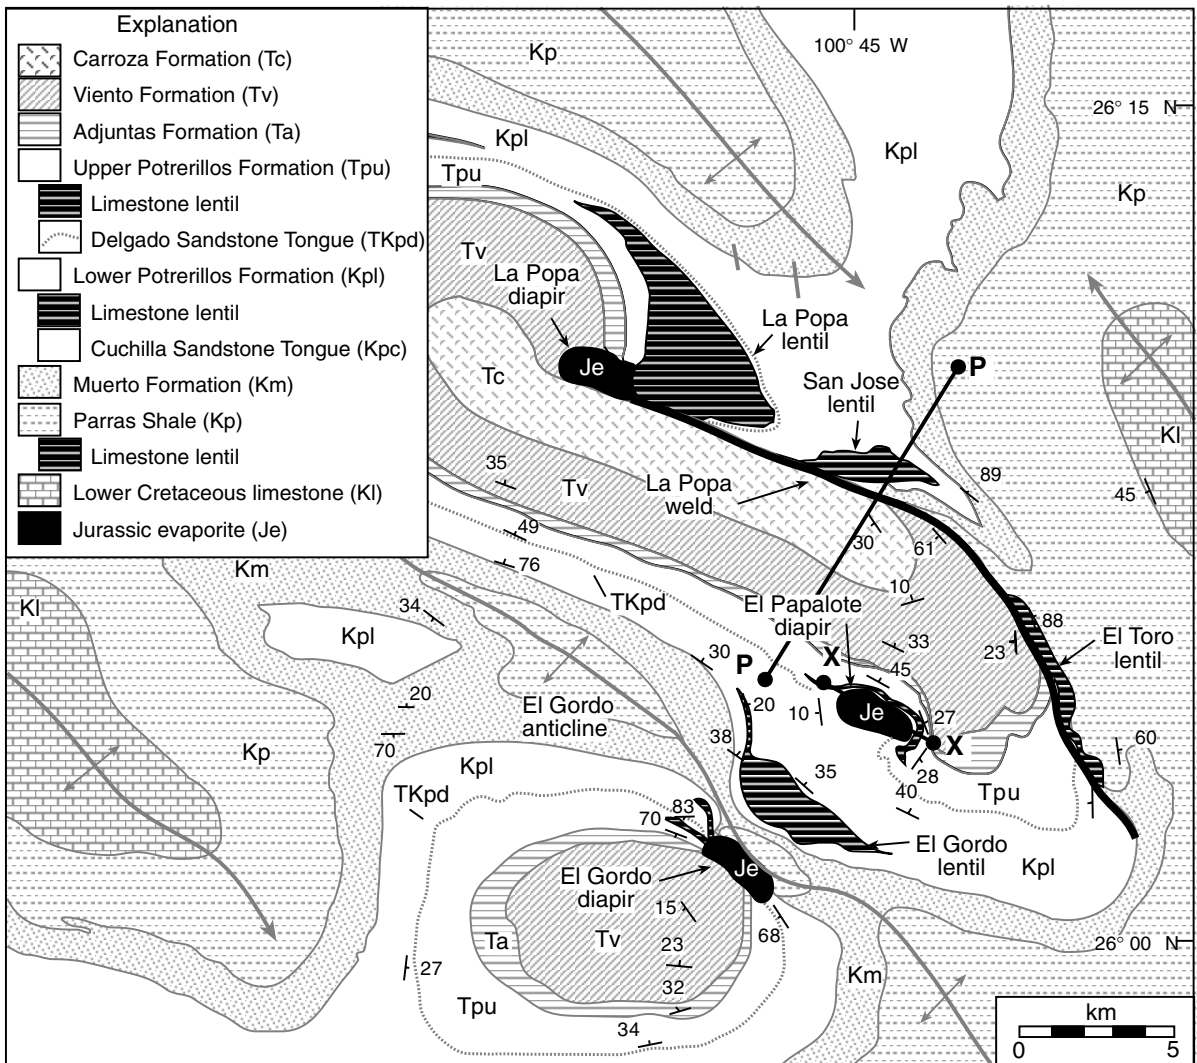

Figure 6.59. Geologic map of the La Popa Basin, Mexico. Anticlinal fold axes indicate structures attributed to the Hildagoan (Laramide) shortening (after Giles and Lawton, 2002). P-P' and X-X' are the locations of cross sections in Figures 6.60 and 6.61.

the Cretaceous and Lower Tertiary in what was a dominantly fine-grained siliciclastic shelfal environment.

The La Popa structure is interpreted as a 25 km long salt weld with parallel flanking synclines, previously it was considered to be a reverse fault (Figure 6.60a, b; Giles and Lawton, 1999). The displacement surface is convex to the southwest and dips south to southwest. Stratigraphic displacement at the surface is zero at either end and increases to ≈ 5 km halfway along the trace of the structure. The structure is the result of hanging-wall subsidence during evacuation of Jurassic salt along a former diapiric salt wall. Sedimentation patterns on either side of the weld indicate the La Popa structure experienced

a two-phase history in Late Cretaceous to Eocene time: 1) A diapiric phase marked by rise of an elongate, arcuate salt wall that was symmetrically flanked by withdrawal synclines; 2) a subsequent evacuation phase recorded by substantially increased subsidence of the hanging wall relative to the footwall and the stratigraphic “welding” of footwall and hanging wall along a steep planar discontinuity (salt weld) created as salt withdrew from the former diapir.

Superb exposures (over 10km along strike) of the largest reef complexes along the northern side of the La Popa Weld show that during the diapir stage these Paleocene lentils initially accreted as coral, sponge, red algal reef and oyster biostrome

complexes atop and immediately adjacent to the La Popa salt wall (Figure 6.60c). Large, steep (200m relief over 0.5km) foreereef clinofolds indicate northward (downwind) progradation of the La Popa lentil away from seafloor high created by the La Popa salt wall. With a probable lowering of the local rate of salt induced uplift near this part of the salt wall, this reefal system was subsequently truncated, onlapped and possibly overlapped by a southward prograding grainstone bar complex. This shoal was derived from a separate source to the north, perhaps from another salt-related bathymetric high tied to the La Popa Diapir. To the north and west of the La Popa diapir the two carbonate complexes coalesced through time to generate a continuous carbonate sheet that now defines the La Popa lentil. It extended more than 5 km within what was at edge of a low created by a salt withdrawal/contractional syncline as salt was evacuated into the rising salt wall (Figure 6.60c).

Carbonate strata thin and become siliciclastic away from the La Popa salt wall and are intercalated with siliciclastics in the footwall syncline. The Delgado Sandstone Tongue of the Potrerillos Formation is a shelfal sandstone/siltstone that was deposited during salt wall growth as a complex, wave-

dominated, eastward-prograding deltaic depositional system. Typical parasequences in the siliciclastic section comprise offshore shales overlain by lower to upper shoreface sandstone. The Delgado Sandstone contains a lower, progradational parasequence set; it is part of a highstand system tract that is in turn part of the underlying Middle Siltstone Member of the Potrerillos Formation. It also contains an upper retrogradational set, which is part of a transgressive system tract that persisted into the Upper Mudstone Member. The two system tracts are separated by an erosional sequence boundary that incises up to 10 m of underlying strata and locally preserves a lowstand system tract within the incised valleys.

During growth of the salt wall in the Early Tertiary, thick prodeltaic and tidally-influenced shoreface siliciclastics periodically accumulated in the adjacent withdrawal syncline. Flute marks on bases of turbidite beds and channel axis orientations indicate a dominant palaeoflow along synclinal axes, with a component of flow away from the salt wall. Siliciclastic units thin and fine toward the salt wall, near which they are upturned and contain numerous synkinematic angular unconformities. During evacuation the volume of the wall declined, causing the

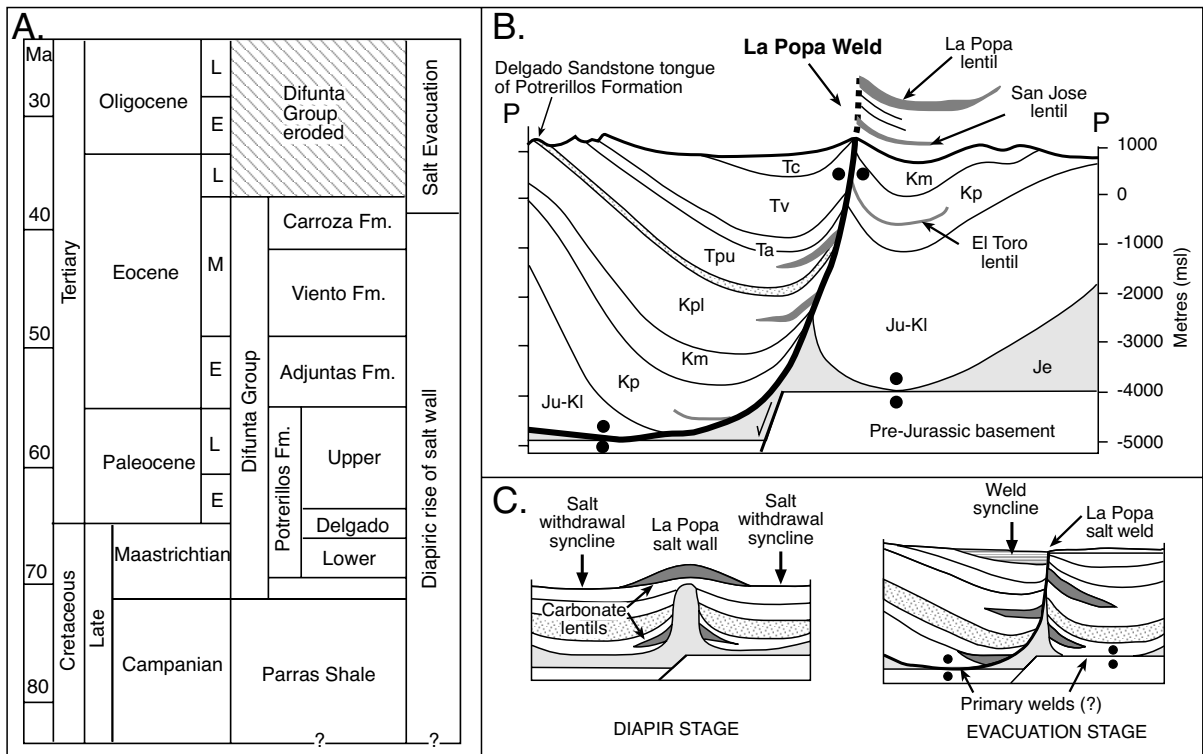

Figure 6.60. The La Popa salt weld. A) Stratigraphy of the La Popa Basin during the time when salt flow occurred (L = Lower; M = Middle; U = Upper). B) Cross section of the La Popa weld (see Figure 6.59 for position). C) Interpreted evolution of the La Popa structure (after Giles and Lawton, 1999).

synclinal hinge of the hanging wall to migrate laterally toward the developing weld. Hangingwall strata deposited during the evacuation phase thicken, rather than thin, toward the weld. They define the weld syncline where sand-rich fluvial channels are concentrated directly adjacent to the weld.

To the south of the La Popa salt weld are the El Papalote and El Gordo diapirs, they have similar dimensions and are located 5 km apart (Figure 6.59). The at-surface diapiric material in both diapirs and portions of the weld is today a complex mixture of gypsum, anhydrite and salt-transported exotic blocks of metamorphosed mafic intermediate igneous rocks and Jurassic carbonates (Garrison and McMillan, 1999). The gypsum is created by rehydration of the anhydrite caprock atop the Jurassic salt of the diapir core. Petrology and geochemistry of the meta-igneous blocks indicate derivation from partial mantle melting during Jurassic rifting with greenschist facies metamorphism dated at 146 Ma ($^{40}\text{Ar}/^{39}\text{Ar}$ dating of biotite and potassium in meta-plutonic blocks). This date is younger than that of the hosting Minas Viejas evaporite beds suggesting high heat flow from the basement continued into the latest Jurassic. The various sedimentary and volcanic blocks were likely intercalated in bedded salt prior to halokinesis, while the plutonics were intruded into the syn-rift fill and all were fragmented by extensional tectonics and salt flow.

El Papalote diapir is located on a major fold limb and has experienced approximately 100 m of net shortening, whereas El Gordo is located along the axis of the same fold and has accommodated over 2 km of shortening (Rowan et al., 2001). The corresponding halo of diapir-related drape folding, which is at most 800 m wide at El Papalote, is up to 2 km wide at El Gordo. Carbonate lentils, which formed over the bathymetric highs associated with both diapirs, are overall shallower, thicker, broader and record fewer halokinetic sequences at El Gordo than at El Papalote.

Sandstone units start thinning within 300-800 m of the edge of El Papalote but within 1000-1500 m at El Gordo. Differences in style and distribution of halokinetic strata about the two diapirs imply that the uplift histories of the two features were different and that the buildup atop the El Gordo structure more closely approached sealevel (Rowan et al., 2003).

Sediments flanking the El Papalote diapir have been studied in more detail than the other two structures with a view to defining typical successions in an ancient withdrawal sink and to test if such successions are amenable to sequence stratigraphic analysis (Figures 6.61, 6.62; Giles and Lawton, 2002). At the time sediments were accumulating, diapir-flanking strata thinned toward the diapir and were characterised by abrupt lateral facies changes and intense local deformation. Strata can be broken out into a series of "halokinetic sequences," which are defined as unconformity-bounded strata, genetically related to halokinetic processes.

Each halokinetic sequence contains a basal debris-flow bed overlying an unconformity, which is angular directly adjacent to the diapir and becomes disconformable to conformable with increasing distance from the diapir. Debris-flow or mass

wasting beds contain polymict clasts derived from the diapir and material that mantled the diapir (Figure 6.62). At the various times these beds were forming the diapir crest was exposed at the sediment-water interface and shedding carapace debris into the surrounding sediments. These mass wasting deposits are dominated by carbonate clasts. They are interlayered with autochthonous reefal and biostromal strata and together constitute the lentils mentioned earlier. Hence, debris and mass wasting beds grade upsection into oyster- and red algal-rich carbonate banks. This carbonate section is then onlapped by black basal shales and capped by upward-shallowing and coarsening, lower shoreface siliciclastic strata, which lack diapir-derived detritus (Figure 6.62). This lack of diapir detritus indicates that the diapir crest was no longer at the surface or had insufficient seafloor relief to act as a sediment source. Lower shoreface deposits are abruptly overlain by outer shelf shales that in turn underlie the angular unconformity of the next halokinetic sequence.

Each halokinetic sequence was generated by the waxing and waning of an episode of salt fountaining and salt glacier flow (Figures 6.60c, 6.62; Giles and Lawton, 2002). Periods of salt rise and salt glacier advance followed by retreat create unconformities near the salt structure. They correspond to times of slow sedimentation and regional black shales in interdiapir withdrawal sinks. These black shales perhaps reflect basin deepening (maximum flooding events). Advances of glaciers over diapir-flanking beds provided a mechanism of deforming and overturning strata that underwent subsequent local truncation

Figure 6.62. Halokinetic sequence in a marine shelf setting, based on the stratigraphy of the lentil and associated sediments in the vicinity of the El Papalote diapir. Lower figure also shows the interpreted relationships between sediments and angular unconformities tied to diapir rise and to the sequence stratigraphic interpretation of the surrounding shelf and slope sediments. SB = sequence boundary; TST - transgressive system tract; HST = highstand system tract (after Giles and Lawton, 1999).

via subaqueous erosion processes during glacial retreat. As in the modern Gulf of Mexico, glacial salt advance was also marked by development of a siliciclastic “shadow zone” on the downcurrent flank of the salt diapir high. Glacier advance at El Papalote is only displayed by strata on the east side of the diapir, indicating a down gradient flow of seafloor salt into the regionally extensive withdrawal syncline created by asymmetric salt supply to the adjacent and inflating La Popa salt wall. Quaternary counterparts to these carbonate debris aprons have been documented in weathering haloes about salt structures in the Arabian Gulf, while older counterparts occur in the Neoproterozoic salt structures in the Flinders Ranges of Australia. For example, Lemon (1985) documented and modeled similar asymmetric salt withdrawal controls on sedimentation about the Neoproterozoic Oratunga diapir in the Flinders Ranges, Australia.

Internally, the various halokinetic sequences show stratal onlap and thinning of beds toward the diapir. Adjacent to the diapir stem each halokinetic sequence is tightly folded and angular unconformities have truncation angle as high as 90 degrees (Figure 6.62b). The intensity of deformation and angle of truncation decrease rapidly away from the diapir and sequences are typically conformable by a distance of 250 m from the diapir. The geometry resembles the hook of the letter ‘J’ (e.g. Sequence 3 in Figure 6.61; Rowan et al., 2003). These ‘J’ hook unconformities terminate directly against the diapir and outline salt cusps created by a combination of drape folding and fault reactivation during halokinesis. The amount of fault reactivation on these unconformities can be significant with the unconformity/fault preserving evidence of brittle shear and sense-of-shear indicators showing older beds were displaced away from the diapir. Away from zones directly influenced by the diapirs and ‘J’ unconformities sediments tend to lack evidence of mass wasting and the interdiapir lows were filled by facies that shallow from middle shelf lower shoreface shale to upper shore-

face foreshore sandstones and tidal-lagoon sequences. These sequences do not terminate at the diapir but are spatially separated by a thick/wide package of older more tightly folded drag-zone strata (Figure 6.61).

Subsalt sections

Subsalt sediments, originally deposited adjacent to a seafloor allochthon and subsequently sealed beneath overflowing salt and its basal shear zone, have been studied most extensively in the Gulf of Mexico, where more than 50 exploration wells have been drilled with subsalt targets (Chapter 10). Sub-allochthon sands in the Gulf of Mexico are mostly Miocene-Pleistocene deepwater-slope submarine fan channel and levee settings. The sandstones were deposited by turbidity currents associated with channel-levee systems carrying sediment from the outer shelf into bathyal water depths in the middle to lower continental slope (Snyder and Nugent, 1995). Drilled facies vary from thick fining upward channelised deposits to thinly bedded levee sands and overbank splays. Sands range from friable to moderately consolidated, very fine to fine-grained, moderately to well sorted and slightly calcareous. Channel orientations can be strongly influenced by the seafloor topography generated by nearby salt allochthons. Once deposited the sands were then overridden and sealed by lateral flow of the allochthon sheets. The encroachment of the salt allochthon is associated with the creation of a salt-sealed gumbo or basal shear zone and defines one of four positions where subsalt sandy reservoirs are likely (Figure 6.63). Economic and stratigraphic aspects of this very

Figure 6.63. Subsalt sediments buried beneath an encroaching allochthon is one (Style D) of four subsalt trap styles discussed in Snyder and Nugent (1995).

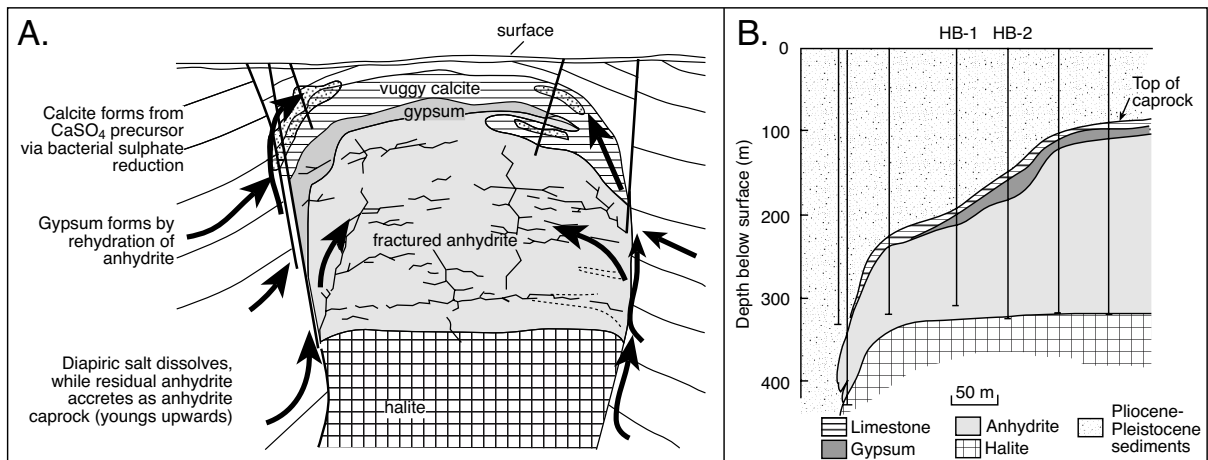

Figure 6.64. Caprock zonation. A) Caprock forms by the dissolution of the upper part of a salt structure once salt supply dwindles the rate of rise slows and it is flushed by undersaturated phreatic waters (black arrows). Dissolution of the halite leaves behind anhydrite that then accretes into an anhydrite caprock. The upper portion of the anhydrite unit rehydrates to gypsum that is then converted to limestone by bacterial sulphate reduction. B) Section of Hockley dome caprock showing relative thickness of the caprock zones and depth below the landsurface based on drilling (after Hallager et al., 1990).

important subsalt-hydrocarbon association are discussed in detail in Chapter 10.

Caprock Formation (diagenesis)

Caprock is a limestone/anhydrite carapace found atop many buried diapirs and allochthons (Figure 6.64a; Halbouty, 1979; Light and Posey 1992; Prikryl et al., 1988; Kyle and Posey, 1991). It forms as a dissolution residue atop diapirs, seafloor allochthons and even buried subaerial namakiers. Suprasalt caprocks thicken once salt supply starts to dwindle and the head of the salt plug or the top of any residual salt sheet is buried to shallow depths where it can no longer actively pierce and shed sediment. The edge of any buried salt mass feels the increased effects of dissolution via the undersaturated crossflow of phreatic waters. Atop a buried but still buoyant diapir, halite preferentially dissolves from the upper part of the salt mass/stem and a CaSO₄ unit accretes via underplating. The caprock underbelly has a continued supply of anhydrite residues as the top of the rising and dissolving salt stem is dissolved (Figure 6.65; Hallager et al., 1990). In zones of longterm fluid crossflow and ongoing slow salt supply, this interface becomes a widespread laminar sulphate carapace, encasing a salt mass with caprocks some tens to hundreds of metres thick.

Caprock is most common and thickest on diapir crests that are currently close to the earth's surface but can be found atop structures buried as deep as 3000 m. Most diapir capstones are 100 to 150 metres thick, but can be thicker than 300 metres. Caprock is thickest over the crest of shallowly

buried diapiric spines and thins toward the flanks. Oil drilling over the Hockley dome, near Houston Texas, clearly defines a mineralogical layering of diagenetic products that is typical of caprocks worldwide (Figure 6.64b). At its crest the Hockley Dome caprock is covered by only 30 m of Plio-Pleistocene sediments. The upper part of the caprock is a calcite unit up to 30 metres thick. Over the crest the calcite is underlain by a gypsum zone up to 30 metres thick. Further toward the flanks and somewhat deeper the gypsum unit is absent or very patchy and the calcite is in direct contact with anhydrite. The calcite zone grades downward across a transition zone into a laminar anhydrite capstone up to 244 metres thick. The Hockley caprock thins toward its edge and disappears, but in some other nearby Gulf of Mexico diapirs the steep vertical walls of the diapir stem are also mantled with caprock.

Caprock extent reflects hydrodynamics about the upper part of the salt stem. The gypsum and limestone intervals in a caprock typically contain accessory minerals such as baryte, celestite, strontianite, metal sulphides, rare tourmaline and fluorite derived from ascending basinal brines (Figure 6.64a, b). Sulphur forms in vugs and fractures in the upper parts of caprocks where H₂S is oxidised by crossflowing waters (Figure 11.58a). Reactivated salt flow and associated carapace destruction means earlier allochthon and namakier residues can be carried to the margins and shed to become part of a polymict debris flow aprons.

The bulk of an actively accreting caprock is laminated and composed of unoriented, interlocking xenoblastic anhydrite crystal mosaics. Laminae are defined by thin intervals of dark

Figure 6.65. Development of laminar anhydrite caprock via underplating across a zone of periodic dissolution at the halite-anhydrite contact.

sulphide/bitumen accumulations or by intervals of more intense pressure-solution-sutured anhydrite. Deformed, banded anhydrite clasts are also contained locally within cm-spaced lamina (Ulrich et al., 1984, 1985). The laminar nature of a caprock reflects its formation via underplating, whereby the less soluble anhydrite and a few carbonate rhombs are left behind as undersaturated groundwaters dissolve halite from the upper part of the buoyant diapir stem (Figure 6.65; Ulrich et al., 1985).

Anhydrite and carbonate typically comprise 1-5% of the original undissolved salt mass in Gulf of Mexico diapirs. The salt/anhydrite contact tends to be subhorizontal to undulose, with local cm-thick metres-wide pockets of unconsolidated idioblastic anhydrite sand (euhedral grains freed from their encasing halite matrix). Above the halite contact and its sand pockets the anhydrite is laminated and consists of tightly interlocked xenoblastic crystals (Ulrich et al., 1985; Hallager et al., 1990). The transition from euhedral idioblastic anhydrite sand to xenoblastic anhydrite mosaics occurs in the first few centimetres above the salt stock. Outside of the sand pockets the porosity and permeability are consistently low to negligible.

Enclosed coarsely crystalline halite pockets, still with disseminated idioblastic anhydrite, can occur along some horizons in the caprock, especially in the lower portions of the anhydrite zone. Pocket shapes vary from tall and thin to broad and squat, maximum dimensions range from less than 0.5 m to about 2.0 m. These moundlike halite structures are mega-inclusion in the

caprock anhydrite and are remnants of former zones of salt spine penetration along the salt-anhydrite contact. As the halite spine dissolves through several cycles of dissolution and accretion, a laminated anhydrite mound is preserved that sometimes contains minor amounts of base metals. Other clasts within the laminar anhydrite caprocks are remnants of anhydrite beds first deposited along with mother salt, and then deformed and boudinaged into anhydrite "pencils" during salt flow (Hoy et al., 1962).

Gypsum forms sporadically along the upper side of the anhydrite portion of a caprock by hydration and is driven by the crossflushing of cooler less saline waters. Depending on permeabilities, this gypsum band is variably developed on and through the anhydrite, but many deeper caprocks in the onshore Gulf of Mexico lack a gypsum zone. Given the relatively high salinities and elevated temperatures that characterise the zone of onset of caprock formation it may well be that gypsum formation postdates the formation of most calcite and sulphide minerals in the caprock and requires the pervasive entry of cooler meteoric water or seawater.

The calcite portion of the caprock occurs in hydrocarbon-bearing zones, mostly in the anhydrite zone where anaerobic SO_4 -reducing bacteria break down the CaSO_4 phase into CaCO_3 and H_2S . Like the anhydrite zone, a calcite cap rock exhibits horizontal banding defined by alternating dark- and light-coloured layers of calcite that formed along the prevailing anhydrite/calcite contact during dissolution of anhydrite, coupled with SO_4 reduction (e.g. Prikryl et al., 1988). Dark calcite bands consist of fine-grained and typically pelletoidal calcite containing minor amounts of Fe, Zn, and Pb sulphides and bitumen. Light-coloured bands consist of coarse-grained euhedral calcite that apparently precipitated in open spaces and can also fill vugs.

Massive amounts of the Sr minerals celestite (SrSO_4) and strontianite (SrCO_3) occur in the lower portions of some calcite cap rocks primarily in the light-coloured bands, along with minor amounts of baryte. Sulphide minerals can also be locally abundant in the lower portions of calcite cap rocks. The calcite cap rock at the Hazlehurst salt dome in Texas is approximately 30

m thick in the 2 drill holes that fully penetrated it (Saunders and Thomas, 1996). The upper half of the cap rock consists of banded calcite similar to other Gulf Coast salt domes. Numerous near-vertical banded calcite-sulphide veins are also present in this part of the cap rock. The lower part of the calcite cap rock consists of horizontal sulphide + calcite bands that alternate with coarse-grained (white) calcite bands. Locally, sulphide-rich zones are more than a metre thick and consist principally of marcasite and pyrite, with minor amounts of sphalerite, galena, pyrrhotite, celestite, baryte and strontianite. Sulphate minerals are commonly intergrown with sulphides.

Fluid inclusion data in the calcite caprock of Hockley Dome, Texas, indicate that baryte and celestite precipitated at temperatures less than $\sim 60^{\circ}\text{C}$, from brines averaging around 200,000 mg/l total dissolved solids (Figure 6.66; $\sim 18\%$ NaCl equiv.; Saunders and Thomas, 1996). Fluid inclusion salinities in caprocks do not vary significantly with depth, suggesting that brine salinity did not change dramatically over time. Sulphur and carbon isotopic evidence also supports a biogenic origin for both carbonate and sulphide minerals in calcite caprocks (Saunders and Swann, 1994) or a combined basinal and biogenic origin (Hallager et al., 1990).

In the last two decades there have been a growing number of studies dealing with mineralised portions of caprock and the results are used to improve geological understanding of processes that create Mississippi Valley Type (MVT) base metal deposits (Kyle and Price 1986; Bechtel et al., 1999). In Tunisia, some of these mineralised caprocks the associated biolaminated muds and the iron-rich haloes adjacent to the salt stems contain sufficient lead, zinc or siderite to be mineable (Bechtel et al., 1998; Warren, 2000b). Porosity in biogenic calcite caprocks can be as high as 40%, with porosity types ranging from pinpoint to fracture to vuggy to cavernous. Caprock reservoirs^{6.6} are shallow and so were attractive targets in the early heyday of drilling in Texas and many of the famous early discoveries were in caprocks; examples include Spindletop, Sour Lake, and Humble. Caprock reservoirs tend to be relatively small; the most difficult thing about working them in the early 1920s was their lack of predictability.

The earliest-formed anhydrite lies at the top of the anhydrite zone, and the oldest calcite lies at the top of the calcite zone (Figure 6.65). In other words the anhydrite and calcite caprock units grow from the bottom up and can be thought

Figure 6.66. Plot of fluid inclusions-based salinities in barite and celestite in calcite cap rock versus depth (ft) in the Hockley Dome, Texas (after Saunders and Thomas, 1996).

of as having a half life, like the basal anhydrites of the Maha Sarakham Fm in Thailand (Figure 7.33). That is, the thickness of any caprock zone is dependant on the rate of fluid flushing at the lower contact where it is forming and at the upper contact where it is being converted to another mineral phase or is dissolving. Ultimately, if crossflow continues, all that will be left of a caprock is a dissolution breccia or a weld. Paleomagnetic age measurement of stratiform laminae of pyrrhotite and other sulphides in anhydrite cap rock, over a sampled section that

^{6.6}The early oil history of Gulf Coast, USA, has an interesting aside. Oldtime drillers found that drilling wells in graveyards led to a significant number of successes. High success rates associated with "graveyard-tology" meant that early last century the church elders and many still-living relatives developed a sudden if somewhat belated attachment to long-since-departed great aunt Maude. Bitter legal battles, fraught with claims along the lines of being the bastard child of aunt Maude, were fought over the percentage of royalties that one would receive for part of, or even a distant ownership of, a small piece of "Boot Hill." A reason exists for these early success rates. Many early east Texas fields were salt-structure associated, with the shallow reservoirs (vuggy and fractured caprock) lying directly over the crest of the structure. The surface expression of an underlying salt structure in the Texas Gulf coast is a small topographic high or hill, and since John Wayne was a whippersnapper, graveyards have been "up on Boot Hill." The first oil discovered in southern Louisiana in 1901 came from a similar salt-formed topographic feature known as Jennings Hill about 100 km west of Baton Rouge.

represents about two thirds of the total anhydrite thickness in the Winnfield salt dome in northern Louisiana, indicate it formed between 157 and 145 Ma (latest Jurassic; Kyle and Gose, 1991). Accumulation rates from these data indicate that the average rate for the oldest cap rock sampled is 5.7 m/m.y. and decreases to 2.8 m/m.y. for the younger lower parts of the caprock, indicating a waning rate of salt supply. The nearby 285 m-thick Hockley Dome cap rock is believed to have developed within the last 45 Ma giving same order of magnitude for the caprock accumulation rate (≈ 6 m/m.y.)

Caprocks are residuum responses to throughflushing waters atop and about largely inactive and buried salt structures. Historically they were interpreted as a diagenetic response to largely continental meteoric hydrologies imposed on dissolving diapiric crests. Halbouty (1979), for example, noted that only 5 of 77 offshore wells drilled in diapiric crests intersected a caprock, but this analysis was done before any notions of allochthon shedding had been developed. Without doubt, actively forming caprock is found onshore wherever the active meteoric phreatic comes into contact with the upper part of a buoyant diapiric crest (Schelkes et al., 2001). Yet, caprocks also form in offshore halotectonic slope and rise realms atop largely inactive salt structures that have not experienced substantial meteoric crossflow.

For example, a core through the Eureka dome, a structure located in the upper slope of the Gulf of Mexico, encountered 36 m (117 ft) of anhydrite caprock above the salt massif (Lehner, 1969). Assuming an anhydrite content of around 5% in the Louann Salt, this thickness of caprock requires the dissolution of more than 700 metres of salt. Burk et al. (1969) reported caprock in core recovered from the Challenger Knoll in the Sigsbee abyssal plain. The allochthonous Sigsbee salt mass overrode the abyssal plain sediments with its upper surface at or near the seafloor throughout the entire Cenozoic era and was probably never in contact with large volumes of meteoric waters. Apparently, circulating meteoric water is not necessary for salt dissolution and caprock formation. If it is present, its relatively low salinity compared to phreatic seawater does accelerate the process of caprock creation. Substantial caprock can even form subaerially and active salt glaciers in Iran have a brownish laminated gypcrete capstone that can be 3-10 m thick over the actively flowing parts of the salt (Bosak et al., 1999).

The term “cap” may be somewhat of a misnomer as layered CaSO_4 dissolution residues also form offshore in the Gulf of Mexico in zones of active fluid flushing on the undersides of salt beds and allochthon sheets (see fractionated dissolution discussed in Chapter 7). For example, cores taken from the base

salt contact in the Amoco #1 SL 12878 well in Plaquemines Parish, Louisiana, sampled a mineral assemblage of calcite, euhedral dolomite, ferroan dolomite, anhydrite, banded diagenetic calcite and trace mineral, the typical mineral association of a Gulf Coast caprock (House and Pritchett, 1995).

Complications of shale diapirism

Both salt and shale form diapiric structures that, without drilling, can appear quite similar in seismic sections. In a benchmark paper Morley and Guerin (1996) discuss the similarities and differences present in salt and shale diapiric provinces and outline ways to distinguish the two styles of diapirism. Salt's mobility is a fundamental material property; so that structures in a mobile salt belt continue to evolve until the salt is completely dissolved or ongoing salt withdrawal produces sufficient overburden touchdowns to stop further flow. Shale, on the other hand, only “flows” while it is overpressured. Whenever the main shale body depressurizes it freezes. While a shale is mobile it can generate a progression of kinematic geometries similar to those generated by the reactive and active phases of salt diapirism (Figure 6.67a; Morley and Guerin 1996, Van Rensbergen et al., 2003).

Halokinetic flow in a salt province builds diachronous levels and tiers of allochthons all the way up through the basin stratigraphy to the seafloor. Salt flows and evolves at higher levels in the stratigraphy, long after the original salt level has become a primary weld. Movement of a shale diapir tends to be much more episodic and related to particular overpressuring events within the shale-dominated section of a prograding typically deltaic continental margin (e.g. load driven compaction or thermobaric release of water or hydrocarbon generation). Once a mobile and chaotic shale mass approaches the surface and the pressure buildup is released via mud volcanoes, the shale freezes.

Mud diapirs are not the same as salt diapirs, even if they show similar patterns of gravity-driven compressional folding. There is an important distinction to be made between the actual volume of sediment flowing in a mud “diapir” or allochthon versus the distribution of overpressured mud leaking pores fluid. What we resolve seismically as a mud diapir is not sediment that has experienced Newtonian flow. Rather, it is muddy sediment that is disturbed because it contains, or once contained, overpressured fluid. This is not the same as a body of flowing salt in the salt allochthons and diapirs that characterises slope and rise regions in the Gulf of Mexico, the Middle East and the North Sea. This means that there are no equivalents to salt

canopies and tongues in regions of mud diapirism. Rather there are local, often relatively narrow and cylindrical structures (mud diapirs) that define the vent and escape positions of overpressured fluids. Allochthons and diapirs in halokinetic systems act as a focus to fluid flow, in mud diapirs and walls they are the zones of fluid flow.

For this reason shallow allochthons and widespread raft tectonics atop thin shallow décollement layers are much less common in mobile shale belts. Most shale diapirs show affinities to autochthonous rather than allochthonous salt systems. Laterally limited shale allochthons do occur in the Niger Delta, where they form imbricate thrusts that pass down dip into gravity flows and slumped blocks of shale derived from the exposed mobile shale.

Another significant difference between salt and shale diapiric provinces lies in the permanence of the contact between the flowing unit and adjacent strata. While flow in halokinetic terrains only takes place within the salt unit, shale mobility can spread out into adjacent beds as the overpressured interval spreads. While overpressured, a mobile shale interval can cannibalise adjacent shale strata and so cut across time/bed boundaries giving an overpressured shale interval a chaotic indistinctly-layered appearance in seismic (Figure 6.67b).

Morley and Guerin (1996) noted how such differences in mechanical behaviour lead to differences in structural style between shale and salt deformation, although many basic aspects of the gravitational tectonics are the same in both provinces. They note that prekinematic and synkinematic structures occur in both provinces, but much of the prekinematic deformation in mobile shale deltas, such as the Niger Delta of Africa and the Baram/Champion systems of Brunei, are destroyed by aggrading cannibalisation

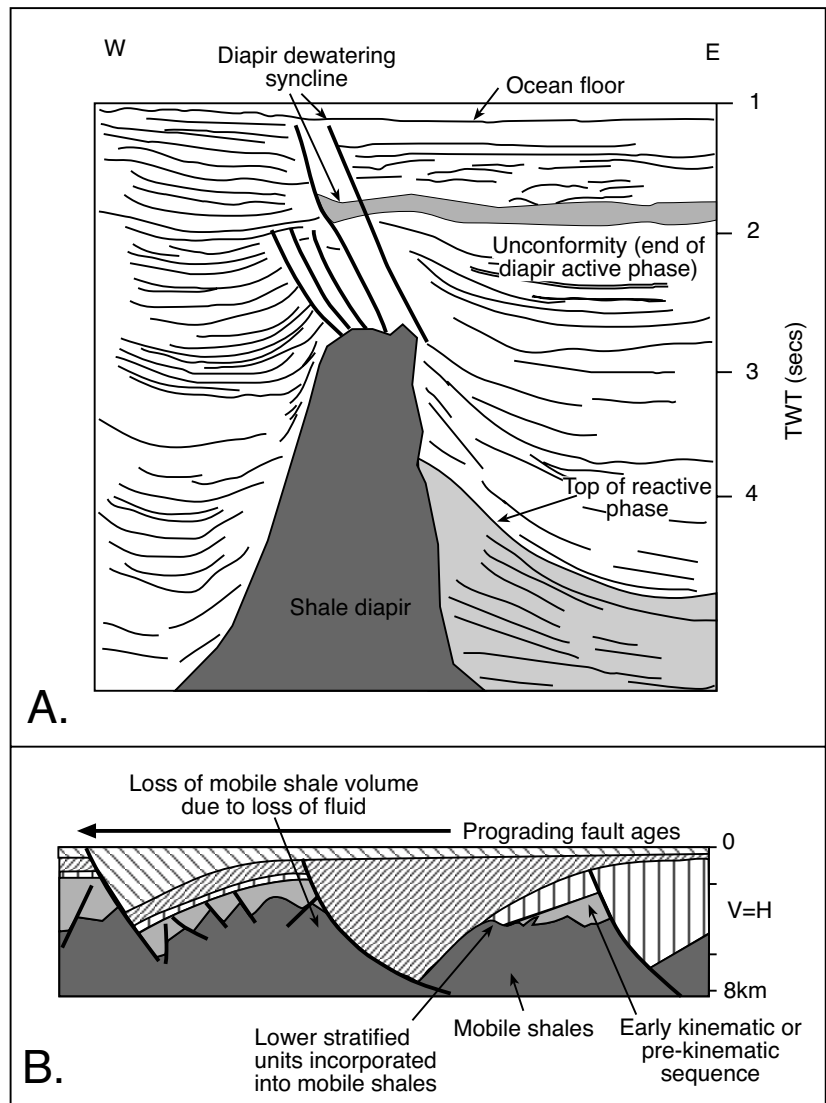

Figure 6.67. Shale diapirs. A) Shale diapir from the offshore diapir province of the Niger Delta, Africa. Adjacent sediments show synkinematic evidence of reactive and active phases of shale diapirism. The reflectors in the shaded region show thickening toward the shale diapir stem, suggesting expansion into an active growth fault during the reactive phase. B) Idealised evolution of growth faults associated with thick mobile shales (after Morley and Guerin, 1996).

of the overpressured shale. Not recognising this cannibalising effect can lead to the inappropriate placement of the lower portions of growth faults during seismic interpretation of shale diapiric belts (Van Rensbergen and Morley, 2000).

