Human Herpesviruses

This comprehensive account of the human herpesviruses provides an encyclopedic overview of their basic virology and clinical manifestations. This group of viruses includes human simplex type 1 and 2, Epstein–Barr virus, Kaposi's Sarcoma-associated herpesvirus, cytomegalovirus, HHV6A, 6B, and 7, and varicella-zoster virus. The viral diseases and cancers they cause are significant and often recurrent. Their prevalence in the developed world accounts for a major burden of disease, and as a result there is a great deal of research into the pathophysiology of infection and immunobiology. Another important area covered within this volume concerns antiviral therapy and the development of vaccines. All these aspects are covered in depth, both scientifically and in terms of clinical guidelines for patient care. The text is illustrated generously throughout and is fully referenced to the latest research and developments.

ANN ARVIN is Professor of Pediatrics, Microbiology, and Immunology at Stanford University.

GABRIELLA CAMPADELLI-FIUME is Professor of Microbiology and Virology at the University of Bologna, Italy.

EDWARD MOCARSKI is Professor of Microbiology and Immunology at Emory University.

PATRICK MOORE is Professor of Molecular Genetics and Biochemistry at the University of Pittsburgh.

BERNARD ROIZMAN is Professor of Molecular Genetics, Cell Biology, Biochemistry, and Molecular Biology at the University of Chicago.

RICHARD WHITLEY is Professor of Pediatrics, Microbiology, Medicine, and Neurosurgery at the University of Alabama Birmingham.

KOICHI YAMANISHI is Professor of Microbiology at Osaka University, Japan.

Preface

Diseases caused by the human herpesviruses were recognized by the earliest practitioners of medicine. Hippocrates, Celsus, Herodotus, Galen, Avicenna and others described cutaneous lesions typical of infections caused by herpes simplex viruses (HSV) 1 and 2, and varicella-zoster virus (VZV). 'Herpes,' the family name of these viruses, is traced to the Greek term for lesions that appeared to creep or crawl over the skin. Among the duties of John Astruc, physician to King Louis XIV, was to understand the diseases of French prostitutes, in Latin, the '*Puellae publicae*', which led to his description of *herpes genitalis*. Distinguishing between genital herpes and syphilis was an obvious concern in this social context as it is now. The modern scientific investigation of HSV can be dated to the work of Gruter, who first isolated the virus and demonstrated its serial transmission in rabbits. During the 19th century, experiments in human subjects showed that HSV and VZV could be transmitted from fluid recovered from HSV and VZV lesions. Demonstrating that Koch's posulates were fulfilled was important but arguably the truly revolutionary discovery about the herpesviruses was made by Andrews and Carmichael in the 1930s who showed that recurrent *herpes labialis* occurred only in adults who already had neutralizing antibodies against HSV. Since our modern understanding of all of the human herpesviruses revolves around latency and reactivation as established facts of their biology, it is important to remember that these concepts are far from obvious and to appreciate the creative insights of Doerr who proposed that recurrent HSV was not an exogenous infection but resulted from stimuli to the cell that caused the endogenous production of a virus-like agent and of Burnet and Williams who perfected the notion that HSV persists for life and "*remains for the most part latent; but under the stimulus of trauma, fever, and so forth it may at any time be called into activity and provoke a visible herpetic lesion.*"

Although their relationships to HSV and VZV were by no means appreciated, the more subtle members of the herpesvirus family began to be discovered after an interval of many hundreds of years. The first of these was human cytomegalovirus (HCMV), which was initially associated with human disease through the detection of enlarged cells containing unusual cytoplasmic inclusions in the urine and organs of infants who were born with signs of intrauterine damage that had been attributed to syphilis. In the early 1950s, HCMV as well as VZV were the first human herpesviruses to be isolated in cultured cells. Within a decade, Epstein-Barr virus (EBV) particles were found in Burkitt's lymphoma cells and EBV was shown to be associated with mononucleosis. By the mid-1990s, three more human herpesviruses, HHV-6A, HHV-6B and HHV-7, which share a tropism for T lymphocytes, were discovered and the etiologic agent of the unusual vascular skin tumor called 'Kaposi's sarcoma, first described in 1872, was identified as "Kaposi's sarcoma-asscoiated herpesvirus (KSHV, HHV8). These four new human herpesviruses were identified during the early years of the human immunodeficiency virus (HIV) epidemic because these viruses caused aggressive disease in HIV-infected patients or were discovered during intensive research on human T cell biology. In each instance, discovery of the human herpesviruses paralleled technologic progress, illustrated by animal models for HSV, cell culture methods for VZV and CMV, the cultivation of B lymphocytes for the detection of EBV and of T lymphocytes for identification of HHV-6 and 7, and differential nucleic acid detection for revealing the existence of HHV8.

Molecular genetics methods demonstrate that the human herpesviruses share a common ancestor. However, each virus has evolved to occupy a particular niche during millions of years of co-evolution with their primate, and eventually human, host. Understanding the nuances of the adaptive strategies that have allowed all of these viruses to be transmitted efficiently and to persist so successfully in the human population, and often in the same individual, constitutes a fascinating enterprise. At the same time, infections caused by these ubiquitous viruses create a substantial global burden of disease affecting healthy and immunocompromised patients and among people living in developed and developing countries. Because of their serious and potentially life-threatening consequences, the human herpesviruses are medically important targets for basic and clinical research.

The goal of this book is to describe the remarkable recent progress towards elucidating the basic and clinical virology of these human pathogens, in conjunction with a summary of the many new insights about their epidemiology, mechanisms of pathogenesis and immune control, approaches to clinical diagnosis and the recognition of the clinical illnesses that result from primary and recurrent herpesvirus infections across the age spectrum. All of the herpesviruses have common genes, structures, replication strategies and mechanisms of defense against the host response but each virus also has unique properties that allow it to find its particular ecological refuge. An unexpected outcome of research over the past decade is the finding that the human herpesviruses have devised many different ways to achieve the same biologic effect, as illustrated by their unique strategies for down-regulation of major histocompatibility complex proteins. Functional similarities exist among these viruses even when they do not share similar genes or infect similar tissues. Each chapter of the book explores these viral themes and variations from the virologic and clinical perspectives. The contributions of the many distinguished authors highlight the basic science aspects of the field, emphasizing the comparative virology of the human herpesviruses and virus-host cell interactions, and the significant clinical developments, including antiviral drugs and vaccines, that are essential for the best practice of medicine in the 21st century. The concluding chapter illustrates how therapies for cancer may emerge from these advances in basic and clinical research, to create a fundamentally new era in the complex history of the relationship between the human herpesviruses and their hosts.

The editors are deeply grateful for the generosity of the authors who have shared their comprehensive knowledge of the human herpesviruses. We hope that this book will serve as a resource for investigators and physicians, and most importantly, that it will motivate a new generation of students and trainees to address the many unresolved questions about these herpesviruses as agents of human disease. Since the genomes of all of these viruses have been sequenced, it is obvious that many genes exist for which functions have not been identified and we now understand that most herpesviral proteins can be expected to have multiple functions. Basic research on the human herpesviruses also reveals fundamental facts about human cellular biology, including surface receptors, metabolic pathways, cell survival mechanisms, malignant transformation as well as innate antiviral defenses. In the clinical realm, every improvement in diagnostic methods expands the spectrum of clinical disorders that are recognized as being caused by these viruses. Clinical interventions exist that could not have been imagined fifty years ago but the need for better therapeutic and preventive measures has become even more apparent as the burden of herpesvirus disease is defined with precision. Given that four human herpesviruses have been discovered in the past 15 years, are there others?

Part I

Introduction: definition and classification of the human herpesviruses

Edited by Bernard Roizman

Overview of classification

Andrew J. Davison

MRC Virology Unit, Institute of Virology, Glasgow, UK

Introduction

Taxonomy aims to structure relationships among diverse organisms in order to provide a broader understanding of Nature than is afforded by consideration of organisms in isolation. Since biological systems are shaped by evolution, which is not influenced by the human desire to impose order, any taxonomical scheme is bound to be incomplete and to some extent arbitrary. The criteria applied are necessarily confined to what is technically possible, and thus taxonomy has an important historical component. In addition, taxonomy develops conservatively, since striving for the ideal must be tempered by the need to maintain utility. It is also an unfortunate fact that taxonomy provides fertile soil for debate among a few but is of little interest to most. However, it is beyond dispute that the setting of herpesviruses in a taxonomical framework is vital for understanding the origins and behavior of this fascinating family of organisms.

Historically, herpesvirus taxonomy has been addressed since 1971 by the International Committee on Taxonomy of Viruses (ICTV) (Wildy, 1971). A provisional approach to endowing herpesviruses with formal names (Roizman *et al.*, 1973) was followed by grouping into subfamilies largely on the basis of biological criteria (Roizman *et al.*, 1981). This effort was rather successful, but not free from what turned out in hindsight to be a few misclassifications (Roizman *et al.*, 1992). Further division of the subfamilies into genera utilized molecular data to a greater extent than before, primarily in relation to genome characteristics such as size and structure (Roizman *et al.*, 1992). In the latest report of the ICTV Herpesvirus Study Group (Davison *et al.*, 2005), the family *Herpesviridae* consists of three subfamilies: *Alphaherpesvirinae* (containing the *Simplexvirus*, *Varicellovirus*, *Mardivirus* and *Iltovirus* genera), *Betaherpesvirinae* (containing the *Cytomegalovirus*, *Muromegalovirus* and *Roseolovirus* genera) and *Gammaherpesvirinae* (containing the *Lymphocryptovirus* and *Rhadinovirus* genera). In addition, there is a genus (*Ictalurivirus*) unattached to any subfamily and a large number of species not assigned to genera. The current list is given in Table 1.1. All but one of the viruses assigned to taxa infect mammals or birds, although a substantial number of unassigned herpesviruses have lower vertebrate (reptilian, amphibian and fish) or invertebrate (bivalve) hosts.

Morphological criteria

The primary criterion for inclusion of an agent in the family *Herpesviridae* is that of virion morphology. The virion is spherical, and comprises four major components: the core, the capsid, the tegument and the envelope (see Chapter 3). The diameter of the virion depends on the viral species, but is approximately 200 nm. The core consists of a single copy of a linear, double-stranded DNA molecule packaged at high density into the capsid. The capsid is an icosahedron, and has an external diameter of 125–130 nm. It consists of 162 capsomeres, 12 of which are pentons and 150 hexons, each containing five and six copies, respectively, of the major capsid protein. The capsomeres are joined via the triplexes, each of which contains two copies of one protein and one copy of another. The tegument, which surrounds the capsid, contains perhaps 30 or more viral protein species and is poorly defined structurally. In the tegument, structures positioned with symmetry corresponding to that of the capsid are detectable only in the region close to the capsid. The lipid envelope surrounds the exterior of the tegument, and is studded with at least ten viral membrane

Table 1.1. Herpesvirus taxonomy and nomenclature

Formal name[a]	Abbrev.	Common name[b]	Abbrev.[c]
Subfamily Alphaherpesvirinae			
Genus Simplexvirus			
Ateline herpesvirus 1	AtHV-1	Spider monkey herpesvirus	
Bovine herpesvirus 2	BoHV-2	Bovine mamillitis virus	
Cercopithecine herpesvirus 1	CeHV-1	B-virus	HVB
Cercopithecine herpesvirus 2	CeHV-2	SA8 virus	
Cercopithecine herpesvirus 16	CeHV-16	Herpesvirus papio 2	
Human herpesvirus 1	HHV-1	Herpes simplex virus [type] 1	HSV-1
Human herpesvirus 2	HHV-2	Herpes simplex virus [type] 2	HSV-2
Macropodid herpesvirus 1	MaHV-1	Parma wallaby herpesvirus	
Macropodid herpesvirus 2	MaHV-2	Dorcopsis wallaby herpesvirus	
Saimiriine herpesvirus 1	SaHV-1	Herpesvirus tamarinus	
Genus Varicellovirus			
Bovine herpesvirus 1	BoHV-1	Infectious bovine rhinotracheitis virus	BHV-1
Bovine herpesvirus 5	BoHV-5	Bovine encephalitis virus	BHV-5
Bubaline herpesvirus 1	BuHV-1	Water buffalo herpesvirus	
Canid herpesvirus 1	CaHV-1	Canine herpesvirus	
Caprine herpesvirus 1	CpHV-1	Goat herpesvirus	
Cercopithecine herpesvirus 9	CeHV-9	Simian varicella virus	SVV
Cervid herpesvirus 1	CvHV-1	Red deer herpesvirus	
Cervid herpesvirus 2	CvHV-2	Reindeer herpesvirus	
Equid herpesvirus 1	EHV-1	Equine abortion virus	
Equid herpesvirus 3	EHV-3	Equine coital exanthema virus	
Equid herpesvirus 4	EHV-4	Equine rhinopneumonitis virus	
Equid herpesvirus 8	EHV-8	Asinine herpesvirus 3	
Equid herpesvirus 9	EHV-9	Gazelle herpesvirus	
Felid herpesvirus 1	FeHV-1	Feline rhinotracheitis virus	
Human herpesvirus 3	HHV-3	Varicella-zoster virus	VZV
Phocid herpesvirus 1	PhoHV-1	Harbour seal herpesvirus	
Suid herpesvirus 1	SuHV-1	Pseudorabies virus	PRV
Tentative species in genus Varicellovirus			
Equid herpesvirus 6	EHV-6	Asinine herpesvirus 1	
Genus Mardivirus			
Gallid herpesvirus 2	GaHV-2	Marek's disease virus type 1	MDV-1
Gallid herpesvirus 3	GaHV-3	Marek's disease virus type 2	MDV-2
Meleagrid herpesvirus 1	MeHV-1	Turkey herpesvirus	HVT
Genus Iltovirus			
Gallid herpesvirus 1	GaHV-1	Infectious laryngotracheitis virus	ILTV
Unassigned species in subfamily Alphaherpesvirinae			
Psittacid herpesvirus 1	PsHV-1	Parrot herpesvirus	
Subfamily Betaherpesvirinae			
Genus Cytomegalovirus			
Cercopithecine herpesvirus 5	CeHV-5	African green monkey cytomegalovirus	SCMV
Cercopithecine herpesvirus 8	CeHV-8	Rhesus monkey cytomegalovirus	RhCMV
Human herpesvirus 5	HHV-5	Human cytomegalovirus	HCMV
Pongine herpesvirus 4	PoHV-4	Chimpanzee cytomegalovirus	CCMV
Tentative species in genus Cytomegalovirus			
Aotine herpesvirus 1	AoHV-1	Herpesvirus aotus 1	
Aotine herpesvirus 3	AoHV-3	Herpesvirus aotus 3

glycoproteins, in addition to some cellular proteins. The protein composition of the tegument and envelope varies widely across the family.

Serological criteria

In contrast to virion morphology, which operates as a criterion at the level of the family, serological relationships are useful only for detecting closely related viruses. Neutralizing antibodies form a subset of serological tools, and are directed against some of the envelope glycoproteins.

Biological criteria

The observation that several distinct herpesviruses have been found in the most extensively studied animals implies that the number of herpesvirus species in Nature must far exceed that catalogued to date. The natural host range of individual viruses is usually restricted to a single species. Occasional transfer to other species can occur, although it could be argued that the settings involved (farms, zoos and keeping pets) are the results of human activities. In experimental animal systems, some members of the *Alphaherpesvirinae* can infect a wide variety of species, whereas *Beta-* and *Gammaherpesvirinae* are very restricted. The same general observation characterizes growth in cell culture.

Herpesviruses are highly adapted to their hosts, and severe symptoms of infection are usually limited to very young or immunosuppressed individuals. Natural transmission routes range from aerosol spread to mucosal contact. Most herpesviruses establish a systemic infection associated with a cell-associated viraemia, although infection with some members of genus *Simplexvirus* is limited to the epithelium at the inoculation site and to innervating sensory neurons. Herpesviruses have elaborate means of modulating the host responses to infection, and are able to establish lifelong latent infections. In simplified, general terms, the cell types involved in latency are the neuron for the *Alphaherpesvirinae*, the monocyte lineage for the *Betaherpesvirinae*, and lymphocytes for the *Gammaherpesvirinae*.

Genomic criteria

Herpesvirus genomes studied to date range in size from about 125 to 240 kbp, and the most extensively characterized contain from about 70 to 165 genes. Prior to the generation of extensive sequence data, genome structures (see Chapter 2) were an aid to classification. However, the usefulness of this criterion is limited, since similar structures have evidently evolved more than once in the family. Nucleic acid hybridization data also provided input and, like serological data, are limited to demonstrating relationships between closely related viruses. As with other groups of organisms, data derived from nucleotide and amino acid sequences have gained increasing prominence and now dominate herpesvirus taxonomy. Figure 1.1 shows one example of such data, a phylogenetic tree based upon amino acid sequence alignments (McGeoch *et al.*, 1994, 1995, 2000). Another approach yielded different schemes of relationships, but was based on analytical criteria not widely accepted in depicting evolutionary relationships (Karlin *et al.*, 1994).

It has long been thought from the apparent adaptation of herpesviruses to their hosts that a substantial degree of co-evolution has occurred. Similarities between the phylogenetic relationships among the viruses and those among their hosts provide strong support for this model, and in some instances indicate that co-speciation has occurred. A number of possible exceptions have been noted and are discussed in further detail in Chapter 2.

Species definition

A virus species is defined as a polythetic class of viruses constituting a replicating lineage and occupying a particular ecological niche (Van Regenmortel, 1989, 1990). Members of a polythetic class share a subset of properties, with each property possessed by several members but no property possessed by all. Herpesviruses are defined as separate species if their nucleotide sequences differ in a readily assayable and distinctive manner across the entire genome and if they occupy different ecological niches by virtue of their distinct epidemiology and pathogenesis or their distinct natural hosts (Roizman *et al.*, 1992; Roizman and Pellett, 2001; Davison *et al.*, 2005). However, genomic data have come to dominate biological properties, with taxa corresponding to genetic lineages defined by sequence comparisons and identification of genes unique to certain lineages. An increasing number of herpesviruses in the tissues of various animals are being inferred from short PCR-derived sequences, usually from a single locus in the genome and often in the absence of any other information. These "virtual viruses" cannot readily be classified under the current species definition. However, their incorporation (perhaps in a special category) could be facilitated by

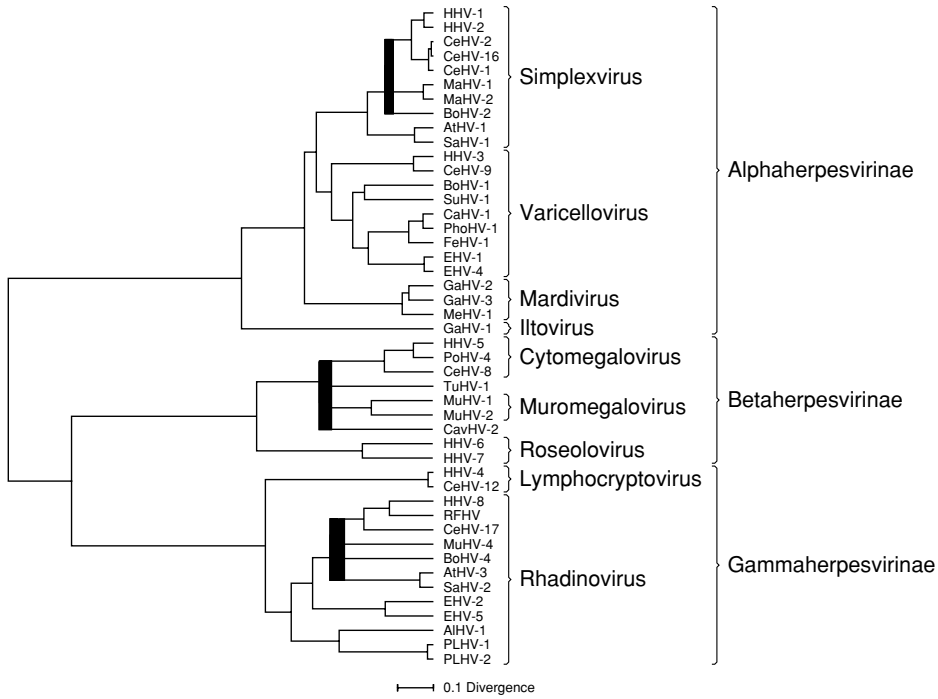

Fig. 1.1. Composite phylogenetic tree for herpesviruses. The tree is based on amino acid sequence alignments of eight sets of homologous genes, constructed from maximum-likelihood trees for subsets of these genes, with molecular clock imposed. Thick lines designate regions of uncertain branching. Formal species abbreviations and designations for genera and subfamilies are given on the right (see Table 1.1). Viruses that are not yet incorporated formally into genera are denoted in italics. Three unclassified viruses are included (RFHV, retroperitoneal fibromatosis herpesvirus of macaques; PLHV-1 and PLHV-2, porcine lymphotropic herpesviruses 1 and 2). Modified from McGeoch *et al.* (2000) with permission from the American Society for Microbiology.

addition to the species definition of a third criterion, that of phylogeny based on the relatedness of conserved genes. Recognition that taxonomy should reflect evolutionary history would also aid rational incorporation of herpesviruses of lower vertebrates and invertebrates into a taxonomy that is currently dominated by herpesviruses of higher vertebrates. Current problems in this area, and a suggested solution, are given in Chapter 2.

Acknowledgment

I am grateful to Duncan McGeoch for a critical reading of this chapter.

Comparative analysis of the genomes

Andrew J. Davison

MRC Virology Unit, Institute of Virology, Glasgow, UK

Introduction

Members of the family *Herpesviridae* replicate their genomes in the infected cell nucleus and have a characteristic virion morphology, which consists of the envelope, tegument, capsid and core (Davison and Clements, 1997). An extensive description of virion structure is given in Chapter 3. The present chapter focuses on the viral genome, which occupies the core of the virus particle. Electron microscopy of negatively stained capsids gives the impression that the core consists of the viral DNA molecule wrapped toroidally around a protein spindle (Furlong *et al.*, 1972). Images reconstructed from electron micrographs of virions frozen in ice in the absence of stain, a technique by which morphology is better preserved, show that the core consists of the DNA packed at high density in liquid crystalline form, probably as a spool lacking a spindle (Booy *et al.*, 1991; Zhou *et al.*, 1999).

Herpesvirus genomes consist of linear, double-stranded DNA molecules that range in size from about 125 to 240 kbp and in nucleotide composition from 32 to 75% G+C, depending on the virus species (Honess, 1984). The genome termini are not covalently closed (as in the *Poxviridae;* Moss, 2001) or covalently linked to a protein (as in the *Adenoviridae*; Shenk, 2001). In those herpesvirus genomes that have been examined in sufficient detail, unpaired nucleotides are present at the termini; for example, HSV-1, VZV and HCMV have a single 3′-overhanging nucleotide at each terminus (Mocarski and Roizman, 1982; Davison, 1984; Tamashiro and Spector, 1986). Larger herpesvirus genomes are accommodated in larger capsids, but the relationship is not proportional, as the packing density of the DNA varies somewhat between species (Trus *et al.*, 1999; Bhella *et al.*, 2000). The reasons for the striking range in nucleotide composition of herpesvirus genomes are not clear, but a similar phenomenon is found in other virus families and in cellular organisms. In contrast to the *Alpha-* and *Betaherpesvirinae*, the genomes of most *Gammaherpesvirinae* are generally deficient in the CG dinucleotide (Table 2.1). In vertebrate genomes, this phenomenon is thought to be due to spontaneous deamination of 5-methylcytosine residues in DNA to thymidine residues, followed by fixation through DNA replication. CG depletion in herpesviruses, and concomitant enrichment in TG and CA, has been taken as indicative of latency in dividing cell populations, in which the latent genome is obliged to replicate as host cells divide (Honess *et al.*, 1989). Thus, HSV-1, which is resident in non-dividing neurons, has a CG content consistent with its nucleotide composition, whereas EBV, which latently infects dividing B cell populations, is depleted. Local CG suppression of the major immediate early gene locus of HCMV has also been noted (Honess *et al.*, 1989).

Genome structures

Herpesvirus genomes are not simple lengths of unique DNA, but characteristically contain direct or inverted repeats. The reasons for this are not known, but it is intriguing that similar structures appear to have arisen independently on several occasions during herpesvirus evolution. Herpesvirus genomes are thought to replicate by circularization, followed by production of concatemers and cleavage of unit-length genomes during packaging into capsids (Boehmer and Lehman, 1997). The explanation for the presence of repeats is probably connected in some way with the mode of DNA replication, rather than with any advantage gained by having multiple copies of certain genes. Although greater expression would be a consequence of repeated genes, this appears a simplistic explanation in an evolutionary context, since subtler processes of nucleotide

[a] Square brackets indicate the strain that was used most extensively in assembling a sequence combining data from several strains. A hyphen indicates that the strain was not specified.

[b] Sizes were obtained from the latest version of the accessions, and may differ from those in the references through correction of errors. Square brackets indicate sequences that fall marginally short of full length: for MDV-1 and HCMV strains, sequences are for bacterial artificial chromosomes, the sizes representing a deleted form of the genome plus the vector; for HHV-8 strains, the sequence at the right end of the unique region was not determined. For members of subfamily *Gammaherpesvirinae* other than EHV-2, actual genome sizes are larger than those listed (approximately 150–180 kbp), owing to the presence of variable copy numbers of terminal repeats at both ends of the genome. Where a single value is given, this represents either the unique region flanked by partial terminal repeats or the unique region only. Where two values are given, the first is for the unique region and the second is for the terminal repeat.

[c] G + C content is given as moles %, CG content is given as observed/expected frequency, taking into account overall nucleotide composition. Where multiple strains have been sequenced for a species, values are given for one strain only. For members of the *Gammaherpesvirinae*, values are given for the deposited sequences, which consist either of the unique region flanked by partial terminal repeat sequence, the unique region only, or separate accessions for the unique region and terminal repeat.

[d] This taxon is used for the purposes of discussion, and, unlike the others in the Table, has no formal standing.

[e] PsHV-1 is the closest relative of ILTV and is placed informally in this genus.

[f] MHV-68 strains g2.4 and WUMS are essentially identical, since the latter was derived from the former.

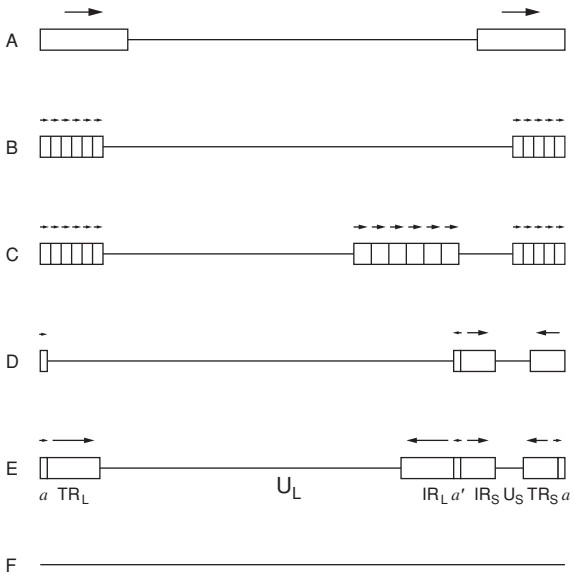

Fig. 2.1. Classes of herpesvirus genome structures (not to scale) as defined by Roizman and Pellett (2001). Unique and repeat regions are shown as horizontal lines and rectangles, respectively. The orientations of repeats are shown by arrows. The nomenclature of unique and repeat regions, including the terminal redundancy (*a*) and its internal, inverted copy (*a*′), is indicated for the class E genome.

substitution can readily alter transcriptional levels over a much greater range. In addition, repeats often do not contain protein-coding regions. As elaborated below, certain genomes exhibit a further structural complexity known as segment inversion, in which unique regions flanked by inverted repeats are found in both orientations in virion DNA. Thus, a genome with two such unique regions would produce either two or four isomers depending on whether one or both regions invert. This phenomenon is probably a consequence of recombination between repeats in concatemeric DNA. Isomers are functionally equivalent (Jenkins and Roizman, 1986), and segment inversion appears to be unrelated to the biology of the virus.

Figure 2.1 shows the major classes of genome structure found among the herpesviruses, as summarized by Roizman and Knipe (2001). The class A genome consists of a unique sequence flanked by a direct repeat. It was first described for CCV (Chousterman *et al.*, 1979), but is also represented among the *Betaherpesvirinae* (HHV-6: Lindquester and Pellett, 1991; Martin *et al.*, 1991; HHV-7: Dominguez *et al.*, 1996; Ruvolo *et al.*, 1996) and one member of the *Gammaherpesvirinae* (EHV-2; Browning and Studdert, 1989). In these examples, the direct repeat is several kbp in size. Other members of the *Betaherpesvirinae* also have this arrangement, but the repeat is smaller, at 504 bp in RCMV (Vink *et al.*, 1996) and 30–31 bp in MCMV (Marks and Spector, 1988; Rawlinson *et al.*, 1996).

Class B genomes also have directly repeated sequences at the termini, but these consist of variable copy numbers of a tandemly repeated sequence of 0.8–2.3 kbp. This arrangement characterizes most *Gammaherpesvirinae* in the *Rhadinovirus* genus, such as HVS and HHV-8 (Bornkamm *et al.*, 1976; Russo *et al.*, 1996). The repeated regions may comprise up to 30% of the DNA molecule (Bornkamm *et al.*, 1976; Lagunoff and Ganem, 1997). The presence of additional terminal repeat sequences in inverse orientation internally in the genome gives rise to a related structure, which is present in another member of the *Gammaherpesvirinae*, cottontail rabbit herpesvirus (Cebrian *et al.*, 1989). The virion DNA of this virus exhibits segment inversion because the two unique regions are flanked by inverted repeats. The class C structure represents another derivative of class B, in which an internal set of direct repeats is present but is unrelated to the terminal set. EBV, a member of the *Gammaherpesvirinae* in the *Lymphocryptovirus* genus, has this arrangement (Given and Kieff, 1979). Segment inversion does not occur because the internal and terminal repeats are not related.

Class D genomes contain two unique regions (U_L and U_S), each flanked by inverted repeats (TR_L/IR_L and TR_S/IR_S). This structure is characteristic of *Alphaherpesvirinae* in the *Varicellovirus* genus, such as PRV and VZV (Rixon and Ben-Porat, 1979; Dumas *et al.*, 1981), and has also evolved separately in salmonid herpesvirus 1 (Davison, 1998). Segment inversion occurs inasmuch as equimolar amounts of genomes containing the two orientations of U_S are found in virion DNA, but U_L is present predominantly or completely in one orientation. The latter feature cannot be explained solely by recombination, and is probably due also to the presence of the cleavage signal solely or largely in the region comprising TR_L/IR_L and one end of U_L (Davison, 1984; Rall *et al.*, 1991).

Class E is the most complex genome structure, and was the first to be described, for HSV-1 (Sheldrick and Berthelot, 1975). It is similar to class D, except that TR_L/IR_L is much larger and segment inversion gives rise to four equimolar genome isomers (Wadsworth *et al.*, 1975; Hayward *et al.*, 1975; Delius and Clements, 1976; Clements *et al.*, 1976; Wilkie and Cortini, 1976). Also, class E genomes are terminally redundant, containing a sequence of a few hundred bp (termed the *a* sequence) that is repeated directly at the genome termini and inversely at the IR_L-IR_S junction (Sheldrick and Berthelot, 1975; Grafstrom *et al.*, 1975a,b; Wadsworth *et al.*, 1976; Hyman *et al.*, 1976).

Minor proportions of genomes contain multiple copies of the *a* sequence at the left terminus or the IR_L-IR_S junction (Wilkie, 1976; Wagner and Summers, 1978; Locker and Frenkel, 1979). The class E arrangement is characteristic of *Alphaherpesvirinae* in the *Simplexvirus* genus, and has evolved independently in the lineage giving rise to HCMV and CCMV, members of the *Betaherpesvirinae* (Weststrate *et al.*, 1980; DeMarchi, 1981; Davison *et al.*, 2003a). A structure similar to both class D and E genomes has also evolved in an invertebrate herpesvirus, OsHV-1 (Davison *et al.*, 2005). This contains two segments, each consisting of a unique region flanked by an substantial inverted repeat, linked via an additional small, non-inverting unique region. As in class E genomes, the two segments undergo inversion, but, like class D, the genome is not terminally redundant.

Class F is represented by a member of the *Betaherpesvirinae*, THV, which apparently lacks the types of inverted and direct repeats that characterize other herpesvirus genomes (Koch *et al.*, 1985; Albrecht *et al.*, 1985). However, since the genome ends of THV have not been analyzed directly, the existence of this unusual structure is considered tentative.

Genome sequences

Table 2.1 lists the 39 herpesvirus species for which genome sequences are currently available in the public databases. Additional strains have been sequenced for some species, yielding a total of 63 sequenced strains. The ease of generating data will continue to expand the number of herpesvirus species and strains sequenced in coming years. Indeed, substantial inroads have been made into large-scale studies of strain variation for certain of the human herpesviruses. It appears that the scale and extent of variation is lineage dependent, with *Betaherpesvirinae* more variable than *Gammaherpesvirinae*, and *Alphaherpesvirinae* the least variable (Murphy *et al.*, 2003b; Dolan *et al.*, 2004; Poole *et al.*, 1999; Midgley *et al.*, 2003; Muir *et al.*, 2002; Gomi *et al.*, 2002). The development of tools to study variation in increasing detail will enhance understanding of viral epidemiology, in terms both of its relation to human evolution and migration and of the changes that are occurring in human populations at the present time.

Gene content

Sequencing herpesvirus genomes is now routine, but the process of describing gene content (annotation) is not trivial. Thus, as with other groups of organisms, the quality of annotation of herpesvirus entries in the public databases varies widely. It is an unfortunate fact that no set of objective criteria is sufficient to interpret the gene content of a sequence completely. Although most genes can be catalogued relatively easily, there are genuine difficulties in identifying all of them, even in the best characterized herpesviruses.

A primary criterion in defining gene content involves identifying open reading frames (ORFs), usually those initiated by methionine (ATG) codons. A tendency to include ORFs that do not encode proteins may be reduced by setting a minimum size. Comparative genomics, which operates on the principle that genes are conserved in evolution, and algorithms that compare sequence patterns within ORFs to the protein-coding regions of known genes, are also useful. However, these tools yield results with least confidence when applied to small, spliced, overlapping or poorly conserved ORFs, and in instances where translation initiates from internal codons, alternative splicing occurs, or esoteric translational mechanisms are employed (e.g., suppression of termination codons and forms of translational editing). In addition to sequence analysis, experimental data on production of an RNA or protein from an ORF provides important imput, although even this falls short of proving functionality. Also, most approaches are aimed at identifying protein-coding genes, and cannot detect genes that encode functional transcripts that are not mRNAs.

The use of different criteria for gene identification may create a degree of uncertainty and debate, and lead to different pictures of gene layout. The case of HCMV provides a contemporary example. In the first analysis of the gene content of HCMV strain AD169, Chee *et al.* (1990) catalogued 189 protein-coding ORFs (counting duplicates once only). Later, the gene number was reduced to 147 by comparing the HCMV and CCMV genomes, allowing, where appropriate, for the presence of genes unique to either genome (Davison *et al.*, 2003a,b). As modified criteria were applied, this number rebounded in a series of increments, first to 157 (Yu *et al.*, 2003), next to 171 (Murphy *et al.*, 2003a), then to 220 (Murphy *et al.*, 2003b) and finally to 232 (Varnum *et al.*, 2004). Although the conservative numbers in this example are more supportable, the existence of unrecognized genes should not be ruled out even in well-characterized genomes, and candidates should be examined rigorously. For example, new genes were identified in previously analysed sequences for VZV (Kemble *et al.*, 2000) and HHV-8 (Glenn *et al.*, 1999).

The genes of HSV-1, presumably like those of all herpesviruses, are transcribed by host RNA polymerase II

(Wagner, 1985; Roizman and Knipe, 2001). Transcription of the first genes to be expressed, the immediate early genes, does not require ongoing protein synthesis, and is enhanced by a tegument protein at low multiplicities of infection (O'Hare, 1993). Some of the immediate early proteins regulate expression of early and late genes (Honess and Roizman, 1974). Early genes, defined as those expressed in the presence of immediate early proteins and before the onset of DNA replication, include enzymes involved in nucleotide metabolism and DNA replication and a number of envelope glycoproteins. Some late genes are expressed at low levels under early conditions, but full expression of "leaky" and "true" late genes is dependent on DNA replication; these genes encode mainly virion proteins. Although the details differ, a similar pattern of regulated gene expression is characteristic of all herpesviruses examined; for example, HCMV (Stinski, 1978), HHV-8 (Sarid *et al.*, 1998) and CCV (Silverstein *et al.*, 1995). In addition, herpesviruses express RNAs whose functions apparently do not involve translation. The best characterized are small RNAs probably transcribed by RNA polymerase III in *Gammaherpesvirinae* such as EBV (Rosa *et al.*, 1981) and MHV-68 (Bowden *et al.*, 1997). Larger noncoding RNAs transcribed by RNA polymerase II include the latency-associated transcripts in HSV-1 (Stevens *et al.*, 1987) and several virion-associated RNAs in HCMV (Bresnahan and Shenk, 2000).

With the exception of a small number of genes that are expressed by splicing from a common 5′-leader, such as the EBNA genes of EBV (Bodescot *et al.*, 1987) and the IE1 and IE2 genes of HCMV (Stenberg *et al.*, 1985), herpesvirus genes have individual promoters. However, it is common for genes to share a polyadenylation site, leading to families of 3′-coterminal transcripts (Wagner, 1985). Apart from families of duplicated genes, there is no pronounced clustering of genes on the basis of function or kinetics of expression. Splicing is uncommon throughout the family, affecting no more than about 20% of the gene number in any genome. Most splicing involves genes that are relatively recent evolutionary developments, and *Beta-* and *Gammaherpesvirinae* have more spliced genes than *Alphaherpesvirinae*.

Genome comparisons and evolution

The availability of extensive sequence data for herpesviruses has facilitated detailed phylogenetic analyses of the family based on amino acid sequence comparisons of conserved genes, as described in Chapter 1. In this section, an overview is given of genetic relatedness at selected levels in the phylogenetic tree, starting with the three major groups that encompass all known herpesviruses, proceeding to the best characterized of these groups, and ending with one subfamily in this group. In chronological terms, this proceeds from earlier to more recent evolutionary events. Detailed information on the gene content of, and the relationships between, the human herpesviruses is available elsewhere in this book.

Three major groups

Three major groups of viruses possess the herpesvirus morphology, including closely similar capsid structures, but share very little genetic similarity (Davison, 1992; Booy *et al.*, 1996; Davison *et al.*, 2005). Viruses in the best characterized group infect mammals, birds and reptiles, viruses in the second group infect amphibians and fish, and the third group contains the single known herpesvirus of an invertebrate, the oyster. Currently, the family *Herpesviridae* comprises the first group classified into three subfamilies and component genera, one member (CCV) of the second group representing an unassigned genus, and the oyster virus is a floating species. The most logical means of accommodating all known herpesviruses taxonomically would be to establish three families under the umbrella of a new order (*Herpesvirales*), containing herpesviruses of mammals, birds and reptiles, of amphibians and fish, and of bivalves, respectively. Since these taxa are presently a proposal and lack any formal standing, the terms mammalian, fish and bivalve herpesvirus groups are used to denote the proposed families in the following discussion.

Only three genes have clear counterparts in all three groups that are detectable by amino acid sequence comparisons. The proteins encoded by two (DNA polymerase and dUTPase) have ubiquitous cellular relatives and could have been captured independently from the host repertoire. The third gene apparently lacks a counterpart in the host cell but has distant relatives in T4 and similar bacteriophages (Davison, 1992; Mitchell *et al.*, 2002). The T4 gene is known to encode the ATPase subunit of a DNA packaging enzyme complex called the terminase (Rao and Black, 1988; Bhattacharyya and Rao, 1993), and the HSV-1 gene has properties that are consistent with a similar function (Yu and Weller, 1998).

The existence of groups of viruses that exhibit close morphological similarities but generally lack detectable genetic relationships is not unique to the herpesviruses, and may be explained as the result either of convergence

from distinct evolutionary sources or as divergence from an ancestor so ancient that sequence similarities have been obliterated. The latter hypothesis is currently favored, but the existence of a common ancestor of all herpesviruses and any contingent dates for divergence of the groups must be viewed cautiously. More speculatively, apparent similarities in aspects of DNA packaging (Booy *et al.*, 1991) and capsid maturation (Newcomb *et al.*, 1996) could be interpreted as supporting an even earlier common evolutionary origin between herpesviruses and certain double-stranded DNA bacteriophages, including T4.

Phylogenetic analyses strongly support the view that herpesviruses have largely co-evolved with their hosts, often co-speciating with them. As would be expected of evolutionary phenomena, a number of problematic observations and exceptions have emerged as data have multiplied, especially in relation to early divergences. From comparisons between the phylogenies of the viruses and their hosts, McGeoch and Cook (1994) proposed an evolutionary timescale for the *Alphaherpesvirinae* in which the *Simplex-* and *Varicellovirus* genera diverged about 73 million years ago, roughly coincident with the period of the mammalian radiation. Even at this stage, potential exceptions to the co-evolution model were apparent. For example, the taxonomical position of avian herpesviruses among the *Alphaherpesvirinae* did not fit well, and prompted the suggestion of ancient interspecies transfers between mammals and birds. In this scheme, a similar argument may be necessary to explain the position of reptilian (turtle) herpesviruses in the same subfamily (Quackenbush *et al.*, 1998; Yu *et al.*, 2001; Coberley *et al.*, 2002), especially given their distance from amphibian herpesviruses (Davison *et al.*, 1999 and unpublished data). Assuming the constancy of the molecular clock derived for the *Alphaherpesvirinae*, McGeoch *et al.* (1995) tentatively dated the divergence of the *Alpha-*, *Beta-* and *Gammaherpesvirinae* at 180–220 million years ago. Given the contrasting lack of relationships between the groups and substantial relationships within them (see below), this date did not fit well qualitatively with a model in which the fish and mammalian herpesvirus groups co-speciated when teleosts separated from other vertebrates. In a recent analysis utilizing improved algorithms and the latest estimates for host divergence dates, McGeoch and Gatherer (2005) pushed back the common ancestor of the *Alpha-*, *Beta-* and *Gammaherpesvirinae* to about 400 million years ago, which permitted a greater degree of support for co-evolution of the *Alphaherpesvirinae*, including avian and reptilian members. In this scheme, a much earlier, non-co-speciative divergence may be indicated for the mammalian and fish herpesvirus groups (along with one of similar or greater antiquity for the bivalve herpesvirus group). However, this would lack the advantage of explaining the segregation of the viral groups to distinct parts of the animal kingdom and necessitate additional arguments involving viral extinction.

The mammalian herpesvirus group

In contrast to the lack of extensive relationships between the three groups, members of the mammalian herpesvirus group are clearly related to each other (Davison, 2002), as are those in the fish herpesvirus group (Bernard and Mercier, 1993; Davison, 1998; Davison *et al.*, 1999; Waltzek *et al.*, 2005, and unpublished data). Figure 2.2 shows the gene layout in representatives of two genera for each of the three subfamilies in the mammalian herpesvirus group. The subfamilies share 43 genes, termed "core genes," which were presumably inherited from a common ancestor (McGeoch and Davison, 1999). This number assumes a small degree of approximation, since amino acid sequence conservation among the set varies from substantial to marginal. The core genes are shaded grey in Fig. 2.2, and are largely confined to the central regions of the genomes, as is especially apparent with HCMV. Accumulation of more recently evolved genes near the termini is a feature of linear, double-stranded DNA genomes from other virus families, such as the *Poxviridae* (Upton *et al.*, 2003; McLysaght *et al.*, 2003; Gubser *et al.*, 2004) and the *Adenoviridae* (Davison *et al.*, 2003c), and also of eukaryotic chromosomes (Kellis *et al.*, 2003). The core genes are ordered similarly in the same subfamily, except for certain members of the *Alphaherpesvirinae* in which different arrangements are apparent: PRV in the *Varicellovirus* genus (Ben-Porat *et al.*, 1983; Davison and Wilkie 1983; Dezelee *et al.*, 1996; Bras *et al.*, 1999) and ILTV in the *Iltovirus* genus (Ziemann *et al.*, 1998). However, as shown in Fig. 2.2, the core genes are arranged differently in the different subfamilies, in the form of blocks, some of which are inverted (Davison and Taylor, 1987; Gompels *et al.*, 1995; Hannenhalli *et al.*, 1995). As indicated in Table 2.2, core genes are involved in vital aspects of herpesvirus growth, and many are involved directly or indirectly in DNA replication, in packaging of replicated DNA into capsids, and in capsid formation and structure. Most of the core genes are essential for growth of virus in cell culture (Ward and Roizman, 1994; Yu *et al.*, 2003; Dunn *et al.*, 2003).

Most core genes are present in all three subfamilies of the mammalian herpesvirus group, but three (encod-

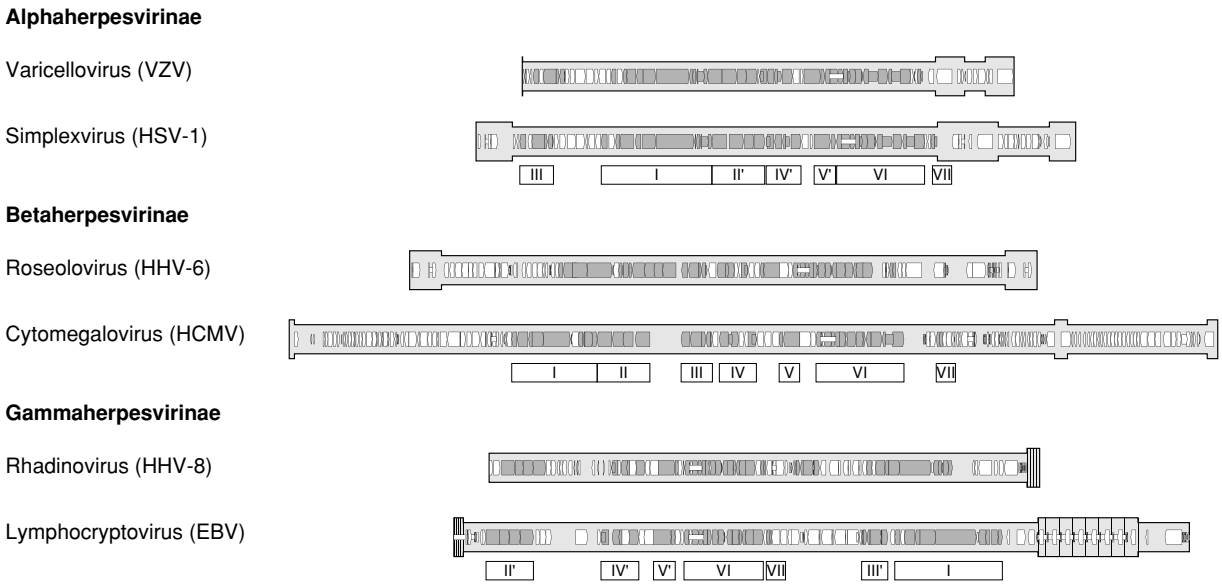

Fig. 2.2. Layout of genes in mammalian herpesvirus genomes. Repeat regions are shown in thicker format than unique regions. Protein-coding regions are shown as arrows shaded grey (core genes) or white (non-core genes), and introns as narrow white bars. Blocks of core genes that are rearranged between the subfamilies are indicated by rectangles I–VII for HSV-1, HCMV and EBV, with inverted blocks marked with a prime (Chee *et al.*, 1990). Block II also contains a local inversion and transposition of one gene (encoding DNA polymerase) that is not indicated. Genome coordinates and gene locations were obtained from accessions X04370 (VZV), X14112 (HSV-1), X83413 (HHV-6) as modified by Megaw *et al.* (1998), AY446894 (HCMV), U93872 (HHV-8) as extended at the right end of the unique region by Glenn *et al.* (1999), and AJ507799 (EBV). Variable numbers of terminal repeats are present in HHV-8 and EBV, but are shown at one end or the other other according to the accessions.

ing thymidine kinase, the small subunit of ribonucleotide reductase and the helicase that binds to the origin of DNA synthesis) have been lost from individual lineages. Thus, the origin-binding helicase gene has been retained in the *Roseolovirus* genus, but lost from other genera in the *Betaherpesvirinae*. This is mirrored in the presence of an origin of lytic DNA replication with similar structure in lineages that have retained this gene (Dewhurst *et al.*, 1993; Inoue *et al.*, 1994).

In addition to protein-coding regions, certain *cis*-acting sequences are conserved. These include the origin of lytic DNA replication, which is located similarly in each subfamily in comparison with adjacent genes, allowing for rearrangement of gene blocks. Certain members of the *Alpha-* and *Gammaherpesvirinae* contain additional lytic origins. Also, short elements near the genome termini that are involved in cleavage and packaging of unit-length genomes are conserved in all subfamilies (Broll *et al.*, 1999).

As well as the part played by the gradual processes of nucleotide substitution, insertion or deletion in generating diversity, acquisition of genes from the cell or from other viruses has played an important role throughout the evolution of the herpesviruses. There are examples of captured genes in all herpesvirus lineages. Among the mammalian herpesvirus group, the *Gammaherpesvirinae* exhibit a particularly impressive number of such genes, ranging from one encoding a product related to an enzyme involved in *de novo* purine biosynthesis (phosphoribosylformylglycineamide amidotransferase; FGARAT; Ensser *et al.*, 1997), which is present in all *Gammaherpesvirinae*, through a cyclin D gene (Nicholas *et al.*, 1992), which features in a subset of the *Rhadinovirus* genus, interferon regulatory factor genes (vIRFs), which are found only in HHV-8 and RRV (Russo *et al.*, 1996; Searles *et al.*, 1999), to a relatively recently captured core 2 β-1,6-*N*-acetylglucosaminyltransferase-mucin gene in BHV-4 (Markine-Goriaynoff *et al.*, 2003).

Duplication of genes, captured or otherwise, followed by divergence, is also apparent in all herpesvirus lineages. For example, up to three copies of the FGARAT gene are present in *Gammaherpesvirinae* (Virgin *et al.*, 1997), and HHV-8 and RRV contain four and eight vIRF genes, respectively (Searles *et al.*, 1999; Jenner *et al.*, 2001; Cunningham *et al.*, 2003). Examples of duplicated genes among other members of the mammalian herpesvirus group include

Table 2.2. Core genes in human herpesviruses, grouped according to functional class. HSV-2 and HHV-7 are not included, since their nomenclatures are the same as those for HSV-1 and HHV-6, respectively. HSV-1 and HCMV genes that are essential for growth in cell culture are marked by asterisks

HSV-1	VZV	HCMV	HHV-6	EBV	HHV-8	Function
DNA replication machinery

[a] Probably not an active enzyme, as catalytic residues are absent.
[b] This assignment is tentative and is excluded from the total of 43 core genes given in the text. It depends on positional, rather than sequence, conservation, and is compromised by that fact that UL21 is not flanked in each subfamily by clear homologues, unlike other core genes assigned on a positional basis.
[c] Also referred to as UL49.5.

a family of glycoprotein genes in the *Alphaherpesvirinae* (McGeoch, 1990) and 12 families, each containing up to 14 genes, in HCMV as a representative of the *Betaherpesvirinae* (Dolan *et al.*, 2004). There are four gene families in the fish herpesvirus, CCV (Davison, 1992), and 12 in the bivalve herpesvirus, OsHV-1 (Davison *et al.*, 2005). Given that gene duplication has been widely employed in host evolution (Prince and Pickett, 2002), and the greater evolutionary rates of herpesviruses, it seems likely that this means for generating diversity has played a greater part in herpesvirus evolution than can be detected by primary sequence comparisons.

The *Alphaherpesvirinae* subfamily

The employment of gene capture and duplication among the *Beta-* or *Gammaherpesvirinae* to generate diversity has received extensive attention in the literature (for details, see Chapters 15 and 22). In contrast, the *Alphaherpesvirinae* have evolved less adventurously in terms of gene content since their divergence from a common ancestor, and it is clear that gene loss has occurred. This mode of survival is considered in the following paragraphs.

The *Alphaherpesvirinae* contain four genera, plus the reptilian herpesviruses. Several complete genomes have been sequenced for the *Simplexvirus*, *Varicellovirus* and *Mardivirus* genera (Table 2.1). Data for the *Iltovirus* genus are more sparse. Limited sequence data are available for reptilian herpesviruses. Figure 2.3 illustrates the genetic content of members of the *Varicello-*, *Simplex-* and *Mardivirus* genera. Three examples (VZV, EHV-1 and BHV-1) were chosen to represent the major lineages in the *Varicellovirus* genus (see Chapter 1), plus SVV as a close relative of VZV. Core genes are shown in grey, and other genes that have counterparts in all three genera are shown in white. All of these genes were presumably present in the common ancestor, which is estimated to have existed 135 million years ago (McGeoch and Gatherer, 2005), and they comprise all or nearly all of the genes in extant *Alphaherpesvirinae*. It seems that only a few genes have developed since that era, and that the most of these are located near the genome termini.

Figure 2.4 shows a scheme of relationships between the genes at the left end of the genome, based on sequence conversation and the observation that two genes (UL56 and ORF1) encode potential membrane proteins. Also included are data for PRV (whose closest sequenced relative is BHV-1), MDV-2 and ILTV. Since U_L inverts in HSV-1, and U_L in the prototype genome orientation turned out to be inverted in comparison with the *Varicellovirus* genus (Hayward *et al.*, 1975; Wadsworth *et al.*, 1975), the genes at the left end of HSV-1 U_L are presented in the reverse order. In Fig. 2.4,

Fig. 2.3. Layout of genes in genomes of the *Alphaherpesvirinae*. Repeat regions are shown in thicker format than unique regions. Protein-coding regions are shown as arrows shaded grey (core genes), white (other genes shared by two or more genera) or black (other genus-specific genes that have presumably evolved more recently), and introns as narrow white bars. Genome coordinates and gene locations were obtained from accessions listed in the legend to Fig. 2.2, and from AF275348 (SVV), M86664 (EHV-1), AJ004801 (BHV-1) and AF243438 (MDV-1).

UL56 and UL55 thus precede UL54, which is a core gene. VZV has two extra genes (ORF1 and ORF2) sandwiched between UL55 and UL56, and the other viruses have between one and four genes in this region. For example, SVV lacks ORF2 and has a partial duplication of UL54 near the end of the genome. A parsimonious approach indicates that the ancestor preceding divergence of the *Iltovirus* genus had at least one of the genes at the left genome terminus (UL56; 180 million years ago; McGeoch and Gatherer, 2005), that the ancestor preceding divergence of the *Mardivirus* genus had at least three (UL56 (since lost), UL55 and ORF2; 135 million years ago), that the ancestor of the *Varicellovirus* and *Simplexvirus* genera had at least three (UL56, UL55 and ORF2; 120 million years ago) and that the ancestor of VZV and EHV-1 had all four genes (82 million years ago). Various of these genes have been lost during subsequent evolution of the mammalian viruses.

Gene loss is also apparent at the right genome terminus (Fig. 2.4), where, again, few genes are specific to one virus or a few closely related viruses. Even the more recently evolved genes may have substantial histories. Of the three HSV-1 genes in this category, two at the right end of U_S (US11 and US12) have counterparts in related viruses of monkeys (HVB and SA8; Ohsawa *et al.*, 2002; Tyler *et al.*, 2005). HSV-1 and HVB are considered to have co-speciated with their hosts about 23 million years ago (McGeoch *et al.*, 2000). The gene at the left genome terminus (RL1; repeated internally) has a counterpart at a similar location in a wallaby herpesvirus genome (Guliani *et al.*, 2002).

Outlook

Investigation of the genome structures, genetic contents and evolution of herpesviruses is a maturing field that undergirds the rest of herpesvirology. As with other complex analytical subjects, future advances will require incisive examination of both new data and the framework into which they are fitted. There is yet room for more surprises.

"It is a mistake to try to look too far ahead. The chain of destiny can only be grasped one link at a time." *Winston Churchill.*

Acknowledgment

I am grateful to Duncan McGeoch for many helpful discussions and for a critical reading of this chapter.

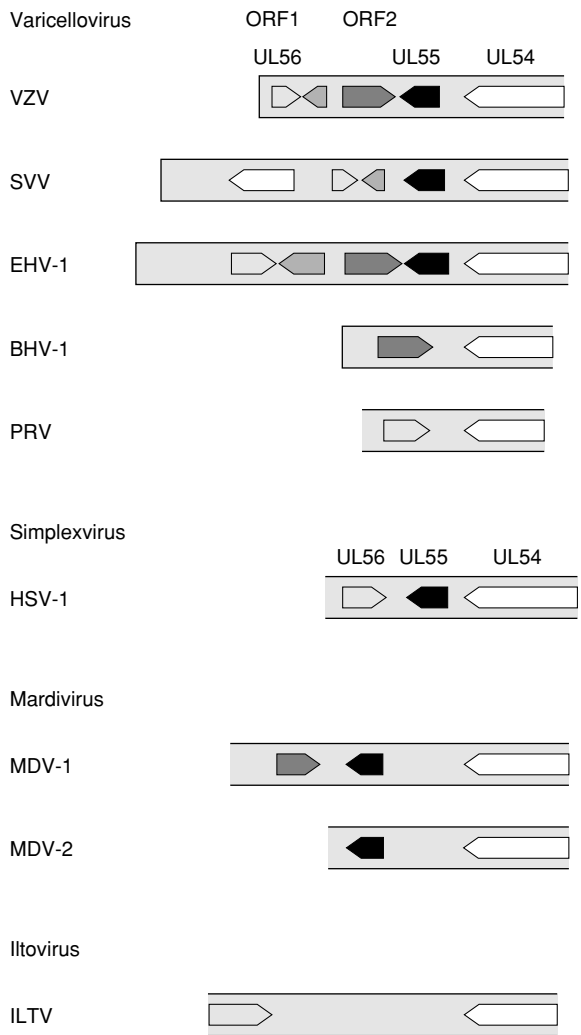

Fig. 2.4. Layout of genes at or near the left terminus in genomes of the *Alphaherpesvirinae*. The left terminus, where included, is shown by a vertical line. Homologous genes are shaded equivalently, and their nomenclature is indicated. An additional non-homologous gene is present in the *Mardi-* and *Iltovirus* genomes down stream from UL55, but is not shown. Gene locations were derived or deduced from accessions listed in the legend to Fig. 2.3, and from BK001744 (PRV), AB049735 (MDV-2) and U80762 (ILTV).

Introduction

The herpesvirus family consists of a group of viruses distinguished by the large size of their linear double-stranded DNA genomes (~130–250 kbp) and a common architecture of infectious particles (Fig. 3.1) (Chiu and Rixon, 2002; Gibson, 1996; Steven and Spear, 1997). Indeed, before the birth of molecular biology and the availability of genomic sequencing, the common hallmark structural features shared by these viruses were the most important criteria for the classification of a herpesvirus (Roizman and Pellett, 2001). All herpesviruses identified to date, which include eight different types that are known to infect human, and more than 170 other viruses that are found in animals as well as in fish and amphibians (Roizman and Pellett, 2001), exhibit identical structural design as illustrated using human cytomegalovirus shown in Fig. 3.1. These viruses have a highly ordered icosahedral-shape nucleocapsid of about 125–130 nm in diameter, which encases the viral DNA genome. The nucleocapsid is surrounded by a partially ordered proteinaceous layer called the tegument, which in turn is enclosed within the envelope, a polymorphic lipid bilayer containing multiple copies of more than 10 different kinds of viral glycoproteins that are responsible for viral attachment and entry to host cells.