Fault-dominated minibasins occur above the flowing unit in both salt and shale mobile belts. For example, in the Niger Delta, the interval of overpressured shales beneath the actively

Figure 6.68. Seismic section from the thrust-floored compressional slope and rise of offshore Brunei Darussalam. Vertical line shows the position of a seep atop an erosionally breached anticlinal crest with an overpressured mud diapir core. The growth anticline has ponded deepwater sediment on its updip side.

accumulating delta prism varies from relatively thin intervals to massive chaotic zones some 4-6 km thick. The maximum depopod thickness is the thickness of the mobile shale plus the thickness of the overlying pregrowth fault strata (i.e. some 4-8 km). Such thicknesses are similar to those in salt-induced minibasins in the Gulf of Mexico.

Classic autochthon geometries are common to both salt and shale provinces, as are normal fault haloes that are created during reactive diapirism (Figure 6.67a). Early counter-regional faults and toe thrusts are early controls on the formation and position of depopods. Salt has the potential to completely evacuate as it evolves into salt welds or overburden touchdowns. Mobile shale deformation may also create local touchdown areas, but complete shale collapse is uncommon and large volumes of immobile dewatered shale are usually left after diapirism has ceased. Van Rensbergen et al. (2003) go on to note that due to the requirement of overpressure for shale mobility and the need for hydrocarbon generation to instigate overpressuring, a gas-charged mobile shale can forcibly stope upward through its overburden via a process of shale cannibalisation. This creates narrow near vertical mud pipe typically issuing onto the landscape as mud volcanoes. There are no equivalent narrow pipe-like cannibalistic stoping or diatreme-like features in the realm of salt tectonics.

Compressional growth anticlines cored by salt or overpressured mud can influence the distribution of deepwater sediments in the continental slope and rise in both settings. Such an anticline from the shale diapiric zone of offshore Brunei is illustrated in Figure 6.68. The geometry can be compared with similar anticlines, but with salt cores in the Gulf of Mexico and Angola (Figures 6.35, 6.38).

Summary

With the increasing use of 3D seismic for oil exploration in Phanerozoic basins, it has become obvious that models of predominantly vertical movement of salt from a mother salt bed into thumb-like autochthonous appendages are limiting. We now know that huge salt sheets (allochthons) can climb the stratigraphy as a series of predominantly subhorizontal sheets or tiers that are continually moving and squeezing as they are loaded by ongoing sedimentation. The end result is a feedback system where flowage create lows that fill with sediment, while the filling of the low with sediment triggers further salt flow. The upper side of the deforming salt sheet can flow into more classic thumb-like styles of diapirs.

Prior to the advent of forward-modelling techniques in seismic processing and the gathering of 3D data networks we could not image beneath salt bodies and so tended to interpret the upper salt surface as the primary level of the salt body. We now know this is not the case, many deforming salt beds flow into allochthons, which become rootless once the connection to the primary source or mother salt bed is converted to a salt weld or a fault weld. A salt weld forms as salt migrates or dissolves away to allow the former upper and lower contacts of the salt to come together or touchdown to form a salt weld. A fault weld forms where salt that was once within or lubricating a fault or shear plane is lost and the two sides of the fault come together. When a thrust plane is lubricated by salt that is subsequently lost by migration or dissolution, the plane may convert to a characteristic nearsurface dissolution breccia called *rauhwacke* (Chapter 7).

The end result of salt allochthons climbing through an aggrading and prograding shelf sequence is a layered and faulted stratigraphy with former sheets left as salt welds and fault welds, rather like a slug leaves a slime trail as it moves through a pile of leaf debris. The amount of salt left behind in the basin stratigraphy depends on the efficiency of salt evacuation. When the evacuation of the allochthonous salt sheet is efficient, all that is left behind is a series of stepped counter-regional fault welds and associated landward dipping faults. When the evacuation is less efficient the result is a series of salt rollers along the salt weld and an overlying fault-segmented sedimentary sheet cut by dominantly basin-dipping growth faults (a Roho system).

Wherever a salt allochthon is near the seafloor it can load, deform, coalesce or disaggregate as it continues its climb through the aggrading stratigraphy. Sediment loading atop a deforming allochthon creates fault-defined suprasalt basins or minibasins, often interacting with salt glaciers on the seafloor. Minibasins typically fill with a characteristic upward shoaling pattern of sediments passing from initial deeper-water laminated shales and mud to shallow water sands and carbonates. Processes of ongoing halokinesis and minibasin formation cease once the salt allochthon is sufficiently thinned, dissolved or buried. Thus, throughout the sedimentation history of a passive margin that is underlain by early thick salt beds there are many intervals where thick sheets of flowing allochthonous salt are present just beneath the deep sea floor and sandwiched into what are otherwise normal deeper marine bottom sediments.

Salt tectonics is also active in compressional terrains, which occur at the foot of a gravity glide sheet basinward of the continental slope; but is especially obvious in ancient foreland fold and thrust belts and inverted basins where weak subsurface salt acted a *décollement* layer. The resulting anticlines are narrow and salt cored while the intervening synclines are broad. Most of the thrusts are blind and backthrusts typically occur in association with forward directed thrusts. Much of the salt in the cores of the anticlines is strongly folded and diapiric; although the notion that compressional diapirs can breach their overburden, without being erosionally thinned or disrupted by tear faults, has yet to be proven. There is a growing body of evidence that a substantial number of compressional diapirs are actually reactivated extensional structures.

Chapter 7: Karst, breccia, nodules and cement: Pointers to vanished evaporites

Introduction

Given enough time all subsurface evaporites eventually dissolve. Even in the sedimentary realm there are probably more intervals of dissolution residues than there are beds of salts. The rate of evaporite dissolution changes with temperature and rate and volume of crossflowing undersaturated pore waters (Figure 7.1) Solubility of the chloride salts consistently increases with increasing temperature (prograde solubility), with the sulphates and the sodium carbonates it initially increases, but can then decrease at higher temperatures (retrograde solubility). Dissolution typically begins in the shallow subsurface as the edges of salt beds are flushed by meteoric or marine waters and continues deeper in the

Figure 7.1. Solubility of common salts in pure water as a function of temperature, expressed in mole anhydrous salt per kg H₂O, (after Braitsch, 1964).

Mineral Name	Composition	Solubility in freshwater (moles/litre)	Solubility with respect to limestone
Limestone	CaCO ₃	0.00014	1
Magnesite	MgCO ₃	0.001	7.1
Gypsum	CaSO ₄ ·2H ₂ O	0.014	100
Nahcolite	NaHCO ₃	1.22	8.7 x 10 ³
Mirabilite	Na ₂ SO ₄ ·10H ₂ O	1.96	14.0 x 10 ³
Natron	Na ₂ CO ₃ ·10H ₂ O	2.77	19.8 x 10 ³
Epsomite	MgSO ₄ ·7H ₂ O	3.07	21.9 x 10 ³
Thenardite	NaSO ₄	3.45	24.6 x 10 ³
Hexahydrate	MgSO ₄ ·6H ₂ O	4.15	29.6 x 10 ³
Bischofite	MgCl ₂ ·6H ₂ O	5.84	41.7 x 10 ³
Halite	NaCl	6.15	43.9 x 10 ³
Antarcticite	CaCl ₂ ·6H ₂ O	7.38	52.7 x 10 ³

Table 7.1. Solubilities in freshwater of various evaporite salts in comparison to limestone (relative solubility calculated from molar concentrations).

subsurface, wherever and whenever bed edges are flushed by undersaturated basinal brines. Partial dissolution, whereby crystals of more saline salts (typically halite and bitterns) are flushed, leaves behind residues of the less saline salts (typically gypsum-anhydrite, as in many caprocks).

Solubilities vary from salt to salt (Table 7.1). For example, gypsum is moderately soluble in nearsurface meteoric waters with a saturation concentration of around 2500 ppm at 40°C. Halite is much more soluble, its saturation concentration is ≈350,000 ppm at 25°C and, unlike the calcium sulphate salts, its solubility consistently increases with rising temperature (Figure 7.1). Limestone dissolves more slowly than gypsum or halite, with a saturation concentration that varies according to ambient pH and CO₂ levels, but typically in the range 50-400 ppm. Thus, when exposed to meteoric crossflows, gypsum is one to two orders of magnitude as soluble and halite is more than three orders of magnitude as soluble as limestone. Whatever the mineralogy, an evaporite mass will rapidly dissolve when in contact with a crossflow of meteoric or undersaturated basinal water. Put simply, if a block of gypsum the size of a transit van fell into a river it would completely dissolve in less than two years, a block of halite in days. The same is true in the subsurface; it just takes a little longer because the rate of crossflow is less.

Unlike carbonate karst, the effects of nearsurface evaporite solution on cavern formation and land surface subsidence are obvious in time frames measured in years, not millennia and can be impressive. The cluster of sinkholes atop dissolving evaporites and locally known as Hell's Kettles to the south of Darlington, UK, formed in 1179 AD via catastrophic collapse of the landsurface. A twelfth century annalist describes their formation as follows:

“In the reign of Henry II, the earth rose high at Oxendale, in the District of Darlington, (Oxendale is now Oxney flat) in the likeness of a lofty tower, and so remained from nine in the morning until evening, when it sank down with a terrible noise, to the terror of all that heard it, and being swallowed up it left behind a deep pit.”

This chapter on karst deals with subsurface and near surface regions where hypersaline depositional and burial hydrologies are replaced by pore waters undersaturated with respect to the various evaporite salts. This situation is ubiquitous wherever ancient evaporites are exhumed and have once again entered the active phreatic zone. It is also typical of evaporites in the deeper subsurface wherever undersaturated basinal waters are flushing the edges of impervious evaporite beds (Chapter 8). Dissolution leaves behind solution breccias and other indicators of the former presence of now-leached evaporites (vanished evaporites or “the salt that was”).

Even as an evaporite bed accumulates, or soon after its deposition ceases, the depositional environs can be periodically freshened, either by climatic excursions or by progradation of sheetwash/fluvial/marine flood sediment. In this scenario karstification is part of the ongoing depositional story and explains many microkarst textures described in chapter 1. In one of the first uses of the term “the salt that was,” Schreiber and Schreiber (1977) described Miocene gypsum beds in Sicily where early halite layers were seasonally dissolved, even as the gypsum bed was accreting. This is an example of the syndepositional end of a salt dissolution spectrum that extends into much longer time frames that encapsulate the burial and even the metamorphic realm.

At the millennial scale, the periodic evolution of syndepositional hypersaline hydrology into less saline groundwater system creates karst effects and textures at the contact between the evaporite bed and its overburden. It can drive pervasive karstification into the upper 5-10 metres of an accumulating evaporite bed. This scenario is common in many continental playas where fluvial and bajada sediments periodically build

out over a saline pan or where transgressive coastal zones pass over saltern beds. Its effects are discussed later in this chapter in the section dealing with syndepositional karst. But most of the chapter deals with the various outcomes and indicators of longer time frames where overburden is indurated and the dissolution process effects deeper subsurface (mesogenetic) and uplifted (telogenetic) bedded and diapiric salts.

Because of their high solubility, exhumed ancient evaporites outcrop best in arid or frozen regions of the world. These are areas with lower crossflow volumes of liquid groundwater and so are zones where even halite can make it back to the shallow subsurface before complete disintegration. Exhumed anhydrite typically converts to gypsum some tens to hundreds of metres below the landscape over those areas of the world featuring subcropping and outcropping evaporites. This telogenetic gypsum has a fresh set of textures that make it difficult to interpret its original depositional fabric (Chapter 1). Subcropping halite, with its much higher solubility, tends to dissolve completely before reaching the surface. In all but the most arid environments, gypsum, not halite or anhydrite, is the commonplace outcrop expression of an underlying evaporite mass, be it bedded or halokinetic.

Outcropping gypsum caprock, with well-developed karst, encases salt diapirs in the Middle East, north Africa and central Australia and defines halite subcrop in the Qinghai (Tibetan) plateau, the Pecos Valley of west Texas, the Magdalen Islands in the Gulf of St. Lawrence, Canada, and in the Sierra del Fraile, in northeastern Mexico. Gypsum capstones can occasionally outcrop in humid tropical regions. For example, a gypsum caprock sporadically outcrops along the erosional banks of the Nam Theun river in Laos. This site lies within the axis of an evaporite-floored synclinal trough, it is surrounded by tropical pine forest, and caps an actively dissolving residual mass of stratiform, Cretaceous halite (*pers. obs.*). Halite can reach the surface in arid zones where salt is actively flowing into diapirs and allochthons, as at Mt Sedom in the Dead Sea Valley and in the salt glaciers (namakiers) of Iran.

Individual exposures of outcropping salts are usually no more than a few square kilometres, whereas dissolution breccias, insoluble residues and their characteristic subsidence terrains such as blind-valleys and suffusion karst, subcrop more widely. The mining of rock salt, or the drilling of boreholes into or through rock salt, have accidentally intersected or created caverns leading to a number of large, anthropogenic collapse sinks, subsidence cones and subsrosion features, which are discussed further in Chapter 12. Natural karst hazards are discussed later in this chapter.

Table 7.2. Continued.

Complete evaporite dissolution means no salt remains, while partial or preferential dissolution means the vertical or lateral extent of the remaining salt sequence is reduced and the more soluble salts have gone. Salt bed dissolution can be syndeositional, as can nodule and crystal replacement, or can occur later during shallow burial with vadose or shallow phreatic flow driving cavern formation and overburden collapse. Bed alteration and solution can occur much later under deeper phreatic basin hydrologies, where circulation is driven by compactional and thermobaric flushing. It can occur later still, when uplifted salts beds are once again flushed by deeply circulating meteoric waters during collision, inversion and overthrusting, (Table 7.2). Dissolution also occurs in the more enigmatic meta-evaporitic and igneous realms, where it is accompanied by deep burial mineral transformations such as scapolitisation, albitisation and tourmalinisation (see Warren, 1999; Chapter 6 for details).

Brines generated at an evaporite dissolution front can seep into adjacent sediments where new authigenic evaporite cements and nodules precipitate. Dissolution brines can be carried up along brine escape conduits, such as faults and fractures, into the higher portions of the sediment pile where they cool or mix with waters of differing chemistries and so precipitate as authigenic cements. Although dissolutional hydrology is transitory, the evidence of former evaporite beds—the evaporite that was—is permanent and ranges from dissolution breccias and residues, to replaced evaporite crystals and nodules, to authigenic evaporite cements near flow conduits such as unconformities, faults and fractures.

Evaporite landforms

As salt dissolves in the shallow subsurface it creates void space into which overlying strata can drape or brecciate to create characteristic landforms at both local (m to km) and regional (km to tens of km) scales (Figure 7.2). We can divide

solution-related landforms into two styles: active karst and palaeokarst. Paleokarst refers to ancient karstic features that are no longer active and were tied to basinal flushing hydrologies or landsurfaces no longer present. Active karst is responding to the ambient hydrology and typifies the landscapes discussed in the following section.

Local scale karst

Regions underlain by evaporite subcrop exhibit dissolution landforms similar to carbonate karst and include many varieties of karren, sinkholes (dolines), blind valleys and poljes (Ford and Williams, 1989). Bedrock exposures of gypsum or salt at a finer scale are sculpted into irregular surfaces called rillenkarrren and other solution flutes (Macaluso and Sauro, 1996; Stenson and Ford, 1993).

Dolines or sinkholes

Dolines (aka sinkholes, esp. in North America) are closed circular to elliptical hollows or depressions, often funnel shaped, with diameters ranging from a few metres to a few kilometres and depths from a metre or so to hundreds of metres (Figure 7.2). They indicate subsidence and/or collapse of underlying salt or carbonates. Because exhumed evaporites make it to the surface or nearsurface in mostly arid to hyperarid climates, sinkholes atop shallow bedded evaporites tend to occur at the terminations of dry arroyos in deserts. Valley sides may be steep and can expose karstified gypsum, or be gentle and covered by desert soils. Larger sinkholes may also enclose one or more smaller sinkholes and can be further subdivided into collapse, suffosion and solution dolines (Figure 7.2). A collapse doline forms by the collapse of a roof span into an underlying solution cavity. Suffosion dolines are smaller features (1-5m diameter) covered and filled with soils and debris washed into its fissures by rainfall or sheetflood. They indicate that the dissolving salt mass is close to the landsurface. Solution (subsidence) dolines tend to be larger downwarped doline craters or bowl-like subsidence depressions. Compared to collapse and suffosion dolines

they have lower slopes into the deeper parts of the doline, the doline walls are usually hosted in nonevaporites and the dissolving salt bed lies some distance below the landsurface. At the larger end of the scale of doline development a subsidence doline merges into a subsidence basin. This is a large solution hollow that creates enough accommodation space to be considered a small sedimentary basin that is filling with varying combinations of fluvial and lacustrine sediments.

Dissolution, collapse and suffosion are more active, more rapid, more frequent and more obvious in evaporite terrains compared to carbonates. In the Perm and Bashkir regions of Russia, Gorbunova (1979) reported doline densities atop weathering evaporites and carbonates of 32 and 10/km² respectively, although densities of up to 1,000/km² can occur in evaporite-cored fold axes or at contacts of evaporites with other lithologies. Densities of 1,100-1,500/km² have been documented in evaporite karst in the Italian Alps. Such high densities occur in regions of high hydraulic gradients and mean the dolines have diameters around 5 m (Belloni et al., 1972). The inherently high solubility of evaporite salts also explains densely-packed schloten depressions and large karren shafts seen in gypsum karst of Antigonish County, Nova Scotia, where extrapolated doline densities range up to 10,000/km² (Martinez and Boeber, 1997). Extrapolated, because such dense networks do not extend over any more than a square kilometre or two and are typically found near retreating escarpment edges underlain by shallow subcropping salts.

It is a form of mantle karst where the dissolving salt bed is never far below the landsurface.

Collapse dolines

Collapse dolines are steep-sided sinkholes, often defined by cave entrances. They form when solution of an underlying evaporite bed creates a roof span in the regolith that can no longer be supported by the overlying lithology. Doline walls are frequently asymmetrical; one wall is steep and the other one is gentle. Doline floors tend to display either concave-up or flat geometries. Apart from blocks of the collapsed roof span, active doline floors can be veneered by thin collapse breccias. The high density of dolines in areas of evaporite subcrop and the ubiquity of the associated breccias indicates the inherently higher solubility of the evaporite salts compared with interbedded and overlying carbonates (Figure 7.2b).

Solution Dolines

Larger sinkholes (subsidence dolines) with characteristic low angle widespread edge flexures and slopes indicate deeper, more widespread salt dissolution compared to collapse dolines and are linked to the creation of a bowl of subsidence (Figure 7.2c). They occur in most regions of deeper evaporite karst including; Italy (Belloni et al. 1972; Burri 1986; Ferrarase et al., 2002), Spain (Gutiérrez, 1996) and the Pecos Valley of

Suffosion dolines

High levels of dispersed impurities in a rapidly dissolving evaporite mass (mostly clays and muds, often dolomitic), means a soil or carapace of insoluble residues quickly covers the subcropping top of a dissolving salt mass (Figures 7.2a, 7.3). This carapace is continually undermined by the rapid solution of the shallow salt mass. Residual debris is washed into the doline crevices to create the characteristic soil-covered dimpled landscape that typifies a high-density doline

Figure 7.2. Typical scales and origins of evaporite karst features formed at the land surface atop a dissolving evaporite unit (grey).

Figure 7.3. Suffosion karst development on subcropping till-covered gypsum in Nova Scotia, Canada.

west Texas and New Mexico (Gustavson et al., 1982; Davies, 1984a, b; Quinlan et al., 1986). In contrast to the numerous small steep-sided suffosion and collapse dolines formed atop shallow subcropping shallow evaporites, these larger, bowl-like dolines can have diameters of 100-500 m and depths of 10-20 m. Most have a soil cover and a thick sediment fill, with dissolving salt units at depths measured in tens to hundreds of metres below the land surface. They are mature dissolution forms and are transitional to subsidence basins where even thicker more widespread sediment fills are to be found (Figure 7.2d).

Breccia Chimneys and Pipes

Breccia pipes develop as landscape features on the same scale as collapse dolines or sinkholes. These steep sided chimney-like features are created by progressive upward stoping from the base of the salt bed, not its upper portions. In regions of thick evaporites the stoping process is driven by the focused upward escape of undersaturated basinal or deeply circulating meteoric waters leaking from levels below the sealing evaporite bed. Waters creating a stoping pipe can be focused into point or line sources via underlying biogenic buildups or fracture networks (Figure 7.4). Quinlan (1978) reviewed the nature and distribution of more than 5,000 breccia pipes within or atop salt or gypsum in the United States. Pipes ranged from 1 to 1,000 m in diameter and up to 500 m in depth. Similar crosscutting pipes in halite of the Devonian Prairie evaporite interrupt workings of potash mines in Saskatchewan, where they may propagate from depths as great as 1,200 m, and may lie beneath 1,000 m or more of cover strata (Figures 7.5). Unexpected intersection with a breccia pipe in an exploited bed can lead to catastrophic flooding and ultimate loss of a mine (Figures 11.27, 11.28).

Breccia pipes in an evaporite mass may exhibit one of four possible states (Figure 7.4): a) Active, and propagating upwards towards the surface, but not yet expressed there - a blind chimney; b) Active or inactive, expressed at the surface as a closed depression or a depression with a surface outflow channel; c) Inactive, and buried by later strata - paleokarst chimney; d) Inactive and standing up as a positive relief feature on the landsurface because the breccia (probably cemented) is more resistant to weathering than the upper cover strata - a residual pipe. Downward flexure in the uppermost strata atop a growing pipe forms a bowl of subsidence and sinkhole.

In some intrasalt pipes the halite or gypsum is entirely removed, leaving only an accumulation of insolubles and collapsed breccia blocks. In others, portions of the less soluble salts remain in the pipe. Mature pipes are typically filled by a jumble of intrasalt and suprasalt breccia blocks. In some, a lower brecciated zone is succeeded by an upper zone in which the overlying strata failed as a coherent block, settling downwards via a cylindrical pattern of steep to vertical faults with downthrows of up to 200 m.

Landscape residuals; karst domes and castles

Karst domes remain as features of positive relief once the surrounding evaporite mass has completely dissolved. Unlike chimneys, the cores of evaporitic karst domes can expose blocks from below, as well as above the original salt level. Some evaporitic karst domes are related to the stratigraphic level of former bedded salt, others are the remains of now dissolved salt thrusts, diapirs and allochthons (see diapiric breccias and rauhwacke). Domes and residuals are dramatic landscape features in the gypsum terrain of northern Alberta, Canada (Wigley et al., 1973; Tsui and Cruden, 1984) and the

Figure 7.4. Interrelationships between larger scale dissolution features, artesian flow and various types of upward stoping breccia pipes (not to scale; in part after Ford, 1989).

Archangel gypsum karst region inland of the Barents Sea coast of Russia (Korotkov 1974). Canadian karst domes range from 10 to 1000 m or more in length or diameter, and can rise up to 25 m above the surrounding land surface. Many domes are highly fractured, with individual overburden blocks displaced by heaving and sliding, with the residual gypsum showing well-developed flow foliation.

At the extreme end of disturbance and dissolution the domes are megabreccias; positive relief features made up of upthrust jumbles of large blocks the size of houses. The largest reported Canadian example is in a steep-limbed anticline that extends along the shore of Slave Lake for a distance of 30 km, it is up to 175m in height with a crest that is marked by a 'chaotic structure and trench-like lineaments' (Aitken and Cook 1969). These spectacular karst domes occur in regions of widespread permafrost so that accumulation of ground ice in initial fractures in the evaporite layer probably contributes to the heaving and other displacement of breccia fragments in the dome. Tsui and Cruden (1984) attributed the examples that they studied in the salt plains of Wood Buffalo National Park Canada (Lat. 59-60°N) to hydration processes operating on subcropping bedded gypsum during the postglacial period. Ford and Williams (1989) argued such features indicate local injection of gypsum residuals during times of rapidly changing glacial ice loading. Whether they are created by glacial unloading/reworking or are a type of gravitationally-displaced dissolution breccia in a permafrost region is debatable; that they are a type of evaporite residue is not. They characterise the region defined by dissolution of shallow subcropping Devonian salt in Northern Alberta.

Residuals composed of cemented sinkhole or breccia pipe fillings can create hills surrounded by lower relief remnants of the former host bed (Figure 7.5). More than a thousand such hills occur on the gypsum plains of western Oklahoma (Fay

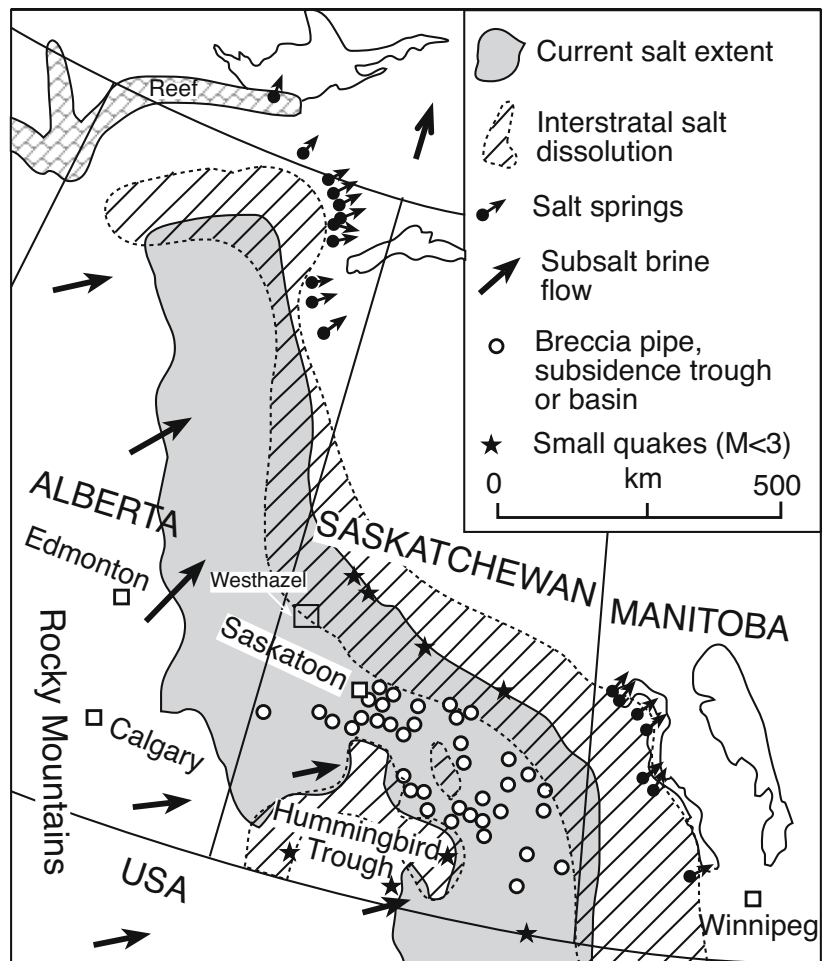

Figure 7.5. Regional distribution of evaporite karst features in the Prairie Provinces of Canada, including a large subsidence basin known as the Hummingbird Trough. These features were created by the dissolution of thick widespread Prairie Evaporite at various times from the Devonian to the present (in part after Ford and Williams, 1989).

and Hart 1978). Those karst mounds or hills with a doughnut form (a central depression) rather than a rounded form are believed to be cemented expressions of former sinkhole fills within bedded evaporites, rather than residual breccia pipes (Myers 1962). Hills of cemented breccia pipe residuals are typically a few tens to hundreds of metres in diameter and can rise 5-40 m above their surrounds.

Castiles are another exhumed feature in a gypsum karst terrain. In their type area of the Delaware Basin, south of Carlsbad Caverns, New Mexico, they make up steep-sided hills and mesas rising 3 to 30 m above the Gypsum Plain (Kirkland and Evans 1976, 1980). They are now exposed by the preferential dissolution of the surrounding bedded gypsum in an area near the solution edge of the sulphate facies of the Castile Forma-

Figure 7.6. Main processes occurring inside an outer gypsum layer directly exposed to the atmosphere in a typical Mediterranean climatic regime. During wet winters, rainfall drives an overland flow and the water dissolves the gypsum at the surface (A) while a portion of the runoff manages to penetrate inside the intercrystalline pores of the rock. The water reaches saturation (with CaSO_4) at the surface and a few decimetres into the rock (the B line (dashed) may be considered a saturation front). The solution continues to penetrate both inside the pores and along fissures and joints (2), creating a downward reaching front of newly arrived meteoric water (C). Near-surface water in this front can also flow laterally (3). During the dry season, the pores lose water by evaporation (4). The inner solution becomes oversaturated and moves by capillary action towards the surface (5). In the D zone, there is precipitation of gypsum both by evaporative loss and by brine heating as it approaches the landsurface (gypsum has retrograde solubility). In the fissures and cavities, the pore fluids now migrate upwards (6) and new gypsum crystals may develop. The mass transfer from the inner towards the outer zone results in pressure relaxation (7) in the C zone, where open fissures may exist, and in pressure increase (8) in the D zone. In the type II environment, the runoff inside the sediment causes solution of the underlying gypsum both at the interface and in the fissures and other discontinuities of the rock. In this way, covered solution pavements and expansion tumuli develop, these features are most obvious after erosion of any soil cover (after Ferrarase et al., 2002).

tion (Figure 7.9). Similar features occur in areas of exhumed Miocene evaporites along the margin of the Red Sea (Aref, 1998b). Castles first form in the subsurface as a byproduct of the metabolic activities of sulphate-reducing bacteria, which locally replace gypsum with biogenic calcite (Figures 7.45a, 9.43).

Expansion morphotypes at outcrop

As well as the classic karst features, which are a response to dissolution and volume loss, some outcropping gypsum beds, especially in regions of anthropogenically induced rapid soil erosion, indicate local volume changes as in parts of Sicily and Spain where weathered late Miocene gypsum is now exposed at the landsurface (Figure 7.6). Such regions are characterised

by extensive alteration and recrystallisation of the gypsum regolith and soil textures that indicate repetitive cycles of expansion and contraction of the near-surface gypsum. The gypsum has evolved into pedogenic mounds and polygons related to exhumation into an active hydrology some millions of years after its deposition (telogenesis). The resulting medium-sized dome-like hills are covered by a mosaic of smaller landforms, related to different types of karren and of “expansion” forms such as tumuli and polygons. According to Ferrarase et al. (2002), the various gypsum morphotypes can be classified into two main categories: those that originated by solution and those that originated through recrystallisation.

Outcrops of gypsum lacking soil cover and influenced by alternating seasonal water conditions of surplus and deficit are

affected by both solution and recrystallisation processes. During the wet season, the water soaks into the rocky subcropping gypsum mass, filling all the fissures and pores of the outer layer from a few centimetres to some metres below the surface. During the dry season, there is a capillary-driven upward motion of the water solution. Near the surface, gypsum precipitates from the oversaturated solution, increasing the crystal size or forming new crystals. In this way, during the dry season, there is a pressure increase in the outer gypsum layers, which is responsible for the development of a “gypsum weathering crust.” It is characterised by many different expansion forms such as gypsum tumuli, pressure ridges and pressure humps. Tumuli are hollow subcircular domes, developed in coarsely crystalline gypsum crusts in the uppermost stratum of the gypsum regolith. They vary from a few centimetres to several metres in diameter and reach maximum heights of a little over a metre. Thicker crusts (≈ 1 m thick) support the development of mega-tumuli and dome-like hills some hm across. Development of dome-like hills does not seem to be controlled by variations in strike, dip, or fissuring of the gypsum beds. Their evolution seems to be linked to the fact that on most of the dome surfaces, the weathering crust is evolving through a nearly isotropic field of stresses, which is a result of capillary-driven volume increase in the outer gypsum layer (Ferrarase et al., 2002).

Regional scale karst

The distribution of landscape features above an actively dissolving salt mass depends on the extent and depth of the underlying salt. That is, at the regional scale is the dissolving salt bedded or diapiric? Elongate depressions, known as subsidence troughs, tend to define the subcropping edges of shallow gently-dipping salt beds. In contrast, smaller zones of circular sinkholes, solution lakes and cenotes tend to form atop the crests of shallow diapiric salt. In regions where the crest of the halokinetic salt is still rising, there is ongoing retention of positive relief atop the structure, even though sinkholes and capstones are continually forming within this zone of positive relief.

Subsidence basins or troughs

Subsidence troughs are large-scale elongate depositional depressions created by interstratal solution along the dissolving edge of shallow salt bodies. They can be filled or partly filled by clastic sediments (Figures 7.7a-c, 7.8; Olive, 1957; Quinlan, 1978). Salt-edge leaching of the shallow dipping salt underscores a set of self-perpetuating processes. Fractures created by the collapse of overburden and intrasalt beds into accommodation space (generated by salt cavities) provide new fissures and

sinks that act as additional conduits for further percolation of meteoric or upwelling of undersaturated basinal waters into the salt. This in turn instigates yet more salt solution in the vicinity of the collapse and typically creates an elongate corridor of subsidence at the surface.

Large solution-induced depositional basins and monoclines outline the edges of the great interstratal salt deposits of the world. Depression corridors some 5-500 km long, 5-250 km wide, with up to 100 to 500 m of subsidence induced relief and sediment fill define saline karst plains along the edges of bedded and dissolving saline giants in the Devonian subcrop of Canada (Tsui and Cruden 1984), the Permian Basin of New Mexico, Oklahoma and Texas (Bachman 1984), the Perm region of Russia (Gorbunova, 1979) and the Jurassic Hith region of Saudi Arabia (Amin and Bankher, 1997a, b). Associated sediment infill typically reduces the regional solution edge landscape to a few tens of metres of relief. For example, the Rosetown Low and the Regina Hummingbird Trough accumulated more than 100 metres of depression trough sediment during interstratal dissolution of the underlying Prairie salt (Devonian) in southern Saskatchewan (Figure 7.5b; DeMille et al., 1964). The concurrence of a supra-unconformity thick, adjacent to the sub-unconformity feather edge of a bedded salt sequence, is at a scale that is easily recognised in seismic and constitutes one of the classic signatures of a salt collapse-induced hydrocarbon trap (Figures 7.7a, 10.63).

A solution depression tends to capture rivers which, via seepage loss, tend to be losing streams in the vicinity of the solution front, so encouraging further salt solution and collapse. Examples of modern fluvial capture by subsidence troughs include the nearsurface edges of the Hutchison Salt Member in Kansas, the Maha Sarakham Formation in NE Thailand and along the Nam Theun valley in Laos (Figure 7.7c; Anderson et al., 1994; Supajanya and Friederich, 1992) and rivers in the Ebro Basin, NE Spain (Benito et al, 2000). The associated accumulation of fluvial and other sediments rapidly fill most modern solution troughs, so that surface relief is usually no more than metres to tens of metres across the subsidence corridor. Pleistocene and Holocene sedimentation rates in active US and Canadian subsidence corridors are ≈ 5 to 10 cm/1000 years. The Uralian troughs of the former Soviet Union are no longer active and so show somewhat lower rates of 0.3 to 3 cm/1000 years.

Interestingly, the foci of many small recent Saskatchewan earthquakes (magnitude $<3-4$ on the Richter scale) are located near the dissolving edge of the Prairie Evaporite salt (Figure 7.5; Gendzwill and Unrau, 1996). As bedded salt dissolves,

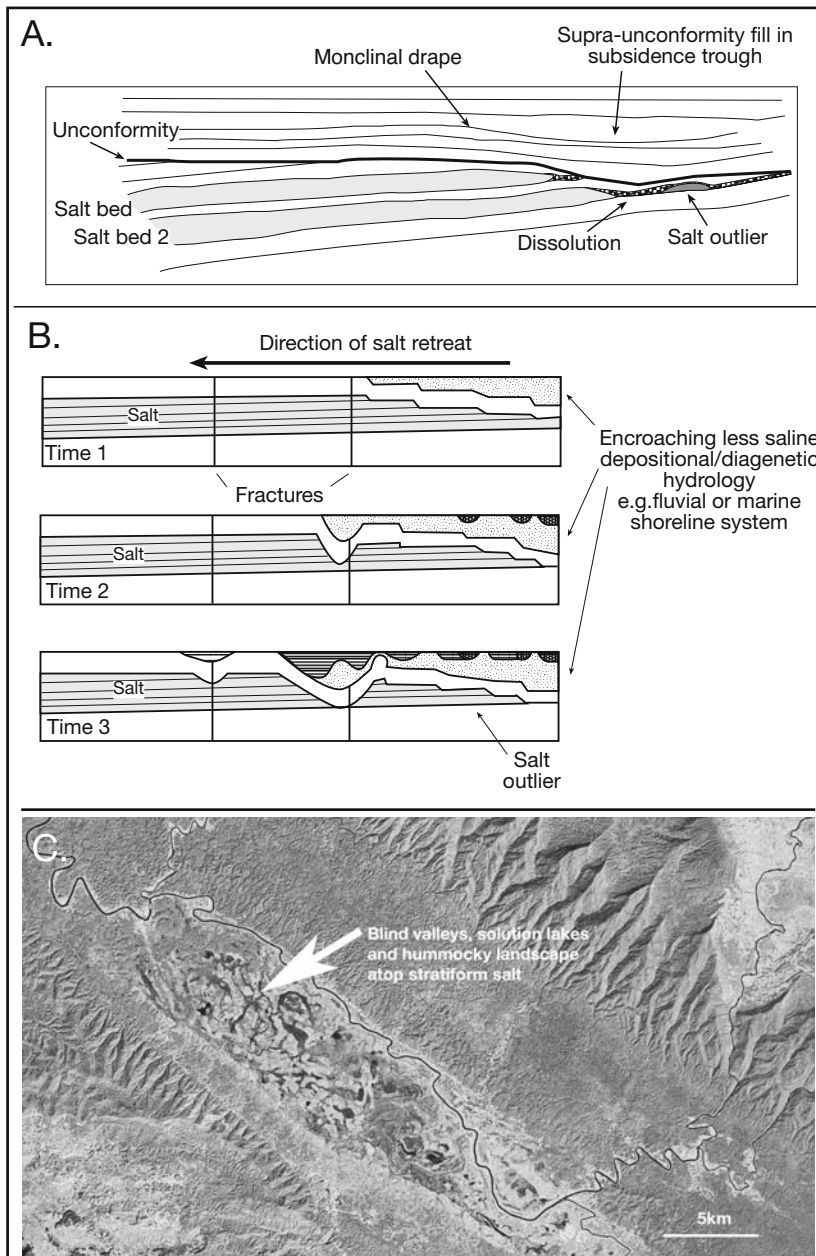

Figure 7.7. A) Subcrop salt dissolution creates characteristic sag geometries visible in seismic reflectors. B) Schematic dip section showing the sequential development of a regional subsidence trough, based on studies of the Hutchison Salt Member, Kansas (modified in part from Anderson et al., 1994). C. Nam Theun syncline, Laos, with Nam Theun River running along the northeastern edge of a dissolving stratiform salt mass that is equivalent to the Cretaceous Maha Sarakham salt of Thailand (Landsat image courtesy of NASA).

support is removed from the overburden, which then slumps. If the overburden is weak or extensively fractured, it settles quietly. However, if the overlying rock is an indurated carbonate, it may resist movement, forming a bridge over the growing

cavern. The roof span can fail violently when the undermined area gets large enough, so causing a small earthquake. Dissolution of the salt is possibly localized by faults and fractures, which provide seepage paths for the entry of undersaturated ground waters. Landscapes above many of the small Saskatchewan earthquakes lack extensive solution lakes, implying they may be sites upward sloping breccia pipes that have not yet breached (blind chimneys). Similar scale earthquakes can also define times of catastrophic failure in some salt mines and brine fields. On March 12, 1994 a 3.5 M quake documented the collapse of a mine panel in the Retsof Mine near Cyberville, New York state. Ensuing flooding caused the loss of the mine, which was until then the largest salt mine in the United States (Figure 12.19).

Hutchison Salt, Kansas

As well as their vertical expression being maintained by dissolution, subsidence troughs also migrate laterally, mirroring the retreat of the dissolving salt front (Figure 7.7b, 7.8a). The westward-dipping Hutchison Salt Member of the Permian Wellington Formation is 50-90 m thick and underlies much of central and south-central Kansas. Ongoing edge dissolution since the late Tertiary has created a subsidence corridor with contemporaneous valley-fill of Quaternary alluvium. In places, the alluvial fill extends more than 25 km to the east of the present-day edge of the main body of contiguous rock salt. The salt margin has receded this distance over the past several million years. Subsidence and collapse atop the active dissolution front creates numerous sinks, blind valleys and other salt karst features in the land surface and a pockmarked irregular thickness in the shallower parts of the salt bed (Figure 7.8b).

Oil well drillers call this region of dissolution cavities and fractures the “Wellington Lost Circulation Zone” and it extends for more than 100 miles N-S parallel to the dissolution edge of the salt bed (Figure 7.8a). Hutchison Salt is leaching vertically from the top down, and horizontally inward along the outer edge of the salt shallow dipping salt bed. Dissolution is driven by sustained contact with a crossflow of unconfined and undersaturated groundwater. As a result, over distances of 5-15 km westward, the eastern margin of the dipping and dissolving salt bed thickens by up to 90 m (from east to west). Locally, the salt member is preferentially leached along NNE-trending palaeoshear/fracture zones to leave behind thick stepped outliers (Figure 7.8b). Walters (1978) calculated an average lateral retreat of 3.2 km per million years since the late Pleistocene. He also pointed out that this rate is not constant. Dissolution was more rapid in the Early Pleistocene as the salt front was shallower. Now, when the front affecting the shallow dipping beds is deeper, groundwater crossflow and associated dissolution is slowing.

Natural subsidence and the rapid appearance of collapse dolines atop the dissolving Hutchison Salt Member has resulted in periodic ponding of surface waters in numerous dolines, abandonment of at least one oil well, and ongoing damage to numerous county roads (Figure 12.24). Because this damage can be in the vicinity of an oilfield much of the surface subsidence has been popularly attributed to poorly controlled drilling and development by unscrupulous oil companies. Any subsidence that occurs significant distances from any known well site is popularly attributed to unrecorded abandoned wells or complex asymmetric patterns of salt dissolution that originates at a drillhole. To test the validity of this widely accepted anthropogenic

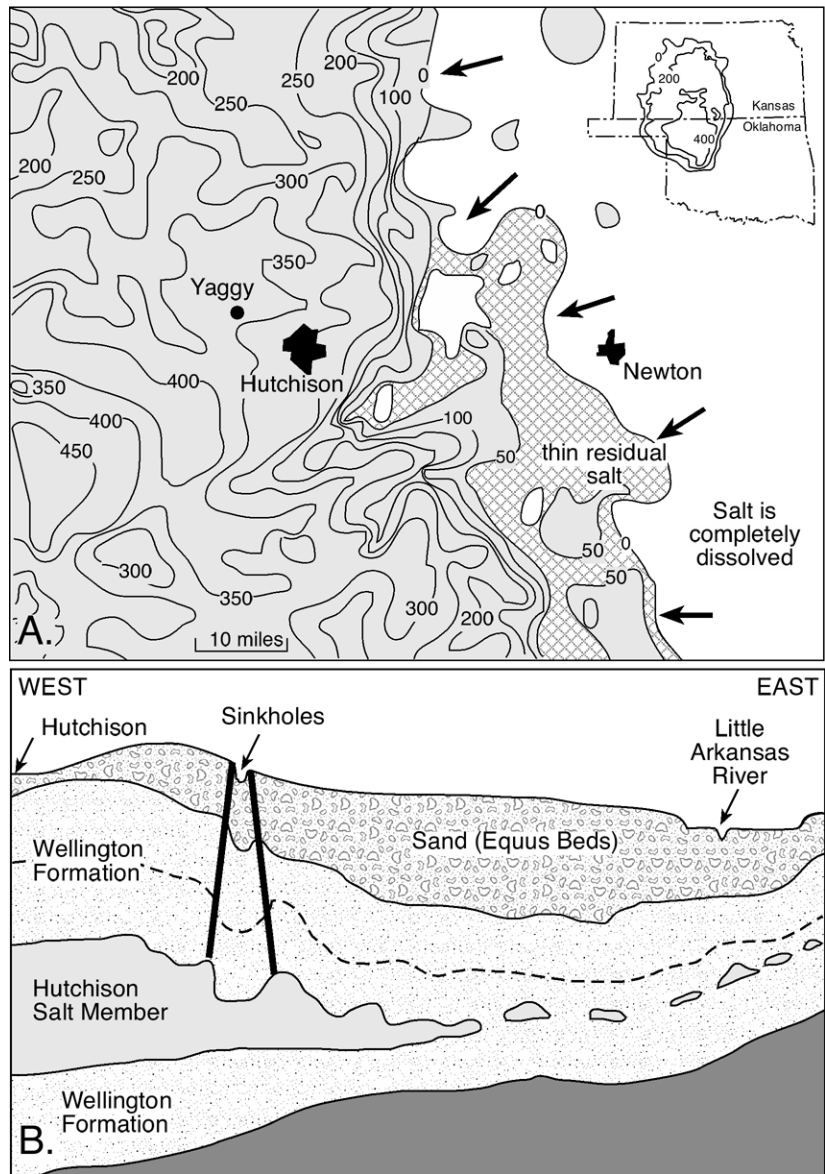

Figure 7.8. Karstified edge of Hutchison Salt Member. A) Thickness of the Permian Hutchison Salt, Kansas. Arrows indicate the direction of retreat of the dissolution feather edge of the salt body, Thickness is in feet and grey shading indicates salt thicker than 50 feet. Note the remnant outliers to the east of the dissolution edge (after Walters, 1978). B) Schematic east-west section in the vicinity of the town of Hutchison (after Watney et al., 2003).

salt-dissolution model, so popular with the environmental movement, a 4 km seismic reflection profile was acquired along an east-west-oriented county road adjacent to an abandoned oil well (Anderson et al., 1998). The expectation was that the residual Hutchinson Salt Member would be anomalously thin near an area of historical subsidence such as near the Burton oilfield. It should be thicker away from intensely drilled areas.

Contrary to expectations, the residual Hutchinson Salt Member is relatively thick (20–30 m) below areas of significant recent surface subsidence.

Nor is there any evidence of recent surface subsidence at locations along the seismic profile where the rock salt edge has been totally leached. Dissolution and subsidence at these sites largely predates European settlement of Kansas. Sinkhole development via catastrophic collapse is apparently a natural phenomenon and should be expected along this irregular salt dissolution front. Anderson et al. concluded that no modern catastrophic sinkhole development in the area has a clear-cut anthropogenic cause. As in the Prairie Evaporite, it seems focused collapse is largely a natural process influenced strongly by preexisting geologic conditions. This means sinkhole formation was only slightly and then rarely enhanced by the poor drilling and well abandonment procedures of 1920 though 1950s. However, the anthropogenic hazards created by a combination of gas storage in

shallow bedded salt and the presence of old poorly-documented solution wells, is another matter (see Hutchison gas explosion; Chapter 12). Natural salt karst collapse occurs quickly, well within a human lifetime. We cannot greatly influence the process of salt karst collapse, so we should plan geographic placement of infrastructure so that as much as possible it avoids it.

Delaware Basin, west Texas

The Delaware Basin of west Texas and southeast New Mexico, in the southwest portion of the Permian Basin, contains bedded evaporites of the Late Permian Castile, Salado and Rustler Formations. Outcrops and subcrops of these three formations constitute an area of widespread subsidence troughs, collapse sinks, dolines and breccia chimneys, all created by ongoing removal of underlying bedded Permian salts. The Delaware is an eastward-dipping basin, largely surrounded by the Capitan Reef and its equivalents (Figure 7.9). The area called the

“Gypsum Plain” of Texas lies to the west of the Pecos River and comprises about 2,600 square kilometres of subcropping gypsum of the Castile Formation. It is where the “Castile” landforms mentioned earlier are to be found. Additional gypsum outcrops are present to the east in the Rustler Hills and to the north in Reeves County, Texas.

In the centre of the Delaware Basin the thick evaporites of the Castile and Salado Formations and the thinner evaporites of the Rustler Formation are underlain by relatively permeable carbonates and siliciclastics, including some prolific hydrocarbon reservoirs in Permian backreef of the Central Basin Platform. Reef mounds, fractures and faults in these underlying sediments have provided focused conduits for upward stoping chimneys through the buried evaporites as well as the subsurface formation of now-exhumed Castiles to the west. An eastward-flowing deeply-circulating regional artesian hydrology, in combination with centripetal escape of buoyant hydrocarbon-rich basal waters, drives the formation of these features, with their surface expressions occurring in areas such as the Wink Sink (chain of breached chimneys) and

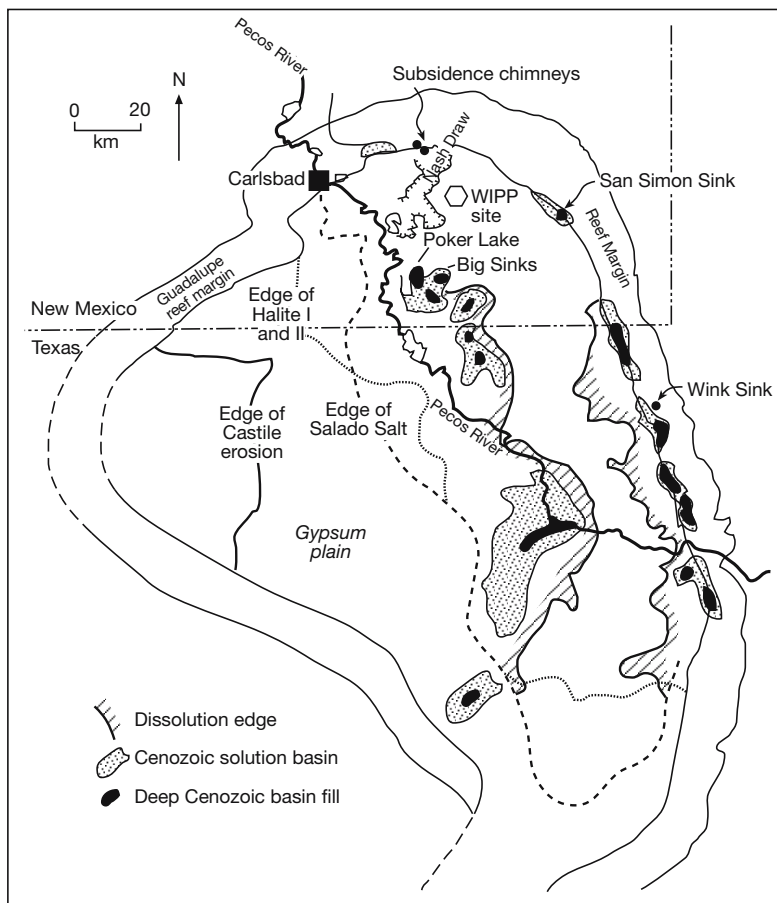

Figure 7.9 Karst features in the Delaware Basin and the positions of dissolution edges of various salt units, USA (after Davies, 1984a, b).

the Gypsum Plain (Castiles).

The upper sides of the shallow dipping salt beds are also affected by the hydrologies of the zone of active phreatic circulation. The Pecos River has migrated back and forth across the top of subcropping evaporites for much of the Tertiary. Its ancestral positions drove substantial salt dissolution, now evidenced by large sediment-filled subsidence

basins and troughs in the centre of the Delaware basin (Figure 7.9). The regional eastward dip of the Delaware basin sediments means first halite and then gypsum has disappeared along the updip eastern edge of the basin. Relatively undisturbed salt remains along the more deeply buried western side of the basin. Bachman and Johnson (1973) estimate the horizontal migration rate of the dissolution front across the basin as high as 10-12 km per million years. Multiple smaller examples of sediment-filled subsidence troughs occur at the edge of the gypsum plain of the Delaware Basin south of Carlsbad Caverns, where depositional troughs, 0.7 to 15 km in length, 100 to 1,500 m wide and no more than 5-10 m deep, are well documented (Quinlan et al. 1986).

The San Simon Swale is a 25 km² depression defining a residual karst feature atop the Capitan Reef on the northeastern margin of the Basin (Figure 7.9). San Simon Sink is the lowest point in the depression and is some 30 m deep and 1 km² in area. It in turn encloses a secondary collapse sink some 100 metres across and 10 metres deep. During a storm in 1918 a sinkhole formed a gaping hole about 25 metres across and 20 metres deep in the sink. In one night, nearly 23,000 cubic metres of soil and bedrock disappeared into the cavern. Annular rings that cut the surface around the San Simon sink today suggest ongoing subsidence and readjustment of the sinkhole is still occurring in response to earlier collapses. The position of

Figure 7.10. Differential dissolution of halite in Rustler Formation in the vicinity of the WIPP site (see Figure 7.9 for location). Note the anhydrite-gypsum and breccia residuals (as distinct from the bedded anhydrite). The solution trough lies some 400 metres above the level of the salt-encased WIPP (waste isolation pilot plant) subsurface waste storage facility in the Salado Formation.

the San Simon sink over the Permian reef crest led Lambert (1983) and many others to suggest that the sinkhole originated as a groundwater cavity breakthrough atop a series of stoping reef-focused breccia pipes.

Nash Draw is a southwesterly trending depression some 25 km long and 5-15 km wide, at the northern end of the Delaware Basin with its sump in a salt lake (Poker Lake) at the southern end of the draw (Figure 7.9). The underlying evaporitic Rustler Formation and parts of the Salado Formation has largely dissolved so that more than 100 caves, sinks, fractures, swallow-holes, and tunnels make up a complex local karst topography, which is apparently still active today (Bachman, 1981). An extensive drilling program conducted for the nearby WIPP site (now a low level radioactive waste repository) showed that dissolution of halite in the Rustler and upper Salado formations is responsible for the subsidence and overall formation of Nash Draw (Lambert, 1983).

To the west of Nash Draw the WIPP/DOE drilling program clearly defines the formation of a solution trough in the Dewey Lake Redbeds, created by preferential leaching of halite beds in the Rustler Formation, with interstratal anhydrite and breccia residuals (Figure 7.10). This dissolution occurred at a level some 400 metres above the salt-encased storage level of the WIPP waste isolation facility. A heated scientific (and at times not so scientific!) debate of just how deep surface karst penetrates

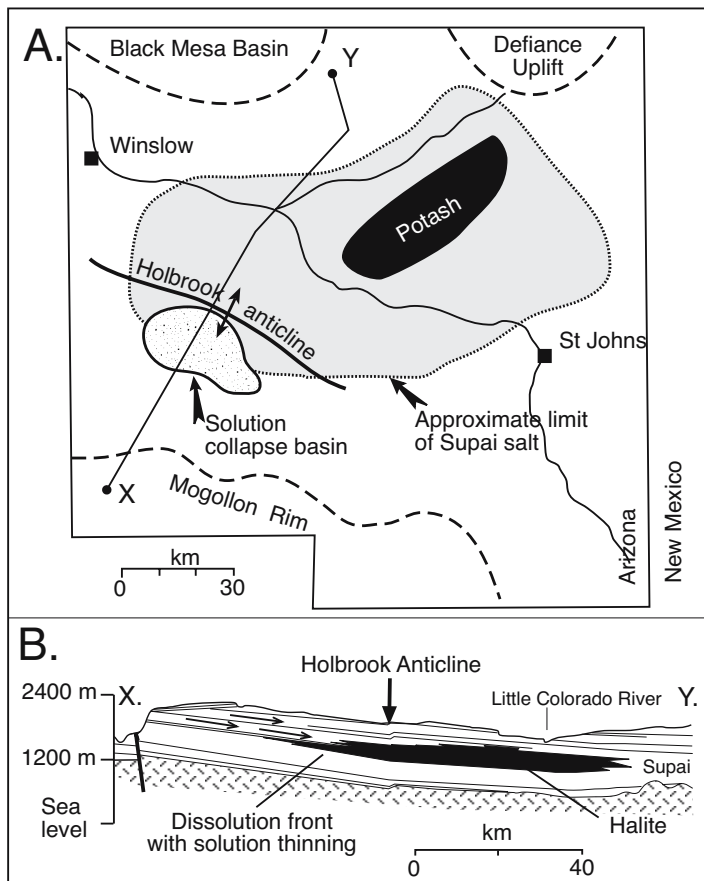

Figure 7.11. Holbrook Anticline, Arizona. A) Distribution of dissolution features seen at the surface and their relationship to the underlying Permian Supai Salt. B) Cross section showing how the Holbrook Anticline is a monocline flexure created by dissolution of the underlying Supai Salt (after Neal, 1995).

into the bedded halite of the Salado Formation in the vicinity of the WIPP site continues today (see Chapter 12 for detail of waste isolation in bedded and diapiric salt).

Further north, near the subcropping western edge of the Northwest Permian Shelf is Bottomless Lakes State Park, located some 20 kilometres east of Roswell. Outcropping about and underlying the lakes are the gypsum, halite, dolomite and red beds of the Artesia Group and San Andres Formation. Away from the lakes the area has numerous other sinkholes and collapse dolines, most of which are circular, steep walled or vertical holes, 50-100 metres across and 30-60 metres deep, with the greatest density of features aligned along the eastern side of the Pecos River floodplain. Water in the various sinks that make up the Bottomless Lakes is crystal clear and generally brackish to saline (6,000-23,000 ppm), attesting to its passage through subsurface layers of gypsum and salt. Although the

lakes are around 30 metres deep, dark-green moss and algae coat the bottoms giving the impression of great depth and hence the name of the park. To the west, many of the playas in depressions near Amarillo in the High Plains of Texas have a similar genesis as solution depressions atop dissolving Permian salt, but most do not intersect the regional water table and so do not hold permanent surface water (Paine, 1994).

Holbrook Anticline, Arizona

Subsidence driven by natural salt solution at depth generates regional-scale drape or monoclinical folding in strata atop the retreating salt edge. This is the corollary of the formation of a subsidence trough (Figures 7.7a, 7.8b). The 70-km long dissolution front in the Permian Supai Formation of Arizona is defined by more than 300 sinkholes, fissures and subsiding depressions (Neal, 1995). Away from the dissolution zone the northeasterly-dipping Supai Formation is composed of up to 150 metres of bedded halite, with local areas of sylvite along its northern extent (Figure 7.11a). Atop the solution front there are a number of topographic depressions with playa lakes that in total cover some 300 km². This expanse of salt removal has produced a regional gravity depression, largely coincident with a surface topographic depression where as much as 100 metres of collapse and topographic displacement has occurred. The solution front is also essentially coincident with the updip end of the Holbrook Anticline, a flexure defined by dip reversal in an otherwise northeasterly dipping succession (Figure 7.11b).

Rather than orogenically driven, the Holbrook Anticline is a subsidence-induced monoclinical flexure created by the northward migrating dissolution front (Figure 7.11b). It may be the largest single solution-collapse fold structure in the world (Neal, 1995). The reverse dip of the flexure directly overlies the salt-dissolution front and marks the location of two major collapse depressions known as The Sinks and Dry Lake Valley, both occur where salt is within 300 m of the surface (Peirce, 1981). Although it has periodically held surface water, reports of several hundred acre-feet of flood water in the Dry Lake Valley playa draining overnight supports the notion of active fissure and cavern formation related to salt removal at depth. Major surface drainage events took place in 1963, 1979, 1984

and 1995, with more than 50 new sinkholes forming in the valley during that period. The continuing rapid appearance of new sinkholes testifies to the ongoing nature of dissolution in the underlying evaporites. According to Neal (1995), dissolution front features began forming in the landscape in the Pliocene and continue to form today.

Other karst features attributed to evaporite dissolution in the Holbrook basin are; pull-apart fissures, graben sinks (downward-dropped blocks), breccia pipes and plugs, and numerous small depressions with and without sinkholes (Neal et al., 1998, 2001). The presence of the more than 500 karst features in the Holbrook basin, some of which formed in days, evokes practical karst hazard and infrastructure concerns, even in such a sparsely populated region (Martinez et al., 1998).

Black Hills, South Dakota

Another area of ongoing evaporite karstification is the Black Hills of South Dakota (Epstein, 2001). There, substratal salt bed dissolution, centred on anhydrites of the Minnelusa Formation (Pennsylvanian - Permian), has produced breccia pipes and pinnacles, regional collapse breccias, sinkholes, and extensive disruption in the overburden of otherwise stratiform beds. Anhydrite removal in the Minnelusa probably dates back to the early Tertiary when the Black Hills were first uplifted and it continues today^{7.1}. Evidence for recent natural collapse includes fresh scarps surrounding shallow depressions, steep-sided sinkholes more than 20 metres deep, and sediment disruption and contamination in water wells and springs. Several sinkholes in the Spearfish Formation west of Spearfish, South Dakota, which today support fish hatcheries and are used for local agricultural water supply, probably originated as the surface expressions of stopping chimneys initiated some 150 metres below in the salts of the Minnelusa Formation (Figure 7.12;).

As the anhydrite dissolution front migrates further down dip and radially away from the centre of the Black Hills uplift, resurgent

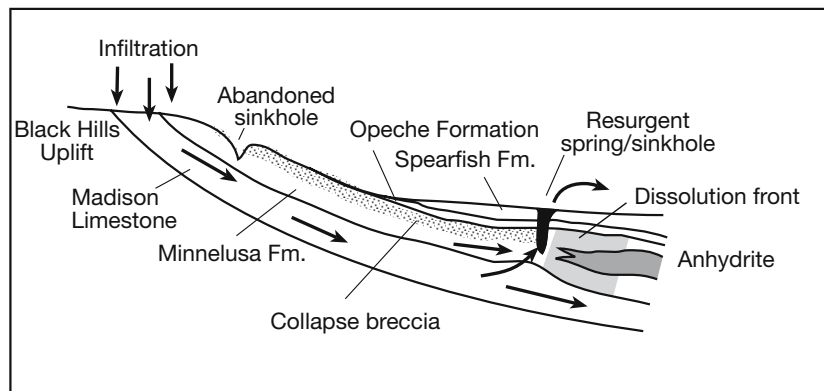

Figure 7.12. Minnelusa dissolution. As the Black Hills are slowly lowered by erosion, the anhydrite dissolution front in the subsurface Minnelusa moves downdip and radially away from the centre of the uplift. As the front expands the resurgent springs defining the outflow pipes dry up and new ones form down dip (after Epstein 2001).

springs that once defined the active edge of the subsidence trough are overstepped. They dry up and new ones form further down dip. Abandoned sinkholes and breccia pipes, preserved in cross section on downcut canyon walls, attest to the former positions of the outward migrating artesian dissolution front (see also Figure 7.52). The Spearfish Formation, mostly comprising redbed shale and siltstone, is regionally considered to be a confining layer to the aquifer system. However, secondary fracture porosity develops locally within the lower Spearfish Fm. It is the result of cavity creation via salt dissolution in the Minnelusa Fm. (volume contraction fractures) or the hydration of anhydrite to gypsum (volume expansion fractures). Thus, updip of the anhydrite solution front, fracturing in overlying lower Spearfish Formation makes a respectable aquifer, especially for a regional shale, and it yields potable water through both pumped wells and springs.

Subsidence and landscape in diapiric regions

When diapiric salt is actively flowing near the surface it typically elevates the landscape (Table 6.3). In continental settings this places highly soluble halite and somewhat less soluble gypsum/anhydrite caprocks in the zone of active phreatic and vadose groundwater flow. This in turn leads to dissolution caverns, cavern collapse, slumping and landscape/gully retreat, typically focused in to the vicinity of subcropping salt dome crests. Sinkholes in such settings tend to form atop landscape highs, rather than in the intervening lows between the diapirs. Such diapir karst landforms dominate the Texas coast of the Gulf of Mexico, the Zagros/Hormuz region and parts of the drainage feeding the Ebro Basin of Spain.

^{7.1} The Plains Indians that inhabited the area 300 years ago trapped and slaughtered thousands of buffalo for their primary food by stampeding the animals over the steep rim of one of the large sinkholes near Beulah, Wyoming (the Vore Buffalo Jump).

Five Islands, Gulf of Mexico

Five salt dome crests, locally known as “the Five Islands,” are located near the western boundary of the Mississippi River delta plain in coastal south Louisiana. The present landscape of the islands reflects a combination of salt induced uplift and salt dissolution (Autin, 2002; Autin and McCulloh, 1995). The islands, aligned in an approximately NW-SE trend, are named Jefferson Island (JI), Avery Island (AI), Weeks Island (WI), Cote Blanche Island (CBI) and Belle Isle (BI) (Figure 7.13a). The five salt domes coring the islands have pierced, uplifted

and shed sediment, while their surrounding flanks subsided and accumulated sediment. Each dome is nearly circular in plan, with maximum elevation ranging from approximately 52 m asl on Weeks Island to 23 m asl on Jefferson Island. Avery, Weeks, and Cote Blanche Islands are large mounds with small sinkhole ponds, whereas the crests of Jefferson Island and Belle Isle are marked by large lacustrine collapse structures (Figure 12.25). Each “island” landform is, surrounded by lowland Pleistocene terraces and/or Holocene delta plain marshes (Figure 7.13a, b). Sediment cover on the mound is made up of the Late Wisconsin Peoria Loess covering alluvial deposits of the Prairie Complex.

The Prairie Complex crops out parallel to the coast and consists of alluvial deposits of the Late Pleistocene Mississippi and Red Rivers.

On Weeks Island the high salt island landform has a base that is marked by a pronounced increase in topographic slope between 15 and 23m MSL. A generally north-south trending ridge is mostly underlain by loess-covered sandy deposits of the Prairie Complex and so forms the “Devil’s Backbone,” which defines the highest part of the island (Figure 7.13b). The middle salt island landform occupies elevations of 8 to 23m, and the low salt island landform occupies lower elevations. Both landforms are underlain by mostly sandy, but locally loam-covered deposits of the Prairie Complex. The lowermost landscapes are tributary gully fills and perimeter colluvial aprons maintained by uplift of the salt core. Geomorphic evidence of ongoing salt-induced uplift on Weeks and the other islands includes; surface lineations, linear gullies, and excessively steep land surface topography coincident with steep topography on spines that define the top of the underlying salt (Autin and McCulloh, 1995).

Thus topographic features on all of the Five Islands were formed by a combination of; (i) rising diapiric salt spines, (ii) sediment reworking and

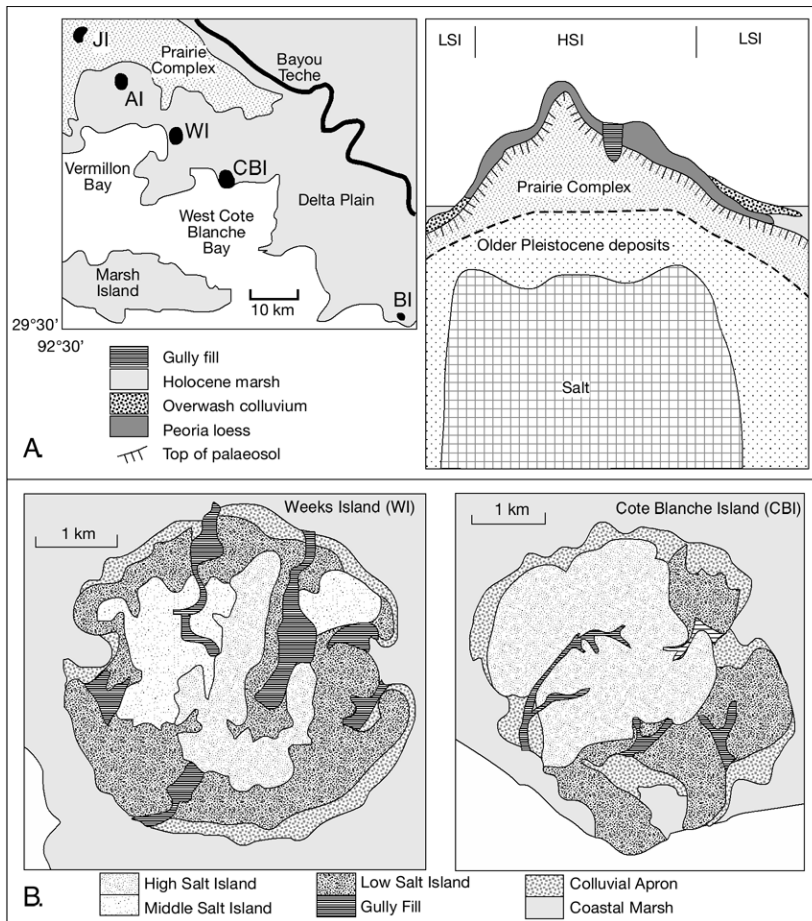

Figure 7.13. Five Islands Domes, after Autin (2002) and Autin and McCulloh (1995). A) The Five Islands of south Louisiana are aligned in a NW-SE direction along the western margin of the Mississippi River delta plain. The idealised salt dome cross section illustrates the relationship between salt island landform components and surficial stratigraphy. A palaeosol marks the top of the uplifted Prairie Complex across the islands. Beneath the high salt island landsurface (HSI) the Peoria Loess and local gully fill sediment veneer the Prairie Complex. Holocene marsh and overwash colluvium occur as veneer deposits beneath the low salt island (LSI) landsurface. B) Geomorphic features of Weeks Island and Cote Blanche Island, the surface features of Weeks Island largely reflect the dissolution topography of the underlying salt (see Figure 12.26).

development of a drainage network moving sediment away from uplifted areas, and (iii) subsidence creating sediment sinks (Autin, 2002). Uplands are drained by small gullies that dissect the dome landscape and cut into the Peoria Loess. The gullies contain a graded wash fill that passes laterally and downdip into the aggrading colluvial aprons. Where the low salt island landform approaches sea level, the apron's fill in turn interfingers with finer grained aggrading sediment of the adjacent Holocene coastal marsh. Active dissolution of the salt crest creates sinkholes and water-filled ponds atop the salt and typify degradational dissolution zones on both the high and low salt island landscapes.

The boundary between aggradational and dissolutorial components of the landscape may in part coincide with underlying anomalous zones of differential shear within the underlying salt indicated by shear zones, locally known as black salt (Kupfer, 1976). The problematic development of an active sinkhole on Weeks Island, first noticed in 1992, occurs in a position of sharp change in landform slope (transition from high island to gully fill). It lies atop the projected alignment of what is known as Shear Zone E in the underlying salt (Figure 12.26; Autin and McCulloh, 1995).

Zagros/Hormuz region, Arabian (Persian) Gulf

Active salt glaciers (namakiers) typify the foreland fold region of the Zagros-Hormuz province, in a region made up of a number of E-W trending anticlinal mountain ridges and synclinal valleys (Figure 6.45). Many islands and ridges further to the south also have squeezed salt cores, but salt is now longer at the surface. More than 200 degraded namakiers and salt plugs (diapirs, domes) occur throughout the Arabian Gulf region, many are associated with hydrocarbon and metal shows (Kent, 1979; Talbot and Jarvis 1984).

Salt flow at the surface in the region of Zagros namakiers of southeast Iran began in the Pliocene and continues today with average uplift rates $\approx 2\text{mm/year}$. Actively flowing namakiers retain no deeply penetrating caves beneath their sediment carapace due to ongoing salt replenishment. Karst and karren features are most obvious around the edges of active glaciers,

Figure 7.14. Landform evolution in an area where salt is flowing at the surface in a salt glacier (namakier). Based on various salt plugs in the Zagros foreland belt near the Straits of Hormuz (e.g. Figure 6.45).

especially in areas where the salt supply has slowed and the namakier edge is retreating. Iranian namakiers show different diameters (1-15 km) and range in outline from conical to cigar shaped, with varying intensities of surface karst and rilling. Salt plug landscapes can be divided in 4 types based on the intensity of supply versus dissolution (Bosak et al., 1999); active, passive, ruins of plugs and unbreached plug domes (Figure 7.14). Active plugs are positive relief features with centrifugal drainage networks and the plug surface dominated by flowing halite with relatively minor development of karst. Small ephemeral features, including shallow caves, are typical of the salt glacier surface, but in an active namakier the salt is flowing too fast to preserve them.

Once salt flow has ceased, karstification can be so well developed in some former namakiers that only the edges of the relict plug still show any positive relief. Salt plug ruins are even more disturbed and indicate a complete cessation of surface salt flow. Overall, inactive plugs tend to be negative landscape features (depressions) in the local Iranian landscape. Exotic "Hormuz" blocks of various sizes are scattered as dissolution residues about the edges of the "ruined" depressions, but no salt outcrops. Internally draining dendritic stream networks feed into the collapse doline centres of the ruined plug, the reverse drainage to that of an active plug.

To the south of the active namakier province are numerous salt-cored islands such as Hormuz, Das and Yas islands (Figure 6.56). These once diapiric salt masses are now largely inactive with only minor at-surface evaporite present, mostly as gypcretes and caprock remnants. Highest parts of the islands are typically covered by dissolution breccias that form a cap to the salt core below. Salt beneath the breccia carapace is pervasively karstified

and where relatively shallow, as at Hormoz Island, it is covered by suffusion karst and crosscut by tube caves (Figure 7.40). Active flow of the squeezed salt in the various island cores seems to have ceased sometime in the Miocene and much of the surface expression of the former outcropping salt is now defined by terrains of exotic blocks (Figure 7.22).

Salt Dissolution: Solution breccias and residues

Evaporite solution breccias (syn. evaporite collapse breccias) form whenever the removal of evaporite salts allows the intercalated or overlying rock to settle and become fragmented. Breccia horizons and a pile of finer-grained insolubles are the typical end result of complete subsurface dissolution of an evaporite. Frequently, especially in outcrop or about the buried edges of an evaporite bed, they are the only evidence of a former evaporite unit (McWhae, 1953; Middleton, 1961; Stanton, 1966; Elliott and Warren, 1989; Swennen et al., 1990). In evaporite paleokarst such breccias are one of the most reliable indicators of the former evaporites, even in situations where all soluble salts have been flushed.

The impervious internal make-up of a buried salt mass means it dissolves like a melting block of ice. That is, it shrinks via a series of retreating fronts, all moving from the edges inward and all defined by an expanding rind of insoluble residues. Retreat is most rapid along solution fronts in contact with

large volumes of undersaturated pore water crossflow, as occurs along the upper side of shallow salt layers, atop shallow diapir crests, in zones near active faults that intersect bedded or halokinetic salt, or about the feather edge of subcropping inclined beds and allochthons. Pervasive and rapid dissolution creates cavities filling with clasts of the adjacent lithology (solution breccia). Slow dissolution creates higher salinity pores where residual rinds made up of less soluble salts (typically anhydrite or gypsum) can form. As dissolution eats inward it can also create free-flowing residues of sand- to mud-sized insolubles, which in their turn infiltrate, and sometimes fill, the spaces between the breccia clasts. These fines, known as dissolution flour, are varying combinations of quartzofeldspathic muds and microcrystalline dolomite and calcite rhombs, all previously dispersed through the now dissolved salt mass.

Defining evaporite dissolution breccia

Breccia is a nongenetic rock type that ranges across sedimentary, igneous and structural regimes. As a rock descriptor it needs a prefix to define its origin. Depositional breccias can be considered “proto-conglomerates” that is, deposits composed of clasts or eroded fragments which were not transported sufficient distances to become rounded and so become a conglomerate (Figure 7.15). Nonevaporitic sedimentary breccias of this kind are commonplace. They form in glacial or alluvial outwash, can be an outcome of waves impacting reefs or sea cliffs, or can form in response to slope failure. As a group, depositional breccias tends to indicate rapid changes in transport energy, with clast diversity a pointer to lithologic variation in the source area.

In contrast, evaporite dissolution breccias are diagenetic horizons, usually dominated by cm-metre angular collapse clasts in a mud-sand matrix of dissolution flour. Commonly used sandstone and carbonate breccia classifications do not adequately address the variable character of solution breccias as they emphasise depositional energy levels and the style and rate of evaporite dissolution, not overburden and intrasalt collapse. Hence, we need to define a relevant breccia classification (Figure 7.16), then we can discuss how evaporite solution breccias relate to sedimentary breccias.

Figure 7.15. Evaporite solution breccias classification (based on the degree of clast movement and mixing after von Engelhardt et al., 1977).

Breccias are by definition composed of angular clasts, typically rock fragments of granule or pebble size and larger. Whenever classifying a breccia one should ask the following (Morrow, 1982):

- Are clasts of a single lithic type (monomict/oligomict) or of widely variable types (polymict); are lithic types in clasts similar or different from the rocks bounding the breccia body; are clasts composed of durable rock fragments or of a mixture of hard and soft clasts?
- Are clasts closely fitted, loosely fitted, or spatially independent, i.e., crackle - mosaic - packbreccia - floatbreccia (Figure 7.16a)?
- Do clast shapes and clast-to-clast contacts indicate either plasticity of clasts or brittle behaviour at the time of sedimentation? What is the nature of the clast edge (Figure 7.16b)?
- Are spaces between clasts filled with cement or with detrital matrix; i.e. clast-support or matrix-support?
- Does a weathering rind or coat extend all around a clast, or is it developed only on one side, or is there no indication of weathering?
- What is the nature and style of clast size and size grading; evidence for bedding; imbrication or other spacial alignment of clasts?
- What is the overall size and shape of the breccia deposit; is there a sharp lower contact and/or sharp upper contact; is the breccia body discordant (trans-stratal) or concordant (interstratal) in relation to bounding rocks?

Packbreccias are clast-supported, while floatbreccia clasts float in a finer matrix of granules, sands or mud. The distinction between crackle, mosaic and rubble breccia depends on whether the clasts are fitted, mildly disoriented or totally independent (Figure 7.16a). Crackle denotes a fabric in which there is little relative displacement of fragments. Mosaic implies fragments are largely but not wholly displaced. Rubble breccias are completely disordered and no fragment boundaries match. Some packbreccias have particulate matrices, others are cemented by spar or silica, indicating clast support. Elements other than fabric, such as the size and shape of the breccia body, its stratigraphic setting, the depositional setting of adjacent sediments and lateral equivalents to the breccia provide evidence of origin.

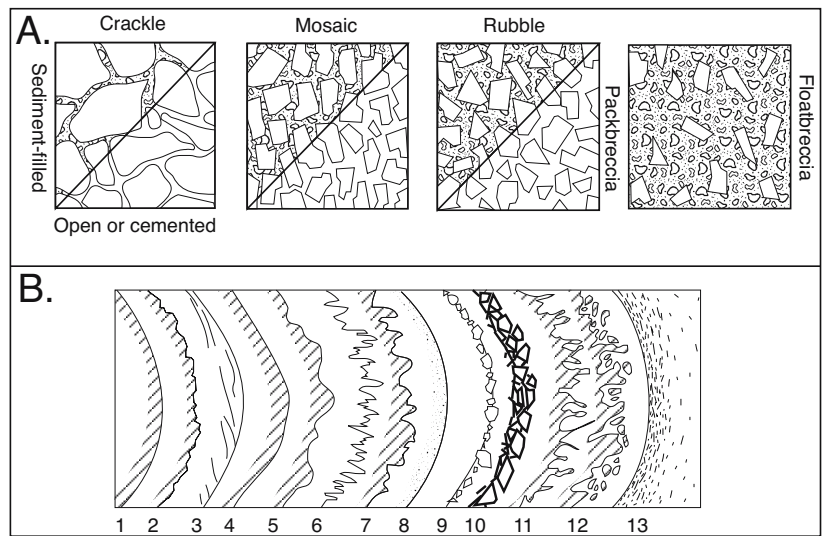

Figure 7.16. Breccia description. A) Nongenetic classification of breccias (after Morrow, 1982). B) Nature of clast contacts; 1. smooth, 2. slightly pitted, 3. striated, polished, 4. faceted, 5. solution rounded and pitted, 6. stylolitic, 7. ragged, 8. weathering rim or alteration rind, 9. microfragment armouring, 10. fragments in process of breaking out, 11. jagged, 12. crumbled, 13. diffuse, gradational (after Laznicka, 1988).

Intrastratal breccias indicate former bedded salts, while trans-stratal breccias characterise breccia chimneys and halokinetic dissolution breccias.