Based on their biological properties such as growth characteristics and tissue tropism, herpesviruses can be further divided into three subfamilies. Among the eight human herpesviruses, the alpha subfamily includes neurotropic viruses and contains the herpes simplex virus (HSV) 1 and 2, and Varicella zoster virus (VZV). The members of the gamma subfamily are lymphotropic viruses and include Epstein–Barr virus (EBV) and Kaposi's sarcoma-associated herpesvirus (KSHV). The viruses of the beta subfamily appear to be able to establish infections in many different types of cells and tissues, and include human cytomegalovirus (HCMV), and human herpesvirus 6 and 7. This subfamily classification system is largely consistent with the extensive genomic information that is now available (McGeoch *et al.*, 2000). While studies have been attempted to investigate the structure and architecture of each of the eight human herpesviruses, virion and virus-related particles of herpes simplex virus 1 (HSV-1), the prototype of all herpesviruses, have been subjected to the most extensive structural studies (Booy *et al.*, 1991; Newcomb *et al.*, 1993, 2000; Schrag *et al.*, 1989; Trus *et al.*, 1996; Zhou *et al.*, 1999, 2000). During the last several years, significant progress has also been made in understanding the structure of cytomegaloviruses (Bhella *et al.*, 2000; Chen *et al.*, 1999; Trus *et al.*, 1999), the prototype of the beta herpesvirus family, and KSHV, a representative of the gamma herpesvirus family (Lo *et al.*, 2003; Nealon *et al.*, 2001; Trus *et al.*, 2001; Wu *et al.*, 2000). Using HSV-1, HCMV, and KSHV as examples for each of the subfamilies, this chapter focuses primarily on the structures of these three viruses, and discusses the recent progress on understanding the structures of human herpesviruses.

Different virus-related particles found in infected cells

Summary of virion assembly pathway

Each of the herpesviruses encodes a specific set of proteins that form the different compartments of the virion (e.g. capsid, Table 3.1). Although many of the primary amino acid sequences of these proteins are not highly conserved among different viruses, the assembly pathway of the virus particles is highly similar (Fig. 3.2) (Gibson, 1996; Roizman and Knipe, 2001; Yu *et al.*, 2003). The nucleocapsid

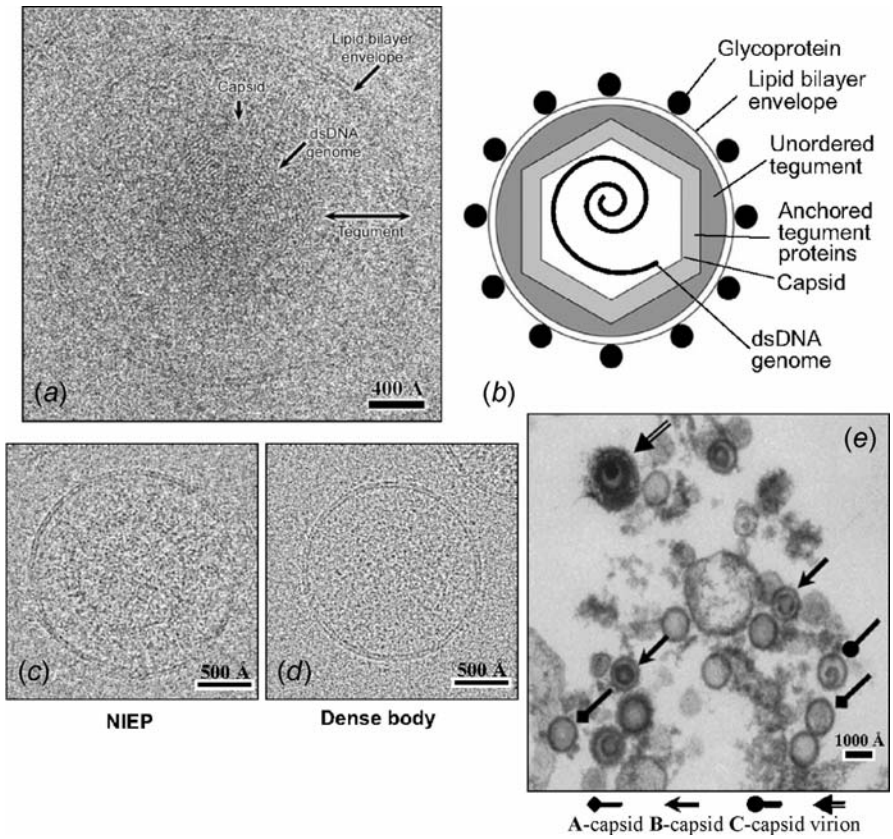

Fig. 3.1. Herpesvirus architecture. (*a*) Electron cryomicrograph of a human cytomegalovirus virion showing the different compartments of a herpes virion. (*b*) Schematic diagram illustrating the multilayer organization of human herpesviruses. Also shown are the electron cryomicrograph of a non-infectious enveloped particle (NIEP) (*c*) and a dense body (*d*) isolated from HCMV virion preparations. (*e*) Virions and different kinds of capsids observed in the thin sections of human foreskin fibroblasts infected with HCMV by negative stain electron microscopy.

is formed in the nucleus and follows a pathway that bears a marked resemblance to those of DNA bacteriophages (Casjens and Hendrix, 1988). First, a procapsid is assembled with the formation of the capsid shell and the internal scaffolding structure. Second, the procapsid is converted into mature nucleocapsid, during which time, the morphogenic internal scaffolding protein is released and replaced by the viral DNA genome, concomitant with a major conformation change of the capsid shell (Newcomb *et al.*, 1999; Yu *et al.*, 2005). Subsequent events, however, differ from the phage assembly pathway (Fig. 3.2). The mature nucleocapsid exits the nucleus and acquires its tegument and envelope, through repeated fusion with and detachment from nuclear membranes and other cellular membranous structures. Eventually, the mature infectious virion particles are released into the extracellular space via cellular secretory pathways. During this assembly process, different virus-related particles and structures, including the mature nucleocapsids and virions as well as the intermediate and aberrant products, can be found in the infected cells and the extracellular media (Figs. 3.1(*c*)–(*e*) and 3.2).

Different virus-like particles secreted from infected cells

Since the discovery of the herpesviruses, it has been long recognized that, in addition to producing infectious virus particles, the infected host cells also generate noninfectious particles such as noninfectious enveloped particles (NIEP, Fig. 3.1(*c*)) and dense bodies (DB) (Figs. 3.1(*d*) and 3.2) (Gibson, 1996; Steven and Spear, 1997). Both NIEP and DB are commonly found in the culture media of cells that are lytically infected with HSV-1 and HCMV. The ratio

Table 3.1. Major virion proteins present in HSV-1, HCMV and KSHV

		HSV-1			HCMV			KSHV			
Location	Common name	Protein name	ORF	Size (aa)	Protein name	ORF	Size (aa)	Protein name	ORF	Size (aa)

Abbreviations: MCP, major capsid protein; TRI-2, triplex dimer protein; TRI-1, triplex monomer protein; SCP, smallest capsid protein; Pr, protease; AP, assembly protein.

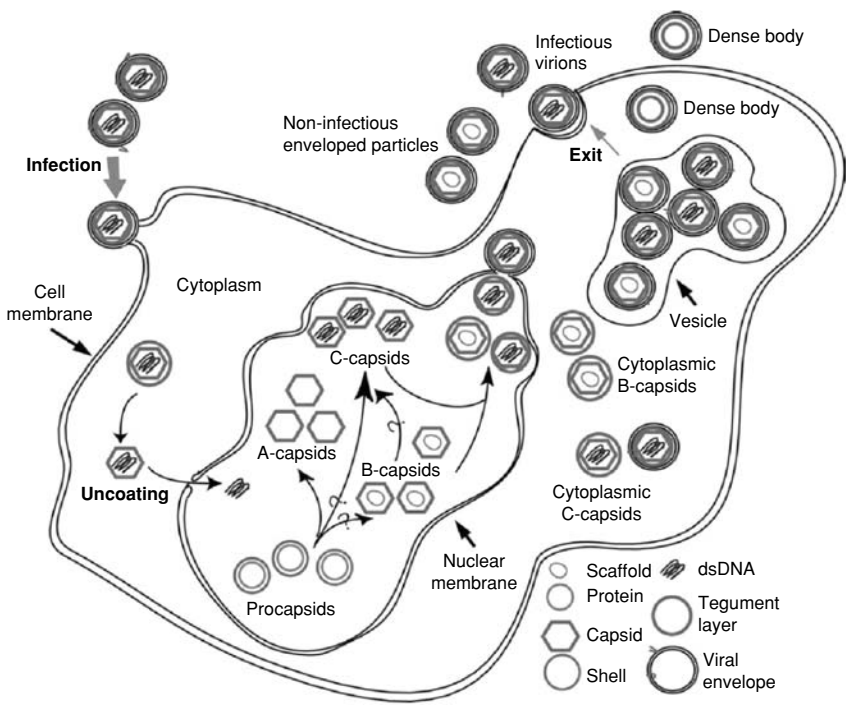

Fig. 3.2. Different virus-like particles and structures during lytic cycle of herpesvirus replication. The infectious virion initializes infection by either endocytosis or fusion with the cell membrane, which releases the nucleocapsid and some tegument proteins into the cytoplasm. The nucleocapsid is uncoated and transported across the cytoplasm (Sodeik *et al.*, 1997), allowing injection of the viral DNA through nuclear pores into the nucleus, where replication and capsid assembly take place. Procapsids mature into the C-capsid by encapsidating the viral dsDNA. Failure of DNA encapsidation results in the abortive A-capsid. Both B-capsid and C-capsid can acquire a layer of tegument proteins at the nuclear membrane of the host cell to become cytoplasmic capsids, and are enveloped and released by exocytosis to become non-infectious (NIEP) and infectious particles, respectively. Dense bodies, which contain a large amount of tegument proteins but no capsids or viral DNA, can also be found in the extracellular media.

of these particles to mature infectious virion particles can sometimes reach 20:1, suggesting that they are produced in great excess (Gibson, 1996; Steven and Spear, 1997). The exact function of these non-infectious particles in viral infection and replication is currently unknown, although they have been proposed to act as decoys that saturate and overwhelm the immune surveillance thereby facilitating the survival of the infectious virions in the hosts (Gibson, 1996; Steven and Spear, 1997).

Structurally, both the NIEP and DB are significantly different from the infectious virion (*cf.* Fig. 3.1(*a*), (*c*), (*d*)). They can be easily distinguished using electron cryomicroscopy (cryoEM) and separated from the mature infectious virions using ultracentrifugation approaches. As described above, all infectious herpesvirus virions share four common structural features (Fig. 3.1(*b*)). First, all herpesviruses contain a large double-stranded DNA (dsDNA) genome. The genomic DNA represents a dense core of ~90 nm in diameter, which can be stained with uranyl acetate and visualized using electron microscopy (Gibson, 1996; Steven and Spear, 1997) and appears as "fingerprint" patterns when examined by electron cryomicroscopy (Fig. 3.1(*a*)) (Booy *et al.*, 1991; Zhou *et al.*, 1999). Second, a capsid of icosahedral shape, which primarily consists of many copies of four different viral proteins, encases the genomic DNA. Third, a protein layer structure, named as the tegument first by Roizman and Furlong (Roizman and Furlong, 1974), surrounds the capsid and occupies the space between the capsid and the envelope. The tegument structure contains many virus-encoded factors that are important for initiating viral gene transcription and expression as well as modulating host metabolism and shutting down host antiviral defense mechanism (for a brief review, see Roizman and Sears, 1996). Finally, a lipid-bilayer envelope constitutes the outermost perimeters of the particles, and contains all the surface virion glycoproteins that are responsible for viral infectivity and entry (Fig. 3.1).

Unlike infectious virion particles, a NIEP does not contain a genomic DNA core and its capsid core appears to be B-capsid-like under electron microscopy (Figs. 3.1(*c*) and 3.2). In contrast, a dense body does not contain a capsid and appears as a cluster of tegument proteins encased by the lipid-bilayer membranous envelope (Fig. 3.1(*d*)). The presence of NIEP and DB indicates that neither packaging of viral genome nor capsid formation is required for viral envelopment.

Different capsid-like structures inside the infected cells

The capsid assembly is a continuous sequential process, leading to the synthesis of the highly ordered capsid structures. In cells that are lytically infected with herpesviruses, several kinds of virus capsid-like structures have been identified as representing stable endpoints or long-lived states (Figs. 3.1 and 3.2). Gibson and Roizman first introduced the terms A-, B-, and C-capsids to describe these intracellular capsid-like structures in HSV-1 infected cells (Gibson and Roizman, 1972). Similar capsid structures have been observed in cells infected with HCMV (Gibson, 1996; Irmiere and Gibson, 1985). Recent work has revealed A-, B- and C-capsids of comparable chemical composition and structural features in the nuclei of gammaherpesvirus infected cells and this suggests that the gammaherpesvirus capsid assembly probably also proceeds in a similar manner (O'Connor *et al.*, 2003; Yu *et al.*, 2003). These capsids all have a distinctive polyhedral shape when examined under electron microscope. Another capsid type, termed procapsid, can be obtained from in vitro assembly experiments using recombinant capsid proteins or from cells infected by a HSV-1 mutant containing a temperature sensitive mutation at the gene encoding the viral protease (Rixon and McNab, 1999; Trus *et al.*, 1996). The procapsid has a distinctive spherical shape and is only transiently stable. They undergo spontaneous structural rearrangement to become the stable angular or polyhedral form similar to the other types of capsids (Heymann *et al.*, 2003; Yu *et al.*, 2005; Zhou *et al.*, 1998b). A-capsids represent empty capsid shells that contain neither viral DNA nor any other discernible internal structure. They are thought to arise from abortive, dead-end products derived from either the inappropriate loss of viral DNA from a C-capsid or the premature release of scaffolding protein from a B-capsid without concurrent DNA packaging (Gibson, 1996). B-capsids are capsid shells containing an inner array of scaffolding protein. C-capsids are mature capsid shells that are packaged with viral DNA and do not contain the scaffolding proteins. B-capsids are believed to be derived from the procapsids upon proteolytic cleavage of the scaffolding protein, and their fate in viral maturation is controversial. Early pulse-chase experiments have suggested that B-capsids can mature to C-capsids, which in turn serve as the infectious virus precursors (Perdue *et al.*, 1976), and recent studies suggest that they might also be a dead-end product in capsid assembly similar to A-capsids (Trus *et al.*, 1996; Yu *et al.*, 2004). It remains unclear whether the spherical procapsids first adapt to the stable angular form before or after the cleavage of its scaffolding protein. The C-capsid buds through the nuclear membrane using an envelopment and de-envelopment process and acquires an additional layer of proteins that forms the tegument in the cytoplasm (for review, see Mettenleiter, 2002). Enveloped virions are then released by exocytosis (Fig. 3.2).

Assembly of viral capsid

A-, B- and C-capsids represent the stable intermediates or the end products of the herpesvirus capsid assembly process (Figs. 3.1(*e*) and 3.2). In HSV-1, capsid assembly begins with the formation of the spherical procapsid through the association of the carboxyl terminus of the scaffolding protein with the amino terminus of the viral major capsid protein (MCP), similar to bacteriophage proheads (Conway *et al.*, 1995; Jiang *et al.*, 2003). Previous experiments have shown that the procapsid can be assembled in vitro from the capsid and scaffolding proteins, in the absence of the viral capsid maturation protease (Newcomb *et al.*, 1999) or from cells infected with viruses containing a temperature-sensitive protease mutant (Heymann *et al.*, 2003). These procapsids can spontaneously rearrange into a large-cored, angular particle resembling the B-capsid, but these large-cored particles do not encapsidate DNA or become mature virions. Past studies have also shown that cells infected with a HSV-1 mutant containing a temperature-sensitive mutation in the protease gene produced capsids that assemble at the non-permissive temperature, similar to the in vitro-assembled procapsids (Rixon and McNab, 1999). The capsids matured when protease activity was restored (Rixon and McNab, 1999), demonstrating that the procapsid is the precursor to the angular capsid (Fig. 3.2). The proteolytic cleavage of the intra-capsid scaffolding proteins at their C-termini by the viral protease (Hong *et al.*, 1996; Liu and Roizman, 1991, 1992; Preston *et al.*, 1992; Welch *et al.*, 1991) interrupts the interactions between the scaffolding proteins and the major capsid proteins (Zhou *et al.*, 1998b). The interactions between the scaffolding protein, the major capsid protein, and viral protease are important targets for antiviral drug design in treating and controlling herpesvirus infections (Flynn *et al.*, 1997; Qiu *et al.*, 1996; Shieh *et al.*, 1996; Tong *et al.*, 1996, 1998). Proteolytic cleavage of the scaffolding protein is followed by the recruitment of the smallest capsid protein, VP26, through an ATP-dependent process (Chi and Wilson, 2000), leading to the formation of the intermediate or B-capsids. The mature procapsids are believed to arise spontaneously by packaging the viral genome DNA, a process that is currently not completely understood (Yu *et al.*, 2005).

Compositions and three-dimensional structural comparisons of alpha, beta and gammaherpesvirus capsids

A-, B-, and C-capsids (Yu *et al.*, 2005) can be isolated from the nucleus of the host cells lytically infected by herpesviruses and they have been subjected to three-dimensional structure studies for HSV-1 (Zhou *et al.*, 1998a, 1994), HCMV (Butcher *et al.*, 1998; Chen *et al.*, 1999; Trus *et al.*, 1999), and KSHV (Nealon *et al.*, 2001; Trus *et al.*, 2001; Wu *et al.*, 2000; Yu *et al.*, 2003). While these three types of capsids have different composition (e.g., viral DNA and internal scaffolding protein), they all have a common shell structure that consists of 150 hexameric (hexon) and 12 pentametric (penton) capsomers, which are connected in groups of three by the triplexes, asymmetric structures that lie on the capsid floor (Fig. 3.3). During the last few years, considerable progress of the three-dimensional structure of the capsids and the assembly of the capsomers and triplexes has been made on the studies.

The capsid, approximately 1250–1300 Å in diameter, is a $T = 16$ icosahedron with 12 pentons forming the vertices, 150 hexons forming the faces and edges, and 320 triplexes interconnecting the pentons and hexons (Rixon, 1993; Steven and Spear, 1997). One of the 20 triangular faces of the icosahedral capsid is indicated by the dotted triangle in Fig. 3.3(*a*) with three fivefold ('5'), a twofold ('2') and threefold (through triplex Tf) symmetry axes labeled. The six fivefold axes pass through the vertices, the ten threefold (3f) axes pass through the centers of the faces, and the 15 twofold (2f) axes pass through the middle of the edges. The structural components in one asymmetric unit are labeled, including 1/5 of a penton ('5'), one P (peri-pentonal) hexon, one C (center) hexons a half E (edge) hexon (Steven *et al.*, 1986), and one each of Ta, Tb, Tc, Td and Te triplex and 1/3 of Tf triplex (Fig. 3.3(*a*)) (Zhou *et al.*, 1994).

HSV-1 is the easiest to grow among all human herpesviruses and has been subjected to the most thorough structural analyses, and its capsid has been reconstructed to 8.5 Å resolution (Fig. 3.3(*a*)) (adapted from Zhou *et al.*, 2000 with permission from the publisher). The capsid shell has a total mass of about 200 MDa. The structural features of the capsid are built from four of the six capsid proteins: 960 copies of the major capsid protein (MCP), VP5; 320 copies of triplex monomer protein (TRI-1), VP19c; 640 copies of triplex dimer protein (TRI-2), VP23; and 900 copies of the smallest capsid protein (SCP), VP26. At this high resolution, details of secondary structure can be resolved that are not visible at lower resolution. Alpha-helices, for example, appear as extended, cylindrical rods of 5–7 Å diameter. The VP5 major capsid protein of HSV-1 was found to contain 24 helices. These assignments of helices to densities were corroborated by docking the cryoEM structure with X-ray crystallographic data which were subsequently obtained for the upper domain of VP5 (Fig. 3.3(*c*)) (Baker *et al.*, 2003; Bowman *et al.*, 2003). A group of seven helices is clustered near the area of the protein that forms the narrowest part of the

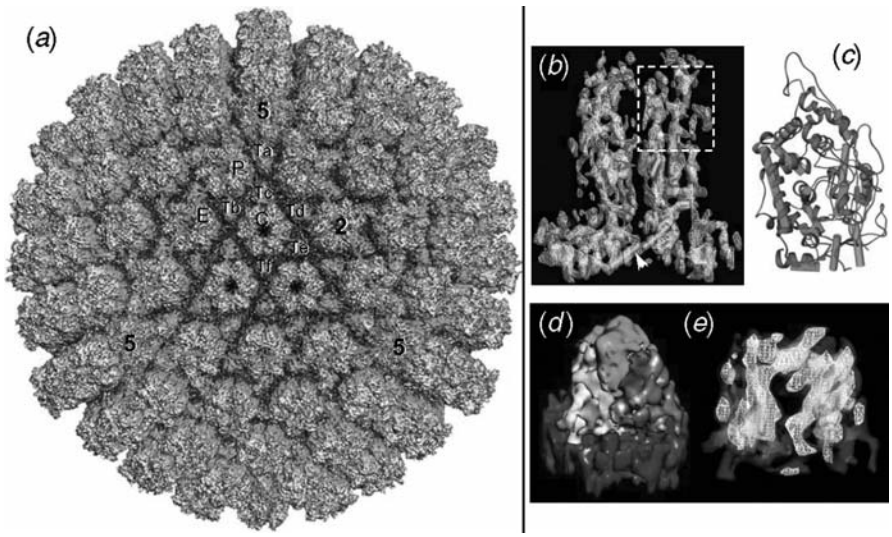

Fig. 3.3. HSV-1 capsid at 8 Å resolution (Zhou *et al.*, 2000) and atomic model of upper domain of the major capsid protein (MCP), VP5 (Bowman *et al.*, 2003). (*a*) Radially color-coded surface representation of the HSV-1 B capsid structure at 8.5 Å. One of the 20 triangular faces is denoted by dashed triangle. The penton and three types of hexons are indicated by '5', P, E and C. Also labeled are the six quasi-equivalent triplexes, Ta, Tb, Tc, Td, Te, Tf. (*b*) Two hexon subunits were shown in wire frame representation with α helices identified in one of the VP5 subunit illustrated by orange cylinders (5 Å in diameter). The red arrowhead points to the 7 helix bundle in the middle domain and the white arrow identifies the long helix in the floor domain that connects adjacent subunits.
(*c*) Ribbon representation of the atomic structure of the HSV-1 MCP upper domain determined by X-ray crystallography (Bowman *et al.*, 2003). The helices identified in the hexon VP5 subunit in the 8.5 Å HSV1 capsid map (Zhou *et al.*, 2000) are shown as cylinders: those in green match with helices present in the X-ray structure and those in yellow are absent in the X-ray model, suggesting possible structural differences of MCP packed in the crystal and inside the virion. (*d*) One single triplex is shown as shaded surface representation with individual subunits in different colors: VP19c in green and the two quasi-equivalent VP23 subunits in light and dark grey, all situated on the capsid shell domains of VP5 (blue). (*e*) α-helices identified in the two quasi-equivalent VP23 molecules (in red and yellow cylinders of 5 Å diameter, respectively). Adapted with permissions from publishers. (See color plate section.)

axial channel of the pentons and hexons (indicated by the red arrowhead in Fig. 3.3(*b*)). Shifts in these helices might be responsible for the constriction that closes off the channel to prevent release of packaged DNA. The floor domain of VP5 also contains several helices, including an unusually long one that interacts with the scaffolding core and may also interact with adjacent subunits to stabilize the capsid (arrow in Fig. 3.3(*b*)). Structural studies of in vitro assembled capsids that are representatives of capsid maturation stages suggest that substantial structural rearrangement at this region is directly related to the reinforcement of penton and hexons during morphogenesis (Heymann *et al.*, 2003).

The higher resolution of this reconstruction also revealed the quaternary structure of the triplexes, which are composed of two molecules of VP23 and one molecule of VP19c (Fig. 3.3(*d*), (*e*)). The lower portion of the triplex, which interacts with the floor of the pentons and hexons, are threefold symmetric with all three subunits roughly equivalent. This arrangement alters through the middle of the triplex such that the upper portion is composed mostly of VP23 in a dimeric configuration. It appears that all three subunits of the triplex are required for the correct tertiary structure to form because VP23 in isolation exists only as a molten globule with no distinct tertiary structure (Kirkitadze *et al.*, 1998).

The capsids of other human herpesviruses have also been studied by electron cryomicroscopy, including HCMV and simian cytomegalovirus (SCMV), and KSHV, members of the beta and gammaherpesviruses, respectively (Fig. 3.4) (Bhella *et al.*, 2000; Chen *et al.*, 1999; Trus *et al.*, 1999, 2001; Wu *et al.*, 2000). The HCMV capsid structure is very similar to HSV-1 in overall organization, with four homologous structural proteins at the same stoichiometries (Fig. 3.4(*a*) and (*b*)). The main difference is that the HCMV capsid had a larger diameter (650 Å) than HSV-1 (620 Å), resulting in a volume ratio of 1.17 (Bhella *et al.*, 2000; Chen *et al.*, 1999; Trus *et al.*, 1999). The increased size of the HCMV

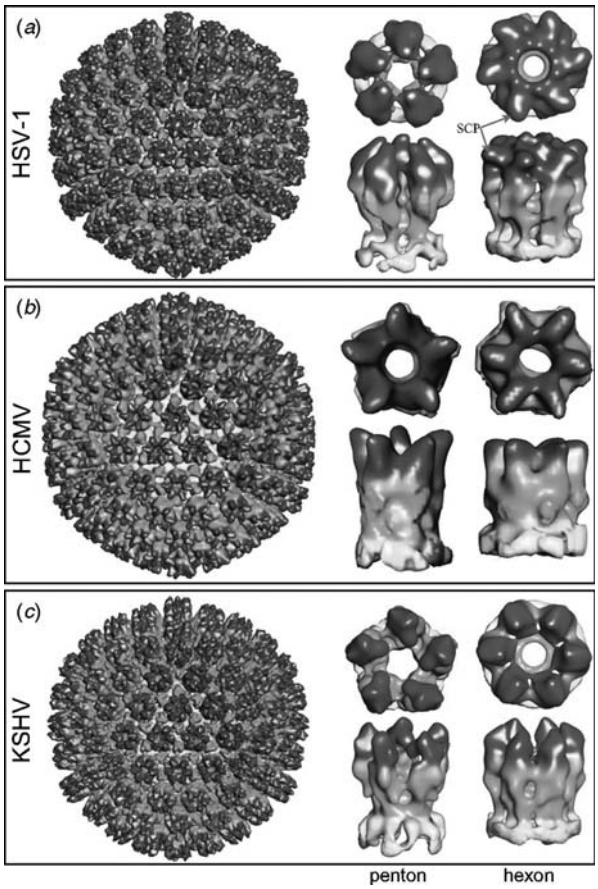

Fig. 3.4. Comparison of the three-dimensional structures of alpha, beta and gammaherpesvirus capsids. The capsid maps of HSV-1 (*a*), HCMV (*b*) and KSHV (*c*) are shown as shaded surfaces colored according to particle radius and viewed along an icosahedral three-fold axis. The resolution of the HSV-1 and KSHV capsid maps is 24 Å and that of the HCMV capsid (Butcher *et al.*, 1998) is 35 Å. The right two columns are detailed comparisons of a penton and an E hexon, which were extracted computationally from each map and shown in their top and side views. (See color plate section.)

capsid despite the similar molecular mass of its component proteins results in a greater center-to-center spacing of the capsomers compared to HSV-1 (Fig. 3.4(*b*)).

The structure of KSHV capsids was also determined by cryoEM to 24 Å resolution and exhibit structural features very similar to those of HSV-1 and HCMV capsids (Fig. 3.4(*c*)) (Trus *et al.*, 2001; Wu *et al.*, 2000). The KSHV and HSV-1 capsids are identical in size and capsomer organization. However, some notable differences are seen upon closer inspection. The KSHV capsid appears slightly more spherical than the HSV-1 capsid, which exhibits a somewhat angular, polyhedral shape. When viewed from the top, the hexons in the KSHV capsid appear flower-shaped, whereas those of HSV-1 have slightly tilted subunits and as a result appear more gear-shaped (see below). Also, the KSHV triplexes are slightly smaller and deviate less from threefold symmetry than the much-elongated triplexes in the HSV-1 capsid. The differences in the upper domains of HSV-1 and KSHV triplexes indicate that the HSV-1 triplexes are slightly taller. The radial density profiles show that the KSHV and HSV-1 capsids have identical inner radii of 460 Å (Wu *et al.*, 2000). Because both viruses also have similar genome sizes, their identical inner radii suggest that their DNA packing densities inside the capsids are similar. In contrast, betaherpesvirus capsids, such as those of HCMV, have a somewhat larger internal volume than HSV-1 or KSHV capsids (Bhella *et al.*, 2000; Chen *et al.*, 1999; Trus *et al.*, 1999). However, the increase in volume is disproportionate to the large increase in the size of the HCMV genome over the HSV-1 and KSHV genomes. This implies that the viral DNA is more densely packed into HCMV virions than into HSV-1 or KSHV virions.

In herpesvirus capsids, both the penton and hexon have a cylindrical shape (about 140-Å diameter, 160-Å height) with a central, axial channel approximately 25 Å in diameter (Fig. 3.4). The penton and hexon subunits both have an elongated shape with multiple domains, including upper, middle, lower, and floor domains. The middle domains of the subunits interact with the triplexes. The lower domains connect the subunits to each other and form the axial channels. While the upper domains of adjacent hexon subunits interact with one another, adjacent penton subunits are disconnected at their upper domains, resulting in the V-shaped side view of the pentons (Fig. 3.4). Another major difference between the penton and hexon concerns their floor domains. These domains play an essential role in maintaining capsid stability, as suggested by the higher-resolution structural studies of the HSV-1 capsid (Zhou *et al.*, 2000), where a long α-helix inserts into the floor domain of the adjacent subunit (Fig. 3.3(*b*)). The relative angle between the floor and lower domains is about 110° in the penton subunit and becomes less than 90° in the hexon subunit, making the penton to appear longer in its side view.

The HSV-1 penton and hexon subunits have the same basic shape as the HCMV and KSHV subunits (Fig. 3.4). Each consists of upper, middle, lower, and floor domains. However, the upper domains of the HSV-1 penton subunits point inward toward the channel, whereas those of the HCMV and KSHV penton subunits point outward. The upper domain of the KSHV subunit has a rectangular

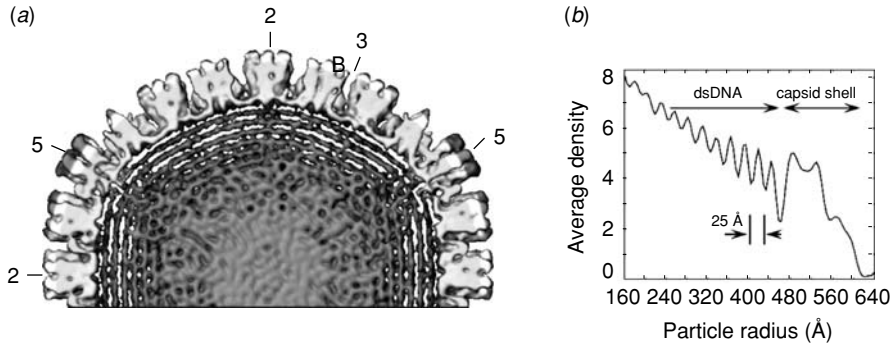

Fig. 3.5. Packing of dsDNA inside herpesvirus capsid (Yu *et al.*, 2003). (*a*) The upper half of a 100-Å thick central slice extracted from the 21 Å resolution reconstruction of the C-capsid of the rhesus rhadinovirus (RRV), a gammaherpesvirus and the closest KSHV homologue. The slice exhibits high-density features organized as multiple spherical shells inside the inner surface of the capsid floor. At least six concentric shells can be distinguished before the pattern becomes indistinct toward the center of the capsid. (*b*) Radial density distribution of the C-capsid obtained by spherically averaging the C-capsid reconstruction and plotted as a function of radius. It is evident that the distance between neighboring peaks is about 25 Å.

shape, while that of the HSV-1 penton subunit appears as a triangle. The most striking difference is that the HSV-1 hexon subunits contain an extra horn-shaped density which is not found in the HSV-1 penton (Fig. 3.4(*a*), arrow in right panel). This extra density binds to the top of each HSV-1 hexon subunit and has been shown to be the SCP, VP26, by difference imaging (Trus *et al.*, 1995; Zhou *et al.*, 1995), which associate with one another to form a hexameric ring around the hexon at a radius of approximately 600 Å. This accounts for the tilted or gear-like appearance of the HSV-1 hexon top view. The KSHV homolog of HSV-1 VP26 is ORF65. Difference map of anti-ORF65 antibody labeled and unlabeled KSHV capsids also showed that ORF65 binds only to the upper domain of the major capsid proteins in hexons but not to those in pentons (Lo *et al.*, 2003). The lack of horn-shaped densities on the hexons indicates that KSHV SCP exhibits substantially different structural features from HSV-1 SCP. The location of SCP at the outermost regions of the capsid suggests a possible role in mediating capsid interactions with the tegument and cytoskeleton proteins during infection.

Structure and packaging of viral genomic DNA

The sizes of the dsDNA genomes of different human herpesviruses vary substantially, e.g., the HCMV genome is 51% longer than HSV-1 (Davison *et al.*, 2003; McGeoch *et al.*, 2000). The major point of interest concerns the packing of their genomes within the capsids. The HCMV capsid is 117% larger than HSV-1. Besides the volume, factors such as DNA density, capsid capacity, and capsid expansion can also influence DNA packaging in viruses. The genome of HCMV might be more densely packed than that of HSV-1, or might induce expansion of the capsid upon packaging. Alternatively, the two viruses might have a similar capacity but differ in the amount of unoccupied space at the center of the capsids.

In HSV-1, the genomic DNA within the nucleocapsid is closely packed into multiple shells of regularly spaced densities, with 26 Å between adjacent DNA duplexes (Zhou *et al.*, 1999). The central slice and radial density plot in Fig. 3.5 indicate that the C-capsid of Rhesus rhadinovirus (RRV), a gammaherpesvirus, has an almost identical pattern of DNA organization to those observed in HSV-1, though slightly more compact, with a 25-Å inter-duplex distance (Yu *et al.*, 2003). Although the RRV capsid, like the KSHV capsid, has nearly the same diameter as the HSV-1 capsid (1250 Å), RRV has a slightly larger genome size than HSV-1, ~165 vs. 153 kb, respectively (Alexander *et al.*, 2000; Lagunoff and Ganem, 1997; Renne *et al.*, 1996; Searles *et al.*, 1999). Therefore, the smaller inter-duplex distance may merely reflect the need to compact this greater amount of DNA into the same volume within the capsid. HCMV has the largest genome (~230 kb) of all human herpesviruses but has a capsid that is only slightly larger (1300 Å diameter), and its DNA was shown to pack with an interduplex distance of only 23 Å (Bhella *et al.*, 2000). Based on the interduplex spacing and the genome sizes, we estimate that the closely packed DNA genomes of HSV-1, RRV, and HCMV would occupy a total volume of 3.52×10^8 Å^3, 3.51×10^8Å^3, and 4.05×10^8Å^3, respectively (Yu *et al.*, 2003). These volumes would measure approximately 92%, 92%, and 90% of the total available spaces inside the HSV-1, RRV, and

HCMV capsids, as estimated on the basis of their inner diameters of 900 Å, 900 Å and 950 Å, respectively. The 23–26 Å packing of strands of herpesvirus dsDNA is very close to the 20-Å diameter of B-type dsDNA, suggesting that herpesvirus genomes are packed as "naked" DNA without any bound histone-like basic proteins. In this regard, SDS-PAGE analyses demonstrated that the A-capsids and C-capsids have the same protein composition (Booy *et al.*, 1991; O'Connor *et al.*, 2003). In the absence of histone-like proteins, close packing of naked DNA would lead to a potentially strong electrostatic repulsion between the juxtaposed negatively charged DNA duplexes. This would make the packaging of DNA into procapsid energetically unfavorable, supporting the need for an energy-dependent DNA packaging machinery such as the bacteriophage-like connector recently reported in HSV-1 capsids (Newcomb *et al.*, 2001). Even so, it is conceivable that the negative charge of DNA may at least be partially neutralized by binding polyamines (Gibson and Roizman, 1971) or some other undiscovered small basic molecules to reduce the strong electrostatic repulsion.

Structure and assembly of tegument

Composition of viral tegument

The tegument occupies the space between the capsid and the envelope. Since the capsid and virion are ~125 nm and ~220 nm in diameter, respectively, the tegument represents a significant part of the virion space and indeed, contains approximately 40% of the herpesvirus virion protein mass (Gibson, 1996;). Since they are components of virions, tegument proteins are delivered to cells at the very initial stage of infection and they have the potential to function even before the viral genome is activated. Extensive studies, including amino acid sequencing and mass spectrometric analyses, have been carried out to determine the protein content of the tegument. These results have revealed the compositions of the teguments of HSV and HCMV, and provided insight into its function.

The tegument of HSV-1 contains more than 20 virus-encoded proteins (Roizman and Knipe 2001). The most notable proteins include the α-trans-inducing factor (αTIF, VP16), the virion host shutoff (vhs) protein (UL41), and a very large protein (VP1–2). VP16 functions as a transcription activator to induce the transcription of viral immediate–early genes, and in addition, plays an essential function as a structural component in the tegument (McKnight *et al.*, 1987; Preston *et al.*, 1988; Weinheimer *et al.*, 1992). The protein vhs is a non-sequence specific RNase that degrades most of the host mRNAs during the initial stage of viral infection, and facilitates the translation of viral mRNAs and viral gene expression (Everly *et al.*, 2002; Read and Frenkel, 1983). VP1–2 is found to be associated with a complex that binds to the terminal *a* sequence of the viral genome, which contains the signal for packaging the genome into the capsid (Chou and Roizman, 1989).

At least 30 virus-encoded proteins have been found in the HCMV tegument (Gibson, 1996; Mocarski and Courcelle, 2001). Significant progress has been made to delineate the function of these HCMV-encoded tegument proteins. For example, the UL69 protein acts to block cell cycle progression, while the UL99-encoded pp28 protein is required for cytoplasmic envelopment of the nucleocapsids (Hayashi *et al.*, 2000; Sanchez *et al.*, 2000; Silva *et al.*, 2003).

There are five predominant protein species found in the HCMV tegument: the high molecular weight protein (HMWP) encoded by UL48, the HMWP-binding protein encoded by UL47, the basic phosphoprotein (BPP or pp150) encoded by UL32, the upper matrix protein (UM or pp71) encoded by UL82, and the lower matrix protein (LM or pp83) encoded by UL83 (Gibson, 1996; Mocarski and Courcelle, 2001). Although their organization within the virion is not completely understood, these abundant proteins are believed to form the structural backbone of the tegument. UL48 and UL32 products, both of which are essential for viral replication (Dunn *et al.*, 2003; Meyer *et al.*, 1997), have been proposed to interact intimately with nucleocapsids (see below). Blocking UL32 expression resulted in accumulation of the nucleocapsid, suggesting that this protein is essential for tegument formation (Meyer *et al.*, 1997).

UL82 is also believed to be involved in direct interaction with the newly synthesized nucleocapsid, and is important for initiation of tegument assembly (Trus *et al.*, 1999). Moreover, the UL82-encoded pp71 protein is a transcriptional activator that helps to induce the transcription of the immediate-early genes within the infected cells (Liu and Stinski, 1992). UL83, the most abundant tegument protein, accounts for more than 15% of the virion protein mass (Gibson, 1996). The encoded pp65 protein has been reported to block major histocompatibility complex class I presentation of a viral immediate–early protein, and more recently, has been implicated to inhibit the induction of host interferon response (Browne and Shenk, 2003; Gilbert *et al.*, 1996). Remarkably, pp65 is not essential for viral replication and infectious virion production (Schmolke *et al.*, 1995). However, UL83 constitutes 90% of the protein mass in the noninfectious dense bodies, which have similar envelope structure, but lack a capsid core (Gibson, 1996). Non-infectious envelope particles, which contain B-capsid like core without the viral DNA genome, have a

reduced amount (30–60% lower) amount of pp65, as do low passage clinical isolates, compared to the laboratory-adapted AD169 and Towne strains (Gibson, 1996; Klages *et al.*, 1989). These observations suggest that UL83 serves as a nonstringent, volume-filling function in facilitating the assembly of virions, non-infectious enveloped particles, and dense bodies. Furthermore, the abundance of this protein in the viral particles and its function in blocking host immune response is believe to allow the virus to escape immune surveillance and significantly contributes to CMV survival (Browne and Shenk, 2003; Gilbert *et al.*, 1996).

Comparative structure of viral tegument

Overview of tegument structure

While significant progress has been made during the last few years to identify tegument proteins and study their functions, little is currently known about the structure of the tegument and the organization of the proteins within the tegument. Equally elusive is the pathway of the assembly and formation of the tegument, which involves the packaging of all the tegument proteins and is certainly a highly regulated, ordered process.

Recent electron cryomicroscopy studies on the virus-related particles of HSV-1, HCMV, and simian CMV (SCMV) provide significant insight into the structure and organization of the herpesvirus tegument (Chen *et al.*, 1999; Trus *et al.*, 1999; Zhou *et al.*, 1999). In these studies, the three-dimensional structures for the infectious virions or cytoplasmic tegumented capsids were reconstructed, and compared to the structures of the intranuclear capsids. The tegument can be seen in the virion as a region of relative low density covering an area in the 60–100 nm radius (Figs. 3.1(*a*), (*c*) and 3.6(*a*), (*c*)) (Chen *et al.*, 1999; Zhou *et al.*, 1999). Although the diameters of the nucleocapsids in different particles appear uniform, the sizes and shapes of the virus particles and the relative locations of nucleocapsids inside the particles vary. These observed variations suggest that most of the tegument proteins do not maintain rigid interactions with the enclosed nucleocapsids, and thus the bulk of the tegument layer does not possess icosahedral symmetry (Chen *et al.*, 1999; Zhou *et al.*, 1999).

The protein densities are also unevenly distributed across the tegument space. Studies on the localization of the tegument proteins have been reported using immunoelectron microscopy with antibodies specifically against tegument proteins and chemical treatment approaches for step-wise removal of layers of virion particles (Gibson, 1996; Steven and Spear, 1997). Several proteins have been found to be located at the tegument space distant to the nucleocapsids. For example, UL23 and UL24 are localized in the HCMV tegument space close to the inner side of the envelope membrane (Adair *et al.*, 2002).

Detailed comparison of the electron cryomicroscopic images of the intact virion particles, the cytoplasmic tegumented capsids, and the nucleocapsids, revealed the unique tegument densities that are present in virion and tegumented capsids but not in capsid preparations. Some of these tegument densities, which are closely associated with nucleocapsid, also exhibit a certain degree of symmetry, and their structures were reconstructed to a resolution of 18–30 Å (Fig. 3.6) (Chen *et al.*, 1999; Trus *et al.*, 1999; Zhou *et al.*, 1999). Since the surface of the nucleocapsid represents the starting site for tegument acquisition and envelopment, these tegument densities are believed to involve specific and direct interactions with capsid proteins and serve as anchors to recruit other tegument proteins for initiation of tegument formation. The tegument densities of HSV1 that are closely associated with the capsids exhibit a dramatic difference from those of HCMV and SCMV (Chen *et al.*, 1999; Trus *et al.*, 1999; Zhou *et al.*, 1999) (Fig. 3.6). This may not be unexpected since there is little evolutionary conservation in the sequence of tegument proteins between HSV-1 and CMV, and many CMV tegument proteins do not have sequence homologues in HSV-1 (Davison *et al.*, 2003; McGeoch *et al.*, 2000).

Tegument structure of HSV-1

Comparison of the maps of HSV-1 intact virion particles and B capsids revealed the marked differences between the two maps in the region of the pentons, which are highlighted in color in the superposition of the difference map on the B-capsid map (Fig. 3.6(*b*)). The most obvious difference is the presence of additional material extending from the surface of the pentons. The extra material has a molecular mass of 170–200 kDa, extends from the interface between the upper domains of two adjacent VP5 subunits in the penton and connects to the nearby triplexes that are made up of VP19C and VP23 proteins (Fig. 3.6(*b*)). The restriction of the tegument contacts to the pentons is consistent with previous observations of tightly attached tegument material at the vertices of capsids in negative stain and freeze-etching images of detergent-treated equine herpevirus virions (Vernon *et al.*, 1982). An identical pattern of tegument protein interaction was observed in a VP26-minus virion mutant (Chen *et al.*, 2001). This result indicates that the lack of tegument association of the HSV-1 hexons is not due to the presence of VP26 on the hexon upper domain, but rather likely due to the inherent structural difference on the upper domains of penton and hexon VP5.

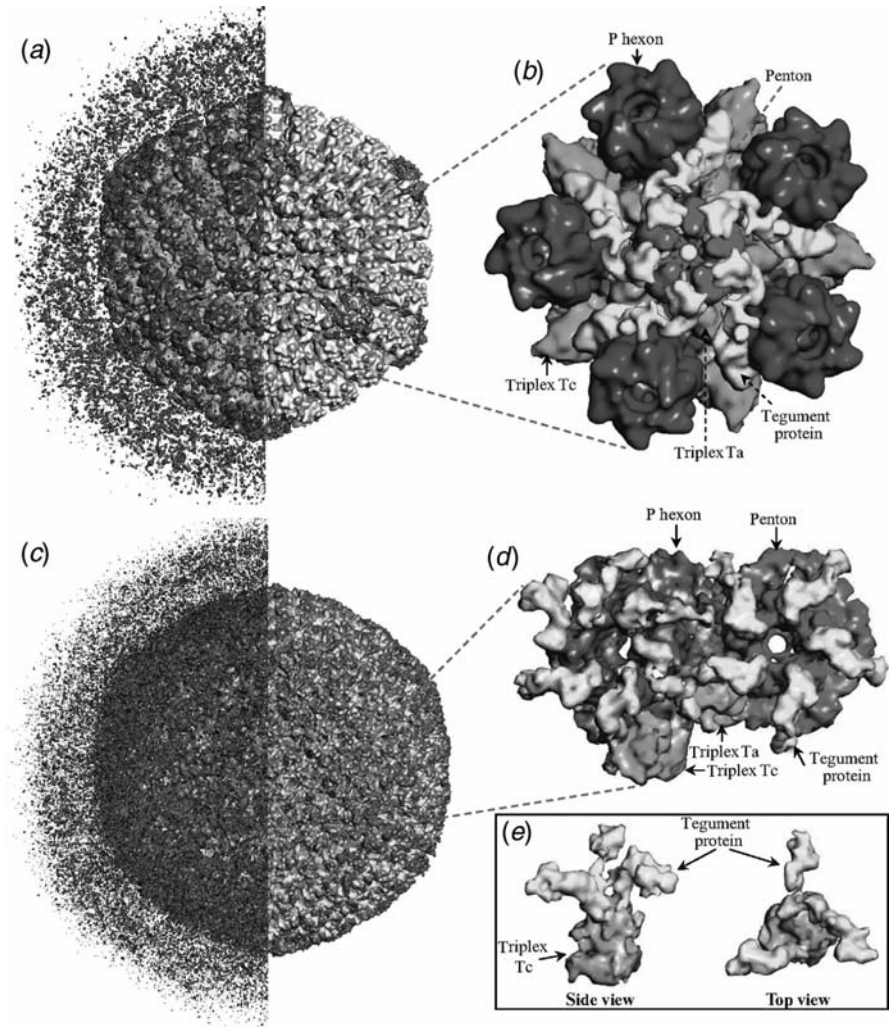

Fig. 3.6. Difference of the anchored tegument proteins between HSV-1 ((*a*) and (*b*)) and HCMV ((*c*)–(*e*)). ((*a*) and (*c*)) Radially color-coded shaded surface views of the three-dimensional reconstruction of HSV-1 (*a*) and HCMV (*c*) virions as viewed along an icosahedral three-fold axis. The bulk of the tegument components and the viral envelope are not icosahedrally ordered or polymorphic, thus appearing as disconnected low densities in the icosahedral reconstruction. These disconnected densities were masked out for the right hemisphere to better reveal the icosahedrally ordered tegument proteins, which are shown in blue to purple colors in (*a*) and in purple in (*c*). ((*b*) and (*d*)) Close-up views of the region indicated in (*a*) and (*c*), respectively, showing the molecular interactions of the tegument proteins (yellow) with the penton (red), P hexon (blue) and triplexes (green). In HSV-1, contrary to the extensive tegument association with all hexons, the tegument densities do not interact with any hexon. (*e*) Extracted triplex HCMV Tc with its attached tegument densities. Three tegument densities interact with the upper domain of each triplex (insert Table 3.1). (See color plate section.)

Based on its close association with the capsid and relative abundance in the tegument, the essential tegument protein VP1–3 has been proposed to constitute a major part of the protein complexes representing the tegument material (Zhou *et al.*, 1999). VP1–3 is an interesting yet poorly characterized protein. It has been shown that VP1–3 is associated with a complex that binds to the terminal *a* sequence of the viral genome, which contains the signal for genome packaging into the capsid (Chou and Roizman, 1989). A temperature-sensitive mutant (*ts* B7) with a mutation in VP1–3 fails to release viral DNA from the infecting capsids into the nucleus during viral decoating process (Batterson and Roizman, 1983). Since the penton has been suggested to be the route by which viral DNA leaves the capsid (Newcomb and Brown, 1994), an interaction between VP1–3 and the penton proteins would place it in an appropriate

position to influence the passage of the viral genome. Further studies are needed to test these hypotheses and completely reveal the identity of the proteins coding for the tegument material.

Tegument structure of CMV

The tegument densities of HCMV that are closely associated with nucleocapsid are dramatically different from those of HSV-1 (*cf.* Fig. 3.6 (*a*) and (*c*)) (Chen *et al.*, 1999). A difference map between the HCMV particles and B-capsids revealed a thin shell of loosely connected filamentous densities, representing the icosahedrally ordered, capsid-proximal portion of the tegument in HCMV (Fig. 3.6(*c*)–(*e*)). Unlike HSV-1, the tegument densities interact with all of the structural components of the nucleocapsid: penton (made up of major capsid protein UL86), hexon (consisted of UL86 and smallest capsid protein UL48.5), and triplex (composed of minor capsid protein UL85 and its binding protein UL46). Figure 3.6(*d*) shows the close-up views of a region from the intact virus reconstruction that includes one penton (red), one P hexon (blue), and two representative adjacent triplexes Ta and Tc (green). Superimposed on the penton and hexon are their associated tegument densities (yellow). Clusters of five and six tegument densities attach to the pentons and hexons, respectively. Moreover, neighboring clusters associate with each by bridging over the intercapsomer space, apparently using triplexes as piers. Each of the filamentous tegument densities, which is about 12 nm in length and 2–3 nm in diameter, acts as the bridge arch. Thus, the capsid appears to act as the scaffold of the ordered tegument protein layer. These results imply that the ordered tegument layer cannot form without the underlying capsid and are consistent with the observations that no such tegument layer was found in dense bodies (Chen *et al.*, 1999).

Detailed examination of the interactions between triplexes and tegument densities further revealed minor differences between the structures of SCMV cytoplasmic tegumented capsids and HCMV particles (Chen *et al.*, 1999; Trus *et al.*, 1999). In SCMV cytoplasmic capsids, two tegument densities were found to be associated with each triplex. In contrast, three densities were shown to be attached to each triplex of the nucleocapsid of the HCMV particles (Fig. 3.6(*e*)). It is conceivable that the extra tegument densities observed in HCMV structure may represent those that were loosely associated with the capsids and probably lost during the purification of the SCMV capsids.

Based on their relative abundance and close association with the nucleocapsids, two CMV tegument proteins, UL32 and UL82, have been proposed to constitute the majority of the observed tegument material that attach to the capsids (Chen *et al.*, 1999; Trus *et al.*, 1999). UL82, which encodes a transcriptional activator (Liu and Stinski, 1992), has a molecular weight of ~70 kDa, similar to the estimated molecule mass of the capsomer-capping tegument protein densities. UL32 has been suggested to be involved in the transport of DNA-containing capsids through nuclear membrane during envelopment or in the stabilization of capsids in the cytoplasm (Meyer *et al.*, 1997). In recent experiments, CMV virion particles were subjected to different chemical conditions, which do not disrupt the integrity of the nucleocapsids, to selectively remove the components not tightly associated with the capsids. These experiments showed that most of the known tegument proteins, including UL99 and UL83, are removed, but UL32 is not affected (Yu, X., Lee, M., Lo, P., Liu, F., and Zhou, Z. H., unpublished results). Thus, these results further suggest that UL99 and UL83 are loosely and distantly associated with capsids and that UL32 is in close proximity and possibly involved in direct interactions with the capsids.

Structure and assembly of viral envelope

The envelope contains most, if not all, of the virion glycoproteins. Each of the herpesviruses encodes a set of 20–80 glycoproteins, very few of which are highly conserved among all the herpesviruses (Kieff and Rickinson, 2001; Mocarski and Courcelle, 2001; Roizman and Knipe, 2001). For example, HSV-1 encodes at least 20 glycoproteins, 11 of which are found in the virions (Roizman and Knipe, 2001). HCMV potentially encodes more than 75 membrane-associated proteins, at least 15 of which are found in the virions (Mocarski and Courcelle, 2001). The exact organization of viral surface glycoproteins in the envelope is not completely understood. Virion glycoproteins are found to aggregate into complexes on the surface of the virion. For example, HCMV glycoproteins gH, gL, and gO are associated to form a heterotrimeric envelope glycoprotein complex (Gibson, 1996; Mocarski and Courcelle, 2001). These proteins may form their complexes in the cellular membrane compartment before trafficking to the viral envelope. However, it remains possible that further higher-order complexes are assembled after these protein components are delivered in the viral envelope membrane.

In addition to the viral encoded glycoproteins, the envelope also contains numerous host proteins or constituents. For example, host proteins associated with HCMV envelope include β2-microglobumin, CD55 and CD59, and annexin II (Grundy *et al.*, 1987a, b; Wright *et al.*, 1995). These molecules may participate in the induction of host cellular responses. It is conceivable that these host proteins, in combination with the viral encoded G protein-coupled

receptors associated with the HCMV envelop, play an important role in modulating host cell response during initial virus attachment, as observed in recent studies (Compton *et al.*, 2003; Zhu *et al.*, 1998).

Herpesvirus envelopment is believed to take place initially at the inner nuclear membrane, and then further proceeds with an envelopment/de-envelopment process that allows the capsid to cross the double nuclear membranes and other cytoplasmic membrane structures (Gibson, 1996; Steven and Spear, 1997). Cytoplasmic envelopment of HSV-1 and CMV capsids can also take place in endosomes as well as Golgi networks (Eggers *et al.*, 1992). Thus, it is not surprising that the envelope contains diverse lipid components that are associated with different parts of the cytoplasmic membrane system in addition to the nuclear membrane. These components include the phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol (Roby and Gibson, 1986). Whether these lipid components may be important in maintaining the integrity of the viral envelope has not been determined and their functional role in stabilizing virion structure is unknown.

The envelopment process appears to be not affected in the absence of a mature capsid since noninfectious enveloped particles and dense bodies can be produced and contain similar envelop contents. In the case of HCMV, pp65 constitutes at least 90% of the dense body protein mass (Gibson, 1996). It is conceivable that this protein may contain signals that promote its own envelopment. There are presumably interactions between proteins of the tegument and envelope that promote the envelopment process. Indeed, recent results indicate that HCMV UL99, a tegument protein, facilitates the cytoplasmic envelopment of the nucleocapsid (Sanchez *et al.*, 2000; Silva *et al.*, 2003). Two HSV-1 membrane proteins, UL34 and UL31, are also implicated to be essential for viral envelopment (Reynolds *et al.*, 2001). Further studies on the organization of the proteins in these particles and their potential interactions with envelope components will provide insight into the process of their assembly.

Other constituents in the virions

Recent studies indicated that viral mRNAs were found in HSV-1 and HCMV virions (Bresnahan and Shenk, 2000; Sciortino *et al.*, 2001). These mRNAs appear to be packaged selectively into the infectious virion particles. They have been proposed to function to facilitate the initiation of viral infection upon viral entry. It is unknown whether these virion mRNAs play a role in maintaining the integrity of the virion structure, as ribosomal RNAs provide the backbone for ribosome assembly.

Depending on the approach of how the virions are prepared and the quality of the preparations being analyzed, numerous host constituents, including lipids, polyamines, and cellular enzyme and structural proteins, are also found to be associated with the viral particles. In particular, two of these host constituents, polyamines and actin-related protein (ARP), may play an important role in stabilizing and maintaining the intact structure of the infectious particles. Two kinds of polyamines, spermidine and spermine, have commonly been found in herpesvirus virions, including HSV-1 and HCMV (Gibson and Roizman, 1971; Gibson *et al.*, 1984). In highly purified HSV-1 virion preparations, there are about 70 000 molecules of spermidine and 40 000 molecules of spermine per virion (Gibson and Roizman, 1971). The functions of these polyamines are believed to provide positive charges to neutralize the highly negatively charged viral DNA genome during the genome replication and packaging. This hypothesis is consistent with the observations that none of the herpesvirus capsid proteins are highly positive charged and addition of arginine facilitates capsid assembly and virion production (Mark and Kaplan, 1971). Spermidine appears to be in the tegument while spermine is localized in the nucleocapsid. It is estimated that the spermine contained in the virion has the capacity to neutralize about 40% of the DNA phosphate, consistent with its role in stabilizing the packed genomic DNA in the nucleocapsid core.

In analyzing highly purified HCMV virions as well as noninfectious enveloped particles and dense bodies, Baldick and Shenk first reported the presence of a substantial amount of a cellular actin-related protein (ARP) in the tegument compartment (Baldick and Shenk, 1996). The exact localization of the ARP is currently unknown, and preliminary studies using stepwise chemical treatment of HCMV virion for removal of different parts of the particles have suggested that ARP is localized in the tegument space distant from the nucleocapsid (Yu, X., Lee, M., Lo, P., Liu, F., and Zhou, Z. H., unpublished results). Based on their roles for providing cytoskeleton and maintaining cellular structure and morphology, it is conceivable that actin-related proteins stabilize the tegument structure. Meanwhile, some ARPs have been implicated in participating dynein-driven microtubule transport system (Lees-Miller *et al.*, 1992; Schroer *et al.*, 1994). Given the fact that viral capsid trafficking from cytoplasm to the nuclear pore complex is driven by the dynein-microtubule system (Dohner *et al.*, 2002; Sodeik *et al.*, 1997), it is possible that these ARPs are specifically incorporated into the teguments and facilitate the transport of the viral particles from the nucleus to

the cytoplasmic membrane during viral envelopment and to the nucleus during post-penetration. Further studies are needed to completely elucidate the function of these proteins in assembly and maintenance of the virus structure.

Comparative analysis of herpesvirus-common proteins

Edward S. Mocarski, Jr.

Department of Microbiology & Immunology, Stanford University School of Medicine, CA, USA

Introduction

Despite the evolutionary and biological divergence represented by the nine human herpesviruses that have been classified into three broad subgroups, a large number of herpesvirus-common (core) gene products are evolutionarily conserved (Table 4.1 see chapter 2). These appear to carry out functions upon which every herpesvirus relies because all exhibit a common virion structure, a core genome replication process, and similar entry and egress pathways. These herpesvirus common functions are most often recognized through deduced protein sequence similarity that extends throughout alpha-, beta-, and gammaherpesviruses subfamilies infecting mammals, reptiles and birds (see Chapter 2, Table 2.2). These herpesviruses exhibit conservation that suggests a shared common ancestor at least 50 million years ago. Other evolutionarily distant herpesviruses infecting fish, amphibians, and invertebrates share less similarity with these better-studied herpesviruses, suggesting a common evolutionary origin dating back over 150 million years. In the more distant relatives, a common virion structure, genome organization and similarity across a small subset herpesvirus-common gene products provide the evidence of a common origin.