Evaporite solution or collapse breccias tend to form diagenetically as undersaturated pore waters flush a buried evaporite bed. Clasts in the resulting breccia can be derived from a lithology that once overlay the dissolving salt bed or from thin stringers and beds that were entrained in the dissolving salt. In many dissolution breccias the distance travelled by the clasts before being redeposited is negligible, often only centimetres to a few metres. Timing of clast movement may be episodic or a single widespread instantaneous event. Clasts in an evaporite solution breccia may have moved into a cavity in concert, like a school of fish, or they may have gently sloughed and foundered a few at a time, with little breakage or change in orientation. The distance of movement is dependent on the size and lateral extent of the solution cavity into which the clasts move and whether the clasts originally resided in thin interbeds within the dissolving evaporite or if they were part of a thick strong roof-spanning lithology that once overlay the dissolving salt bed. If the cavity is only a few millimetres to centimetres high, the overburden founders gradually and gently and so clast orientation and fitting is little disturbed by the process of dissolution. Crackle and mosaic breccias will be commonplace. If large local cavities develop, the collapse of the roof span is more likely to be catastrophic and the result to be dominated by disturbed rubble or packbreccias (Figure 7.17a).

Figure 7.17. Lithological distribution in an evaporite dissolution triggered collapse breccia. A) lateral facies distribution. Left half of figure illustrates relationships in a trans-stratal chimney, right half in a stratiform solution collapse breccia. B) Ideal vertical sequence of breccia cumulates in an evaporite solution breccia.

Bedded solution collapse breccias

Stanton (1966) in a benchmark paper on formation of evaporite dissolution breccias demonstrated solution, subsidence, and evaporite flowage act simultaneously during subsurface brecciation. The resulting evaporite solution breccia in the Upper Devonian Leduc Formation, Alberta Basin, Canada, is made up of cm-dm angular dolomite clasts in a matrix of dolomite mud or anhydrite. He concluded that anhydrite-supported floatbreccias are a transitional stage to a dolomite clast-supported packbreccia in the dissolution of interbedded halite-anhydrite-dolomite. Angular fragments of the dolomite overburden and interburden in an anhydrite-supported breccia (floatbreccia) are loosely supported by solution-thinned, but still abundant, nodular anhydrite with textures indicating viscous flowage during dissolution. As the breccia forms and flows, dolomite fragments are continuously broken and rebroken, while the supporting anhydrite matrix carries a high proportion of loose, whole or broken dolomite rhombs (silt-sand size crystals). Ultimately, a dolomite packbreccia forms by the complete solution of the anhydrite. It consists of tightly packed dolomite fragments and clasts, within a matrix of sand-sized detrital rhombs and dolomite microspar cement.

Evaporite solution breccias typically have planar to slightly irregular, continuous lower contacts, often coated with insoluble residues (Figure 7.17a). The footwall surface to a breccia is usually covered by a few centimetres of mud- to sand-sized insoluble residues. The thickness of a pure evaporite that dissolves to produce a thin layer of insoluble residues may be substantial. For example, the Hartlepool Anhydrite contains only 0.5% - 0.8% insolubles (Smith, 1972). Complete solution of a 100m thick bed produces a layer of insolubles a mere

50-80 cm thick. In many breccia beds the insoluble residues now make up the matrix between clasts that were derived by the breakup of thin beds of carbonates or clastics. These are the fragmented remains of thin intrasalt beds that were once supported and interlayered by the now dissolved salt. This interval tends to be more polymictic than the upper roof-derived parts of the breccia unit.

Insoluble residues typically consist of fragmented chert, detrital quartz, silt, clay and dolomite rhombs, which are later cemented by authigenic phases (typically calcite, dolomite or silica cements). Many evaporite beds originally entrain dispersed syndepositional silt-sized dolomite rhombs. When the encasing salts dissolve, a dissolution residue or matrix is left behind; it is dominated by solution-disaggregated dolomite crystal silts and sands and is sometimes called "chalky dolomite." A high degree of initial intercrystalline porosity in the residue makes it an excellent potential aquifer for later mineralising solutions or hydrocarbons, especially when it forms at burial depths where much of the adjacent nonevaporite sediment is tight, having lost its porosity by mechanical and chemical compaction.

Siliciclastic and carbonate sands bound by early evaporite cements (e.g. halite cements in aeolian, wadi, or oolite sands) can also be leached during burial diagenesis to create permeability in an otherwise tightly cemented sand. In extreme cases the result is disaggregated freeflowing subsurface sand with depositional levels of permeability, which remain until it is recemented by subsurface processes.

Sometimes, rocks in the footwall beneath the breccia bed are locally veined by infiltrations of satin spar and poikilitic

gypsum or anhydrite. Smith (1972) argues the fractures hosting such footwall stockworks were first created by the pressure of crystallisation of the evaporite itself; others envisage a more passive process of cement fill within preexisting joints or fractures. In my own work I have found the joints are often the result of passive fill in joints and fractures created by the extensional stress in units above or below a dissolving salt unit. Because pure halite has often completely dissolved, its former presence is difficult to determine, especially in core or image logs, but these tell-tale fracture-fills remain in the log signature (especially in image logs) and indicate a much thicker former salt bed.

The basal zone of insoluble residues passes up into the main breccia body, an interval dominated by packbreccia or floatbreccia. Breccia fragments and clasts in the main breccia can be angular or solution-rounded (Figure 7.17a). Almost all rubble texture in a breccia is generated by the collapse of overlying or interbedded lithologies into cavities created by dissolving salt beds. Where the original sequence was made up of interbedded salts and other lithologies, the resulting clast rubble typically collapses in sequential order, so that the rubble pile retains the crude stratigraphic order of the former intrasalt beds.

Clasts are composed of varying amounts of sandstone, dolomite, limestone, mudstone and chert fragments. The main breccia may be polymict or monomict, depending on the nature of the intrasalt beds and the overburden. Breccias can be clast- or matrix-supported (packbreccia versus floatbreccia) depending on the amount of residue entrained in the evaporitic interval prior to dissolution. Pure evaporites, interbedded with indurated dolomites and other nonevaporite strata, tend to produce clast-supported packbreccia fabrics. Evaporite sequences interbedded with, or underlying, nonconsolidated sediments, or evaporites with a high content of dispersed impurities, tend to produce matrix-supported floatbreccia fabrics.

Unlike its lower contact, the upper contact of the main breccia interval is typically gradational, progressing from rubble breccia in the main body into mosaic, crackle then ultimately into unaltered overburden (Figure 7.17b). A breccia begins to accumulate on the bottom of a growing cavern marking the contact of undersaturated pore waters and the salt. As the salt begins to dissolve, the insoluble clay-sized material that was present as impurities in the salt accumulates in thin layers on the floor of the cavern. Later in the dissolution process, and higher in the breccia sequence, angular to etched clasts of mixed intrasalt and roof rock form a polymictic breccia. Polymictic breccia passes upward into a monomict breccia made up of

angular clasts of roof rock. Gradually, the overlying rock is not broken into clasts but is merely fractured and expanded to form crackle breccia. Crackle fractures, if they are not filled with cement, can provide excellent pathways for subsurface mineralising fluids and can act as reservoirs for oil and gas.

The contrast between a sharp lower contact and a gradational upper contact is one of the most reliable characteristics of a solution breccia. It can be used both in outcrop and subsurface studies (core and image logs) to separate an evaporite solution breccia from a depositional breccia, which has evidence of syndepositional infiltration and depositional drape along its upper contact, and a tectonic breccia, which has cataclastic and typically symmetrical contacts related to fault or shear zones.

Where complete removal of less soluble evaporites has not yet occurred, evaporite salts, such as flow-textured laminar to nodular anhydrite, remain as part of the matrix within the main breccia interval. In cores through thick-bedded evaporites the upper bed contact is often defined by a zone of disturbance in the anhydrite textures. The typical fabric is very similar to soft sediment disturbance textures associated with rapid water escape in sands. The anhydrite just below the contact is typically made up of angular but contorted anhydrite blocks in a finer anhydrite matrix. Often, there are also highly distorted and folded blocks or fragments of dolomite and other disturbed intrasalt beds. I have seen these zones at the contacts of many thick anhydrite beds with the adjacent nonevaporite strata including; the San Andres and Seven Rivers formations of west Texas, the Khuff Formation in Abu Dhabi and Saudi Arabia, caprocks to Gulf of Mexico diapirs and Zechstein Formation anhydrites in NW Europe. These disturbed contacts define intervals of subsurface dissolution where the process of dissolution and brecciation is not complete. In many cases dissolution processes may no longer be active, as the adjacent nonevaporite beds no longer have sufficient permeability to transmit undersaturated fluids. They are a form of frozen dissolution breccia that define the early fluidisation stage, where the bed is dissolving from its edges inward like a melting block of ice.

Local reprecipitation of evaporites into the breccia matrix may also generate large poikilotopic crystals, which encase the dissolutional residues. Such cements are typically coarse-grained anhydrites with a somewhat anhedral form and isotopic signatures indicative of elevated temperatures. Pseudomorphs of now dissolved evaporite minerals and nodules, composed of calcite, silica or celestite, may also remain either in the matrix or within clasts. Cement may be a fine-grained crystalline precipitate of equidimensional calcite crystals, as described by

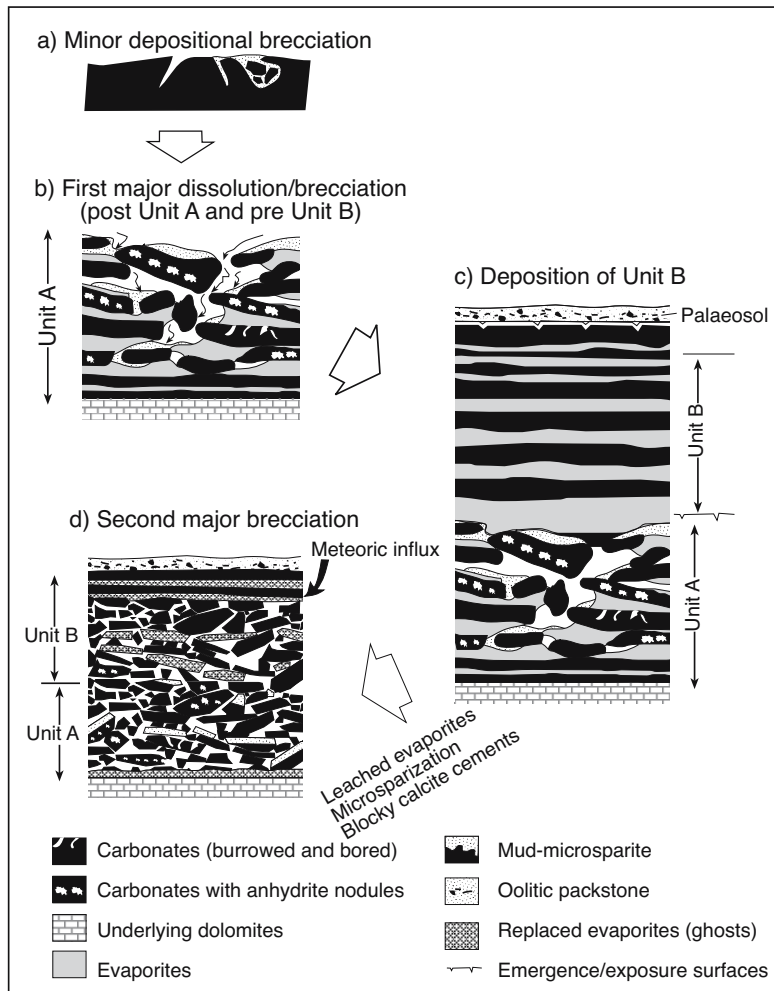

Figure 7.18. Sequential brecciation episodes in the lower Visean Belle Roche breccia (after Swennen et al., 1990). **A)** Minor syndepositional dissolution and fracture brecciation mainly related to shrinkage. **B)** This occurred shortly after deposition of bedded evaporites of unit A and involved incompletely lithified clasts, infiltration of freeflowing mud with ooids. **C)** Resumption of evaporitic sedimentation to deposit unit B with palaeosol cap. **D)** Second major brecciation event driven by meteoric influx. It overprinted both unit B and unit A. The brecciation process was mostly foundering rather than cavern collapse, and so stratigraphic order was retained in the breccia stack. Foundering means the overlying beds parallel the general stratification.

Swennen et al. (1990) in the Belle Roche breccias in Belgium, or a sparry coarsely crystalline dolomite or calcite (burial spar). Coarse sparry or saddle dolomite is often associated with evaporite solution breccias in Mississippi-Valley-type deposits (Olson, 1984; Warren and Kempton, 1997). Isotopic and petrographic character in dolomite burial cements in evaporite solution breccias are often complex and multistage. For example, there are six burial-related stages of dolomite formation and two episodes of breccia formation preserved in the evaporite

solution breccias of the Tripolis Unit, Mainalon Mountain, Greece (Papioanou and Carotsieris, 1993; Karakitsios and Pomonipapaioannou, 1998).

The lower Visean Belle Roche breccia (east Belgium) is a classic multistage evaporite dissolution collapse breccia (Figure 7.18; Swennen et al., 1990). Its origin as a dissolution breccia is indicated by: a) the sharp lower contact of the breccia and a gradual transition into the overlying strata, b) the presence of semicontinuous clast layers within the breccia giving it a crude 'stratification', and c) the existence of several types of evaporite pseudomorphs that are now composed of calcite, dolomite and silica. The majority of the sedimentary carbonates making up the breccia fragments show primary features indicating they were originally deposited under hypersaline subaqueous conditions and were probably interbedded with the now dissolved evaporite beds.

Most Belle Roche breccia has an interlocking packbreccia fabric showing a subparallel clast alignment and crude layering that indicates foundering by gradual subsidence, rather than catastrophic collapse into a large cavity (Figure 7.18b, c; Swennen et al., 1990). Multiple brecciation episodes are obvious in the lower breccia (Unit A), where brecciated and veined fragments occur within a microsparite (neomorphosed mud) matrix. There were at least two major brecciation episodes (Units A and B) driven by the successive dissolution of interlayered evaporite units. The second brecciation event related to infiltration of meteoric water and to the complete dissolution of any remaining evaporites (Figure 7.18d). Meteoric infiltration was probably triggered by uplift related to an orogenic event at the end of the Visean (Sudetic orogenic phase).

Some of the breccias in this region were dolomitized in active-phreatic mixing zones via processes facilitated by bacteria (Nielsen et al., 1997). High degrees of dolomite supersaturation

were produced in the anaerobic to dysaerobic zones of bacterial sulphate reduction. The sulphate came from the dissolving evaporites and the organics from the adjacent interbeds. The resulting dolomite precipitates show characteristic bacterial morphologies, such as spheroidal and dumbbell shaped crystals. The whole breccia was finally cemented by a blocky calcite under deeper burial conditions.

As a thick widespread evaporite bed dissolves, it does so more rapidly and pervasively in zones of greatest fluid access. This can be along a fault-bound edge, along a thinned featheredge, along an upper or lower contact, or along joints and fracture planes that cut the bed. As the salts dissolve, carbonate cements may precipitate as cement rinds within stratiform cavities, or along cross-cutting fracture planes. Alternating episodes of dissolving, fracturing and cementing will form veined fracture infills and fragments with clasts of cement within the disappearing bed. With further collapse, these cements may be brecciated and cemented numerous times into internally complex clasts and fragments. Ongoing repetition of this process can create clasts made up of nothing but multiple episodes of vein and cavity-fill cements (Figure 7.18). Some fracture and block-defining cements can remain, and, with the disappearance of the supporting evaporite, evolve to form an open lacework or cellular grid of cemented materials and residues called a boxwork limestone. Such boxworks are especially obvious in nearsurface dissolution settings, as in rauhwacke terrains or phreatic zones of growing tepee structure crusts. Once a rock is more deeply buried and compressed, the boxwork either collapses or is only preserved as delicate laceworks encased within massive cements. For example, even after burial, local relics of boxwork texture can still be seen beneath the V's of the Permian tepees of west Texas and the Triassic tepees of Italy (Kendall and Warren, 1987).

Figure 7.19. Size and shape of various breccia bodies that occur in sedimentary successions (modified in part after Laznicka, 1988). Evaporite-related ("evaporites that were") geometries are illustrated in the lower part of the figure.

Flow of water through cavities during breccia collapse in the active phreatic zone can rework fine-grained matrix material. Localised cm-dm cavities can fill with waterlain laminae that are typically overprinted by water escape features, slumps and, less commonly, with ripples and crossbeds. If the cavity lies in the vadose zone, or if a deeper phreatic cavity contains biogenic or thermochemical gases, such as methane or H₂S, then the cavity may be ornamented with microstalactites, "snottites" and other speleothems. Calcitic vadose speleothems ornament cavities in dissolution breccias in the Kirschberg Evaporite breccia of central Texas (Warren et al., 1990), while pendulous sphalerite stalactites, precipitated in thermochemically-de-

Characteristic features of an interstratal dissolution breccia	Commonplace textures and features of the adjacent crackled matrix. They also occur in some recemented breccia fragments, details on their genesis given later.
<ul style="list-style-type: none"> • Sharp lower contact and irregular upper contact to breccia bed. • Oligomict clasts derived from overlying and intrasalt lithologies. • Breccia body shows a crude stratification, with clasts of differing lithologies often stacked in original stratigraphic order. • Depositional textures in some breccia fragments indicate hypersalinity during deposition. • Zone of insoluble residues (silt, chalky dolomite, etc.) lies atop lower contact, and sometimes has infiltrated into fractures beneath. • Evaporite cements in fractures beneath lower contact. • Several types of evaporite pseudomorphs (nodules, radial textures, length slow chalcedony, etc.) are present in clasts or matrix and interclast cements. 	<ul style="list-style-type: none"> • Pseudomorphs of former crystals retaining shapes after bird-beak gypsum, axe-head anhydrite or halite hoppers, now filled or partially filled (moulds and casts) with calcite, chalcedony or quartz, baryte, celestite, strontianite. • Thumbnail to fist-sized rounded moulds or vugs, in limestone or dolomite host, with irregular edges defining positions of former chicken-wire, nodular or spherical evaporite (cauliflower vugs). Vugs may be filled or partially filled with calcite, chalcedony or quartz, baryte, celestite, strontianite. • Silica fill in vugs (geodes) is a varying combination of length-slow chalcedony (quartzine) and spherulites composed of lutecite. • Euhedral crystals of authigenic limpid dolomite or quartz (some are double-terminated) in dolomites adjacent to breccia horizon. • Minute rectangular relics of anhydrite in quartz or other minerals such as calcite (obvious in quartz because of contrasting moderate birefringence and the rectangular cleavage - but are very small). • Coarsely recrystallized (sparry) limestone and dolomite, often porous, and without skeletal debris. Internally the sparry interval may be massive, laminated or contorted. Form by calcitization of dedolomitization when evaporite dissolved (especially common in association with telogenetic alteration). • Net-textures, a small-scale relic of original bedded gypsum/anhydrite, typically with displaced impurities that outline edges of structures, typically relict patches in secondary, sparry limestone. • Small contortions typically related to flow of insoluble residues and characterised by sedimentary structures that are slumped or fractured during subsurface movement in response to evaporite dissolution.

Table 7.3. Features of an interstratal breccia created by foundering, which is the most common mechanism creating an evaporite solution breccia (in part after West, 1979).

rived H₂S/methane-filled ^{7.2}bathypneatic cavities, typify the evaporite-replacing breccia ores in the Cadjebut Pb-Zn mine, Australia (Warren and Kempton, 1997).

Breccia extent

Evaporite solution breccia beds can be syndepositional, or form much later after millions of years and hundreds to thousands of metres of burial, halokinesis, and uplift. Breccia beds tend to be widespread and stratabound, with geometries that reflect the distribution of the precursor evaporite (Figure 7.19). If the precursor layer was part of a stacked cyclic sequence of platform evaporites interlayered with carbonates or siliciclastics, the breccias tend to stack into interstratal cyclic horizons. This is the most easily recognised style of evaporite solution breccia. If the precursor evaporite was part of a halokinetic or remobilised sequence then the solution breccia is trans-stratal and follows the distribution of former salt stems, salt welds, or thrust planes. Recognising this second type of collapse breccia is more difficult, especially in core.

Intensity of brecciation and the general geometry of the foundered strata in the breccia bed can vary widely from place

to place, even within a single unit (e.g. Smith, 1972). The geometry of collapse is related to variations in:

- a) Inflow geometry of the solution front: water may enter along a fracture, fault, blanket aquifer, reef, diapir margin, etc. The timing of development of the solution front may in turn be related to episodes of seismic or tectonic instability (e.g. seismic pumping driving episodic basin dewatering, or periodic uplift or sea level lowering creating a gravity head to drive meteoric flow).
- b) Rate of evaporite solution: this is dependent on the rate of formation water crossflow and the saturation state of the crossflow. This is in turn controlled by climate, tectonics, regional uplift, development of major unconformities, etc.
- c) Confining pressure: related to thickness of overburden at the time of collapse. This is in turn related to the age of collapse (burial/uplift timing).

Stratiform breccias

The simplest and most general styles of interstratal collapse are typified by blanket aquifers and broad areas of gentle sagging and foundering where diffuse undersaturated water flow over large areas has slowly removed bedded evaporites (Table 7.3; Figure 7.19; Hauptdolomit). The blanket aquifer can lie above, below, or even within the dissolving evaporite bed. Overburden brecciation in such gently foundering regions is minor, so fossils and sedimentary structures are mostly preserved in blocks with

^{7.2}Bathypneatic is used to describe deep, stagnant waters situated at depths well below the zone of active pneumatic circulation.

near upright orientations. Larger interbed and overburden clasts tend to be tabular, and only slightly separated or disorientated, i.e., dominated by mosaic to crackle breccias.

In areas of more focused dissolution where large caverns and solution planes have formed within the dissolving evaporite beds, the whole of an overlying sequence can be reduced by chimney stoping and doline collapse to a rubble breccia — a mass made up of completely disarticulated and rotated (commonly rectangular) blocks and fragments ranging from silts to blocks many metres across. In still other areas the foundered strata can be bound by sharp folds or dislocations that are in effect normal faults. Such areas of intense brecciation are often the end product of localised collapse and can grade laterally and vertically into almost unbrecciated equivalents. These dislocations can be sharp and clean, or associated with areas of intense diagenetic alteration such as calcitisation and precipitation of ferroan carbonates. This latter group of intensely altered and replaced breccia intervals within a carbonate or sandstone host is part of a larger group of fault-focused, often metalliferous, deposits with hydrologies driven by evaporite solution (Warren, 2000b).

Hydrology and texture

Salt beds that dissolve during early burial tend to create characteristic ductile breccia textures and soft sediment slumps in the overburden. These are features that can be used to distinguish syndepositional from later modes of breccia formation related to subsurface or basinal waters or to even later uplift and re-entry into the active phreatic zone. Evaporites dissolving early in their burial cycle, even while subjacent strata are accumulating, tend to evolve into ridge and furrow dissolution geometries that influence thickness and depositional style in the lower parts of the overlying sediments. Overlying clastic beds are typically no more than partially lithified when the underlying evaporite dissolves and so are highly disturbed by ongoing collapse of their substrate. Syndepositional collapse and accommodation creates widespread intrabed slumps, water escape textures and other soft sediment deformation features in the beds immediately above the dissolution horizon. Breccia clasts in such scenarios can be contorted (plastic) and typically show rounded to crumbly edges.

In contrast, bed collapse after induration tends to create angular clasts and breccias dominated by structures indicative of more brittle collapse failure and sharp-edged angular clasts. This group includes trans-stratal joint and chimney stopes that may have tens to hundreds of metres of relief, as well as pervasive interstratal

angular breccias derived from overlying strata where the clasts show little or no evidence of internal deformation (Figure 7.4). Stopes form in the rock above the salt as the roof collapses and accumulates in the cavern formed by dissolution of the salt. Fractures and faults form in the rock layers for some distance above and around stope perimeters. Porosity and permeability created by this fracturing and faulting can provide pathways for late stage cements and can trap or transmit hydrocarbons and metalliferous fluids (Chapters 8 and 10).

Early dissolution of a nearsurface evaporite tends to be a response to facies-controlled permeability corridors in the blanketing unconfined aquifers. Areas of preferential ingress into the evaporite bed are controlled by depositional permeabilities within the overburden (e.g. ingress beneath porous and permeable sand-rich fluvial channels versus less ingress beneath relatively impervious mud-rich floodplain sediments). In contrast, the hydrologies of later dissolutional systems tend to be more directional and focused by secondary permeability features. By then the overlying and underlying beds are indurated and relatively impervious so that major zones of undersaturated infiltration or crossflow are controlled by joints, faults, fractures or reef crests, as well as regional tilting or sag. Water arriving at the site of dissolution can be either from meteoric or basinal sources and enter from above or below the evaporite bed.

The feedback between early shallow salt dissolution and partially consolidated overlying sediment styles can be traced for over 35 km of the outcrop length in the Blomiden Formation (Late Triassic) of the Mesozoic Fundy rift basin of Nova Scotia (Ackermann et al., 1995). This unit exemplifies syn-dissolutional salt loss, which was induced by shallow groundwater freshening tied to fluvial sedimentation. Fluvial sands of variable thickness (unit C) lie atop a highly chaotic and slumped mudstone with evaporite nodules still visible in its lower parts (unit B; Figure 7.20). The primary lamination in clasts in the chaotic mudstone unit preserves much of the evidence of syndepositional collapse of the evaporite substrate. It is characterized by highly disrupted bedding that is commonly cut by small (<0.5 m) domino-style syndepositional normal faults. It also preserves evidence of downward movement of fines, of geopetal structures, of variable thicknesses related to local hollows after evaporite solution, and of irregular, partially faulted contacts with the overlying unit. Unit B is underlain by a normally faulted massive mudstone (unit A).

Although the thickness of the fluvial sandstone (unit C) is highly variable, the overlying flat-bedded mudstone exhibits only gentle

Figure 7.20. Syn depositional collapse features related to dissolution of an underlying evaporite bed in the Lower Blomidon Formation (Late Triassic) near Blomidon, Nova Scotia. See text for discussion of units A-C (after Ackermann et al., 1995).

regional dip, hence the bulk of the evaporite layer must have dissolved prior to the deposition of the flat bedded floodplain mudstones. Like unit B, the sands of unit C exhibit numerous soft sediment deformation features including; dewatering structures, convoluted bedding, kink bands, and convergent small-scale fault fans. The frequency and intensity of these features increases dramatically above low points in its base, showing unit C sands were laid down within local solution depressions or furrows that were still expanding as sediment was deposited. Unit B (the chaotic unit) is characterised by blocks of laminated claystone, which become increasingly disrupted and brecciated downward toward its base where locally abundant gypsum nodules are still preserved. Lenses and fissure fills of mudstone to coarse sandstone within the chaotic unit often entrain clasts of laminated mudstone originally derived from immediately overlying beds.

Both the chaotic unit and the overlying fluvial sands were deposited as an underlying evaporite layer underwent syn depositional subsidence and karst collapse. Groundwaters driving the dissolution were probably tied to the same river system that was depositing units B and C. The former presence of underlying evaporites is now solely indicated by residual gypsum nodules within the lower part of unit B (Figure 7.20).

In contrast, breccias that form after induration of overlying strata tend to be combinations of interstratal and trans-stratal

geometries with breccia clasts that are made up of well-indurated angular blocks. Post-induration interstratal breccias tend to follow the lateral distribution of the evaporite bed from which they formed, while trans-stratal (transformational) breccias tend to cross cut the strata and form by a combination of chimney growth and overburden stopping (Figure 7.17). Soft sediment deformation features are less pervasive in post-induration breccias and are typically restricted to intervals where insoluble residues accumulated in joint and fracture-defined fluid-filled cavities.

Post-induration interstratal breccia beds tend to have sharp flat bases and uneven, wavy to transitional blocky upper surfaces, as described earlier. If the dissolved evaporite was pure, with few intrasalt beds, the resulting rubble breccia unit is thin, but widespread. For example, a clean 100 m thick bed of salt may, when dissolved, leave behind a residue bed and rubble breccia that is no more than 0.5 - 2 m thick, but that residue may form a continuous marker horizon with a lateral extent of hundreds of kilometres. Core recovery from such intervals is often difficult. Even with good core recovery, recognising beds composed of little more than solution residues is difficult, they are easily misinterpreted as unconformities, tectonites, or syn depositional intraclast breccias. Preserved evaporite indicators, such as "cauliflower" chert or calcite concretions, are one way to define the evaporite association of such breccias.

Spectacular breccia-filled trans-statal solution chimneys dominate Silurian outcrops in the Mackinac Straits area of Michigan and western Lake Erie (Carlson 1992, Black 1997). They are paleokarst features created by evaporite dissolution and joint-controlled stoping. There are three styles of breccia in the region: 1) megabreccia beds in which blocks up to several hundred metres in size moved intact except for some minor tilting; 2) relatively thin intraformational or intrastatal breccia developed along the bedding planes both regionally and within layers in the megabreccia blocks; 3) thicker trans-statal breccias extending vertically from a few feet to several hundred metres and abutted by undisturbed bedded strata. The thickest trans-statal breccias slope vertically up to 460 m and at one site the individual blocks have fallen 290 m. Some solution caverns have recently been reactivated on a much smaller scale (Carlson, 1992). But most of the intense evaporite karstification, chimney stoping and celestite replacement took place in the Late Silurian. Not all breccia chimneys reach the surface, and areas of this “blind” salt karst can only be located using geophysical techniques.

ples, where little or no salt remains, outcrop extensively in the Mesozoic and Tertiary sediments of the La Popa Basin in Mexico, in the Neoproterozoic strata of the Flinders Ranges of South Australia, the Macdonnell Ranges of the Amadeus Basin of Central Australia, and in sediments caught up in the Damara Orogen and the Lufilian foldbelt of southern and central Africa (Giles and Lawton, 2002; Mount, 1975; Lemon, 1985; Kennedy, 1993; Behr et al., 1983; Jackson et al., 2003). Some of the breccia blocks carried up from depth by flowing salt can be large (a kilometre or more across); they typically line up parallel to the salt stem edge or weld, or form a chaotic carapace at the exposed top of the former salt stem.

Diapiric breccias are always trans-statal and clasts tend to be polymict associations of allochthonous fragments. Clasts of varying diameters are combinations of; a) material that was once an intrasalt bed, b) buoyed material that was plucked or was enclosed by flowing salt, and c) material that was derived from the collapse of overburden as the active diapir deflated and dissolved (Figure 7.21). The complex folding that accompanies salt flow means breccia bodies defining a former diapir are much less likely than bedded solution breccias to

Diapiric solution breccias

Salt diapir (halokinetic) breccias are transtratal features that ultimately contain no salt, but outline a former diapir geometry. Diapiric solution breccias and their reworked debris aprons (salt ablation breccias) are forming today in and around at-surface salt diapirs in the Arabian Gulf and the resulting landscape was discussed earlier in this chapter (Figure 7.14). Once the stem salt or its allochthon has dissolved, the only evidence of former flowing salt may be a few pseudomorphs after halite or calcium sulphate, either in the breccia clasts or in the interclast matrix. The breccia itself is typically an allochthonous assortment of angular clasts in a matrix made up of insoluble residues (sometimes called “rock flour”), which is typically dominated by finely crystalline carbonate, clay, sericite and chlorite. Classic exam-

Figure 7.21. Distribution of diapir associated breccias. 1) Slabs of anhydrite in granular halite; 2) internal flowage breccia formed by dismemberment of competent internal beds; 3) breccia pockets in “clay sheath”; 4) transported flowage breccia of wallrock fragments incorporated into outer zones of stock; 5) peridiapiric ablation breccia, extent is greater in zones of former salt glaciers; 6) caprock breccia; 7) false caprock breccia, a dissolution breccia generated by salt collapse (after Laznicka, 1988).

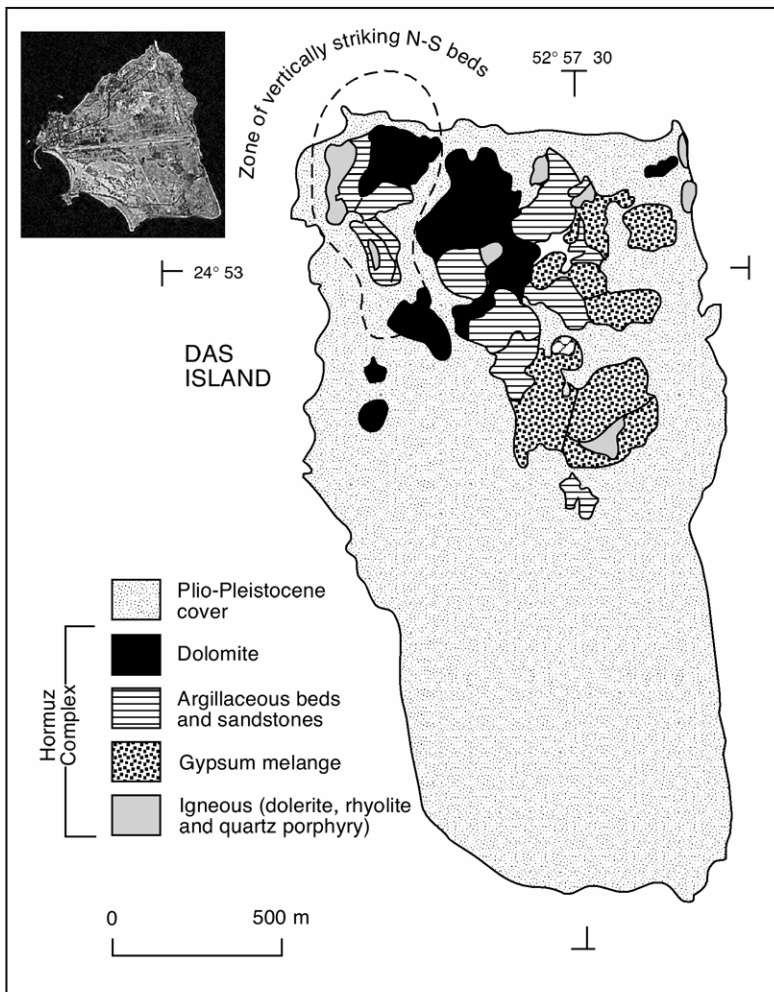

Figure 7.22. Das Island, Arabian Gulf, showing chaotic nature of the Hormuz Complex; it includes blocks of ferruginised and rafted material that are hundreds of metres across (after Kent, 1987). preserve original stratigraphic layering of any intrasalt beds (Figures 6.8, 6.9).

Breakage and rotation of intrasalt beds begins once the encasing salt begins to move (Figure 7.21). Flowing salt can also pluck large blocks from strata adjacent to a salt wall or in contact with the flowing bed of the mother salt layer. Once caught up in flowing salt, the clasts are carried toward the surface to accumulate as breccia masses in stratigraphically higher regions of former salt, either in stems and feeders or spread out laterally across areas of former allochthons. Clasts often include metamorphic-grade minerals, such as magnesian-talc, sodian-scapolite and dravite-uvite tourmaline, which indi-

cate the clasts were carried from depths where the metamorphic/diagenetic grade was higher than the current stratigraphic level of the breccia. Solution breccia emplacement in the Damara Orogen also encompasses processes of fluidisation and cataclasis within mobile evaporite units in thrust belts and welds. These breccias were actively forming at greenschist and higher metamorphic grades and so lie outside the sedimentary focus of this book (see Warren 1999 - Chapter 6).

Recognising the occurrence of higher temperature and metamorphic grade indicators is useful when a core has intersected a breccia body and an attempt is made to distinguish interstratal breccias and transtratal chimneys from diapiric breccias and welds, as well as from associated allochthon debris aprons. Halokinetic breccias can also outline former thrust or glide planes after the dissolution of the original halite or calcium sulphate horizons that lubricated the thrust. Such thrust-weld breccias are termed *rauhwacke* and are discussed later in this chapter.

Diapiric dissolution breccias define areas above subcropping salt plugs in numerous islands in the Arabian Gulf, in what is one of the world's largest salt provinces and also one of its largest hydrocarbon provinces. Most of these diapir-cored Gulf Islands are plug ruins that have experienced little salt movement since being squeezed by the mid Miocene collision of the Arabian and Iranian plates (Figures 7.14: 7.22). Today these regions of outcropping Hormuz Complex are heavily eroded and largely covered by Neogene shoal water carbonates and marine cut platforms.

These diapiric breccias are the outcrop expressions of what is locally called the Hormuz Complex, from the type section on Hormoz Island (Figure 6.45a). It is a polygenetic assemblage of lithologies that includes both the nonevaporite blocks carried along by salt flow, as well as the supporting salt and gypsum/anhydrite matrix. The Hormuz Formation was originally deposited as a basinwide evaporite at a time near the

Precambrian/Cambrian boundary and has since been mobilised numerous times into salt structures (Kent, 1987). The range of clasts in the Hormuz Complex is diverse, but uniform over most of the Gulf islands. In none of the outcropping breccias are there any clasts derived from the cubic kilometres of indurated Palaeozoic and later sediment through which the salt passed on its passage to the surface (Kent, 1987). One of the most characteristic raft lithologies is a black foetid finely laminated and bedded dolomite that is often coarsely recrystallised and shows evidence of deep burial diagenesis. It was deposited in the same hypersaline setting that was also responsible for the deposition of the thick salt beds that became the Hormuz Complex. Similar foetid dolomite blocks characterise megabreccias in regions of outcropping diapiric breccias of the Neoproterozoic Ara Formation in Oman (Peters et al., 2003). Siliciclastic blocks composed of sandstones and siltstones are also widespread in the Arabian Gulf breccias, they are mostly reddish, grey or greenish grey and variably indurated. Throughout the region, both dolomites and siliciclastics can outcrop as spectacular rafted blocks up to several hundred metres across (Figure 7.22).

Igneous rocks are another important component of rafted megabreccia blocks in many diapiric breccias worldwide. In Gulf island breccias the igneous rafts tend to be dominated by acid tuffs (trachytes and rhyolites) along with acid intrusives

and dolerites. On the Iranian mainland the igneous rafts in namakier residues are referred to as “greenstone” blocks, as they are dominated more by basalts and dolerites. Throughout the salt-cored Gulf islands and on the Iranian mainland, large volumes of red specular haematite characterise outcrops of the Hormuz Complex. Some rafts of silicified shale are crosscut by malachite stained joints. On Hormoz Island the outermost ring of the salt plug itself is made up of haematitic tuffs, locally so rich in iron oxide that it is mined as a source of pigment (Kent, 1987). The significance of Fe-rich phases in terms of ferroan chloride brine haloes and metal transport in halokinetic provinces is discussed further in Chapter 9 and in Warren (2000b).

Texturally identical Neoproterozoic diapiric megabreccias, breccias and breccia trains crop out in the Flinders Ranges of South Australia (Figures 7.23, 7.69b; Dalgarno and Johnson, 1968). Many breccias in anticlinal cores are still located at or near the level of the mother salt bed (Callanna Beds) and so are remnants of former autochthonous salt pillows or glide planes rather than true diapirs. Others, such as the Oratunga and Wirrealpa diapirs show subcircular patterns of outcrop and breccia wings at stratigraphic positions well above the level of the original mother salt bed. Almost all the transtratal breccias line up along major regional shears and faults (welds)

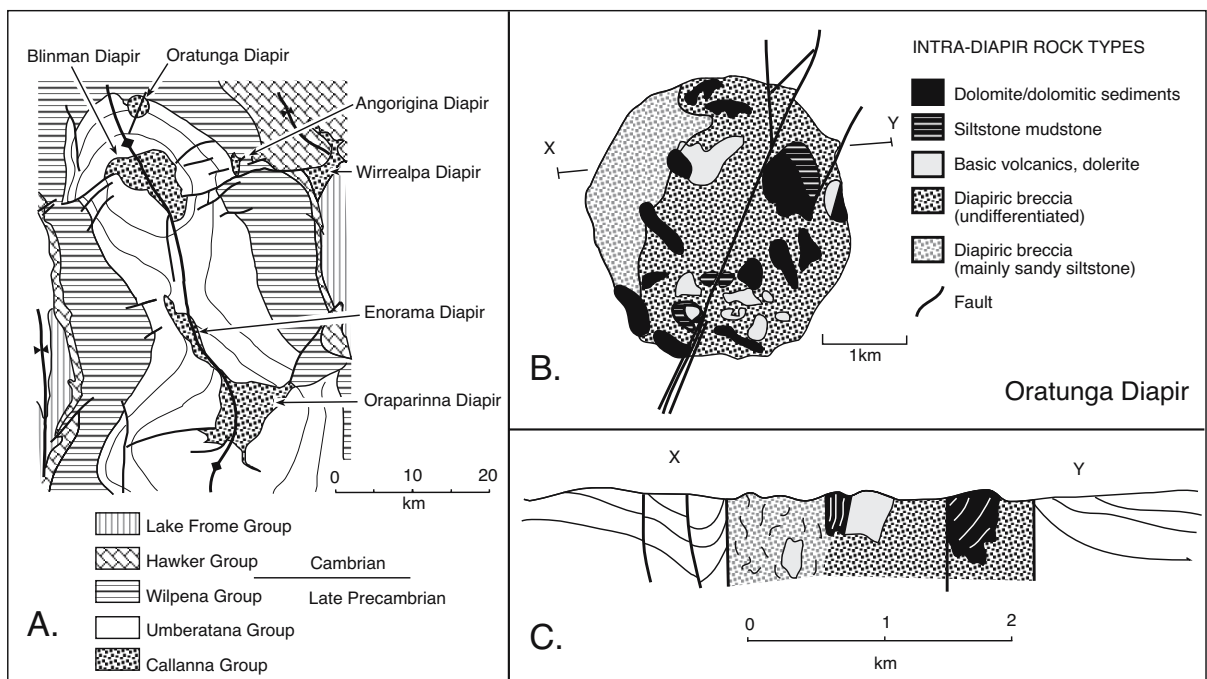

Figure 7.23. Halokinetic breccias, Flinders Ranges, Australia. A) Regional distribution of halokinetic breccia in the Callanna Formation. B) Distribution of large megabreccia lithoclasts or rafts in outcropping breccia matrix that define the Oratunga Diapir. C) East-west cross section of Oratunga Diapir (modified from Lemon, 1985).

surrounded by jostling depopods or minibasins, indicating that the mother salt bed was flowing while the basin was under extension (Figure 7.23a). Lemon (1985, 1988, 2000) clearly illustrates synkinematic controls on sedimentary facies and thicknesses adjacent to many of these breccia masses (Figure 7.23b, c).

Diapiric breccias in Flinders Ranges are heterogenous, with polymict clasts set in a strongly folded and disrupted matrix dominated by weathered pale-grey siltstones and fine sandstones. Clasts are mixtures of dolomites with gypsum and anhydrite pseudomorphs, dolomitic sandstones, siltstones and sandstones with displacive halite casts along bedding planes, and angular igneous fragments of diabase and basic volcanics, including amygdaloidal basalts (Lemon, 1985). The margins of many former diapirs in the Flinders Ranges are also characterised by numerous sub-economic copper shows in a haematitic matrix, much like the copper shows in the Gulf Islands.

Banded and aligned fabrics of clasts in the breccia masses of the Flinders Ranges diapirs indicate that shaping, disruption, mixing, and alignment of clasts occurred during salt-buoyed flow. Rafts showing coherent flow alignment can be blocks of megabreccia up to 500 metres across (Figure 7.23b, c). Long axis alignments of large raft blocks near the edge of a breccia mass are frequently near vertical and aligned subparallel to the diapir margin. Rafts nearer the centre of the breccia mass are more randomly distributed, a feature that indicates frictional alignment of large clasts near the diapir edge at the time salt was flowing or flow was collapsing. There is similarity between the size and lithology of rafts found in Neogene diapir crests in the Arabian Gulf and those in breccia masses in the Flinders Ranges. Steeply dipping bedding in rafts located near the diapir edge is also a feature of both areas and suggests flow alignment (Figure 7.22 and Figure 7.23b).

Matrix minerals in the Flinders Range's breccias include: carbonate, chlorite, feldspars (both detrital and authigenic), haematite, magnesio-riebeckite, quartz, stilpnomelane, and talc. Mount (1975) interpreted them as zeolite facies minerals formed during breccia emplacement via reactions involving hypersaline fluids. Although all the at-surface breccias lack preserved salts he argued conditions during breccia formation were aqueous, low pressure, and hypersaline. Mineral-forming reactions occurred in an oxidative low-grade metamorphic environment replete with CO₂, with open system fluid throughput and low temperatures (150° - 300°C). He concluded this palaeohydrochemical system had strong affinities to natural hydrothermal and geothermal systems. It indicated a later deeper

burial stage comparable to the current salt-filled diagenetic systems of the Iranian namakiers. The matrix minerals formed as solution flour at a time when most of the salt had already dissolved from the system and only the breccia bodies remained to outline the former salt geometry.

The late extension-stage geometries shown by the halokinetic breccias of the Flinders Ranges also means that where the crestal rather than the stem or feeder portions of the diapir breccia crop out they tend to show classic "falling diapir" geometries with suprasalt depopods, along with oversteepening related to subsequent compression and diapir squeezing (Figure 7.69b). Examples include the Wirrealpa and Oraparinna diapirs (Dyson, 1998, 1999). The falling diapir stage is characterised by crestal collapse and the formation of fault-defined graben thicks in the overlying sediments (Figure 6.17). As the diapir was collapsing, the underlying salt was thinning and dissolving. This facilitated the growth-fault focused escape of formerly confined basinal fluids on to the seafloor. This mechanism explains the formation of large fault-fed baryte masses atop many former diapir crests, along with the various small copper shows found in association with the diapir breccia margins (Warren, 2000b).

Mount (1975) noted breccia/host rock contacts were invariably abrupt and coincided with planes of weakness in the host strata. The breccia edge - country rock contacts match across some diapir stems, despite synformational sculpting and quarrying by invading diapir material. Adjacent host strata were rarely brecciated against a diapir, illustrating again the passive nature of the intrusion. His observations help explain why material from overburden strata located adjacent to a rising salt stem is not broken into rafts and transported to the surface. Salt emplacement is predominantly a passive process driven by the flow of pressurised salt into preexisting planes of entry. Where contact deformation has occurred, it usually predates diapirism and was due to glide plane faulting that then controlled subsequent breccia geometry. Mount (op. cit.) termed this style of contact 'permitted intrusion.' He argued it occurred under extension of the cover or overburden, perhaps induced by regional extension. Alteration of the host rock adjacent to contacts was absent but for minor dolomitisation and sideritisation in certain areas.

Instead of using models of forcible injection for diapir emplacement that prevailed in the 1960s and 1970s in the Flinders Ranges, Mount (op. cit.) used the outcrop geometries to stress the passive nature of salt flow into tensional structures. He concluded that "diapir" in terms of the then popular notion of active piercement, was not the most appropriate term to explain

breccia emplacement in the Flinders Ranges. His understanding of the dominantly passive nature of the diapiric process preceded by almost two decades our current models of brittle overburden atop weak flowing salt. In 1975 he stated, "... The overburden was relatively brittle, its weight the prime driving force to the intrusions. Mobility of source material, rather than factors such as density, was paramount to diapirism. The mobility is explained by the former presence of saline evaporites in the interstices of the breccias."

Diapiric breccia versus salt ablation (retreat) breccia

Diapiric collapse breccias are classified as a type of evaporite solution breccias in the preceding discussion (Table 7.4). Diapiric solution or collapse breccias are typically considered to be the result of subsurface dissolution of a diapiric feature that retains the outline of the original subsurface salt stem or allochthon. But this definition does not encompass the notion of breccias created by the leaching of an at-surface salt allochthon or namakier. When a namakier retreats it does so via at-surface dissolution of the salt mass, much in the same way a glacier retreats as it melts (Figure 7.14). Likewise, the outer edge of a salt glacier expands and contracts like the outer edge of an ice glacier. When the salt mass retreats it leaves behind a jumbled mass of material it once buoyed, which can include megabreccia blocks tens of metres across, as well as the insolubles of its carapace and insoluble intrasalt layers. These chaotic breccias are similar to a diapiric collapse breccia, but contain a much more polymict assemblage of clasts than an evaporite collapse breccia (after bedded salt) and often show evidence of mechanical reworking of portions of the breccia material by waves or currents. A separate term is probably needed to distinguish them from the more general term diapiric breccia; I call them salt ablation or salt-retreat breccias (Table 7.4)

Salt ablation breccias are forming today atop and peripheral to the dissolving edges of retreating namakiers in the Zagros of southwestern Iran (Figure 6.46a; Talbot and Jarvis, 1984; Bosak et al., 1999). Wherever an active but shrinking salt tongue subcrops or lies beneath a dissolution-derived gypcrete carapace, the clasts accumulate by breakup of the soft overburden and by stacking of fragments and rafts formerly held within the now dissolved salt matrix. The resulting namakier breccia is composed of a coarse, unsorted, heterolithic (polymict) rubble supported by a fine-grained calcareous matrix dominated by solution flour. This material can be mixed with fluvial and alluvial material or marine carbonate debris from times when the sea encroached on the salt tongue.

Ongoing dissolution of the namakier leaves behind a rubble moraine at the level of the former salt allochthon. Thus, salt ablation breccias associated with salt cores of the various island diapirs of Arabian Gulf are jumbles of exotic material carried to the surface by upwelling salt, which is then combined with the disrupted remnants of the Neogene marine carbonate shoals and buildups that once covered earlier now-dissolved salt tongues (Hormuz Complex). The mixing of contemporary sediment with salt-buoyed megabreccia blocks and insolubles in the salt, and the stratiform circum-stem or circum-weld nature of its occurrence, is what distinguishes a salt ablation breccia from a diapiric breccia (Table 7.4).

Breaking out the age of the former cover sediments within buried salt ablation breccias is useful in attempting to time episodes of at-surface salt in Phanerozoic successions adjacent to former salt stems. Belous et al. (1984) described reworked breccia trains (salt ablation breccias) composed of fragments of Devonian basalt and limestone at several stratigraphic levels in sediments surrounding the Late Palaeozoic Adamovsk salt stock in the southern Ukraine. They attributed breccia trains to lateral redeposition of salt-lifted blocks during periods of stock

Feature of interest	Evaporite collapse breccia (stratiform after bedded salt)	Evaporite collapse breccia (transtratal after diapiric salt)	Salt ablation (retreat) breccia (stratiform after an at-surface allochthon)
Timing of brecciation	Subsurface	Subsurface	Can be at-surface or nearsurface
Overall shape of unit	Stratiform (sometimes with local chimneys) with passive base	Transtratal (includes salt and thrust welds), shale sheath drag zone	Stratiform with disturbed lower contact (former gumbo)
Diversity of breccia clasts	Upward transition from low-polymict to monomict (crackle)	Polymict from intrasalt layers and plucked subsurface material	Polymict intermixed with surface sediments (e.g. fluvial, alluvial, reef)
Metamorphic grade of clasts in breccia	Matches adjacent sediments	Higher than adjacent sediments	Higher than adjacent sediments
Vertical stacking in the breccia mass	Broadly matches the original stratigraphic order, even in any stoped transtratal chimneys	Chaotic (salt flow churns clasts along diapir stem then via dissolution and welding)	Chaotic for salt-carried clasts, but more cover sediment toward its top (e.g. reef carapace on blocks)

Table 7.4. Comparison of salient features for separating three main types of breccias created by dissolving

unroofing, possibly via a salt glacier mechanism. Similarly, drilling in 1991 in the Tapley Hill Formation on the flank of the Blinman Diapir (Flinders Ranges, South Australia) intersected an anhydrite-cemented breccia with most clasts not derived from the enclosing shale (Cooper, 1991). The intra-Tapley breccia is interpreted as a salt ablation breccia, it is a residue of a salt glacier once flowing across the Neoproterozoic seafloor under a relatively deep water mass. Recognition of numerous salt ablation breccia levels in circum-stem positions about the Pinda and Wirrealpa structures in the Flinders Ranges, South Australia, led Dyson (1998, 2004) to describe them as “Christmas-tree” diapirs.

Salt-cored thrust breccias, rauhwacke and orogeny

Rauhwacke horizons are the weathered and leached remnants of what were once ‘weak’ salt-entraining tectonised layers (Jeanbourquin, 1988, 1994; Warren, 1999). Under stress, their evaporitic precursors acted as rheologic inhomogeneities providing surfaces of décollement during orogeny. Halite, or sometimes anhydrite/gypsum, is the main lubricant during the formation of stratiform tectonite or décollement layers. The inherent lack of strength of halite or anhydrite/gypsum under stress, when compared to other lithologies, focuses the greater part of the detachment or thrust plane movement into the salt-entraining interval, which can also move salt into higher levels in the thrust sheet (Chapter 6).

Conceptually a rauhwacke overlaps with both salt and fault welds and in some situations may have once fed salt into what are now salt ablation breccias. It forms a dissolution residue in the nearsurface and at outcrop as the more soluble evaporite components are leached from an unroofed thrust breccia, or deeper in the subsurface as the sheared evaporite and its surrounds are metasomatically converted to less soluble salts, such as calcite spar or dolomite. Halite probably is a major component at depths where translant thrusting occurred, but was subsequently dissolved to leave behind deformed anhydrite at shallower depths. Rauhwacke breccias in outcrop are dominated by carbonate and clastic fragments in a cataclastic matrix. Boxwork and cellular honeycomb textures, so common in rauhwacke horizons, are the outcrop expressions of pervasive weathering of an evaporite precursor.

Rauhwacke are evaporite solution breccias that define outcrops and subcrops of evaporite lubricated thrust-planes and have been described from the Jura Mountains of Switzerland, the Atlas

Mountains of Morocco and the Salt Range of Pakistan. Jordan and Nuesch (1989) and Jordan et al. (1990) describe deformed anhydrite textures in décollement horizons preserved in tunnels intersecting the main Alpine thrust planes. These anhydrites are deeper less-leached equivalents of near-surface zones where meteoric waters create rauhwacke from their evaporitic tectonite precursor. That is, rauhwacke units are the weathered outcrop expressions of evaporite-lubricated thrust planes, glide planes and detachment terranes within orogenic belts. In some older studies, the rauhwacke itself was considered to have facilitated thrusting. In other seemingly conflicting studies rauhwacke was considered to be obviously nontectonic as it could contain channel fill sediments, parallel lamination, cross-lamination, graded bedding, clastic dykes and other sedimentary structures. Now we know that much of this confusion was created by a lack of understanding of its evaporite genesis and poor definition of the term itself. An evaporite-lubricated thrust horizon or décollement is where the rauhwacke protolith forms. Subsequent weathering of the thrust horizon first in subcrop and then outcrop created rauhwacke layers with sedimentary structures. That is, rauhwacke is herein defined as an exhumation-driven post-thrusting evaporite dissolution/alteration overprint on a former salt-lubricated thrust or tectonic melange. Erosional unroofing to the level of the evaporite-facilitated thrust creates rauhwacke, which can then be reworked by fluvial and other surface processes. Rauhwacke is an evaporite dissolution overprint, it is not the cause of the thrust event.

As well as this tectonite specific usage of rauhwacke, the term is sometimes still used interchangeably with the French terms *cornieule* or *cargneule*. It then describes a porous or cavernous carbonate sedimentary rock (especially a cellular dolomite), with angular cavities filled with soft, friable, evaporitic residues that easily dissolves or falls out to leave a rough, corroded and fretted angular surface (e.g. Schreiber 1988). This less specific usage is associated with widespread textures indicating preferred dissolution of dolomite or evaporite clasts leaving behind the surrounding calcite cement. Evaporite boxwork or cellular or honeycomb fabric, all nongenetic terms, and not rauhwacke should be the preferred descriptors when angular salt solution textures cannot be tied to décollement.

Surface-related karsting of different tectonised protoliths forms structurally and geometrically distinct types of rauhwacke in the Swiss Alps. Schaad (1995) identified two end members in rauhwacke outcrop in the region (Figure 7.24a, b): a) dolomite-bearing gypsum, and b) gypsum-bearing dolomite. Dolomite-bearing gypsum rauhwacke develops as karst-fill sediment within the thrust plane, and is typified by unstructured, often

polymictic units, with geometries that reflect the shape of the precursor karst cavity. In contrast, gypsum-bearing dolomite rauhawacke makes up stratiform geometries that are dominated by dolomite breccias with crackle to mosaic textures. This form of rauhawacke is a solution-collapse breccia developed after the solution of widespread tectonised evaporite beds. Sometimes, karstification of thrust plane evaporites is aided by synformational fluvial or fluvio-glacial processes that are focused into valley depressions created by salt edge retreat, much in the same way as gently-dipping evaporite beds dissolve in the near subsurface (Figure 7.7). Pomoni-Papaioannou and Karakitsios (2002) recognise similar features to Schaad (*op. cit.*) in the rauhawacke horizons that define major evaporite (Carnian)

lubricated thrusts in central western Crete and the Ionian zone of the Greek mainland (Figure 7.24c). They go on to note that rauhawacke can be observed for more than 700 km along the outcropping base of the external nappes of the Hellenides.

Most of the deformation/lubrication in the precursor horizon to a rauhawacke breccia comes from the unique Newtonian flow properties of halite. But there is an under appreciated aspect of gypsum flow in a dissolution zone that may also contribute to the deformation in a rauhawacke horizon. Gypsum tends to deform more rapidly when bathed in increasingly saline solutions (de Meer and Spiers, 1999). This means that when an exhumed anhydrite unit has converted to gypsum, those parts of the gypsum subject to crossflow by increasingly saline brines are more susceptible to ongoing deformation.

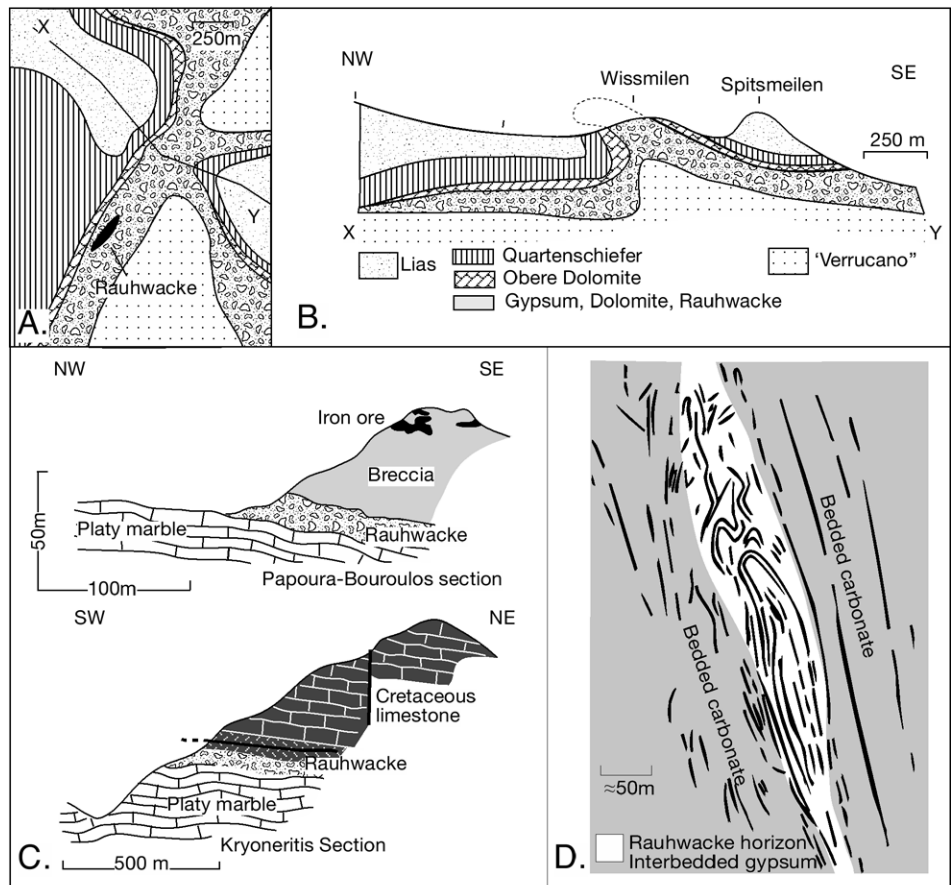

Figure 7.24. Rauhawacke. A) Plan view of rauhawacke developed atop subcropping gypsum (after anhydrite) in thrust décollement of the European Alps (from Schaad, 1995). B) Cross section X-Y, with position shown in 7.22a. C) Geological sections in the Rodakino region, Crete showing development of rauhawacke along décollement, which was lubricated by Triassic evaporites (after Pomoni-Papaioannou and Karakitsios, 2002). D) Outcrop trace showing increase flow deformation in a rauhawacke layer (formerly halite-rich) in the Gillen Member of the Neoproterozoic Bitter Springs Formation, Amadeus Basin, central Australia (after Lindsay, 1987).

As with all evaporite solution breccias, much information relevant to the rauhawacke protolith must be inferred rather than directly observed at outcrop. But in some relatively unleached thrust windows in the European Alps there are transitions between salt-cored tectonite protolith and rauhawacke that are still preserved as subcrop and even occasional outcrop. In the Austrian Alps, Spötl (1989b) describes tectonised evaporitic breccias that were created, and are still preserved, in the faults and thrusts of the mostly Permian Haselgebirge Formation. All these salty tectonic breccias flowed and fragmented during the Alpine Orogeny (Middle Cretaceous - Late Eocene) and are part of a giant regional tectonic melange. The Haselgebirge Fm. was also involved in tectonism well before the Alpine thrust event.

Figure 7.25. Frequency distribution of Sulphur isotope values for sulphates, sulphides and native sulphur from the Haselgebirge Fm. melange, Austria (after Spötl et al., 1998). Theoretical $\delta^{34}\text{S}$ distribution curves for pyrite produced during bacterial (BSR) and abiogetic thermal sulphate reduction (TSR) processes are shown. Note that pyrite $\delta^{34}\text{S}$ values are close to and within compositions expected for TSR.

Haselgebirge Fm. breccias are composed of polymict clasts (from cm to several tens of metres in diameter) that in the subsurface are often embedded in a halite matrix (Spötl et al., 1998). The breccia matrix contains varying amounts of clay and silt impurities (normally in the range of 15–55 %) plus minor quantities of anhydrite. In addition to clasts derived from the tectonic breakup of the initial intrasalt beds (shales, silts, sandstones, anhydrites, scarce pyroclastic rocks), nappe transport drove huge blocks of faulted Mesozoic carbonates, marls and shales into the underlying visco-plastic (halokinetic) Haselgebirge Fm. Like their brecciated surrounds, these partially or completely isolated overburden blocks show evidence of severe strain that includes; internal fragmentation, stretching, translation and rotation. Overburden pressure seems to have controlled the degree of brecciation and slickensides within these detachments.

In the subsurface the tectonised “Haselgebirge” breccias sit within intervals of recrystallised halites and anhydrites, still preserving what at first sight appears to be mm-cm scale depositional lamination. Closer inspection of the layered halites and anhydrites defines preserved isoclinal noses and overfolds, clearly illustrating the tectonite origin of the laminae (Spötl, 1989b). Pervasive salt flow and recrystallisation means any relics of primary structures in the halite beds are almost all destroyed. Preserved remnants of primary sedimentary features in the Haselgebirge Formation only remain within blocks and fragments composed of carbonate and anhydrite.

These fragments and blocks were once more competent intrasalt beds, which were progressively fragmented by tectonism and flowage, and now make up the majority of clasts in the Haselgebirge Fm. breccias. The breccias preserve evidence of their progressive tectonic evolution from limited ductile deformation → brittle fracturing → boudinage → individual rotation of newly developed clasts → development of localised matrix-supported breccias (not laterally persistent) → laterally persistent matrix breccias with increasingly homogenous grain sizes (Spötl, 1989b, 1998). In the early stages of intrasalt bed breakup the clasts were angular. With ongoing clast deformation and rotation, the clasts become rounded and develop slickensided boundaries.

The brecciation of the intrasalt beds reflects the different responses of anhydrite or carbonate to strain, when compared with halite. In response to shear stresses of much less than 1 MPa at geologically significant strain rates, halite typically flows and recrystallises via pressure solution (Figure 6.3a). Due to their higher strength, the shale, carbonate and anhydrite intrabeds respond in a brittle fashion and tend to brecciate, not flow, at the same strain rates.

The higher temperature origin of the diagenetic products in the Haselgebirge is clearly seen in the sulphur isotopic evolution of sulphate reduction products (Spötl et al., 1998). Sulphates in the Haselgebirge matrix largely preserve their Permian-early Triassic marine signatures and range in $\delta^{34}\text{S}$ from +9.8 to +13.8‰ (Figure 7.25). Matrix dolomite alteration was driven by thermochemical sulphate reduction (TSR) and is indicated by the replacement of anhydrite by calcite + pyrite ± native sulphur (See Chapter 9 for detail on TSR and BSR). Pyrite associated with TSR is coarsely crystalline and characterized by a small sulphur isotope fractionation relative to the precursor Permian anhydrite. Interestingly, the carbonates associated with TSR show low Fe/Mn ratios reflecting rapid reaction of ferrous iron during sulphide precipitation. As a result, TSR-related dolomite and calcite typically show bright Mn(II)-activated cathodoluminescence. This is in marked contrast to the dull cathodoluminescence of many (ferroan) carbonate cements in nonevaporitic deep-burial settings. In addition to carbonates and sulphides, authigenic silicate formation was closely related

to TSR, and included quartz, K-feldspar, albite and K-mica. Increasing illite crystallinity in the Haselgebirge also defines the sequence's entry into the anchizone (see Warren, 1999, Chapter 6, for further discussion of meta-evaporites and related clay transformations). The subduction or tectonism driving this salt-cored thrust melange was tied to the closure of the Meliata-Hallstatt ocean to the south of the Northern Calcareous Alps and may have preceded the main Alpine Orogeny by 50 million years (Spötl et al., 1998).

Likewise, the rauhwacke that characterises outcrops of the Triassic Burano Evaporite Formation from the Secchia River Valley of Italy is intensely modified and tectonised as its evaporitic precursor was the main décollement horizon during the formation of the Northern Apennines chain (Lugli, 2001). Inclusion temperatures of the various burial products clearly show a high temperature (greenschist) genesis (Figure 7.26). Regionally, the Burano Formation is up to 2200 m-thick and composed of metre-to decametre-scale interbeds of gypsum-anhydrite and dolostones with minor halite. The deposit has been affected by a complex array of postdepositional modifications, thermal events and large-scale evaporite dissolution, all acting to destroy an evidence of the environment of deposition. Carbonate clasts are composed of; massive and/or laminated dolomitic mudstones, wackestones, oolitic packstones and oolitic, peloidal, bioclastic grainstones. All can appear as mega-boudins within a calcium sulphate groundmass. The dolostones, (with a $\delta^{18}\text{O} = -5.7$ to -3.7‰ ; $\delta^{13}\text{C} = +1.3$ to $+3.0\text{‰}$; PDB) have been overprinted by sparry magnesite during Mg-metasomatic replacement ($\delta^{18}\text{O} = -14.0$ to -2.6‰ ; $\delta^{13}\text{C} = -2.6$ to $+1.4 \text{‰}$; PDB) via orogenically-driven hydrothermal circulation (Lugli 2001; Lugli et al., 2002). Homogenization temperatures of fluid inclusions in hydrothermal magnesite range from 275 to 310°C (Figure 7.26a).

Anhydrites in the Burano are characterized by flow structures such as centimetre-scale pseudolamination composed of aligned prismatic

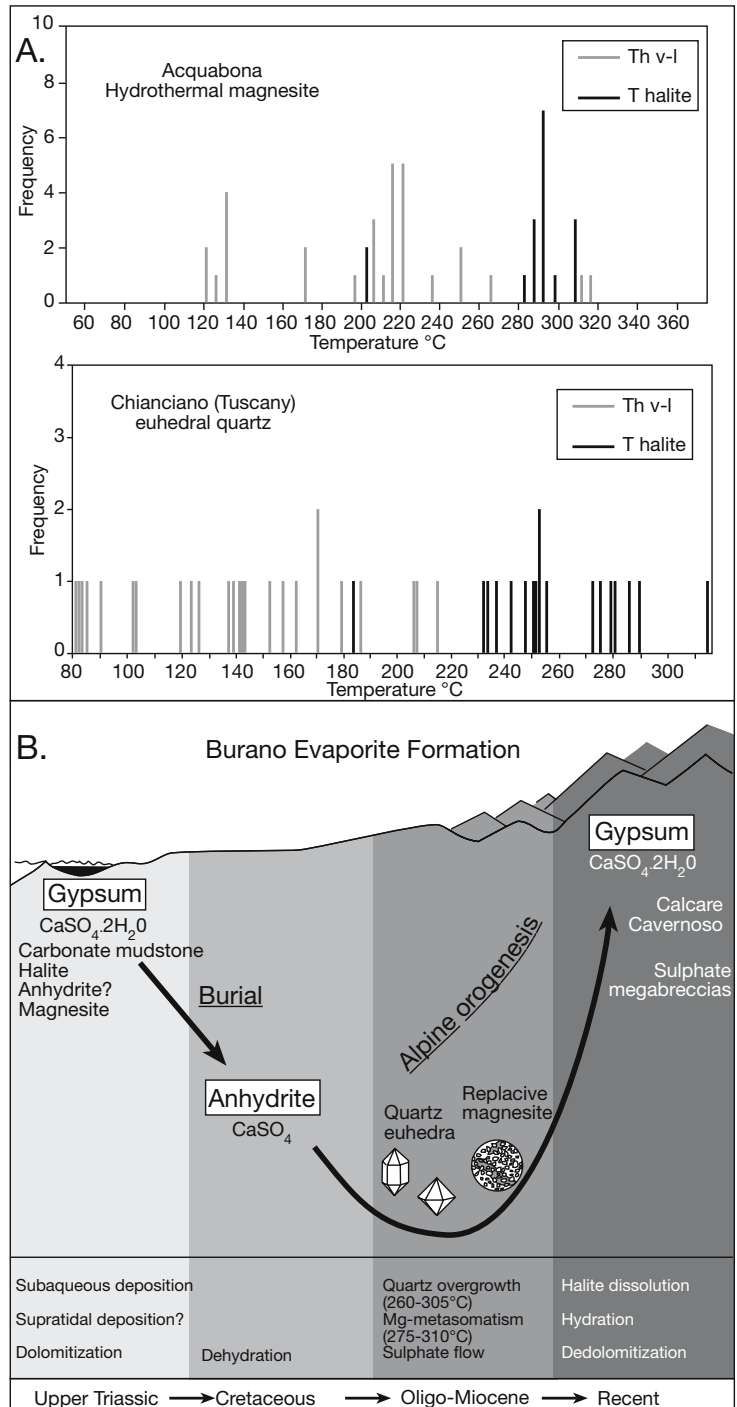

Figure 7.26. Burano Evaporite Formation (after Lugli, 2001), A) Frequency histogram of fluid inclusion results from vapour to liquid homogenization temperatures (v-l) and halite melting temperatures (halite) in fracture-filling sparry magnesite from the Acquabona region and authigenic quartz euhedra from Chianociano region in Tuscany. B) Reconstruction of the geologic history. Not to scale and adapted from the original gypsum-anhydrite-gypsum burial cycle of Murray (1964).

crystals with transposed isoclinal folds outlined by dolostone fragments. No primary textures remain. Homogenization temperatures of fluid inclusions in authigenic quartz incorporated into sulphate rocks range from 260 to 305 °C (in the Emilia area) and from 230 to 315 °C (in the Tuscany area; Figure 7.26a). Outcropping and nearsurface gypsum is composed of xenotopic irregular cloudy crystals and, more rarely, by centimetre-scale idiotopic crystals showing the same structures as the anhydrite rocks. The gypsum is a late alteration product from anhydrite, formed during migration of sharp hydration fronts and meteoric flushing. Hydration is a two step process as indicated by the presence in the gypsum encasing corroded anhydrite micro-relics and by authigenic quartz crystals that still include anhydrite (Figure 7.26b).

Evolution of Burano Evaporites during the Apennines tectogenesis was ongoing and tectonically driven by the processes of burial compression and exhumation (Figure 7.26b; Lugli, 2001). It can be divided into: (a) prevalent deposition of gypsum in the Upper Triassic; (b) gypsum dehydration at burial conditions to form anhydrite (Cretaceous?); (c) syntectonic flow of anhydrite rocks, brecciation of dolostones; syn-growth stage of quartz euhedra at deep burial conditions possibly related to the development of the Oligocene-Miocene greenschist facies of the Apuane metamorphic complex; (d) hydrothermal deposition of sparry magnesite and partial Mg-metasomatic replacement of dolostones by magnesite; (e) sub-surface dissolution of halite to form thick matrix-supported residual caprock-like anhydrite mega-breccias; (f) complete regypsification of anhydrite at sub-surface conditions; and (g) evaporite dissolution at surface exposure producing dolostone breccias with partial calcitisation and removal of most evaporite clasts ("calcare cavernoso" or *rauhwacke*).

Rauhwacke sheets (carbonate thrust breccias) also define outcrop of tectonic slices in nappe piles now dominated by pelitic rocks of Early Mesozoic age in the Carson Sink region of Nevada (Muttlebury and Lovelock Formations; Speed, 1975; Speed and Clayton, 1975). There the most extensive carbonate breccia nappe, the Muttlebury Nappe, extends over an area of 100 km² (Figure 7.19). The outcropping *rauhwacke* sheets are interlayered and interlensed with non-brecciated marble slabs. The coarse grain size and granuloblastic texture of the marbles suggests an origin via metamorphic overprint of at least moderate grade. But the degree of apparent recrystallisation in the marbles contrasts with a lack of recrystallisation and metamorphic alteration in the intercalated limestones and *rauhwacke* breccias. That is, the apparent metamorphic grade of these marbles is seemingly incompatible with that of the

adjacent unmetamorphosed sedimentary carbonates and is best explained by emplacement along an evaporite-lubricated thrust. A nearby 30m -thick gypsum klippe shows internal isoclinal folding due to strong translational movement. Speed and Clayton (op. cit.) correlate it as a lateral equivalent to *rauhwacke* of the Muttlebury Nappe. Remnants of the same folding style are preserved in the matrix of some breccia beds in the *rauhwacke* of the Muttlebury Nappe.

Chert caught up in the granuloblastic calcite marbles, and interlayered with *rauhwacke* sheets of the Muttlebury Nappe, contains ubiquitous length-slow chalcedony, implying a possible evaporite precursor for the marbles. But the genesis of the marble is best resolved using their stable isotopic signatures (Speed and Clayton, 1975). Carbon and oxygen isotope ratios of calcites from various carbonate rocks in the Carson Sink, including the marbles, fall into two distinct trends. One has nearly constant $\delta^{13}\text{C}$ and variable $\delta^{18}\text{O}$; the other has nearly constant $\delta^{18}\text{O}$, and a $\delta^{13}\text{C}$ signature that varies between -7 and -25 ‰ (PDB). The first trend encompasses all the fine-grained carbonate rocks and calcarenites of the region, whereas the second encompasses all analyses of the problematic granuloblastic calcitic marbles. Speed and Clayton's (1975) interpretation of the isotopic trend of the marble is that the marble's precursor was a coarse-grained gypsum or anhydrite-lubricated décollement caught up in active thrust and glide planes. When active it had acted much like the anhydrite-lubricated Alpine thrusts (Figure 8.26).

These calcium sulphate-cored décollement sheets were subsequently calcitised bioepigenetically, with the sulphate-reducing bacteria utilising sulphate from the décollement plane and organic carbon from sources outside of the sulphate beds, perhaps the nearby euxinic limestones, or perhaps hydrocarbons percolating and focused by the now inactive thrust sheet (hence its $\delta^{13}\text{C}$ signature). Thus, Speed and Clayton argue the process of marble formation was similar to that now forming the calcitised sulphurous cap rocks of diapirs in the Gulf of Mexico (Figures 6.64).

Thus the *rauhwacke* breccias in the Muttlebury Formation, interlayered with these enigmatic marbles, are intraformational tectonic breccias. They were created by near-surface meteoric dissolution of calcium sulphate remnants in previously salt-lubricated thrusts. Crossbedded calcarenites and quartz sands are water-reworked matrix components in the *rauhwacke* breccia, much like in the type area of the Alps; they are mechanically reworked accumulations of insoluble residues and stringers that were originally disseminated through the antecedent sulphate beds.

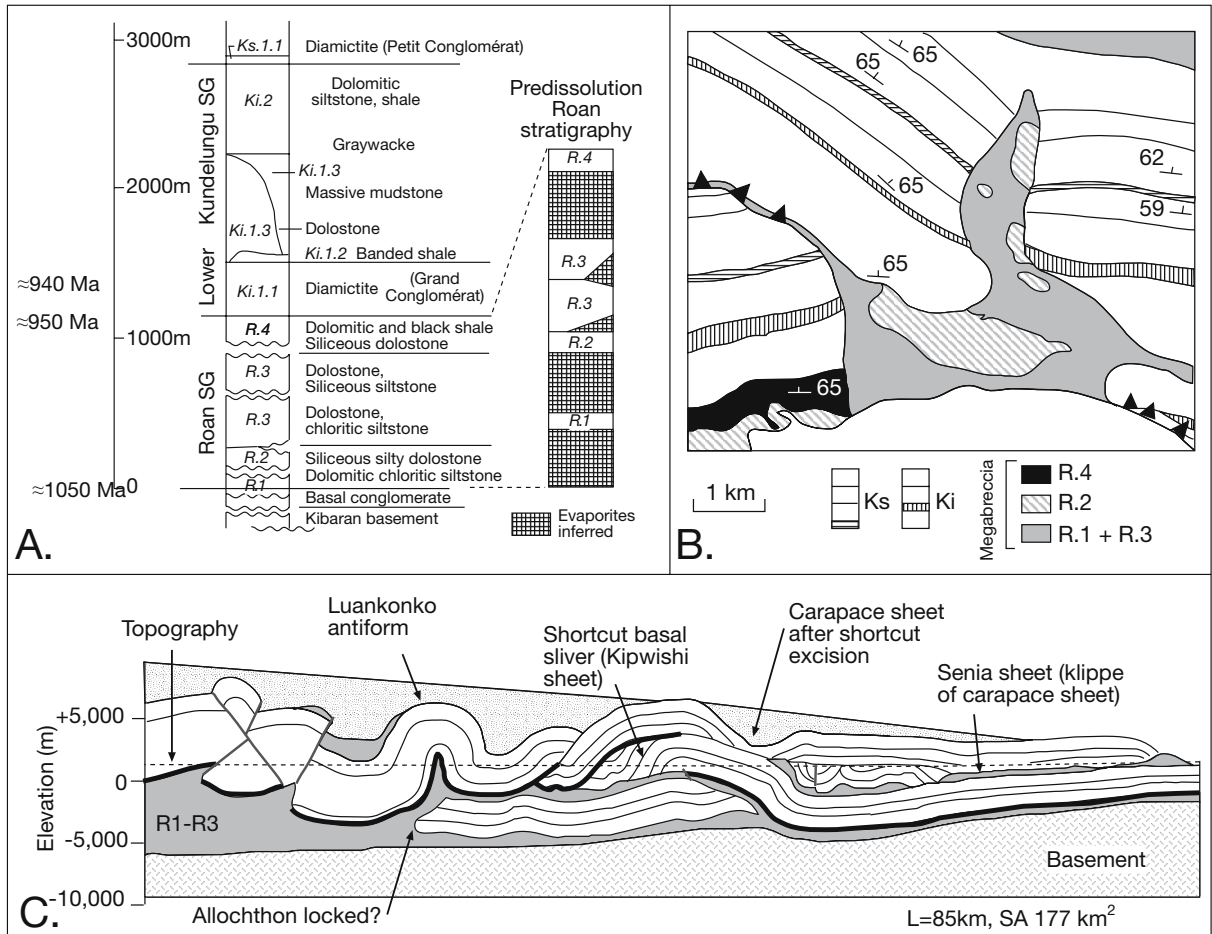

Figure 7.27. Lufilian halokinetic breccia or rauhwacke (after Jackson et al., 2003). A) Katangan stratigraphic column with a side column showing qualitatively restored evaporite thicknesses. Basal units below R.1 are based on the Zambian Copperbelt not the Katanga region. B) Map of Mukondo Diapir, representing a down-plunge oblique section. In the diapir's northern apophysis, the Roan evaporite-gigabreccia passively pierced 2 km upward through accumulating Ki and Ks overburden in the southern limb of Mutaka Synform. This diapir appears to be rooted in autochthonous Roan. The separate Roan diapir in the extreme northeast is allochthonous. C) Regional reconstruction of Katangan thrust section at the end of Lufilian time with no vertical exaggeration. The level of the modern topography indicated by dashed line.