A few herpesvirus-common gene products have been recognized via a common enzymatic or binding activity long before any systematic genome sequence analysis became available. The homologous function of envelope glycoprotein B, DNA polymerase, alkaline exonuclease and single strand DNA binding protein, to give a few examples, emerged from biochemical studies in a number of herpesvirus systems. Given the high level of conservation and the importance of DNA synthesis as a target for antiviral inhibitors, these remain among the most broadly studied and best understood of the core gene products. DNA synthesis functions and virion structural components are also among the most highly conserved based on sequence comparisons. Importantly, however, common activity of well-recognized core functions, such as the DNA polymerase processivity factor, the smallest capsid protein or a capsid triplex component, is not based on the level of primary amino acid sequence identity, but rather is supported by a common role in several herpesviruses. Additional core functions initially recognized based on activity have undergone evolutionary divergence to take on new functions. For example, the large subunit of ribonucleotide reductase (HSV-1 *UL39* gene product), which associates with a small subunit to form an active enzyme in the alphaherpesviruses and gammaherpesviruses, is expressed without small subunit in the betaherpesviruses (HCMV, HHV-6, HHV-7) and completely lacks enzymatic activity. This leaves a question as to its true role. Thus, herpesvirus-common proteins may preserve common function as well as sequence homology, function with only limited sequence homology, or sequence homology with distinct function. Homologs may therefore be predicted to carry out similar functions in most situations, but will certainly not behave identically in all settings.

Herpesvirus-common gene products have been recognized as key proteins that form the characteristic herpesvirus virion structure and provide key common functions for the replicative cycle, beginning with entry into cells, continuing through the process of viral DNA synthesis and nucleic acid metabolism and concluding with capsid maturation and egress of virions. The presence of herpesvirus-common genes (see Chapter 2) allows predictions about functional conservation; however, most functional information has been derived from studies in a single or at most two herpesvirus subfamilies. The requirement for herpesvirus-common functions varies considerably with cell type, as well as between viruses of the same

Table 4.1. Identity, function and proposed nomenclature for known and putative functions of herpesvirus-common gene products of human herpesviruses

Common name[a]	Abbrev. name	HSV	VZV	HCMV	HHV 6/7	EBV	KSHV	Key function
Capsid								
major **c**apsid **p**rotein[c]	MCP	UL19	40	UL86	U57	BcLF1	ORF25	hexon, penton, capsid structure
triplex monomer[c]	TRI1	UL38	20	UL46	U29	BORF1	ORF62	TRI1 and TRI2 assoc to form TRI complex, capsid structure
triplex dimer[c]	TRI2	UL18	41	UL85	U56	BDLF1	ORF26

[a] proposed.
[b] required for replication in some viruses or some settings.
[c] required for replication in all viruses and settings tested.
[d] AP and NP are related proteins derived from different primary translation products.

or different subfamilies. Currently, 36 of the 40 core functions have an impact on replication in at least one herpesvirus and in at least some experimental setting (Table 4.1), although many are not absolutely essential for replication in any of the herpesviruses where they have been studied. The striking cell type dependence of so many herpesvirus functions suggests that many of these proteins carry out activities that are redundant with other viral or cellular functions. This chapter will seek to deduce the general role of each core function based on data available in different systems. The phenotype of mutants showing even a modest growth defect under any conditions will be an important component for consideration. All core functions are likely to be important for viral replication and pathogenesis in the host even when considered dispensable for replication in cultured cells. While even limited information is useful, experimental confirmation across several distinct viruses builds confidence in the common role of homologs, but this information is limited in many cases.

All herpesviruses form particles that have a characteristic 125–130 nm icosohedral capsid containing a linear DNA genome, surrounded by a protein-containing tegument enclosed in a host-membrane derived lipid bilayer envelope modified by virus-encoded glycoproteins. The overall virion particle size ranges from 200 to 300 nm, depending on the particular virus. This common structure provides the strongest evidence for evolutionary conservation in the replication and maturation processes. The set of core, homologous open reading frames (ORFs) are predominantly involved in the processes of DNA replication through maturation and egress from cells (Fig. 4.1). These also facilitate estimations of the evolutionary relatedness of the three major subfamilies (alpha-, beta-, and gammaherpesviruses) comprising mammalian and avian herpesviruses (see Chapter 2). Recognizable sequence homologs of only three of these proteins (DNA polymerase, DUT and a terminase subunit are conserved in the genomes of every known herpesviruses, including those infecting amphibians, fish, and invertebrates. Of these, the gene for the terminase subunit is remarkable, producing a conserved spliced mRNA that remains a key genomic feature (Davison, 2002) of every herpesvirus genome that has been annotated. The nine distinct human herpesviruses, including three members of alphaherpesviruses (HSV-1, HSV-2 and VZV), four members of the betaherpesviruses (CMV, HHV-6A, HHV-6B and HHV-7) and two members of the gammaherpesviruses (EBV and KSHV/HHV-8) share 40 of the 43 ORFs that have been included in the core set (see Chapter 2 Table 2.2). Although widely distributed amongst alpha- and gammaherpesviruses characterized to date, a thymidine kinase (TK) and a small subunit of ribonuclease (RR2) are absent from all betaherpesviruses. Although all herpesviruses appear to use sequence-specific DNA binding proteins to initiate DNA replication, a homolog of DNA replication origin binding protein (OBP) is not conserved in cytomegaloviruses or gammaherpesviruses.

This chapter stresses common features, while evolution has clearly provided the herpesviruses with a broad canvas on which to evolve the remarkable range of biological properties that characterize individual members. Genome annotation and comparison has suggested a higher level of similarity within subfamilies than between biologically distinct subfamilies. Even though biological properties of the individual subfamily members are distinct, they retain a recognizable evolutionary link.

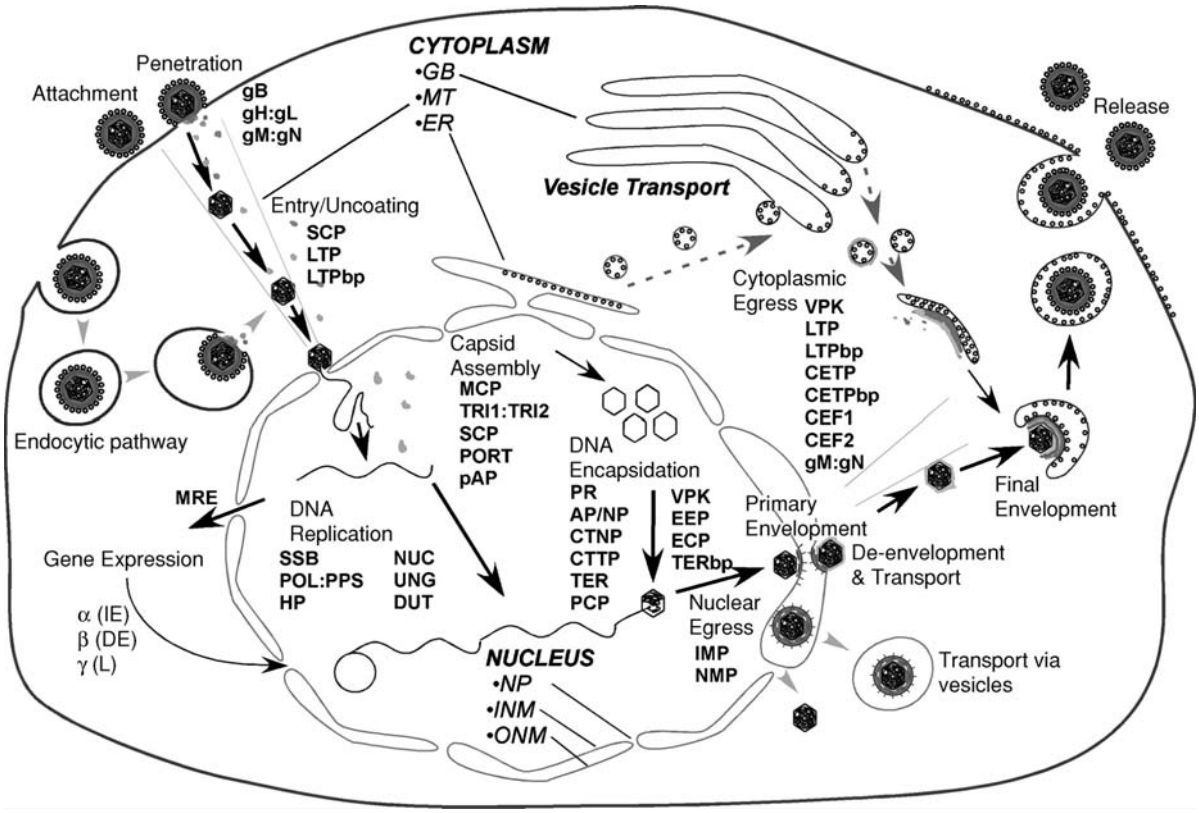

Fig. 4.1. Summary of replication functions carried out by herpesvirus-conserved gene products. Major steps in productive replication are indicated in larger font style and core functions contributing to each step are listed by their proposed abbreviated designations (see Table 4.1). The major entry pathway (black arrows) employs direct fusion at the cell surface (attachment and penetration), which is dependent upon gB and the gH:gL complex, followed by nucleocapsid transport along microtubules to nuclear pores where viral DNA is released into the nucleus. Alternatively, in certain cell types, entry follows the endocytic pathway and virion fusion with an endocytic vesicle (grey arrowheads). Uncoating requires the envelope fusion machinery (gB, gH:gL and in some cases gM:gN) as well as the LTP:LTPbp to direct docking at nuclear pores and release of virion DNA into the nucleus. Following entry and uncoating, one core regulatory protein (MRE) is involved in transcriptional and post-transcriptional regulation. DNA replication depends on several core replication fork proteins (SSB, POL:PPS, HP) as well as accessory functions (NUC, UNG, DUT). Capsid assembly uses MCP, TRI1:TRI2, SCP, and PORT. Pre-formed capsids translocate to sites of DNA replication where PRO, AP/NP (AP and NP are related proteins), CTNP, TER, TERbp and PCP, with possible accessory functions EEP, ECP and CTTP complete the encapsidation of viral DNA. Nuclear egress is controlled by NEMP and NELP. The main pathway of cytoplasmic egress (black arrows) and secondary (final) envelopment is controlled VPK, LTP:LTPbp, CETP, and CETPbp, with possible accessory proteins CEF1, CEF2 and gM:gN. Nucleocapsids are transported on MT and virion envelope glycoproteins follow vesicle transport to sites of final envelopment. Alternative maturation pathways of vesicle formation at the outer nuclear membrane with the mature virion following vesicle transport pathways or release of nucleocapsids directly through nuclear pores into the cytoplasm for transport to sites of final envelopment remain possible (grey arrowheads). Golgi body (GB), microtubules (MT) and endoplasmic reticulum (ER) are identified in the cytoplasm, and nuclear pores (NP), inner nuclear membrane (INM) and outer nuclear membrane (ONM) are identified in the nucleus. The cellular vesicle transport pathway from the ER to GB is also designated (dashed grey arrows).

There is little doubt that herpesviruses encode additional structurally related, functionally similar proteins that are not recognized as sequence homologs and all herpesvirus-common components cannot be recognized through sequence information alone. Other structural and functional properties complement sequence information and may constitute an independent set of criteria on which comparisons can be based. Relative position in a cluster of conserved ORFs, biological activity and the phenotype of mutant viruses all provide important comparative information. The existence of ORFs that fail to show sequence identity but are included in the list of core proteins due to

other information, such as the functional information on DNA polymerase processivity subunit already mentioned, suggests future work will require consideration of a broader set of characteristics. Additional structural and functional homologs will likely emerge as viral proteins are studied in greater detail by X-ray diffraction as by well as computer programs that model primary amino acid sequence on known protein structures.

Available information on the activities of core functions has often been generated in only one of the nine human herpesviruses, sometimes using herpesviruses of veterinary interest (e.g., PRV) and sometimes using rodent herpesviruses (e.g., MCMV). The remarkable diversity in functional organization, replication, latency and disease patterns exhibited by diverse human herpesviruses contrast the common activities of core functions which are key to viral replication. Functions will therefore be presented in relationship to the virus replicative cycle, starting with virion structure and entry, proceeding through regulation of gene expression, DNA synthesis, processing, and packaging and, finally, maturation and egress. Some of the functions involved in entry are structural components that are also involved with maturation and release of progeny virus, but most of the core functions can be implicated in at least one step in the replication pathway, and this is sometimes dependent on cell type. These core replication processes, including entry into cells and viral DNA synthesis, as well as the overall scheme of assembly, maturation and egress occur via evolutionarily conserved proteins and mechanisms. The role of core functions is best understood where they have been subjected to study by a combination of genetics and cell biology, this is often in alphaherpesviruses such as HSV-1 and PRV or in betaherpesviruses such as HCMV and MCMV. There have been many reviews dealing with herpesvirus-common features and evolutionarily common themes that have emerged over the years, both from a biological perspective (Roizman, 1999; Roizman and Pellett, 2001) as well as from a variety of analyses derived from genomic sequence (Davison, 2002; Karlin *et al.*, 1994; McGeoch *et al.*, 2000).

There are several common genome features described in Chapter 2 beyond the ultrastructural appearance of capsids and core proteins described in Chapter 3. All herpesviruses have a linear DNA genome that is cleaved from concatemers formed during replication, which where known, uses a conserved recognition sequence and leaves single base 3 overhanging nucleotide at each genomic terminus (Mocarski and Roizman, 1982). The position of origins of DNA replication that control DNA synthesis during the replicative cycle is conserved in most herpesviruses with a common location adjacent to the conserved single stranded DNA binding protein gene. While exceptions exist, the common evolutionary origin of these viruses is very clear from the range of conserved *cis*-acting elements as well as proteins.

Virion structural proteins

The virion particle of herpesviruses consists of a DNA-containing nucleocapsid with 162 regularly arranged capsomeres arranged in a $T = 16$ icosohedral lattice forming the protein shell. Detailed structural information has been derived from cryo-electron micrograph (cryo-EM) reconstructions involving studies on several different herpesviruses (Chapter 3). In the virion, the nucleocapsid is covered by a protein matrix or tegument that is surrounded by a lipid bilayer envelope derived from host cell membranes into which at least a dozen viral envelope proteins are inserted. Human herpesviruses have been estimated to have as few as 37 (e.g., alphaherpesviruses) and to well over 50 (e.g., cytomegaloviruses) virion proteins (Bortz *et al.*, 2003; Johannsen *et al.*, 2004; Kattenhorn *et al.*, 2004; Varnum *et al.*, 2004; Zhu *et al.*, 2005). About half (22) of the herpesvirus-conserved proteins are components of the virion, providing a genetic basis for the common ultrastructural appearance of all herpesviruses. Additional core proteins collaborate with structural proteins during maturation and egress (see below). Although similar in size, herpesvirus nucleocapsids package double-stranded DNA genomes range from a low of 125 kilobase pairs (VZV) to a high of 240 kilobase pairs (CCMV), which is remarkable given such a uniform capsid shell. The virion provides protection of the viral genome during transmission and mediates a two-stage entry process, first a fusion event between the envelope and cellular membranes that leads to release of the nucleocapsid into the cytoplasm and second a trafficking event that delivers the viral nucleocapsid to the nucleus where the genome is released.

Icosohedral herpesvirus capsids are composed of five herpesvirus-conserved proteins, the major capsid protein (MCP, HSV-1 *UL19* gene product), triplex monomer and dimer proteins (TRI1 and TRI2, HSV-1 *UL38* and *UL18* gene products, respectively), the smallest capsid protein (SCP, HSV-1 *UL35* gene product) and the portal protein (PORT, HSV-1 *UL6* gene product). The 150 hexons that make up the bulk of the capsid consist of six MCP molecules together with six molecules of SCP. Eleven of the 12 capsid pentons consist of five MCP molecules without SCP. One specialized penton consists of 12 molecules of PORT and has an axial channel for entry and exit of viral

DNA. The 125–130 nm diameter capsid has a wall that is 15 nm thick. Although different in shape, each hexon and penton appears cylindrical. Based on cryo-EM studies of HSV-1, HCMV, and KSHV (Chapter 3), the hexons and pentons are held in place by interactions between their bases on the inner side as well as by interconnections via triplexes located midway through the capsid shell. Detailed analyses suggests that beta- and gammaherpesvirus capsids resemble one another more closely than either resembles alphaherpesvirus capsids. Although the least conserved of the structural proteins, SCP is located at hexon tips, and absent from penton tips, in all herpesviruses (Yu *et al.*, 2005). There is a discernible SCP ring around hexons in HSV-1 where this structure contributes to the shape of the outermost capsid surface. Although widely conserved, the SCP is not universally essential for virion maturation and is, for example, dispensable for HSV-1 replication in cell lines (Desai *et al.*, 1998) but essential for HCMV replication (Borst *et al.*, 2001). Thus, the nucleocapsid of every human herpesvirus consists entirely of herpesvirus-conserved proteins, but the functional requirements for capsid maturation vary to some extent.

A large number of tegument proteins are located between the capsid and envelope in herpesviruses. Tegument proteins carry out a remarkably diverse range of activities during infection, although the most well-characterized functions and the most abundant tegument proteins in any herpesvirus are often not in the core set. Eleven proteins are conserved (see Chapter 2). Many are essential for replication in those viruses that have been subjected to systematic study, HSV-1 (Roizman and Knipe, 2001), PRV (Mettenleiter, 2004) and HCMV (Dunn *et al.*, 2003; Yu *et al.*, 2003). In HSV-1, five of the conserved tegument proteins are essential for replication (HSV-1 *UL7*, *UL17*, *UL25*, *UL36*, and *UL37* gene products), including a largest tegument protein (LTP, HSV-1 *UL36* gene product) and the protein that binds to the largest tegument protein (LTPbp) encoded by the adjacent (*UL37*) gene. These play roles in entry as well as in egress. The viral serine–threonine protein kinase (VPK, HSV-1 *UL13* gene product), and five additional tegument proteins (homologues of HSV-1 *UL11*, *UL14*, *UL16*, *UL21*, and *UL51* gene products) exhibit compromised growth, sometimes in specific cell types or under certain growth conditions. In contrast, HCMV requires an overlapping, but distinct set of seven homologs to replicate, without an absolute need for some that are essential in HSV-1. In HCMV, the LTP (UL48), UL77 and UL93 (homologs of HSV-1 *UL36*, *UL25*, and *UL17*, respectively) as well as UL99, UL95, UL94, and UL71 (homologs of HSV-1 *UL11*, *UL14*, *UL16*, and *UL51*, respectively) are required for replication when the entire ORF is eliminated (Dunn *et al.*, 2003). Mutants in the LTPbp (UL47) and UL103 (homologs of HSV-1 *UL37*, and *UL7*, respectively) as well as mutants in VPK and UL88 genes exhibit a reduced level of growth. While it is possible that some of these differences stem from experimental variability or the choice of different host cells in which to study mutants, evolutionary differences are likely to dictate the extent to which each virus relies on overlapping functions as well as the extent to which functional redundancy occurs. HSV-1 UL11 and HCMV UL99 proteins are known as small myristolated tegument proteins, localize to cytoplasm of infected cells, and are involved in the latter stages of virion egress. The HSV-1, *UL11* protein interacts with two other conserved tegument proteins, *UL14* and *UL16* as well as with the envelope glycoprotein, gM, which is part of the gM/gN glycoprotein complex. Although ultrastructural analysis does not provide much information on tegument organization, an association between the LTP:LTPbp complex with the SCP ring or with triplexes in the region of the capsid vertices has been suggested with HSV-1. Investigation of tegument protein activities and capsid : tegument interactions remain important areas for experimental investigation.

One additional protein is conserved amongst herpesviruses, represented by the *UL24* gene of HSV-1 about which little is known. The HCMV homologue (UL76), a minor tegument constitutent that is essential for replication (Dunn *et al.*, 2003), localizes in a pattern that suggests it may be involved in regulating events immediately following infection or during maturation (Wang *et al.*, 2004).

One enzyme contained in this set of conserved proteins, VPK apparently acts in tandem with host cell cycle kinases to regulate a variety of replication events. VPK ensures efficient phosphorylation of other viral proteins, some of which have been reported to increase the efficiency of the host translation machinery as well as other events in gene expression and DNA replication extending from early times during infection to egress. This enzyme is dispensable for replication in alphaherpesviruses as well as in rapidly dividing host cells infected with HCMV where its role is presumably redundant with host protein kinases, possibly including Cdk2. A requirement for VPK is most readily demonstrated in primary, non-dividing host cells that have lower levels of host cell kinases. VPK is also critical for efficient replication in host animals. Interestingly, the homologue in HCMV (UL97) as well as in HHV-6B is a nucleoside kinase required for phosphorylation of the antiviral drug ganciclovir, in addition to being a protein kinase. The UL97-encoded VPK is also the primary target of a candidate antiviral compound, maribavir, which is specifically active against HCMV and EBV, but not other herpesviruses.

Human herpesvirus envelopes are estimated to carry between 12 (HSV-1) and 20 (HCMV) viral integral membrane proteins. Many envelope proteins are specific to each herpesvirus type. Five, gB, gH, gL, gM, and gN, are conserved broadly amongst herpesviruses. Sequence conservation resulted in the adaptation of a common nomenclature for structural glycoproteins, using names originally applied to HSV-1 envelope constituents. Although these names do not imply function, they are now widely used by investigators in the field. One gene product that is an O-glycosylated glycoprotein in some herpesviruses, gN, does not undergo glycosylation in some alphaherpesviruses, such as HSV-1 and VZV. Furthermore, the specific interaction between gH and gL drives stable expression of these proteins, suggesting that they are molecular chaperones as well as functional partners. A similar relationship also appears to occur with gM and gN. Although gB does not form a complex with other viral proteins, complexes of gH:gL and gM:gN form in cells and associate with cellular membranes to be incorporated into the viral envelope of progeny virions during egress. In betaherpesviruses and gammaherpesviruses, gH:gL complexes may be further modified by additional viral glycoproteins that influence cell tropism.

Entry into host cells

Attachment and entry, which typically occurs by fusion with the plasma membrane is followed by translocation of the nucleocapsid through the cytoplasm and delivery of viral genome to the cell nucleus (Fig. 4.1). This process involves a series of distinct steps that have each received varying amounts of attention in different human herpesviruses: (i) binding to specific cell surface receptors, (ii) fusion of envelope with the cellular membrane to release nucleocapsids into the cytoplasm, (iii) nucleocapsid association with cytoskeletal elements and translocation towards the nucleus, (iv) nucleocapsid interaction with nuclear pores and (v) release of the viral genome into the nucleus (see Fig. 4.1). These steps are controlled by unique as well as herpesvirus-common functions. The first step in this process involves multiple cell surface components interacting with viral envelope glycoproteins in a stepwise process that leads to membrane fusion and delivery of the nucleocapsid to the cytoplasm of host cells (Spear, 2004; Spear and Longnecker, 2003) (see specific chapters on individual viruses). Attachment to cells has been studied in most human herpesviruses and usually requires both unique and conserved, sometimes functionally redundant, viral envelope glycoproteins. With the apparent exception of EBV, cell surface proteoglycans such as heparan sulfate play a role for initial contact with cells. Heparan sulfate-dependent entry has been demonstrated in alpha- (HSV-1, VZV), beta- (HCMV, HHV-6A, HHV-6B, HHV-7) and gammaherpesvirus (KSHV/HHV-8) subfamily members (Spear, 2004; Spear and Longnecker, 2003). As a result, many herpesviruses exhibit a broad cell tropism for attachment and entry steps. In these eight human herpesviruses, gB and typically other unique viral envelope proteins exhibit heparan sulfate binding activity and direct the first attachment step in entry. Binding appears to be part of the essential role of gB in the viruses where the process has been dissected. In EBV, gB lacks the domain that controls interaction with the glycosaminoglycan and this step does not seem to be required for entry. In addition to the initial binding step, viruses where entry has been studied in detail engage additional receptors using herpesvirus-conserved as well as unique viral envelope proteins. Attachment steps may rely on unique viral envelope proteins such as EBV gp350/220, which interacts with host CD21 and EBV gH:gL:gp42 complex which interacts with MHC class II protein, KSHV K8.1A which interacts with proteoglycan, or HSV-1 gD, which interacts with nectins as well as a TNF receptor family member. In some herpesviruses conserved envelope glycoproteins are responsible for subsequent steps, such as the role of KSHV gB in binding to integin $\alpha 3\beta 1$ or the role of HCMV gB in binding to the EGF receptor, although these may be more important in the fusion step (Spear and Longnecker, 2003). Thus, except for initial contact with proteoglycan, herpesvirus attachment mechanisms appear unique to each type of virus.

In most cells that have been studied, binding through specific cellular receptors leads to fusion of the viral envelope and plasma membrane, releasing the viral nucleocapsid into the cytoplasm. Fusion typically occurs at the plasma membrane and is under the control of the herpesvirus-conserved envelope glycoproteins, gB and gH:gL which are essential for this step in all studied herpesviruses. In HCMV gH:gL may associate with additional unique proteins that provide receptor specificity, either gO encoded by UL74 or a complex of glycoproteins encoded by UL128, UL130. In HHV-6, either gO encoded by V47 or gQ encoded by U100 provide specificity. There are parallels in human beta- and gammaherpesviruses. In EBV, the presence of gp42-containing complexes reduces epithelial cell tropism, whereas the presence of gp42-free complexes reduces tropism for B lymphocytes (Borza and Hutt-Fletcher, 2002). gM:gN complex is required for entry in some settings, a feature that suggests this complex may also contribute to host cell specificity. Although entry by fusion at the plasma membrane is the most common entry

mechanism, entry via endocytosis has been characterized in some systems (Fig. 4.1). EBV entry into epithelial cells occurs by fusion directly at the cell surface whereas entry into B lymphocytes involves endocytosis (see Chapter 24). The viral functional requirements for different entry processes are still incompletely understood. Thus, both major modes of virus entry may be employed by herpesviruses depending on the setting. Signaling that results from gB or gH:gL binding to cellular receptors has also been implicated as a step in replication but no common themes have emerged from such studies. Essential core glycoproteins seem to play key roles for entry, rather than later in the replication cycle or during egress. All core glycoproteins are incorporated into infected cell membranes as well as into the virion envelope. The evolutionarily conserved manner in which gB and gH:gL control membrane fusion between the viral envelope and plasma membrane has been studied most extensively in the alphaherpesviruses where mutations in each of these gives rise to syncytial viral strains that have provided initial clues to gene products controlling this step.

Herpesviruses exploit normal cytoplasmic transport systems that control cell shape and vesicular traffic, making use of tubulin-containing microtubules and actin-containing microfilaments (Dohner and Sodeik, 2004) to control nucleocapsid transit through the cytoplasm. Like many viruses that traverse the cytoplasm, herpesviruses rely on microtubules to gain access to the nucleus and nuclear pores where uncoating is completed and the viral genome is released into the nucleoplasm. This process was suspected long ago, initially in studies with adenoviruses and herpesviruses (Dales, 1973) and has been the focus of growing attention. Microtubule-destabilizing drugs such as nocadazole and colchacine block transport and entry (Mabit *et al.*, 2002). Net transport proceeds towards microtubule minus ends that terminate at the microtubule organizing center, which is located adjacent to the nucleus. The bidirectional nature of microtubule-directed transport (Welte, 2004) allows these filaments to act as the major highways of virus particle translocation during entry as well as egress (Fig. 4.1). Microfilaments do not play as direct a role during entry; however, evidence suggests depolymerization of the actin-containing cortex may be a requisite event during entry (Jones *et al.*, 1986). Intracellular transport mechanisms that have been intensively studied in neurotropic alphaherpesviruses, predominantly HSV-1, HSV-2 and PRV, because of the requirement to translocate across long expanses of cytoplasm. Herpesvirus-conserved capsid proteins appear to rely on common cellular pathways for movement in neurons as well as all other cell types. Nucleocapsid movement occurs in both directions on microtubules (Smith and Enquist, 2002) and is likely to be regulated in ways similar to vesicle transport (Welte, 2004). Minus-end-directed transport during entry depends on the dynein:dynactin motor complex (Dohner *et al.*, 2002), which is the same motor used for directional vesicle transport. Although still controversial, contact between the SCP of HSV-1 and the cellular constituent of the dynein complex, RP3 (and possibly other proteins) has been implicated in transport (Douglas *et al.*, 2004), suggesting that this herpesvirus-conserved protein may play a similar role in other viruses. Thus, a common bridge may be built between the nucleocapsid and the microtubule to allow an appropriate direction of movement to initiate infection. Thereafter, capsid and tegument proteins act in concert to release viral DNA into the nucleus at nuclear pores although the exact process that occurs once the nucleocapsid reaches the nucleus remains largely unexplored. A conditional, temperature sensitive HSV-1 mutant together with biochemical studies have long implicated the herpesvirus-common LTP in the uncoating process (Chapter 7). The LTP of HSV-1 is needed for uncoating and release of viral DNA at nuclear pores. Studies of other tegument proteins have employed null mutants propagated on cells that complement function in egress, and result in virions that contain the protein. This approach generally masks any role tegument proteins play during entry, leaving this an important area for future exploration.

Regulation of gene expression and replication

Most regulatory proteins encoded by herpesviruses are unique. Only one core protein is purely regulatory, acting as a multifunctional regulator of expression (MRE). MRE has been most extensively studied in HSV-1 (see Chapter 9) where it is the product of *UL54* called ICP27, and EBV (Hiriart *et al.*, 2003) where it is the product of BMLF1 called EB2. MRE binds RNA and localizes to sites of transcription in the nucleus and interacts with components of the RNA polymerase II transcription machinery, the spliceosome complex and pre-mRNA export machinery. MRE stimulates late gene transcription (Jean *et al.*, 2001) and dictates the location of viral transcripts in infected cells (Pearson *et al.*, 2004). MRE is best known for impeding cellular mRNA splicing to allow the mostly intronless viral transcripts to be preferentially exported from the nucleus (Sandri-Goldin, 2001). During the early phase of infection, MRE causes splicing to stall by recruiting host cell kinases to the nucleus to inactivate splicing factors through phosphorylation. In alphaherpesvirus and gammaherpesvirus systems, MRE also recruits an export

adaptor protein (Aly/REF) to sites of viral transcription to facilitate export. This inhibition is relieved during the late phase of infection when splicing and export of host and viral transcripts resumes. Based on studies in HCMV (Lischka et al., 2006; Toth et al., 2006), the function of betaherpesvirus MRE interacts with an RNA helicase, UAP56 to promote cytoplasmic accumulation of unspliced mRNA, and this process is independent of an RNA-binding motif. The MRE may also influence shut-off of the host cell and transcriptional events through a mechanism(s) that remains to be elucidated. Although the level of sequence conservation among MRE homologs is quite limited, others appear to carry out regulatory activities and are sometimes incorporated into the virion tegument, such as in HCMV (Mocarski and Courcelle, 2001).

Viral DNA synthesis and nucleotide metabolism

All herpesviruses encode a core set of six DNA synthesis enzymes that direct the synthesis of viral DNA during productive (lytic) infection. Herpesviruses initiate lytic DNA replication at defined sites on the viral genome that are readily assayed as virus-infection-dependent autonomously replicating sequences. Some herpesviruses have a single origin of DNA replication (ori_{Lyt}), such as in the betaherpesviruses (HCMV, HHV-6A, HHV-6B, HHV-7). Others have either two (VZV, EBV, KSHV) or three (HSV-1, HSV-2) ori_{Lyt} sites that retain sequence homology, although the reason for multiple origins in the biology of viruses that carry them remains a mystery. The relative position of one copy of ori_{Lyt} adjacent to the single stranded DNA binding protein (SSB) gene is conserved in many alpha-, beta- and gammaherpesviruses, even though the primary DNA sequence of ori_{Lyt} is not conserved in all of these settings. All herpesviruses appear to rely on virus-encoded DNA binding proteins to control initiation at ori_{Lyt}. In alphaherpesviruses and the reseolavirus subgroup of betaherpesviruses, a dedicated *ori* binding protein (OBP, HSV-1 *UL9* gene product) is essential for replication. Gammaherpesviruses and cytomegaloviruses rely on DNA binding regulatory proteins that control gene expression and also function during initiation of replication.

In general, DNA replication of herpesviruses, as in other DNA viruses, starts near nuclear structures, called nuclear domain 10, which become disrupted in the course of viral infection. This process overtakes the nucleus and leads to the formation of large, distinct replication compartments where viral replication proteins and DNA accumulate (Wilkinson and Weller, 2003). Viral DNA levels can equal cellular DNA content at late times of infection. Herpesvirus DNA replication proceeds through either of two potential mechanisms that have continued to be the focus of experimental investigation. Initial models of herpesvirus DNA replication have been analogous to bacteriophage lambda (Kornberg and Baker, 1992), starting with genome circularization and theta form replication for which evidence is scant and proceeding to a rolling circle form which has been experimentally well documented (Boehmer and Lehman, 1997; Boehmer and Nimonkar, 2003; Lehman and Boehmer, 1999). This model is based on the existence of ori_{Lyt} sites and site-specific DNA binding proteins and the expectation that the viral genome circularizes upon entry into cells. More recently, a recombination-dependent branching mechanism has been proposed (Wilkinson and Weller, 2003) and supported by the failure to detect circular intermediates during infection as well as by the behavior of HSV-1 mutants that exhibit increased accumulation of circular genomes early after infection (Jackson and DeLuca, 2003). This model has been reinforced by the observation that circular forms of HSV-1 DNA do not correlate with productive replication, but rather with latency. A mechanism analogous to that in the T even bacteriophages (Kornberg and Baker, 1992) has been suggested (Wilkinson and Weller, 2003). Either mechanism of synthesis results in the production of multi-genomic length concatemers that are the substrate for progeny genome packaging using conserved viral gene products. Distinct DNA replication origins separate from ori_{Lyt} sites that are responsible for the synthesis of viral DNA during latent infection have been identified in gammaherpesviruses but not in other subfamilies.

There are two structural categories of ori_{Lyt}. In alphaherpesviruses and non-CMV betaherpesviruses that rely on OBP, the initiation of DNA replication involves a targeted unwinding to enable the assembly of a replication fork complex. This process is best understood in HSV-1. An OBP complex with the viral single stranded DNA binding protein (SSB; HSV-1 *UL29* gene product also called ICP8) unwinds DNA and binds specific sequence motifs (called Box I and Box II in HSV-1) that are symmetrically arranged within ori_{Lyt} (Macao *et al.*, 2004). This allows a more dramatic unwinding at an AT-rich region that is located between Box I and Box II followed by replication fork machinery initiating uni- or bidirectional replication (Boehmer and Lehman, 1997). Beta- and gammaherpesviruses rely on DNA-binding transactivators that are not conserved between subfamilies but act in an analogous fashion to increase transcription across the ori_{Lyt} region which opens the DNA and allows interaction with replication machinery (Xu *et al.*, 2004). Studies in HCMV, EBV and KSHV have all provided evidence for a transcriptional activator-dependent initiation that appears to be distinct

from OBP-dependent initiation in alphaherpesviruses and the betaherpesviruses like HHV-6. The betaherpesvirus HCMV encodes a virion-associated transcript that associates with ori_{Lyt} to form a three-stranded structure whose precise role in DNA synthesis is still under investigation (Prichard *et al.*, 1998). The replication fork machinery includes a highly conserved set of six herpesvirus gene products: SSB, a viral catalytic subunit of DNA polymerase (POL; HSV-1 *UL30* gene product) and associated polymerase processivity subunit (PPS; HSV-1 *UL42* gene product) and a heterotrimeric helicase-primase (HP) consisting of an ATPase subunit (HP1; HSV-1 *UL5* gene product), a primase subunit (HP2; HSV-1 *UL52* gene product) and an accessory subunit (HP3; HSV-1 *UL8* gene product). These proteins direct continuous, leading strand viral DNA replication in a rolling circle mode when used in cell-free assays (Boehmer and Lehman, 1997; Boehmer and Nimonkar, 2003; Lehman and Boehmer, 1999). Following OBP binding to specific sites in ori_{Lyt}, an interaction with single stranded DNA binding protein (SSB) leads to localized unwinding and access of replication fork proteins. Specific interaction of the HP complex with the OBP and synthesis of RNA primers may be an intermediary step leading to DNA replication mediated by the POL–PPS complex. Recombination-directed initiation may be the consequence of SSB and HP activities (Boehmer and Nimonkar, 2003) and may underlie continued viral DNA synthesis (Wilkinson and Weller, 2003; Wilkinson and Weller, 2004). Thus, these six functions provide the core DNA synthesis machinery and mediate homologous recombination during viral replication. Cellular enzymes such as ligase and topoisomerases are highly likely to be required for replication; however, a complete understanding of the steps of herpesvirus DNA replication awaits the development of defined cell-free assay conditions.

Although a high level of recombination has long been associated with herpesvirus replication (Wilkinson and Weller, 2003) and with the isolated biochemical properties of replication proteins (Boehmer and Nimonkar, 2003), only recently has this process received some support as a component of DNA replication (Jackson and DeLuca, 2003). Under conditions where replication is blocked, the HSV-1 genome circularizes more efficiently, suggesting an association of circularization with latency rather than productive replication. Though provocative, this work provides little insight into the steps required for herpesvirus replication. The circumstantial evidence that recombination plays some role either early or late in replication remains strong. In addition to its role in coating single stranded DNA at the replication fork, SSB of HSV-1 appears to direct recombination in a manner similar to *E. coli* RecA (Kornberg and Baker, 1992). Homologous recombination requires SSB as well as another herpesvirus-conserved gene product, alkaline deoxyribonuclease (NUC, HSV-1 *UL12* gene product) (Wilkinson and Weller, 2003; Wilkinson and Weller, 2004). Interestingly, this DNase is absolutely required for HCMV replication (Dunn *et al.*, 2003). In addition to the contribution of sequence specific recombination to DNA replication, circularization of the genome may itself be dependent on recombination and number of herpesviruses that undergo genome isomerization via a recombination event mediated by the *a* sequence which is located at genomic ends and at an internal junction (Mocarski and Roizman, 1982).

Two different nucleotide metabolism enzymes are also broadly conserved, deoxyuridine triphosphatase (DUT; HSV-1 *UL50* gene product) and uracil-DNA glycosidase (UNG; HSV-1 *UL2* gene product). These seem to play accessory roles in replication that are redundant with cellular enzymes. The DUT eliminates pools of dUTP, preventing the incorporation of deoxyuridine into viral DNA and produces dUMP which can be converted to TTP through cellular pathways. The DUT appears to be inactive as an enzyme in betaherpesviruses. UNG cleaves deaminated cytosines (uracil) from the sugar backbone of DNA, leading to base excision and the activation of cellular DNA repair synthesis. In cytomegalovirus, where UNG is required for replication in quiescent cells, the process of uracil incorporation and excision has been proposed to introduce strand breaks that facilitate DNA replication (Courcelle *et al.*, 2001). Functions that are important for replication in nondividing cells where cellular nucleotide metabolism enzymes would be low or absent appear to be critical for replication in the host where differentiated cells lack cellular DNA metabolism enzymes.

Finally, the large subunit of ribonucleotide reductase (RR1, HSV-1 *UL39* gene product) is conserved in all herpesviruses; however, RR1 only forms an active enzyme with a small subunit (RR2, HSV-1 *UL40* gene product) in alphaherpesviruses and gammaherpesviruses. Somewhat surprisingly, betaherpesviruses retain an RR1 that lacks enzymatic activity and do not carry a homolog of RR2 at all. RR1 may have role in cell death suppression in the betaherpesviruses as well as in some alphaherpesviruses.

Capsid assembly and DNA encapsidation

The basic features of herpesvirus capsid maturation common to all herpesviruses have been established through a combination of work with HSV-1 infected cells, recombinant baculovirus-infected cells (Thomsen *et al.*, 1994)

and, importantly, cell-free systems (Newcomb *et al.*, 1996). Assembly employs the herpesvirus-conserved components of the capsid shell (MCP, SCP, TRI1 and TRI2) working in conjunction with a precursor of the assembly protein (pAP, HSV-1 *UL26.5* gene product). Assembly of HSV-1 capsids can proceed without SCP, but at a lower efficiency. A protease (PR, also called assemblin) is required to mature the capsid. This protein is made as a precursor consisting of PR as its amino terminus fused to a longer polypeptide that contains the pAP sequence as its carboxyl end (together called prePR, e.g., HSV-1 UL26 gene product). PR is a serine protease that processes both pAP and prePR. The protease domain self-cleaves in prePR to release PR as well as a variant of pAP, and also processes the carboxyl terminus of PR, pAP, and all variants of pAP (Gibson, 1996). This processing leads to the production of multiple forms of pAP, all colinear at the carboxyl terminus. The presence of pAP is sufficient for capsid assembly, but the presence of prePR, its self-cleavage to PR and variant pAP, and its cleavage of pAP to AP are all necessary for DNA encapsidation to proceed following capsid assembly. In addition, PORT is completely dispensable for the formation of normal appearing capsids, however, this protein is absolutely required for encapsidation of viral DNA. PORT associates with pAP in order to be incorporated into capsids (Newcomb *et al.*, 2003; Singer *et al.*, 2005). During infection, pNP must be cleaved into PR and variant AP for encapsidation to follow capsid formation but both of these proteins, as well as AP, are absent from capsids once encapsidation has occurred. Phosphorylation by VPK has been implicated in the encapsidation step (Wolf *et al.*, 2001).

Once herpesvirus DNA has replicated, encapsidation is controlled by a conserved *cis*-acting element (cleavage/packaging or *pac* site) and a series of seven herpesvirus conserved *trans*-acting functions (Yu and Weller, 1998). Encapsidation has been most extensively studied in alphaherpesviruses but these studies have implications for all herpesviruses. Although initially assigned roles in viral DNA packaging, two of the conserved proteins play roles in transporting preformed capsids to DNA replication compartments, the sites of viral DNA synthesis where packaging also occurs. These two proteins, capsid transport tegument protein (CTTP, HSV-1 *UL17* gene product) and capsid transport nuclear protein (CTNP, HSV-1 *UL32* gene product) are necessary for packaging to proceed. Little is known about the way that these proteins work, except that CTTP is a virion tegument protein and may bind to the capsid (Thurlow *et al.*, 2005). CTNP is a non-structural protein and remains in the nucleus.

Packaging of progeny viral genomes follows a modified head full packaging process reminiscent of bacteriophage λ (Campbell, 1994). Capsid localization, packaging and cleavage of viral DNA are regulated by the conserved VPK as well as by cellular kinases. VPK and cellular kinases may be redundant. The packaging machinery includes a heterodimeric terminase (TER) consisting of an ATPase subunit (TER1; HSV-1 *UL15* gene product) encoded by a conserved spliced gene and a DNA recognition subunit (TER2; HSV-1 *UL28* gene product). This machinery associates with the vertex of the specialized portal penton for the introduction of a free end of a viral DNA concatemer. The PORT protein interacts with TER and brings the packaging machinery and viral DNA to the capsid vertex. This machinery controls the threading of one genome length of DNA into the capsid before scanning for a *pac* site and determining the position of DNA cleavage and therefore the genomic ends. Thus, packaging and cleavage reactions are triggered by *pac* elements located near genomic termini, typically within terminal repeats (*a* sequences). The *pac* signal is composed of at least two elements, referred to as *pac* 1 and *pac* 2, and is broadly conserved among herpesviruses such that the *pac* from HCMV can direct packaging into HSV-1 virions (Spaete and Mocarski, 1985). All studies thus far have suggested that packaging yields single base 3′ extensions at both genomic ends and that packaging proceeds directionally with regard to the viral genome orientation as originally determined for HSV-1 (Mocarski and Roizman, 1982). The conservation of signals, functions and structure strongly suggests that this process is similar across all herpesviruses.

The heterodimeric TER, which is non-structural, and the portal complex, which takes the place of one penton of the capsid, associate with two additional conserved proteins, a TER binding protein (TERbp, HSV-1 *UL33* gene product) that interacts with capsids independent of PORT and a portal capping protein (PCP; HSV-1 *UL25* gene product). PCP remains associated with the nucleocapsid after packaging and thus appears as a minor capsid protein in mature virions. These five proteins are sufficient for recognition of a *pac* site on multi-genome DNA concatamers, docking with the appropriate site on a capsid, threading viral DNA into the caspid, cleavage at a *pac* site and sealing the genome into the progeny nucleocapsid (Fig. 4.1). As such they define a set of viral functions that are likely to be required for genome packaging in all herpesviruses. Once DNA has been packaged and PCP has covered the portal, the packaging stage of replication is completed and the nucleocapsid undergoes initial envelopment at the inner nuclear membrane (Fig. 4.1).

Two additional nuclear proteins, HSV-1 *UL7* and *UL14* gene products contribute to events in capsid maturation or DNA packaging. The *UL14* gene product is a minor tegument protein that appears to act as an encapsidation chaperone protein (ECP) to bring SCP and TERbp into the nucleus (Nishiyama, 2004). The *UL7* gene product appears

to act as an encapsidation and egress protein (EEP), colocalizing with capsids in patterns that suggest a role in DNA encapsidation or egress from the nucleus.

Maturation

Following the formation of the nucleocapsid, the best evidence from several systems suggests that tegument proteins function together with non-structural proteins to control a complex two-stage envelopment and egress process that starts in the nucleus and leads to virion release by exocytosis at the plasma membrane. This two-stage envelopment process has been controversial but strong evidence has accumulated in favor of this pathway in all three herpesvirus subfamilies. The alphaherpesviruses HSV-1 and PRV have been extensively studied, along with the betaherpesviruses HCMV and MCMV (Mettenleiter, 2002; Mettenleiter, 2004). Evidence suggests that nuclear egress starts with primary envelopment at the inner nuclear membrane followed by a de-envelopment event at the outer nuclear membrane, a process that releases the nucleocapsid into the cytoplasm (Fig. 4.1). Secondary envelopment occurs in the cytoplasm at endosomal (or possibly Golgi complex) membranes with resulting vesicles carrying the fully mature virions to the cell surface using the cellular exocytic pathway. Alternatively, the older model of egress has the enveloped viral particle itself following a vesicle transport pathway without deenvelopment (Roizman and Knipe, 2001) (see Chapter 10). These steps, like the initial entry process, rely on membrane fusion events; however, envelopment and egress are relatively independent of viral envelope glycoproteins that play critical roles during entry. Non-replicating mutants in gB or the gH:gL complex mature normally but show defects in entry. Only the gM:gN complex may contribute to secondary, or final, envelopment.

Initial envelopment event occurs at the inner nuclear membrane, following and dependent upon genome packaging that produces nucleocapsids. Capsids lacking DNA do not mature efficiently and nucleocapsids must localize correctly in the nucleus to properly egress. Studies in alphaherpesviruses and betaherpesviruses have shown that two conserved proteins form a nuclear egress complex on the inner nuclear membrane to control egress from the nucleus (Mettenleiter, 2004) and disruption of the nuclear lamina. The nuclear egress membrane protein (NEMP, HSV-1 *UL34* gene product) acts as a type II membrane-spanning protein to anchor the nuclear egress lamina protein (NELP, HSV-1 *UL31* gene product), a phosphoprotein that interacts with the nuclear lamina as well as with membrane-associated NEMP. NEMP and NELP are dependent on one another for proper transport and localization to the inner nuclear membrane. Additional viral proteins or the process of viral maturation itself appear to be necessary for the formation of the nuclear egress complex. Direct binding to nucleocapsids has not been observed, however, the complex recruits viral and/or cellular protein kinases that appear to be important for phosphorylation and disruption of the nuclear lamina to allow egress. Viral mutants in NEMP or NELP are debilitated for egress, likely unable to bud through the inner nuclear membrane (primary envelopment) and so accumulate nucleocapsids inside nuclei. The nuclear egress complex may also participate in membrane fusion events at the outer nuclear membrane that are required to deposit the nucleocapsid in the cytoplasm (de-envelopment). Although NEMP, as a primary envelope protein, and NELP, as a primary tegument protein, are important components of primary virions, neither is retained in fully mature virions.

Primary envelopment delivers viral particles to the perinuclear space between the inner and outer nuclear membranes, a compartment contiguous with the endoplasmic reticulum. Over the past 10 years evidence has accumulated in several different herpesviruses that final herpesvirus envelopment occurs in the cytoplasm at late endosomal or Golgi body membranes. It is likely that primary envelopment is followed by a de-envelopment step that releases the nucleocapsid into the cytoplasm. It remains possible, but topologically unlikely that nucleocapsids move to the cytoplasm without any envelopment step through modified nuclear pores. Either way, movement of nucleocapsids to sites of final envelopment appears to be a microtubule-dependent process. Protein kinases appear to play regulatory roles in primary envelopment as well as de-envelopment occurring at the outer nuclear membrane or endoplasmic reticulum. In alphaherpesvirus, viral US3 kinase facilitates these processes by facilitating phosphorylation of NEMP or other proteins. Primary envelopment and de-envelopment may also rely on cellular kinases. In HCMV, the conserved VPK contributes to nuclear egress (Krosky et al., 2003) whereas in other betaherpesviruses such as MCMV, host protein kinase C has been implicated in nuclear egress (Muranyi *et al.*, 2002). All of this data suggests that there is redundancy and possible interplay between viral and host kinases (presumably in conjunction with host phosphatases) in establishing the appropriate phosphorylation state for egress from the nucleus.

While some virion tegument proteins are associated with nucleocapsids during nuclear egress, many are added in the cytoplasm. Major tegument proteins, though not conserved, localize to the cytoplasm in all herpesviruses that have been studied and it now appears that the bulk of tegument proteins found in mature herpesvirus virions are

added to the nucleocapsid as it traverses the cytoplasm or at sites of final envelopment. There is currently little precise understanding of how nucleocapsids engage microtubules to traverse the cytoplasm, how final envelopment at endosomal (or Golgi complex) membranes occurs or how tegument proteins might be added prior to final envelopment. There is growing suspicion that addition may be nucleated by the conserved, very large LTP:LTPbp protein complex (Mettenleiter, 2004). This and a number of additional interactions between tegument proteins (Vittone et al., 2005) may be important in function. Current evidence on alphaherpesviruses and betaherpesviruses suggests that a conserved cytoplasmic egress tegument protein (CETP, HSV-1 *UL11* gene product) plays a central role in the secondary, or final, envelopment process. In alphaherpesviruses and betaherpesviruses, CETP is a myrisoylated and pamitoylated protein that localizes to the cytoplasmic face of cellular membranes and is known to interact with another herpesvirus-conserved tegument protein, the CETP binding protein (CETPbp, HSV-1 *UL16* gene product). Together, these may form a complex involved in transport. An additional tegument protein called cytoplasmic egress facilitator 1 (CEF1, HSV-1 *UL51* gene product) is a palmitated protein that is conserved amongst herpesviruses and also associates with cytoplasmic membranes (Nishiyama, 2004). In PRV, mutants in CEF1 fail to egress properly. One final tegument protein, called cytoplasmic egress facilitator 2 (CEF2, HSV-1 *UL21* gene product) enhanced maturation and interacts with CETPbp. Limited evidence supports a role for the gM:gN complex in secondary envelopment, particularly when disrupted together with *UL11*(Kopp *et al.*, 2004; Tischer *et al.*, 2002), although this complex is dispensable for replication in a number of other alphaherpesviruses, including HSV-1. Both gM and gN are essential for HCMV replication (Dunn *et al.*, 2003) as well as for assembly in EBV (Lake and Hutt-Fletcher, 2000). gM:gN is a major EBV structural component and has recently been recognized as the major glycoprotein complex on the HCMV envelope (Varnum *et al.*, 2004).

Thus, final envelopment occurs in the cytoplasm and, as a consequence the tegument of virions includes small amounts of cellular proteins, in particular actin (Bortz *et al.*, 2003; Johannsen *et al.*, 2004; Kattenhorn *et al.*, 2004; Varnum *et al.*, 2004; Zhu *et al.*, 2005), as well as RNAs (Sciortino *et al.*, 2001; Terhune *et al.*, 2004) that may represent a quantitative sampling of the cytosol, although a role for any virion component in replication cannot be discounted as yet. Once final envelopment has occurred, exocytosis is believed to carry the mature virion inside of a vesicle to the cell surface for release. Thus, the final step in egress is fusion of an exocytic vesicle with the plasma membrane, a process that is likely to follow cellular vesicle trafficking pathways (Fig. 4.1).

This analysis of the role of herpesvirus-conserved gene products has attempted to evaluate data generated in a wide variety of systems. As a result, some data will certainly have been generalized inappropriately as further investigation reveals unique characteristics or distinguishing activities. While many common names are already in use across the different herpesviruses, the hope is that a common nomenclature for herpesvirus-common functions should emerge to facilitate comprehension of work in otherwise diverse systems. This presentation is intended to provide a starting point for evaluation of data on herpesvirus core functions no matter what virus system is being studied or discussed.

Part II

Basic virology and viral gene effects on host cell functions: alphaherpesviruses

Edited by Gabriella Campadelli-Fiume and Bernard Roizman

5

Genetic comparison of human alphaherpesvirus genomes

Joel D. Baines[1] and Philip E. Pellett[2]

[1]College of Veterinary Medicine, Cornell University, Ithaca, NY, USA
[2]Lerner Research Institute, The Cleveland Clinic, Cleveland, OH, USA

Human herpesviruses 1, *2*, and *3* (herpes simplex virus 1 (HSV-1), herpes simplex virus 2 (HSV-2), and varicella-zoster virus (VZV)) have been classified as alphaherpesviruses based originally upon their biological properties, and subsequently on the sequences of their respective genomes (Minson *et al.*, 2000; Pellett and Roizman, in press). All of these viruses maintain latent infections in sensory ganglia, and can productively infect a variety of human cells, including the living cells of mucous membranes and skin. These epithelial sites also provide exit points for the virus to infect other individuals.

The structure of the genomes of the alphaherpesviruses that infect humans are quite similar at first glance (Fig. 5.1). All have two unique segments that are flanked by repeats of different lengths. The unique segments are designated short (S) and long (L) and the repeats designated as internal (IR) or terminal (TR). Members of the genus simplexvirus (HSV-1 and HSV-2) exist as four roughly equimolar isomers, each isomer differing in the relative orientations of the long and short components. The orientation of one of the HSV isomers has been designated prototypical, and could therefore be designated TRL-U_L-IRL-IRS-U_S-TRS. VZV also produces 4 genomic isomers, but those in which the long component is inverted are significantly reduced in frequency, to about 5% of total genomes. It is tempting to speculate that this is a consequence of the shorter repeats flanking the VZV long component (88.5 bp) as compared to the repeats flanking U_S in human alphaherpesviruses (6000–7400 bp) and U_L in HSV-1 and HSV-2 (around 9,000 bp). The shorter repeat region would be expected to reduce the frequency of homologous recombination events leading to less frequent inversion of the long component in VZV genomes.

The 129 kbp VZV genome is the smallest genome of the human herpesviruses, whereas the HSV-1 and HSV-2 genomes are over 152 kbp in length. The G + C content of the human simplexviruses is around 68% whereas the VZV genome is only 46% G + C. Thus, considerable numbers of mutations have occurred since the two lineages arose from a common progenitor. All three viruses encode well-conserved sequences that guide lytic replication (oriLyt) and genome cleavage and packaging (Frenkel & Roffman 1996). Copies of oriLyt are present in IRS and TRS of all three viruses, and near the center of L for HSV-1 and HSV-2.

Several features are apparent in the global sequence comparisons shown in Fig. 5.2. HSV-1 and HSV-2 are much more closely related to each other than is either to VZV. HSV-1 and HSV-2 genomes are most similar in their U_L components, and least similar in the inverted repeats that bound U_L (TRL and IRL). The VZV sequence is most closely related to HSV in their U_L components. These observations can be extended by measuring the level of sequence identity along the dot plot diagonal, as shown in the nucleotide sequence similarity plot for HSV-1 vs. HSV-2 (Fig. 5.3). As can be seen, the similarity is highest across U_L, with most of the peaks corresponding to protein coding regions, and the valleys to intergenic regions, the exceptions being U_L 42 through U_L 44, and U_L 49. The L component repeats are much less well conserved, with the peak of similarity being in the region encoding ICP0 (RL2). The most highly conserved region in the S component repeats is the ICP4 gene (RS1). Overall, U_S is less well conserved than U_L. This region includes the U_S 4 (gG) gene, which is approximately 1500 bp longer in HSV-2 than in HSV-1 and represents the region of greatest dissimilarity between HSV-1 and HSV-2.

The gene arrangement in the long component of the most common isomer of the VZV genome is inverted relative to the U_L of the prototypical isomer of HSV (Fig. 5.1). With this inversion in mind, the genes in the HSV-1 and HSV-2 U_L segments are mostly collinear with VZV U_L (Fig. 5.2), and all but a few U_L genes are conserved across all human alphaherpesviruses. This consideration also underscores the significance of the overall similarity of the genes,

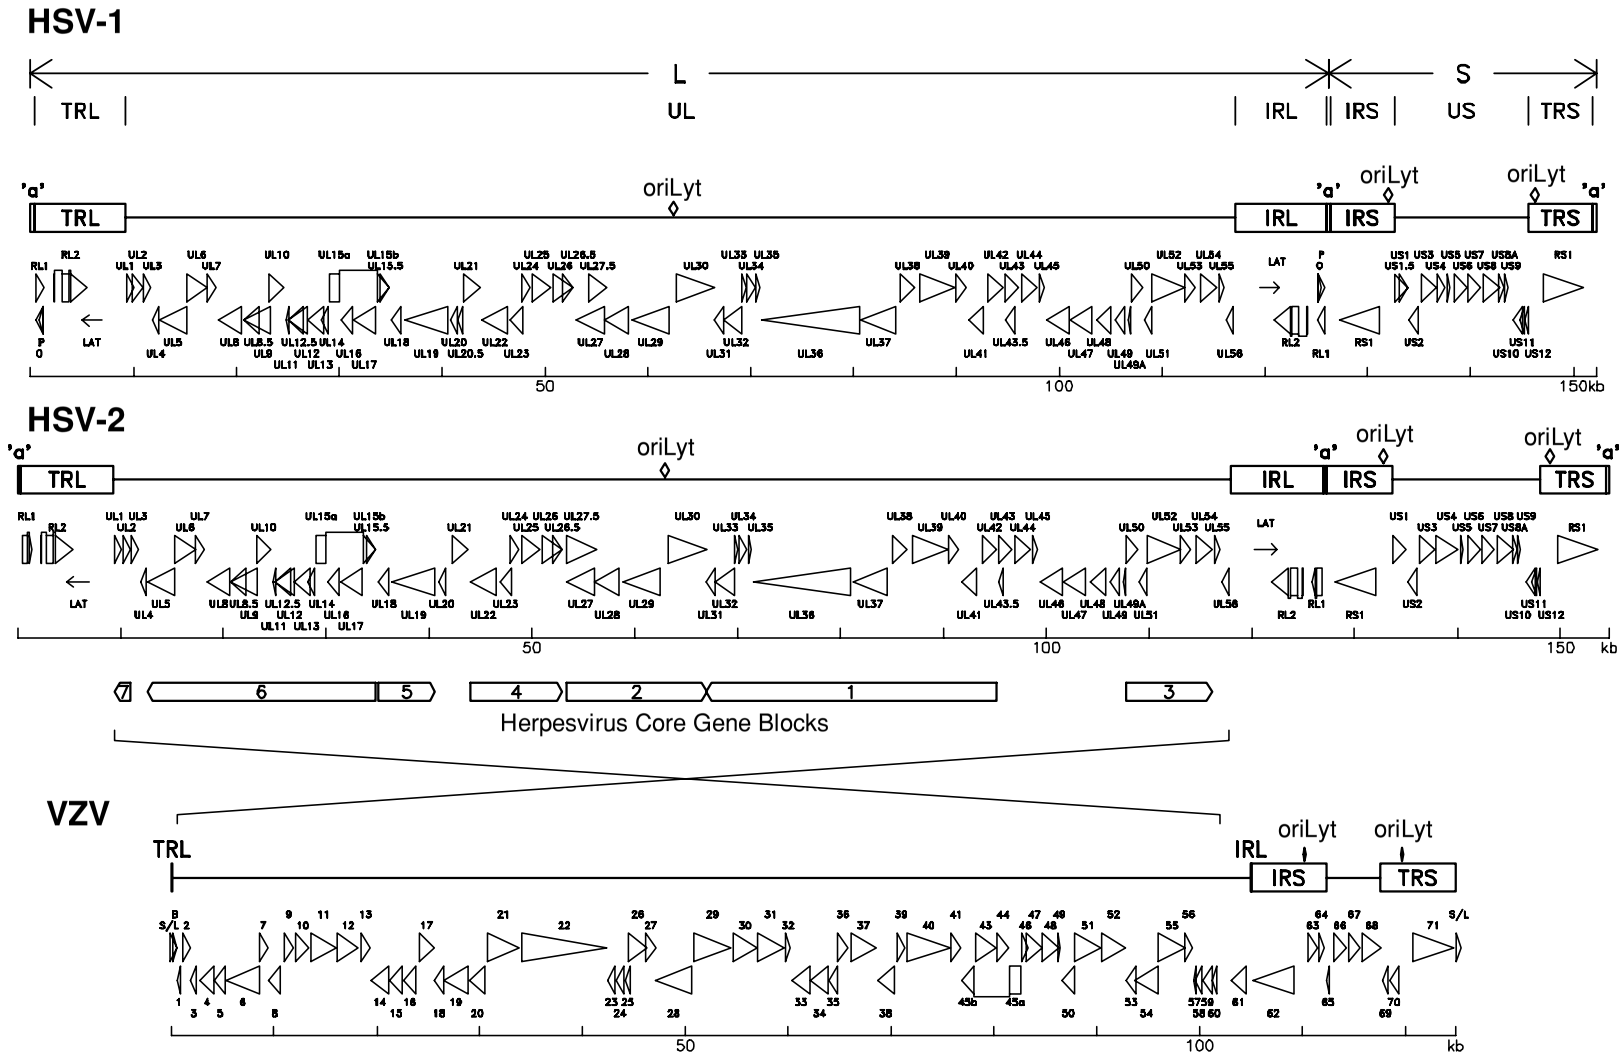

Fig. 5.1. Genomic and genetic architectures of the human alphaherpesviruses. Note that the VZV L component is inverted relative to the HSV prototypic arrangement. The representations are based primarily on annotations in Genbank Accession numbers X14112 (HSV-1 strain 17), Z86099 (HSV-2 strain HG52), and X04370 (VZV strain Dumas), and information in references cited in the text. L, long component; S, short component; TRL, long component terminal repeat; IRL, long component internal repeat; IRS, short component internal repeat; TRS, short component terminal repeat.

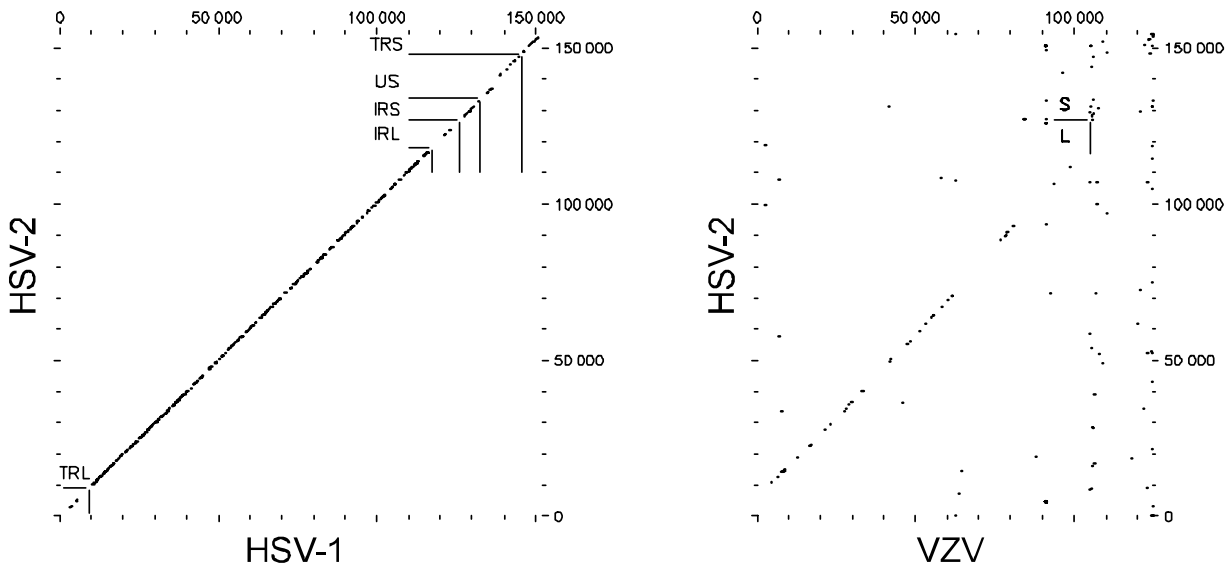

Fig. 5.2. Global genome sequence similarity comparisons among the human alphaherpesviruses. Dot similarity plots were constructed from comparisons of complete genome sequences. For HSV-1 vs. HSV-2, the window was 50 and the stringency was 45 identical residues. For HSV-2 vs. VZV, the window was 50 and the stringency was 25 identical residues. This reduced stringency was needed, because there were no dots when the HSV-2 and VZV were compared at the same stringency used for the HSV-1/HSV-2 comparison. Because the prototypic genomes of HSV-2 and VZV have relatively inverted L components, the HSV-2/VZV comparison was done with a VZV sequence in which the L component was inverted. Sequence sources and abbreviations are the same as for Fig. 5.1.

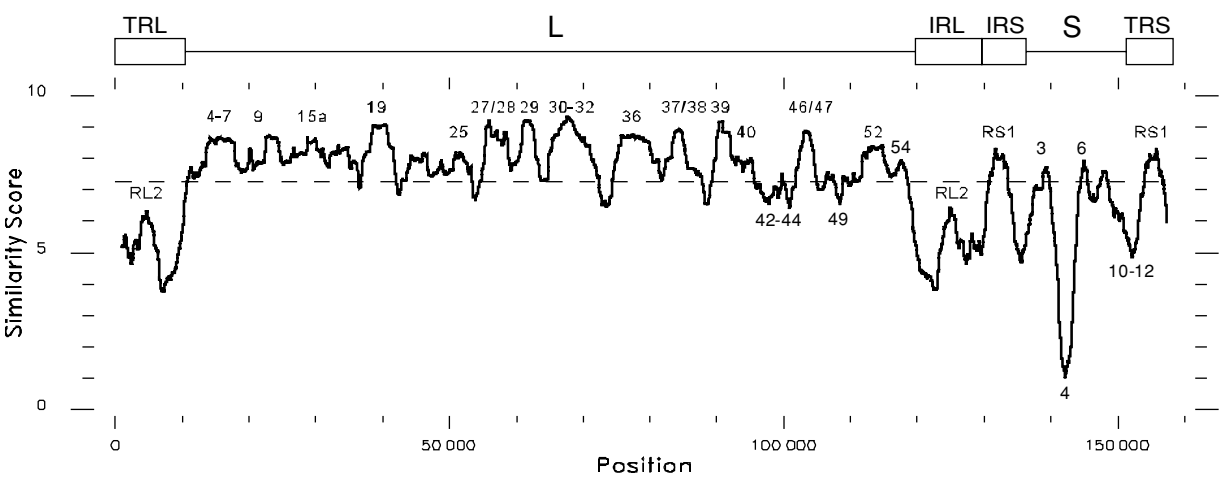

Fig. 5.3. Nucleotide sequence similarity between HSV-1 and HSV-2. HSV-1 and HSV-2 nucleotide sequences were aligned in approximately 20 kb segments, the aligned segments were joined to generate genome-length alignments, and then the similarity along the aligned genomes was plotted as a running percentage of identity in windows of 2000 residues. x-axis positions do not correspond precisely to genomic coordinates because of spaces inserted during the alignment. Boundaries of major architectural features are indicated, as are the locations of various genes along the plot. Sequence sources and abbreviations are the same as for Fig. 5.1.

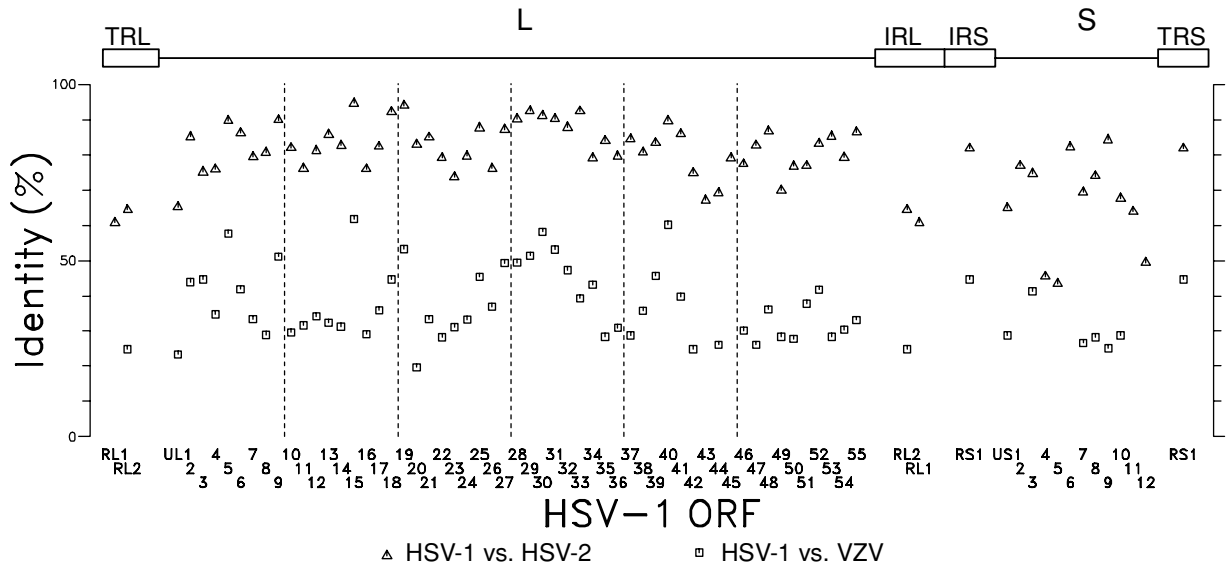

Fig. 5.4. Amino acid sequence identities between proteins encoded by the human alphaherpesviruses. Homologous protein sequences were aligned, and the percentage of identical residues determined in comparisons between HSV-1 and HSV-2 (triangles), and between HSV-1 and VZV (squares). Identity scores were plotted as a function of their location in the HSV-1 genome, relative to the major genomic architectural features. As detailed in the text, some HSV genes do not have identified homologues in VZV, and vice versa, and some genes are encoded within and in frame with others (and are thus not represented individually in this figure). Sequence sources and abbreviations are the same as for Fig. 5.1.

suggesting that they are considerably constrained by their respective functions. The most highly conserved genes between VZV and HSV-1 (HSV U_L 5, U_L 15, U_L 30, and U_L 40) are among the most highly conserved between HSV-1 and HSV-2 (Fig. 5.4). Their encoded proteins are enzymes involved in DNA replication and metabolism. This suggests that there is both little external pressure for these genes to change and little tolerance for accepting the products of random mutation. The least conserved genes between HSV-1 and HSV-2 are encoded in the S component and TRL/IRL; as detailed below, many of these genes do not have homologues between HSV and VZV. These gene products are likely to be important in defining the precise biological niche occupied by each virus.

VZV genes that are absent from HSV genomes

Although homologues of most long component genes exist in HSV-1, HSV-2 and VZV, there are some notable exceptions. Six VZV U_L genes have no homologue in the HSV U_L (ORF1, ORF2, ORF13, ORF32, ORF57 and ORF S/L). All of these genes are dispensable for replication in cell culture in at least some cell types.

ORF1 encodes an integral membrane protein of approximate M_r 17 000 with a C-terminal hydrophobic domain. Its function is not known, but it is completely dispensable for growth of the virus in MeWo cells (Cohen and Seidel, 1995). Equine herpesvirus 1 (EHV-1) and EHV-4 are both members of the genus *Varicellovirus* in the subfamily *Alphaherpesvirinae* (Telford *et al.*, 1992, 1995). Although these viruses encode a gene (termed EHV gene 2) in a position that corresponds to VZV ORF1, it has no obvious similarity with the VZV counterpart.

VZV ORF2 also encodes a phosphorylated membrane-associated protein that is dispensable for growth in cell culture and establishment of latency in dorsal root ganglia of cotton rats (Sato *et al.*, 2002). Genes with very limited homology with VZV ORF2 are present in other Varicelloviruses including gene 3 of EHV-1 and EHV-4. The functions of these genes are not known.

VZV ORF13 encodes thymidylate synthetase. Interestingly, homologues are not present in other alphaherpesviruses, but the genomes of several gammaherpesviruses, including human herpesvirus 8, herpesvirus saimiri, herpesvirus ateles, and equine herpesvirus 2 contain functional homologues. Moreover, human cytomegalovirus upregulates cellular thymidine synthetase (Gribaudo *et al.*, 2002). Thus, incorporation into the viral genome, or other means of upregulation of thymidylate synthetase in the host cell likely confers a selective advantage to these

viruses, possibly as it promotes availability of nucleotides for viral DNA replication in quiescent cells. Within the region corresponding to VZV ORF13, HSV-1 and HSV-2 encode U_L 45, which is encoded on the opposite strand and has no homologue in VZV. The U_L 45 gene encodes a type II membrane protein that is dispensable for replication in cell culture (Cockrell and Muggeridge 1998; Visalli and Brandt 1991).

VZV ORF32 is homologous to gene 34 of EHV-1 and EHV-4, but has no counterparts in other herpesvirus genera. The encoded protein of 16,000–18,000 M_r is posttranslationally modified by the ORF47 protein kinase and is dispensable for change replication in cell culture and the establishment of latency (Reddy *et al.*, 1998; Sato *et al.*, 2003).

VZV ORF57 is located in a region of unusually high diversity among the U_L segments of alphaherpesvirus genomes. VZV ORF57 has no sequence similarity to genes in herpesviridae for which DNA sequence data are available. In HSV, the corresponding region encodes no obvious open reading frame, and in fact has served as an insertion site for the expression of exogenous genes and bacterial artificial chromosome vector sequences without obvious detriment to the virus in cultured cells or animals (Baines and Roizman, 1991; Tanaka *et al.*, 2003). On the other hand, the region between U_L 3 and U_L 4 in the Suid herpesvirus 1 (Pseudorabies virus or PRV) genome encodes gene U_L 3.5 that is necessary for viral egress (Fuchs *et al.*, 1996). Like VZV ORF57, the PRV U_L 3.5 has no obvious homologue in any other herpesvirus.

ORF S/L is also unique to VZV. The encoded protein is located in the cytoplasm of infected cells and varies in size from about 21 000–30 000 apparent M_r among different VZV strains (Kemble *et al.*, 2000). The initiation codon of ORF S/L lies at the right end of TRS with translation crossing into the L component (this requires genome circularization or concatemerization). VZV ORF B is translated from within the same ORF, but initiates within the L component, terminating at the same stop codon as ORF S/L (Mahalingam *et al.*, 2000). The functions of either protein are unknown.

L component genes unique to the simplexviruses

Unless otherwise noted, it should be assumed that the following genes are encoded by HSV-1 and HSV-2, but not VZV.

The 248 residue ORF P lies in the repeats bordering U_L (TRL and IRL). The associated transcript is antisense to the RL1 gene encoding γ_1 34.5, and ends where the full length latency associated transcript (LAT) terminates. The gene is expressed primarily under conditions where other HSV genes, including those of the immediate early or alpha class, are not expressed (Lagunoff and Roizman, 1994). Deletion of an ICP4 binding site in the ORF P promoter augments expression, suggesting that ICP4 normally acts to repress ORF P (Lagunoff *et al.*, 1996). Because HSV alpha genes are not expressed during latent infection, it has been speculated that ORF P might be expressed preferentially in latently infected neurons, although this has not been demonstrated. The predicted HSV-2 counterpart of ORF P is 130 amino acids in length and has substantial similarity over the first 49 codons, after which the similarity drops off significantly at a site corresponding to an intron in HSV-2 RL1, which is encoded on the opposite strand (Dolan *et al.*, 1998). It has not been determined if the HSV-2 counterpart to ORF P is expressed.

ORF O of HSV-1 is shorter than, and entirely contained within, ORF P. The protein is regulated in a similar fashion to ORF P, and appears to be translated from the same inititation codon, but shifts frame by an unknown mechanism after codon 35 to a different reading frame, resulting in translation of a 20 000 apparent M_r protein. The protein can interact with ICP4 and preclude the latter's binding to DNA (Randall *et al.*, 1997). Similar to ORF P, the homology to an HSV-2 counterpart is only convincing at the extreme N-terminus and it is not known if the HSV-2 protein is expressed.

The γ_1 34.5 protein is encoded by RL1 in the repeat region, with the promoter located in the a sequence, and the open reading frame in the b sequence. The protein is a major determinant of neurovirulence and has a number of interesting functions including the recruitment of phosphatase alpha to dephosphorylate elongation initiation factor alpha and thus preserve translation of viral proteins, even in the presence of PKR (He *et al.*, 1997). The HSV-2 counterpart contains an intron, but is otherwise conserved. There is no obvious homologue in VZV or in herpes B virus (Perelygina *et al.*, 2003).

The U_L 8.5 gene is present in both HSV-1 and HSV-2. The gene product, designated OBPC, represents the C terminal 438 amino acids of the U_L 9 gene that encodes the origin binding protein (OBP). OBPC can bind origin sequences and can interfere with DNA replication in vitro (Baradaran *et al.*, 1996; Baradaran *et al.*, 1994).

The U_L 12.5 open reading frame is translated in frame with U_L 12 to yield a 60 000 M_r protein. It retains some of the nuclease activity of U_L 12, but lacks a nuclear localization signal at the N-terminus, perhaps explaining why U_L 12.5 cannot complement a U_L 12 null mutant. The precise function of U_L 12.5 is not known (Martinez *et al.*, 1996; Reuven *et al.*, 2004).

The U_L 15.5 open reading frame is present in VZV, but in contrast to the case with HSV-1, it is not known if the VZV protein is expressed. The open reading frame constitutes most of exon II of U_L 15 and the protein is in frame with U_L 15. The function is not known (Baines *et al.*, 1994, 1997; Yu *et al.*, 1997).

The U_L 20.5 open reading frame is located upstream of U_L 20. The gene product is expressed in infected cells and localizes in discrete sites in the nucleus. The open reading frame is not conserved in HSV-2 or VZV and the function is not known (Ward *et al.*, 2000).

U_L 27.5 is encoded in opposite sense to U_L 27, which encodes glycoprotein B. The 43 000 apparent M_r protein identified in infected cells is much smaller than the 575 codon open reading frame would predict. An HSV-2 protein of similar size that shares epitopes with the HSV-1 gene product is derived from an open reading frame of 985 codons (Chang *et al.*, 1998). The mechanism by which these large open reading frames lead to production of smaller than expected proteins is unknown.

U_L 43.5 is a 311 aa ORF that is encoded completely within U_L 43 coding sequences but is translated in opposite sense to that of U_L 43 (Ward *et al.*, 1996). The genomic region encoding these open reading frames is dispensable for viral growth in cell culture (MacLean *et al.*, 1991). The protein localizes in assemblons, discrete sites within infected cell nuclei that contain a variety of capsid and tegument proteins. The U_L 43.5 open reading frame is not conserved in HSV-2 (Dolan *et al.*, 1998).

The U_L 56 gene is unique to the simplexviruses of humans. The gene lies in a region that is necessary for a virulent phenotype of certain HSV-1 strains, but the gene itself does not contribute substantially to this virulence, at least in mice (Nash and Spivack, 1994). The gene product is associated with virions and is not essential for growth in cultured cells (Rosen-Wolff *et al.*, 1991).

The unspliced latency associated transcript or LAT is around 7–9 kbp in length, and this is extensively spliced. The introns of approximately 1.5 and 2.0 kbp are presumably very stable and accumulate to high levels in the nuclei of latently infected sensory neurons. Both the large and small transcripts are derived from transcriptional units within IRL and TRL and are transcribed in a sense opposite to that of RL1 (encoding ICP0) with which they overlap. Transcription through the repeat regions and antisense to ICP0 is a common theme among many alphaherpesviruses including bovine herpesvirus 1 and PRV, but these transcripts are not greatly similar to HSV LAT, other than in regions that overlap conserved open reading frames (Cheung, 1991; Rock *et al.*, 1987). More extensive discussions of the latency associated transcripts are included elsewhere in this volume.

S component genes unique to the human simplexviruses

The short components of the human alphaherpesviruses are considerably less well conserved than the long components (Figs. 5.1 to 5.4). Perhaps the most striking difference is that homologues of six HSV genes, including U_S 6 encoding the essential glycoprotein D, are not present in the VZV genome (Dolan *et al.*, 1998; McGeoch *et al.*, 1988). In addition, the order of the existing homologues of U_S is considerably rearranged (Davison and McGeoch, 1986).

The U_S1 gene of 420 codon encodes ICP22 whereas the $U_S1.5$ open reading frame of 273 codons is contained within the U_S 1 gene, and is translated in the same reading frame as ICP22 but from a different initiation codon (Carter and Roizman, 1996). A homologous, but highly diverged gene to that encoded by U_S 1.5 is present in HSV-2, but this lacks an obvious start codon. The VZV counterpart is ORF 63/70 (the gene is duplicated at the ends of the short component of VZV); the region of highest similarity with HSV-1 is limited to the C-terminus which includes US1.5.

The U_S2 gene of HSV is present in many other alphaherpesviruses, but is conspicuously absent from the VZV genome. The function of the gene is not known but the gene product is found in HSV-2 virions and can associate with cytokeratin 18 in vitro and in infected cells (Goshima *et al.*, 2001). U_S2 is not essential for growth in cell culture and the HSV-2 gene is dispensable for virulence in mice inoculated by the footpad route (Jiang *et al.*, 1998; Longnecker and Roizman, 1987). The homologous gene product of pseudorabies virus (PRV) is prenylated, a modification that changes its localization from association with membranes to punctate regions in the cytoplasm (Clase *et al.*, 2003). The gene product is associated with virions and this association may be regulated by postranslation modification, inasmuch as the virion-associated gene product is not prenylated.

The U_S 4 gene encodes glycoprotein G (gG). The gene is dispensable for growth in cell culture and differs significantly in sequence such that the HSV-2 gene is approximately 1500 bp larger (Ackermann *et al.*, 1986; Dolan *et al.*, 1998; Longnecker *et al.*, 1987; McGeoch *et al.*, 1988). This difference is exploited in serologic assays to distinguish HSV-2 specific antibodies from those induced by HSV-1

(Lee *et al.*, 1985). The function of gG is not known, but speculation that it has something to do with tropism unique to HSV-2 vs. HSV-1 seems warranted.

U_S5 encodes glycoprotein J (gJ) (Ghiasi *et al.*, 1998). gJ prevents apoptosis in cells infected with HSV-1 gD null mutants, and precludes apoptosis induced by granzyme B and Fas ligation, such as would be expected upon attack of an infected cell by cytotoxic T-lymphocytes (Jerome *et al.*, 2001; Zhou *et al.*, 2000). Interestingly, HSV-2 does not preclude apoptosis induced by ultraviolet radiation or Fas antibody, whereas HSV-1 blocks apoptosis through these stimuli, suggesting a difference in function of anti-apoptotic mechanisms mediated at least partly through gJ (Jerome *et al.*, 1999).

U_S6 encodes gD that is necessary for HSV entry and has been shown to bind a variety of proteinaceous viral receptors (Spear, 2004). The fact that a gene essential for entry of HSV is absent from the VZV genome suggests that the essential steps mediated by gD must be mediated by different VZV proteins. This issue is treated extensively in chapters dealing with herpesvirus entry.

$U_S8.5$ encodes a phosphoprotein that localizes to nucleoli (Georgopoulou *et al.*, 1995). The gene is dispensable for replication in cultured cells and the function is not known. Although $U_S8.5$ is a late gene, the mRNA is packaged into virions and presumably delivered to infected cells upon entry (Sciortino *et al.*, 2002).

The 161 codon U_S11 of HSV-1 is an RNA binding protein that is unique to the simplexviruses of humans. If expressed as an alpha gene, the protein can dephosphorylate EIF2α and thereby rescue the ability of a γ_1 34.5 deletion mutant to replicate in neuronal cell lines (Mohr and Gluzman, 1996; Roller *et al.*, 1996).

U_S12 encodes ICP47, an 88 amino acid immediate early protein. ICP47 can block the transporter associated with antigen transport (TAP) and thus preclude loading of antigenic peptides onto class 1 molecules in the ER (York *et al.*, 1994). Although ICP47 may be unique to human simplexviruses, it can be viewed as functionally conserved inasmuch as interference with antigen presentation is a function common to many viral proteins, including a number from both gamma- and betaherpesviruses (Vossen *et al.*, 2002).

In considering the information outlined herein, the authors would like to include a note of caution. While comparison of the sequences of the human alphaherpesviruses with one another and with other herpesviruses leads to a series of hypotheses regarding functions of individual genes, such an analysis is at once both potentially valuable and misleading. Fortunately, such hypotheses are experimentally testable in the context of the most relevant viral genome. It is anticipated that some surprises will result from these studies. Perhaps this is best illustrated by studies of herpesvirus glycoproteins, as various sequence homologues may have markedly different functions depending on the viral system studied. At the least, the preceding analyses of similarities in the genetic content of the human alphaherpesviruses should be considered with this caveat in mind.

Alphaherpes viral genes and their functions

Bernard Roizman[1] and Gabriella Campadelli-Fiume[2]

[1]The Marjorie B. Kovler Viral Oncology Labs. The University of Chicago, IL, USA
[2]Department of Experimental Pathology, University of Bologna, Italy

Introduction

In this chapter the emphasis is on viral replication and on the viral gene products that define the outcome of the interaction of the alphaherpesviruses with their host. Viral replicative and host management functions account for some of the RNAs and a large number of proteins encoded by the viruses. There are, however, numerous viral gene products whose functions have not been identified or which do not play a prominent role in viral replication in the systems in which these have been tested. The objective of the table contained in this section is to summarize the functions of all known gene products and provide at least a few references for each product. It should be noted however that: of the three human alphaherpesviruses, we know more about the functions of herpes simplex virus-1 and -2 (HSV-1 and HSV-2) genes than about those of varicella zoster virus (VZV). We have identified in this table the VZV genes that are related to HSV by amino acid sequence homology. We note that partial sequence conservation does not necessarily mean that the homologous HSV and VZV gene products perform identical functions.

The list understates both the number of the products and their functions. The problem is twofold. The HSV genome encodes a large number of open reading frames (ORFs) with 50 or more codons and not all of the ORFs have been probed for to determine whether they are expressed. In addition, standard annotations exclude ORFs that are antisense to known ORFs or that do not have TATA boxes or other motifs that indicate that they encode proteins. HSV encodes several proteins whose ORFs are antisense to each other. An additional problem is that transcripts arising late in infection frequently do not terminate at predicted termination signals. In addition, several viral RNAs either do not encode a protein or the protein is made in undetectable amounts. In several instances, ORFs contain within their domain a transcriptional unit encoding proteins identical to the C terminal domain of the protein encoded by the larger ORF. In essence, we do not know the absolute number of transcripts or proteins encoded by the viral genome.

The third limitation of the table stems from the observation that virtually all viral proteins studied in detail appear to perform multiple functions. Not all of the functions are known and, in some instances, the table lists the most prominent functions of the gene product.

We further note that (i) some alphaherpesvirus genes are found only in HSV-1 (ORF-O and ORF-P), some in HSV-1 and HSV-2 ($\gamma_1$34.5), some in HSV-1, HSV-2 and B virus (the simplexviruses), some in the simplexviruses plus pseudorabies virus, and some are in all of the above, plus VZV. This is annotated in the "Conservation" column. (ii) Some genes have positional homologues (conserved size, orientation, and conserved surrounding genes) for which no functional data are available. We included positional homologues, in cases in which good candidates are present in members of all three herpesviruses subfamilies.

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
$\gamma_1$34.5		This ORF encodes a 248-residue γ_1 protein consisting of two unequal domains linked by a variable number of alanine-proline-threonione repeats. The C-terminal domain is homologous to the C-terminal domain of GADD34 and functions as a phosphatase accessory factor which binds phosphatase 1α and redirects it to dephosphorylate the α subunit of the translation initiation factor 2 (eIF-2). In the absence of $\gamma_1$34.5 gene, protein kinase R is activated, eIF-2α is phosphorylated and all protein synthesis ceases. The loss of this function is responsible for the loss of the capacity of mutants to replicate in experimental animal systems (loss of neurovirulence). $\gamma_1$34.5 protein is also involved in the evasion of MHC class 2 responses and encodes other, as yet poorly defined functions. γ_1.[a]	HSV-2, Gadd34 (MyD116)						(100, 101, 230)
ORF-P		A 233-residue ORF encoded on the strand complementary to $\gamma_1$34.5. The transcription of ORF-P is blocked by ICP4 bound to a high affinity transcription initiation site of the ORF. Derepression of ORF-P results in decreased expression of the $\gamma_1$34.5 ORF. ORF-P protein binds p32 and localizes in spliceosomes. Overexpression of ORF-P results in decreased expression of viral products of spliced RNAs. Pre-α.	not in HSV-2 or B virus						(128, 129)
ORF-O		The product of ORF-O is made of 117 residues. The amino terminus is identical to that of ORF-P. The amino acid sequence beyond residue 35 is in an alternate reading frame. Expression of ORF-O is repressed by ICP4. In vitro ORF-O blocks the binding of ICP4 to its cognate high affinity DNA binding sites. Viral gene products encoded by these ORFs have not been detected in murine ganglia harboring latent virus. Pre-α.	not in HSV-2 or B virus						(198)
α0	ICP0	The 3 exons encode a 775-residue protein containing a RING finger domain. ICP0 is dispensable for viral replication in cultured cells. In transfected cells it acts as a promiscuous transactivator of genes introduced by transfection or infection although activation of resident genes has been reported. ICP0 expresses multiple functions, including those of a double ubiquitin ligase targeting promyelocytic leukemia protein to block exogenous interferon, cdc34 to block turnover of cyclin D3, CNP-C, CNP-A, and DNA dependent protein kinase. ICP0 is also associated with the restructuring of chromatin. Additional functions have been described. α	α-HV		ORF61				(99, 171, 222)
U_L1	gL	224 residue soluble glycoprotein. It interacts with and serves as the chaperone of gH. In its absence gH is not transported to plasma membrane and is not fully glycosylated. Essential glycoprotein for virion infectivity and cell-cell fusion. Locus of syncytial mutation. Stimulates neutralizing antibody. γ_1.	α-HV, β-HV, γ-HV	7	ORF60	ORF47	UL115	U82	(78, 106, 203)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L2		U_L2 encodes uracil-DNA glycosylase, a highly conserved enzyme associated with the base excision repair pathway. Uracil-DNA glycosylase replaces uracil in G:U base pairs resulting from deamination of cytosine residues in DNA. U_L2 is highly conserved and no other functions have been ascribed it. 334 aa. β or γ_1.	α-HV, β-HV, γ-HV.	7	ORF59	ORF46	UL114	U81	(41, 244)
U_L3		U_L3 is a 235 residue phosphoprotein forming multiple bands in denaturing polyacrylamide gels due in part to phosphorylation mediated by U_L13 protein kinase. It co-localizes with ICP22-$U_S1.5$ proteins in small dense nuclear structures. In the absence of ICP22 or $U_S1.5$ it is diffuse throughout the nucleus. The function is unknown: the gene can be deleted without impairment of viral replication in cultured cells. The protein is transcribed predominantly from the second methionine of its reading frame. γ_2	α-HV Possible positional homologue in γ-HV		ORF58	ORF45			(10, 152, 245)
U_L4		U_L4 is a 199-residue virion protein. In infected cells it localizes in small dense nuclear structures formed prior to the onset of viral DNA synthesis together with ICP22/$U_S1.5$. In the absence of other viral proteins it remains in the cytoplasm. U_L4 and is dispensable for viral replication in cultured cells. γ_2	α-HV		ORF56				(110, 113, 249)
U_L5		U_L5 is a component of the helicase – primase complex. The 882-residue protein contains sequence motifs shared by members of the superfamily of RNA and DNA helicases ranging from bacteria to mammals. Stable U_L5-U_L52, complex has DNA-dependent ATPase and GTPase, DNA primase and DNA helicase activities. A viral mutant in U_L5 exhibiting a neuron specific restriction was shown to produce lower levels of viral DNA in restricted cells. β.	α-HV, β-HV, γ-HV	6	ORF55	ORF44	UL105	U77	(28, 76)
U_L6		The 676-residue protein forms a dodecameric ring located at the vertices of the HSV capsid. The ring structure is similar to the portal for the entry of DNA in bacteriophages. U_L6 has been reported interact with U_L15 and U_L28 (the putative terminase) proteins. Resistance of a class of thiourea drugs that blocks cleavage and packaging of DNA was mapped to U_L6 ORF. Unknown.	α-HV, β-HV, γ-HV	6	ORF54	ORF43	UL104	U76	(176, 232, 242)
U_L7		The 296-residue protein is well conserved among herpesvirus families and may be a component of the tegument. Its function is not known. It is not essential for replication in cell culture. γ_1.	α-HV, β-HV, γ-HV	6	ORF53	ORF42	UL103	U75	(181)
U_L8		The 750-residue U_L8 protein is required for the transport of U_L52 and U_L5 to the nucleus. It interacts with both U_L9 and U_L30. One likely function of U_L8 protein is to facilitate the synthesis of RNA primers on the DNA template. β.	α-HV, β-HV, γ-HV	6	ORF52	ORF41	UL102	U74	(18, 40, 153, 159, 229)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L8.5		The 487-residue U_L8.5 protein corresponds to the C-terminal domain of U_L9 protein. U_L8.5 was reported to be synthesized both early and late in infection and to bind to the origin of DNA synthesis. In transient assays the U_L8.5 protein inhibited DNA synthesis. It may play a role in shifting the pattern of synthesis for de novo initiation at origins to a rolling circle model of viral DNA synthesis. γ_1.	α-HV						(15, 16)
U_L9		U_L9, a 851-residue protein, binds to two specific sites flanking the origin of viral DNA synthesis. ICP8 (U_L29) which binds and separates the DNA strands, enables the unwinding of the DNA at the site of the origin by U_L9 protein and allows the entry of the machinery that replicates the DNA. U_L9 is conserved in α-herpesviruses and except for HHV6 and HHV7 it is absent from the genomes of β- or γ-herpesviruses. The function of U_L9 after the initiation of viral DNA synthesis has not been demonstrated. U_L9 protein was reported to interact with two proteins. hTid-1 enhances the binding of a multimer of U_L9 to the origin of DNA synthesis. NFB42, a F box component of the SCF ubiquitin ligase, binds phosphorylated U_L9 protein and targets it for ubiquitin-proteasomal degradation. The phosphorylation and degradation of U_L9 may be a mechanism by which the virus favors a rolling circle type of DNA replication instead of de novo initiation of DNA synthesis at the origins or replication. β.	α-HV, Roseolo-viruses	6	ORF51			U73	(50, 81, 126, 132, 148, 224, 238)
U_L9.5		The transcript of U_L9.5 is coterminal with those of U_L8, U_L8.5, and U_L9. 472 aa. γ_2							(16)
U_L10	gM	Abundant virion glycoprotein of 473 residues, with apparent M_r 53–63,000. Topology predicts six to eight transmembrane segments. A deletion mutant virus has no major phenotype. In other herpesviruses, gM forms a complex with gN, or gN-gO. Based on phenotype of ΔgM-gE-gI PrV and ΔgM EBV viral mutants, gM is thought to play a role in virion maturation and exocytosis, but this function may be redundant. However, a ΔgMgE HSV mutant shows no defect. $\gamma_.$	α-HV, β-HV, γ-HV	6	ORF50	ORF39	UL100	U72	(11, 35)
U_L11		U_L11 is a 96-residue tegument protein that is both myristoylated and palmitoylated. ΔU_L11 mutants exhibit reduced levels of envelopment and egress of virus from infected cells. The protein binds the cytoplasmic face of cellular membranes and is particularly abundant in Golgi. U_L11 protein interacts with and directs U_L16 to the Golgi. The precise function of U_L11 is not known. $\gamma_.$	α-HV, β-HV, γ-HV	6	ORF49	ORF38	UL99	U71	(12, 140, 141, 143, 144)
U_L12	Alkaline nuclease	U_L12 is a 626-residue alkaline nuclease that functions as a resolvase, an enzyme required for processing of replication intermediates-structures defined by their inability to enter pulse field gels and that would interfere with the packaging of viral DNA into capsids. β.	α-HV, β-HV, γ-HV	6	ORF48	ORF37	UL98	U70	(93, 154, 241)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
$U_L12.5$	No VZV	The ORF encodes a 500-residue product from a 1.9 kb RNA and corresponds to the C-terminal portion of the U_L12 alkaline nuclease. The protein does not have nuclease activity, does not complement U_L12-null mutants and does not appear to be a structural component of capsids. Its function is not known. Unknown							(154)
U_L13	Protein kinase	U_L13 encodes a 518-residue (M_r 56,000) serine/tyrosine protein kinase for viral and cellular proteins. Its function as a tegument protein is unknown. The gene is essential for viral replication in experimental animal systems but not in cells in culture. U_L13 appears to regulate multifunctional proteins. The substrate specificity of U_L13 protein kinase is similar to that of the mitotic cyclin dependent kinase cdc2. (Y. Kawaguchi, personal communication). γ_1.	α-HV, β-HV, γ-HV	6	ORF47	ORF36	UL97	U69	(25, 67, 116, 117, 196, 217)
U_L14		The ORF encodes a tegument protein of 219 residues. ΔU_L14 mutants replicate well in cell culture but are highly attenuated in the mouse. The only function attributed to U_L14 protein is enhancement of nuclear localization of U_L17 and U_L26. Co-expression of U_L14 enhances nuclear import of the U_L35 (VP26) and U_L33 proteins and increases luciferase expression suggesting that it may facilitate folding of a variety of proteins. γ_2.	α-HV, β-HV, γ-HV	6	ORF46	ORF34	UL96	U67	(65, 250)
U_L15		The ORF consists of two exons. The intron encodes a sequence antisense to U_L16 and U_L17 proteins. U_L15 is a 735-residue (M_r of 83,000) protein that binds U_L28 protein. U_L15 is required for cleavage and packaging of viral DNA and with U_L28 may function as a terminase. U_L15 is cleaved near the amino terminus, a reaction coupled with maturation of viral DNA into unit length molecules. γ_1.	α-HV, β-HV, γ-HV	6	ORF 42/45	ORF29a	UL89ex1	U66 ex1	(9, 64, 206, 208)
$U_L15.5$		$U_L15.5$ Exon 2 or U_L15 encodes a M_r 55,000 protein associated with capsids. 293 aa. Unknown	α-HV, β-HV, γ-HV	6		ORF29b	UL89ex2	U66ex2	(9)
U_L16		The 373-residue U_L16 protein is encoded in the intron located between exon 1 and 2 of U_L15. It is a virion component not essential for viral replication. γ_1.	α-HV, β-HV, γ-HV <positional>	6	ORF44	ORF33	UL94	U65	(174, 208)
UL17		The U_L17 ORF is contained in the intron located between exon 1 and 2 of U_L15, and encodes a 703-residue protein essential for DNA cleavage and packaging. In productive infection U_L17 localizes preformed capsid to the replication compartment. U_L17 has also been reported to be a tegument protein. γ_1.	α-HV, β-HV, γ-HV <positional>	6	ORF43	ORF32	UL93	U64	(206, 207, 227)
U_L18	VP23	The 318-residue (M_r 34,000) protein encoded by U_L18 is a capsid protein designated VP23. Together with the VP19C encoded by U_L38 it forms triplexes consisting of two copies of VP23 and one copy of VP19C. The 320 triplexes connect adjacent hexons (150) and pentons (12). γ_1.	α-HV, β-HV, γ-HV	5	ORF41	ORF26	UL85	U56	(124, 231)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L19	ICP5	Major capsid protein made of 1311 residues (M_r 149,000). Capsid hexons appear as tower like complexes containing 6 copies of the protein whereas pentons contain 5 copies. γ_1.	α-HV, β-HV, γ-HV	5	ORF40	ORF25	UL86	U57	(32, 175, 177, 243)
U_L20		U_L20 is a 222 residue polytopic membrane protein, with four predicted transmembrane segments. It localizes to virions, nuclear membranes and Golgi but is absent from plasma membranes. When expressed singly, it localizes mainly to endoplasmic reticulum. Coexpressed with gK, It localizes to the Golgi. Dispensable in cell culture. A deletion mutant in UL20 gene is detective in transport of the virions out of the perinuclear space, particularly in cells with fragmented Golgi. The ΔUL20 mutant is syncytial. Together with gK, inhibits cell-cell fusion. Its postulated role is to prevent fusion of the infected cells with adjacent cells. γ.	α-HV		ORF39				(5, 6, 13, 86)
$U_L20.5$		The $U_L20.5$ ORF is located 5′ to U_L20. The 160-residue protein localizes at small dense nuclear structures containing ICP22, $U_S1.5$, U_L3, and U_L4 proteins and is dispensable for viral replication. Its function is not known. γ_2.	None						(237)
U_L21		The 535-residue U_L21 protein is in tegument and may be weakly associated with capsids. U_L21 binds to microtubules but not to purified tubulin. In overexpressed cells it induces the formation of long cytoplasmic projections possibly due to its interaction with microtubules. It is not required for viral replication in cultured cells. γ_1.	α-HV		ORF38				(8, 226)
U_L22	gH	The 838-residues glycoprotein is essential for virion infectivity and cell-cell fusion. In cells infected with a deletion mutant virus in gH or a *ts* mutant at non permissive temperature, viruses lacking gH egress from the cell but are non infectious. Transport of gH from the endoplasmic reticulum to the Golgi and plasma membranes requires the interaction with the soluble gL. gH is an essential component of the complex enabling cell-cell fusion and induces neutralizing antibodies. VZV gH carries an endocytosis motif in the C-tail, absent from HSV gH. γ. Carries elements typical of viral fusion proteins. Possible fusogen.	α-HV, β-HV, γ-HV	4	ORF37	ORF22	UL75	U48	(36, 73, 79, 85, 94, 184)
U_L23	Thymidine kinase	Although known primarily as a thymidine kinase, it is a wide spectrum nucleoside kinase capable of phosphorylating both purine and pyrimidine nucleosides and their analogues. 376 aa. β.	α-HV, γ-HV		ORF36	ORF21			(63, 89, 158, 170)
U_L24		A 269-residue membrane-associated nuclear protein with an apparent M_r of 30,000. Mutations or deletions result in formation of small polykaryocytes in cell culture, somewhat diminished virus yields and decreased virulence in mice. The bulk of the protein is translated from the first AUG. A shorter transcript containing the second in frame AUG is also translated but the translation of 2 additional 3' co-terminal transcripts encoding C-terminal portions of U_L24 protein is uncertain. The UL24 ORF partly overlaps the TK gene in antisense direction. UL24 is dispensable in cell culture. γ_1.	α-HV, β-HV, γ-HV	4	ORF35	ORF20	UL76	U49	(185)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d] VZV	γ-HV	HCMV	HHV-6	Ref.
UL25		The 580 residue product of the U_L25 ORF encodes a capsid protein involved in packaging of viral DNA into capsids. Dispensable for generation of the S terminus but required for correct generation of the L-terminus and possibly for retention of DNA in the capsid. γ_2.	α-HV, β-HV, γ-HV	4	ORF34	ORF19	UL77	U50	(161, 223)
U_L26	capsid scaffolding protein and protease	This ORF encodes a protein of 635 residues that is cleaved in *cis*- or *trans*- by itself at two sites. The N-terminal polypeptide is a protease required for assembly of a scaffolding within capsids for DNA packaging. The larger, middle cleavage product is a component of the scaffolding. γ.	α-HV, β-HV, γ-HV	4	ORF33	ORF17	UL80	U53	(90, 136, 137)
$U_L26.5$		The promoter and coding domain of $U_L26.5$ is contained in its entirety within the U_L26 ORF. The protein product of 328 residues is identical to the corresponding sequence of the U_L26 protein. It is cleaved by the protease at its C-terminus at the same site as the U_L26 protein. γ.	α-HV	4	ORF 33.5			U53.5	(137)
U_L27	gB	A 904-residue glycoprotein with apparent M_r of 110.000. It carries two, or three trasmembrane segments. Essential for virion infectivity and cell-cell fusion. Virions lacking gB egress the cell but are non infectious. The protein binds heparan sulfate and is a component of the cell-cell fusion complex. The cytoplasmic tail carries syncytial mutations, and endocytosis motifs, which mediate gB endocytosis into large vacuoles. Down modulation of gB at cell surfaces may be responsible for negative control of the cell-cell fusion. A *ts* mutation in ectodomain affects virus entry into the cell (*ts* B5). Induces neutralizing antibodies. γ_1. Crystal structure shows a trimer. Possible fusogen.	α-HV, β-HV, γ-HV	2	ORF31	ORF8	UL55	U39	(37–39, 109, 151, 186)
$U_L27.5$		The $U_L27.5$ ORF maps antisense to U_L27 and yields a γ_2 protein with an apparent M_r of 43,000. The predicted size of the coding capacity of the ORF is much larger. The protein accumulates in the cytoplasm. Its function is unknown. 575 aa. γ_2.	HSV-2						(46)
U_L28		A component of cleavage and packaging complex. See Functions of U_L15 and U_L6. 785 aa. Binds *pac1* sequences and is required for correct generation of the L-terminus. See functions of U_L6, U_L14 and U_L33. γ.	α-HV, β-HV, γ-HV	2	ORF30	ORF7	UL56	U40	(23)
U_L29	ICP8, single-stranded DNA binding protein	ICP8 is an essential 1196 residue single stranded DNA binding protein made very early in infection. ICP8 is required for viral DNA synthesis. β.	α-HV, β-HV, γ-HV	2	ORF29	ORF6	UL57	U41	(150, 253)
U_L30	DNA pol.	DNA polymerase. 1235 aa. γ.	α-HV, β-HV, γ-HV	2	ORF28	ORF9	UL54	U38	(29, 114, 234, 239, 240)
U_L31		Nuclear phosphoprotein that requires U_L34 protein for localization at the inner nuclear membrane. Binds lamin A/C in the nuclear lamina and directs envelopment at inner nuclear membrane. Carries a nucleotidylation recognition sequence. 306 aa. γ.	α-HV, β-HV, γ-HV	1	ORF27	ORF69	UL53	U37	(27, 48, 49, 147, 200, 201)
U_L32		U_L32 is 596-residue protein required for cleavage and packaging of viral DNA. The predominant localization of U_L32 in the cytoplasm suggests that either it shuttles between the nucleus and cytoplasm, or that it encodes additional functions. γ_2.	α-HV, β-HV, γ-HV	1	ORF26	ORF68	UL52	U36	(47, 130)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L33		A 130-residue capsid associated protein that forms a complex with the U_L15 and U_L28 proteins. Required for packaging of viral DNA into preformed capsids. γ_2.	α-HV, β-HV, γ-HV	1	ORF25	ORF67A	UL51	U35	(22, 199)
U_L34		An essential membrane-associated virion protein of 275 residues was reported to be a type 2 membrane protein phosphorylated by U_S3 kinase. Required for virion envelopment at inner nuclear membrane. Exclusive localization of UL34 protein at the nuclear membrane requires U_L31 protein. Extracellular virions do not contain UL31-UL34 proteins. The U_L34 homologue in murine cytomegalovirus recruits cellular protein kinase C to the nuclear lamina and induces lamin phosphorylation. γ_1.	α-HV, β-HV, γ-HV	1	ORF24	ORF67	UL50	U34	(200, 201, 215)
U_L35	VP26, capsid protein NC7	The 112-residue (M_r 12,000) protein forms a hexameric structure located on the outer surface of each hexon. Previously know as NC7. Dispensable for growth in cell culture but not in vivo. γ_2.	α-HV, β-HV, γ-HV	1	ORF23	ORF65	UL49	U32	(57, 71)
U_L36	VP1/2	The 3165-residue (M_r 270,000) protein essential for viral replication is located in the tegument essential for egress of virions through the cytoplasm. A *ts* mutation in UL36 blocks release of viral DNA into the nucleus at the non permissive temperature. γ_2.	α-HV, β-HV, γ-HV	1	ORF22	ORF64	UL48	U31	(20, 72)
U_L37	tegument protein	A 1123-residue (M_r 120,000) tegument phosphoprotein binds to DNA in the presence of ICP8. It is essential for viral replication. In its absence, nucleocapsids accumulate aberrantly in the nucleus and unenveloped capsids accumulate in the cytoplasm. γ_1.	α-HV, β-HV, γ-HV	1	ORF21	ORF63	UL47	U30	(146, 213, 247)
U_L38	VP19C Capsid protein	This 465-residue protein forms triplexes together with VP23, consisting of two copies of VP23 and one copy of VP19C. The 320 triplexes connect adjacent hexons (150) and pentons. γ_2.	α-HV	1	ORF20	ORF62	UL46	U29	(219, 231)
U_L39	Ribonucleotide reductase, large subunit	This ORF encodes a 1137-residue protein of M_r of 136,000. The protein is anchored in membranes and has protein kinase activity mapping to the N terminus but not required for ribonucleotide kinase activity. U_L39 may play a role in maintaining dTTP pools in infected cells. β.	α-HV, β-HV, γ-HV	1	ORF19	ORF61	UL45	U28	(54, 68, 189)
U_L40	Ribonucleotide-reductase small subunit	This ORF encodes the 340-residue small subunit of ribonucleotide kinase. β.	α-HV, γ-HV		ORF18	ORF60			(108)
U_L41	vhs, virion host shutoff protein	*vhs* (virion host shutoff protein) is a 489-residue protein packaged in the tegument and mediates the degradation of RNA early in infection. The degradation appears to be selective for viral RNAs. At late times after infection it is associated with VP16 (product of U_L48) and no longer exhibits this function. γ_1.	α-HV		ORF17				(82, 83, 211, 216, 225)
U_L42		DNA polymerase accessory protein. Binds double stranded DNA. It also associates with cdc2 and topoisomerase IIa. 488 aa. β.	α-HV, β-HV, γ-HV	1	ORF16	ORF59	UL44	U27	(3, 96)
U_L43		Non-essential protein. Sequence suggests that it is a hydrophobic, myristylated integral membrane protein. 434 residues. γ.	α-HV		ORF15				(44, 144, 145)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L43.5		This ORF is located antisense to U_L43. Tagged epitope revealed the synthesis of a M_r 32,000 γ_2 protein, dispensable for growth in cell culture. Its function is not known. γ.	HSV-2						(44, 236)
U_L44	gC	A 511 residue glycoprotein heavily N- and O-glycosylated. Some gC-minus mutants arise in culture, but all primary isolates express gC. A deletion gC mutant attaches to cells with reduced efficiency, but is viable. gC mediates attachment of virions to glycosaminoglycans of heparan sulphate, or chondroitin sulphate. The heparan sulphate binding site on gC maps to the N-terminus of the ectodomain. gC is part of the immune evasion strategy of HSV, as it carries two domains involved in modulating complement activation; one binds C3, and the other is required for blocking C5 and properdin binding to C3. Each region contributes to virulence, as viruses lacking these domains are less virulent than wt-virus. γ_2.	α-HV		ORF14				(88, 103, 122, 142)
U_L45		The 172 residue type 2 membrane protein is dispensable for viral replication in cultured cells. U_L45 is required for herpes simplex virus type 1 glycoprotein B-induced fusion. It is dispensable for growth in cell culture. γ_2.	HSV-2, B virus						(98, 233)
U_L46	VP11/12 tegument protein,	The ORF encodes the 718-residue tegument proteins VP11 and VP12, differentiated solely by their migration in denaturing gels. The ORF is dispensable in cultured cells. Available data suggests that it is a γ_1 protein present along with U_L47 in stechiometric amounts with U_L48 gene product and capable of enhancing its activity. In the absence of U_L48 protein, U_L46 protein inhibits activation of α promoters. γ.	α-HV		ORF12				(157, 252)
U_L47	VP13/14 tegument protein	The two products of the ORF have apparent M_r of 82000 and 81000. They are abundant glycosylated, phosphorylated components of the tegument, dispensable for viral replication in cells in culture. U_L47 binds RNA and is reported to shuttle between the cytoplasm and nucleus. 693 aa. γ_1.	α-HV		ORF11				(77, 123, 164)
U_L48	α-TIF, VP16, ICP25	α-TIF (α-trans-inducing factor), a 491 residue protein, is a multifunctional tegument protein. It induces α-genes by interacting with two cellular proteins, HCF and Oct-1. The complex binds to specific sequences with the consensus GyATGnTAATGArATTCyTTGnGGG-NC. It is also required for virion assembly. Essential for growth in cell culture and has gamma expression regulation. Crystal structure of the conserved core has been solved. γ.	α-HV		ORF10				(59, 138, 172, 187)
U_L49	VP22	Encodes the nonessential tegument protein VP22. VP22 translocates into cells exposed to the protein. Prior to cell division it localizes to microtubules in the cytoplasm. After cell division it is bound to chromatin. VP22 binds RNA and is thought to translocate mRNA from infected to uninfected cells. It has also been reported to bind membranes, and to induce the stabilization and hyperacetylation of microtubules (putative microtubule-associated protein). It is not required for tegument assembly and its role in viral replication is unclear. γ.	α-HV		ORF 9				(33, 80, 194, 214)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_L49.5	gN	This 91 residues membrane-associated protein with apparent M_r of 6700 is abundant in virions. The PrV homologue is gN, which forms a complex with gM. In other herpesviruses the complex is gM-gN-gO. PrV gN is not accessible in the infected cell plasma membrane. In other herpesviruses, it forms a complex with gM that inhibits fusion. In PrV, gN may be disulphide-linked to the tegument, and gN was absent from gM-negative PrVirions, whereas gM was readily detected in virions in the absence of gN. Thus, gM appears to be required for virion localization of gN. UL49.5 is dispensable for viral replication in cultured cells. γ2.	α-HV, β-HV, γ-HV						(2, 17, 19, 134)
U_L50	deoxyuridine triphosphatase, dUTPase	U_L50 encodes a dUTPase. The ORF is not essential for viral replication in cells in culture. 371 aa. β.	α-HV, β-HV, γ-HV		ORF 8				(14, 17, 205)
U_L51		The 244 residue protein is a component of the virion tegument. Dispensable for growth in cell culture. γ_1.	α-HV, β-HV, γ-HV		ORF 7				(17, 66)
U_L52		U_L52 is a component of the helicase-primase complex. It strongest affinity appears to be for ICP8, but both U_L52 an U_L5 proteins are required for DNA binding. 1058 aa. β.	α-HV, β-HV, γ-HV		ORF6				(26, 62)
U_L53	gK	The 338 amino acid protein encoded by this ORF is a low abundance glycoprotein with M_r 40000. Sequence predicts three or four transmembrane segments. Topology, investigated by epitope mapping, shows an extracellular N-terminus and intracellular C-terminus. In infected cells gK localizes to Golgi apparatus. Plasma membrane localization is debated. gK is the most frequent locus of syncytial (syn) mutations. A deletion mutant in gK is defective in exocytosis of virions, and is syncytial. When expressed singly, gK localizes mainly at ER. Its transport to the Golgi apparatus requires the UL20 protein. gK inhibits fusion in the cell-cell fusion assay. Inhibition is augmented by coexpression with UL20 protein. gK role appears to prevent infected cells from fusing with adjacent cells. γ.	α-HV		ORF5				(4, 5, 70, 87, 107, 167, 193)
U_L54 α27	ICP27	ICP27 is a multifunctional 512-residue protein with two well defined functions. Early in infection it blocks splicing of RNA, thereby enabling the transport of unspliced RNA into the cytoplasm. At late times it acts as an RNA transporter and shuttles between the nucleus and cytoplasm. α.	α-HV, β-HV, γ-HV		ORF4	ORF57	UL69	U42	(21, 51, 52, 173, 210, 220)
U_L55		This ORF encodes a nonstructural 186-residue protein associated with sites of virion assembly. It is dispensable for viral replication in cultured cells. γ_2.	α-HV (not PrV)		ORF 3				

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d] VZV	γ-HV	HCMV	HHV-6	Ref.
U_L56		This ORF encodes a phosphorylated 234-residue, type II membrane protein associated with virions. The protein is essential for pathogenesis in experimental animal systems but is not required for viral replication in cultured cells. γ_2	HSV-2						(127, 204)
α4	ICP4	ICP4 is an essential regulatory 1298-residue protein. It acts as a transactivator and a repressor of viral gene functions. As a repressor it binds to high affinity sites overlapping the transcription initiation sites of its own ORF and that of ORF P and ORF O. The interaction of ICP4 together with transcriptional factors to low affinity sites -some significantly divergent from the high affinity sites – may account for the trans activating function of ICP4. While the interaction of ICP4 with transcriptional factors has been well documented, the role of low affinity sites remains unclear. α.	α-HV		ORF62/71				(61, 97, 121, 183, 188)
α 22 U_S1	ICP22	This ORF encodes a 420-residue regulatory protein of 420 residues essential in some cells and in experimental animal systems but not in human or primate cells in continuous cultivation. See $U_S1.5$ for details regarding its functions. The protein is extensively phosphorylated by viral and cellular kinases and nucleotidylylated by casein kinase II. α.	α-HV		ORF63/70				(3, 7, 31, 118, 139, 165, 195, 209)
$U_S1.5$		The promoter and coding domain of $U_S1.5$ is contained within the α22 ORF and the α22 met 14 acts as the initiator methionine of $U_S1.5$ protein. Most of the known functions of ICP22 map to the $U_S1.5$ ORF. Thus in the absence of ICP22 or U_L13 a set of late proteins (U_L41, U_S11 and U_L38) accumulates in smaller amounts. The results of two studies may account for this observation. Thus, both ICP22 and U_L13 are required for the activation of cdc2 and degradation of the partners, cyclin A and B. cdc2 partners with U_L42 and together bind and mediate posttranscriptional modification of topoisomerase IIα. In other studies the two proteins have been shown to mediate an "intermediate" phopshorylation of RNA Polymerase II. ICP22 also affects the accumulation of α0 mRNA. 274 aa. VZV ORF63/70 appears to correspond to Us1.5 rather than to ORF Us1. α.	α-HV		ORF63/ 70				(3, 43)
U_S2		The ORF encodes a 291 residue tegument protein not essential for viral replication in culture or in experimental animals. It is conserved among most α-HV. Its function is not known. The PrV homologue is prenylated. γ_2.	HSV-2 and B virus, but not PrV or VZV						(55, 112, 163)
U_S3	Serine/threonine protein kinase	A multifunctional protein kinase that phosphorylates a large number of both cellular and viral proteins. The kinase is not essential for viral replication. U_s3 protein kinase blocks apoptosis induced by viral mutants or exogenous agents. 481 aa. γ_1.	α-HV		ORF66				(24, 102, 119, 120, 133, 197)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d]				Ref.
					VZV	γ-HV	HCMV	HHV-6	
U_S4	gG	A 238 residue envelope glycoprotein of unknown function used in serologic assays to differentiate HSV-1 from HSV-2 antibody responses. The HSV-2 gG is larger that HSV-1 gG. γ_1.	α-HV except VZV						(1, 131)
U_S5	gJ	This 92-residue glycoprotein protects the cells from apoptosis induced by gD−/+ and gD−/− virions. Dispensable in cell cultures. γ.	HSV-2, B virus, not PrV or VZV						(111, 254)
U_S6	gD	gD is a virion glycoprotein of 394 residues, with apparent M_r of 56000, essential for virus entry into the cell, and cell-cell fusion. gD is the receptor-binding glycoprotein, and interacts with three alternative receptors, named HVEM, nectin, and modified heparan sulphate. Major determinant of HSV tropism. Crystal structure shows an Ig-folded core with N- and C-terminal extensions. Upon receptor binding, a change in conformation ensues. A deletion gD mutant produces virions that exit the cell, but are non infectious. Soluble gD blocks infectivity. Ectopic expression of full length gD induces in the cell restriction to infection, by sequestering the gD receptor. Mutations at N-terminus allow usage of an alternative receptor. gD protects the cell from apoptosis induced by gD−/+ and gD−/− virions. Antiapoptotic activity is mediated by mannose-phosphate receptor. β-γ.	α-HV except VZV						(42, 53, 56, 92, 135, 180, 254)
U_S7	gI	gI is a 390-residue virion glycoprotein. It forms a heterodimer with gE. The gI-gE complex constitutes a viral Fc receptor for monomeric IgG. The gE-gI complex has basolateral localization in epithelial cells and facilitates basolateral spread of progeny virus in polarized cells. Dispensable in transformed cells, but critical in non transformed cells. γ_1.	α-HV		ORF67				(74, 75, 149, 168, 235)
U_S8	gE	gE is a 550-residue virion glycoprotein. It forms a heterodimer with gI. See, gI. gE is phosphorylated by UL13 protein kinase. γ_1.	α-HV		ORF68				(74, 75, 166, 182, 255)
$U_S8.5$		The 159-residue (M_r 19,000) protein localizes to nucleoli and is dispensable for viral replication. Its mRNA is among the most abundant species packaged in virions. γ_1.	HSV-2, B virus, not PrV or VZV						(91, 214)
U_S9		A dispensable type II membrane-associated protein of 90 residues, reported to play no role in neurovirulence or latency. May be involved in anterograde axonal transport of virions. γ.	α-HV		ORF65				(34, 58, 178, 179)
U_S10		A dispensable tegument phosphoprotein made of 312 residues. Reported to play no role in neurovirulence or latency and to copurify with the nuclear matrix. γ_1.	α-HV		ORF 64/69				(179, 218, 248)
U_S11		This ORF encodes an abundant 161-residues protein expressing multiple functions. Virion associated U_S11 localizes to polyribosomes. Late in infection U_S11 is also found in nucleoli. $U_S11$synthesized under an α promoter blocks phosphorylation of eIF-2α. U_S11 binds RNA in sequence and conformation dependent fashion and is in part responsible for the packaging of RNA in virions. γ_2.	HSV-2						(45, 202, 214)

(*cont.*)

Gene designation	Alternative name	Main properties	Conservation[b]	Gene Block[c]	Homologues[d] VZV	γ-HV	HCMV	HHV-6	Ref.
U_S12, α47	ICP47	The small 88-residues ORF encodes a M_r 9776 protein that binds to TAP1/TAP2 and blocks the transport of antigenic peptides to ER for presentation by MHC class 2 proteins. α.	HSV-2, B virus, not PrV or VZV						(104, 155, 156, 251)
LAT		The primary latency associated transcript is a low abundance transcript 8.5 to 9 kb in size and extends through the length of the ab and b'a' sequences flanking the unique long sequences. Both productively infected and latently infected cells accumulate transcripts 2.0 and 1.5 kb in size thought to be stable introns of the primary transcript. The smaller LAT sequences terminate antisense to and within the coding sequences of α0 gene. Deletion of the sequences encoding LAT reduces the mortality and morbidity in experimental animal systems and the number of neurons harboring latent virus. The decrease in the number of neurons in LAT minus mutants has been linked to pro-apoptotic manifestations of latent virus. Pre-α.							(191, 221, 246)
ORI_S RNA		This RNA originates in the **c** sequences flanking the unique short sequences at or near the transcription initiation sites of α22 or α47 genes, extends across the ORI_S sequence and co-terminates with the transcript encoding ICP4. The RNA is detected after the onset of viral DNA synthesis. Its function is not known.							(105)
αX and βX RNAs		These overlapping RNAs 0.9 and 4.9 Kb in size originate upstream of ORF P and extend across the L-S junction. Their function is not known.							(30)
AL-RNA		RNA reported to be antisense to the 5' sequence of LAT							(192)
VZV ORF1		Membrane protein			ORF1				(60)
VZV ORF 2					ORF2				(212)
VZV ORF 13		Thymidylate synthetase			ORF 13				
VZV ORF 32					ORF 32				
VZV ORF 57					ORF 57				
VZV ORFS/L					ORF S/L				(115)

[a] kinetic class: α, β, γ, Unknown.
[b] Abbreviations: alphaherpesvirinae or α-HV, betaherpesvirinae or β-HV, gammaherpesvirinae or γ-HV
[c] Conserved gene block to which the sequences belongs
[d] Identification of homologues in other herperviruses was based on informations contained in ref.s 69, 95, 125, 162, 169, 190, 228

Acknowledgments

We thank Drs. Ann Arvin, Joel Baines, Laura Menotti and Phil Pellett for invaluable help in reviewing the table.