Older but impressive examples of salt-lubricated thrust sheets and evaporite-hosted rauhwacke melange outcrop in Neoproterozoic sediments caught up in orogenic belts in the Katangan copper belt of Central Africa, and in outcrops in the Flinders Ranges of South Australia and the Amadeus Basin of Central Australia (Figures 7.27, 7.23, 7.24d, respectively). The original evaporite matrix to the breccias has long since dissolved in these regions leaving behind a complex highly brecciated melange, sometimes entraining large megabreccia blocks that can be kilometres across. Rauhwacke occurs in close association with diapiric breccias that define an extensional halokinetic stage that preceded compression and thrusting. Both the breccia blocks and the finer-grained matrix still retain a number of indicators of the former presence of widespread

evaporites and include; a) pseudomorphs of gypsum, anhydrite and halite crystals, b) dolomite textures in breccia fragments that mimic anhydrite nodules, enterolithic folds, and chickenwire textures, c) doubly terminated euhedral quartz and length-slow quartz, d) minor volumes of actual calcium sulphate (mostly regypsified at outcrop) as a pore filling cement, e) hypersaline fluid inclusions in authigenic phases and f) meta-evaporitic alteration haloes about the breccias bodies that indicate an evaporite source. These rauhwacke horizons are the structured remnants of much thicker salt masses (Figure 7.27a).

Melanges of dissolution residues in both areas outline both diapiric structures and subsequent thrust welds. The original salt in both areas was precipitated in rifts, which evolved into passive

margins, with both autochthonous diapirs and allochthonous salt tiers, and then into a salt-lubricated thrust belt during subsequent orogenesis. The salt was sourced in the Callanna Group in the Flinders Ranges and the Roan Supergroup in the Katangan Copper belt (Lemon, 1985; Jackson et al., 2003). The details of the diapiric breccias in the Flinders Ranges were discussed in the previous section (Figure 7.23). Many workers in the Flinders Ranges have focused on the diapiric nature of the breccias, although salt-lubricated thrust plane *rauhwacke* breccias are widely visible in outcrop. Work by Jackson et al. (2003) has clearly defined the intimate interrelationship between halokinesis, thrust plane development and salt in the Katangan fold belt. Classic diapiric geometries are outlined by the brecciated residuals of the Roan Supergroup, as in the Mukondo Diapir (Figure 7.27b). Former salt-lubricated thrust planes are now outlined by *rauhwacke* breccia sheets in both the Katangan Copperbelt of Shaba (Democratic Republic of the Congo) and Zambia. These regions also contain the world's largest concentration of stratiform copper-cobalt ores, with their genesis largely focused by the interactions between metalliferous basinal brines and salt sheets (Warren 2000b).

During the Lufilian orogeny, the Katangan basin structure was radically transformed first by extrusion of allochthonous evaporites, then by orogenic shortening (Figure 7.27c; Jackson et al., 2003). Salt tectonics began during deposition and gravity gliding of the Roan Supergroup between 1050 and 950 Ma. In mid-Roan time, salt walls and extrusions of evaporites began to be emplaced (former salt now outlined by breccias and *gigabreccias* - as in Flinders Ranges). In early Kundelungu time (940-850 Ma) the evaporitic diapirs enlarged. Lufilian deformation began by laterally squeezing diapirs to form salt welds between 850 and 650 Ma. Then, a large sheet of commingled Roan evaporite and carbonate-dominated sediments and ores was extruded northward by ≈ 65 km. Extrusion was fast enough to blanket a uniform pre-orogenic footwall unit without overriding any synorogenic deposits, much like the Salt Range in Pakistan today (Figure 6.40). Continued shortening then emplaced large thrust sheets, lubricated by the preexisting salt-sediment extrusive sheet. Restorations by Jackson et al. (2003) suggest that the Lufilian foreland in the Katangan area shortened from 193 km to 85 km and that the depositional northern edge of the evaporite basin controlled the shape of the Outer Lufilian Arc.

Bed geometries in both the Flinders Ranges and the African copper belt show that a post salt-solution distinction between *rauhwacke* and diapiric breccias is difficult in core, and without sufficient outcrop analogues or seismic is near impossible.

Lithologically, at the lower temperature end of the burial spectrum, the components of *rauhwacke* and diapiric breccias are identical. Our increased understanding of tiered allochthon emplacement of salt masses, and the time equivalence of early updip extension and downdip compression, makes such a distinction increasingly irrelevant at the lower temperature end of burial. When formed, updip extensional diapirs pass downdip into compressional toe-of-slope regions and both areas will become compressional later in the Wilson Cycle (Figures 5.27, 6.38).

Rauhwacke and its precursor salt-lubricated thrust planes and alteration haloes tend to be dominantly interstratal stratiform surfaces defined by focused slippage, adjacent fault plane brecciation and subsequent solution collapse. Such thrust planes often separate a brittle-faulted hanging wall from a less altered footwall succession (thin-skinned tectonics discussed in Chapter 6 and illustrated in Figure 7.27c). Occasionally a *rauhwacke* breccia cuts upsection as a thrust ramp or riser. In contrast, diapiric solution breccias tend to be identified by largely trans-stratal geometries that outline the shape of the precursor salt diapir. But salt-lubricated allochthon sheets evolve into thrust planes, while former salt welds and diapirs can be reactivated to become the base of salt-lubricated thrust sheets (see Figure 6.41). When diapirs, allochthons, depopods and detachment surfaces are part of the same salt-lubricated system, the two breccia styles merge and become near impossible to separate. Older 1950s vintage notions that salt diapirs indicated active halite intrusion and so were a separate tectonic style to thrusting, led to heated but possibly unnecessary argument in the 1960s and 70s on ways to separate diapirs from *décollement* in the Flinders Ranges (e.g. Burns, 1977). We now know they are part of the same salt-lubricated association with diapiric intervals and salt tiers often acting as a plane of weakness for subsequent thrusting as the basin passes from extension into compression (Wilson cycle).

Where the concept of salt allochthon breccia versus *rauhwacke* needs to be better defined is in the higher-temperature higher-pressure realm of metamorphism. *Rauhwacke* when used to define a type of breccia has inherent notions of a thrust sheet and an alteration halo about the salt-cored thrust plane. Fluids focused along the salt cored thrust can penetrate, alter and even mineralise adjacent strata. Salts can survive as halite to burial temperatures in excess of 450°C and as anhydrite to temperatures >900°C (Warren, 1999). *Rauhwacke* as a concept explaining near fault alteration has been applied to salt-lubricated thrust residues and alteration/mineralisation haloes within this temperature range (greenschist to amphibolite facies).

But notions of diapirs and salt welds are largely restricted to the sedimentological literature yet they too must pass into the metamorphic realm. Salt allochthon and weld models, based largely on seismic interpretations of sedimentary basins, have no such notion of alteration haloes, yet they have extensive ferroan carbonate haloes as seen in outcrop in Algeria, the Flinders Ranges and the McArthur Basin (Warren, 1999; Chapter 8). Combining the two notions into a single model of structural evolution and mineralised fluid focusing will give increased exploration success in copper and base metal metamorphic/halokinetic terrains such as the Mt Isa-Cloncurry belt of Queensland, Australia and the Yunnan province of China (Warren, 2000b).

Partial salt dissolution: residues of less-soluble salts

Whenever a thick evaporite bed comes into contact with undersaturated waters it dissolves to leave behind a bed of insoluble residues. So far we have concentrated on characteristics of evaporite solution breccias with insoluble residues that no longer retain preserved salts. But there are intermediate stages in many subcropping and subsurface beds and diapirs in sedimentary basins, where less soluble salts remain after the more soluble salts have dissolved. The result is a cumulate laminar layer or breccia dominated by less soluble salts, typically anhydrite, that were originally dispersed through a now largely dissolved halite bed. At the same time as the beds dissolve, pore fluid salinity increases at the dissolution contact. As this water mixes with throughflowing waters in adjacent beds it can precipitate anhydrite or gypsum cements in nonevaporitic strata (burial and telogenetic salts).

If the dissolution is rapid and focused, overburden and intrasalt beds brecciate and fail via incremental crack-seal processes, with residual anhydrite or alabaster matrices surrounding the former intrasalt breccia blocks. If the dissolution is slower and subsidence or “let down” of the overburden gentler, then a residue bed of layered sulphates forms (Figure 7.28). In this case the overburden span or roof tends to subside in parallel, with no more than minor crackle fracturing at the contact with the accreting laminar sulphate bed. If the subsiding overburden is a clay, then satin spar veins fed by high salinity brines coming off the dissolution front can infill any gravitational and hydraulic fractures forming in response to collapse-induced extensional stresses (Figure 1.40).

Less soluble salts tend to accrete at the boundary of the salt bed in contact with the undersaturated crossflow. If dissolution occurs at the top of a salt bed then accretion occurs along the base of the residue bed (younging downward - as in anhydrite caprock atop a diapir). If it occurs along the underside of a thick salt unit, the less soluble salts accrete to the top of the bed (younging upward - an “upside-down” caprock known as a basal anhydrite). In either case, the accretion of less soluble salts generally leads to a distinctive wavy-laminated fabric, either in anhydrite or in mud-sized residual material (that includes carbonates as well as clays). The wavy structure forms as small and disaggregated layers of insolubles are wrapped around larger clasts or nodules of anhydrite.

The mineralogy and thickness of the residue layer depends on the proportion of insolubles in the original evaporite bed and the salinity and chemical composition of the undersaturated waters. Relatively pure halite or potash units tend to produce thin layers of residual impurities. Anhydrite or mudstone insolubles hosted in the original intrasalt beds are typically first incorporated as bedding-parallel elongate clasts in the bed, often with minimal modification to their pre-collapse textures. Ultimately, with enough time, freshening and flushing, all the residual anhydrite dissolves and only nonevaporite clasts and fine-grained insolubles remain (typically muds and loose silt-sized dolomite rhombs).

Focused rapid dissolution - Evaporite clasts

Differing solubilities between bittern, halite and CaSO_4 salts means that breccias can be derived from the collapse of intrasalt beds of less soluble salts into cavities formed by the rapid dissolution of more soluble salts. Brecciated beds of less soluble strata are typically composed of angular blocks of bedded gypsum/anhydrite, which fragment and settle as the supporting halite or bittern beds dissolve. These breccia beds are sometimes encased or underlain by halite showing evidence of flow or slippage into the subsurface space created by differential dissolution. Other times the breccias have characteristic smooth bases and more irregular tops. Sulphate collapse breccias typify parts of the subcropping margin of the Permian Castile Formation of the Delaware Basin in west Texas and New Mexico (Hovorka, 2000), and the Middle Miocene (Badenian) gypsum of southern Poland and the Ukraine (Babel, 1991) and the Permian Khuff Formation of Abu Dhabi and Saudi Arabia (pers. obs.).

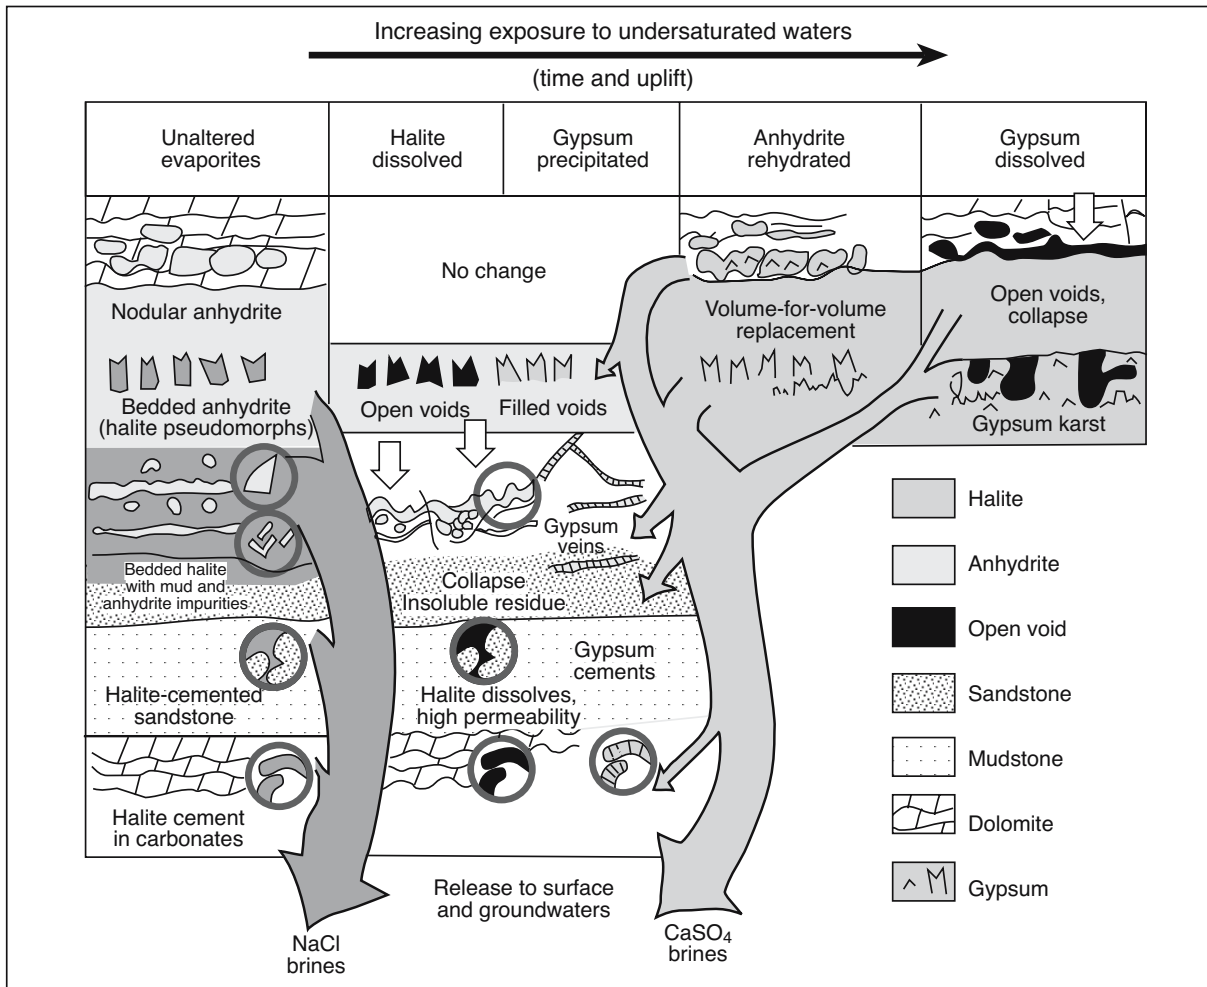

Figure 7.28. Salt-dissolution processes related to ongoing exposure to undersaturated waters. Unaltered evaporite is shown on the left, initial alteration in contact with somewhat undersaturated water in the middle, and intense alteration after prolonged contact with undersaturated water is shown on the right. Degree of exposure to undersaturated water is largely related to uplift and time (after Hovorka, 2000).

Babel (op. cit.) describes preferential intra-evaporite dissolution processes in gypsum of the Middle Miocene (Badenian), southern Poland. Gypsum-clast breccias formed by the early diagenetic dissolution of halite beds within a thick laminated gypsum section. Sometimes the effected interval is a single cm-thick bed and halite dissolution is interpreted to have occurred during a short freshening interval that only affected sediments just below the sediment-brine interface. Other times, the dissolution front was thicker, dissolving substantial thicknesses of halite to form crackle/rubble zones in bedded calcium sulphates that are tens of metres thick. Dissolution in some areas took place while parts of the gypsum beds were still water-saturated and soft, leading to complex soft-sediment deformation textures. Dissolution in other areas occurred after

the gypsum was indurated and created classic collapse breccia intervals, with smooth bases and irregular crackled upper surfaces. Residuals within the gypsum karst are defined by very fine-grained gypsum and clay horizons that typically also define the base of a collapse interval. The brecciated intervals pass up or laterally into faint or unlaminated gypsum alabaster (aka compact gypsum).

Because such partially dissolved evaporite breccias define the edges of many buried evaporite units, and are typically associated with syn-dissolutional flowage of some of the remaining salt layers, they are easily confused with primary debris flows in the evaporite bed. This is especially so when the dissolving salt beds are adjacent to pinnacle reefs, which have acted as

artesian aquifers during evaporite drawdown, as is the case with many of the inter-reef salt beds adjacent to the pinnacle reefs in the Silurian of the Michigan Basin (pers. obs.). Separating primary emplacement from a secondary dissolution origin can be very difficult in such brecciated and clast-rich beds and residues. Genesis is best resolved using oriented core, image logs and ties to detailed seismic mapping of salt collapse haloes above and around pinnacles.

**Diffuse dissolution-
Markers and residue beds**

Gypsum-anhydrite caprocks atop diapirs are widely recognised products of preferential salt dissolution (Figure 6.64). Less widely recognised stratiform equivalents to caprocks occur where undersaturated groundwaters flush the upper and lower contacts of stratiform halite. Such a set of processes affects halite beds in Maha Sarakham evaporites beneath the Khorat Plateau of NE Thailand (Sessler, 1990; Utha-aroon et al., 1995; Warren, 1997) and the San Andres salts of the Palo Duro Basin of west Texas (Hovorka 2000; Gustavson et al., 1994). As a thick salt mass dissolves the mineralogy of the various residues typically depends on how long the evaporites were in contact with invading undersaturated waters and on the chemical make up of the crossflowing waters (Figure 7.28). Invading waters can be meteoric or basinal.

Gentle dissolution at the top
Uplift, or simply the cessation of evaporite deposition allows undersaturated waters to come into contact with a buried salt bed. Undersaturated meteoric pore waters tend to pond atop the relatively impermeous buried salt and so the salt mass dissolves from the top down.

Maha Sarakham salt, Thailand

The Maha Sarakham sediments of NE Thailand are of upper-middle to late Cretaceous age and unconformably overlie continental deposits of the Khorat Group (Utha-aroon, 1992; El Tabakh et al., 1995). Maha Sarakham sediments were deposited as a thick sequence (up to 1000 m) of basinwide evaporite. Beds tend to be stratiform about the basin edge and halokinetic in the thicker, deeply buried beds of the present centre (Figure 7.29a). Three thick evaporite units (informally called the Lower, Middle and Upper Salt), or their residual

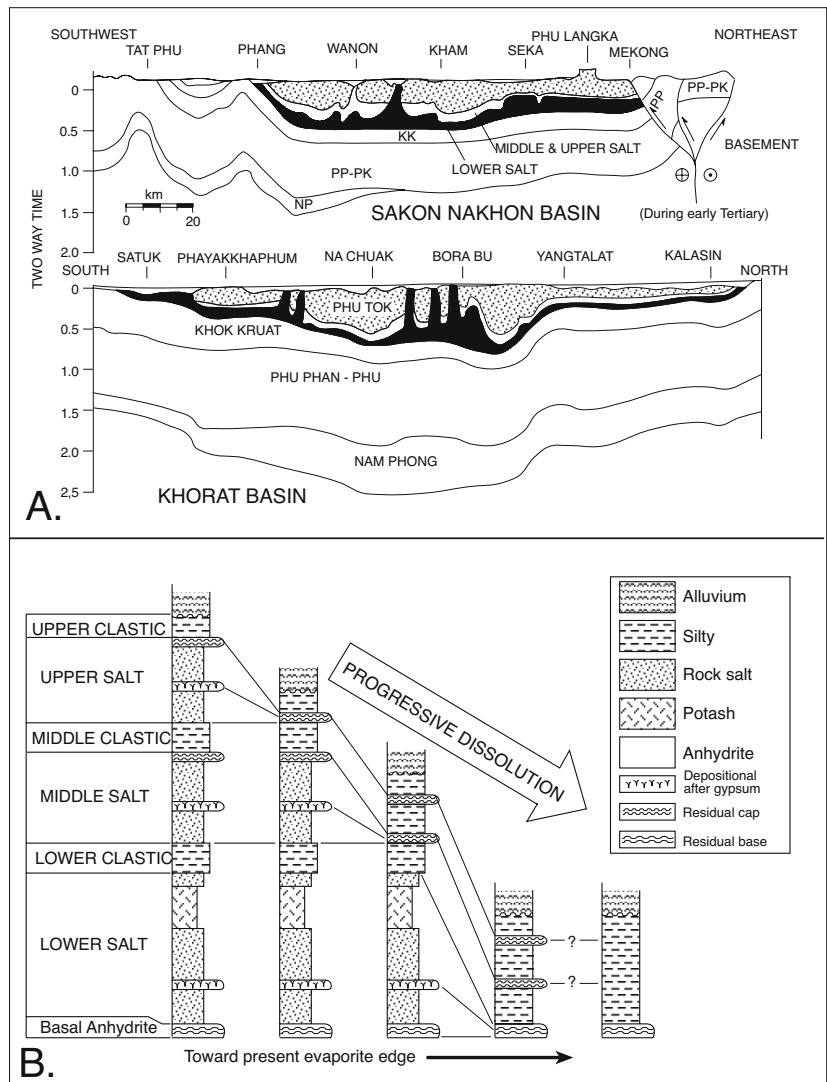

Figure 7.29. A) Regional subsurface structure of Maha Sarakham Formation showing preferential development of diapirs in lower salt toward the basin centre and dissolution toward structural edges of basin. B) Progressive dissolution of halite and accretion of residual anhydrite beds toward the present basin edge (after Utha-aroon et al., 1995). See Figure 11.13 for locality and detailed stratigraphy.

Figure 7.30. Formation of the laminar bed of nodular anhydrite residues at the upper contact of the lower halite member of the Cretaceous Maha Sarakham Formation, NE Thailand. A) General distribution of white-grey anhydrite nodules and layers dispersed in chevron halite in core. B) Contact between dissolving halite and upper white-grey unit of dispersed anhydrite nodules and blebs. This laminar accretionary anhydrite bed defines the upper dissolution contact of the lower halite member. Some 2 metres above this contact are the redbeds of the lower clastic member. The anhydrite unit preserves the shapes and sizes of the anhydrite blebs that were dispersed through the halite prior to its dissolution (as in Figure 7.30a). These nodules and blebs are left behind to form a layered and accreting sulphate unit as halite is dissolved at the halite anhydrite contact (Scale bar is 5 cm long).

equivalents, are present throughout the basin (Figure 7.29b). Evaporite minerals in the various beds include: sulphates, rock salt and potash minerals. Potash is found mostly in the upper part of the Lower Salt unit, but saltern halite is by far the most common salt and many beds preserve pristine chevron textures. The salterns occasionally freshened so that cm-scale gypsum nodules and beds with subaqueous textures (<1m thick) were deposited. All the gypsum converted to anhydrite during shallow burial. The three main halite units that make up the Maha Sarakham Formation are laterally continuous and are traceable basinwide. Nevertheless, ongoing interplays between salt dissolution and flowage has been active from the Cretaceous until today. Lithostratigraphic correlation from one place to another is not a straightforward exercise (Figure 7.29b).

Thick clastic redbeds of mudstone separate each of the three main salt beds and are informally called the Upper, Middle and Lower Clastics (Figure 7.29b). In core the clastic units are largely homogeneous clay beds, with locally laminated and stromatolitic horizons, infrequent nodular caliche horizons, occasional anhydrite nodules, root structures and mudcracks. Near their contact with adjacent salt beds there are beds of anhydrite residues overlain with clays hosting fractures and fissures filled with satinspar anhydrite and halite, indicating dissolution of a portion of the adjacent salt bed (Chapter 1).

Depositionally, the lower halite in the Maha Sarakham is composed of chevron halite with dispersed cm-scale anhydrite nodules and stringers after gypsum (Figure 7.30a). The earliest evidence for salt dissolution is cm-dm karst-pits filled by coarse recrystallised halite cement forming a syndepositional dissolution texture identical to that in the modern Qaidam Basin (Figure 11.3). Salt dissolution next occurred in the shallow subsurface along bed boundaries where clastic units were in contact with bedded salts. Waters undersaturated with respect to halite, moved through adjacent redbed aquifers, initially as the clastics underwent deep weathering then as the buried clastics acted as conduits for compactional and basinal waters. This style of clastic-groundwater-driven dissolution left behind accreting residue textures at each major salt/clastic contact. Where the dissolving salt bed was composed mostly of clean halite all that now remains is a thin laminar residue of accreted insoluble clay residues. Due to the highly saline and anoxic nature of the brine leachate, the iron in these zones is reduced and where the salt bed is still actively dissolving the colour of the adjacent clastic has been altered from red to green.

In other regions of the basin, where the dissolving halite contained numerous anhydrite nodules and stringers, the resulting dissolution residue is composed of stacked anhydrites that can be partially rehydrated to gypsum. These residual beds can occur along both the upper and lower dissolving bed contacts of all three salt units. At the contacts of the Upper and Middle Salt members the CaSO_4 residuals tend to be dm-m thick on

the upper bed contact, but somewhat thinner on the underside (cm-dm). On the underside of the Lower Salt member, the CaSO_4 residual is much thicker ($\approx 1\text{-}2\text{ m}$) and probably reflects a much greater focused throughflushing from the underlying and dewatering Khorat Group sediments (see basal anhydrite discussion).

Each CaSO_4 residual bed is made up of undulose thinly-layered to laminated light grey to off-white anhydrite/gypsum nodules and micronodules. Individual layers may be as thick as 2 cm (Figure 7.30b). Lamina/layer orientation ranges from horizontal to vertical, with clays and organic matter defining the laminae and the nodule edges. Where a halite residual undergoes more localised dissolution the anhydrite beds are broken and brecciated with interclast matrix infiltrating from the adjacent clastic member. Brecciated textures are most common in residues of the Upper Salt member as this unit is more effected by modern nearsurface meteoric leaching. If the Upper Salt member is still present in the stratigraphy it protects the Middle Salt member from surface driven dissolution.

Within the Middle Salt member is a basinwide dm-m-thick anhydrite marker bed. Complete dissolution of the halite encasing the marker bed of the Middle Salt member, and associated gentle foundering of the overlying middle clastic member, stacks the marker bed along with other anhydrite nodules and stringers in their original stratigraphic order (Utha-aroon et al., 1995). This gentle style of oriented solution stacking of the intrasalt sulphate beds even preserves the subaqueous gypsum pseudomorphs of the anhydrite marker bed in their original growth position. Recognition of preferential dissolution occurring in a basin's stratigraphy allows a correlation across areas where halite beds have disappeared and only the anhydrite residuals remain (Figure 7.29b). The final stage of salt dissolution occurs when the anhydrite residuals completely dissolve and brecciate to leave the three clastic members stacked one atop the other.

Where the Upper and Middle Salt members of subcropping Maha Sarakham Fm have completely dissolved, the present-day landsurface is defined by topographic depressions adjacent to a blind valley karst system atop a suprasalt high. Fluvial systems

flow into this depression and feed subsurface waters to the dissolution front, which in turn focuses and stacks Quaternary fluvial channel sands. Outcropping and subcropping examples of this style of sequential halite dissolution define caprock outliers of the Maha Sarakham Formation in the Nam Theun syncline in central Lao (Figure 7.7c). As on the much larger Khorat Plateau, Cretaceous halite along the syncline axis is retreating from the meteoric-flushed edges and top of the salt bed leaving behind distorted and slumped remnants now patchily exposed in erosional banks along the river (pers. obs).

Some geomorphologists working in the salt solution terrains of NE Thailand have not recognised the effects of salt solution on the stacking pattern of fluvial systems. Instead, they have interpreted the thickened sections of Quaternary fluvial sediments as indicating a deepening of the river thalweg and have related it to Quaternary uplift and not dissolution downcutting. Effects of preferential dissolution along the edges of a bedded halite unit further emphasize the pitfalls of using simplistic notions of lateral correlation between thin marginward anhydrite and thick basin-centre halite (Figure 5.30).

Palo Duro Basin, west Texas

Hovorka (2000) has described the textures and effects of salt solution on the widespread Permian salt beds of west Texas (Figure 7.31). She focused on the solution processes occurring beneath the High Plains of the Texas Panhandle, an area typified by landscape stability and the slow, longterm deposition of the overburden. There the upper surface of the salt approximately

Figure 7.31. Crossflow of undersaturated groundwater at the top of an impure halite bed creates an insoluble residue of anhydrite and mud under conditions of regional, low-angle salt dissolution and passive letdown of overlying strata, which fracture and are cemented by satin spar gypsum (after Hovorka, 2000).

parallels the hydrologic flow lines and so lies at a low angle to the land surface. In the Palo Duro Basin the top-of-salt lies at a depth of 250 - 300m, approximately paralleling the low relief Southern High Plains. This salt dissolution surface regionally crosscuts Permian stratigraphy, so that in the northwest, the Seven Rivers Formation is the uppermost salt-bearing unit and overlying salts have been dissolved; while down hydrologic gradient to the southeast, the younger Salado halite is partly preserved.

Hovorka's examination of the residues left after regional low-angle salt dissolution in the Palo Duro Basin showed that salt dissolved and residues formed by incremental dissolution of the uppermost salt unit over a wide area. It was accompanied by passive stratiform subsidence of overlying strata (Figure 7.31). Horizontal fractures in overlying strata indicate vertical extension, while syntaxial satin spar gypsum fillings show that the fracture opening occurred incrementally as underlying salt was dissolved (Gustavson and others, 1994). Typically, the creation of overburden voids atop most salt beds in west Texas does not lead to catastrophic collapse. Rather, stratiform beds of insoluble residues are the best evidence that impure salt beds have been dissolved.

Diagnostic features of the regional low-angle crosscutting dissolution surface atop salt units in the Palo Duro Basin are: (1) Mixtures of insoluble components from the previously underlying halite with a wavy lamination in anhydritic intervals. This reflects the accretion of newly released insoluble components against existing insoluble residues. (2) Residual beds in positions that are laterally equivalent to preserved salt, (3) Anhydrite residual beds that stack one atop the other with little or no internal deformation, providing there were depositional sulphate beds in the original salt. (4) Syntaxial, horizontal, gypsum-filled fractures in overlying units. These are the same sets of features that define regional dissolution atop Cretaceous halite in the Maha Sarakham of Thailand (Utha-Aroon et al., 1995) and probably characterise all shallow low angle salt beds undergoing exhumation.

Dissolution at the bottom
Undersaturated escaping basinal waters, or deeply circulating meteoric waters, can drive dissolution on the

underside of a thick salt bed. In this situation the salt dissolves from the bottom up, and the residual wavy-layered anhydrite bed has a finite thickness controlled by its inherent crossflushing hydrology. To date this mode of preferential salt solution has only been documented in Maha Sarakham, probably because it is one of the few, if not the only, saline giant where both the upper side and the underside of the thick salt unit has been extensively cored and studied.

Basal anhydrite, Thailand

Preferential dissolution of the underside of the Maha Sarakham Formation of NE Thailand is occurring where it is bathed in a crossflow of compactional and thermobaric waters (Warren 1997; El Tabakh et al., 1998a). The resulting basal anhydrite passes downward, via a thin cm-thick organic-rich residue layer, into underlying nonevaporite sediment made up of calcite-cemented fluvial sands and shales of the Khok Kruat Group. The basal anhydrite bed is characterised by a near constant basinwide thickness and consistent stratigraphic textures across the underside of large portions of the salt (Figure 7.32). In many evaporite basins of the world, similar constant thickness beds are described as basal anhydrites, but are assigned a primary depositional origin.

To explain the subsurface processes that effect the underside of thick evaporite beds, the salts of the Khorat Plateau of Thailand are ideal. The region is unique in that the various salt layers of the Maha Sarakham Formation have been extensively and continuously cored from top to bottom and a simple gamma log suite run in the borehole. This was done in the 1970s and 1980s in a World Bank funded exploration project for potash

Figure 7.32. Crossplot of thickness of the basal anhydrite unit versus thickness of the overlying "Lower Salt" in the Maha Sarakham Formation, Thailand.

salts. The cores were double-sealed in plastic wrap and archived at a DMR core store in Udon Thani, where they are still available for study. Everywhere it was cored the underside of the thick Lower Salt of the Maha Sarakham Formation is a thin, distinctive basal anhydrite bed composed of nodular anhydrite, with a thickness that is surprisingly consistent (Figure 7.32). Work to date has clearly shown the basal anhydrite is a diagenetic unit created by ongoing salt dissolution. It is a pressure-welded nodular anhydrite unit that accreted in the subsurface as a buildup of insoluble residues on the underside of a basinwide dissolving halite sequence (Figure 7.33a). The process was driven by the escape of undersaturated compactional and thermobaric waters. It is, in effect, an upside-down caprock (Figure 7.33b).

Unlike depositional anhydrites in saline giants, which typically thicken into the lowstand platform wedge, the basal anhydrite of the Maha Sarakham has a near constant thickness across the entire basin that is independent of the thickness of the overlying Lower Salt (Figure 7.34). There are a few wells where the anhydrite is thicker than 1-2 metres, but there the anhydrite shows evidence of flow thickening and the wells are typically located at or near the dissolution edge of the Lower Salt where larger karst cavities can form and suprasalt and subsalt sulphate residues can stack. The near constant thickness of the basal anhydrite across the basin reflects the intrinsic self-limiting permeability of a nodular anhydrite bed accreting beneath a salt overburden. Wherever upwelling basinal waters contact the underside of the Lower Salt unit it dissolves, leaving behind a nodular anhydrite residue. The nodular residue continues to accrete along its top by gathering anhydrite nodules via preferential solution of the salt host. These nodules were originally suspended within the now dissolving bedded halite. At the same time as new nodules are accreting along the upper side of the basal anhydrite, the anhydrite may be dissolving along its underside.

Figure 7.33. Mode of formation of a diagenetic basal anhydrite. A) Vertical profile through a dissolution-generated basal anhydrite. B) Schematic cross section with box showing relative position of vertical profile (modified from Warren, 1997).

The overall dissolution process is driven by escaping compactional waters flushing the underbelly of the salt (Figure 7.33b). If the basal anhydrite accretes to where it is more than a metre or two thick it starts to act as an aquitard for waters seeping through its internodular porosity. This slows water access to the halite contact. Thickness can increase until it reaches a point where undersaturated compactional waters can no longer flow through internodule permeability, to reach the halite-anhydrite dissolution front. Once undersaturated waters no longer access the halite dissolution front, anhydrite accretion slows and even shuts down along the upper side of the anhydrite unit. Even so, compacting undersaturated waters continue to flow along the underside of the basal anhydrite, where anhydrite dissolution occurs. Once sufficient anhydrite dissolves from its underside, undersaturated waters can again reach the halite and dissolve it anew. Basinwide near-constant thickness of the basal anhydrite reflects a buffering interaction between the rate of anhydrite nodule accretion or docking on its upper surface and the rate of anhydrite loss on its lower surface. In effect a basal anhydrite has a “half-life.” The actual thick-

ness is determined by the inherent transmissivity of the material between the nodules.

Coarse and saddle burial-stage calcian dolomite precipitates from brines flushing internodular zones in the basal anhydrite. Crystals continue to grow and re-equilibrate into higher temperature forms in response to ongoing burial. This is shown by the evolving carbon and oxygen isotope signatures, as well as $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, which all define a burial trend from early limpid dolomite through coarsely crystalline dolomite through to saddle dolomite with precipitation signatures indicating increasingly higher temperature basinal fluids (Figure 7.34a, b; El Tabakh et al., 2003; Warren, 2000a).

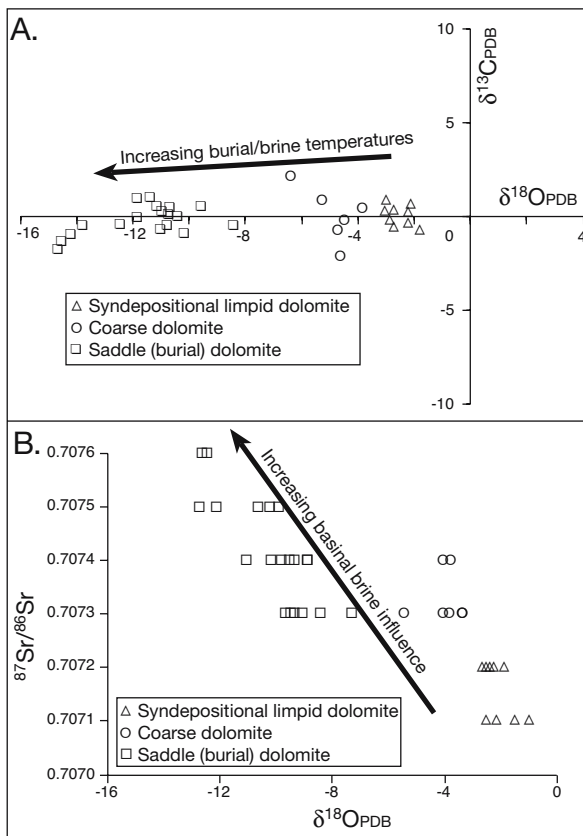

Figure 7.34. Isotopic signatures in the three types of dolomite occurring in the basal anhydrite of the Maha Sarakham Fm. Thailand. A) Cross-plots of dolomite $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotopic values showing influence of increasing temperature related to ongoing burial. B) Crossplot of $\delta^{18}\text{O}$ versus $^{87}\text{Sr}/^{86}\text{Sr}$ showing influence of ongoing basin brine evolution from limpid dolomite through coarse and saddle dolomite precipitates (after El Tabakh et al., 2003).

Table 7.5. Various basins with possible dissolution-derived basal anhydrites (in part after El Tabakh et al., 2003).

The laminar underside of the basal anhydrite is made up of what remains once the anhydrite is dissolved, namely, an undulose cm-thick microlaminar organic-rich insoluble residue layer. It contains micronodules and fissure fills of metal sulphides (mostly pyrite and bornite) created by metal fixing and driven by thermochemical sulphate reduction (Warren 2000b).

Overall this “upside-down” cap rock is very similar to a pressure solution mega-seam and its mode of formation is not all that dissimilar except that the fluid flow is more one sided. This model, explaining laterally extensive, constant thickness basal anhydrites on the undersides of thick halites as a form of dissolution residue, has implications for other evaporite basins that possess basal anhydrite units with near constant thickness. Table 7.5 lists some other possible regions where dissolution-generated basal anhydrites may characterise the bottoms of thick dissolving halite units.

Caves in salt karst

At first sight, medium to large scale evaporite karst surface landforms, such as dolines, polje-like depressions, subsidence bowls and collapse dolines, appear near-identical to those found in and on carbonate karst. Likewise, all the smaller-scale intracavern features, both dissolutional (pipes and cavities) and constructive (speleothems), can be preserved karst in and above an evaporite host, even when the formative hydrology becomes inactive and the system is buried (palaeokarst). But, as we shall see, the much higher rates of dissolution of halite and gypsum compared to limestone or dolomite means there are differences in rates of formation and cave geometry compared to carbonate caves in nonevaporitic hosts. One cannot simply take models of caves developed by studies of carbonate karst and use them to unreservedly interpret evaporite caves. Differences reflect the inherently higher solubility and flowability

of the host salts at earth surface conditions and means most evaporite-hosted caves have their own peculiarities.

The high solubility of evaporite beds atop deeply circulating pressurised and jointed aquifers means deep phreatic chimneying is a common cave forming mechanism in and atop buried salt beds. When a stoping chimney cave breaches the water table, it can lead to the rapid creation of numerous steep-sided water-filled collapse dolines in suprasalt regions with strong roof spans and high volumes of sediment being swallowed if loose sediment covers the roof span.

Most of the action in uplifting salt beds and masses begins well below the watertable. It takes place hundreds of metres below the surface at bathyphreatic depths where anhydrite is reconvertng to gypsum and where caprocks and other dissolution residues are forming. Early dissolution is greatest at contacts between the salt bed and joints or fractures in adjacent aquifers. Thus patterns of jointing or fracturing control the extent and style of caves in a salt host and typically creates high-density maze caves. With halite, the only type of NaCl mass that makes it to the surface, and so becomes a host to accessible vadose caverns, is in active or recently active diapirs. Prior to its dissolution this cave-hosting diapiric halite was impervious, flowing and reannealing. Hence, most of the karst action accessible for study in halite caves is vadose and tied to perched water tables. If phreatic caves ever do form in diapiric halite, these early cavities are quickly closed by the pressurized salt flow needed to bring salt to surface and make it accessible to speleologists. Some of the metre-scale blebs of finely-layered gravitationally-aligned laminar halite seen in deep salt mines within diapirs and floating in a matrix of flow foliated coarse-crystalline halite is probably the result of mesogenetic salt precipitating in gas-filled open cavities within the diapir mass. They are not relict blocks with primary depositional texture of the mother salt. Nitrogen-filled cavities are a hazard occasionally encountered during potash mining in the diapirs of NE Germany. Their presence and their ability to blow out mine walls clearly show that open gas pockets are not uncommon in flowing salt.