Entry of alphaherpesviruses into the cell

Gabriella Campadelli-Fiume and Laura Menotti

Department of Experimental Pathology, Alma Mater Studiorum-University of Bologna, Italy

Introduction

Herpes simplex virus (HSV) represents the most comprehensive example of virus-receptor interaction in the *Herpesviridae* family, and the prototype virus encoding multipartite entry genes. Whereas small enveloped viruses package the functions required for entry and fusion into one or two fusion glycoproteins, in HSV the same functions are distributed over several distinct glycoproteins, each with a specialized activity. In addition, HSV encodes a highly sophisticated system for promoting and blocking fusion between the viral envelope and cell membrane. Because the most obvious models of virus entry into the cell do not fit with the HSV complexity, and despite our detailed knowledge of the HSV receptors and of the crystal structure of glycoprotein D (gD), the receptor-binding glycoprotein, and of gB, HSV entry is still, in part, a puzzle (WuDunn and Spear, 1989; Cocchi *et al.*, 1998b; Geraghty *et al.*, 1998; Carfi *et al.*, 2001).

The current model of HSV entry envisions that, first, the virus attaches to cell membranes by the interaction of gC, and possibly gB, to glycosaminoglycans (GAGs) (Herold *et al.*, 1991). This binding likely creates multiple points of adhesion, is reversible, and the detached virus maintains its infectivity, indicating that fusion has yet to take place. Penetration requires gD, whose ectodomain contains two physically separate and functionally distinct regions, i.e., the region made of the N-terminus that carries the receptor-binding sites, and the C-terminus that carries the profusion domain (Ligas and Johnson, 1988; Cocchi *et al.*, 2004). The role of gD in entry is to interact with one of the entry receptors, to signal receptor-recognition and thus trigger fusion, by recruiting three additional glycoproteins – gB, gH, gL. The trio of gB, gH, gL, execute fusion with the plasma membrane or endocytic vesicle of the target cell (Fig. 7.1) (Cai, W. H. *et al.*, 1988; Forrester *et al.*, 1992; Roop *et al.*, 1993; Campadelli-Fiume *et al.*, 2000; Spear *et al.*, 2000; Nicola *et al.*, 2003). Of these, gH carries elements characteristic of viral fusion glycoproteins, i.e., a hydrophobic α-helix with attributes of an internal fusion peptide, and two heptad repeats with propensity to form coiled coils (Gianni *et al.*, 2005a,b). gB is a trimer with a coiled coil core; its structure closely resembles that of viral fusion proteins (Heldwein *et al.*, 2006; Roche *et al.*, 2006). Following fusion, the released tegumented nucleocapsid travels along microtubules to the nuclear pore, where the viral DNA is released into the nucleus (Sodeik *et al.*, 1997).

Much less is known about varicella zoster virus (VZV) entry. The process may be very different from that of HSV inasmuch as virion-to-cell infection is inefficient in the VZV system, and the viral genome presents a striking difference from that of HSV, namely the lack of gD (Davison and Scott, 1986).

The membrane proteins

The HSV envelope contains at least eleven glycoproteins (gB, gC, gD, gE, gG, gH, gI, gJ, gK, gL, and gM). Additional membrane proteins not detected in the extracellular virion envelope are UL20, UL34, UL45 and possibly US9. The transcripts for UL24, UL43, and UL49.5 ORFs have been recognized, but the proteins have yet to be identified. A summary list with references is presented in Chapter 6.

From a structural point of view, the majority of HSV glycoproteins are type I glycoproteins. Variants include gL, which is soluble (Hutchinson *et al.*, 1992a); gB, which may carry two or three α-helices in the transmembrane (TM) region (Pellett *et al.*, 1985) and gK, gM, and UL20, which carry information for multiple transmembrane segments

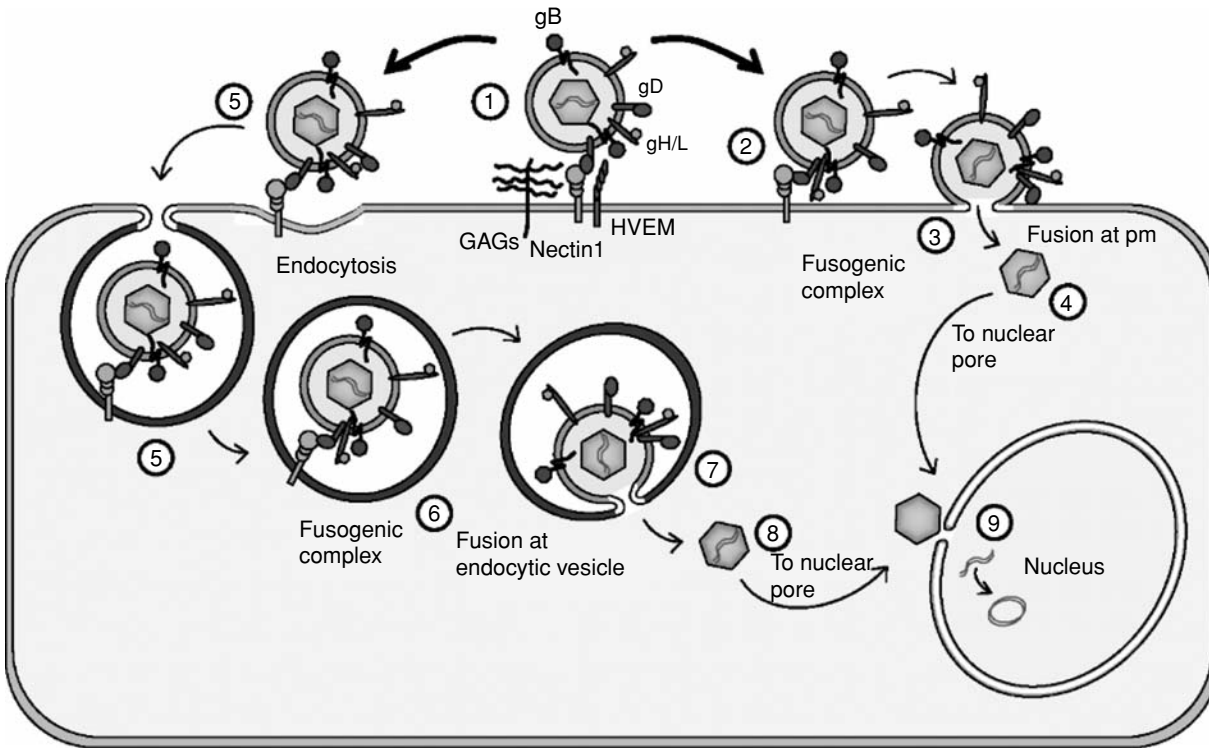

Fig. 7.1. Schematic drawing of HSV entry. Entry can occur either by endocytosis (pathway at the left), or by fusion at the plasma membrane (pathway at the right). Following attachment to cells, gD binds to a cellular receptor (frame 1), and presumably following a conformational change it recruits the glycoproteins B, H and L in an active fusogenic complex (frame 2), triggering the fusion between viral envelope and cellular plasma membrane (frame 3). The naked nucleocapsids are transported to the nucleus (frames 4 and 9). In a cell line-dependent manner or with modified forms of the receptor (see text for details) bound virions can enter cells by endocytosis (frame 5). It is conceivable that at this stage the four fusogenic glycoproteins are in a non-fusion-active form. Following acidification/maturation of the endocytic vesicles, a fusogenic complex may form (frame 6) and fusion ensue between the virion envelope and the vesicle membrane (frame 7). Nucleocapsids delivered to the cytoplasm are transported to the nucleus (frames 8 and 9).

(McGeoch *et al.*, 1988). US9 and HSV-2 UL45 are type II glycoproteins with a C-terminal ectodomain.

At the ultrastructural level, HSV glycoproteins form long thin spikes, each made of a single species. As visualized in cryo-electron tomograms of isolated virions, the envelope contains 600–750 glycoprotein spikes that vary in length, spacings, and in the angle at which they emerge from the membrane. Their distribution in the envelope suggests functional clustering (Grunewald *et al.*, 2003). In contrast, slender spikes have not been seen in varicella zoster virions (VZV) grown in cultured cells. Instead, the virion appears to be covered by an envelope studded with protrusions rather than spikes. An example is shown in Fig. 7.2. Further studies at even higher resolution will be required to determine differences between HSV and VZV envelopes.

HSV

Attachment to cells

Attachment of HSV to cells occurs upon binding of gC to GAGs that decorate heparan sulphate or chondroitin sulphate (Spear *et al.*, 1992) (Fig. 7.1). This step enhances HSV infectivity, but is not an absolute requirement, as cells defective in heparan sulphate and chondroitin sulphate exhibit a 100-fold reduced susceptibility to infection, yet can be infected (Gruenheid *et al.*, 1993). A large variety of viruses use heparan sulphate proteoglycans as receptors; their broad expression argues that they can not be responsible for any specific viral tropism.

The major actor during attachment is gC, a non essential glycoprotein encoded by the UL44 gene. gC is a

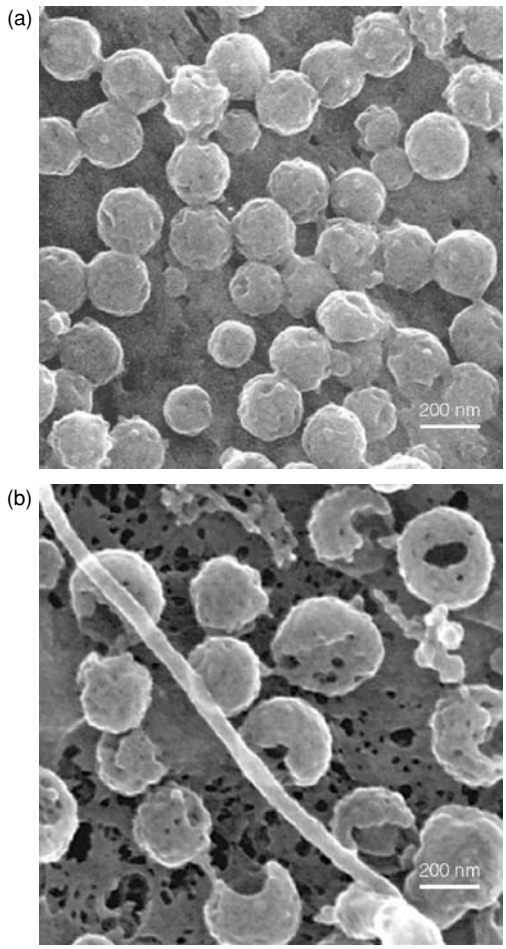

Fig. 7.2. Scanning electron micrographs of HSV-1 and VZV. Images of both viruses were taken by SEM after infection of cultured cells. HSV-1 virions have a more uniform appearance although indentations are seen in an occasional virion envelope (a). In contrast, VZV virions are more aberrant (b). Several of the virions have indentations, while other virions have incomplete envelopes. Since both viruses were examined under the same SEM conditions, it is unlikely that the aberrant nature of the VZV envelope is due to fixation artifacts. Micrographs kindly provided by Dr. Charles Grose.

mucin-type glycoprotein because of its high content in N-linked and O-linked oligosaccharides. Its ectodomain structure is provided in part by 8 cysteines, and harbors two physically separate antigenic regions, antigenic sites I and II, that map at the C- and N-termini of the molecule, respectively (Dolter *et al.*, 1992). Evidence for the role of gC in attachment rests on several lines of evidence. Initially, it was observed that the polycations neomycin and polylysine inhibit attachment of HSV-1, but not HSV-2 to cells, and this differential effect was mapped to gC (Campadelli-Fiume *et al.*, 1990). gC and gB bind heparin-Sepharose columns (Herold *et al.*, 1991). The affinity of binding to heparan sulphate is on the order of 10^{-8} M (Rux *et al.*, 2002). The region important for the interaction with heparan sulphate maps to the N-terminus of gC (Tal-Singer *et al.*, 1995). Virion binding to cells is reduced in HSV-1 mutants lacking gC-type1 gene, but not in HSV-2 mutants lacking gC-type2 (Herold *et al.*, 1991; Gerber *et al.*, 1995). The majority of these studies were performed with mutants constructed in the background of the HSV-1(KOS) strain. In contrast, deletion of gC gene in the genetic background of Sc16 and HFEM strains yielded viruses with unimpaired attachment activity, suggesting that in different virus strains, attachment may be carried out by different proteins (Griffiths *et al.*, 1998). gC has also been implicated in virus attachment to the baso-lateral domain of MDCK polarized epithelial cells, and to the apical domain of polarized human CaCo2 cells.

Interaction of gD with its receptors

gD

The ectodomain of gD is required and sufficient to enable HSV entry into cells. It is made of two separate and distinct regions, i.e., the N-terminus, carrying the receptor-binding sites (approximately contained between residues 1 and 250–260), and the C-terminus carrying the profusion domain (residues 250–260 to 305) (Cocchi *et al.*, 2004).

A breakthrough in our understanding of HSV entry came from resolution of the crystal structure of a soluble form of gD, initially up to amino acid residue 259 (Carfi *et al.*, 2001), and later on up to residue 306 (Krummenacher *et al.*, 2005). The initial structure was determined for gD alone and for gD in complex with one of the gD receptors, HVEM (herpesvirus entry mediator) (Fig. 7.3). The N-terminus consists of three portions, an Ig-folded central core (residues 56–184) made of β-strands forming two antiparallel β-sheets, and two extensions, one N-terminal (residues 1–37) and one C-terminal (Fig. 7.3). The N-terminus, which harbors all the contact residues to HVEM, is disordered in the crystal of gD alone, but forms a hairpin when gD is complexed with HVEM. gD and HVEM thereby form an intermolecular β-sheet, which is believed to stabilize the complex. Formation of the N-terminal hairpin documents a conformational change to gD when it binds HVEM.

The crystal structure of gD in complex with nectin1 has not yet been solved. The nectin1-binding site on gD, determined by means of insertion-deletion or substitution mutants, appears to be more widespread than the HVEM interaction region, (Milne *et al.*, 2003; Yoon *et al.*, 2003; Zhou

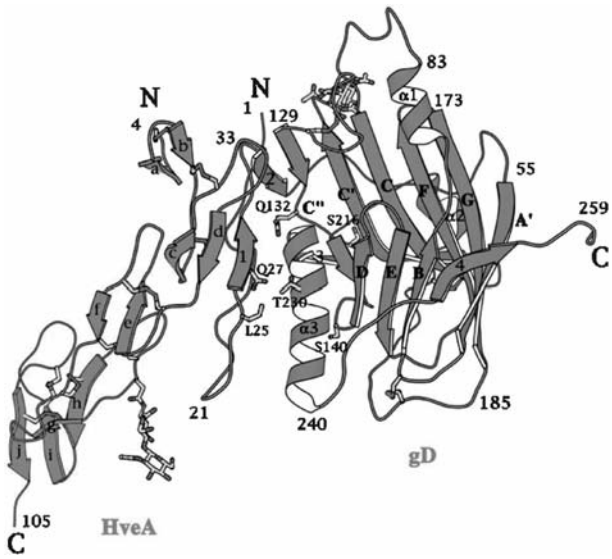

Fig. 7.3. Ribbon diagram of the 3D structure of a soluble truncated form of gD (gD285t, colored in orange) bound to HVEM receptor (HveA, colored in green) as determined by X-ray crystallography. The N-terminus (residues 1–37) of gD is devoid of a specific structure when in the unbound state, but folds into a hairpin when bound to HVEM receptor. The β-strand formed by residues 27–29 (indicated with number 1) forms an intermolecular β-sheet with HVEM residues 35–37 (letter d). The core of gD (residues 56–184) has a V-type immunglobulin domain structure, composed of 9 parallel and antiparallel β-strands (letters A to G) that form two opposing β-sheets, and carries an additional α-helix (α1). The residues 185–259 form two α-helices that fold back to the N-ter (α2 and α3), and two β-strands (numbered 3 and 4). The α3 helix supports gD's N-terminal hairpin. An additional β-strand (number 2) is located in the connector sequence (residues 33–55) that precedes the Ig-like core. Reprinted from (Carfi *et al.*, 2001), with permission. (See color plate section.)

et al., 2003; Jogger *et al.*, 2004; Manoj *et al.*, 2004; Connolly *et al.*, 2005). The only recombinant described so far debilitated for interaction with nectin1 carries the V34S substitution (Zhou and Roizman, 2006).

Receptors

Entry receptors interact with gD. This notion was established long before the actual receptors were identified, and rests on two lines of evidence. First, soluble gD binds in a saturable manner to cells and prevents infection (Johnson, D. C. *et al.*, 1990; Nicola *et al.*, 1997). Second, expression of gD from a transgene renders cells resistant to infection, because of its ability to sequester the receptor, a phenomenon designated restriction to infection or gD-mediated interference (Campadelli-Fiume *et al.*, 1988; Johnson, R. M. and Spear, 1989).

The search for HSV receptors was an active field in the 1990s, and a number of molecules were described as potential receptors. A breakthrough came from Spear and coworkers, who made use of HSV-resistant CHO cells, and identified a HeLa cell cDNA clone that encoded HVEM (Montgomery *et al.*, 1996). However, three observations in that study suggested the existence of additional receptors. First, HVEM appeared to be expressed by a limited number of cell lines. Second, antibodies to HVEM failed to completely block HSV infection. Third, several virus strains were unable to enter CHO cells expressing HVEM but were otherwise viable. This boosted further efforts in the field, which quickly led to the discovery of nectins, and, later on, of modified heparan sulphate. Altogether, the receptors known to date belong to three unrelated molecular families. Their present and past nomenclature, and the viruses for which they serve as receptors are reported in the table.

Nectins are intercellular adhesion molecules

Research in the field of nectins has proceeded in parallel with their characterization as HSV receptors (Takai *et al.*, 2003). Nectins 1–4 form a subfamily of Ca^{2+}-independent immunoglobulin (Ig)-type intercellular adhesion molecules. Together with nectin-like molecules and poliovirus receptor, they share the same overall structure consisting of three Ig-type domains. Splice variant isoforms are designated with Greek letters. Nectins form homo *cis*-dimers on the plasma membranes and *trans*-dimers with nectins present on the adjacent cell. Each nectin has a specialized pattern of *trans*-dimer formation with itself or other nectins (Reymond *et al.*, 2000; Takai *et al.*, 2003). Their main attribute is the formation, together with cadherins, of the adherens junctions of epithelial cells, and in cooperation or not with cadherins, the organization of claudin-based tight junctions. In addition, they are involved in the formation of synapses in neurons and the organization of heterotypic junctions between Sertoli cells and spermatids in the testis (Takai *et al.*, 2003).

Most nectins carry a C-terminal conserved motif that binds afadin, thus anchoring the adhesion molecules to the cytoskeleton (Takai *et al.*, 2003). This domain is absent from nectin1β which is not restricted to adherens junctions. Nectin-mediated signalling activity leads to activation of a variety of extracellular and intracellular molecules, such as scatter factor/hepatocyte growth factor, Ras, Cdc42 and Rac small G proteins (Takai *et al.*, 2003).

Table 7.1. Human HSV receptors and the viral strains for which they serve

		Human α-herpesvirus				
		Unrestricted/*rid*			Animal α-herpesvirus	
Receptor name	Alternative name	HSV-1	HSV-2	mutants	PrV	BHV-1
HVEM	HveA	+	+	−	−	−
Nectin1	PRR1, HIgR, HveC	+	+	+	+	+
Nectin2	PRR2, HveB	−	+/−	+	+	−

Nectin1

Human nectin1 is a broad spectrum receptor for human and animal alphaherpesviruses (Table 7.1). Three isoforms are known, two of which: -α and -β are membrane-bound (Cocchi *et al.*, 1998a,b; Geraghty *et al.*, 1998; Krummenacher *et al.*, 1998; Krummenacher *et al.*, 1999; Campadelli-Fiume *et al.*, 2000). Their main properties as HSV receptors are as follows.

(i) Nectin1 is broadly expressed in human tissues, including tissues and organs targeted by HSV, like CNS, ganglia and muco-epithelia (Cocchi *et al.*, 1998b; Haarr *et al.*, 2001; Matsushima *et al.*, 2003; Richart *et al.*, 2003; Linehan *et al.*, 2004). It is expressed in virtually all human cell lines, including epithelial cells, neurons and fibroblasts (Campadelli-Fiume *et al.*, 2000; Spear *et al.*, 2000). Some of these cells simultaneously express HVEM (Krummenacher *et al.*, 2004).

When HSV initially infects mucosal epithelium, the apical domain of polarized epithelial cells are targeted initially, whereas basolateral domains of epithelial cells are available to the virus only if a lesion disrupts the integrity of the lining. It was therefore of interest to know whether nectin1 can serve as an HSV receptor in polarized epithelial cells. Human CaCo2 cells can be infected with HSV from the apical domain (Griffiths *et al.*, 1998), whereas MDCK cells and primary human keratinocytes are preferentially infected from the basolateral domain (Schelhaas *et al.*, 2003; Marozin *et al.*, 2004). These differences may reflect cell line-dependent differences in the pattern of polarization of a same molecule, or distribution of receptors like nectin1-β and HVEM, which do not appear to be restricted to adherens junctions.

(ii) Nectin1 interacts physically with gD (Krummenacher *et al.*, 1999). The interaction requires the first 250 residues of gD and the V domain of nectin1. The affinity ranges from 10^{-6} to 10^{-8} molar, with the highest affinity observed with forms of gD that were truncated at or after residue 250. Affinity decreases by 100-fold with gD_{306t}, reflecting a folding of the most C-terminal portion of gD towards the core (Whitbeck *et al.*, 1999; Krummenacher *et al.*, 2005). Insertion mutations alter the binding affinity; insertions at the N-terminus (e.g., at residues 34, and 43) modify the binding to HVEM but not to nectin1 (Milne *et al.*, 2003; Jogger *et al.*, 2004). Remarkably, even when the binding affinities are low, or undetectable, the mutant forms of gD maintain the ability to mediate HSV entry and cell–cell fusion, implying that gD functions in virus entry and cell fusion regardless of its receptor-binding affinity and kinetics, and that as long as interaction with a functional receptor occurs, entry takes place (Milne *et al.*, 2003; Zhou *et al.*, 2003).

Human nectin1 also binds isoforms of gD from animal α-herpesviruses. The affinity may be even higher than for HSV-1 gD (in the case of PrV), or very low (in the case of BHV-1) (Connolly *et al.*, 2001). Even when the affinity is very low, human nectin1 is capable of mediating entry (Cocchi *et al.*, 1998b; Geraghty *et al.*, 1998).

(iii) The domain of nectin1 functional in HSV entry and in binding to gD was initially mapped to the N-terminal V domain, and subsequently to the C-C′-C″ ridge (Krummenacher *et al.*, 2000; Cocchi *et al.*, 2001; Menotti *et al.*, 2002b). Critical residues that may be part of the interface with gD are amino acids 77 and 85 (Martinez and Spear, 2002).

(iv) Nectin1-γ is a natural soluble isoform of nectin1 generated by alternative splicing. Although it contains the three Ig domains, it has a narrow distribution in human tissues, unlike nectin1-α and -β. Like soluble recombinant forms of nectin1, it has the capacity to bind to virions and block infectivity. An unexpected property was that the soluble nectin1-γ molecules suffices to mediate virus entry into receptor-negative cells. This may be consequent either to an association to endogenous nectins, or to a direct binding of the soluble receptor to virions (Lopez *et al.*, 2001).

Nectin 2 and the unrestricted or rid *mutations*

The remarkable feature about nectin2 is that a single amino acid substitution in gD confers to HSV the ability to use nectin2 as an alternative receptor, without hampering its ability to use nectin1 (Table 7.1). At the same time, this mutation abolishes the interaction with HVEM (Connolly *et al.*, 2003; Yoon *et al.*, 2003). The end result is that the

host range of the virus is modified. The mutations are L25P, Q27P, or Q27R, and are present in the unrestricted, or *rid* HSV-1 mutants. Nectin2 also serves as a weak receptor for some strains of HSV-2, but is inactive for wt-HSV-1 (Warner *et al.*, 1998; Lopez *et al.*, 2000; Krummenacher *et al.*, 2004). Physical interaction studies were in agreement with these properties (Warner *et al.*, 1998; Lopez *et al.*, 2000; Yoon *et al.*, 2003). The nectin2 residues critical for HSV entry were identified as amino acids 75–81 and 89, which lie adjacent to the predicted C′C″ β-strands, i.e., the region corresponding to the nectin1 region involved in interaction with wild-type gD.

The TNF receptor family

TNFRs (tumor necrosis factor receptors) form a family of signal transduction molecules involved in regulation of cell proliferation, differentiation and apoptotic death. Structurally, their ectodomain is composed of four typical cysteine-rich domains (CRDs). The family includes twenty nine human members, classified into three groups according to their cytoplasmic sequences and signaling properties. Members of the first group (exemplified by Fas) contain a death domain (DD) in the cytoplasmic tail. After binding to their ligands they interact with intracellular adaptors, which, in turn, induce apoptosis by activation of the caspase cascade. Members of the second group (exemplified by TNFR2 and HVEM) lack a death domain, and instead contain one or more TRAF (TNFR-associated factor) interacting motifs (TIMs), which trigger a variety of signal transduction pathways, including those for activation of nuclear factor κB (NF-κB), Jun N-terminal kinase (JNK), p38, extracellular signal-related kinase (ERK) and phosphoinositide 3-kinase (PI3K). Members of the third group (e.g., TNFR3, TNFR4, etc.) lack intracellular signaling motifs, and act as decoy receptors.

The natural ligands of the TNFRs are a family of cytokines whose prototype is TNF, and include lymphotoxin (LT)α, LTβ, and LIGHT. They are biologically active as trimers: their binding to the receptors causes the trimerization of the intracellular domains, which, in turn, interact with high affinity with trimeric cellular adaptors (e.g., TRAFs). Each cytokine interacts with more than one receptor.

HVEM

HVEM was first identified as a HSV receptor and was classified as a novel member of the TNFR family based on structural motifs (Montgomery *et al.*, 1996). The cytoplasmic tail interacts with several members of the TRAF family, leading to the activation of targets like NF-κB, Jun N-terminal kinase, and AP-1, and the consequent induction of T cell activation, proliferation, cytokine release, and expression of cell surface activation markers (Harrop *et al.*, 1998). Its ligands are $LT\alpha_3$ and LIGHT (Mauri *et al.*, 1998). LIGHT–HVEM interactions contribute to the cytotoxic T-lymphocyte-mediated immune response.

The main properties of HVEM as an HSV receptor are as follows.

(i) In early studies HVEM was found to be expressed mainly in cells of the immune system, and in a number of non-hematopoietic tissues and organs. Expression was not observed in brain or skeletal muscle (Montgomery *et al.*, 1996; Kwon *et al.*, 1997).

(ii) HVEM serves as receptor for HSV-1 and HSV-2, as a weak receptor for the U10 HSV mutant (L25P substitution), but not for HSV *rid*-1 and *rid*-2 unrestricted mutants (Connolly *et al.*, 2003; Yoon *et al.*, 2003).

(iii) HVEM binds wild-type gD. The affinity of the binding is of the same order of magnitude as that of nectin1/gD binding, and the interaction requires the same region of gD, i.e., the first 250 residues, or longer (Willis *et al.*, 1998). gD and LIGHT compete with each other for the binding to HVEM; accordingly, LIGHT interferes with HSV entry in HVEM-expressing cells (Mauri *et al.*, 1998).

(iv) The gD contact site on HVEM involves CRD1 and 2, with the majority of contacts lying in CRD1. Residues 35–37 form the intermolecular antiparallel β-sheet with gD (Carfi *et al.*, 2001; Connolly *et al.*, 2003). A systematic structure-based mutagenesis approach revealed that 17 residues in CRD1 and 4 in CRD2 are directly involved in the HVEM-gD interface. Some mutations completely abolish the HVEM binding to gD and its function as an HSV-1 receptor (Connolly *et al.*, 2002).

Modified heparan sulphate

3-O-sulphated heparan sulphate represents the third identified HSV receptor, structurally unrelated to nectins and HVEM (Shukla *et al.*, 1999). It serves as receptor for HSV-1, but not for unrestricted *rid* mutants or HSV-2. Thus, HSV-1 can use heparan sulphate GAGs not only for the initial step of attachment to the target cell, but it also recognizes some specifically modified sites on heparan sulphate (Shukla and Spear, 2001). The physical interaction with gD is in the range of 10^{-6} M, as measured by affinity co-electophoresis, and was not detectable by ELISA.

The sites on heparan sulphate recognized by gD are generated by heparan sulphate D-glucosaminyl 3-O-sulfotransferases (3-OSTs). 3-O-sulphates are rare substitutions in heparan sulphate, generated by at least six 3-OSTs isoforms identified in humans and mice, 3-OST-3_A and 3-OST-3_B, 3-OST-2, 3-OST-4 and 3-OST-5 (Shukla and

Spear, 2001). Of note, 3-OST-3s are not receptors *per se,* consistent with the finding that gD does not bind to the purified enzymes; rather, they catalyze the substitutions, which, in turn, generate the receptors and render CHO cells susceptible to HSV.

The relevance of this potential receptor to HSV infection in human cell lines and in humans remains to be ascertained. In terms of distribution, the 3-OST-3s are broadly expressed isoforms in cells of different origins and tissues; 3-OST-2 and 3-OST-4 expression is mainly in the brain. 3-OST-5 expression is limited to the skeletal muscle.

Receptor preference and usage

The availability of multiple alternative receptors raises a number of questions, such as: What receptor is preferred in cells that coexpress both molecules? Do both serve as *bona fide* receptors in humans? Are they differentially distributed, or employed in different tissues? Limited information is available on these topics.

Two parameters that may guide receptor preference in cell cultures are the affinity of the binding and the cell surface density of the receptors. Neither appears to be relevant in the case of gD, since gD affinity to nectin1 and to HVEM is of the same order of magnitude (Krummenacher *et al.*, 1998). Moreover, cells that appear to be nectin1-negative by fluorescent antibody cell sorting (e.g., EA-1 cells) can be infected and entry is inhibited by antibody to nectin1 (our unpublished result), implying that low density receptors suffice to mediate entry. The same phenomenon is observed with HVEM (Krummenacher *et al.*, 2004).

As far as infection of animal and human tissues is concerned, nectin1 is expressed in nearly every neuron of adult mice, in rat sensory neurons, in some synapses, and serves as the primary receptor for HSV-1 infection in sensory neurons (Haarr *et al.*, 2001; Mata *et al.*, 2001; Richart *et al.*, 2003). Nectin1 is also expressed in the epithelium of the human and murine vagina where it mediates HSV-1 and -2 entry in the genital mucosa of female hosts (Linehan *et al.*, 2004). Nectin1-α is detected at the cell–cell adherens junctions in human skin (Matsushima *et al.*, 2003). Cumulatively, these data are compatible with a major role of nectin1 in the infection of sensory neurons and mucoepithelia in vivo. The tissue distribution of HVEM suggests that it serves as the principal receptor for HSV in activated T lymphocytes, or in lymphoid organs (spleen and thymus), in liver and lung. However, these organs are not target of HSV in the natural history of infection, except in the rare cases of disseminated infection. Recent data show that several clinical/primary isolates can use both receptors, as laboratory strains do (Krummenacher *et al.*, 2004). The fact that viruses of different origin retain the ability to use both receptors suggests that this is a requirement for successful infection and spread in the host (Krummenacher *et al.*, 2004). The interaction with HVEM in particular may have a role in immune evasion (La *et al.*, 2002).

For other viruses, formal proof that a given receptor plays a critical role in humans has rested on correlations between genetic defects in the locus encoding the receptor and a diminished susceptibility to viral infection. A rare truncation of the nectin1 gene has been identified. The phenotypes associated with loss of both alleles include cleft lip/palate, hidrotic ectodermal dysplasia (CLPED1), hair abnormalities, developmental defects of the hands and, in some cases, mental retardation. Studies on the serostatus of these patients for evidence of HSV infection have not been published. A few studies investigated nectin1, nectin2 and HVEM gene polymorphisms and correlations with HSV infection. At present, no relatively common polymorphism has been found to correlate with HSV serostatus or symptoms (Patera *et al.*, 2002; Struyf *et al.*, 2002; Krummenacher *et al.*, 2004). Wild-type HSV can infect CLPED1 fibroblasts through HVEM in vitro, indicating that the ability to exploit redundant receptors may be favorable to the virus in vivo as well (Krummenacher *et al.*, 2004).

The animal orthologues of nectin and HVEM

HSV infects numerous mammalian species, some of which – mice, rabbits and primates – are extensively employed as animal models. The question arises whether they are faithful models in terms of receptor usage.

Porcine and bovine alphaherpesviruses promiscuously use human nectin1, implying that animal orthologs of nectins serve as receptors of these viruses in their hosts (Cocchi *et al.*, 1998b; Geraghty *et al.*, 1998; Warner *et al.*, 1998). Indeed, nectins are conserved among mammals, and nectin1 orthologs have been found in cells derived from mice, hamsters, pigs, cows and monkeys, and nectin2 has a mouse ortholog, suggesting a conserved function in the evolution of these proteins (Milne *et al.*, 2001). A HVEM ortholog is expressed in mice (Yoon *et al.*, 2003). In turn, the murine orthologs of nectin1, nectin2, HVEM, and the porcine and bovine hortologs of human nectin1 can serve as species non-specific HSV receptors when transfected into receptor-negative cells (Menotti *et al.*, 2000; Shukla *et al.*, 2000; Menotti *et al.*, 2001; Milne *et al.*, 2001; Menotti *et al.*, 2002a). The affinity of these potential receptors for gD ranges from as high as that of human nectin1, to very low or undetectable. Because the animal orthologs of nectin, and perhaps also of HVEM serve as receptors of HSV in mice and other animal species, these systems appear to relatively faithfully model HSV receptor usage in humans.

Site of HSV entry into the cell

It has been a long held paradigm that HSV enters cells by fusion at the plasma membrane. Recent evidence indicates that in some cells entry is through an endocytic pathway, and that both the cell type, and the structural features of the receptors are determinants that control the site of entry. Specifically, in cells like HeLa and CHO expressing nectin1 or HVEM, entry is inhibited by drugs that modify the pH of the endosomal compartment (low pH-sensitive entry) (Nicola *et al.*, 2003). However, when nectin1 or HVEM are expressed in J cells, they mediate entry at the plasma membrane. Furthermore, when nectin1 is retargeted to endosomes, by means of a chimeric nectin1-EGFR (epidermal growth factor receptor) chimera, or is sorted to lipid rafts, by means of a nectin1-glycosylphosphatidylinositol anchor chimera, the pathway of entry into J cells becomes endocytic (Gianni *et al.*, 2004). Of note, when HSV infects cells carrying wt-nectin1, neither nectin nor gD localize at lipid rafts, but gB does (Bender *et al.*, 2003). All in all, HSV fusion glycoproteins are well suited to perform two quite different pathways of entry.

Role of gD-receptor interaction in triggering fusion

Crucial to our understanding of how HSV enters cells is the comprehension of how gD binding to its receptor triggers fusion. A hint has come from the unexpected observation that the soluble gD ectodomain is both necessary and sufficient to rescue the infectivity of the non infectious gDnull HSV mutant (Cocchi *et al.*, 2004). Entry mediated by soluble gD requires not only the N-terminus, carrying the receptor-binding sites, but also the C-terminus carrying the pro-fusion domain, required to trigger fusion but not for receptor binding. These findings, together with the observation that a glycosylphosphatidylinositol-anchored form of gD, or substitution of the transmembrane and cytoplasmic tail with heterologous regions leave gD function unaltered (Browne *et al.*, 2003) demonstrate that the transmembrane region and cytoplasmic tail do not play any demonstrable function, except to ensure that gD is delivered to the gD receptor along with the virion, and argue that the role of gD in HSV entry is to signal receptor-recognition to the downstream glycoproteins and to trigger fusion (Cocchi *et al.*, 2004).

Biochemical and structural studies indicate that the receptor-mediated activation of gD takes the form of a conformational change (Cocchi *et al.*, 2004; Fusco *et al.*, 2005; Krummenacher *et al.*, 2005). In the unliganded state the virion gD adopts a conformation in which the flexible C terminus folds back, wraps the N-terminus and masks the receptor binding sites. At receptor binding, the C-terminus is displaced from its binding site on the N-terminus, the receptor binding sites are unmasked and become occupied by the receptor. The binary complex made of receptor plus gD with the displaced C-terminus must create a surface suitable for gB and gH-gL recruitment.

Execution of membrane fusion and its control

gB, gH, gL are essential for entry of all herpesviruses, since they are conserved among all human herpesviruses, with the highest extent of sequence conservation seen in gB. Heterodimer formation between gH and gL is also a conserved feature amongst herpesviruses. Altogether, gB, gH and gL appear to be the executors of fusion and constitute the conserved fusion machinery across the herpesvirus family.

Critical properties of gH and gB have been elucidated recently, and provide an intriguing scenario. On one hand, molecular and biochemical analyses of gH highlighted properties typical of class 1 fusion glycoproteins. Because the gH structure has not yet been solved, these properties wait for confirmation at the structural level. On the other hand, the crystal structure of gB has been solved, it exhibits a remarkable similarity to that of vesicular stomatitis G protein, and to viral fusion glycoproteins in general. Biochemical and mutational confirmation are still to be provided. At present, a most likely scenario is that both gB and gH·gL are fusion executors. How the two glycoproteins cooperate to execute fusion, and why two, and not one, fusion executors are required in the herpesviridae family is unclear. It is worthwhile to note that entry by fusion at plasma membrane, and entry by fusion in endocytic vesicles require all four glycoproteins (gD, gB, gH and gL) (Nicola *et al.*, 2003; Nicola and Straus, 2004). These requirements rule out the possibility that gB serves as fusion executor in one cellular compartment, and gH·gL serves as fusion executor in another cell compartment.

The glycoproteins that execute fusion

gH –gL

gH is a type-1 virion glycoprotein encoded by the UL22 gene (Gompels and Minson, 1986). Soon after its discovery, it was recognized as an essential glycoprotein for virion infectivity, as its deletion produced non infectious progeny and abolished cell–cell fusion (Forrester *et al.*, 1992). Neutralizing antibodies to gH block virus entry but permit attachment, indicating a role at a post-attachment step (Fuller *et al.*, 1989). gH appears to contain elements associated with fusion of membranes, i.e. a hydrophobic α-helix 1 (residues 377-397) with properties typical of a fusion peptide and two heptad repeats with propensity to form a coiled coil. α-Helix 1 is positionally conserved in all the

gH orthologs across the herpesviridae family; in HSV-2 it is located in a loop made of two cysteins. α-Helix 1 is able to interact with biological membranes, can convert a soluble glycoprotein (gD amino acid residues 1-260) into a membrane-bound glycoprotein, and can be functionally replaced by fusion peptides derived from glycoproteins of other, unrelated viruses (Gianni *et al.*, 2005a). A peptide with the sequence of α-helix 1 induces fusion of liposomes and exhibits a strong flexibility documented as ability to adopt an α-helical conformation (Galdiero, S. *et al.*, 2006; Gianni *et al.*, 2006a). These properties strongly argue in favor of α-helix 1 as a candidate fusion peptide loop. Two heptad repeats, capable to form coiled coils and to interact with each other, form a structure of increased α-helical content and are potentially suitable to form a six-helix bundle (Gianni *et al.*, 2005b; Galdiero, S. *et al.*, 2006; Gianni *et al.*, 2006b). Additional elements in gH are a second predicted α-helical domain of lower hydrophobicity than the candidate fusion peptide (aa 513-531), and a pre-transmembrane sequence (aa 626-644) with predicted propensity to partition at membrane interface (Galdiero, S. *et al.*, 2006; Gianni *et al.*, 2006a).

Synthetic peptides corresponding to the heptad repeats inhibit virus infection if present at the time of virus entry into the cell (Gianni *et al.*, 2005b; Galdiero, S. *et al.*, 2006; Gianni *et al.*, 2006b). The presence of coiled coil motifs predicts that gH must undergo profound conformational changes at fusion. Because fusion peptides and coiled coil heptad repeats represent characteristic functional domains in type 1 viral fusion glycoproteins, gH is a candidate fusion executor in HSV.

It remains to be determined whether gH interacts with cellular receptors. The interaction with an integrin is not critical given that mutagenesis of a RGD motif did not reduce virus entry and cell fusion (Galdiero, M. *et al.*, 1997). It is of interest that the transmembrane and C-terminal tail regions of gH can not be exchanged with those of heterologous proteins, in contrast with what happens with gD (Harman *et al.*, 2002; Jones and Geraghty, 2004).

A *ts* mutant, tsQ26, exhibited a phenotype characterized by the production of non-infectious extracellular virions, along with the intracellular retention of gH and of infectious virions (Desai *et al.*, 1988). This phenotype suggested a peculiar mechanism of intracellular retention of gH. A clue to understanding the intracellular trafficking of gH came from the observations that, when expressed from a transgene, gH had a M_r lower than that of mature gH, was not transported to the cell surface, and was retained in the ER unless the cells were superinfected (Gompels and Minson, 1986; Foà-Tomasi *et al.*, 1991; Roberts *et al.*, 1991). The gene product required for gH trafficking and maturation, identified by Johnson and coworkers, is gL (Hutchinson *et al.*, 1992a); gL is required for proper folding and traffiking of gH in all human Herpesviruses (Kaye *et al.*, 1992; Liu *et al.*, 1993).

gL is a soluble glycoprotein encoded by UL1 gene; its presence in the virion envelope is ensured by complex formation with gH (Hutchinson *et al.*, 1992a). In accordance with gH attributes, an HSV mutant unable to express gL could not enter cells, and its particles lacked glycoprotein H (Roop *et al.*, 1993). Both gH and gL are required for fusion in the cell–cell fusion assay (Turner *et al.*, 1998). The first 323 amino acids of gH and the first 161 amino acids of gL can form a stable secreted hetero-oligomer, while the first 648 amino acids of gH are required for reactivity to conformation-dependent antibodies, indicative of correct conformation and oligomerization (Peng *et al.*, 1998). gL is a locus of a *syn* mutation, confirming a role of the gH-gL hetero-oligomer in HSV fusion. The exact role of gL in fusion remains to be elucidated. Because its binding site on gH maps both upstream and downstream of the hydrophobic α-helix, it has been proposed that its role may be to shield the gH hydrophobic sequence, and thus to enable gH water solubility and solvent interface (Gianni *et al.*, 2005a).

gB

gB plays two opposite roles in fusion, i.e. it participates in fusion execution, and it exerts anti-fusion activity. The two functions are physically separated and reside in the ectodomain and the cytoplasmic tail, respectively. gB is a type-1 virion glycoprotein encoded by the UL27 gene (Bzik *et al.*, 1984; Pellett *et al.*, 1985). Its crystal structure reveals a trimer with a coiled coil core. Remarkably, its structure resembles closely that of vesicular stomatitis virus G protein (Heldwein *et al.*, 2006; Roche *et al.*, 2006). Despite the facts that a canonical fusion peptide has not been detected by biochemical, molecular or structural analyses, and that the region homologous to the fusion peptide loop in vesicular stomatitis virus G protein appears to be suboptimal for membrane insertion, the structural similarity between gB and vesicular stomatitis virus G protein strongly relates gB to viral fusion glycoproteins. It has been proposed that the two glycoproteins may represent a novel class of fusion glycoproteins (Heldwein *et al.*, 2006; Roche *et al.*, 2006).

From a structural point of view, gB is a trimeric spike. Each of the three protomers (residues 103–730) appears to be composed of five distinct domains (named I-V), displaying multiple contact sites (Heldwein *et al.*, 2006). Domain I, the "base", is a continous chain with a fold typical of pleckstrin homology domains. Domain II, the "middle", is made of two discontinuous segments, forming a structure

reminiscent of a pleckstrin homology superfold. Domain III, the "core", comprises three discontinuous segments: its prominent feature is a 44-residue α-helix that forms the central coiled coil with its trimeric counterparts. Domain IV, the "crown", adopts a novel structure, and is fully exposed on top of the trimeric spike. Domain V, the "arm", is a long extension spanning the full length of the protomer. Of note, its residues do not contact residues of the same protomer, but instead accommodate into the groove formed by the "cores" of the other two protomers.

The role of gB in virion infectivity and cell–cell fusion is inferred by numerous lines of evidence, including (i) the phenotype of a gB deletion mutant virus which produces non-infectious particles, (ii) the neutralizing activity of antibodies to gB, (iii) gB as a genetic locus of syncytial mutations, and (iv) the requirement for gB in the cell-cell fusion assay (Manservigi *et al.*, 1977; Cai, W. Z. *et al.*, 1987; Turner *et al.*, 1998). Functional domains in the ectodomain were identified by means of two sets of mutations: temperature sensitive mutations for viral growth, and resistance to antibodies with potent neutralizing activity. The first ones, exemplified by the mutants tsB5 and tsJ12, reside in the gB ectodomain, confer a temperature-sensitive phenotype, and affect the rate of virus entry (Bzik *et al.*, 1984). Likely, these mutations affect the gB domain involved in execution of fusion. Following the determination of gB crystal structure, it was recognized that the epitopes of potent neutralizing antibodies, either centered around single amino acid residues or formed by continuous regions, reside on the trimer surface, on the lateral faces of the spike or on the tip of the crown (Pellett *et al.*, 1985; Kousoulas *et al.*, 1988; Highlander *et al.*, 1989; Pereira *et al.*, 1989; Qadri *et al.*, 1991; Heldwein *et al.*, 2006).

The quartet of gD, gB, gH and gL assemble into a complex at virus entry

The nature of the interactions between the complex formed by gD plus its receptor and the executors of fusion is critical to understand the mechanisms by which HSV (and by extension all other herpesviruses) enter cells.

The quartet of glycoproteins essential for HSV entry and fusion (gD, gB, gH and gL) assemble into a complex at virus entry and in infected cells. Complex assembly strictly requires one of the gD receptors, either nectin1 or HVEM. The same complex is assembled also in cells transfected with the quartet, implying that no additional viral protein other than those that participate in the complex itself is required. Because the complex is assembled at virus entry and in transfected cells committed to form polykaryocytes, and fails to be assembled in the absence of either a receptor to gD or of gD, complex assembly appears to be a critical step in the process of virus entry and fusion.

The proteins that negatively control fusion

Cells infected with wt-virus do not form syncytia, despite the fact that they express the fusion glycoproteins at their surface. Syncytia are only formed when the virus carries one of the syncytial (*syn*) mutations, which map to genes encoding gB, gL, gK, UL24, or UL20. By contrast, cells expressing the quartet of gB, gD, gH and gL readily form syncytia (Turner *et al.*, 1998). The paradox may be explained by assuming that the wt-alleles of proteins that are target of *syn* mutations exert a negative control on fusion. This has, in fact, been verified for gB, gK, and UL20 (Fan *et al.*, 2002; Avitabile *et al.*, 2003; Avitabile *et al.*, 2004). As outlined below, HSV has evolved at least two mechanisms by which it blocks fusion. One is exerted through downmodulation of gB cell surface expression, the other is exerted through the concerted action of gK and UL20p. Still other proteins (UL24 and UL45) are likely to exert anti-fusion activity. The evolution of functional redundancy implies that uncontrolled fusion is inimical to HSV-1 replication and spread in nature, and therefore the virus needs to exert a tight control on it.

gB

The anti-fusion activity of gB is located in the cytoplasmic tail, which carries at least two physically distinct functional domains: the *syn* mutation and the endocytosis motifs. Each of them, separately, appears to reduce fusion. Structurally, the cytoplasmic tail carries two predicted α-helices. The *syn* mutations are located immediately downstream of the most N-terminal α-helix. Embedded in the region of the C-terminal α-helix is one, and possibly two functional endocytosis motifs (YTQV889–892 and LL871 (Fan *et al.*, 2002; Avitabile *et al.*, 2004; Beitia Ortiz de Zarate *et al.*, 2004). Deletion of the membrane-proximal α-helix abrogates virus infectivity, implying that this region is critical. Its role, and the molecular mechanism of the *syn3* mutation remain to be elucidated. The membrane-distal α-helix is also implicated in the negative control of fusion, since its deletion increases fusion in the cell fusion assay, and confers a syncytial phenotype upon virus-infected cells (Foster, *et al.*, 2001a; Avitabile *et al.*, 2004). Its antifusion activity is mainly exerted through endocytosis, which acts to decrease the steady state amounts of gB from the cell surface, such that gB becomes a limiting factor in fusion. Of note, the gB-decorated endocytosis vesicles-vacuoles represent the hallmark of gB localization in infected cells.

gK

gK is a polytopic glycoprotein encoded by the UL53 gene, whose topology is still debated (Hutchinson *et al.*, 1992b; Foster, *et al.*, 2001b). It carries an N-terminal extracellular domain, and two or three TM regions connected by loops (Foster, *et al.*, 2003b). Its hydrophobicity, poor immunogenicity and overall problems in its detection have made this glycoprotein a difficult one to study. In infected cells, gK localizes mainly to the Golgi apparatus. One controversial aspect is whether it localizes to the plasma membranes and to virions. When expressed from a transgene, gK is primarily located is at the ER (Hutchinson *et al.*, 1992b; Avitabile *et al.*, 2003; Foster, *et al.*, 2003a). When coexpressed with UL20, both proteins localize to the Golgi apparatus (Avitabile *et al.*, 2004).

gK exerts anti-fusion activity in the cell–cell fusion assay (Avitabile *et al.*, 2003). Mutant viruses carrying a partial or a complete deletion in the gK gene have two major phenotypes (Hutchinson and Johnson, 1995; Foster, and Kousoulas, 1999). First, they form syncytia, arguing that the anti-fusion activity is exerted also in the context of infected cells. Second, they are defective in virus egress, arguing that the anti-fusion activity of gK is exerted not only at the plasma membrane, but also in the membranes of the exocytic compartment. This would provide an explanation as to why these membranes are heavily decorated with fusion glycoproteins, yet do not fuse one with the other. According to this model, the gK role in virion egress may be exerted by maintaining a functional exocytic pathway. It should be stressed that, if indeed gK is also a virion constituent, then, at virus entry into the cell, the trigger to fusion must simultaneously relieve the block to fusion exerted by gK (Avitabile *et al.*, 2004).

UL20

UL20p is a polytopic unglycosylated protein with several analogies to gK. Its hydrophobicity and scarce immunogenicity have hampered its characterization. UL20p is predicted to carry 4 transmembrane segments (McGeoch *et al.*, 1988; Melancon *et al.*, 2004). In the infected cells UL20p localizes at the Golgi apparatus and the nuclear membranes, and is not detectable at the plasma membrane. It has not been detected in virions. When expressed from a transgene, UL20p predominant localization is at the ER (Avitabile *et al.*, 1994; Ward *et al.*, 1994). It relocalizes to the Golgi apparatus, when coexpressed with gK (Foster, *et al.*, 2003b; Avitabile *et al.*, 2004).

Two mutant viruses deleted in UL20 gene have been constructed, both of which are highly defective in secretion of virions to the extracellular space (Baines *et al.*, 1991; Foster, *et al.*, 2004). The first deletion virus was subsequently reported to carry an in-frame fusion between UL20.5 (not known at the time the deletion virus was constructed) and the C-terminus of UL20 gene, and was characterized by syncytia formation and by the entrapping of virions in the perinuclear space (i.e., the space between the inner and outer nuclear membranes) – a phenotype particularly evident in cells whose Golgi apparatus became fragmented following infection (Baines *et al.*, 1991). This phenotype can be interpreted as indication that the UL20p exerts a negative control on fusion. Cells infected with the second deletion virus showed enveloped virions as well as unenveloped nucleocapsids accumulating in the cytoplasm, and occasionally virion envelopes containing multiple capsids within intracytoplasmic vacuoles. These phenotypes were also interpreted to mean that UL20p acts as an inhibitor of membrane fusion, and, interestingly, that UL20p may act to maintain a single nucleocapsid for each envelope and to prevent fusion of enveloped virions among themselves (Foster, *et al.*, 2004). The complexity of these phenotypes reflects both direct and indirect effects of UL20p, including the role of UL20p in the intracellular transport of gK and possibly of the fusion glycoproteins.

The possibility that UL20p exerts an anti-fusion activity was probed in the cell–cell fusion assay, which showed a block to fusion in cells coexpressing UL20p and gK, but not in cells expressing UL20 alone. The block was cell line dependent (Avitabile *et al.*, 2004). The similar behavior of gK and UL20p, their colocalization, their mutual ability to influence each other localization, and their concerted anti-fusion activity make it likely that the two proteins act in a complex, and that they share a common target.

Nucleocapsid transport to the nuclear pore

Virus entry culminates in the release of capsids and approximately twenty tegument proteins into the cytosol. The capsids and some of the tegument proteins, e.g., αTIF, travel to the nuclear pore. Since diffusion of molecules larger than 500 kDa is restricted in the cytoplasm, viruses and nucleocapsids require a transport system. This is particularly true for neurotropic viruses that travel long distances in the axon during retrograde or anterograde transport (Enquist *et al.*, 1998). It has been calculated that in the absence of an active transport mechanism, it would take a herpes virus capsid 231 years to diffuse 10 mm in the axonal cytoplasm (Sodeik, 2000).

Microtubules represent the cytoplasmic highways on which HSV is transported (reviewed in Döhner and Sodeik, 2005). At virus entry, capsids co-localize with microtubules, and their depolymerization reduces capsid transport to

the nucleus (Sodeik *et al.*, 1997; Mabit *et al.*, 2002). Microtubules are polar structures with fast growing plus-ends typically localized in the cell periphery, and less dynamic minus-ends that are usually anchored in close proximity of the nucleus at the microtubule organizing centre (MTOC). Molecular motors use ATP-driven conformational changes to transport cargo along microtubules. Transport to the plus-ends is catalyzed by kinesins and that to minus-end by cytoplasmic dynein and dynactin (Döhner and Sodeik, 2005). Dynein and dynactin mediate capsid transport to the cell centre, since incoming capsids colocalize with these motors (Sodeik *et al.*, 1997; Döhner *et al.*, 2002), and overexpression of dynamitin, a subunit of the dynactin complex, inhibits capsid transport (Döhner *et al.*, 2002). How capsids move further from MTOC to the nuclear pore complex is unclear.

Analysis of HSV-1 entry by digital time-lapse fluorescence microscopy showed that GFP-tagged capsids can move along microtubules both towards and away from the nucleus, with maximal speeds of 1.1 μm/s. The transport is saltatory and bidirectional, but in neuronal processes it shows a retrograde bias towards the cell body (Smith *et al.*, 2001). Efforts are underway to identify the virion proteins that may interact with kinesins as well as dynein or dynactin. Two candidates are UL34p, which, however, is absent from mature virions, and US11, which appears to bind the heavy chain of conventional kinesin (Diefenbach *et al.*, 2002). Once the capsids have reached the proximity of the nucleus, they seem to bind to filaments emanating from the nuclear pores (Batterson *et al.*, 1983; Sodeik *et al.*, 1997). This docking is believed to induce capsid destabilization, release of the viral DNA, and its translocation through the nuclear pore into the nucleoplasm (Ojala *et al.*, 2000). Temperature-sensitive mutants in the UL36 gene accumulate filled viral capsids at the nuclear pore complexes at the non-permissive temperature, suggesting that the large tegument protein VP1–3 is involved in uncoating of the viral genome (Batterson *et al.*, 1983; Ojala *et al.*, 2000).

VZV

There are several remarkable differences between VZV and HSV entry. Because the respective viral glycoproteins undoubtedly influence these differences, the VZV gene products will be briefly summarized.

Is VZV gE a substitute for functions of HSV gD?

All but one of the proteins that have been illustrated above for HSV have a counterpart in VZV. For those glycoproteins for which sufficient information is available, a substantial functional similarity is observed. The single most notable difference between VZV and HSV in terms of the glycoproteins is the absence of gD in the VZV genome. At the same time, VZV is well suited for cell-to-cell spread, which takes place by fusion of the infected cell with an adjacent uninfected cell, whereas HSV is better suited for virion-to-cell infection (at least in cultured cells). So, it is tempting to speculate that the absence of a VZV gD gene may contribute to these differences.

Despite the fact that gD plays such a pivotal role in HSV entry, gD is not conserved throughout the alphaherpesviruses. In the porcine herpesvirus PrV, gD is required for virion-to cell infectivity but not for cell-to-cell spread of the virus. Consistently, gD is not a requirement for the PrV cell-cell fusion assay, although its presence greatly enhances fusion efficiency. Assuming that common basic mechanisms are shared by all of the alphaherpesviruses and given that the triplet gH-gL-gB is conserved, the question then arises: which VZV glycoprotein substitutes for the functions encoded in HSV gD, i.e., receptor recognition and triggering of fusion. The two functions might well be distributed over different entities, but a trigger to fusion consequent to virion interaction with a receptor appears to be essential.

In VZV, four glycoproteins are known to be essential. They are gB, gH, gL and gE (Keller *et al.*, 1984; Montalvo and Grose, 1986; Forghani *et al.*, 1994; Duus *et al.*, 1995; Mallory *et al.*, 1997; Mo *et al.*, 2002). Of note, the HSV gE gene lies in the S component of the genome, proximal to gD; as stated above, VZV lacks the gD gene. Instrumental to our understanding of the role of gE are the results of VZV glycoprotein cell–cell fusion assays. In transfected cells, fusion is induced by coexpression of either gH-gL or of gB-gE (Duus *et al.*, 1995; Duus and Grose, 1996; Maresova *et al.*, 2001). With regard to genome stability, VZV is considered to be one of the more genetically stable herpesviruses. However, viral mutants carrying missense mutations in the gE ectodomain are being isolated from humans; one of them is more fusogenic in cell cultures and in the SCID-hu mice (Santos *et al.*, 1998, 2000). Cumulatively, both circumstantial and genetic evidence supports the possibility that VZV gE subsumes at least some of roles of HSV gD.

Endocytosis of the VZV glycoproteins gE, gB, gH, and the negative regulation of fusion

Three VZV glycoproteins carry functional tyrosine-based endocytosis motifs; they are gE, gB and gH.

The gE cytoplasmic tail has a YAGL sequence beginning with a tyrosine residue 582. As determined by mutagenesis studies, the tyrosine residue is part of a conserved YXXL endocytosis motif. The internalized gE trafficks to the trans-Golgi or is recycled to the cell surface. In addition, the C-tail also contains phosphorylation sites (Kenyon *et al.*, 2002). It has been suggested that serine/threonine and tyrosine phosphorylation of gE may serve as sorting signals for internalized receptors and that formation of a gE–gI complex facilitates gE endocytosis (Olson and Grose, 1997; Olson *et al.*, 1998).

VZV gB contains three predicted endocytosis motifs within its cytoplasmic domain: YMTL (aa 818–821), YSRV (aa 857–860), and LL (aa 841–842). Both tyrosine-based motifs mediate gB internalization, but only the YSRV motif is absolutely required for endocytosis. The YMTL motif functions in trafficking of internalized gB to its subsequent localization in the trans Golgi. The third potential endocytosis motif is a dileucine sequence, whose function is under study (Heineman and Hall, 2001). Of note, VZV gI, the partner of VZV gE, also contains a dileucine endocytosis motif in its C-tail (Olson and Grose, 1998).

Like VZV gE and gB, VZV gH contains a functional but previously unrecognized tyrosine based YNKI motif in its short cytoplasmic tail, which mediates clathrin-dependent and antibody-independent endocytosis. Alignment analysis of the VZV gH cytoplasmic tail with other herpesvirus gH homologues reveals two interesting features: (i) herpes simplex virus types 1 and 2 homologues lack an endocytosis motif while all other alphaherpesvirus gH homologues contain a potential motif, and (ii) the VZV gH C-tail is actually longer than predicted in the original sequence analysis and thus can provide the proper context for a functional endocytosis motif (Pasieka *et al.*, 2003). Surprisingly, the endocytosis-deficient VZV gH mutant plasmid effects greater cell-cell fusion than the wild-type gH plasmid. This result leads to the conclusion that VZV gH endocytosis represents a mechanism through which cell–cell fusion is negatively regulated, i.e., by modulating the amount of fusogenic gH on the cell surface (Pasieka *et al.*, 2004). In this respect, therefore, VZV gH shares a basic mechanism of negative regulation of fusion with HSV gB.

Cumulatively, this comparison of the VZV and HSV-1 systems is very instructive as it highlights that both viruses have evolved an essentially similar mechanism of control of fusion, based on endocytosis and consequent limitation of cell surface expression of the fusion executors themselves. A notable difference between the two viruses is that this type of control appears to be is exerted in HSV-1 mainly by gB and in VZV mainly by gH.

Acknowledgments

We are grateful to Drs. Roselyn Eisenberg, Joel Baines, Charles Grose, and Beate Sodeik for critical reading of this chapter.

Early events pre-initiation of alphaherpes viral gene expression

Thomas M. Kristie

National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

The regulated transcription of the HSV IE (immediate–early, α) genes has been a model system for elucidating principles and mechanisms of combinatorial-differential regulation, basic RNAPII-directed transcription, and multiprotein assembly specificities. The regulation exemplifies viral mechanisms dedicated to the recruitment of cellular components into complex viral–host interactions that illustrate general parameters of protein–protein, DNA–protein, RNA transcription, and protein complex assembly. Continued studies hold promise of advancing the understanding of the complexities of biochemical interactions in gene expression as well as complex cellular response pathways. The regulation of the IE genes within specific contexts may also lead to the understanding of signals and pathways which modulate viral infection and determine the extent of lytic-latent infection. While HSV has been extensively studied and will represent the focus of this review, the regulatory domain of the VZV IE gene (IE62) contains similar elements and is regulated by similar mechanisms.

The HSV IE regulatory domains: multiple sites for differential regulation

The regulatory domains of the HSV IE genes have been the focus of numerous studies that have defined the sequence elements and their contributions to the basal and induced levels of transcription. These IE domains typically consist of a reiterated inducible enhancer core element (consensus: TAATGARAT) that is flanked by binding sites for members of the ets and kruppel transcription family (Fig. 8.1, left) (Roizman and Sears, 1996; Vogel and Kristie, 2001).

The primary focus has been on the regulated induction of the expression of the IE genes by the HSV IE transactivator (VP16, αTIF, ICP25) via the enhancer core element (Phillips and Luisi, 2000; Roizman and Sears, 1996; Roizman and Sears, 1996; Vogel and Kristie, 2001; Vogel *et al.*, 2001; Wysocka and Herr, 2003). This focus led to the identification of cellular proteins (Oct-1 and HCF-1) that are required for the stable enhancer complex assembly and the induction of the IE gene transcription (Kristie *et al.*, 1989, 1995; Kristie and Sharp, 1993; Roizman and Sears, 1996; Vogel and Kristie, 2001; Vogel *et al.*, 2001; Wilson *et al.*, 1993; Wysocka and Herr, 2003). Extensive characterization of these components illustrates the multiple levels of complex regulatory interactions inherent in this process.

The assembly of the HSV IE enhancer core complex

The assembly of the HSV IE enhancer core complex illustrates the basic elements of the specificities governing the regulatory process. The stages of the assembly are modeled upon in vitro studies of protein–DNA recognition, protein-protein interactions, selective recognition, affinities, and cooperative interactions. As shown in Fig. 8.1 (Right), the cellular Oct-1 POU domain protein recognizes the divergent octamer element in the IE core and provides a nucleation point for the association of the heterodimeric protein complex consisting of VP16 and HCF-1. Specificity for the HSV IE element is determined by selective recognition of the Oct-1 POU-homeobox and the enhancer core DNA sequences by VP16 while the complex is stabilized by HCF-1 interactions. The full enhancer domain complex contains additional cellular transcription factors such as GABP and Sp1. The activation potential is dependent upon the core complex, likely through additional protein–protein interactions. The complexity of the regulatory complex provides for multiple levels of regulation dictated by various protein combinations, interactions, and the specific regulation of the individual components. Therefore, each component

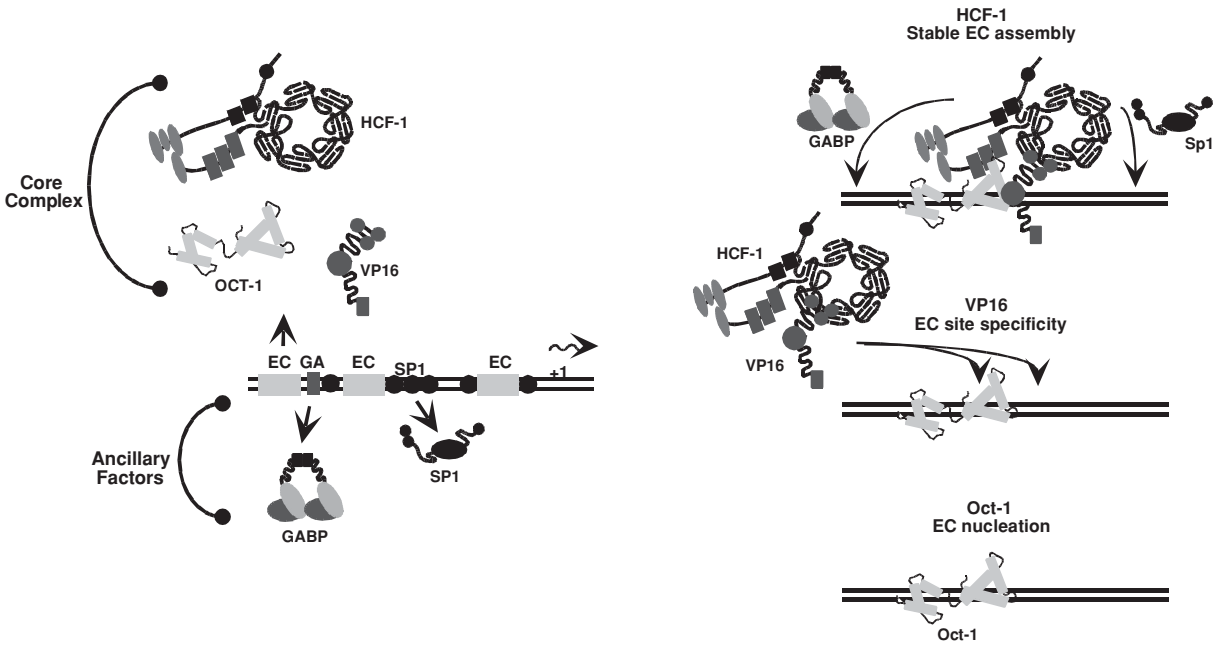

Fig. 8.1. The HSV IE enhancer domain elements, components, and assembly process. (Left) Representation of a typical HSV IE enhancer-promoter domain containing the reiterated enhancer core (EC), GABP (GA), and Sp1 (Sp1) binding sites. The enhancer core components (HCF-1, Oct-1, VP16) and ancillary transcription factors (GABP, Sp1) are represented. (Right) Specificities and interactions in the assembly of the multiprotein enhancer core complex. Oct-1 binds to the octamer element in the 5′ end of the ATGCTAATGARAT enhancer core and nucleates the association of the heteromeric HCF-1/VP16 protein complex. VP16 cooperatively interacts with the Oct-1 POU-homeobox and recognized the 3′ sequences of the core element. The stable enhancer core complex may recruit or interact with the additional factors to form the fully assembled enhancer complex.

will be described with respect to its defined structure, function, interactions, and regulatory mechanisms.

Oct-1

Oct-1 is a representative of the POU family of proteins (Pit, Oct, unc86) containing bipartite DNA binding domains (POU-specific box, POUs and POU-homeobox, POUh) consisting of helix-turn-helix structures that cooperate to recognize the consensus element (ATGCAAAT) (Clerc *et al.*, 1988; Phillips and Luisi, 2000; Sturm *et al.*, 1988). The structure and DNA contacts of the POU-specific box are analogous to the λ repressor in which all four helices make significant network DNA backbone contacts while DNA recognition by the POU-homeobox is characteristic of homeodomains in which helix 3 lies in the major groove and provides sequence recognition. The two DNA binding units recognize bases (POUs, ATGC; POUh, AAAT) in the major groove on opposite sides of the helix and are separated by a flexible and disordered linker region (Fig. 8.2-Oct-1) (Klemm *et al.*, 1994).

In the case of the HSV IE domains, Oct-1 nucleates the enhancer core assembly by binding the divergent octamer sequences of the core consensus (ATGCTAAT). Selective recognition of the Oct-1 POU-homeobox by VP16 was elucidated by comparative analysis of Oct-1 and the highly related Oct-2 protein. While only seven amino acids differ between the exposed homeodomain surfaces of these two proteins, VP16 selectively interacts with Oct-1(Lai *et al.*, 1992; Pomerantz *et al.*, 1992). As shown (Fig. 8.2-Oct-1), four amino acids (K18, S19, E22, E30) in helixes 1 and 2 are required for high affinity recognition by VP16. Strikingly, only the single position 22 (Oct-1, E22) determines the specificity that accounts for the affinity difference in the recognition of Oct-1 over Oct-2 by VP16. This selective recognition by VP16 elucidated a principle of homeobox protein interaction and specificity that has been reflected in multiple Oct-1 interactions in differential positive, negative, and inducible regulatory events. Studies addressing these contextual interactions elucidate the functions of the protein and illustrate the various diverse mechanisms used to regulate these processes:

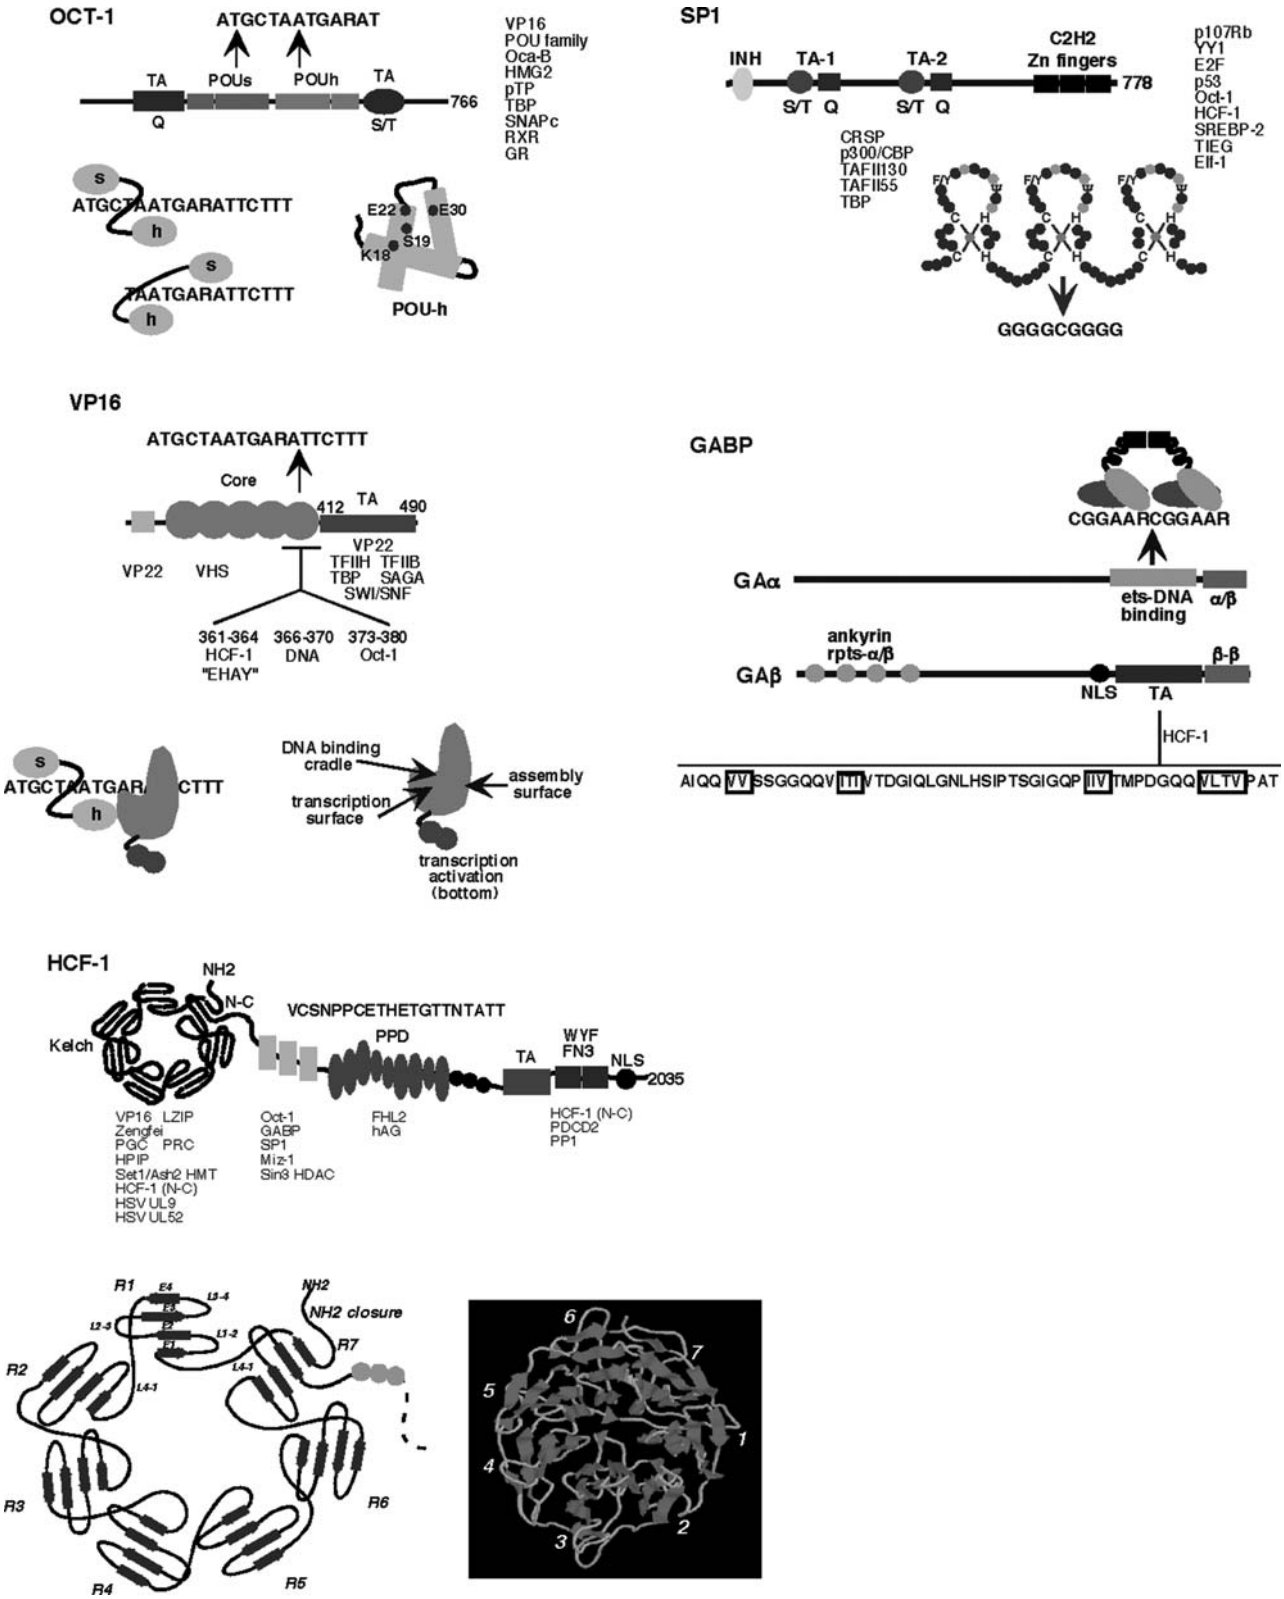

Fig. 8.2. The protein components of the HSV IE enhancer complex.
Oct-1: The transactivation (TA-Q and TA-S/T) and POU (POUs and POUh) domains are shown. The POU-specific box recognizes ATGC while the POU-homeobox recognizes TAAT within the enhancer core element (ATGCTAATGARAT). Proteins that bind to the Oct-1 POU domain are listed. The inherent flexibility of the POU domain and the potential orientations of the POUs box in recognition of the core element are depicted. In the schematic representation of the Oct-1 POU-homeobox, the residues which are important for the recognition by VP16 are indicated. (*cont.*)

(i) The stimulation of transcription preinitiation complex formation via the interaction of the Oct-1 POU domain with TBP in a non-DNA dependent manner has suggested that the interaction enhances TBP-TATA box binding by alleviating TBP autorepression, thus resulting in synergistic activation of octamer containing promoters (Mittal *et al.*, 1999; Zwilling *et al.*, 1994). Similarly, snRNA transcription is regulated via Oct-1/SNAPc interaction in which SNAPc is recruited to the snRNA proximal element via interactions that relieve SNAPc autorepression (Mittal *et al.*, 1999). The interaction of Oct-1 POU with SNAPc utilizes the same POU interaction surface as is bound by specific Oct-1 coactivators illustrating that the DNA site context is a determining factor in the selection of cofactors and coactivators (Hovde *et al.*, 2002).

(ii) Oct-1 stimulates transcription from TATA-less promoters via recruitment of TFIIB, functioning in lieu of TBP to orient the basal factor for RNAPII positioning (Phillips and Luisi, 2000).

(iii) Numerous synergistic interactions with other transcription factors also determine the roles of Oct-1 in positive, negative, and inducible regulation of gene expression. This regulation may be DNA dependent, promoter context dependent, or via DNA-independent protein-protein interactions. At the mouse mammary tumor virus (MMTV) promoter, interaction of the glucocorticoid receptor with the Oct-1 POU domain mediates glucocorticoid induction. Similarly, interaction with the androgen receptor promotes SRC-1 coactivator recruitment and transcription enhancement (Phillips and Luisi, 2000). In contrast, Oct-1 POU-homeobox interaction with the zinc finger domain of RXR disrupts the thyroid hormone receptor TR/RXR heterodimer, leading to repression of TR-dependent transcription (Gonzalez and Robins, 2001).

At the cyclin D1 promoter, interaction of CREB with the Oct-1 POU domain occurs independently of an octamer element and results in CBP coactivator recruitment in the absence of the normally responsive mechanism that depends upon CREB phosphorylation (Boulon *et al.*, 2002). Induction of GADD45 following UV-induced DNA damage is a second example of Oct-1 mediated regulation that is distinct from the defined primary p53 dependent regulatory mechanism (Jin *et al.*, 2001).

(iv) Another level of regulation is exemplified by Oct-1 interactions with cell-type or process-specific coactivators (Phillips and Luisi, 2000; Wysocka and Herr, 2003). The stimulation of immunoglobulin gene transcription by Oct-1 is mediated by binding of the B-cell specific coactivator OCA-B that interacts in a hydrophobic pocket with both subdomains of the Oct-1-POU domain. This interaction requires the Oct-1-DNA assembly, preferentially interacting with Oct-1 bound to the consensus ATGCAAAT vs. the HSV ATGCTAAT. The selection of site-specific Oct-1-DNA complexes by OCA-B is determined by binding a different surface of the Oct-1 POUs/POUh subdomains than VP16 that is positioned to the center of the consensus octamer element and includes OCA-B-DNA contacts (Babb *et al.*, 1997; Chasman *et al.*, 1999). Recent studies have identified a second process-specific coactivator, OCA-S that is involved in the S-phase, cell-cycle dependent stimulation of the histone H2B promoter by Oct-1. Strikingly, this coactivator contains the enzyme GAPDH that may link cellular metabolism to cell growth and division (Zheng *et al.*, 2003). These differential interactions illustrate the structural versatility in Oct-1 protein interactions.

(v) Oct-1 also plays a role in the stimulation of DNA replication as exemplified by the binding of the adenovirus pTP-Pol to the POU-homeobox (Coenjaerts *et al.*, 1994; Phillips and Luisi, 2000). The interaction enhances the association of the pTP-pol with the origin-binding complex. In this case, the interactions are via the DNA binding surface of the

Fig. 8.2. (*continued*) *VP16*: The structure and protein interactions of VP16 are represented. The core structure contains the clustered residues that are critical for the assembly of the IE enhancer complex (HCF-1, Oct-1, DNA) while the transactivation domain (TA, aa 412–490) interacts with a number of basal factors and chromatin modifying components. A schematic representation of the VP16 protein structure is shown (left) indicating the various protein interaction surfaces oriented in recognition of the Oct-1 POU-homeobox/ DNA complex.
HCF-1: The amino-terminal kelch, mid-aminoterminal, proteolytic processing (PPD), autocatalytic (Auto), transactivation (TA), WYF-rich, FN3 repeat, and nuclear localization signal (NLS) regions are represented. The proteins that interact with each region are listed below the appropriate domain. The PPD is represented as a series of consensus (large oval) and divergent (small oval) reiterations of the HCF-1 cleavage sequence shown above. (Bottom left) A stylized representation of the HCF-1 kelch domain is shown illustrating the seven predicted blades (antiparallel sheets, E1 through E4; loops, L1–2 through L4–1). For HCF-1, the predicted ring closure utilizes E4 from the animoterminus and E1-2-3 from the carboxyterminus of the domain (NH2 closure). (Bottom right) The derived molecular model of the HCF-1 kelch domain structure is depicted.
Sp1: The inhibitory domain (INH), transactivation domains (TA-1, TA-2), and DNA binding domains (C2H2, Zn fingers) are represented. Proteins or protein complexes that interact with Sp1 are listed. The structure of the C2H2 Zn finger domain is schematically represented: C, cysteine; H, histadine; F/Y, phenylalanine or tyrosine; y, hydrophobic residue. Light circles represent amino acids that are predicted to make DNA contacts.
GABP: The α subunit contains the ets DNA binding domain recognizing the GA box and the heterodimerization domain (α/β). The β subunit contains ankyrin repeats (α/β heterodimerization region), nuclear localization signals (NLS), transactivation domain (TA), and tetramerization sequences (β−β). The sequence of the transactivation domain is shown and the residues that are critical for both transactivation and interaction with HCF-1 are boxed. (See color plate section.)

POU-homeobox and are distinct from those of the VP16-Oct homeobox complex (de Jong *et al.*, 2002).

Clearly there are a number of distinct mechanisms by which Oct-1 may regulate the basal level expression, induction, or repression of target genes via interactions with specific sites, transcription factors, and coactivators that are mediated through the POU domain. In addition, the protein contains two transactivation domains (Fig. 8.2-Oct-1) that flank the POU domain and function in a promoter context dependent manner, suggesting that additional protein interactions at a given promoter further modulate the regulatory process (Tanaka *et al.*, 1992). The multitude of promoter targets and protein interactions and the diverse regulatory mechanisms involving Oct-1 is reflective of an innate flexibility of the protein conferred by the linker segment separating the POU subdomains (Phillips and Luisi, 2000; Wysocka and Herr, 2003). This flexibility allows for the recognition of sequences and contexts that are divergent from the consensus octamer element. As illustrated by binding to both octamer + and octamer – TAATGARAT elements, the flexibility of the Oct-1 POU domain allows for alternative configurations or positions of the POU-specific box relative to the POU-homeobox (Fig. 8.2-Oct-1). This ability allows for interaction of these domains with proteins in nonconsensus configurations. The configuration is dictated by the sequence of the DNA element and can provide distinct interfaces for various coregulators that are promoter dependent.

The activity of Oct-1 is also regulated by a number of post-transcriptional mechanisms including: (i) enhancement of DNA-binding activity following UV-induced DNA damage (Zhao *et al.*, 2000); (ii) phosphorylation by PKA, PKC, and CKII (Grenfell *et al.*, 1996); (iii) interaction with HMG2 which may function to order the DNA-binding domain for high affinity recognition (Zwilling *et al.*, 1995) and (iv) enhanced phosphorylation of Oct-1 via interaction with MAT1 cyclin dependent kinase activating kinase (Inamoto *et al.*, 1997). Similarly additional levels of regulation exist which impact the function of Oct-1 as illustrated by the modulation of the levels of the OCA-B coactivator by the ring finger protein Siah-1 (Tiedt *et al.*, 2001). The various types of interactions and levels of regulation that impinge on the function of Oct-1 will clearly have implications for the function of the protein in the stimulation of the HSV IE genes in different cellular contexts.

VP16

Vp16 (ICP25, VMW65, αTIF) is the HSV-encoded component of the enhancer core complex that determines the specificity for the HSV elements. Approximately 900 molecules of the protein are packaged within the tegument structure of a virion and are released into the cytoplasm of the cell upon infection (Roizman, 1996). The protein is transported to the nucleus and assembled into the stable enhancer core complex. VP16 is a critical component of the complex as it determines the specificity of the HSV IE core complex by direct recognition of the TAATGARAT DNA element and by selective recognition of the DNA bound Oct-1 (Figs. 8.1 and 8.2) (Kristie and Sharp, 1990; Lai *et al.*, 1992; Pomerantz *et al.*, 1992).

The 490 amino acid protein consists of a conserved structural core (aa 49–403) that contains the specificity surfaces for interaction with Oct-1, DNA, and HCF-1 (Lai and Herr, 1997; Simmen *et al.*, 1997; Wysocka and Herr, 2003) as well as a highly characterized transcription activation domain (aa 412–490) that interacts with both basal transcription factors and chromatin remodeling/nucleosome modification factors (Fig. 8.2-VP16). Surprisingly, the protein lacks a nuclear localization signal and nuclear transport is provided by protein interaction with HCF-1 (La Boissiere *et al.*, 1999). As HCF-1 is a key cell-cycle component, this interaction may play a significant role in the initial "sensing" of the cell state for viral replication.

Advances in the determination of the structure of VP16 have provided an understanding of the protein–protein and protein–DNA interactions that are critical for the protein's selective induction of the HSV IE genes. The highly structured core domain consists of internal symmetry that is dominated by two-stranded antiparallel coiled coils. The resulting structure resembles a "seat" complete with bottom, back, and headrest regions (Fig. 8.2-VP16). Interestingly, the region representing the interaction domain for Oct-1, HCF-1, and DNA (aa 350–394) is disordered in the crystal, suggesting that this domain adopts a structure upon binding these components (Babb *et al.*, 2001; Liu *et al.*, 1999). Correlation of the structure with numerous mutagenesis studies clearly indicates that there are distinct surfaces for interaction with components involved in virion assembly (right surface) vs. transcription (left surface) while the DNA recognition surface is formed by a cleft in the seat structure (Fig. 8.2-VP16, bottom right) (Babb *et al.*, 2001; Liu *et al.*, 1999). As different VP16 orthologs such as those encoded by VZV and BHV recognize different TAATGARAT elements dependent upon the 3′ sequences, the VP16 structure presents a model by which the unstructured region may also contribute to DNA binding by adopting a structure to specifically recognize the GARAT sequences while the "seat" recognizes the 3′ portion of the element. Furthermore, the DNA binding model predicts that the Oct-1 POU-specific box may lie to either side of the TAAT in the enhancer complex

(refer to Fig. 8.2 -VP16) and may modulate the VP16-DNA interaction.

The specific residues that are important for the interactions of VP16 in the IE enhancer core complex have been defined by numerous mutagenesis and peptide inhibition studies (Vogel and Kristie, 2001; Wysocka and Herr, 2003). This work elucidated a clustered core of residues for interaction with HCF-1 (E361, H362, Y364) that is now recognized as the HCF-1 interaction (D/E HXY) motif in a number of cellular proteins that interact with this coactivator protein (Freiman and Herr, 1997; Lu *et al.*, 1998; Wysocka and Herr, 2003). Mutations in residues (Y373, G374, S375) affect the VP16- Oct1 interaction while mutations in residues (R360, R366, R368, K370) affect DNA binding (Lai and Herr, 1997). Interestingly, S375 is a target for CKII-dependent phosphorylation. This residue is normally modified in cell extracts and is required for efficient complex formation, suggesting post-transcriptional modulation of the VP16 interactions required for the IE complex assembly (O'Reilly *et al.*, 1997).

The second unstructured region in the crystal determination is the transcription activation domain (TA, aa 412–490) that is located at the "bottom" of the determined structure (Liu *et al.*, 1999). The VP16 TA domain has been perhaps the most utilized tool in studies of the mechanisms involved in transcription activation. Initially, mutagenesis studies defined the TA domain and determined that this region consisted of two distinct subdomains containing important aromatic and hydrophobic residues (Regier *et al.*, 1993). The effects of substitutions at these positions also suggested that the structure of these subdomains were distinct and were likely to be involved in different stages of transcription stimulation. The unstructured nature of the domain both in solution and in the crystal determination suggests that this region also becomes structurally constrained upon protein-protein interactions (Shen *et al.*, 1996).

Many studies on the mechanisms of transcription activation have utilized the VP16 TA domain, generally in the context of a DNA binding domain fusion protein. These studies have elucidated protein interactions and general principles or mechanisms in the regulation of transcription activation. While early studies demonstrated that activators promote "open complex" formation by enhancing the formation of the RNAPII preinitiation complex and promoter assemblies; later analyses addressed the rate limiting stages, protein interactions, and stepwise activation stages that were affected by the TA domain in given promoter contexts. The data from many such studies have resulted in general models for promoter activation via multiple steps which are not necessarily strictly ordered but can be affected by activators including: activator access and binding, histone modification and chromatin remodeling, binding and assembly of the basal factor-RNAPII complexes, open complex formation, RNAPII promoter escape, RNAPII pausing, transcription elongation, coupled transcription-mRNA splicing, and transcription reinitiation (Cosma, 2002).

Studies that focus upon protein interactions of the VP16 TA domain have suggested that the unstructured domain adopts conformations upon binding specific targets. This flexibility allows for numerous conformations and sequential interactions with factors involved in different stages of promoter activation (basal factors TFIIB, TFIIH, TBP; histone modification SAGA; and chromatin remodeling SWI2/SNF2) (Gold *et al.*, 1996; Hall and Struhl, 2002; Herrmann *et al.*, 1996; Herrera and Triezenberg, 2004; Krumm *et al.*, 1995; Memedula and Belmont, 2003; Nishikawa *et al.*, 1997; Vignali *et al.*, 2000; Walker *et al.*, 1993; Xiao *et al.*, 1994; Yudkovsky *et al.*, 2000). Consistent with early studies, the two subregions of the TA domain interact with distinct factors and function in multiple steps or activation stages including: (i) the ATP-dependent chromatin remodeling and histone modifications that allow factor access and promoter targeting (SWI, SAGA, p300) as demonstrated by the ability of the TA domain to mediate large scale chromatin remodeling; (ii) the assembly of the RNAPII preinitiation complex by alleviating TBP autorepression or by direct recruitment of the protein followed by competition with TBP-basal TAFs interactions to promote enhanced activation; (iii) recruitment of TFIIB leading to RNAPII positioning and open complex formation; (iv) recruitment of TFIIH and CTD kinases that mediate RNAPII promoter escape; (v) regulation of the efficiency of the initiation complex formation that functions to increase the elongation competency of the complexes, thereby affecting the coupled mRNA splicing efficiency; and (vi) stabilization of the reinitiation scaffold (TFIID, TFIIA, TFIIE, mediator and TFIIH) via interactions with TFIIH, leading to efficient reassembly and reinitiation.

These studies have resulted in significant advances in the understanding of general transcription initiation and promoter activation and have suggested mechanisms by which the VP16 TA domain may participate in the activation of the IE gene transcription. It remains, however, to be determined exactly what the inherent rate-limiting steps are for the activation of the IE genes and what the contribution(s) of the VP16 TA domain are within this context. In addition, clearly the contributions of all of the core and ancillary factors will be affected by the interplay of the regulatory proteins and signals within a given cellular milieu.

HCF-1

The last required component for the stable assembly of the core enhancer protein complex is the cellular coactivator HCF-1. Originally identified as a required component derived from extracts of insect or mammalian cells for the formation of a stable core complex in vitro, HCF-1 was subsequently biochemically purified and the gene encoding it was cloned (Kristie *et al.*, 1989, 1995; Kristie and Sharp, 1993; Vogel *et al.*, 2001; Wilson *et al.*, 1993; Wysocka *et al.*, 2003). Interestingly, rather than a single polypeptide, the protein is actually a family of polypeptides ranging from 68–230 kD that are derived from a common precursor via site-specific proteolysis (Kristie *et al.*, 1995; Vogel and Kristie, 2000a; Wilson *et al.*, 1993). The protein is ubiquitously expressed and localized in the nucleus of all cell types with a notable exception (discussed below). Numerous studies in recent years have illuminated both the functions of the protein in HSV IE gene expression as well as its functions in basic cellular processes. The importance of both lies in the strict requirement for HCF-1 in the initiation of HSV lytic cycle as well as the importance of the protein in several basic cellular processes that may impact the viral cycle.

As shown in Fig. 8.2, multiple functional domains and protein interactions have been defined which have identified HCF-1 as a critical component of processes such as cell-cycle control, positive and negative transcription regulation, chromatin modulation, DNA replication, and mRNA splicing. Many studies have focused upon the amino terminal domain of the protein as this region is required for the formation of the HSV IE enhancer core complex as well as for cell cycle progression (Goto *et al.*, 1997; Hughes *et al.*, 1999; LaBoissiere *et al.*, 1997; Wilson *et al.*, 1997). The predicted structure of the amino-terminus of HCF-1 is based upon structural alignments to related "kelch" domain proteins (Adams *et al.*, 2000; Wilson *et al.*, 1997) and a molecular model has been derived based upon the crystal structure of galactose oxidase "kelch" domain (Fig. 8.2 -HCF-1, bottom right) (J.L. Vogel and T.M. Kristie, unpublished data). The domain model consists of seven reiterations of four antiparallel β sheets that form the blades of a propeller-type structure. The ring is closed via the E4 sheet of the aminoterminus with the E1-E2-E3 sheets at the carboxyterminus of the domain to form the 7th blade (Fig. 8.2-HCF-1, bottom left). Kelch domain proteins are involved in a broad range of functions from structural assemblies to signal transduction and the domain presents several distinct protein interaction surfaces formed by the seven L2-3 loops, the L4-1 loops, and the E4 sheets (Adams *et al.*, 2000).

As defined in numerous studies, the kelch domain mediates the high affinity interaction of HCF-1 with VP16 in the assembly of the HSV IE enhancer complex. The analysis of this interaction led to the elucidation of the HCF-1 interaction motif (D/E HXY) recognized in VP16 and subsequently determined to be a common motif found in cellular proteins that interact with the HCF-1 kelch domain (Freiman and Herr, 1997; Lu *et al.*, 1998; Simmen *et al.*, 1997). However, selective mutagenesis has suggested that distinct surfaces within the reiterated kelch structure are involved in the interactions that are mediated by this short common motif (Mahajan and Wilson, 2000). Differences between HCF-1 and the highly related HCF-2 in blades 5 and 6 encode part of the specificity for the preferential binding of VP16 to HCF-1 in a manner analogous to the discrimination between Oct-1 and Oct-2 (Johnson *et al.*, 1999). While the kelch domain is the minimal domain required for the assembly of the VP16 enhancer core complex, it is unlikely to represent the only domain involved in this assembly. Some studies have suggested that additional domains are required, perhaps to constrain or alter the positioning of the VP16 activation domain for stable assembly into the complex (La Boissiere *et al.*, 1997). Notably, multiple other cellular proteins that interact with the kelch domain have also been isolated including transcription factors (LZIP, Zhangfei) E2F1, E2F4, Krox 20 (Freiman and Herr, 1997; Knez *et al.*, 2006; Lu and Misra, 2000b; Lu *et al.*, 1997; Luciano and Wilson, 2002, 2003), transcription coactivators (PGC, PRC) (Lin *et al.*, 2002), a nuclear export protein (HPIP) that may control the nucleo-cytoplasmic pool of HCF-1 (Mahajan *et al.*, 2002), and chromatin modification components (set1/Ash HMT) (Wysocka *et al.*, 2003); suggesting that the protein is involved in numerous or global cellular transcription functions.

In its role during the initial stages of the HSV lytic cycle, the protein is described as the coordinator of the HSV IE enhancer complex assembly as it has interactions with each of the enhancer components (VP16, Oct-1, Sp1, GABP) and may orient the assembled factors for effective activation of the IE gene transcription (Vogel and Kristie, 2000b; Vogel *et al.*, 2001). The interactions may also reflect a central role in the activation of the IE transcription in response to multiple distinct regulatory signals that are mediated by the various factors involved (see below). An additional function of the protein in the regulation of the IE genes is evidenced by its activity as a mediator or coactivator of transcription via interaction with various transcription factors, chromatin modification components and other coactivators (Fig. 8.2 -HCF-1). Several lines of evidence support the proposal that HCF-1 can function as

a general coactivator and mediates transcription activation of the assembled IE complex including: (i) an activation domain in the carboxyterminus of HCF-1 functions synergistically with the VP16 TA domain and may affect a distinct rate-limiting stage (Luciano and Wilson, 2002); (ii) HCF-1 is required to mediate the transcriptional activation potential of LZIP at CRE sites (Lu *et al.*, 1997); (iii) HCF-1 interacts directly with the TA domain of GABP where mutations which affect the transactivation potential correlate directly with affects upon the GABP-HCF-1 interaction (Vogel and Kristie, 2000b); (iv) HCF-1 interacts with chromatin modifying proteins presumably to recruit these enzymes in early stages of transcription activation (Wysocka *et al.*, 2003); and (v) depletion of HCF-1 results in ablation of HSV 1E expression (Narayanan *et al.*, 2005). Significantly, HCF-1 dependent transcription events such as defined for GABP can provide a VP16-independent alternative mechanism for the induction of the HSV IE gene expression outside of the TAATGARAT element core.

In addition to its role in the direct assembly of the IE enhancer core complex, studies delineating the HCF-1 NLS (aa 2015–2035) have demonstrated that HCF-1 is required for the nuclear transport of VP16 during productive infection (La Boissiere *et al.*, 1999). These results suggest that the pool of HCF-1 that is utilized by HSV is likely to be free cytoplasmic protein and that preassociation with VP16 is a critical stage in the enhancer complex assembly. Proteins such as the nuclear export factor HPIP, which interacts with the kelch domain of HCF-1, may play a role in regulating the nucleo-cytoplasmic shuttling of the protein, can therefore have a significant regulatory impact on the availability of cytoplasmic HCF-1 for the HCF-1/VP16 interaction and transport.

HCF-1 is also a critical control component of the cell-cycle as initially demonstrated by the isolation of a ts mutant (P134S) that resulted in G0-G1 cell cycle arrest (Goto *et al.*, 1997). While the exact mechanism(s) of HCF-1 dependent cell-cycle progression remain unclear, studies indicate that the protein has multiple roles in promoting several cell-cycle stages: (i) the dissociation of ts-HCF-1 from cell chromatin at the non-permissive temperature suggests a global effect on cellular transcription (Wysocka *et al.*, 2001); (ii) the interaction of HCF-1 with the TA domain of Miz-1 results in repression of Miz-1 activation of cdk $p15^{INK4b}$ expression, potentiating cell cycle progression (Piluso *et al.*, 2002); (iii) the WYF domain (aa 1793–2005) in the carboxyterminus of HCF-1 interacts with PDCD2 which can suppress complementation of growth arrested ts-HCF-1 cells suggesting that PDCD2 may negatively regulate HCF-1 functions possibly through the association with additional transcription repression components such as NcoR (Scarr and Sharp, 2002); (iv) RNAi-mediated depletion of HCF-1 results in defects in both G_0–G_1 progression and cytokinesis/exit from mitosis which can be rescued by expression of the HCF-1 aminoterminus or carboxyterminus, respectively (Julien and Herr, 2003; and (iv) array studies have implicated HCF-1 in the expression of critical cellular proteins involved in general transcription, cell cycle progression, DNA replication-repair, and signal transduction (Khurana and Kristie, 2004). These studies collectively suggest that HCF-1 regulates cell cycle progression through its multiple roles in the regulation of gene expression. Interestingly, observations that novel HCF-1 aminoterminal polypeptides accumulate in the cytoplasm of cells arrested in G_0 may indicate that specific subdomains of the protein are localized in a regulated manner to control cell-cycle progression (Scarr *et al.*, 2000).

Located in the central region of the 230 kD HCF-1 precursor is one of the more unusual domains consisting of a series of 20 amino acid reiterations that are sites of the specific proteolytic cleavages that results in the family of HCF-1 amino and carboxyterminal polypeptides (PPD domain, Fig. 8.2 -HCF-1). However, the amino and carboxyterminal proteins do not segregate but remain tightly associated via interactions between fibronectin type II repeats in the carboxyterminus (aa 1800–2000) and the 7^{th} blade of the kelch domain (Kristie *et al.*, 1995; Kristie and Sharp, 1993; Wilson *et al.*, 2000). The processing of the protein has been determined to be autocatalytic and requires the PPD and residues carboxyterminal to this domain for efficient processing in vitro (Vogel and Kristie, 2000a). The functional role of the processing remains elusive but may represent a regulatory mechanism for controlling HCF-1-protein interactions and amino-carboxyterminal cooperativity. A novel regulatory function is proposed by the identification of a series of protein-protein interactions within the PPD in which specific reiterations encode an inherent specificity for particular protein binding partners. This model predicts that processing of HCF-1 would regulate the ability of the resulting cleavage products to interact with a specific subset of cofactors, thereby determining the activity of the particular HCF-1 cleavage product (Vogel and Kristie, 2006). Ultimately, the processing may control the protein's nuclear transport, cell-cycle functions, and/or determine its transcription activation or repression potential.

While the emphases of HCF-1 studies have been the roles of the protein in transcriptional regulation and cell cycle progression, the protein has also been implicated in mRNA splicing where it may be a general cofactor (Ajuh

et al., 2002) and in protein modification complexes (HCF-1-Protein Phosphatase 1) (Ajuh *et al.*, 2000) where it may regulate the activity of the phosphatase or determine it's targets. In addition, HCF-1 may play roles in the later stages of HSV lytic replication as suggested by the interaction of the kelch domain with HSV DNA replication proteins (Peng M.L., Nogu eira, and T.M. Kristie 2006, unpublished data).

Clearly HCF represents one of the more complex components of the HSV IE regulatory assembly and has diverse and essential cellular functions. This protein may also be the component that is most critical for viral IE expression suggesting that the evolution of the virus to usurp the functions of this factor has more implications for the regulation of the HSV lytic cycle than is initially readily apparent.

Ancillary factors: Sp1 and GABP

In addition to the enhancer core complex, each IE regulatory domain contains a number of binding sites for cellular transcription factors such as Sp1 and GABP. The expression of the IE genes, even in the absence of VP16, attests to the significance of these components. However, the potential of these elements are dependent upon and enhanced by the presence of the assembled IE enhancer core complex, reflecting an interdependence of the elements.

Sp1

Sp1 is a member of the Zn finger/krupple family and was the first transcription factor to be purified and cloned (Black *et al.*, 2001; Kaczynski *et al.*, 2003; Suske, 1999). The protein recognizes the element GGGCGG (GC box) that is present in multiple copies in the HSV IE regulatory domains (Fig. 8.1) and has been determined to contribute to the basal expression level (Jones and Tjian, 1985). Originally considered to be a ubiquitously expressed, housekeeping factor, the protein is now known to be a member of a large family of related proteins that are subject to and involved in distinct regulatory pathways. Sp1 through Sp6 are highly related proteins which all interact with the GC element although there is some variability in specific binding affinity.

Sp1 is a 778 amino acid protein consisting of a three C2H2 Zn-finger DNA binding domain (C-X_{2-5} C-X_3-(F/Y)-X_5-ψ-X_2-H-X_{3-5}-H) located in the carboxyterminus with an embedded nuclear localization signal (NLS, Fig. 8.2-Sp1). Models that predict the DNA binding contacts are based upon similar structures and suggest that key residues in the various Sp family members determine the specificity for the GC box (Kaczynski *et al.*, 2003). The protein also contains two TA domains [(S/T) and Q-rich] that function in a promoter-dependent context, conceptually similar to those in Oct-1 (Black *et al.*, 2001; Suske, 1999).

Sp1 interacts with a number of known transcription activators (e.g., Oct-1), transcription coactivators (e.g., HCF-1, p300/CBP), and basal transcription factors (e.g., TBP)(Gunther *et al.*, 2000; Kaczynski *et al.*, 2003; Suske, 1999). In a manner analogous to Oct-1, the protein interactions and functional significance can largely be determined by the promoter context. Most significantly, the accumulating data illustrates that this family of proteins is subject to several regulatory signals and pathways in which specific GC boxes mediate responses to particular stimuli via binding proteins involved in those pathways. In addition, the particular regulatory response of a given GC box can also vary depending upon the particular cell context. These proteins interact with factors such as Rb-p107, p53, E2F, and Oct-1 and respond to signals as diverse as growth stimuli, NGF, TGFb, hormones, DNA damage, and apoptosis (Black *et al.*, 2001; Gunther *et al.*, 2000; Kaczynski *et al.*, 2003; Ryu *et al.*, 2003; Suske, 1999; Yan and Ziff, 1997). An additional level of regulation is provided by varying levels of the Sp family within a given cell type and under specific response conditions. As Sp1 and Sp3 are expressed in the same cell types, bind with equal affinity to the GC box, and have distinct functions; the ratio of the proteins can determine the activation vs. repression of given target genes. This regulatory mechanism is exemplified by alterations in the ratios of these proteins during cell differentiation or specific signaling pathways (Black *et al.*, 2001; Gunther *et al.*, 2000; Kaczynski *et al.*, 2003; Suske, 1999). The activation and repression functions of the Sp family are hypothesized to be mediated via interactions with HAT or HDAC complexes, respectively.

Finally, as expected by the involvement of these proteins in response to environmental signals, modifications of the factors also modulate that activity of the family. For example, acetylation of Sp1 in response to neuronal oxidative stress plays a role in neuronal survival pathways (Ryu *et al.*, 2003). In an HSV infection, phosphorylation of Sp1 later in infection decreases the protein's TA potential and may contribute to the down regulation of the IE gene expression (Kim and DeLuca, 2002).

GABP

GA rich sequences adjacent to at least one TAATGARAT element in each of the HSV IE regulatory domains were originally identified in mutagenesis studies and reporter assays where these elements contributed to the VP16-dependent induction of IE expression (Triezenberg *et al.*, 1988). In vitro transcription assays further demonstrated the

significance of the elements for VP16-mediated transcription and suggested that the sites functioned synergistically with the enhancer core (Wu *et al.*, 1994).

The factors binding to these elements (GABP) are related to the ets and notch protein families and consist of an α-subunit containing a carboxyterminal ets DNA binding domain and a β subunit containing the TA domain, NLS, and series of ankyrin repeats that mediate dimerization with the α subunit as well as contributes to DNA binding (Fig. 8.2-GABP) (LaMarco *et al.*, 1991; Thompson *et al.*, 1991). The proteins also form tetrameric structures via carboxyterminal sequences in the β subunits forming helical intertwined coiled coils (de la Brousse *et al.*, 1994). In the β-subunit, the TA domain consists of a series of hydrophobic clusters which are critical for the TA potential (Gugneja *et al.*, 1996; Gugneja *et al.*, 1995). These regions correlate with the ability of the domain to interact with the enhancer core coactivator HCF-1, indicating that HCF-1 mediates the activation potential of the factor (Vogel and Kristie, 2000b).

The focus of many GABP studies has been in elucidating the role of the protein in the activation of nuclear encoded mitochondrial respiration component and assembly genes (Puigserver and Spiegelman, 2003; Scarpulla, 2002). These studies have delineated multiple levels of regulation and have indicated that an important mechanism for regulation of these factors is via regulation of the coactivators which respond to a variety of stimuli resulting in phosphorylation, induction, activation, and stabilization of these coactivators. The coactivators subsequently recruit additional cofactors, coactivators, and histone modification complexes. Two coactivators have been intensely studied in this context: PRC that mediates activation in proliferative responses and PGC that mediates thermogenic effector responses (Scarpulla, 2002). Interestingly, PGC has not been shown to directly interact and modulate GABP activity but may, in fact, do so via its interaction with the kelch domain of HCF-1 (Fig. 8.2-HCF-1). The activity of GABP and its cofactors are modulated by several signaling pathways such as p38 MAPK. For PGC, p38 mediated phosphorylation results in stabilization of the cofactor (Puigserver and Spiegelman, 2003). The phosphorylated PGC is also involved in direct induction of the expression of GABP.

Numerous regulatory response pathways are mediated by GABP including (i) induction of neuregulin expression (Fromm and Burden, 1998); (ii) insulin dependent prolactin gene expression via MAP pathway phosphorylation of GABP (Ouyang *et al.*, 1996); (iii) TPA stimulated IL2 induction which is mediated via JNK activation of GABP (Hoffmeyer *et al.*, 1998); (iv) the HIV LTR induction mediated via Raf-1 kinase activation of GABP (Flory *et al.*, 1996) and (v) the MMTV LTR which is synergistically activated by GABP in the presence of glucocorticoids (Aurrekoetxea-Hernandez and Buetti, 2000). The protein is also involved in numerous regulatory events by synergistic interactions with other transcription factors such as Sp1 and the cAMP responsive proteins CREB and ATF (Bannert *et al.*, 1999; Sawada *et al.*, 1999).

VZV IE gene expression: parallels and divergence

This review has focused on the regulation of HSV IE genes as a representative model of the mechanisms involved in the IE expression of an alpha herpesvirus due to the focus of studies in this area. In contrast, little has been elucidated concerning the mechanisms involved in the regulation of VZV IE gene expression. What has been determined, however, shows striking parallels to the HSV model. In VZV, the expression of the IE gene (IE62) is controlled by an enhancer domain (Fig. 8.3) consisting of multiple defined elements (Bannert *et al.*, 1999; McKee and Preston, 1991; Moriuchi *et al.*, 1995; Sawada *et al.*, 1999).

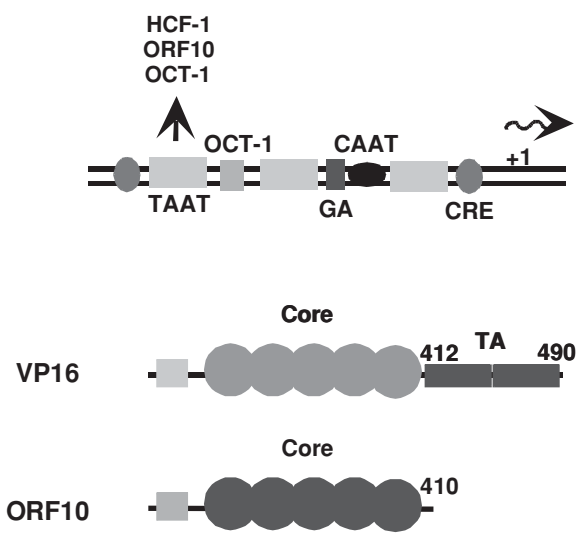

Fig. 8.3. The VZV IE62 regulatory domain. (Top) The arrangement of elements that have been delineated in the VZV IE62 regulatory region are indicated (TAAT, enhancer core element TAATGARAT; Oct, Octamer element; GA, GABP binding site; CAAT, CAT box; CRE, c-AMP responsive element). The assembly of the components HCF-1, Oct-1, and the VZV VP16 ortholog ORF-10 on the TAAT element is indicated. (Bottom) Comparison of the domain structure of HSV VP16 and VZV ORF-10 illustrates conservation of the aminoterminus and core domain and the absence of an ORF-10 transactivation domain.

Similar to HSV, the domain contains reiterations of a TAATGARAT element that is important for induction via the VZV virion component ORF10, the ortholog of the HSV VP16 (Moriuchi *et al.*, 1995). Additional elements include a GABP binding site and c-AMP responsive sites (CRE) that also contribute to the ORF10-mediated stimulation of the IE62 gene expression. As has been demonstrated for HSV, the VZV IE62 TAATGARAT elements can nucleate the assembly of enhancer core complexes that contain Oct-1 and HCF-1 in concert with the ORF10 protein (Moriuchi *et al.*, 1995).

The VZV ORF10 transactivator, while sharing significant homology to VP16, exhibits a striking difference that impacts the regulatory process. In contrast to VP16, ORF10 does not contain a transactivation domain, indicating that the interaction of the protein with other factors and coactivator components (e.g., Oct-1, HCF-1) must provide this function. A second significant difference between the regulatory mechanisms involved in the induction of HSV IE and the VZV IE genes is the autoregulatory response mediated by the major IE gene products (Perera *et al.*, 1992). In HSV, α4/ICP4 functions to down regulate the IE genes in the transition from IE to E gene expression (Roizman, 1996). In VZV, IE62 functions to induce or enhance its own transcription. Interestingly, IE62 is also a component of the virion tegument structure (Kinchington *et al.*, 1992) and may be a significant component of the IE induction response, thus compensating for the lack of the transactivation potential of the ORF10 activator. However, despite minor variations, data on the regulation of the VZV IE62 gene closely parallels the components and mechanisms defined in the regulation of HSV IE genes.

Regulation of the IE genes: multiple levels and response potentials

Studies on the regulation of the IE genes and the various components involved have led to advances in the understanding of enhancer complexes, ordered assembly processes, protein surfaces and interactions, mechanisms of transcriptional activation, and orders of interplay regulation. In addition to the modulation of DNA site recognition, the various transcription factors themselves are subject to modifications, alterations in turnover rates, subcellular localization, and signaling response pathways. Transcription factor synergy (activation or repression) is also dependent upon the cellular milieu and the balance of factors including the availability, competition, activator/repressor ratios, and cell-specific cofactors and coactivators. Additional higher orders of regulation are dependent upon the regulation of the coactivator levels, interactions, and functions. The ability and efficiency of the various assembled complexes to circumvent or alter rate limiting stages in the transcriptional assembly, initiation, elongation, and reinitiation is also likely to depend upon the cell type and state as the consequences of chromatin/nucleosomal structure, available factors, and signal environment will impinge upon a given rate limiting stage and determine the requirements for efficient transcription.

Most strikingly, the complex interactions of the components involved in the regulation of the IE enhancer complexes (e.g., Oct-1, Sp1, GABP, HCF-1) and the ability of these components to respond differentially to multiple environmental signals point to the evolution of the IE regulatory domains to respond to diverse signals.

The regulation of the IE genes: reactivation of HSV from the latent state

The components expressed in specific cell types may impact the normal lytic cycle regulation as suggested by the low levels of Oct-1 expression in sensory neurons. In this situation, other POU proteins such as Oct-2 or members of the Brn family may play a role in suppression or inefficient activation of the IE gene (Brownlees *et al.*, 1999; Latchman, 1996; Latchman, 1999; Lillycrop *et al.*, 1994). For the Brn family, Brn3a functions as an activator while Brn3b functions as a transcriptional repressor and the relative levels of these proteins change upon differentiation or neuronal stimulation (Latchman, 1999). Similarly, the levels of Sp1/Sp3 provide potential for repressor assemblies that may play a role in modulating IE expression in neuronal cells.