Cave-forming processes are either vadose or phreatic and many caves show textural evidence indicating transit from one realm to the other. At any one time the transition from vadose to phreatic landforms is tied to depth to water table. This is seen in the cap karst to gypsiferous diapirs in Spain (Calaforra and Pulido-Bosch, 1999). The crests of the salt structures are dominated by collapse dolines (vadose), this passes radially out into the belt of solution dolines occupied by seasonal saline

lagoons and further out into rim of saline springs that form wherever the watertable intersects the landsurface (phreatic). Some caves pass from phreatic to vadose a number of times in response to watertable fluctuations tied to varying climate and tectonics.

Vadose processes characterise the uppermost part of a karst aquifer and have air in pores above any water surface or perched water table. Drainage is free-flowing under gravity; cave passages drain downslope and show strong gravitational orientations (numerous sub-vertical features). Because they form above the water table, vadose cave walls are subject to surface seepage, evaporation and drying. Speleothems decorating the cave walls indicate varying combinations of gravity and airflow and include; stalactites, stalagmites, cave popcorn, helictes and flowstones.

Caves can form in a salt bed on its way down (syndepositional to early burial phreatic), on its way up (telogenesis begins at bathyphreatic depths) and at the bottom of the bed's burial history (mesogenetic karst).

Gypsum caves

Active caves beneath gypsum karst landforms first formed as phreatic maze caves and are characterised by dense passage networks with numerous contemporaneously closed loops. Vadose sections of the same system can be quite large due to the high solubility and relative homogeneity of the host, especially if formed in a thick capstone. Heimkehle in the Zechstein anhydrites in the Harz Mountains of Germany has a overall passage length of more than 2 km, with large rooms up to 22 metres high and 65 metres wide. It was large enough to be used in World War II to house a factory manufacturing parts for JU88 aeroplanes. Gypsum caves are well documented in Miocene gypsum hosts in west Ukraine (Table 7.6; Klimchouk, 2000; Klimchouk and Andrejchuk, 2003; Andrejchuk and Klimchouk, 2004) and much of our current understanding of process comes from this region.

Gypsum cave walls in the vadose realm are relatively undecorated compared to carbonate caves. But speleothems can form and are well documented as alabastrine flowstones and selenite rinds on cave walls in northwest Texas (McGregor et al., 1963), in Alabaster Cave in the Blaine Gypsum in western Oklahoma (Bretz, 1952; Myers, 1960a), and in quarries intersecting the gypsum karst system in the Kirschberg Evaporite member near Fredericksburg, Texas (Warren et al., 1990).

Table 7. 6. Representative morphometry of gypsum maze caves that formed as confined aquifer phreatic systems, compared to Mammoth Cave (unconfined aquifer system) and Carlsbad and Lechuguilla caves (now both unconfined aquifer systems but first formed as sulphuric acid caves with gypsum precipitates; after Klimchouk, 2003; Palmer and Palmer, 2000; and listed references).

Phreatic gypsum caves

Phreatic caves in bedded evaporites atop artesian aquifers typically grow as upward stoping and branching blind flow loops caverns (phreatic cupolas) and chimneys, which begin to grow deep below the water table (bathypheatic karst). For example, deep artesian systems drive cupola karst and blind chimney stopes in the Black Hills of Dakota (Figure 7.13) and the Elk Point Basin of Canada (Figure 7.5). Even deeper in a basin, where bathypheatic caves are bathed by centripetal mesogenetic crossflows, water flow is even slower and phreatic karst is driven by the escape of H₂S and CO₂ rich basinal waters, not meteoric head. Fluid flow at these greater depths is driven by pore water gradients that reflect potentiometric variations in temperature, pressure and salinity of basinal waters.

Passages in mesogenetic and telogenetic caves tend to first develop about fractures and joints in adjacent aquifers and then expand into maze cave networks. Once growing in the main salt mass some phreatic maze passages can show internal upward-directed switchback gradients independent of jointing in adjacent aquifers and tied to internal inhomogeneities in the host bed such as intrasalt beds and changes in mineral proportions.

A phreatic tube is the most common passage shape in smooth-walled blind dissolution pockets and cupolas in bathypheatic gypsum caves. Tube or channelway shapes range in cross section from near-circular (isotopic dissolution of soluble host) to elliptical tubes to canyon-shaped keyholes (Figure 7.35; Klimchouk, 1992, 1996). Ornamentation is minimal where undersaturated crossflow drives the rapid dissolutional breakdown of the cave wall and the resulting passages are smooth, with local scalloped dissolution irregularities. Dense intersecting maze cave networks first form in the early stages of exhumation at the contact between tight but soluble gypsum/anhydrite and a less soluble carbonate or siliciclastic aquifer. This less soluble bed is the supply conduit for groundwaters that dissolve the edges of the initially impervious anhydrite/gypsum bed. The greatest rate of water supply into the dissolving gypsum contact is along joints and fractures in the adjacent aquifer bed (especially with limestone aquifers). Accordingly, the meshwork of caves penetrates the gypsum bed and tends to follow joint and fracture patterns of the adjacent aquifer.

The more stagnant phreatic portions of telogenetic CaSO₄ cave systems can be saturated and so precipitate isopachous crusts and crystal rinds. Gypsum is the commonplace isopachous precipitate in voids in this setting, while anhydrite tends to

dominate in cavities in the deeper mesogenetic realm (Garcia-Guinea et al., 2002). By the time phreatic maze caves are exhumed into a vadose setting, where they are accessible for study, much of the earlier phreatic ornamentation has already been dissolved by the increasing undersaturated throughflow and the cavern interconnection associated with uplift into the more active phreatic realm, which always precedes entry into the vadose realm (Warren et al., 1990).

Some of the longest and most complex phreatic maze cave systems in the world are found in Miocene gypsum in west Ukraine. Optimisticheskaja Cave, with more than 188 km of surveyed passages, is the world's longest gypsum cave and the second or third longest cave of any type (Table 7.6; Klimchouk, 2000, 2003). The world's longest cave, at 550 km, is the carbonate-hosted Mammoth Cave of Kentucky. The West Ukraine region contains the five longest known gypsum caves in the world, accounting for well over half of the total known length of gypsum caves on Earth. By area and volume the world's largest gypsum caves are: Ozernaja (330,000 m² and 665,000 m³; with 122 km of documented passages it is also the world's 10th longest), Zoloushka (305,000 m² and 712,000 m³), followed by Optimisticheskaja Cave (260,000 m² and 520,000 m³). They are all complex joint-controlled maze caves, formed under confined aquifer conditions that existed from the Pliocene to the Early Pleistocene (karstification on the way up - telogenesis or gypsum exhumation). Their growth patterns indicate upward-transverse phreatic groundwater circulation, with ultimate cavern fusion across the gypsum bed. All these west Ukrainian caves were fed by artesian crossflow in sub-gypsum and supra-gypsum aquifers and sourced in the Carpathian Mountains (Figure 7.35a).

High rates of dissolution in phreatic gypsum caves, relative to rates of water crossflow, are

indicated by the bevelled, faceted and “keyhole” cross sections of the Ukrainian caves (Figure 7.35a; Klimchouk, 1996; Pfeiffer and Hahn, 1976). Keyholes indicate density stratification and convectonal circulation in cave-forming waters, with shapes sometimes complicated by lithological discontinuities in the gypsum bed (Figure 7.35b; Kempe, 1972). Convection in caves is most pronounced where sluggish artesian flow and low flow velocities dominate.

This was the case in the Pliocene to early Pleistocene history of the maze caves of the western Ukraine (Figure 7.35c; Klimchouk and Andrejchuk, 2003). At that time the deeply buried gypsum dissolved via upward growing but blind, phreatic cavities, with a reflux of somewhat denser “spent” waters sinking toward the base of the cave. Spent water was replaced by less dense inflow waters supplied from the lower

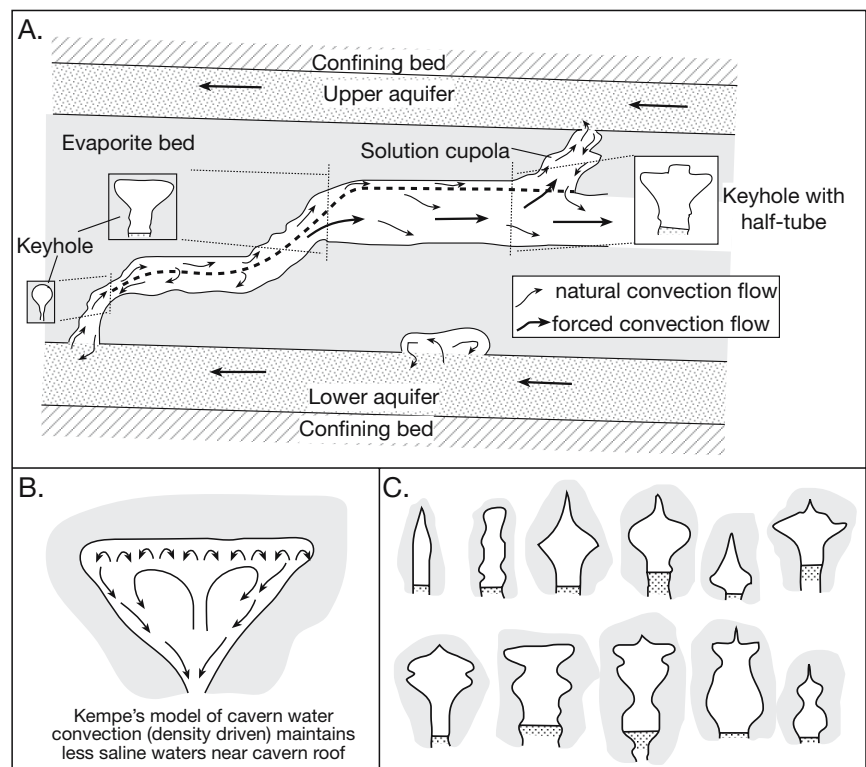

Figure 7.35. Maze caves. A) Formation of upward expanding dissolution cupolas by pressurized buoyant currents, such a system drives the formation of gypsum caves in the western Ukraine. The diagram shows the schematic relationship between lines of natural and forced convection flow on the mature stage of artesian speleogenesis, when conduit connection has already been established through the gypsum, but forced flow is slow due to the major constraint of the upper confining bed. B) Cross section of Kempe's (1972) model for cavern development by dissolution due to natural density convection, C) examples of typical cross-sections from the gypsum caves of the western Ukraine showing varieties of notching or faceting effects from differing rates of lateral expansion (dissolution). (after Klimchouk, 1992, 1996; Kempe, 1972).

aquifer. This sets up a natural density-stratified convection, which maintained fresher (less dense) waters near the phreatic cave roof. Upward growing blind caves tend to expand more at their tops driving the transition from subcircular to keyhole caverns along the cave conduit. After dissolving gypsum and increasing in density, a portion of the “spent” cave water sank all the way back into the underlying aquifer where it once again joined the regional throughflow in the lower aquifer. Once a stopping cave breached the top aquifer water flow direction in the cave was controlled by temperature, pressure and density contrasts between aquifers on either side of the gypsum bed. It seems that post-breach most of the cave water continued to rise through the cave system into the overlying aquifer (Figure 7.35a). Similar keyhole and cupola morphologies are developed in low flow rate bathyphreatic sulphuric acid caves in carbonate hosts (e.g., early stages in the formation of the Carlsbad and Lechuguilla caverns; Figure 7.45).

But the formation of keyhole passages is not an exclusively phreatic phenomenon in density-stratified gypsum caves. Keyholes in the vadose portions of many telogenetic carbonate caves indicate the transition of the cave passage from phreatic, with circular cross sections, to vadose with deepening drainage slots at the base of the passages (e.g. Calaforra and Pulido-Bosch, 2003).

Vadose gypsum caves

A lowering of the water table, either by uplift or climatic change, converts a former phreatic cave into a vadose cave. This is the recent history of the accessible portions of the gypsum maze caves in the western Ukraine and Saudi Arabia where the passage into the middle-upper Pleistocene marks the transition from phreatic to vadose in most of the accessible caves. It is also characteristic of the very recent history of some naturally phreatic caves where watertables were artificially lowered to allow quarrying of gypsum (Klimchouk, 2000). In both cases, the current vadose diagenesis is driven by telogenetic processes. The hydrological regime is passing from phreatic to vadose (the bed is on its way up = exhumation).

Climate change or water table lowering at the other end of the burial cycle can create vadose conditions in gypsum beds in the early stages of burial. That is, the gypsum bed hosting the vadose cave is on its way down, although it may pass through the water table a number of times before its final burial. This is the case today in the captured recharge playas in central Australia (Figure 2.45) and about the edges of some of the halite-filled salars in the Andes (Figure 3.41) and many Ca-

nadian salt lakes (Last, 1993a) Similar change in climate has karstified the gypsiferous sediments of many modern Sinic playas. Yauro and Cooper (1997) documented Pleistocene lake basins in north-west China, such as the Chaidamu Basin, where exposed gypsum beds have karst overprints that include: corroded flutes, fissures, small caves and associated collapse breccias and roof falls. Water table lowering is a hydrological overprint that is preserved as ornamented surfaces in gypsum caves, disconformities and cave fills in many ancient lacustrine gypsum units.

Miocene karst in the Madrid Basin, Spain

The Miocene sedimentary record of the Madrid Basin displays several examples of palaeokarstic surfaces sculpted within the gypsum at the same time that the overlying strata were deposited (Rodriguez-Aranda et al., 2002). The karst indicates a time of freshening in the same lacustrine setting that was depositing the gypsum (early burial karst). One of the better documented of these palaeokarstic surfaces separates the Lower and Intermediate units at the boundary between what are two main lithostratigraphic units in the basin (Figure 7.36). There ^{7.3}epikarst formed in Aragonian lacustrine gypsum as it was covered by terrigenous deposits of the overlying Intermediate unit. Karst features include infiltrations of the overlying Aragonian marls into the gypsum of Lower unit for up to 5.5 m below the epikarst surface. The presence of a shallow water table at the time of karstification, along with low hydraulic gradients in the evaporite basin, were the main factors controlling karst style.

Karstification was extensive and rapid, it took place in a relatively short time frame of several thousands of years (Figure 7.36; Rodriguez-Aranda et al., 2002). Stage 1 of the karstification was the accumulation and bioturbation of a bed of lenticular gypsum in a moderately saline lake (Figure 1.23). During periods when the lake dried out, plants colonised the poorly indurated and exposed gypsum ground (Stage 2). These halophytic plants contributed to the local transformation of primary gypsum to anhydrite through a dissolution–reprecipitation process, similar to that reported from vadose zones in supratidal sabkhas,

^{7.3}*Epikarst*: pertains to the upper/outer layer of karstified rock in the unsaturated zone, immediately below the soil layer.

Exokarst: pertains to features found on a surface karst landscape, ranging in size from karren to dolines and subsidence bowls.

Endokarst: pertains to all features beneath the surface and hosted by a vertically layered karst system. It includes the full spectrum of underground voids and the dissolutional features present on the rock surfaces surrounding them.

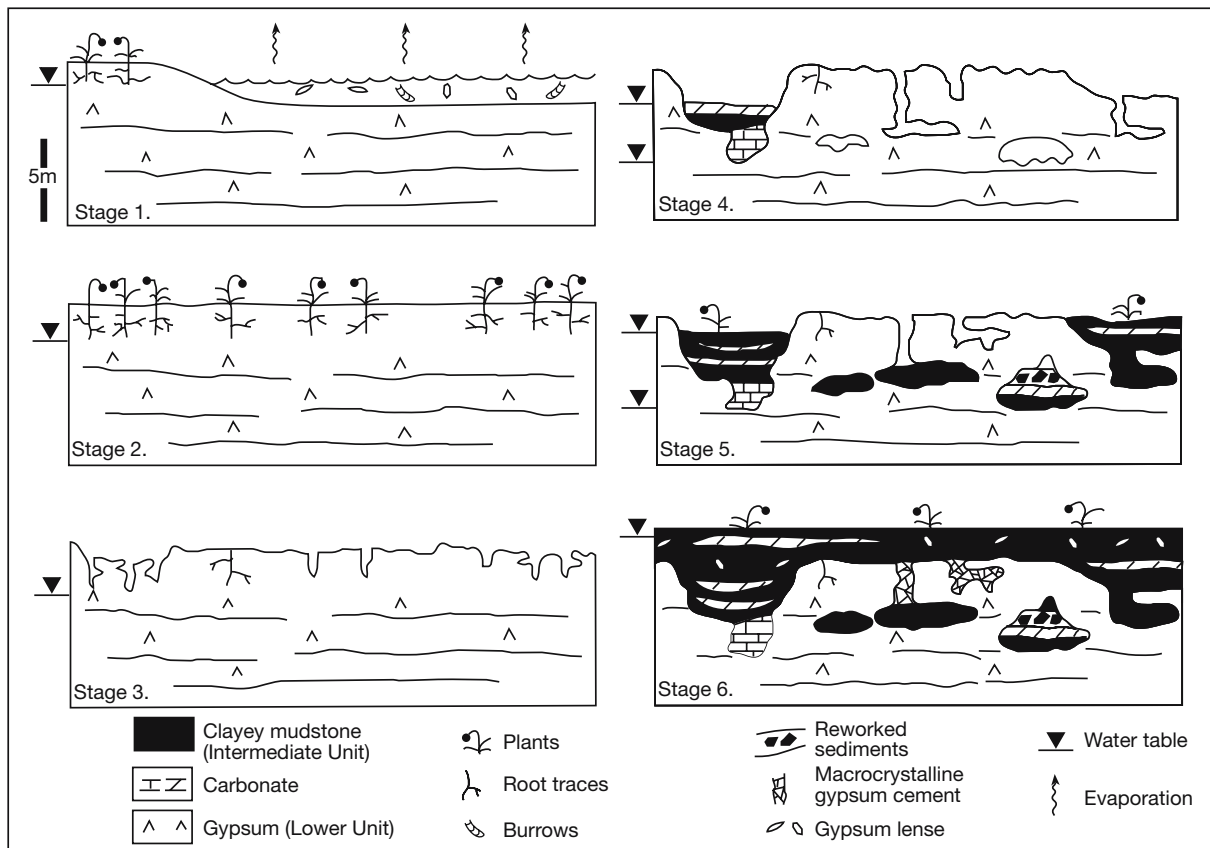

Figure 7.36. Development of epikarstic surfaces and associated endokarst in the Miocene Gypsum of the Madrid Basin. See text for detail of the evolutionary stages (after Rodriguez-Aranda et al., 2002).

salinas and losing playas. Stage 3 corresponds to the death and decay of plants, with the root holes behaving as preferential conduits for entry of meteoric water. Anhydrite, which had formed in the soil via respiring plant roots, was unstable and transformed to secondary gypsum. Continued vadose flushing of the initial conduits resulted in the formation of cylindrical and funnel-shaped pits that mimic, but do not strictly represent, root casts or rhizoconcretions (Stage 4). Both the vertical vadose conduits and gypsum caves only penetrated a few metres below the palaeokarst surface, suggesting the ongoing presence of a shallow, still saline water table. The position of the water table played a critical role throughout (stages 1-6) and limited the depth reached by both exokarst and endokarst features (Figure 7.36). In addition, the formation of roughly planar, horizontal cavities was probably related to the top of the water table, which also represented the maximum depth for root penetration (stage 4).

Formation of horizontal caves was constrained by stratification planes in the gypsum host rock. Conduits and caves were

coeval with larger gypsum dolines, and all were partially to completely filled by varying combinations of clayey mudstone, carbonate and detrital gypsum (stage 5). Clays in the karst fill are mostly coarsely laminated, green mudstone beds, possibly reworked from mudflat and alluvial fan deposits that are laterally associated with the lacustrine gypsum (Rodriguez-Aranda, 1995). Clay infiltration was probably tied to periodic floods of the karstified surface, with the caves and doline floors making depressions where waters ponded with a relatively high concentration of suspended fine-grained siliciclastic material and organic detritus. These mudstone fills in the gypsum caves are similar to the mud-filled cavities observed by Last (1993a) in modern saline lakes of the northern Great Plains of western Canada, and are consistent with the episodic clastic input patterns recognized by Calaforra and Pulido-Bosch (1999) in similar gypsum karst in the Sorbas Basin, SE Spain.

Carbonate is present in the sedimentary fill of both dolines and gypsum caves. Carbonate in the dolines consists of massive to peloidal dolomicrite or nodules developed in laminated

claystone, whereas carbonate in caves typically consists of calcite rafts and patches of reworked calcitised gypsum. The doline carbonates were probably deposited in shallow water that was episodically ponded in the karstic depressions. The carbonate nodules are probably pedogenic, arguing for punctuated deposition with times of subaerial exposure during the sedimentary fill of the dolines. Calcite rafts in clayey cave deposits suggest inputs of clastic sediment alternated with periods of standing water when calcite rafts precipitated at the air–water interface of pools in the caves (Taylor and Chafetz, 2004).

Alluvial fine-grained sediments of the Intermediate unit then accumulated and filled any remaining irregularities in the epikarst surface, which was pocked by numerous doline depressions and unfilled cavities (pits and conduits) (Stage 6). Once dolines were entirely filled by fine-grained sediment and the adjacent epikarst surface was also covered, a sedimentary discontinuity was preserved between the top of the bedded gypsum and the overlying clay. Clay had by then accumulated in the various pits and conduits that were not filled in earlier stages of karstification.

Infill of the remaining cavities includes macrocrystalline gypsum cement meshworks or mosaics that are especially obvious in cavities with little or no earlier detrital fill (Stage 6). They indicate saline phreatic conditions where a rise in the water table accompanied the deposition of the terrigenous sediments that now sealed the palaeokarstic surface. The same saline pore waters, perhaps derived by ongoing subsurface gypsum dissolution, also drove the precipitation of displacive gypsum crystals in some nearsurface clays.

Modern karst in Cretaceous gypsum, Texas

At the other end of the vadose gypsum karst spectrum are caves formed by uplift of buried anhydrite beds and the transition from phreatic maze caves to vadose caves with gypsum and calcite speleothems. Ornamented vadose gypsum caves, a late stage of this conversion, are today exposed within the workings of the Fredericksburg Gypsum Quarry in a 10-metre (30 feet) thick gypsum bed. The gypsum is the nearsurface remnant of the Cretaceous Kirschberg Evaporite Member, which was exposed during the late Tertiary exhumation of the Edwards Plateau. Early stages of the uplift were typified by the rehydration of anhydrite back to gypsum and the formation of fibrous vein fills (Figure 1.38). The complete telogenetic dissolution of the evaporite level is indicated by a widespread evaporite solution breccia.

Relatively impervious nodular gypsum hosts most of the caves, with nodules showing varying overprint by coarser crystalline gypsum daisy textures. Much of the cave fill and ornamentation is made up of a more permeable alabastrine gypsum precipitate (Figure 7.37a). Where a gypsum bed is completely dissolved by cave expansion all that remains of the former gypsum karst is a jumble of speleothem clasts beneath and within a dolomitic crackle breccia. Most of the larger blocks in the breccia were derived from the overlying Edwards Formation and are now encased in a residuum or matrix of silt- to sand-sized dolomite rhombs (“chalky” dolomite). The rhombs were originally floating in a matrix of gypsum/anhydrite and their equivalents can still be found as dispersed rhombs and layers in nearby, as yet undissolved, gypsum beds.

Friable alabastrine gypsum up to 10–20 cm thick coats cave walls in zones of sluggish and perched groundwater crossflow. It is made up of silt-sand sized euhedral prisms with a delicate open “pack-of-cards” texture that could only be preserved in caverns experiencing very low rates of fluid cross flow. Gypsum is also locally reprecipitating as small stalactites and stalagmites in vadose cavities. Walls tend to be smooth and unornamented in other nearby caves with more active throughflow.

The following sequence of exhumation and karsting was listed by Warren et al. (1990) as indicative of the transition from the deep phreatic to the vadose (Figure 7.37b):

- *Formation of nodular “daisy-head” gypsum* As uplift raised this bed of nodular anhydrite into the zone of rehydration, replacement by gypsum was at first slow but pervasive, with near-stagnant phreatic fluids oozing into the calcium sulphate bed. At the microscale, stagnant phreatic waters seeped into the nodular anhydrite bed. Flow was focused along intercrystalline porosity films within the dolomite rims surrounding the calcium sulphate nodules or it was focused along thin-bedded dolomite stringers within the anhydrite bed. Millimetre to cm-sized, aligned gypsum crystals nucleated off these flow paths and grew inward toward the nodule core via dissolution and replacement of the anhydrite to form daisy-textured gypsum. The main mesoscale permeability entries into the gypsum bed were provided by fractures in the adjacent aquifers, which began to render a maze cave network.

With further uplift there was a change to more active hydrologic conditions, which modified the rate of gypsum growth and fine gypsum crystallites that characterise alabaster came to be the dominant precipitate. Replacive gypsum grew more rapidly through the unit as a microcrystalline alabaster texture

overprinted some of the nodules. The adjustment in gypsum texture as the unit was exhumed probably reflects more pronounced fluctuations in temperature and saturation tied to increased groundwater crossflow (Figure 7.37b). This was probably related to greater access of undersaturated phreatic water to the unit as the dense network of joint-controlled maze caves permeated the gypsum and were fed from joints and fractures in the adjacent aquifer.

• *Karst structures and calcite/gypsum speleothems* As the gypsum bed passed into the zone of active phreatic flow and then vadose infiltration, the process of gravity-driven karstification began in earnest. Nodular and alabastrine gypsum now was subject to widespread dissolution. Phreatic groundwater entry was first along joint mazes, while vadose infiltration in the exhumed parts of the unit tended to expand former phreatic caves and to create new vertical pipes with scalloped edges indicating the downcutting process. Gypsum and calcite speleothems formed in caves and pipes with less active vadose crossflow, mainly as popcorn, flowstone and alabastrine laceworks (Figure 7.37a).

• *Brecciation and complete loss of gypsum* Complete dissolution of the gypsum bed produced zones of collapse breccia, with circumclast radial and botryoidal calcite cement (speleothems). Collapse occurred gradually over wide areas of contact between the bedded gypsum and adjacent strata so that the overlying beds tend to be lowered gently into broad folds. Regionally, the overburden stratification was little disrupted by widespread foundering associated with the complete flushing of gypsum. Regionally a residual zone of pulverulent dolomite rhombs (“chalky” dolomite) overlain by packbreccia now defines the cap to the dissolved gypsum bed. Where gypsum remains, some of this unconsolidated dolomite residuum is washed from the upper surface of the dissolving gypsum into karstholes and pipes that cut down into the gypsum to accumulate on the conduit floors with classic “vadose silt” textures.

Figure 7.37. Model karst and related calcite textures developed through sequential complete dissolution and retexturing of an uplifted gypsum bed - based on textures in the subcrop of the Fredericksburg Gypsum in central Texas. A) Schematic cross section through the dissolving now vadose gypsum bed. B) Textural evolution related to groundwater regime (modified from Warren et al., 1990).

There is abundant calcite precipitating as void fill in rubble breccia cavities and pipe linings, but there is no discernable conversion of the chalky dolomite to calcite (dedolomitisation) in this system. XRD shows chalky dolomite remains well ordered and near stoichiometric. The lack of dedolomitisation raises the question: Is it commonplace in evaporite beds on the way down in the burial cycle, when newly formed dolomite is more likely to be a less ordered highly metastable form of dolomite? Is it less common in evaporite beds on the way up (see calcitisation of evaporites discussion later in this chapter)?

The end result of unroofing an ancient evaporite bed in this humid region of central Texas, where the karsted gypsum beds never outcrops, is a stratiform chalky calcitic/dolomitic residuum layer that underlies a gently folded and collapsed packbreccia bed. The former position of a regional decametre-

thick CaSO_4 bed is now defined by cm-metre thick interstratal packbreccia characterised by brecciated and rebrecciated fragments of calcite popcorn, boxwork and botryoidal calcite, all intermixed with fragments of the overlying strata and the dolomite residuum. None of the original evaporite salt remains in the final breccia.

Modern gypsum karst in Saudi Arabia

Similar telogenetic gypsum transformations, associated with gypsite/alabaster replacement, brecciation and karstification, are seen at Dahl Hit (*dahl = cave*) at Ain Hit in eastern Saudi Arabia (Figure 7.38a). There the 72 metre-thick type section of the Hith Formation outcrops in the roof and sides of a large collapse-prone doline mouth to a phreatic tube cave. In the subsurface the Hith Anhydrite is a major regional seal to the prolific reservoirs of the Arab Formation of Saudi Arabia and the western Emirates and it is typically more than 120 m thick in these oilfields (Chapter 10). The tubular cave mouth defines the lower part of the breached doline floor and leads down into a phreatic tube cave that has yet to be completely surveyed. The cave entrance is located at the Hith Anhydrite's contact with the limestones of the overlying Sulaiy Formation. The cave is steeply inclined ($\approx 30^\circ$) and floored by a scree slope composed of packbreccia created by gypsum layer breakdown. Blocks in the packbreccia are jumbled combinations of collapsed carbonate overburden and transforming blocks of Hith Formation anhydrite. Larger blocks range up to 3-5 metres across. Like most phreatic tube caves, the cave walls are smooth and unornamented with the floor covered by angular blocks of fallen roof. Much of the fine bottom sediment that covers the packbreccia on floor of the water-filled parts of the tube cave is composed of insolubles from dissolution of the Hith Anhydrite.

For centuries Hit Dahl at Ain Dit was a source of fresh water for the local population (*Ain = water spring*). But overpumping in the last few decades has led to a drastic drawdown of a potable water layer that once floated atop more saline phreatic water in the cave proper. The rapid lowering of the watertable has now destabilised the cave roof. Dahl Hith is now a dangerous cave to visit. On my last visit (November 2003) a large section of the roof had just collapsed in the preceding days. Much of the interior of the cave fissure is now packed with freshly collapsed blocks making cave access much more difficult than in the past.

At outcrop scale (Figure 7.38b) the retreating dissolution edge of the gently dipping Hith Fm. creates an obvious zone of bedding disturbance and folding in the Sulaiy Formation. The

current contact with the dissolved and monoclinally dipping Hith Formation ($\approx 30\text{--}40^\circ$) at Hit Dahl is defined by large collapse features and rotated mega-blocks of overburden in the flexure zone atop the shallow subcrop edge of the anhydritic Hith. A megabrecciated zone defines overburden collapse along the subcropping monoclinally edge of the Hith in Saudi Arabia and it can be traced as an elongate at-surface expression of the Hith for more than 550 km along strike. Similar, also spectacular, collapse dolines and rotated mega-blocks characterise gypsum karst features in the subcrop belt of the Eocene Gachsaran Formation in the foreland fold belt of Iran (Cucchi and Zini, 2003).

Active collapse fractures, visible in the Hit cave wall, show the effects of solution-related extensional collapse on the meteoric conversion of grey anhydrite to white-buff alabastrine gypsum (Figure 7.38c). The layering in the Hith is largely preserved on conversion to the fine alabaster crystals, which create an almost mimetic preservation of precursor texture. Thin extension fractures parallel to the main fracture/collapse allow the formation of thin alabaster streaks, which are clearly visible in the left third of the photo (Figure 7.38c).

The nature of the anhydrite-to-gypsum conversion front at Dahl Hit varies from fracture parallel, as seen in Figure 7.38c to bedding parallel, as seen in Figure 7.38d. In the latter case the upper boundary of the residual anhydrite block shows a nodular replacement contact with the newly precipitated alabaster. In contrast, its lower contact shows a more feathered relationship. White bedding-parallel satin-spar has formed in small fractures in the anhydrite and are parallel to the main entry fracture creating the alabaster zone. Satinspar is the last gypsum phase to form in this and has also grown in bedding-parallel fractures as well steeper veins that crosscut some anhydrite-alabaster contacts. Veins were created by extension in response to the growth of void space. Most of the grey anhydrite is being replaced from the edges inward, but the alabaster, which is less consolidated and somewhat more permeable, can accommodate a much higher density of bedding parallel fractures. It is a largely inhomogeneous response to tension created by dissolution and contrasts with the more isotropic response seen in the satinspar growing in the Permian clays where the Khuff anhydrite subcrops (Figure 1.39).

The replacement sequence at Hit Dahl is laminated anhydrite passing directly into laminated alabaster. It may reflect the much lower rates of fluid rock interaction experienced by the Hith Fm. during uplift as compared to the more humid conversions occurring deeper and earlier in the uplift history at Fredericksburg, Texas. The greater disturbance in the overburden at Hit Dahl

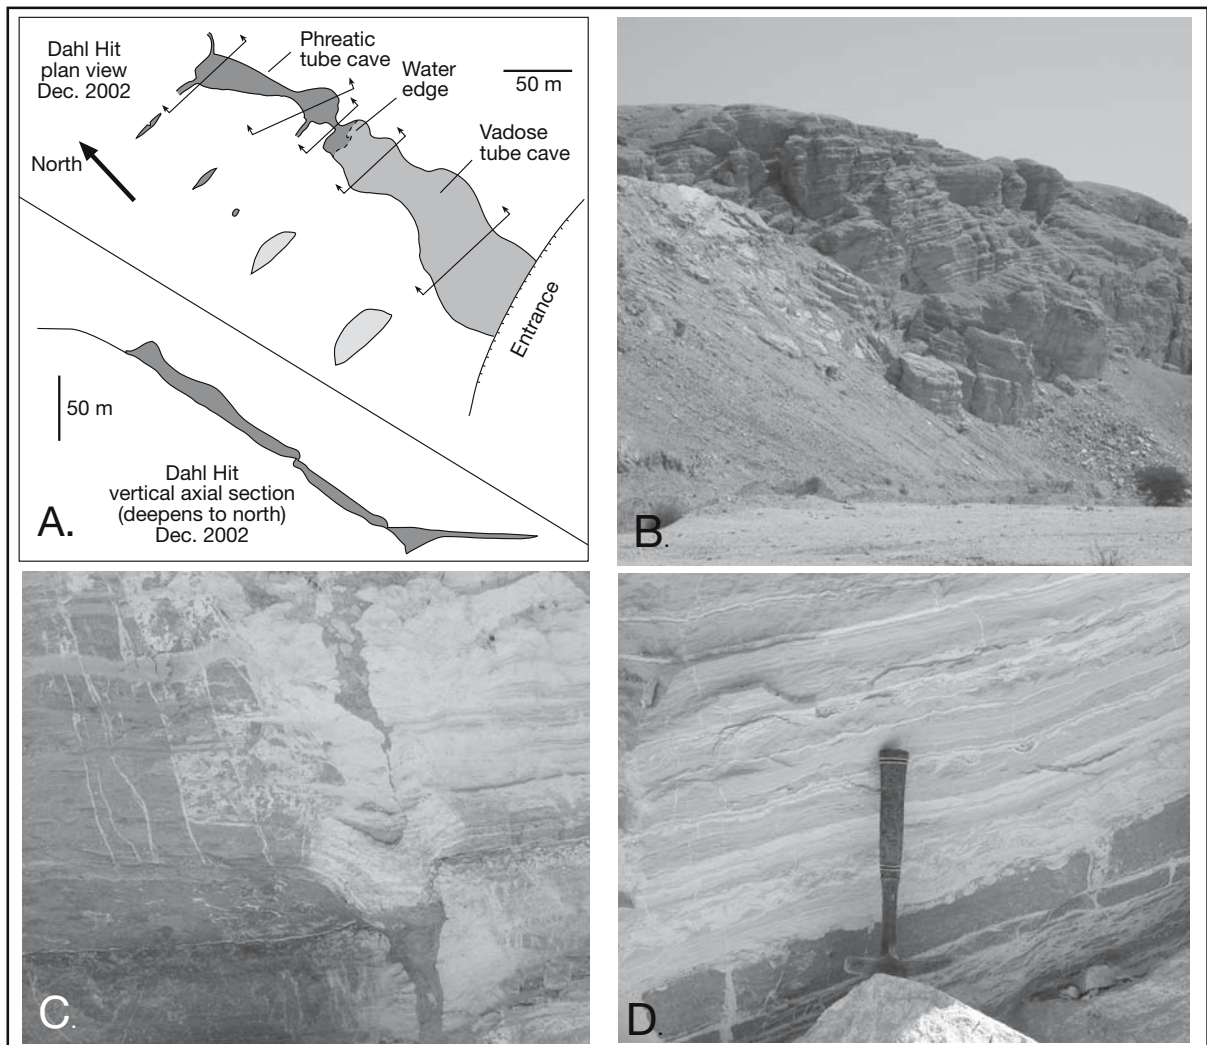

Figure 7.38. Dahl Hit at Ain Hit in Saudi Arabia. A) Surveyed geometry of Dahl Hit (replotted from Gregory et al., 2002). B) Overburden disturbance created by the nearsurface conversion and dissolution of the Hith anhydrite. Cliff \approx 100m . C) Contact between alabastrine gypsum and anhydrite showing a v-shaped breccia- and clay filled cavity some 50 cm across. D) Detail of the conversion front with buff alabastrine gypsum at top, grey remnant anhydrite below, upper conversion contact is nodular, lower transition is feathered, Bedding parallel white veins in the alabastrine gypsum are satin spar gypsum. compared to Fredericksburg reflects the greater thickness and resulting locally steeper dip of the monoclinical defining the edge of the dissolving CaSO_4 bed and perhaps a greater strength in the roof span in Saudi.

Halite Caves

Because of its high solubility, halite does not make it into outcrop or shallow subcrop as easily as gypsum/anhydrite. Where halite is at the surface it tends to be in regions of Pleistocene halite deposition (salt on its way down) or in zones of active diapirism

(salt coming up very quickly). Chabert and Courbon (1997) noted caves in ancient rock salt in several regions: Algeria (in diapirs, mostly as shafts and short caves up to 280 m long), Chile (diapirs, with caves 250-500 m long), Israel (in a diapir as tube caves several hundred metres in length), Romania (in diapirs, with caves up to several hundred metres long), Spain (in diapirs, with caves up to 650 m long), Tadjikistan (several caves 300 to 2,500 m long and up to 120 m deep), and in the namakers of Iran and the offshore island relicts where cavern lengths range from several hundred metres to kilometres.

Halite in an active namakier rises and spreads rapidly, so any karst in an active salt diapir tends to be a feature associated with the immediate underside of a caprock. Karst processes cannot deeply penetrate while salt is flowing, even when the plug rises more than 300 metres above the surrounds. But halite's susceptibility to rapid dissolution means the length of a cave developed below the caprock can be substantial. There is a report of a single salt halite cave in Iran with a passage length of 5.1 km (Bruthans et al., 2002). Once diapir rise has slowed or ceased the positive topography of the now inactive diapir controls the depth of development of doline collapse on the diapir itself. Deeper collapse dolines can now form in the more central topographically higher portions of a salt structure (e.g. Calaforra and Pulido-Bosch, 1999). The high solubility of halite means a halite cave system can form in a few hundred years rather than the thousands to tens of thousands of years needed to form carbonate karst. This means some of our notions of karst process and cave stability, related to the rate and density of cavern expansion, need to be modified when dealing with halite karst.

Modern halite karst in the Dead Sea depression

Halite caves occur in the Mt. Sedom diapir, where halokinetic Miocene salt is sporadically exposed beneath a weathering and fractured gypsiferous caprock (Figure 7.39a; Frumkin, 1996; Frumkin and Ford, 1995). Water enters the various caves in Sedom diapir through breaches in the caprock. Most of the caves in the higher parts of Mt. Sedom salt are vadose inlet caves; these are meandering steeply inclined tubes and canyon slots located within or immediately below the caprock. They form where salt solution quickly carves out near vertical slots and shafts (typically < 2m wide and much deeper) that lead down from the surface, sometimes along pre-existing fractures and shears in the salt. Inlet caves in the central portions of the mountain can only be accessed through their sinks and appear to have no distinct outlet. All terminate several tens of metres above the regional water table (e.g. Karbolot Cave; Frumkin, 1994a, b, 1996).

The lower parts of inlet caves often contain steep silt and clay banks with surge marks that indicate occurrence of low energy water ponding, with variable residence times. Silt and clay sediments settling at the bottoms of inlet caves impede infiltration, extending the residence time of pond water (Frumkin, 1994a, 1996). Three of the studied caves in northern Mount Sedom had perennial ponds throughout the period 1984-1995. The ponds are perched, without any lithologic control, tens of metres above the nearest potential outlet at the foot of the

mountain. Water level in each pond differs from the others by tens of metres. All pond waters are highly concentrated, up to 324 g/l, with solutes consisting mainly of sodium and chlorine. Fresh inflow waters reach halite saturation within a few hours of reaching the pond. Both dissolution and precipitation features form the pond edges, and their equivalents can be seen on cave walls wherever ponds have dried out. Dissolution is indicated by horizontal notches, which connote density stratification in the ponds when aggressive fresh flood waters temporarily diluting the upper parts of the pond. Subsequent saturation of holomictic pond waters is indicated by the growth of cm-scale halite crystals on the bottom and sides of the ponds.