The potential of the IE gene domains to respond to diverse environmental stimuli suggests that these domains may respond to latency-reactivation stimuli by targeting distinct elements or components. Significantly, each of the identified IE regulatory factors is commonly linked by its interaction with the HCF-1 coactivator. Therefore, while distinct signals and factors may respond to distinct stimuli, the critical response component may be represented by the common coactivator. Interestingly, HCF-1 itself is uniquely sequestered in the cytoplasm of sensory neurons and is rapidly transported to the nucleus in response to reactivation signals (Fig. 8.4, Top) (Kristie *et al.*, 1999). This regulated transport may well reflect an important element of the activation of the IE genes during the reactivation process. Furthermore, this provides a mechanism for the induction of the IE gene expression in response to signaling events in a VP16-independent manner, utilizing com-

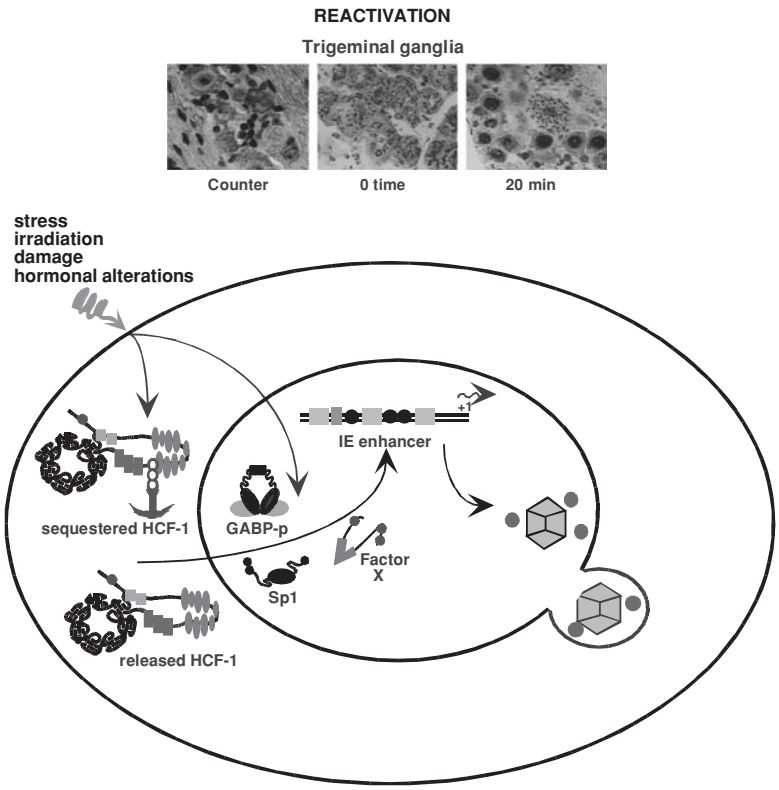

Fig. 8.4. Model of the induction of the IE genes during HSV reactivation from latency. (Top) Immunohistochemistry studies of HCF-1 demonstrate that the protein is specifically sequestered in the cytoplasm of sensory neurons (0 time, middle panel) and rapidly transported to the nucleus under experimental conditions that reactivate HSV from latency (explant reactivation stimuli, right panel). (Bottom) Schematic depiction of the activation of IE enhancer components during the initiation of reactivation. Environmental signal(s) result in the release of cytoplasmically sequestered HCF-1 and the activation of DNA binding factors such as GABP, Sp1, or other factors which function in concert with HCF-1 to activate the IE genes and initiate the viral lytic cycle. (See color plate section.)

plexes such as GABP-HCF-1 and Sp1-HCF-1. In support of these potential mechanisms, studies in Oct-1 knockout cells have demonstrated that the protein is important but not essential for IE expression, thereby suggesting that alternative complexes and factors can initiate the cycle (Nogueira *et al.*, 2004). In contrast, IE expression is not detected in cells depleted of HCF-1 (Narayanan *et al.*, 2005). As proposed in Fig. 8.4, Sp1 and or GABP may be involved in the activation of the IE genes during the reactivation process. However, other factors may be involved as suggested by the activation of ICP0 transcription via L-ZIP. L-ZIP, like HCF-1 exhibits a cytoplasmic sequestering and may also respond to signals that result in reactivation (Lu and Misra, 2000a). It is interesting to speculate that multiple reactivation pathways are possible utilizing distinct subsets of factors that respond to distinct signals.

Questions and future directions

Much has been learned in recent years and as is often the case, new information leads to many new questions and directions. Future studies certainly will extend the work established by the identification of the critical components of the HSV IE transcription complexes. Continuing assessment of the functions of these components in chromatin modulation, alteration of rate limiting stages and transcriptional mechanisms will provide additional basic process information. Determination of the regulation of each component within varying cellular contexts as well as the development of genetic animal models can delineate the response and impact of the factors subject to various signal pathways and stimuli. Protein modifications, localization dynamics, regulation of turnover, and the relationship of the components within a given context are key

areas for the determination of the components which may play central roles in the HSV lytic, latent, and reactivation processes.

Acknowledgments

We thank J. Vogel, M. Nogueria, and A. McBride for their critical reading of this manuscript. We thank all of the laboratories who have made such significant contributions to the field and regret that all primary references could not be included in this section.

Initiation of transcription and RNA synthesis, processing and transport in HSV and VZV infected cells

Rozanne M. Sandri-Goldin

Department of Microbiology & Molecular Genetics University of California, Irvine, CA, USA

Initiation of transcription and RNA synthesis

The alphaherpesviruses, HSV-1 and VZV encode TATA-box containing promoters that are transcribed by the cellular RNA polymerase II

During productive infection by herpes simplex virus type 1 (HSV-1), approximately 80 genes encoded within the linear 152-kbp viral genome are expressed in three sequential phases that are termed immediate early (IE; α), early (E; β) and late (L; γ) (Honess and Roizman, 1974; McGeoch, 1991). The smaller, 125-kbp varicella zoster virus (VZV) genome encodes around 70 genes, which are also expressed as IE, E and L products (Davison and Scott, 1986). HSV-1 and VZV genes are transcribed by the cellular RNA Polymerase II and each viral promoter has a TATA box homology about 25 nucleotides upstream of the start site of transcription (for review, see Wagner *et al.*, 1995). In HSV-1infections, the first genes to be transcribed are the five IE genes, which are distinguished from E and L genes by specific sequence elements termed TAATGARAT sequences in the upstream regions of IE promoters. These elements are recognized by a virion tegument protein, VP16, which binds as part of a protein complex that contains two cellular factors, Oct-1 and HCF, to transcriptionally activate expression of IE genes (Wysocka and Herr, 2003). VZV IE genes do not appear to encode upstream promoter elements similar to the TAATGARAT sequence, however VZV does encode a protein, ORF10 that exhibits similarities with VP16, although its activity has been much less well characterized than that of VP16 (Piette *et al.*, 1995).

HSV-1 E promoters, unlike the IE promoters, do not contain VP16-responsive sequence elements, however they do contain a number of *cis*-acting elements upstream of the TATA box that have been shown to bind cellular transcriptional activators, including Sp1 (Kim and DeLuca, 2002; Wagner *et al.*, 1995). In contrast, HSV-1 late promoters lack upstream *cis*-acting sequence elements, and instead the region downstream of the TATA box has been shown to play an important role in regulating the expression of several late genes (Guzowski and Wagner, 1993; Kim *et al.*, 2002; Pederson *et al.*, 1992). The architecture of VZV promoters appears similar to that of HSV-1 promoters, however, binding sites for the cellular transcription factors Sp1 and USF have been found in a large number of potential promoters for VZV genes from all three kinetic classes (Ruyechan *et al.*, 2003).

Viral factors required for the initiation of transcription on HSV-1 and VZV promoters

Like HSV-1 IE genes, which are activated by VP16, the E and L genes also require a virally-encoded transcription factor to induce expression. The factor that is required is one of the IE proteins, termed infected cell polypeptide 4 (ICP4). ICP4 is a nuclear phosphoprotein that acts as a homodimer to activate or repress transcription depending upon the promoter (Shepard *et al.*, 1990). ICP4 is absolutely required for abundant expression of all E and L gene products, and thus it is essential for productive infection (DeLuca *et al.*, 1985). In the absence of functional ICP4, not only are early genes poorly expressed, but some IE genes are overexpressed. The overexpression of IE genes in the absence of functional ICP4 reflects the ability of ICP4 to repress transcription from its own promoter in an autoregulatory fashion, as well as from other IE promoters (Gu *et al.*, 1995; Leopardi *et al.*, 1995). Genetic and biochemical studies have shown that ICP4 binds to DNA. ICP4 represses transcription from specific viral promoters that have a high-affinity ICP4 binding site spanning the transcription initiation site, and it does so by interacting with the basal transcription

factors TATA-binding protein (TBP) and TFIIB (Faber and Wilcox, 1988; Gu *et al.*, 1995; Leopardi *et al.*, 1995). ICP4 also stimulates transcription from early and late viral promoters through interactions with viral DNA and cellular basal transcription factors. However, despite extensive analyses, specific sequences that bind ICP4 with high affinity that are common to all promoters activated by ICP4 have not been uncovered, although the ICP4 DNA binding domain is essential for activation of transcription (Shepard *et al.*, 1989; Smiley *et al.*, 1992). The minimal *cis*-acting elements required for stimulation of transcription by ICP4 are a TATA box and in some late promoters, an initiator element (Cook *et al.*, 1995; Kim *et al.*, 2002). ICP4 facilitates formation of the preinitiation complex through interactions with one or more components of the cellular transcription machinery. ICP4 forms a tripartite complex with TFIIB and TBP on DNA, enhancing the binding of TFIID to DNA (Grondin and DeLuca, 2000). ICP4 also interacts with TBP-associated factor 250 (TAF250), and promotes the formation of transcription preinitiation complexes on promoters (Carrozza and DeLuca, 1996).

A number of genetic and biochemical analyses have been conducted to determine which of the observed interactions between ICP4, viral DNA, and cellular proteins are relevant to the function of ICP4 as an activator. ICP4 is comprised of 1,298 amino acids. It has been found that ICP4 residues 1 to 315 function as a transactivation domain (Xiao *et al.*, 1997); further, this region binds to the cellular EAP protein (EBV EBER-associated protein) (Leopardi *et al.*, 1997), and is required for formation of a complex with DNA that contains TBP and TFIIB (Smith *et al.*, 1993). ICP4 amino acids 316 to 490 are necessary for homodimerization (Everett *et al.*, 1991a; Gallinari *et al.*, 1994) and DNA binding (Everett *et al.*, 1990; Kristie and Roizman, 1986; Wu and Wilcox, 1990), whereas residues 491 to 796 encompass a nuclear localization signal (Paterson and Everett, 1988). ICP4 residues 797 to 1298 are involved in the interaction with TAF250 (Carrozza and DeLuca, 1996; Yao and Schaffer, 1994), and with the HSV-1 IE proteins ICP0 (Yao and Schaffer, 1994), and ICP27 (Panagiotidis *et al.*, 1997), and are required for efficient transcriptional activation (Bruce and Wilcox, 2002; DeLuca and Schaffer, 1988; Paterson and Everett, 1988). ICP4 is highly phosphorylated during infection by at least three cellular kinases, Protein Kinase A (PKA), PKC and cdc2 (Advani *et al.*, 2001; Xia *et al.*, 1996a,b), however the specific role of phosphorylation in regulating the transcriptional activities of ICP4 has not been fully elucidated.

The homologue of ICP4 in VZV is termed IE62 and is encoded by the duplicated genes ORF62 and ORF71, which map to the internal repeats (Piette *et al.*, 1995). IE62 has been shown to induce transcription of all classes of VZV genes, although it has only been recently demonstrated by genetic analysis that IE62 is essential for VZV infection (Sato *et al.*, 2003). IE62 is to a large extent functionally conserved with HSV-1 ICP4, and in fact ICP4 mutants can be complemented by IE62 (Felser *et al.*, 1988). However, there are several important differences. A substantial amount of IE62 is found in the virion tegument (Kinchington *et al.*, 1992), and this appears to require phosphorylation by a VZV encoded protein kinase, ORF 66, which is required for the cytoplasmic localization of IE62 late in infection and the subsequent incorporation of IE62 into virions (Kinchington *et al.*, 2001). Another VZV encoded kinase, ORF 47, which is also a component of the virion, interacts with IE62 and disrupting either the kinase function of ORF47 or its ability to bind to IE62 blocked infectivity of VZV in vivo (Besser *et al.*, 2003). Further, IE62 encodes a potent acidic activation domain in the N-terminus, which is similar to the acidic activation domain of VP16 (Perera *et al.*, 1993). Thus, IE62 also bears some similarity to the HSV-1 transactivator VP16, which is also a component of the virion tegument. Like ICP4, IE62 has been found to interact with other VZV IE proteins. IE62 interacts with IE63 (Lynch *et al.*, 2002), the VZV homologue of HSV-1 ICP22, and with IE4 (Spengler *et al.*, 2000), the homologue of ICP27. The functional importance of these interactions for transcriptional activation of VZV genes during infection remains poorly understood. It has been demonstrated that, in the context of a minimal promoter, a TATA element is sufficient and essential for IE62 activation of transcription, and like its HSV-1 counterpart, IE62 also binds the basal transcription factors TBP and TFIIB in vitro (Perera, 2000). However, upstream binding sites for the cellular transcription factors USF and Sp1 have also been found to be important for the regulation of a number of VZV genes and numerous Sp1 and USF sites have been identified in VZV promoters from all kinetic classes (Ruyechan *et al.*, 2003). USF is a basic-helix-loop-helix-leucine zipper (bHLH-zip) transcription factor that was shown to cooperate with IE62 in the regulation of an early bidirectional promoter driving both the DNA polymerase and DNA-binding protein genes (Meier *et al.*, 1994), and in the regulation of the IE promoter driving IE4 (Michael *et al.*, 1998). Sp1 sites were reported to be important for the regulation of the gE and gI genes (He *et al.*, 2001; Rahaus and Wolff, 2000), and IE62 has been shown to interact with Sp1 in vitro and in vivo (Peng *et al.*, 2003).

Viral IE proteins that contribute to the induced expression of viral genes

In addition to ICP4, HSV-1 encodes three other IE proteins that have regulatory functions. ICP0, a 775 amino acid

nuclear phosphoprotein was first described as a promiscuous transactivator in transient transfection studies because it can transactivate HSV-1 IE, E and L promoters as well as heterologous promoters (for a review, see Everett, 2000). Activation of gene expression by ICP0 was shown to occur at the level of mRNA synthesis (Jordan and Schaffer, 1997). ICP0 does not bind DNA directly (Everett *et al.*, 1991b), and therefore is likely to activate gene expression through interactions with proteins. A large number of interactions have in fact been reported. ICP0 was found to interact with a ubiquitin specific protease, USP7 (Everett *et al.*, 1997), cyclin D3 (Van Sant *et al.*, 1999), elongation factor EF-1δ (Kawaguchi *et al.*, 1997), transcription factor BMAL1 (Kawaguchi *et al.*, 2001), and the HSV-1 transactivator ICP4 (Yao and Schaffer, 1994). ICP0 has also been shown to activate cdk4 and to stabilize cyclins D1 and D3 (Van Sant *et al.*, 2001). However, the mechanism by which ICP0 activates gene expression remains obscure. A major biological activity of ICP0 is the disruption of nuclear structures, termed ND10 or promyelocytic leukemia (PML) bodies. ICP0 encodes two E3 ubiquitin ligase domains, one of which is specified by a RING-finger motif also found in other U3 ubiquitin ligases (Boutell *et al.*, 2002; Hagglund *et al.*, 2002; Hagglund and Roizman, 2002). ICP0 has been linked to the proteasome-dependent degradation of several proteins including the catalytic subunit of DNA protein kinase (Parkinson *et al.*, 1999), the centromere proteins CENP-C and CENP-A (Lomonte *et al.*, 2001), and two components of ND10, PML and Sp100 (Everett *et al.*, 1998a). Because the proteasome inhibitor MG132 interferes with the ability of ICP0 to stimulate viral infection (Everett *et al.*, 1998b), and mutations in the RING finger correlate with ICP0's ability to transactivate (Everett *et al.*, 1991c), it has been thought the destruction of ND10 by ICP0 is an integral event in viral replication. This is supported by evidence from other viruses that also disrupt ND10 structures (reviewed in (Everett, 2001)). However, it has been shown recently that overexpression of PML protein precludes the dispersal of ND10 structures and yet there was no effect on HSV-1 replication (Lopez *et al.*, 2002). Therefore, the mechanism(s) by which ICP0 acts to contribute to virus expression during lytic infection remains to be elucidated.

VZV also encodes a RING-finger protein termed IE61. The N-terminal RING finger domain is the only obvious similarity to ICP0. IE61 does not contain a USP7 binding domain and does not affect the distribution of USP7 (Parkinson and Everett, 2000). IE61 does induce colocalizing conjugated ubiquitin, suggesting that it may also act as an ubiquitin ligase (Parkinson and Everett, 2001). Little else has been reported on the activity of VZV IE 61.

Another HSV-1 IE protein that has been implicated in the regulation of viral IE and L gene expression is ICP22. ICP22 is not essential for virus infection in cultured cells, and mutants grow as well as wild-type virus in Vero and HEp-2 cells, but ICP22 mutants do exhibit a host range and replicate much less efficiently in primary human, rabbit and rodent cells. In these latter cells the expression of a subset of late genes is greatly reduced (Ogle and Roizman, 1999). Further, phosphorylation of ICP22 by an HSV-1 encoded kinase, UL13, is required for the accumulation of a subset of both IE and L genes in primary human, rodent and rabbit cells (Purves *et al.*, 1993) and this appears to be mediated by the activation of the cdc2 cyclin-dependent kinase (Advani *et al.*, 2000). A possible mechanism for the requirement for ICP22 and UL13 for appropriate expression of L transcripts is the intriguing finding that ICP22 and UL13 are both required for an HSV-1 induced modification of RNA polymerase II (Long *et al.*, 1999). Specifically, infection with HSV-1 results in the depletion of both the hypo- and hyperphosphorylated forms of RNA polymerase II, known as the IIa and IIo forms, which represent the initiating and elongating forms of RNA polymerase II. Instead, early in HSV-1 infection, an intermediately phosphorylated form appears (Rice *et al.*, 1995). Infection of human primary embryonic lungs cells with mutants defective in ICP22 or UL13 led to significantly reduced viral gene transcription at late times after infection (Long *et al.*, 1999). These results suggest that the modification in the phosphorylation of RNA polymerase by ICP22 and UL13 promotes HSV-1 transcription over transcription of cellular genes. However, despite the attractiveness of this model, there are findings that cannot be explained solely by the modification of the phosphorylation of RNA polymerase II. First, ICP22 is not required for L gene expression in many cell lines, and the modification of RNA polymerase II to the intermediate form is not seen in infections with ICP22 or UL13 mutants. Thus, this modification is not absolutely required for transcription of HSV-1 genes. Second, RNA polymerase II is still recruited to viral transcription/replication compartments, whether or not it is modified, thus altered phosphorylation is not a prerequisite for its nuclear relocalization (Rice *et al.*, 1995). Third, an additional change to the RNA polymerase II holoenzyme was reported that depends on HSV-1 IE proteins, but not specifically on ICP22. That is, the loss of the general transcription factor TFIIE from the holoenzyme was found to require HSV-1 IE proteins, which may be redundant because no single IE deletion mutant eliminated this change (Jenkins and Spencer, 2001). TFIIE is necessary for activated transcription initiation in uninfected cells, and thus the loss of this general transcription factor from the complex may result in the repression of

transcription of cellular genes that has been reported following HSV-1 infection (Spencer *et al.*, 1997).

It has been shown recently that the phosphoserine-2 form of the RNA polymerase C-terminal terminal domain, which is found in elongating transcription complexes, is decreased during HSV-1 infection (Fraser and Rice, 2005; Dai-Ju *et al.*, 2006). Furthermore, total levels of RNA polymerase were decreased indicating that this was due to a loss of protein, indicating protein degradation rather than dephosphorylation, and proteasome inhibitors prevented the degradation (Dai-Ju *et al.*, 2006). The degradation appeared to be due to robust HSV-1 transcription because in infections with viral mutants in which viral transcription was greatly reduced, or in which viral transcription was blocked by inhibitors, degradation was prevented. By contrast preventing the degradation of the elongating serine-2 phosphorylated RNA polymerase II decreased late viral gene expression and viral yields (Dai-Ju *et al.*, 2006). These findings suggest that during periods of robust viral transcription in HSV-1 infected cells, elongating polymerase complexes may become arrested or stalled because of a pile-up of transcribing complexes on families of colinear transcripts, or because of collisions of transcribing complexes on opposite strands that are being transcribed at the same time. Resolution of these stalled complexes by proteasomal degradation may thus be required to allow transcription to resume and proceed through the gene.

Interestingly, the VZV homologue of ICP22, termed IE63 has been shown to be essential for VZV infection (Sommer *et al.*, 2001), although it does not appear to play a major role in gene regulation on its own. IE63 was reported to be able to repress two VZV promoters in an activity assay and this repression was regulated by phosphorylation by two cellular casein kinases (Bontems *et al.*, 2002b). However, in another report, IE63 was found to have no transcriptional activating or repressing activity within the context of a minimal VZV glycoprotein promoter, however, the presence of IE63 upregulated IE62 transactivation of the promoter (Lynch *et al.*, 2002). Further, IE63 protein was shown to interact with IE62 through the N-terminal 142 amino acids, and a portion of the IE63 and IE62 proteins colocalized in VZV-infected cells (Lynch *et al.*, 2002). IE63 is phosphorylated in infected cells and can be phosphorylated in vitro by casein kinase II (Bontems *et al.*, 2002a; Stevenson *et al.*, 1996). Further, IE63 has been found to be heavily phosphorylated by, and tightly bound to, the VZV ORF47 kinase (Kenyon *et al.*, 2003), a homologue of HSV-1 UL13, which phosphorylates ICP22. Intriguingly, IE63 protein can be coimmunoprecipitated with the cellular RNA polymerase II from infected cell extracts, indicating that it is present in a complex with that enzyme (Lynch *et al.*, 2002). It has not been demonstrated whether or not the IE63-ORF47 complex can alter the phosphorylation of RNA polymerase II in VZV-infected cells. See Fig. 9.1.

RNA processing and transport

Following synthesis of transcripts in eukaryotic cells, the nascent pre-mRNAs are processed by capping at the 5′ end, cleavage and polyadenylation to form the 3′ end, and splicing to remove intervening sequences. After processing, mRNAs must be exported through the nuclear pore complex to the cytoplasm for translation. Export of mRNAs requires binding by RNA export adaptor proteins, recognition by export factors and translocation through the nuclear pore complex (NPC). Three classes of factors appear to be required for mRNA export: adaptor proteins that bind directly to the mRNA, receptor proteins that recognize and bind to adaptor proteins, and nuclear pore complex components termed nucleoporins that mediate export across the nuclear membrane (for review see (Komeili and O'Shea, 2001; Zenklusen and Stutz, 2001). In metazoan cells, the processing events occur co-transcriptionally because the processing factors are recruited to the sites on the nascent transcripts where their activities are required by binding to the highly conserved C-terminal domain (CTD) of RNA polymerase II (for review see Reed, 2003). In addition, RNA export is closely coupled to splicing (Luo and Reed, 1999). This occurs because a complex of proteins that includes one or more export adaptor proteins binds to the pre-mRNA at a specific site just upstream of what will become exon–exon junctions in the spliced product. This so-called exon junction complex or EJC remains bound to the spliced RNA and escorts the mRNA to the cellular mRNA export receptor, termed TAP or NXF1, with which the export adaptor proteins interact directly. The mRNP complex is then exported through the nuclear pore (for review see Reed and Magni, 2001).

In HSV-1 infected cells, viral transcripts are processed by 5′ capping and 3′ end formation by the cellular machinery. However, it has been reported that some polyadenylation sites present primarily on late transcripts are utilized inefficiently by cellular polyadenylation factors and these sites were operationally defined as weak. The activity of an HSV-1 IE protein, ICP27 stimulated the use of these sites in vitro (McLauchlan *et al.*, 1992). Further analysis suggested that ICP27 recruits the cleavage stimulation factor, Cst64, which is required for poly(A) site recognition, to weak HSV-1 poly(A) sites (McGregor *et al.*, 1996). However, a study investigating differential polyadenylation of two transcripts that arise from the UL24 gene by the use

of two different poly(A) sites, one weak and one strong, found that the accumulation of transcripts during infection from the weak poly(A) site did not require ICP27 (Hann *et al.*, 1998). In addition, a recent study using various HSV-1 gC gene plasmid constructs showed that the stimulatory effect of ICP27 occurred post-transcriptionally but was independent of the inserted polyadenylation site (Perkins *et al.*, 2003). Thus, the role of ICP27 in enhancing the use of weak poly(A) sites has not been firmly established.

The role of ICP27 in another RNA processing event has been defined to a significant extent, namely the effect of ICP27 on pre-mRNA splicing. Although most metazoan mRNAs are multiply spliced, the majority of HSV-1 transcripts are intronless. This presents an interesting paradox for the virus because cellular RNA export is intimately coupled to splicing through the deposition of the exon junction complex on the spliced mRNAs, which marks mRNAs for export by TAP/NXF1 (Cullen, 2000). Although there are cellular transcripts that are intronless, these transcripts have been found to contain specific recognition elements that allows their export via TAP/NXF1 (Huang *et al.*, 2003). Following infection with HSV-1, the cell is presented with thousands of viral intronless transcripts that would compete poorly with cellular transcripts for export. ICP27 shifts the balance by shutting down the cellular splicing machinery, albeit temporarily, thus cellular pre-mRNAs are not fully processed and exported (Bryant *et al.*, 2001; Sciabica *et al.*, 2003). Further, ICP27 recruits an export adaptor protein, termed Aly/REF, which is part of the EJC, to sites of HSV-1 transcription (Chen *et al.*, 2002). Thus, HSV-1 mRNAs are given access to the TAP/NXF1 pathway (Chen *et al.*, 2002; Koffa *et al.*, 2001). ICP27 inhibits cellular splicing at early times after infection by recruiting a predominantly cellular kinase, SRPK1, to the nucleus of infected cells where it inappropriately phosphorylates a family of splicing factors, termed SR proteins, which are required for splicesome assembly (Sciabica *et al.*, 2003). Proper phosphorylation is required for SR proteins to perform their roles in splicing and consequently, splicesome complex formation is stalled. ICP27 interacts with SR proteins and other spliceosomal components (Bryant *et al.*, 2001; Sciabica *et al.*, 2003), and most likely then encounters Aly/REF, the export adaptor, which is part of the EJC (Chen *et al.*, 2002; Koffa *et al.*, 2001). ICP27 recruits Aly/REF to sites of HSV-1 transcription, marked by staining with an antibody to ICP4 (Chen *et al.*, 2005), and ICP27 then binds to HSV-1 intronless transcripts through its RGG box RNA binding motif (Sandri-Goldin, 1998). The RNA-ICP27-Aly/REF complex binds to TAP/NFX1 through the interaction of both ICP27 and Aly/REF with TAP/NXF1 (Chen *et al.*, 2002), and HSV-1 transcripts are exported through the NPC. Splicing is restored at later times of infection, when ICP27 is actively shuttling and exporting viral mRNA. The nature of the switch between these early and late activities of ICP27 has not been defined but could involve post-translational modifications. ICP27 is phosphorylated by several cellular kinases (Zhi and Sandri-Goldin, 1999) and it undergoes arginine-methylation in the RGG box (Mears and Rice, 1996). A recent report suggests that ICP27 may be directed initially to sites of cellular transcription and splicing, similar to cellular RNA processing factors, by interacting with RNA polymerase II. ICP27 was found to co-immunoprecipitate with RNA polymerase II in HSV-1-infected cells (Zhou and Knipe, 2001). Further, ICP27 was found to interact directly with the CTD of RNA polymerase II in vitro and in virus-infected cells (Dai-Ju *et al.*, 2006).

The homologue of ICP27 in VZV is IE4. The IE4 protein is a transactivator of gene expression whose regulatory properties are not fully understood. IE4 stimulates VZV gene expression and it also is capable of heterologous transactivation (Defechereux *et al.*, 1997; Perera *et al.*, 1994), and IE4 has been suggested to exert its function through both transcriptional and post-transcriptional mechanisms (Defechereux *et al.*, 1993; Defechereux *et al.*, 1997; Perera *et al.*, 1994). IE4 shares considerable amino acid sequence homology with HSV-1 ICP27, especially in the carboxyl terminus and in the central part of the protein (Davison and Scott, 1986). The carboxyl-terminal region of ICP27 that is rich in cysteine and histidine residues has been shown to bind zinc (Vaughan *et al.*, 1992) and to be required for multimerization (Zhi *et al.*, 1999). Whereas the carboxyl-terminal region of IE4 also contains cysteine and histidine residues, it is not known whether this region binds zinc, and dimerization of IE4 was found to require the C-terminal cysteine-rich domain and the central region of the protein (Baudoux *et al.*, 2000). The amino-terminal regions of the two proteins have a more limited amino acid homology; however, both are highly acidic. In transfection assays, it was demonstrated that the IE4 N-terminal acidic region was required for its trans-activating function and that it could be replaced in part by substituting the corresponding region of ICP27 (Moriuchi *et al.*, 1995). While IE4 is not a potent transactivator on its own, it can act as a major coactivator of transactivation mediated by IE62, and was found to interact with IE62 in infected cells and in vitro (Spengler *et al.*, 2000). The interaction depended on the phosphorylation state of IE62. The nature of the post-transcriptional activation seen with IE4 has not been defined, and it is not known if IE4 is involved in the regulation of splicing or viral RNA export. Many VZV transcripts are also intronless, and IE4 was reported to shuttle between the nucleus and

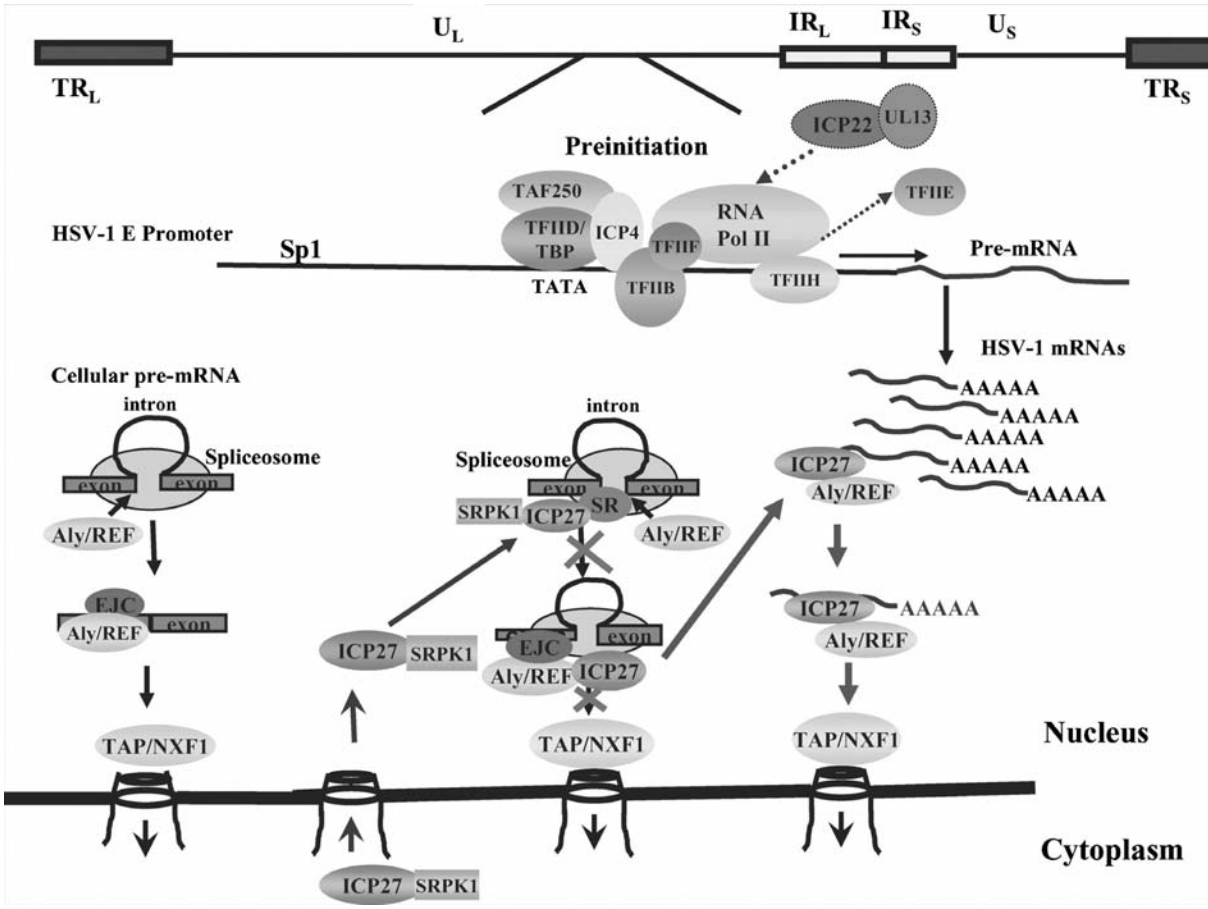

Fig. 9.1. Model of HSV-1 early (E) gene expression showing the initiation of transcription, RNA synthesis and export. The HSV-1 genome is depicted in schematic form. An E gene promoter from the U_L region is blown up to illustrate the upstream Sp1 site and the TATA box. The HSV-1 modified preinitiation complex includes ICP4, which forms a tripartite complex with TBP, a component of TFIID, and TFIIB (Grondin and DeLuca, 2000). ICP4 also interacts with TAF250, which stabilizes the interaction of TFIID with DNA (Carrozza and DeLuca, 1996). In VZV infected cells, IE62 has also been shown to bind TBP and TFIIB (Perera, 2000). The altered phosphorylation of RNA polymerase II by ICP22 and U_L 13 (Long *et al.*, 1999) is shown by a dashed line, as is the release of TFIIE from RNA polymerase holoenzyme (Jenkins and Spencer, 2001). The pathway for mRNA export in uninfected cells is disrupted during HSV-1 infection. ICP27 recruits SRPK1 to the nucleus where it inappropriately phosphorylates the splicing SR proteins and splicesome assembly is stalled (Sciabica *et al.*, 2003). ICP27 encounters the export adaptor Aly/REF, which is part of the EJC and directs it to HSV-1 intronless transcripts (Chen *et al.*, 2002; Koffa *et al.*, 2001). ICP27 binds viral intronless RNA and the ICP27-RNA-Aly/Ref complex interacts with the export receptor TAP/NXF1 to export viral RNAs to the cytoplasm. It has not been demonstrated whether VZV IE4 affects splicing or is involved in viral RNA export.

cytoplasm, however, this activity was not further delineated (Baudoux *et al.*, 2000). See Fig. 9.1.

Concluding remarks

Both HSV-1 and VZV have evolved mechanisms for usurping the cellular machinery to produce viral transcripts to insure the successful generation of viral progeny. The viral regulatory proteins that are involved in the initiation of transcription, RNA processing and export are the IE proteins in both viruses. These proteins all have unique roles in the expression of viral gene products. While the HSV-1 and VZV IE proteins share homology, they have clearly diverged to meet the unique requirements of their parent viruses. For example, HSV-1 IE proteins are not significant components of the virion tegument, whereas, VZV IE62, IE4 and IE63 are. Further, HSV-1 IE proteins are not expressed in latently infected cells; however, VZV IE63 is expressed as a major

protein during latency along with IE4 (Kenyon *et al.*, 2003). Both HSV-1 and VZV encode essential IE proteins, ICP4 and IE62, that transactivate viral gene expression, and both encode IE proteins, ICP22 and IE63, that interact with or modify RNA polymerase II, although the functional repercussions of this are not yet fully appreciated. The roles of the RING finger proteins, ICP0 and IE61 have not been fully elucidated despite the fact that we now know a great about what these proteins do in the infected cell. While HSV-1 hijacks the cellular export machinery via ICP27 to facilitate translation of its transcripts, little is known about how the switch from an early splicing inhibitor to a late viral export factor is controlled. It remains to be seen if VZV IE4 functions in this manner. Thus, there is still much to learn about gene regulation in the alphaherpesviruses.

Alphaherpesvirus DNA replication

John Hay and William T. Ruyechan

Witebsky Center for Microbial Pathogenesis and Immunology, SUNY at Buffalo School of Medicine, NY, USA

DNA replication in alphaherpesviruses has been the subject of study in bursts over the years. Interest in the subject depends not just on simple curiosity about this central feature of the viral growth cycle, but also because DNA replication is a potentially useful target for antiviral therapy, as has already been shown with agents such as acyclovir. The viral contributions to the mechanism of genome replication are quite well understood but we still are unable to duplicate the in vivo situation in an in vitro assay. Much of the recent interesting work involves the host cell's contribution to the process, and this seems likely to remain a focus for the future.

Structure of the genome

There are over 30 alphaherpesviruses that infect a wide range of host species. Their genomes fall into two general categories, either herpes simplex (HSV) – like or varicella zoster (VZV) – like, with four or two, respectively, isomeric forms (Fig. 10.1). There is a wide range of G + C content (32%–75%), with a bias towards higher (>50%) numbers. There is also size heterogeneity (125–180 kbp) which, although quantitatively less than the nucleotide composition variation, may be much more significant for the lifestyle of the virus. All alphaherpesvirus genomes contain four general structural components: unique long and short (U_L, U_S) sequences that encode single-copy genes and inverted repeat regions that bound the unique regions; these may contain diploid genes and sequences required for cleavage and packaging of viral DNA (Fig. 10.1). DNA replication initiates at origin sequences (*ori*), and there are two or three of these in each genome, depending on the virus. Evidence suggests that only one *ori* is required for viral DNA replication, however, and the importance of multiple origins, if any, remains to be discovered (Roizman and Knipe, 2001; Balliet *et al.*, 2005). Only a few of the alphaherpesviruses have been studied at the molecular level regarding DNA replication (e.g., HSV, VZV, equine herpesvirus type 1 (EHV-1), pseudorabies virus (SuHV-1), and infectious bovine rhinotracheitis virus (BoHV-1). Most of the work, however, has been carried out with HSV, reviewed by Boehmer and Lehman (1997) and Lehman and Boehmer, (1999); the majority of the information presented here will be that gathered for HSV.

The origins of DNA replication

For those viruses with an ori_L, this is found in the middle of the U_L segment, in the region lying between DNA polymerase and the major DNA-binding protein for HSV, but not necessarily for other viruses (Telford *et al.*, 1992). The ori_S sequences sit in the repeat regions bounding the

$a_1\ a_n\ b$---------- ori_L ---------- $b'\ a_n'\ c'\ ori_S$ -------- $ori_S\ c\ a_S$

$<TR_L><\qquad U_L \qquad>< IR_L\ IR_S>< U_S><TR_S>$

Fig. 10.1. The structure of alphaherpesvirus genomes. The upper diagram shows the sequence organization of the herpes simplex virus genome, with the origins of DNA replication shown as ori_L or ori_S. The lower diagram shows the general layout of the regions of the genome, with TR = terminal repeat, IR = internal repeat and the subscripts $_L$ and $_S$ denoting long and short regions, respectively. This is the scheme for the simplexviruses, that invert the U_L and U_S regions relative to each other, to yield four isomeric forms of the genome. For the varicelloviruses, the TR_L and TR_S sequences are so short that U_L does not invert, and there are only two isomeric genome forms, resulting from inversion of U_S. In addition, the varicelloviruses have no ori_L but do have two copies of ori_S.

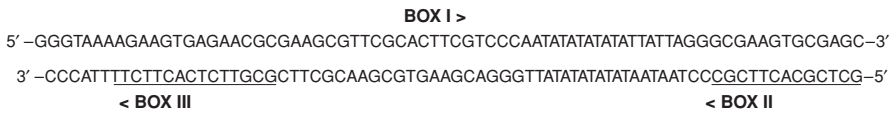

Fig. 10.2. The structure of alphaherpesvirus origins of replication. Shown above is the HSV-1 ori_S sequence. Box III is a low-affinity UL9 recognition site, Box I is a high affinity UL9 binding site and Box II has a ten-fold lower affinity for UL9 than Box I. The ori_S has a large dyad symmetry element (45 bp) centered around an AT region of 18 bp. The ori_L is similar but has a larger symmetry element (144 bp) and AT region (20 bp); in addition, it has a second copy of Box III and, instead of Box II, has a second copy of Box I. Other viral origins have analagous structural elements.

U_S region. The two origins in HSV are very similar but not identical (Fig. 10.2), and other alphaherpesvirus origins also have the same general structural features (Telford *et al.*, 1992; Kuperschmidt *et al.*, 1991), to the extent that HSV infection can support limited replication of a VZV *ori*-containing plasmid (Stow and Davison, 1986), for example. These herpesvirus origins are not dissimilar to other origins in other mammalian viruses, with a dyad symmetry element adjacent to an AT-rich sequence, flanked by binding sites for the origin recognition protein and possibly other factors (Fig. 10.2), implying similar general mechanisms for initiation of genome replication.

Location of DNA synthesis

Viral DNA replication takes place in the nucleus. Prereplicative sites form as DNA-protein complexes that appear as punctuate elements by immunofluorescence microscopy, in association with nuclear domain 10 (ND10) (Ishov and Maul, 1996). As synthesis proceeds, larger areas of the nucleus become involved, and are visualized as globular replication compartments (Quinlan *et al.*, 1984). Recently, it has been demonstrated that active viral transcription assists in the association of viral DNA with ND10 (Sourvinos and Everett, 2002), implying that assembly of transcription and/or replication complexes promote this association. The authors suggest that a critical step in initiating DNA synthesis is ND10 association, and this idea is supported by work with Epstein–Barr virus, in which postreactivation, but not latent, genomes are ND10-associated (Bell *et al.*, 2000).

Proteins involved in DNA synthesis

It is generally accepted that, prior to replication, the linear viral DNA initially circularizes; then synthesis initiates at an origin(s) and proceeds bidirectionally to form theta structures. Soon after, synthesis switches to a rolling circle mode, in which genome-sized pieces are cleaved and packaged as they are produced. This all takes place in the presence of UL9, the origin-binding protein; UL29 (ICP8), a single-strand DNA-binding protein; UL30 and UL42, the DNA polymerase and DNA polymerase processivity factor, which make up the DNA polymerase complex; and UL5, 52 and 8 which make up the DNA helicase/primase complex. These constitute, at present, the essential alphaherpesvirus replication proteins. The assembly of the viral replication complex appears to be an ordered process, in which UL9, ICP8 and the helicase-primase heterotrimer first form replication foci, and the polymerase holoenzyme (UL30 and UL42) are then recruited; this recruitment process seems to require primer synthesis (Carrington-Lawrence and Weller, 2003). Despite our knowledge of the viral polypeptides required for origin-dependent DNA synthesis in vivo, it has still not been possible to reconstitute this theta mode of replication in vitro. Instead, work has focused on rolling circle replication, which can be demonstrated using a replisome containing ori_S and the two viral protein complexes – DNA polymerase/UL42 and the heterotrimeric helicase-primase; the viral SSB (UL29) is not required (Falkenberg *et al.*, 2000).

The origin-binding protein dimerizes and binds to the CGTTCGCACTT *ori* sequence; it also has ATP-binding and helicase functions. Opening the viral *ori* appears to involve several viral and cellular proteins; on a superhelical template in the presence of ATP, UL9 and ICP8 allowed about half of the *ori* s to unwind, and following addition of the cellular topoisomerase I, the extent of unwinding was augmented to >1 kb.

ICP8, the UL29 gene product, is a classical single-stranded DNA binding protein (SSB), with helix-destabilizing activity. It has been shown to interact with all the other replication proteins (above) and seems likely to be the principal scaffold for the generation of prereplication complexes adjacent to ND10 sites. Recent work shows that a C-terminal alpha helix is important in binding viral and/or cellular factors, allowing targeting of ICP8 to specific nuclear sites (Taylor and Knipe, 2003). In addition, it seems to operate in concert with the alkaline endo-exonuclease activity of the virus to constitute a viral recombinase activity similar to that of the bacteriophage lambda (Reuven *et al.*, 2003). In that context, it has recently

been shown to stimulate, and regulate, the processivity of, the pseudorabies virus DNase (Hsiang, 2002).

DNA polymerase is a heterodimer, with the UL30 gene product as the typical polymerase/3′–5′ exonuclease (proofreading) activities, and UL42 as the processivity factor. The holoenzyme has a broad substrate specificity that allows it to be a useful target for antiviral therapy, as discussed elsewhere in this volume. The UL42 protein stimulates polymerase activity and increases the fidelity of replication (Chaudhuri *et al.*, 2003); it has been hypothesized to function by interdigitation of its termini, using a hinge region at aa241–261 (Thornton *et al.*, 2000). C-terminal residues in the polymerase polypeptide are important for UL42 interaction and interference with this may be a useful antiviral tool (Bridges *et al.*, 2000). UL42 is an unusual processivity factor, in that it binds directly to DNA, unlike the "sliding clamps" such as PCNA and the *E. coli* β protein. Nevertheless, it seems to resemble PCNA both in its interaction with polymerase (Zuccola *et al.*, 2000) and its ability to slide downstream with polymerase during replication (Randell and Coen, 2001).

The UL5 and UL52 polypeptides constitute the core of the helicase–primase complex, with DNA helicase, primase and ATPase activities. UL5 and UL52 also demonstrate DNA-binding activity when they form complexes, and this DNA-binding activity is preferentially to forked substrates, as opposed to single-stranded or duplex molecules (Biswas and Weller, 2001). The contribution of UL8 to the complex is to work with ICP8 to promote unwinding activity and to catalyze nuclear localization of the complex. An HSV-1/HSV-2 recombinant, in which UL5 is the only HSV-2 gene, is non-neurovirulent and defective in DNA replication in neurons. The primary defect was in primase activity, suggesting that interactions between subunits in the complex are vital in ensuring its full catalytic activity (Barrera *et al.*, 1998). Inhibitors of helicase–primase activity have recently been investigated as potential antiviral agents. The most powerful compounds inhibited primase, helicase and ATPase activities and, as expected, were active against viral mutants resistant to nucleoside-based therapies (Crute *et al.*, 2002).

A second set of proteins with links to DNA synthesis are considered non-essential for replication in cultured cells, but several appear to be essential for "normal" behavior of virus in animal models. These include: pyrimidine deoxynucleoside kinase; alkaline endo-exonuclease; ribonucleotide reductase; uracil N-glycosylase and deoyuridine triphosphatase.

The pyrimidine deoxynucleoside kinase, popularly known as thymidine kinase (TK) phosphorylates a wide range of nucleoside substrates, as well as TMP, and is responsible for the rise in the TTP pool that is characteristic of HSV-infected cells. The enzyme, because of its broad specificity, also acts on the acyclovir family of antivirals, and has been used extensively in gene therapy in combination with ganciclovir and acyclovir (Hayashi *et al.*, 2002). This broad specificity has recently been analysed and seems to depend on the electric dipole moment of ligands interacting with a negatively charged residue at aa 225 (Glu) (Sulpizi *et al.*, 2001). TK-deletion mutants will establish latency in mouse ganglia but do not reactivate, presumably owing to a lack of an equivalent cellular activity. However, viral strains that only produce small quantities of enzyme are able to reactivate with wild-type efficiency (Griffiths *et al.*, 2003).

The UL12 ORF encodes an endo-exonuclease that is most active between pH 9 and 10; the significance of this is uncertain. This protein interacts with ICP8 and plays a role in the maturation and packaging of viral DNA; this is consistent with the behavior of UL12 null mutants, which make DNA and late proteins, but do not produce infectious virus particles efficiently. The hypothesis is that the enzyme acts on gaps and/or nicks in progeny DNA, either to process or repair it on its way towards encapsidation. The UL12 phosphoprotein and ICP8 can also work in concert to promote strand exchange, similar to recombination events in lambda phage (Reuven *et al.*, 2003).

Ribonucleotide reductase allows formation of deoxynucleoside diphosphates from ribonucleoside substrates and is not negatively regulated by the high TTP pools in HSV-infected cells, as would be the cellular equivalent. It is made up from the products of two ORFs (UL39, R1 and UL40, R2) to form a symmetric heterotetramer, and seems to be necessary for viral growth in "resting" cells. There are reports of protein kinase activity associated with the R1 polypeptide of HSV-2, but there is also evidence that, while HSV-2 R1 is itself a substrate for protein kinase activity, the polypeptide does not itself possess intrinsic protein kinase activity (Langelier *et al.*, 1998). Recently it has been shown that an accessory function of the reductase may be to protect HSV-1 infected cells against cytokine-induced apoptosis.

Uracil N-glycosylase (encoded in UL2) is a repair enzyme that cleaves mutated U residues from the DNA sugar backbone resulting from a cytosine deamination event, subsequent to repair by viral and cellular enzymes. It is curious that the virus should encode an enzyme that is ubiquitous in host cells, but activities may be low in non-dividing cells that the virus encounters in vivo. This may also be the explanation for reduction in neurovirulence and a poor ability to reactivate from latency that is characteristic of UL2-deletion mutants.

Deoxyuridine triphosphatase (dUTPase), the product of the UL50 gene, breaks down dUTP, preventing dU incorporation into viral DNA. At the same time, the product of its action, dUMP, is a substrate for the pathway that leads

to TTP synthesis. UL50 null mutants are impaired in their ability to replicate in the central nervous system in mice, although they seem capable of normal growth in peripheral tissues. They also fail to reactivate effectively.

In addition to the viral proteins described above, there are cellular proteins that contribute both essential and/or accessory roles in viral DNA replication. Among the obvious examples of the former are DNA ligase and topoisomerase activities, as well as repair endonuclease activity and an endonuclease G, that may contribute to maturation of the viral genome (Huang *et al.*, 2002). Among the latter are the numerous cellular enzymes that contribute substrates for DNA synthesis, and that are found in all dividing cells. There will likely be additional cellular proteins found, however, such as the promyelocytic leukemia protein (PML) that is recruited to replication foci following the arrival of the polymerase complex (Carrington-Lawrence *et al.*, 2003), and the OF-1 protein that has a function in initiation of replication (Baker *et al.*, 2000). It also contains the Ku70/Ku80 heterodimer which is present in origin-specific DNA-binding complexes in primates and yeast (Murata *et al.*, 2004).

DNA replication and the cell cycle

HSV downregulates host cell DNA synthesis during lytic infection, implying that the normal cell cycle is dysregulated by the virus. The reason for this, presumably, is to allow the virus maximum access to DNA precursors, replication sites and replication proteins that would otherwise be involved in cellular genome synthesis. In a parallel scenario, it has been shown that, using the inhibitor roscovitine, cyclin-dependent kinases are required for HSV DNA replication, even although the early viral proteins required for synthesis are all present (Schang *et al.*, 2000). Cell cycle arrest has been shown to involve the viral ICP0 protein, using mechanisms that appear to be both p53-dependent and p53-independent. One mechanism whereby ICP0 is effective, is through arresting the cycle at the G1->S stage, blocking cells at the pseudo-prometaphase stage of mitosis (Lomonte and Everett, 1999). The data suggest that viral factors other than ICP0 may be involved in this cell cycle block but that ICP0 alone may be responsible for the mitotic block. The authors make the point that ICP0 expression is incompatible with the growth of a cell population. One additional viral protein that affects the cell cycle is ICP27; it blocks the cycle at S phase, through inhibiting the phosphorylation of pRb (Song *et al.*, 2001). Thus, the virus has evolved a number of different mechanisms to interfere with normal cell cycle progression, emphasizing the potential importance of this step in the viral growth cycle.

Maturation and packaging of viral DNA

The a sequences of the HSV genome (Fig. 10.1) constitute the *cis*-acting signals for cleavage of the newly synthesized DNA, resulting from rolling circle replication, into genome-sized pieces for packaging into capsids. The DR1 repeat sequences that flank the a sequences contain the actual cleavage site, and two unique regions, Uc and Ub, are next to the genomic ends. A fragment, Uc/DR1/Ub, is sufficient to constitute a minimal packaging signal, and elements inside the U sequences can be found in other herpesvirus genomes; these are the pac elements. Data suggest that these pac sequences contain signals for both initiation and termination of packaging (White *et al.*, 2003). The proteins involved in the process are UL6, UL15 and UL28 in HSV-1, and these are sufficient for cleavage of the concatameric DNA, as well as their packaging into procapsids. UL6 likely constitutes the gateway on the preformed capsid for entry of the genome and is present at one vertex, while a UL15/UL28 complex has the properties of the engine that drives the genome into the procapsid. UL6 is capable of specific interaction with both UL15 and UL28 (Hodge and Stow, 2001). A fourth protein, UL25, seems to play a final role in the packaging process, prior to the movement of nucleocapsids into the cytoplasm.

Recombination

Homologous recombination is a frequent event in herpesvirus infected cells, and it has been used experimentally to investigate gene functions, for example, by generation of HSV-1/HSV-2 intertypic recombinants. Viral DNA molecules that are undergoing replication are the best substrates for recombination and the genomic inversions that give rise to the different isoforms of the HSV genome are generated through recombination involving the repeat regions. While it seems likely that cellular enzymes or other proteins will be important in the process, there are clearly roles for viral gene products. For example, ICP8, as outlined earlier, appears potentially to be a key player in the recombination process. In in vitro assays, it promotes strand exchange in conjunction with the viral helicase-primase and catalyzes single-strand invasion in an ATP-independent manner (Nimonkar and Boehmer, 2003). It also may be involved in single-strand transfer, in collaboration with the HSV endo-exonuclease activity, UL12. The 5′–3′ exonuclease activity of this protein shares homology with the lambda exonuclease (Redalpha) that is known to be essential for homologous recombination in the phage. It is proposed that the two viral proteins work in concert to

promote strand exchange, shown experimentally by generating a gapped circle and a displaced strand from an M13 duplex DNA molecule and an M13 single-stranded circular DNA molecule. Interestingly, UL12 polypeptide that lacked nuclease activity was incapable of catalyzing this experimental recombination (Reuven *et al.*, 2003). In addition to the various roles that recombination might play in the virus life cycle, it has been proposed that recombination may also be important for the switch that occurs between the early theta mode of replication of viral DNA and the mainstream rolling circle mode, in a way reminiscent of the mechanisms occurring in the lytic phase of lambda replication (Boehmer and Lehman, 1997).

Latency

Alphaherpesvirus latency, as typified by HSV, is characterized by a lack of infectious virus in latently infected neural tissue and expression of specific LATs (latency-associated transcripts). VZV, on the other hand, has no LATs, and expresses a restricted set of transcripts and proteins seen in the early phases of normal lytic infection. Calculations of the numbers of viral genomes present in latently-infected neurons have shown a small but significant number to be present; in HSV, a recent estimate gives a mean of 178 per LAT-positive neuron using laser capture microdissection (Chen *et al.,* 2002). This number is not dramatically different from less sophisticated measurements on VZV-infected ganglia. This raises the issue of how this number of genomes arises, and the simplest explanation is that initial infection of the neuron proceeds by the normal lytic route, initiates some DNA replication (only through a theta-like mode?) but is quickly curtailed by factors within the cell. At present, we have no clues as to what constitutes this inhibitory mechanism. Reactivation must involve renewed viral DNA synthesis and, indeed, the presence of several viral proteins of the "non-essential-in-cell-culture" variety is necessary to allow the process to proceed. In addition, there is a proposal that the cellular C1 factor, responsible for assembly of transcriptional enhancer complexes, is normally missing from neuronal nuclei but present soon after reactivation (Kristie *et al.,* 1999). Thus, as with other herpesvirus systems (e.g., EBV), it is likely that the HSV reactivation is initiated through production of gene regulatory viral proteins.

Future directions

Future investigation is likely increasingly to focus on the host cell's contribution to viral genome replication. The recent interest in nuclear structures will provide the field with a new set of findings that may provide the clues necessary to allow faithful replication of the in vivo situation in an in vitro environment. Aside from replication, the host cell also plays a role in the repair/recombination events that characterize the viral growth cycle, and these contributions also remain to be precisely defined. Finally, the issue of latent vs. lytic viral behavior has focused primarily on transcription and its control; perhaps it is now time to look more closely at viral DNA replication in latently infected cells.

Envelopment of herpes simplex virus nucleocapsids at the inner nuclear membrane

Joel D. Baines

Cornell University Department of Microbiology and Immunology, Ithaca, NY, USA

Introduction

As in all herpesviruses, Herpes simplex nucleocapsids assembled in the nucleoplasm obtain an initial envelope by budding through the inner nuclear membrane of infected cells. This chapter will focus on the proteins responsible for nucleocapsid budding in the herpes simplex virus system. Of interest is the observation that orthologs of at least the UL31 and UL34 genes of herpes simplex virus genes likely mediate similar functions in members of both the beta- and gamma herpesvirinae (Muranyi *et al.*, 2002; Gonnella *et al.*, 2005). Thus, it is expected that this information will be relevant to the study of nucleocapsid envelopment of all herpesviruses.

Anatomy of the nuclear membrane: it's all connected

The nuclear envelope consists of two leaflets: the inner leaflet or inner nuclear membrane (INM) partitions the nucleoplasm from the lumen of the nuclear envelope, whereas the outer leaflet (ONM) contacts the cytoplasm. The space between the leaflets is ultimately continuous with the lumen of the endoplasmic reticulum. Both leaflets are continuous with the nuclear pore membrane that serves as an anchoring point for nuclear pore complexes (NPCs), which serve as conduits to mediate protein and RNA transport between the nucleus and cytoplasm.

The nuclear lamina lines the inner surface of the INM and is maintained in this orientation by interaction with both chromatin in the nucleoplasm, and integral membrane proteins specifically concentrated in the INM. How proteins are targeted to the INM has been the focus of active research for several years (Ellenberg *et al.*, 1997; Ostlund *et al.*, 1999; Soullam and Worman, 1993). The leading "diffusion and retention" model proposes that proteins destined for the nuclear membrane are translated by membrane-bound ribosomes, and become integrated into the ER membrane. Proteins then migrate laterally towards the nuclear pore membrane. Those with extraluminal domains greater than 60–70 kD are excluded from the inner nuclear membrane, presumably because the bulky domain interferes with migration past the nuclear pore membrane (Soullam and Worman, 1995). Upon passing the nuclear pore membrane, the nucleoplasmic (or extraluminal) domain is in a position to interact with components of the nuclear lamina. For proteins such as lamin B receptor, emerin, and lamin associated proteins 1 and 2, interaction with lamina components essentially anchors the proteins at the INM, completing the targeting mechanism. For most proteins, however, a nucleoplasmic ligand to retain them at the inner nuclear membrane does not exist, so the proteins eventually migrate anterograde past the nuclear pore membrane into the ONM. Such proteins presumably continue in an anterograde direction to the ER, Golgi and beyond. Thus, most integral membrane proteins do not accumulate to high levels within the inner nuclear membrane, although they would be expected to localize there at least transiently.

The nuclear lamina is required for maintaining the structure of the nucleus and has been shown to line the entire inner surface of the nuclear membrane (Belmont *et al.*, 1993). The lamina is also required for functions normally associated with chromatin such as transcription and DNA replication (Gruenbaum *et al.*, 2000). The precise structure of the nuclear lamina is not well understood. Although many components of the lamina have been identified, understanding how these proteins interact to form higher order structures is complicated by the molecular complexity and redundancy of many of the interactions. What is clear is that most of the integral proteins within the INM that have been studied (such as lamin B receptor

and emerin) have been shown to bind lamins. Lamins are type V intermediate filaments and the nuclear lamina contains polymers of lamins A, B and C (McKeon *et al.*, 1986; Stuurman *et al.*, 1998). Lamins A and C are derived from splice variants of *LmnA* transcripts, whereas lamin B1 and lamin B2 are derived from different genes (Fisher *et al.*, 1986; Hoger *et al.*, 1988, 1990; Lin and Worman, 1993). As a result of RNA splicing, the C-terminus of Lamin C contains 6 unique amino acids that replace an isoprenylation motif and the C-terminal 90 amino acids of lamin A.

Lamins, like most intermediate filaments, contain globular head and tail domains separated by a coiled-coil helical rod-like domain that contributes the rigidity and most of the length of the filament. Lamins dimerize as a result of the intertwining of the rod domains, and larger filaments are produced upon multimerization of lamin dimers through the interactions of the rod domains of different protomers. The tail domain can form an immunoglobulin-like fold that likely interacts with chromatin (Dhe-Paganon *et al.*, 2002; Stierle *et al.*, 2003; Taniura *et al.*, 1995).

Envelopment at the nuclear membrane

Herpesvirus nucleocapsids are unique in virology because their nucleocapsids bud through the inner nuclear membrane (INM) to obtain a virion envelope. As a result of the envelopment reaction, the nascent virions accumulate between the inner and outer leaflets of the nuclear membrane. The nuclear membrane in sites that accommodate budding are more electron dense than other regions of the nuclear membrane, suggesting they bear a high density of proteins. Such envelopment sites are readily observed by electron microscopy along the inner nuclear membranes of HSV infected cells. While only a small subset of HSV proteins has been examined in this regard, at least proteins encoded by U_L 11 (a peripheral membrane protein), U_L 31, U_L 34, and glycoproteins B, D and M become incorporated into perinuclear virions and are present at the INM (Baines *et al.*, 1995; Jensen and Norrild, 1998; Reynolds *et al.*, 2002; Torrisi *et al.*, 1992; J. D. Baines, Jacob and B. Roizman, unpublished data). Because no HSV integral membrane protein is predicted to contain an extraluminal domain that exceeds the size that can preclude migration past the nuclear pore membrane (McGeoch *et al.*, 1988), it is likely that additional HSV integral membrane proteins will be discovered along the inner nuclear membrane. It is also likely that at least some tegument proteins are present at the INM, and that some associate with the nucleocapsid before they engage envelopment sites at the INM. Which of the many tegument proteins become targeted to virions in this manner has not been defined.