Towards the periphery of Mt Sedom, the inlet caves lead down to laterally expanding vadose cave levels that drain onto the Dead Sea plain. Sedom Cave, is the longest laterally expanding cave, with an aggregate length between two subparallel conduits of 1.8 km. Malham Cave, another large perched and laterally expanding cave, lies a few hundred metres south of Sedom Cave (Figure 7.39a; Frumkin, 1996). It has an aggregate passage length of more than 5.5 km and reaches to some 194 m below the landsurface. There is an upper tier of largely inactive passages and a lower active channel level. ¹⁴C dates on fossil wood in the upper cave level shows meteoric waters began to sculpt the upper cave more than 5,500 years ago. Ongoing uplift of Mt Sedom salt means the active channel level in Malham Cave is now downcut some 10-12 metres lower than when it began. Malham Cave passages quickly developed an open outlet through which floodwater escaped directly to the Dead Sea floor, proving that during this period some 4000 years ago rock salt had already risen above region hydrological base level at the Malham outlet point within the eastern escarpment (Figure 7.39a). Lashelshet Cave, an inlet cave on the highest point on the diapir cross section, has an even older age of more than 7,000 years since cave initiation. Caves in the northern part of Mt Sedom did not begin to form until some 3,000 years later (Frumkin, 1996).

Based on their study of the caves of Mt Sedom, Frumkin and Ford (1995) concluded cave passages develop in two main stages: (1) an early stage characterized by inlet caves with high downcutting rates into the rock salt bed, and steep passage gradients; (2) a mature laterally expanding stage characterized by lower downcutting rates and the establishment of a wider subhorizontal perched stream bed armoured with alluvial detritus. This style of cave tends to develop toward the periphery of the diapir mound. In the mature expanding stage downcutting rates are controlled by the uplift rate of the diapir and changes of the level of the Dead Sea.

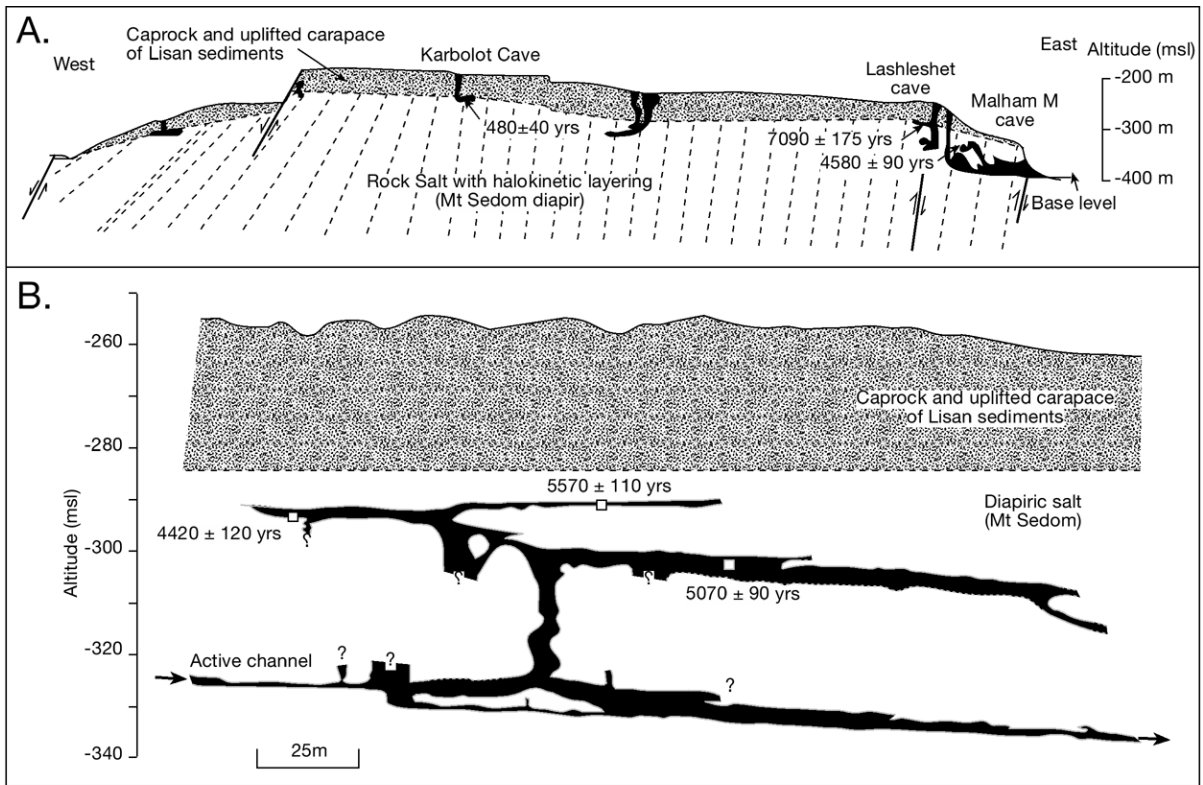

Figure 7.39. Halite caves beneath the caprock carapace of Mt Sedom, Israel (after Frumkin, 1996). A) East-West cross section through the southern part of Mount Sedom, showing ages of upper levels of caves in ¹⁴C yr B.P. Dashed lines indicate dip of salt layers within the diapir. Caves are colored black. The oldest cave date comes from Lashleshet Cave, which lies at the top of the eastern escarpment, implying this was the earliest region on the Sedom uplift to experience vadose flushing. B) Vertical section along part of Malham South Cave, showing several dated levels. The age of the uppermost level (5570 ± 110 yr B.P.) indicate the minimum exposure age of this site created by the halokinetic uplift of the landsurface. See Figure 4.40 for location of Mt Sedom.

Passages may aggrade to create wide flat bevelled passages and slots with thick sediment armoured bases (Frumkin, 1998). A lack of a consistent phreatic level in the blind bottoms of perched water levels and the presence of the horizontal slots in the lower levels of Sedom Cave means dissolution in both types of caves is largely restricted to times of flooding and perched or backed up freshwater in the vadose zone. This explains the tapering passages of inlet caves and the widespread alternation of armouring and bevelling as well as formation of narrow horizontal meandering slots toward parts of the top of the meandering channel that is now Sedom Cave.

Mass balance calculations in the halite caves of Mt Sedom yield downcutting rates of 0.2 mm s⁻¹ during peak flood conditions, this is about eight orders of magnitude higher than reported rates in any limestone cave streams (Frumkin and Ford, 1995). However, floods have a low recurrence interval in the arid climate of Mount Sedom so that longterm mean downcutting

rates are lower: an average rate of 8.8 mm a⁻¹ was measured for the period 1986-1991. This is still at least three orders of magnitude higher than rates established for limestone caves.

The highly impervious nature of halite and its resupply in actively growing diapirs means that, unlike carbonate and gypsum caves, there is no real water table level to define maximum cave development in a rising salt stem. Rather, the inlet caves are simple dissolution tubes where rainwater has accessed halite and sank until it was saturated and then dissolution stopped until the next flood. Toward the edge of the rising stem these inlet caves breached the edge of the salt mound and vented their perched groundwaters to the surrounding plain (Sedom and Malham caves). This creates a downcutting and laterally expanding cave system, which is still some metres to tens of metres above the base level of the regional water table in the surrounding plain. The expanding cave level is dominated by mostly horizontal growth, often with a sediment-armoured

floor. It has numerous benches in the walls that probably reflect changes in the hydrological base level.

Dense anastomosing cave networks that characterise gypsum caves are not found in the halite caves of Mt Sedom. This reflects the ability of diapiric halite to re-anneal and the fact that all exhumed halite that makes it to the surface is diapiric, not bedded. At-surface halite is not sandwiched between jointed aquifers above and below the dissolving layer. Rather it is a growing mound subject to dissolution at its top and sides.

Away from Mt Sedom, there are active collapse sinkholes and caverns forming in the alluvial fans and clastic aprons that overlie the bedded Quaternary lacustrine halite of the Dead Sea (salt on its way down in the burial cycle). In the sediments around the lakeshore the pace of collapse has accelerated in the last 60 years due to a drastic lowering of the circum-lake water table and the associated lakeward migration of the saline-fresh water interface (Figure 2.46; Arkin and Gilat, 2000; Salameh and El-Naser, 2000; Frumkin and Raz, 2001). For example, a series of collapse dolines 2-15 m diameter and up to 7 m deep, appeared in 1990 in the New Zohar area. In January 2001 a large sinkhole, some 20 m deep and 30 m wide, cut through the asphalt surface of the main road along the western shore of the Dead Sea. It was opened by the passage of a busload of tourists on their way from Ein Gedi to the solarium. Existing tourist facilities, such as the Ein Gedi beachside parking, were shut down after the road was damaged and several buildings have since collapsed into sinkholes. Sinkholes have since developed in other areas about the Dead Sea Margin including Qalia, Ein Samar, Ein Gedi and Mineral Beach.

Three main types of sinkhole or doline fill have been recognized atop the dissolving Holocene salt beds; 1) Gravel holes in alluvial fans, 2) mud holes in the intervening bays of laminated clay deposits between fans, and 3) a combination of both types at the front of young alluvial fans where they overlap mud flats. Fossil, relict sinkholes have been observed in the wadi channels cutting into some old alluvial fans, showing this is a natural and ongoing process. While lake levels continue to fall (Figure 4.42), the potential for subsidence hazards related to karst collapse is ongoing.

There is evidence of an older set of widespread ground collapses, sinkholes and caves that are tied to an earlier substantial fall in the Dead Sea water level some 4 ka. It may even be that the events described in Genesis 14 in the Christian Bible took place at the time of a substantially lowered sea level. The described battle, which occurred prior to the fall of Sodom and Gomorrah, perhaps took place on the subaerially exposed flats of the

Southern Basin of the Dead Sea. The “pits of slime” described in the fall perhaps were solution collapse sinkholes activated by the 4000 ka fall in the Dead Sea water level (Frumkin and Elitzur, 2002).

Modern halite karst in crests of diapiric Hormuz salt (Precambrian) in the Arabian Gulf

Namakier outcrops in and about the Arabian Gulf range from structures actively extruding salt to those in ruins where salt has not flowed for tens of thousands of years (Figure 7.14). Likewise the halite caves developed in the namakiers of Iran, or their offshore island counterparts, show a broad range of ages and styles of salt cave development tied to the time since cessation of salt flow.

Surfaces of actively flowing namakiers on the Iranian mainland are characterised by karren flutes and pinnacles, with numerous small-medium dolines, collapse structures, swallow holes and small caves at their base. Caves tend to be sediment-armoured meandering tube caves or subvertical canyon slots that are centred on joints in the salt beneath a thin suffusion mantle. In contrast, the halite caves in the diapiric cores of the many islands in the Arabian Gulf have a more mature bevelled meandering style with thicker sediment armouring on the cavern floor. Many of these caves breach the retreating edges of former namakiers and salt fountains.

Salt movement in the various diapiric cores of these islands is inactive or is greatly reduced compared to the Miocene when these structures were active namakiers. For example, Dragon Breath Cave on Hormoz Island is a linear meander tube cave fed by an ephemeral stream in a shallow valley filling with alluvium (Figure 7.40; Bosak et al., 1999). The surrounding landscape is classic salt karst with numerous depressions, blind valleys, ponors and subsidence sinks. Together they form a highly pockmarked centripetally-ringed topography, which outlines those central parts of the island underlain by shallow subcropping Hormuz salt. The cave itself is one of a number of tube caves exiting about the edge of the zone of diapiric salt. Hosted in steeply dipping diapiric salt, it is around 100 m long with its main passage created by a minor ephemeral stream. Its near flat roof, with an average inclination of 5.4%, is a notable feature and reflects either joint-related dissolutional spalling of the roof or an earlier water table slot related to backup of a freshened water body (Figure 7.40).

The current cave passage has cut down a metre or more into earlier cave floor sediments (sediment armour), which contain clasts up to 50 cm in diameter. The cave formed by initial ingress

along a linear joint, which was then widened by salt dissolution, so allowing meandering of the stream trace within the salt. It is a cave system very similar to the mature stages of laterally expanding caves in Mt Sedom. The base level of the cave correlates with the surface of a widespread marine terrace, which is now uplifted some 20 metres above sealevel and defines much of the periphery of Hormoz Island. The raising of the terrace is related to the ongoing raising of the island via salt flow.

Bruthans et al. (2000) concluded that the style of karst landform developed in dissolving diapiric salt in the Arabian Gulf Islands reflects the thickness of the carapace that caps the dissolving salt core. They distinguished four classes of diapir cap, each with a specific association of superficial and underground karst forms, namely: 1) outcropping salt, 2) thin capping (0.5-2 m), 3) capping with moderate thickness (5-30 m), 4) capping with greater thickness (more than 30 m). Cap thickness controls or reflects: 1) the density of recharge points, with high densities of recharge points in the thinner caps; 2) the amount of concentrated recharge which occurs at each recharge point, with suffusion karst characterising thinner caps; 3) the rate of lowering the ground surface atop the salt, with the faster rates of lowering occurring beneath thinner caps, and 4) the amount of load transported by underground flood-streams into cave systems. The volume of sediment load tends to be locally higher and focused beneath the thicker caps, especially where inflow streams abut the edges of a dissolving salt dome. The thickness of caps atop expanding halite caves does not appear to influence the shape or style of the cave developed within the salt mass; more important seems to be the thickness of cap in the recharge area of the cave and the type of recharge into the salt environment. That is, how much water is passing into the salt and is its flow ongoing or ephemeral?

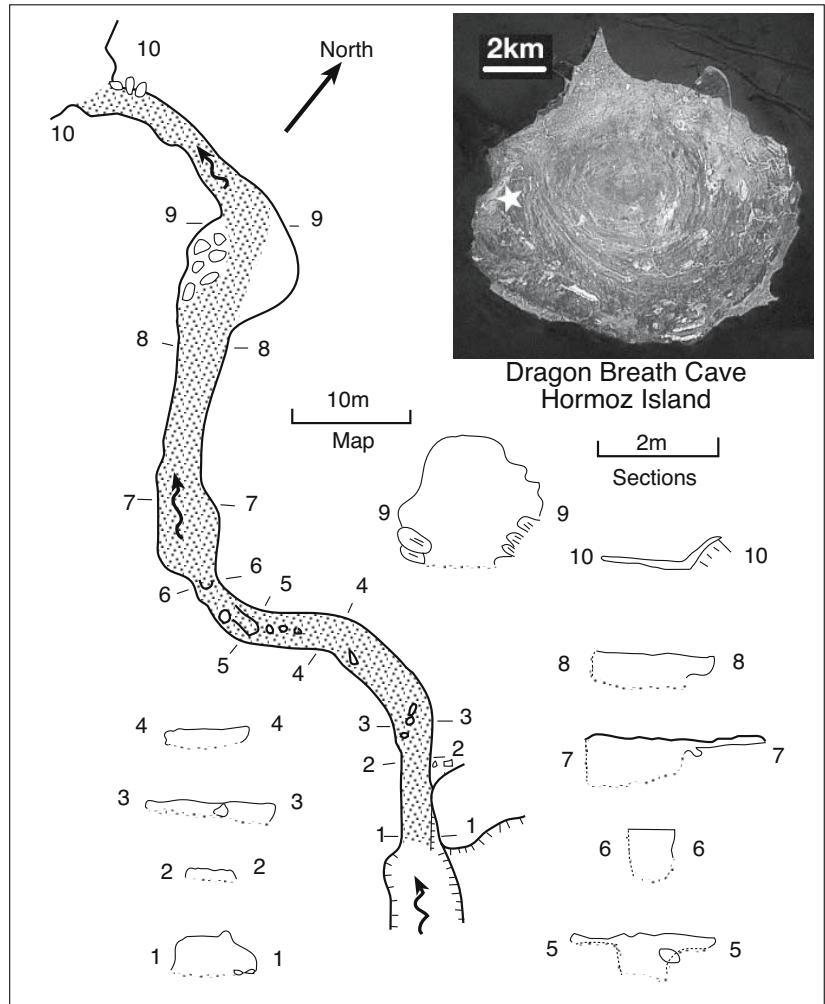

Figure 7.40. Map of Dragon Breath Cave, a meandering karst cavity draining the edge of the inactive diapiric core of Hormoz Island, Arabian Gulf (after Bokacs et al., 1999). Star marks cave position on insert, see Figure 6.45 for location of island. (Landsat image of island courtesy of NASA).

Halite caves in the relatively mature salt stems of the various islands of the Arabian Gulf, unlike carbonate systems, can swallow and store huge volumes of clastic sediment, volumes that would clog the entrance to a carbonate system. The extreme solubility of halite enables the pace of dissolution/corrosion enlargement in a salt cave to keep pace with large amounts of sediment carried into the cave by external inflows. Stream sediments arriving at the cave entrance, including boulders, move inside and are trapped within the salt itself. Sediment is not dumped outside the cave entrance, which is the typical situation in blind valley river mouths at carbonate caves (Bruthans et al., 2003). For example, coarse-grained sediment fractions are carried hundreds of metres into the cave by two large in-

intermittent streams entering the upper part of the Ponor Cave (Hormoz Island). The clasts in the resulting intra-cave alluvial fan conglomerates range from cobble of several centimetres up to 1 m diameter boulders, only sand-sized particles make it to the lower part of the same cave.

Caves capable of storing such coarse alluvium within the cavern itself are halite-specific with no equivalent in a carbonate karst terrain. There the boulder-size fraction in the cave itself is the result of roof fall and almost all stream-borne coarse alluvium is deposited outside the cave.

Cave walls in zones of less intense dissolution and stream crossflow are decorated with halite, gypsum and anhydrite speleothems. Anhydrite forms speleothems in preference to gypsum in those parts of the cave with very high salinity waters. Some of these speleothems can be quite large, up to a few metres long. Compared to the growth rates of calcite speleothems in carbonate caves the growth rates of evaporite speleothems are phenomenal. Halite stalactites, several metres long and curving into the direction of airflow, formed in the mouth of Dragon Breath cave in a few years rather than millennia needed for carbonate counterparts (Bokacs et al., 1999). In August 1997, a network of numerous halite stalagmites and stalactites blocked the entrance to Dragon Breath Cave. In March 1998 there were no remains of the speleothem meshwork, while in February 1999, the stalagmites had reappeared (Bosak et al., 1999). Similar halite structures occur in the caverns of Mt Sedom and on the wet roofs of some salt mines.

Evaporite speleothems in carbonate karst

Evaporites can form speleothems in the drier parts of carbonate caves where airflow dries cave capillary waters to salinities appropriate for precipitation. Gypsum and epsomite speleothems

are especially common in vadose caves in areas receiving less than 250 mm of rainfall per year. Even in the ever-wet climate of New Guinea, powdery gypsum crusts can coat carbonate substrates in caves like Selminum Tem and Atea Kanada in a region where the annual rainfall is more than 4,000 mm. But these are relatively minor portions of the total volume of cave decoration with the sulphate sourced in the weathering of pyritic impurities and are only found in parts of the cavern system subject to vigorous air circulation.

The most common vadose evaporite speleothem is gypsum, which forms as relatively fine-grained granular crusts on the limestone wall of most arid-zone carbonate caves. It grows and accretes via uniform seepage and evaporation of brines escaping from the porous cave wall. This is an ongoing process whereby older crusts become detached, fall off and, if not dissolved by throughflowing waters, accumulate on the cave floor as new crusts continue to form on the walls. It is really a form of salt weathering that just happens to occur inside a cave. Gypsum also accumulates as granular layered rinds in many phreatic and bathyphreatic carbonate caves that were moulded by sulphuric acid speleogenesis in their early stages of formation.

Sulphate speleothems are not restricted to crusts in caves in warmer climates, Harmon et al. (1983) reported at least three sulphates (gypsum, mirabilite and epsomite) in speleothems in Castleguard Cave in the Canadian Rockies, with the most spectacular forming large ice-clear stalactites of epsomite and mirabilite (Table 7.7). Celestite can also form as a crystalline crust or as distinct blue needles atop gypsum crusts, while baryte has been documented as a cement in cave soils. Both minerals, along with fluorite, are also found as phreatic precipitates in hydrothermal bathyphreatic caves.

But the most commonly noticed evaporite speleothems in carbonate karst are not various crusts and prisms but the spectacularly curved gypsum and halite flowers that protrude as lacy intertwined ribbons hanging from ceilings and walls. Epsomite and mirabilite occasionally also form crystal flowers. These cave flowers (oulopholites) typically grow as curved radiating masses of very long (up to 50 cm), narrow crystals. New growth originates at the base of the crystal strings as saturated brines emerge from the cave wall, driven by capillary evaporation. Faster growth in the centre of a bundle of crystals creates the radiating or flower-like pattern. Often they grow from waters issuing

Mineral	Composition	Type of occurrence
Gypsum	$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$	Dripstone, wall crusts, flowers, bladed crystals, pore cement in cave soils
Halite	NaCl	Dripstone, wall crusts, flowers, pore cement in cave soils
Epsomite	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	Dripstone, flowers, pore cement in cave soils
Hexahydrate	$\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$	Loose crusts on cave floor
Mirabilite	$\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$	Dripstone, flowers, loose tufts of crystals
Bloedite	$\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$	Loose crusts on cave floor
Celestite	SrSO_4	Loose crusts on cave floor

Table 7.7. Evaporite minerals and their mode of occurrence in cave speleothems.

from crevices and fractures in the cave wall and their growth contributes to parts of the cave wall breaking away or spalling (salt weathering). Changes in cave atmosphere and rates of capillary supply drive varying growth rates and hence the curvature of the crystals, much like the controls on helictes (twisted stalactites). Oulopholites are especially sensitive to seasonal changes in cave airflow. The growth of gypsum anemolites (wind-controlled oulopholites) in a cave in the Ukraine was found to vary with changes in cave humidity (Maltsev and Ford, 1991). When air moves into this cave each summer, and cave humidity is 70-90%, accretions of up to 7 mm form. In winter, the airflow reverses, the humidity rises and the same structures tend to dissolve.

Hill and Forti (1986) list ten sulphate salts derived from normal vadose karst processes; many others result from the interaction of karst waters with ore bodies. White (1988) lists four possible sources of cave sulphate, divided into two distinct source groups;

- Carbonate bedrock source:
 - a) Dissolution of sulphate bearing bed
 - b) Oxidation of pyrite in the bedrock
 - c) Weathering of anhydrite nodules
- Deep groundwater source:
 - a) Movement of deep H_2S waters into contact with phreatic karst waters to form sulphuric acid, which may dissolve calcite and deposit gypsum.
- To this list Hill and Forti (1986) add guano and weathering basalt.

As well as flowers in carbonate caves, halite is a rapidly growing vadose speleothem in its own right. Halite speleothems in carbonate caves form best in arid regions, where parent materials are leached from the regolith by circulating brackish groundwaters and redeposited under evaporative conditions in the cave environment. Lowry (1967) discussed halite speleothems from the carbonate caves beneath the Nullarbor, while Goede et al. (1992) notes the region has what may be the world's largest halite speleothems in a carbonate cave. Nullarbor's saline speleothems in Mullamullang Cave include the distinctive "coffee and cream" textures made up of a mixture of fine powdery and more coarsely crystalline magnesian calcite crusts, and varying levels of iron and manganese oxide, intermixed with fragments of halite and gypsum flowers.

Huge single evaporite crystals with geode-like textures can form in zones where saturated brine pools covers the cave floor or can rim a deep phreatic cavern. Where fluid chemistry fluctua-

tions are minimal in these gypsum saturated phreatic waters, clear impurity-free gypsum blades can grow as single crystals up to a metre or more in length and decimetres in width (e.g. phreatic crystals in sulphuric acid caves in Lechuguilla caverns of New Mexico, Almeria caverns in Spain and the Dnestro-vsko-Pricernomorskij karst caves of the western Ukraine. The details of this style of "giant" phreatic cement are discussed later in this chapter.

Karst hazards in evaporites

Unlike the relatively slow formation of limestone karst, gypsum/halite karst develops on a human/engineering time-scale. For instance, at Ripon in Yorkshire, a 3 m cube of undercut gypsum that fell into the River Ure was completely dissolved in 18 months and the nearby gypsum face was undercut another 6 metres in the next 10 years (Cooper, 1998). Although halite is even more susceptible to dissolution, it typically is not an urban engineering problem; large numbers of people simply do not like to live in a climate that allows halite to make it to the surface. However, catastrophic doline collapse atop poorly managed halite/potash mines and solution brinefields can be an anthropogenically-induced problem in developed regions (Chapter 12).

Collapse into nearsurface gypsum caves can create stoping chimneys in the overburden, which break out at the surface as steep sided dolines, often surrounded by broader subsidence hollows. Such swallow holes, up to 20 m deep and 40 m wide, continue to appear suddenly in gypsum areas throughout the world. Natural gypsum karst is a hazard in many parts of Europe

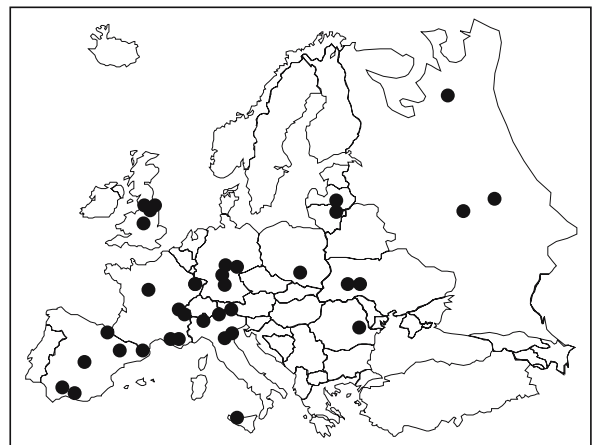

Figure 7.41. Areas in Europe associated with the development of intervals subsidence and collapse associated with gypsum karst.

Action or group of processes	Subsidence mechanisms	Examples
Removal of ground fluid	Loss of buoyant support for soil particles; compaction of sediment; possible failure of material bridging a void, thus, causing catastrophic collapse	Sinkholes overlying gypsum karst in Lithuania (Paukstys et al., 1999)
Shrinkage of organic or clay-rich materials	Consolidation of sediment; net loss of organic material	Shallow depressions from desiccated swelling clays (Biddle, 1983; Driscoll, 1983); subsidence of peat in subsidence hollows (Cooper, 1998)
Hydrocompaction of sediments	Softening and yield of metastable interparticle bonds by the introduction of water	Building subsidence caused by compaction of gypsiferous silt in alluvial fan, e.g., Calatayud Spain (Gutiérrez and Cooper, 2002) This effect is aggravated by broken water pipes in Calatayud and leaking septic tanks in Mosul, Iraq (Jassim et al., 1997)
Fluvial karstification of gypsum bedrock	Loss of mechanical support; syn- and post-sedimentary subsidence of alluvial deposits into depressions forming at the alluvium/gypsum contact	Subsidence depressions on alluvial flood plains, Calatayud Graben, Spain (Gutiérrez, 1996), river valley 'subrosion' (Ford, 1997)
Downwashing of unconsolidated sediments	Downward movement of sediments into existing voids or breccia pipes resulting in gradual growth of shallow depressions	Sinkholes in Lithuania (Paukstys et al., 1999); sinkholes in Ripon (Cooper, 1986)
Gradual collapse of unconsolidated materials overlying gypsum karst	Sagging of materials overlying a void leading to concomitant lowering of the cover/gypsum interface, and growth of a surface depression	Sinkholes in West Ripon (Cooper, 1998)
Catastrophic collapse of unconsolidated sediments into existing voids (may be preceded by a period of gradual subsidence)	Collapse that probably requires a triggering mechanism; ravelling of a void upwards through unconsolidated sediment possibly accompanied by removal of sediment by rapid water flow through the void	Sinkholes in Ripon (Cooper, 1986, 1998); sinkholes in China (Yaoru and Cooper, 1997); sinkholes in glacial drift overlying gypsum karst, Nova Scotia (Martinez and Boehner, 1997)
Catastrophic collapse of competent strata into voids (breccia pipe propagation)	Failure of material bridging void; development of sinkhole generally requires a triggering mechanism	Sinkholes in Ripon (Cooper, 1986), New Mexico (Martinez et al., 1998), NW territories, Canada

Table 7.8. Processes and mechanisms driving the creation of gypsum karst hazards, with examples (after Lamont-Black et al., 2002).

(Figure 7.41) and similar areas of subcropping gypsum in much of the rest of the world (Table 7.8). Areas surrounding the city of Zaragoza in northern Spain are affected as is the town of Calatayud (Gutiérrez and Cooper, 2002). Gypsum dissolution is responsible for subsidence and collapse in urban areas around Paris, France (Toulemont, 1984), in and around Stuttgart and towns peripheral to the Harz Mountains in Germany (Garleff et al., 1997), in Pasvalys and Birzai in Lithuania (Paukstys et al., 1999), in the Perm area of Russia (Reuter and Tolacev, 1990), in the Sivaz region of Turkey (Karacan and Yilmaz, 1997), in the region centred on the city of Mosul in northern Iraq (Jassim et al., 1997) and on a number of areas of rapid urban development in eastern Saudi Arabia (Amin and Bankher, 1997a, b). Large subsidence depressions caused by gypsum dissolution in China have opened up in the Taiyuan and Yangquan regions of Shanxi Coalfield and in the adjacent Hebei Coalfield.

Natural gypsum karst has been responsible for leakage or failure in more than 24 dams worldwide. In the USA they

include: McMillan, Avalon and Rio Hondo dams in New Mexico; San Fernando, Dry Canyon, Buena Vista and Castaic and Olive Hills dams in California; Stanford Dam, Texas; Red Dock Dam, Iowa, Fontanelle Dam, Oklahoma; and the Moses Saunders Tower Dam, New York. Other problem dams include: Kamskaya and Bratsk dams in Russia, El Isiro dam in Venezuela, Allos dam in Spain, Mosul Dam in Iraq, Houspiro dam in China and Hessianheim Dam in Germany.

In the towns of Ripon in the UK and Pasvalys and Birzai in Lithuania about 45,000 people are currently affected by catastrophic subsidence caused by natural gypsum dissolution (Paukstys et al., 1999). Special measures for construction of roads, bridges and railways are needed in these areas and include: incorporating several layers of high tensile heavy duty reinforced plastic mesh geotextile into road embankments and car parks; using sacrificial supports on bridges so that the loss of support of any one upright will not cause the deck to collapse; extending the foundations of bridge piers laterally to an amount that could span the normal size of collapses; and

Figure 7.43. Catastrophic collapse areas of gypsum subcrop, UK. A) Subsidence crater caused by the dissolution of Permian gypsum at the village of Sutton Howgrave, North Yorkshire. The hole started to collapse in December 2000, the photograph was taken on 14th February 2001 when the hole was 5-6m in diameter and 11m deep with water at a depth of 8m. B) Collapse at the rear of a house in the village of Ripon, April 1997 (Photographs courtesy of A. H. Cooper and accessible at <http://www.bgs.ac.uk/programmes/envhaz/uggh/karst/home.html>; last accessed Dec 4, 2004).

artesian sulphate-rich springs issuing from Permian strata in contact with Quaternary gravels of the buried valley (Cooper, 1986, 1995, 1998).

The potentiometric head comes from precipitation falling on the high ground of the Cadeby formation to the west and the Sherwood Sandstone to the east. Groundwater becomes largely confined beneath glacial till as it seeps toward the Ure Valley depression, but ultimately finds an exit into the modern river via the deeply incised sand and gravel-filled palaeovalley of the proto-Ure. Waters recharging the Ure depression pass through and enlarge joints and caverns in the gypsum units of the Edlington and Roxby Formations, so the highest density of subsidence features are found atop the sides of the palaeovalley. This region has the greatest volume of artesian discharge from aquifers immediately beneath the dissolving gypsum. Although created as an active karst valley, the apparent density of subsidence hollows is lower on the present Ure River floodplain than the surrounding lands as floodplain depressions are constantly filled by overbank sediments (Figure 7.42).

^{7.4}*Entrenched karst* occurs where the entire thickness of the soluble rock is entrenched along the sides of valleys but the insoluble cap spans most interfluges.

Subjacent karst occurs where the soluble rock is locally breached by erosion over a minor part of its thickness, karst features may be expressed at the surface as combinations of springs and collapse features.

Mantled karst is wholly or partly covered by a relatively thin veneer of post-karst rock or sediment and is part of the contemporary landscape.

Cooper (1998) defined 16 sinkhole variations in the gypsum subsidence belt at Ripon, all are types of ^{7.4}entrenched, subjacent and mantled karst. Changes in karst style are caused by; the type of gypsum, the nature and thickness of the overlying deposits, presence or absence of consolidated layers overlying the gypsum and the size of voids/caverns within the gypsum.

To the west of Ripon, the gypsum of the Edlington Formation lies directly beneath glacial drift. These unconsolidated drift deposits and the loose residual marl atop the dissolving gypsum gradually subside into a pinnacle or suffusion (mantled) karst. But between Ripon city and the River Ure, the limestone of the Brotherton Formation overlies the Edlington Formation. There the karst develops as large open caverns beneath strong roof spans (entrenched karst). Ultimate collapse of the roof span creates rapid upward-stopping caverns in loosely consolidated sediment. Slopes break through to the surface as steep-sided collapse dolines or chimneys with sometimes catastrophic results. A similar entrenched situation is found east of the Ure River but there karstified gypsum units of both the Edlington and the Roxby formations are involved.

When a chimney breaks through, the associated surface collapse is very ^{7.5}rapid. A recently documented example of one such subsidence crater, which opened up in front of a house on Ure Bank terrace on 23rd and 24th April, 1997, is documented by Cooper (op. cit.) as follows (Figure 7.43a).

“The hole grew in size and migrated towards the house, to measure 10m in diameter and 5.5m deep by the end of Thurs-

day. Four garages have been destroyed by the subsidence. This collapse was the largest of one of a series that have affected this site for more than 30 years. The hole is cylindrical but will ultimately fail to become a larger, but conical, depression. As it does so, it may cause collapse of the house, which is already damaged, and the adjacent road. The house and several nearby properties have been evacuated and the nearby road has been closed. The gas and other services, which run close to the hole, have also been disconnected in case of further collapse.”

Problems with Miocene gypsum, Spain

Karstification has led to numerous problems in areas of subcropping Miocene gypsum in the Ebro and Calatayud basins, northern Spain. Areas affected are defined by subsidence or collapse in Quaternary alluvial overburden and include; urban areas, communication routes, roads, railways, irrigation channels and agricultural fields (Soriano and Simon, 1995; Elorza and Santolalla, 1998). There can be a reciprocal interaction between anthropic activities and sinkhole generation, whereby the ground disturbance engendered by human activity accelerates, enlarges and triggers the creation of new sinkholes. Subsidence is particularly harmful to linear constructions and buildings and numerous roads, motorways and railways have been damaged. Catastrophic collapse in roads and buildings

^{7.5}A. H. Cooper in a lecture to the general public has recently argued that the collapse dolines breaching the landscape between Ripon and Darlington were the inspiration for the rabbit hole in Alice in Wonderland. In Chapter 1, Lewis Carroll wrote.

“The rabbit-hole went straight on like a tunnel for some way, and then dipped suddenly down, so suddenly, that Alice had not a moment to think about stopping herself, before she found herself falling down what seemed a deep well. Either the well was very deep, or she fell very slowly, for she had plenty of time as she went down to look about her, and to wonder what would happen next”

Charles Lutwidge Dodgson, who later adopted the Lewis Carroll pseudonym, was born in Cheshire and spent his early days at Croft, near Darlington. There, a trio of ponds called Hell’s Kettles were believed by locals to be bottomless. The pits are now known to be gypsum collapse features only 22ft deep but they may have inspired this passage from the first chapter. In 1852 Carroll moved with his parents to Yorkshire when his father became Canon Dodgson of Ripon. Here, he first met Mary Badcock. Carroll, a keen mathematician, scientist and photographer, took pictures of Mary that were later adapted by Sir John Tenniel into illustrations in the first edition of Alice in Wonderland.

can have potentially fatal consequences. For example, several buildings have been damaged around the towns of Casetas and Utebo. In the Portazgo industrial estate some factories had to be pulled down due to collapse-induced instability. A nearby gas explosion was attributed to the breakage of a gas pipe caused by subsidence. The local water supply is also disrupted by subsidence and pipe breakage so that 20,000 inhabitants periodically lose their water supply. The most striking example of subsidence affecting development comes from the recently built village of Puilatos, in the Gallego Valley. This was severely damaged by subsidence and abandoned before it could be occupied.

Collapse affects irrigation channels in the countryside with substantial economic losses (Elorza and Santolalla, 1998). In 1996 a doline collapse cut the important Canal Imperial at Gallur village. New dolines often form in close proximity to unlined irrigation canals. The ongoing supply of fresh irrigation waters to field crops can also encourage sinkhole generation in the fields. Though not directly visible, natural sinkholes also form in the submerged beds of river channels cutting regions of subcropping gypsum. On December 19th, 1971, a bus fell from a bridge into the Ebro River at Zaragoza, near where the so-called ‘San Lazaro well’ (a submerged gypsum sinkhole) is located. Ten people lost their lives in this accident, nine of them were never found. Locals suggested that bodies were carried into the sinkhole and sank into the caverns fed by this losing stream.

Variation in the water table level, induced by groundwater pumping, is another anthropogenic trigger for dolines. As the watertable declines it causes a loss of buoyant support to the ground, it also increases the flow gradient and water velocity, which facilitates higher rates of crossflow and deeper aquifer recharge in subsequent floods and so reduces the geomechanical strength of the cover and washes away roof span support. Dolines can also be associated with groundwater quality issues. Collapse dolines or sinkholes are frequently used as areas or sumps for uncontrolled dumping industrial and domestic waste. Because of the direct connection between them and the regional aquifer, uncontrolled dumping can cause rapid dispersion of chemical and bacterial pollutants in the groundwater.

Sometimes even well-intentioned attempts to remediate culturally significant buildings under threat of karst collapse can exacerbate collapse problems. Gutiérrez and Cooper (2002) cite two examples from the city of Calatayud, Spain (Figure 7.44a, b). Subsidence-induced differential loading drives the tilting of the 25 metre high tower of the San Pedro de los Francos church, which leans towards and overhangs the street by about

Figure 7.44. Gypsum karst, Calatayud region, Spain. A) View from the town of Calatayud toward the retreating front of Miocene gypsum and the encroaching floodplain of the Río Jalón. B) Mantled steep edge of a collapse doline exposed in a highway cut on the approach to Calatayud. Bedded gypsum makes up the right half of the exposure, alluvium the left.

1.5 metres. In places, the brickwork of the church indents the pre-existing tower fabric, which probably dates from the 11th Century or the beginning of the 12th Century. This indentation and the non-alignment of the church and the tower walls indicates that most of the tower tilting occurred prior to the construction of the church. In 1840, the upper 5m of the tower was removed and the lower part buttressed for the safety of the Royal family, who visited the town and stayed in the palace opposite. On 3rd June 1931, San Pedro de los Francos church was declared a “Monument of Historical and Artistic value.” Due

to its ruinous condition, the church was closed to worship in 1979. Micropiling to improve the foundation was started in 1994, but this corrective measure was interrupted when only half of the building was underpinned. Very rapid differential settlement of the building took place in the following year, causing extensive damage and aggravating the subsidence problem.

Colegiata de Santa María la Mayor was constructed between the 13th and 18th centuries, it has an outstanding Mudéjar (a 72 m high tower) and numerous Renaissance features; it is considered the foremost monument in the city of Calatayud. As with the San Pedro de los Francos Church, recent micropiling work, applied to only one part of the cloister, has been followed by alarming differential movements that have drastically accelerated the deterioration of the building. Large blocks have fallen from the vault of the “Capitular Hall” and cracks up to 150 mm wide have opened in the brickwork of the back (NW) elevation, which has now been shored up for safety. The dated plaster tell-tales placed in these cracks to monitor the displacement demonstrate the high speed of the deformation produced by subsidence in recent years. On the afternoon of 10 September 1996, the fracture of a water supply pipe flooded the cloisters and the church with 100 mm of muddy water. Ten years earlier a similar breakage and flood had occurred. These breaks in the water pipes are most likely related to

karst-induced subsidence. Once they occur, the massive input of water to the subsurface may trigger further destruction via enhanced dissolution, piping and hydrocollapse (Gutiérrez and Cooper, 2002).

Gypsum karst beneath Mosul, Iraq

A similar quandary of multiple areas of structural damage from gypsum-induced subsidence affects large parts of the historic