A critical question is whether the virions that accumulate in the perinuclear space are infectious. If so, it would seem advantageous to the virus because virions are often abundant in the perinuclear space late in infection, and would therefore represent a source of infectious virus upon immune-mediated cytolysis. The critical experiment to determine whether these virions are infectious has not been performed. Two seemingly disparate pieces of evidence argue both for and against: (i) cells infected with a virus encoding a truncated U_L20 gene fused to $U_L20.5$ contain abundant particles that appear to accumulate in the perinuclear space and these virions are infectious (Baines *et al.*, 1991); (ii) cells infected with a virus lacking U_S3 accumulate virions aberrantly in the perinuclear space, and there is a delay in the onset of infectious virus production (Reynolds *et al.*, 2002). Thus, it would seem that, unless an unforeseen defect in INM envelopment is also mediated by U_S3, these virions are not infectious until they exit the perinuclear space.

Studies of viral mutants lacking the U_L11, U_L31, U_L34, U_L37, and U_L53 (gK) proteins have shown that these proteins either facilitate or are required for nucleocapsid envelopment at the INM (Baines and Roizman, 1992; Desai *et al.*, 2001; Jayachandra *et al.*, 1997; Roller *et al.*, 2000). Except for U_L11 and U_L37 which are always dispensable, these proteins are essential for envelopment in different circumstances. Glycoprotein K is especially important for envelopment in quiescent cells (Jayachandra *et al.*, 1997). While U_L31 and U_L34 are essential for envelopment in Vero and Hep2 cells, U_L31 is dispensable for viral replication in rabbit skin cells (Chang *et al.*, 1997; Liang *et al.*, 2004; Roller *et al.*, 2000). Thus it seems likely that functions of the host cell can sometimes complement the functions of gK, and U_L31.

The U_L31/U_L34 protein complex and the nuclear lamina

The U_L31 protein of HSV-1 is a phosphoprotein that contains a bipartite nuclear localization signal at codons 8–25 and is predominantly intranuclear when transiently expressed in the absence of other viral proteins; in infected cells, however, the protein associates with the nuclear rim (McGeoch *et al.*, 1988; Reynolds *et al.*, 2001; Zhu *et al.*, 1999). Immunogold electron microscopy has revealed that the U_L31 protein associates with both leaflets of the nuclear membrane and that this association is dependent on U_L34 protein (Chang and Roizman, 1993; Reynolds *et al.*, 2001; Reynolds *et al.*, 2002). It was noted that U_L31 protein, like other components of the nuclear matrix, is resistant to extraction with detergent, DNAse and high salt (Chang and Roizman, 1993). Association with the nuclear matrix,

coupled with the distribution at the nuclear rim, strongly suggest that U_L31 protein integrates into the nuclear lamina of infected cells, components of which display similar resistance to extraction (Chang and Roizman, 1993; Reynolds *et al.*, 2001).

In vitro, U_L31 protein binds GST fusion proteins containing U_L34, and lamin A amino acids 369 to 633 (Reynolds *et al.*, 2004). The solubility of U_L31 protein under various extraction conditions strongly parallels the solubilization of lamin A/C, further supporting an in vivo interaction between these proteins. The presence of U_L31 protein in HSV-infected Vero cells reduces immunoreactivity of an epitope located between amino acids 369–519 of lamin A/C, suggesting that U_L31 directly or indirectly induces a conformational change in lamin A/C that masks the epitope. This region of lamin A/C includes the globular tail domain that has been shown to form an immunoglobulin-like fold that may interact with chromatin (Dhe-Paganon *et al.*, 2002; Stierle *et al.*, 2003). Thus, it is possible that U_L31 may compete for sites on lamin A/C that normally interact with chromatin. Such an interaction could conceivably play a a role in the U_L31-dependent HSV-mediated displacement of chromatin from regions of the INM (Simpson-Holley *et al.*, 2004).

Remarkably, overexpression of the U_L31 protein is sufficient to completely displace lamin A/C from the nuclear rim and cause it to colocalize with U_L31 protein within nucleoplasmic aggregates (Reynolds *et al.*, 2003). Similar lamina – disrupting activity has been seen upon overexpression of lamin A head or tail domains (Izumi *et al.*, 2000). The mechanism by which overexpressed U_L31 mediates lamin displacement is unclear. It is possible that this displacement reflects a competition between domains of U_L31 protein and lamin A/C that mediate: (i) anchoring of the lamina to the nuclear membrane or (ii) polymerization of lamin A/C filaments. However, such dramatic lamin A/C displacement is not observed in infected cells. Reasons include the possibilities that: (i) the distribution of U_L31 protein is restricted to the nuclear rim by its association with the U_L34 protein within the nuclear membrane, thus limiting its diffusion within the nucleus (Reynolds *et al.*, 2001), and (ii) the levels of U_L31 protein in infected cells are lower when expression is driven by the U_L31 promoter as opposed to the CMV early promoter/enhancer used to drive transient expression. If the ability of U_L31 to displace lamins reflects its utility as a lamin depolymerizing agent during infection, it seems more likely that in infected cells the U_L31 protein would serve to act within discrete regions of the nuclear membrane rather than globally. Limiting the destructive capacity of U_L31 protein to a local region may thus avoid more global nuclear disruption and preserve nuclear functions for optimal virus production.

U_L34 protein is likely a type II integral membrane protein, with the bulk of its 275 residue protein protruding into the nucleoplasm. Only the last five amino acids are predicted to reside between the lamella of the nuclear membrane or lumen of the endoplasmic reticulum (i.e., the perinuclear space). The U_L34 protein is necessary for nucleocapsid envelopment at the inner nuclear membrane in most cells tested including Vero and Hep2 cells. The U_L34 protein directly interacts with the U_L31 protein, and is essential for proper targeting of the latter to the nuclear membrane (Reynolds *et al.*, 2001). Changes in various charged clusters of U_L34 do not disrupt the interaction with U_L31 protein suggesting a hydrophobic region of the U_L34 protein may be responsible for the interaction or multiple areas interact (Bjerke *et al.*, 2003). Further work has indicated that amino acids 137–181 of UL34 protein are necessary and sufficient to interact with UL31 protein in the context of the infected cell (Liang and Baines, 2005). In the absence of U_L34, the U_L31 protein is more susceptible to degradation by the proteosome, and U_L31-specific epitopes localize mostly in the nucleoplasm (Ye and Roizman, 2000). In the reverse situation, the U_L31 protein is necessary for exclusive localization of U_L34 protein to the nuclear rim (Reynolds *et al.*, 2001).

Taken together, it is likely that the U_L31 and U_L34 proteins form a complex that is targeted to the nuclear rim. In many cell types, this targeting requires expression of both proteins. In rabbit skin cells, however, U_L34 protein localizes to the NM of infected cells even in the absence of U_L31 (Liang *et al.*, 2004). Thus, in certain situations, host cell functions are sufficient to properly target U_L34 protein to the NM.

The similarity of the U_L31/U_L34 protein complex to coupled pairs of lamin receptors and lamins is striking. For example, emerin, like U_L34 protein, is a type II integral membrane protein that interacts with lamin A/C (Clements *et al.*, 2000). Like lamin A/C, U_L31 integrates into the nuclear lamina and becomes associated with the nuclear membrane via binding its cognate lamin receptor (in this case U_L34 protein) at the nuclear membrane. Thus the U_L31/U_L34 protein protein complex is retained efficiently and invariantly at the nucleoplasmic surface of the INM.

Budding from the nuclear membrane

A prominent hypothesis is that the U_L31 and U_L34 proteins are retained at the inner nuclear membrane to engage nucleocapsids during envelopment. Support for

this hypothesis includes the observations that (i) U_L34 protein can interact with ICP5, the major capsid protein (Ye *et al.*, 2000), and (ii) both the U_L31 and U_L34 proteins are incorporated into virions that accumulate between the lamellae of the nuclear membrane. The latter indicates that the U_L31 and U_L34 proteins, directly or indirectly, interact with nucleocapsids in vivo (Reynolds *et al.*, 2002). Neither the U_L31 or U_L34 proteins are detectable in extracellular virions by electron microscopic immunogold staining. Thus, previous observations that the U_L34 protein was present in immunoblots of virions prepared from cytoplasmic lysates probably reflects the presence of at least some perinuclear virions in the cytoplasmic virion preparations (Purves *et al.*, 1992). It is presumed that the U_L31 and U_L34 proteins are released from the nascent virion envelope when this fuses with the outer nuclear membrane and the de-enveloped nucleocapsid is released into the cytoplasm. More detailed information on the cytoplasmic egress pathways of alphaherpesviruses is indicated in Chapter 12 of this volume.

US3: a kinase that phosphorylates U_L34 and U_L31 proteins

The U_L34 and U_L31 proteins are phosphorylated by the protein encoded by U_S3 (Purves *et al.*, 1991; Kato *et al.*, 2005; Poon and Roizman 2005). The U_S3 protein is not essential for growth of HSV in cell culture, but in the absence of U_S3, the onset of production of infectious virus is slightly delayed, and peak infectious titers are reduced about 30-fold, depending on the cell line (Purves *et al.*, 1987; Reynolds *et al.*, 2002). In the absence of U_S3, the architecture of the nuclear membrane is altered such that the membrane contains enveloped virions within round punctate extensions of the nuclear membrane. The virions in these regions also contain U_L31 and U_L34 proteins. It has been speculated that the presence of virions in these punctate nuclear membrane extensions (for simplicity of discussion, here termed NM evaginations) reflects a delay in egress from the perinuclear space (Klupp *et al.*, 2001; Reynolds *et al.*, 2002). The formation of NM evaginations is precluded by U_S3-encoded protein kinase activity (Ryckman and Roller, 2004). Interestingly, NM evaginations do not occur in cells infected with viruses bearing mutations that obviate U_L34 phosphorylation by U_S3. Thus, substrate(s) of the U_S3 kinase other than U_L34 protein are relevant to these particular NM perturbations. The identity of these novel substrate(s) is of considerable interest, and U_L31 is a lead candidate to explain the effects of U_S3 on virion envelopment at the INM .

gK

The localization of gK at the ultrastructural level has yet to be determined, largely because few epitopes in this mostly hydrophobic protein are recognized by available antibodies. In monolayers of tightly packed Vero cells infected with a U_L53 deletion mutant, nucleocapsids accumulate in the nucleus and few are detected in the cytoplasm, suggesting that at least under some conditions, gK plays an important role in nucleocapsid envelopment at the INM (Jayachandra *et al.*, 1997). How the protein facilitates nucleocapsid envelopment is not known.

U_L11

The U_L11 protein, composed of 96-residues, is both myristoylated and palmitoylated (Loomis *et al.*, 2001; MacLean *et al.*, 1989). Both modifications contribute to the association with membranes whereas an acidic cluster mediates trafficking from the plasma membrane to the Golgi apparatus in uninfected cells (Loomis *et al.*, 2001). Cells infected with the U_L11 deletion virus produce infectious virus at levels 100–1000-fold below those of wild-type viruses (Baines and Roizman, 1992). The most striking abnormalities in cells infected with this mutant are abundant unenveloped nucleocapsids in the cytoplasm and abutting the INM. These observations suggest roles in nucleocapsid envelopment at the nuclear membrane or completion of the envelopment reaction, and a second defect in cytoplasmic egress. The latter could reflect a defect that causes de-envelopment or one that precludes re-envelopment at cytoplasmic membranes. Although the U_L11 protein is targeted to the INM and cytoplasmic membranes of infected cells, the protein localizes primarily to the Golgi apparatus in uninfected cells (Baines *et al.*, 1995; Loomis *et al.*, 2001). The disparity between localization in infected and uninfected cells suggests that other infected cell proteins, or alteration of membranes or membrane trafficking by HSV helps mediate trafficking of the U_L11 protein to the nuclear membrane.

U_L37

Unlike many tegument proteins, the low U_L37 protein copy number in the virion tegument is invariant (McLaughlin, 1997), suggesting that it binds a repetitive structure on the nucleocapsid, and might serve as a limiting factor for tegument formation. A likely repetitive feature of nucleocapsids, and possible binding point of UL37 protein, would include capsid pentons which are structurally distinct from hexons and are believed to serve as anchor points for the

tegument (Zhou *et al.*, 1999). In pseudorabies virus, the ortholog of U_L37 has been termed a primary tegument protein to indicate its presence in the tegument layer most intimately assocated with the surface of the nucleocapsid (Mettenleiter, 2002). Deletion of U_L37 does not greatly affect production of nucleocapsides, but causes most of these to remain in the nucleus at time after infection when large amounts of cytoplasmic particles would be expected (Desai *et al.*, 2001). Thus U_L37 is ultimately dispensable for nucleocapsid envelopment, but greatly facilitates the process. Taken together, the data suggest the (perhaps oversimplified) hypothesis that U_L37 protein association with intranuclear capsids serves to bridge the nucleocapsid to a U_L37-interacting protein in the envelopment apparatus at the INM, but how pU_L37 becomes incorporated into the tegument, or whether it interacts with appropriate envelopment proteins to accomplish a bridging function have yet to be determined.

Model of nucleocapsid envelopment at the INM

A model for nucleocapsid envelopment at the nuclear membrane that is consistent with the above data is as follows. (i) The U_L31 protein is imported through the nuclear pores via its N-terminal nuclear localization signal. The protein interacts with the globular tail domain of lamin A/C and thereby becomes incorporated into the nuclear lamina. (ii) The U_L34 protein becomes incorporated into the ER membrane via its C-terminal transmembrane domain with the bulk of the protein located in the cytoplasm. The protein migrates past the nuclear pore complex and into the INM where it engages U_L31 protein located in the lamina, causing it to become anchored in the INM. (iii) Chromatin and associated lamins are displaced from regions containing U_L31 and U_L34 proteins and the conformation of lamins is significantly altered directly or indirectly by the U_L31/U_L34 protein complex, resulting in localized thinning of the lamina. (iv) several other viral proteins including gD, gB, gM, gK, and U_L11 protein are recruited to patches on the nuclear membrane that correspond to areas of lamin thinning. These regions also contain the U_L31 and U_L34 protein complex. (v) Nucleocapsids engage at least the U_L34 protein to initiate nucleocapsid budding at the INM. As a result of the budding reaction, the U_L31, U_L34, and U_L11 proteins, along with gB, gD, gK, and gM (as well as other unidentified proteins) become incorporated into nascent virions (vi) The envelopes of virions within the perinuclear space fuse with the outer nuclear membrane (ONM). The U_L31 and U_L34 proteins are left at the ONM, and the de-enveloped nucleocapsid proceeds into the cytoplasm to receive another membrane from a cytoplasmic organelle.

Although the above model is consistent with current observations, it is likely that certain aspects (and future surprises) will invite revision as more data accumulates. The usefulness of the model lies in its many testable predictions, and it is hoped that such a paradigm will invite vigorous experimentation in the future.

The egress of alphaherpesviruses from the cell

Gabriella Campadelli-Fiume

Department of Experimental Pathology, Studiorum-University of Bologna, Italy

A commonly accepted concept in herpesvirology holds that herpesvirions are formed by budding of nucleocapsids at the inner nuclear membrane and the enveloped virions are released into the perinuclear space (see Chapter 13). This is a closed compartment that virions need to exit, in order to reach the extracellular space and start a new infection cycle. How alphaherpesviruses accomplish this goal is a controversial issue. Of the two pathways of virus exit proposed, the single envelopment and the double envelopment, also referred to as de-envelopment–re-envelopment, each has evidence and supporters in the literature (the topic has been covered in excellent reviews and papers (Enquist *et al.*, 1998; Skepper *et al.*, 2001; Johnson and Huber, 2002; Mettenleiter, 2002). Part of the uncertainties that still dominate this topic comes from the difficulties in interpreting static electron microscopy images. Thus cytoplasmic virions juxtaposed to curved vesicles were interpreted in some studies as budding virions, i.e., as evidence for secondary envelopment and for the deenvelopment-reenvelopment pathway. In other studies they were interpreted as virions undergoing fusion with encasing vesicles, i.e., as evidence of de-envelopment (Campadelli-Fiume *et al*, 1991: Roizman and Knipe, 2001). To solve these ambiguities, several approaches have been undertaken in recent years, including the generation of genetically modified mutants and cytochemistry.

In the single envelopment pathway, credited to a study by Johnson and Spear (Johnson and Spear, 1982) in which monensin was observed to block herpes simplex virus (HSV) glycoprotein maturation and to induce the accumulation of virions in large cytoplasmic vacuoles, virions leave the perinuclear space by becoming encased in vesicles–vacuoles formed by the outer nuclear membrane (Fig. 12.1, left pathway). At this stage they carry immature oligosaccharides in their glycoproteins and glycolipids. The virion-encasing vesicles then travel along the exocytic or secretory pathway, and interact with membranes of the exocytic pathway, mainly the Golgi apparatus, leading to a modification in their content of glycosyl transferases and glycosidases that results in the *in situ* maturation of the oligosaccharides of viral glycoproteins. The mature virions are then released in the extracellular space by fusion of the virion-encasing vesicle with the cytoplasmic face of the plasma membrane. In this pathway the virion maintains the tegument acquired in the nucleus as well as the envelope acquired at the inner nuclear membrane, hence the glycoprotein species present in the initial envelope do not change, but their oligosaccharidic moieties are subject to maturation.

In the de-envelopment–re-envelopment pathway, originally proposed by Stackpole in a study of frog herpesvirus (Stackpole, 1969), the envelope of the virions present in the perinuclear space fuses with the outer nuclear membrane (de-envelopment), thus releasing the nucleocapsids into the cytoplasm. The de-enveloped nucleocapsids acquire a tegument in the cytoplasm and undergo a secondary envelopment (re-envelopment) by nucleocapsid budding into a *trans*-Golgi compartment or *trans*-Golgi network (TGN), or, into an endosomal compartment (Harley *et al.*, 2001) (Fig. 12.1, right pathway). As the virus buds from these membranes, the membrane gives rise simultaneously to the envelope and to a vesicle that surrounds the enveloped virion. The final release of the virions into the extracellular space takes place by fusion of the virion-encasing vesicle with the cytoplasmic face of the plasma membranes, just as it occurs in the single envelopment pathway. In this pathway the virus acquires in the cytoplasm a tegument and a secondary envelope, both of which may differ in protein composition from the ones acquired at the primary envelopment.

The key differences between the two routes are (i) the number of envelopes that the virus acquires: one

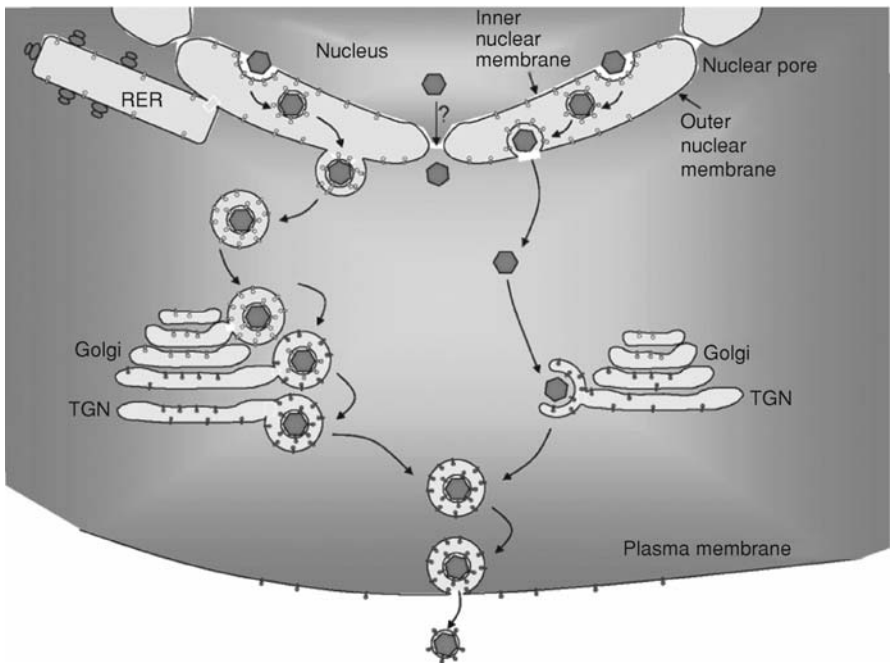

Fig. 12.1. Schematic drawing showing the two alternative pathways of alphaherpesvirus egress from infected cells. The single envelopment pathway is depicted to the left, and the double envelopment, or de-envelopment-re-envelopment is depicted to the right of the illustration. The schematic drawing does not shows the gross ultrastructural modifications of the Golgi apparatus and TGN. Perinuclear virions and nuclear membranes are decorated with glycoproteins of different color than virions at the level of the Golgi apparatus and TGN, as well as extracellular virions, to emphasize that the oligosaccharide moieties of the viral glycoproteins are of the immature type in early exocytic compartment, but are of the mature type in the late exocytic compartments and in extracellular virions. The drawing considers also the possibility that nucleocapsids exit the nucleoplasm through modified nuclear pores, without transiting through the perinuclear lumen. (Drawing by courtesy of L. Menotti.) (See color plate section.)

in the single envelopment, two in the de-envelopment-re-envelopment pathway; the composition of the two envelopes may well differ one from the other; (ii) The significance of the capsids in the cytoplasm. In the single envelopment pathway, the cytoplasmic nucleocapsids are dead-ends that result from fusion of the envelope with the membrane of the virion-encasing vesicles (Campadelli-Fiume *et al.*, 1991). In the de-envelopment–re-envelopment pathway, they are the key players for the secondary envelopment. (iii) The site of tegument assembly, which is necessarily the nucleus in the single envelopment pathway, and can be either the nucleus or the cytoplasm in the double envelopment egress. In the latter case, the tegument may even be absent from perinuclear virions.

In recent years there has been a growing consensus in favour of the de-envelopment–re-envelopment pathway for egress of both HSV and varicella zoster virus (VZV) (Jones and Grose, 1988; Enquist *et al.*, 1998; Wang *et al.*, 2001; Mettenleiter, 2002). As some crucial questions concerning this route remain unsolved, both models are presented here, along with the evidence in favour of or against each of the pathways. For an elegant and in-depth analysis of both pathways, and of strengths and weaknesses of the lines of evidence, also see Enquist *et al.* (1998).

HSV

Single envelopment pathway

Evidence and arguments in favor

A major virtue of this pathway is its simplicity. It became widely accepted some years ago, and was supported by three lines of evidence.

(i) When analyzing the types of oligosaccharides that are present in the glycoproteins and in the glycoplipds of the virion envelope, the model predicts that the perinuclear virions carry immature glycomoieties, the extracellular virions carry mature glycomoieties, and the cytoplasmic virions carry both intermediate and mature glycomoieties. This intermediate type of glycomoieties cannot

be present in virions formed in the de-envelopment–re-envelopment pathway, unless the secondary envelopment takes place at the *cis*- or *medial*-Golgi. If this is the case, then the question arises "how does the virion travel from *cis*- or *medial*-Golgi to farther compartments of the exocytic pathway in order to obtain its final envelope with mature oligosaccharides?" When the HSV oligosaccharides were characterized in a cytochemical study, it was found that perinuclear virions carry immature oligosaccharides, the intracytoplasmic virions carry both intermediate and mature types of oligosaccharides, and extracellular virions carry exclusively mature oligosaccharides (Di Lazzaro *et al.*, 1995).

(ii) A similar line of reasoning applies to the significance of the markers of the *cis*- and *medial*-Golgi in extracellular virions. It is a well-known phenomenon that viral envelopes carry cellular proteins that are constituents of the membranes where budding of virions occurred, or of the compartments which the virus transited. As a consequence, the cellular proteins that are present in the envelope of extracellular virions are indicators of the cellular membranes from which the envelope was derived, or through which the viruses transited. Specifically, if virions undergo a secondary envelopment at *trans*-Golgi or TGN, the extracellular virions are not expected to carry proteins typical of *cis*- or *medial*-Golgi. By contrast, if these markers are present in the extracellular virions, two mutually exclusive implications are possible, i.e., either the virions transited through *cis*- or *medial*-Golgi, as is the case for the single envelopment pathway, or budding took place at *cis*- or *medial*-Golgi. As discussed above, if this is the case, the same question as above arises: "How does the virion move from *cis*- *medial*-Golgi to *trans*-Golgi or TGN?" A detailed immunocytochemical study, summarized below, has been conducted in neurons, and showed that extracellular virions carry giantin and mannosidase II, two markers typical of *cis*- and *medial*-Golgi, respectively (Miranda-Saksena *et al.*, 2002).

(iii) A further issue centers on the glycoprotein composition of the perinuclear virions, and particularly whether the glycoproteins required for virion infectivity are acquired during envelopment at the inner nuclear membrane. It is a well established notion that HSV infectivity requires the four glycoproteins gB, gD, gH, gL (see Chapter 7). Perinuclear virions were isolated from cells infected with a UL20-deletion virus, which induces the accumulation of virions in the perinuclear space. They are infectious, implying that they carry the four glycoproteins gB, gD, gH, gL (Baines *et al.*, 1991; Avitabile *et al.*, 1994a). The actual presence of the essential glycoproteins at nuclear membranes and at the perinuclear virions was established in *in situ* experiments for the two glycoproteins that were analyzed: gD and gB (Torrisi *et al.*, 1992; Skepper *et al.*, 2001; Miranda-Saksena *et al.*, 2002). All in all, the essential glycoproteins that were searched for have been detected in perinuclear virions, suggesting that, if the de-envelopment–re-envelopment takes places, it is not a requirement in order for the virus to obtain its asset of essential glycoproteins.

Evidence and arguments against

There are two major lines of evidence against the single envelopment model. They are: the presence of the UL31 and UL34 proteins at the nuclear membranes and at the perinuclear virions, and their concomitant absence from extracellular virions, and the lipid composition of the virion envelope (van Genderen *et al.*, 1994; Reynolds *et al.*, 2001, 2002). Both rest on the notion that the chemical composition of the virion envelope reflects the composition of the membrane where nucleocapsid budding took place.

(i) The UL31 protein is a matrix-associated phosphoprotein that localizes to the nuclear membranes in the infected cells, and when coexpressed with the UL34 protein (see Chapter 13). The UL34 protein is a predicted type-2 membrane-bound phosphoprotein with the bulk of the protein constituting the endodomain exposed to the interior of the nucleus. It requires the UL31 protein for localization at the nuclear envelope. The two proteins are required for virus envelopment. Specifically, electron microscopic analyses show that morphogenesis of a UL34 gene deletion virus proceeds to the point of formation of DNA-containing nuclear capsids, but enveloped virus particles in the cytoplasm or at the surface of infected cells are absent, suggesting that the UL34 protein is essential for efficient envelopment of capsids. The phenotype of the UL31 gene deletion virus is similar (Roller *et al.*, 2000; Ye and Roizman, 2000). Remarkably, both proteins are present at perinuclear virions but absent from the extracellular virions, providing evidence that the primary envelope differs in composition from the envelope of extracellular virions. This strongly argues in favour of the de-envelopment-re-envelopment pathway (Reynolds *et al.*, 2001, 2002). The same localization is observed with pseudorabies virus (PrV) UL31 and UL34 proteins (Fuchs *et al.*, 2002). An alternative explanation for the absence of UL31 and UL34 proteins from the extracellular virions would be that a specific protease degrades these two proteins during virus maturation, in analogy to what happens for the scaffolding protein VP26, or, less likely, that epitopes become masked.

(ii) The phospholipid composition was determined in infected cells fractionated into three fractions: a nuclear fraction (which contains nuclei and virions at perinuclear space), a cytoplasmic fraction (which contains the

cytoplasmic membranes, the intracytoplasmic virions and the plasma membranes), and a fraction consisting of extracellular virions. It was found that the phospholipid composition of extracellular Herpes Simplex virions and of the cytoplasmic fraction differs from that of nuclei, in that the former contains threefold higher concentrations of sphingomyelin and phosphatidylserine, lipids that are typically enriched in the Golgi apparatus and plasma membrane (van Genderen *et al.*, 1994). This difference implies that the lipid composition of the envelope acquired at the inner nuclear membrane differs from that of extracellular virions. It has been interpreted as evidence in favour of the de-envelopment–re-envelopment pathway (Enquist *et al.*, 1998), even though alternative mechanisms for the modification in lipid composition may be envisioned, e.g., exchange of lipids between the virion envelope and the Golgi membranes during exocytosis in the single envelopment pathway (van Genderen *et al.*, 1994).

De-envelopment–re-envelopment pathway

Evidence and arguments in favor

A major virtue of the double envelopment route of egress is that the separate transport of nucleocapsids and glycoproteins, and their assembly into virions at the cell periphery seems a rational way of transport in the neuron: a key host cell for HSV. In addition to the localization of the UL31 and UL34 proteins, and to the lipid composition of the virion envelope, discussed above, three lines of evidence argue in favour of a double envelopment process, namely the separate transport of nucleocapsids and glycoproteins in neuronal axons, the phenotype of mutants carrying deletions in tegument genes or multiple deletions in glycoprotein genes with accumulation of unenveloped nucleocapsids in the cytoplasm, and the differential distribution of a form of gD retargeted to the endoplasmic reticulum.

(i) A first line of evidence for separate transport of capsids and viral glycoproteins was provided in an electron microscope study of HSV assembly in neurons. Capsids were observed migrating in anterograde direction within axons, whereas the viral glycoproteins (gD) were observed in vesicles which do not colocalize with nucleocapsids, suggesting that virion assembly in axons represents a final step that occurs at the axon end (Penfold *et al.*, 1994).

(ii) Tegument assembly: the tegument is one of the most complex and least understood components of the virion, in terms of structure, assembly and role in virus entry and in virion morphogenesis. Functionally, it is analogous to the matrix layer of other viruses, as it connects the capsid to the intravirion tails of the envelope glycoproteins. Its role is twofold. First, it delivers into the cytosol of the infected cell virion components which are immediately available to the viral metabolism, before the onset of viral protein synthesis. These components facilitate the initiation of infection. Two such examples are *alpha*-TIF (α-*trans*-inducing factor), also named VP16, and *vhs* (virion host shut off), the product of UL41 gene (Batterson *et al.*, 1983; Read and Frenkel, 1983; Campbell *et al.*, 1984).The second function is structural (Mossman *et al.*, 2000). In terms of composition, it is made of almost 20 proteins (see Chapter 7). Despite its amorphous appearance, the tegument appears to contain an inner and an outer layer, of different composition. For both HSV and PrV, the inner layer contains the products of the UL36 (VP1/2) and UL37 genes. The UL36 protein interacts with the major capsid protein, ICP5, which forms both pentons and exons. The outer layer includes major components, UL48-αTIF-VP16, UL49-VP22, *vhs*, and minor components, UL11, UL13-PK (protein kinase), UL14, UL21, UL46-Vp11/12, UL47-VP13/14, UL51, UL56, US3-PK, US10, US11.

Studies of tegument assembly were interpreted as evidence that the site of assembly is the cytoplasm. They fall into two series: electron microscopic analysis and the phenotype of mutant viruses deleted in the tegument-encoding genes.

Work performed mainly with PrV indicates that intranuclear nucleocapsids do not contain a well-defined tegument, detected as an electrondense layer surrounding the capsid, whereas extracellular virions and cytoplasmic nucleocapsids contain an electrondense tegument (Mettenleiter, 2002). In line with these observations, in live virus-infected cells the tegument protein VP22 is observed almost exclusively in the cytoplasm, favoring the cytoplasm as the site of tegument assembly (Elliott and O'Hare, 1999).

In terms of deletion mutant viruses, the UL36 protein appears to play a critical role in tegument assembly, since in its absence capsids acquire the envelope at the inner nuclear membrane, are subsequently translocated into the cytoplasm, but do not mature into enveloped virus and do not exit the cell. Also the deletion of HSV UL37 gene abrogates virus maturation and induces a phenotype similar to that induced by the UL36 gene deletion (Desai, P. J., 2000; Desai, P. *et al.*, 2001). The physical interaction between UL36 and UL37 proteins has been demonstrated in PrV (Klupp *et al.*, 2002). These phenotypes have been interpreted to mean that a defect in tegument assembly hampers the secondary envelopment with consequent accumulation of cytoplasmic nucleocapsids, although they do not formally prove it (Desai, P. J., 2000).

In contrast to the effect of UL36 and UL37 deletions, virion morphogenesis is not hampered in a VP22 deletion mutant HSV, nor in a number of deletion mutant viruses

in the genes encoding other tegument proteins (Pomeranz and Blaho, 2000; Mettenleiter, 2002). A defective phenotype is however observed in the deletion mutant virus of α-TIF, a phenotype complicated by the fact that the protein has two functions, i.e., it is a potent transactivator of α-genes and is required for the structural integrity of the tegument (Batterson *et al.*, 1983; Campbell *et al.*, 1984; Ace *et al.*, 1988; Mossman *et al.*, 2000). The observation that most of the deletion mutants in tegument genes fail to induce a defect in virus assembly and production has been interpreted as evidence that tegument proteins play redundant functions, and that the absence of a single tegument protein does not hamper tegument assembly (Mettenleiter, 2002).

An immunocytochemical study of tegument assembly and envelope acquisition in rat dorsal neurons showed that the site of HSV tegument assembly is the cytoplasm of the neuronal cell body and that major sites of envelope acquisition are the vesicles of the Golgi and TGN. Evidence rested on the finding that the tegument proteins VP13/14, VP16, VP22, and US9 were readily detected in the nucleus, but almost absent from the budding virions at the nuclear membranes and from virions in the perinuclear space. By contrast, they were abundant on cytoplasmic unenveloped and enveloped nucleocapsids and in extracellular virions (Miranda-Saksena *et al.*, 2002). Of note, the same pattern of labelling was observed for gD. Altogether, the results of this study were interpreted as evidence that the pathway of virion egress from the cell body of neurons does not differ from the pathway of egress from axons during anterograde transport, and follows the de-envelopment–re-envelopment pathway. As mentioned above, in this same study the extracellular virions and the cytoplasmic vesicles also labelled for markers of *cis*- and *medial*-Golgi and of TGN. The significance of this finding was not discussed (Miranda-Saksena *et al.*, 2002).

(iii) Multiple deletion of glycoprotein genes, especially non essential glycoproteins. Practically all HSV glycoproteins, both essential and non-essential, have been deleted singly or in groups, and none of the deletion viruses is defective in virus transport out of the perinuclear space (Longnecker *et al.*, 1987; Longnecker and Roizman, 1987; Cai *et al.*, 1988; Ligas and Johnson, 1988; Forrester *et al.*, 1992; Baines and Roizman, 1993; Roop *et al.*, 1993; Dingwell *et al.*, 1994), suggesting that no single glycoprotein plays a critical role in virus exocytosis. The exceptions are the gK- and UL20-deletion mutant viruses discussed below. In contrast, viruses carrying multiple deletions in glycoprotein genes exhibited defects in virus morphogenesis, cumulatively suggesting that gE, gI and gD participate in secondary envelopment and that they act in a redundant manner, such that viruses carrying single or double deletions do not exhibit a marked phenotype, whereas viruses carrying a triple deletion do (Farnsworth *et al.*, 2003). Specifically, gE and gI play a role in the cell-to-cell spread of HSV, visible in untransformed cells (see below). gM is an abundant glycoprotein conserved in all human herpesviruses. While its conservation argues for a role of the glycoprotein, a deletion mutant virus has no phenotype in cell culture. In PrV the simultaneous deletion of gE–gI and gM drastically inhibits plaque formation and replication, and induces the accumulation of nucleocapsids in cytoplasmic areas where tegument proteins accumulate (Brack *et al.*, 1999). This phenotype indicates that the deleted glycoproteins are cumulatively responsible for secondary envelopment. Following these observations, HSV deletion viruses in gE–gI or gE–gI–gM have been constructed. Remarkably, they exhibit no defect in growth, plaque formation, particle to PFU ratio, hence they carry none of the defects of the triple deletion PrV mutant (Browne *et al.*, 2004). In an independent work, HSV mutants carrying a double or a triple deletion in gD–gE or gD–gE–gI, respectively, exhibited severe defects in envelopment, detected as accumulation of a large number of unenveloped nucleocapsids in the cytoplasm (Farnsworth *et al.*, 2003). These aggregated capsids were immersed in an electron-dense layer that appeared to be tegument. Because none of the glycoproteins, when deleted singly, produced this phenotype, it was proposed that gD and the gE–gI act in a redundant fashion to enable the interaction of the virion envelope with tegument-coated capsids. In the absence of either one of these HSV glycoproteins, envelopment proceeds; however, without both gD and gE, or gE/gI, an inhibition of cytoplasmic envelopment is observed (Farnsworth *et al.*, 2003).

(iv) A form of gD carrying an endoplasmic reticulum (ER) retrieval motif. The rational of this study was to engineer into HSV a form of gD carrying an ER-retrieval motif. The ER-retrieved gD was expected to be present at the ER and the nuclear membranes, which are continuous with the ER, but not to travel along the exocytic pathway. Virions at the perinuclear space were expected to be decorated with gD; virions undergoing de-envelopment–re-envelopment were expected to exchange this envelope, so that extracellular virions would be devoid of gD (Whiteley *et al.*, 1999; Skepper *et al.*, 2001). When analyzed by immunocytochemistry, the perinuclear virions and the nuclear membranes were indeed decorated with the ER-retargeted gD, whereas the extracellular virions and the plasma membrane were not (Whiteley *et al.*, 1999; Skepper *et al.*, 2001). These results are consistent with a double envelopment route of egress. However, in the same study quantification

of the distribution of gD in wild-type virus-infected cells showed that the plasma membranes contained 20-fold less, or even lower amount of gD than the nuclear and cytoplasmic membranes (Skepper *et al.*, 2001). This contrasts with the detection of gD in approximately the same amounts at the nuclear membranes and at the plasma membranes in a fracture-label study, with the abundant detection of gD at the plasma membrane by immunofluorescence, and with the detection of gD more abundantly at the plasma membrane than at the nuclear membranes in neurons and raises the possibility that the degree of detection may be affected by the specific reactivity of the antibodies employed (Torrisi *et al.*, 1992; Miranda-Saksena *et al.*, 2002).

Evidence and arguments against

(i) The major weakness of the de-envelopment–re-envelopment pathway is the inability to explain how virions leave the perinuclear space (Campadelli-Fiume and Roizman, 2006). The pathway envisions that perinuclear virions fuse with the luminal face of the outer nuclear membrane, thus releasing the de-enveloped nucleocapsids in the cytoplasm. The glycoproteins necessary for the HSV fusion that leads to virus entry are the quartet of gB, gD, gH, gL (Cai *et al.*, 1988; Ligas and Johnson, 1988; Forrester *et al.*, 1992; Roop *et al.*, 1993). These same glycoproteins are necessary and sufficient to induce cell–cell fusion when transiently expressed in transfected cells (Turner *et al.*, 1998) (see Chapter 7). Absence of each member of the quartet abolishes virion infectivity and fusion in the cell–cell fusion assay, but does not cause any defect in the release of (non-infectious) virions to the extracellular space. Paradoxically therefore, the perinuclear virions of the deleted viruses are able to carry out fusion with the outer nuclear membrane in the absence of each one of the known viral fusion glycoproteins.

To solve this conundrum, three alternative possibilities can be envisioned. First, some of the non-essential glycoproteins or membrane proteins which form the envelope of the perinuclear virions substitute for the fusion activity of the quartet. As a corollary, deletion mutants in these putative fusion proteins are expected to accumulate in the perinuclear space and be defective in the release of extracellular virus. Apart from the fact that a fusion activity has not been observed with ensembles of HSV glycoproteins other than the quartet (Turner *et al.*, 1998), deletion viruses have been produced for almost all of the non essential glycoproteins (gC, gE, gI, gJ, gG, gM), and they are not defective in the release of virions to the extracellular space (Longnecker *et al.*, 1987; Longnecker and Roizman, 1987; Cai *et al.*, 1988; Ligas and Johnson, 1988; Forrester *et al.*, 1992; Baines and Roizman, 1993; Roop *et al.*, 1993; Dingwell *et al.*, 1994). This makes it unlikely that the non-essential envelope proteins carry out fusion with the outer nuclear membrane. The phenotype of two deletion viruses is interesting under this respect. They are a gK-minus and a UL20-minus virus (Baines *et al.*, 1991; Avitabile *et al.*, 1994b; Hutchinson and Johnson, 1995). The first-generation deletion viruses exhibit an accumulation of virions at the perinuclear space. The second-generation deletion mutants are still defective in virus egress, but the unenveloped nucleocapsids appear to accumulate in the cytoplasm rather than in the perinuclear space (Foster and Kousoulas, 1999; Foster *et al.*, 2004). This phenotype is consistent with the hypothesis that gK and/or UL20 proteins, singly or in association, enable fusion. Because these proteins accumulate at the ER, or in the Golgi, but only in minimal quantity, or not at all, in the plasma membrane, when expressed by transgenes (Avitabile *et al.*, 2003, 2004; Foster *et al.*, 2003), the possibility that they induce fusion at the nuclear membranes can not be tested.

Secondly, it can be envisioned that fusion of perinuclear virions with the outer nuclear membranes is carried out by cellular proteins, e.g. members of the v-SNARE and t-SNARE family. This possibility appears untenable because of the topology of these proteins, whose functional domains are located in the cytoplasmic face of the cytoplasmic vesicles. They would need to flip–flop to the luminal face, while maintaining their activity, and travel all the way to the outer and then to the inner nuclear membrane, in order for perinuclear virions to carry them in their envelope. Further yet, these proteins need a number of membrane-bound and soluble factors, all of which are absent from the perinuclear space.

All in all, the virus has to rely on viral fusion proteins other than those known to date in order to exit the perinuclear space, and an unconventional and so far totally elusive mechanism of fusion must be hypothesized in order to explain how virions leave the perinuclear space in the deenvelopment and re-envelopment pathway.

A third possibility is raised by the recent finding that in HSV-and BHV-infected cells the nuclear pores appear to be enlarged such that they allow the exit of nucleocapsids directly from the nucleoplasm to the cytoplasm (Wild and Engels, 2004; Leuzinger *et al.*, 2005).

(ii) A second weakness of the double envelopment pathway is the failure to explain how the de-enveloped nucleocapsids travel from the cytoplasmic face of the outer nuclear membrane to the Golgi or TGN. As discussed in Chapter 7, nucleocapsids that do not travel along microtubules move very slowly (see the calculations that have been present for incoming nucleocapsids), and therefore

the de-enveloped nucleocapsids need to travel along some kind of cellular routes for efficient transport. Transport along microtubules seems untenable since the microtubule architecture is dramatically modified in the course of infection, a modification that appears to be conserved in herpesviruses (Avitabile *et al.*, 1995). The infected cell microtubules form circular rings at the periphery of the cell, and seem rather unsuitable to export nucleocapsids from outside the outer nuclear membrane to the TGN.

Finally, as mentioned above, the presence of *cis*- and *medial*-Golgi markers in extracellular virions produced by neurons suggests that either these membranes were the site of secondary envelopment, or that virions have transited through these compartments, with exchange of components, as may happen in the single envelopment route of egress (Miranda-Saksena *et al.*, 2002).

Cell-to-cell spread

The prominent route by which HSV infection spreads in human tissues is cell-to-cell spread, i.e., the direct passage of progeny virus from an infected cell to an adjacent cell. This occurs at primary infection when progeny virus spreads from the primary infected cell to adjacent cells in the mucocutaneous tissue and then to axonal termini of sensory neurons (retrograde transport). It also occurs at reactivation from latency, when newly replicated virus spreads from the sensory neuron to the mucocutaneous tissue (anterograde transport). It is generally assumed that this mechanism of spread represents an immune evasion strategy, as it shields the virus from antibodies and cells of the immune system. The simplest models of cell-to-cell transmission in cell cultures are plaque formation and the infectious center assay. Some of requirements are relatively well characterized, and coincide with those for virus entry, i.e., the quartet of gD, gB, gH, gL and the presence of a gD receptor on target cells. In addition, gE and gI play a critical role.

gE–gI

gE and gI form a functional heterodimer (gE–gI), found both in infected cell membranes and in virion envelopes (Johnson *et al.*, 1988), an attribute conserved in VZV and PrV (Zuckermann *et al.*, 1988; Yao *et al.*, 1993). The role of the gE–gI complex was not recognized in early studies because single deletion mutants are not hampered in their replication, or in the rate at which extracellular virus particles enter cells, whether the virus is applied to the apical or basolateral surfaces of the cells (Dingwell *et al.*, 1994). The lack of phenotype of the single deletion mutants has been later ascribed to the transformed cells in which they were characterized; in cells that form extensive cell junctions, like normal human fibroblasts and epithelial cells, the mutants are compromised (Collins and Johnson, 2003). The deleted viruses are also severely attenuated in vivo, and fail to spread efficiently into and within specialized circuits of the nervous system (Dingwell and Johnson, 1998). Several mechanisms appear to regulate the gE–gI-mediated cell-to-cell spread. Thus, gE–gI facilitate the movement of HSV across the extensive junctions formed between epithelial cells, fibroblasts, and neurons in vivo, likely by sorting the newly assembled virions to lateral surfaces and cell junctions (Johnson *et al.*, 2001), and by promoting envelopment into vesicles that are sorted to epithelial cells of junctions (Johnson and Huber, 2002).

US9

Although PrV is beyond the scope of this chapter, the role of US9 protein is better illustrated in this system. US9 protein is critical in axonal transport and in interneuronal spread of PrV (Enquist *et al.*, 1998; Brideau *et al.*, 2000). Structurally, it is a phosphorylated type II membrane glycoprotein present in the lipid envelope of viral particles and in the infected cell *trans*-Golgi network in a unique tail-anchored topology. Its maintenance in the TGN region is a dynamic process involving retrieval of molecules from the cell surface, mediated by an acidic cluster containing putative phosphorylation sites and by a dileucine endocytosis signal (Brideau *et al.*, 1999). The role of US9 protein in transneuronal spread of PrV was inferred by the phenotype of US9-null mutants, which exhibited a defect in anterograde spread in the visual and cortical circuitry of the rat. Hence, the US9 protein functions together with gE, and gI to promote efficient anterograde transneuronal infection and in the directional spread in the rat central nervous system (Brideau *et al.*, 2000; Tomishima and Enquist, 2001). The phenotype of the US9-null virus is consequent to the ability of the protein to regulate the intracellular traffic of viral proteins in axons. Specifically, in US9-null mutant infections the viral membrane proteins fail to enter axons, while the capsids and tegument proteins do enter axons. These findings have been interpreted as evidence that virion subassemblies, but not complete virions, are transported in the axon, and consequently that the final assembly of virions takes place at the axon periphery (Tomishima and Enquist, 2001). Although a detailed characterization of HSV US9 is missing, the PrV and HSV proteins are likely to behave in a similar manner.

VZV

As compared to HSV, there have been relatively few studies dealing with the topic of VZV egress; they were performed mainly by transmission electron microscopy and immunocytochemistry and made use of a limited number of viral mutants. Indeed, the wealth of deletion and genetically modified viruses that characterizes the studies of HSV egress has no match in VZV. Cumulatively, these studies led to the conclusion that the pathway of VZV egress involves envelopment at the TGN, thus favouring the idea that the virus undergoes a de-envelopement–re-envelopment process.

Three glycoproteins, gE, gI, and gB, play a role in VZV egress. A major focus has been on gE, the most abundant envelope glycoprotein. By contrast with HSV gE, VZV gE is essential (Jones and Grose, 1988; Mo *et al.*, 2000, 2002; Moffat *et al.*, 2004). Electron microscopy showed that gE is absent from perinuclear virions, but present in TGN-derived membranes, and in the cytoplasmic and extracellular virions. The TGN membranes acquire a flattened "C" shape and are decorated with the tegument proteins on the concave face, which appears to serve as a budding site for envelopment (Gershon *et al.*, 1994). gE carries several structural motifs. A tyrosine-based motif in the C-tail acts as a determinant for TGN-targeting, and was interpreted as a driving element for secondary envelopment at TGN (Zhu *et al.*, 1996). A detailed mutational analysis of this domain indicates that proper subcellular localization and cycling of gE depend not only on the tyrosine-containing tetrapeptide related to endocytosis sorting signals, but also on a cluster of acidic amino acids containing casein kinase II phosphorylatable residues (Alconada *et al.*, 1996). gE is phosphorylated by the tegument ORF47 protein kinase; phosphorylation is critical for gE trafficking to the TGN and for its recycling from the plasma membrane (Kenyon *et al.*, 2002). As mentioned above, in the UL47(PK) deletion mutant the lack of gE phosphorylation results in a recycling back to the plasma membrane (Kenyon *et al.*, 2002).

As in HSV, gE forms a complex with gI, and the gE–gI complex is a determinant of VZV cell-to-cell spread, as well as of the maturation, endocytosis and recycling from the plasma membrane of both glycoproteins (Alconada *et al.*, 1998, 1999; Olson and Grose, 1998; Mo *et al.*, 2002); The role of gI in virion morphogenesis was investigated in cells infected with VZV mutants lacking gI, or a portion of gI ectodomain. It was observed that the TGN loses the ability to bind tegument proteins, a property correlated with an overall reduction in cytoplasmic envelopment, and interpreted as confirmation that the TGN acts as site of envelopment (Wang *et al.*, 2001).

The key contribution of VZV gE to cell-to-cell spread is seen not only in cell cultures, but also in an elegant in vivo model developed by the Arvin laboratory, consisting of T-cells or skin cell xenografts in the SCHID-hu mice system (Santos *et al.*, 2000). Of note, in the same system, gI is necessary, despite the fact that it is dispensable in cell culture (Moffat, *et al.*, 2002).

Recent studies with VZV gE have greatly expanded the role of this glycoprotein in replication in general and egress in particular. As part of a larger project to produce recombinant VZV genomes, several mutations were introduced in the cytoplasmic tail of gE, and the mutated gE was inserted back into an otherwise complete VZV genome (Moffat *et al.*, 2004). A single mutation in the YAGL endocytosis motif was lethal, whereas other mutations were not. Shortly thereafter, endocytosis of gE was documented to be an important trafficking mechanism for the delivery of this glycoprotein to the site of virion assembly in the cytoplasm of infected cells (Maresova *et al.*, 2005). Altogether the properties of gE, its role in fusion, as well as the location of its gene next to that of gD in HSV genome (discussed in Chapter 7) make VZV gE the analogue of HSV gD.

A third protein that plays a role in VZV egress is gB, particularly its endodomain. As is the case with gB from HSV and other herpesviruses, the endodomain contains determinants for the intracellular transport and localization of gB, including an ER to Golgi transport signal, and two tyrosine-based internalization signals for trafficking from the plasma membrane to the Golgi. Deletion of the portion of gB endodomain encoding these motifs alters gB localization at the Golgi apparatus and drastically reduces the transport of VZvirions to the extracellular space (Heineman and Hall, 2001, 2002). VZV gB endocytosis, as it relates to fusion activity, has been reviewed in Cole and Grose (2003), and dealt with in Chapter 7.

Thus, in addition to gE, endocytosis of gB and also that of gH have been documented to be a means for their delivery from the surface of the infected cells to the cytoplasmic site of virion assembly (Pasieka *et al.*, 2003, 2004). These studies were performed by first biotinylating cell surface proteins, and then demonstrating that they were subsequently transported to purified virions isolated from infected cells by density gradient sedimentation (Maresova *et al.*, 2004). The results were confirmed by immunolabeling and transmission electron microscopy. Cumulatively, these findings highlight that endocytosis must be added to the trafficking pathways by which glycoproteins can be transported to the cytoplasmic site of envelopment, as part of the de-envelopment–re-envelopment model.

It should be noted that PrV gE does not follow the same trafficking pathways as VZV gE. Also PrV gE is endocytosed.

However, trafficking studies with PrV gE demonstrated that little or no gE from the cell surface is subsequently carried to and incorporated within the virion (Tirabassi and Enquist, 1999). These differences may be related to the fact that gE is an essential glycoprotein in VZV, but not in PrV.

A peculiar morphological feature of VZV egress, not observed with HSV or other herpesviruses, is the exit from the infected cell surface in a distinctive pattern designated as"viral highways." By scanning electron microscopy, these consist of thousands of particles arranged in a linear pathway across the syncytial surfaces. gE is a determinant of this polarized egress (Santos *et al.*, 2000).

Concluding remarks

A growing support to the de-envelopment-re-envelopment pathway of alphaherpesviruses exit has been provided in recent years. In some cases, the evidence rests on conclusions that are not unique, and alternative interpretations of data are possible. As outlined by Enquist and collaborators a few years ago, "evidence supporting both models of herpesvirus exit can be found, and neither model has been disproved conclusively" (Enquist *et al.*, 1998). This remark still holds true.

We also note that most of the attention has been paid to elucidate the role of viral gene products in virus exocytosis, while the contribution of cellular proteins, and of the exocytic compartment in general, has been largely neglected. Studies of the role of cellular functions is complicated by the fact that the cell is deeply modified following HSV infection, e.g., the Golgi apparatus is fragmented into small, but functional pieces, the TGN is redistributed, the architecture of nuclear and cytoplasmic cytoskeleton are altered (Campadelli-Fiume *et al.*, 1993; Avitabile *et al.*, 1995; Scott and O'Hare, 2001; Reynolds *et al.*, 2004; Wisner and Johnson, 2004), phenomena which contribute to mislocalization of cellular markers. These changes are strongly cell line dependent, and may contribute, in part, to apparent discrepancies between different studies. Finally, it is worth noting that most of the studies on alphaherpesviruses' exocytosis have been carried out in cultures of epithelial cells or fibroblasts. Exit from the neuronal cells may well be different.

Acknowledgments

I am grateful to A. Arvin, J. Baines and C. Grose for critical reading, and to L. Menotti for helpful discussion and artwork.

The strategy of herpes simplex virus replication and takeover of the host cell

Bernard Roizman and Brunella Taddeo

The Marjorie B. Kovler Viral Oncology Laboratories, The University of Chicago, USA

Introduction

The fundamental mission of all viruses is to replicate and spread, and above all, to persist in the host environment to which they have become adapted. Viruses vary with respect to the mechanisms by which they attain their objectives. This variation is reflected not only in the basic mechanisms of viral entry into cells, synthesis of viral proteins, viral nuclei acid synthesis, virion assembly, and egress but also with respect to the basic strategies by which they preclude the enormous resources of the host cell and of the multicellular organism from totally blocking viral replication. The terminology used: "totally blocking" is appropriate; in essence the evolution of functions encoded in the viral genome reflects a fundamental accommodation between replication and spread as well as persistence in the human population. A replication and spread that kills the host will not permit the survival of the virus. The objective of this chapter is to examine the basic strategies evolved by HSV to replicate in its cellular environment.

Gene content, organization, and fundamental design of the viral genome

Several aspects of the structure, content and function of the viral genome are worthy of note. They are as follows.

(i) We do not know with any degree of certainty the exact number of transcriptional units or proteins encoded by the viral genome. The problem stems from several considerations. The initial enumeration of open reading frames (ORFs) excluded sequences that lacked a TATA box, a canonical methionine intiation codon, a suitable length, or that situated antisense to a known or readily demonstrable ORF. The current list of HSV sequences that are expressed (see section on gene content) includes RNAs that do not appear to encode proteins (e.g., Ori_S RNAs), TATA-less ORFs (e.g., $\gamma_1$34.5), and ORFs that are antisense to each other (e.g., ORF P and ORF O vs. $\gamma_1$34.5, U_L43.5 vs. U_L43, U_L27.5 vs. U_L27, U_L9.5 vs. U_L10).

(ii) Viral proteins can express multiple functions. The order of expression of these functions may be regulated by post-translational modification of the proteins or by interacting proteins present within various compartments of the cell. For example, the interaction of ICP22 with cellular proteins is determined by the status of post-translational phosphorylation by viral kinases (Leopardi *et al.*, 1997b; Purves and Roizman, 1992; Purves *et al.*, 1993). Post-translational modification of ICP0 is also required for its ubiquitin-ligase activities (Boutell *et al.*, 2002; Hagglund *et al.*, 2002) but is not necessary for other functions required for optimal replication of the virus such as its interactions with CoREST (Gu *et al.*, 2005).

A powerful mechanism for regulation of specific functions encoded in a single protein is the synthesis from an independent transcriptional unit of a truncated protein whose sequence is colinear with the carboxyl-terminal domain of the larger protein. The functions encoded by the truncated proteins could enhance (e.g., U_S1.5 vs. α22) (Carter and Roizman, 1996; Purves *et al.*, 1993) or inhibit (U_L8.5 vs. U_L9) (Baradaran *et al.*, 1994) the function of the larger protein.

(iii) There is little doubt that herpes simplex virions contain at least three proteins (U_S11, U_L47 and U_L49) that bind RNA from the infected cell and translocate it into the newly infected cell (Roller and Roizman, 1990; Sciortino *et al.*, 2002). Evidence has been reported that this RNA can be expressed (Sciortino *et al.*, 2002). A central issue is the impact of this RNA on the outcome of infection. A fundamental unanswered question is why HSV would carry RNA rather than more tegument proteins. One argument presented by Shenk (2002) is that proteins destined to

membranes or secretory pathway would have to be made *de novo* and cannot be brought as components of the tegument.

(iv) The presence and function of the inverted repeats has been a long-standing puzzle. The repeats are present in many, but not in all herpesvirus genomes. Mutants lacking the inverted repeats replicate well in cultured cells but tend to be avirulent in experimental animals. The loss of virulence has been attributed to the loss of one copy of the $\gamma_1$34.5 genes but in fact one copy of the $\gamma_1$34.5 gene is sufficient to block the shut off of protein synthesis by activated protein kinase R (PKR) (He *et al.*, 1997a).

(v) As detailed in the section on gene content, more than half of the transcriptional units contained in the viral genome are not essential for viral replication at least in cultured cells. The functions encoded by many of these genes are unknown. Preliminary studies suggest that some genes may play a role in viral maturation or spread. Those that have been studied in detail (e.g., ICP0, U_L41, $\gamma_1$34.5, U_S3, U_L47, etc.) as well as some of the essential genes (e.g., α27) appear to encode function designed to block host responses to infection. The key observation relevant to this section is that viruses lacking non-essential genes do not circulate in nature and that in most instances mutants lacking one or more of these genes tend to be either incapable of replication or are less virulent than wild-type viruses in experimental animals.

In essence, the functional content of the HSV genome is not fully understood. We do not know the total number of diverse functions encoded by the viral genome. What is readily apparent is that many of the known functions encoded by the virus are directed toward total control of the infected cell. Some of these functions are redundant: they are expressed by different proteins but ultimately have the same objective. Since the functions of many "dispensable" proteins are not yet identified, there may be additional anti-host functions yet to be discovered.

Mobilization of cellular proteins for enhanced replication of HSV

There are three examples that illustrate recruitment and post-translational modifications that benefit viral replication. Current wisdom is that, on discharge of the viral DNA into the nucleoplasm, it is confronted by a wide range of cellular proteins that assemble around it and, if allowed to prevail, are likely to either enable minimal transcription or silence it, and viral transcriptional factors (e.g., α-transinducing factor or VP16) that activate transcription and ultimately enable its replication. Recent studies from several laboratories indicated the presence of histones associated with viral DNA but it is unclear whether the histones are associated with a small fraction or the vast majority of the DNA (Poon *et al.*, 2003). One perennial candidate for restructuring of DNA protein complexes to enable efficient transcription is ICP0, a product of the α0 gene (for review, see Hagglund and Roizman, 2004). ICP0 is a promiscuous transactivator of genes introduced into cells by infection or transfection, that is presumably of genes associated with cellular proteins but which have not yet assumed a tight chromatin structure. In recent studies unmodified ICP0, i.e., ICP0 made before significant accumulation of viral protein kinases, interacts with CoREST/REST and HDAC1 complexes and disrupts the interaction of HDAC1 with CoREST/REST complex (Gu *et al.*, 2005). Ultimately, late viral functions promote the export of CoREST and HDAC1 to the cytoplasm. This function of ICP0 is consistent with the hypothesis that activation of transcription of the viral genome is essential for efficient expression of viral genes and for denuding the DNA from cellular proteins that impede transcription and ultimately replication of viral DNA.

The second example centers on the observation that, early in infection, HSV-1 U_L13 kinase mediates the hyperphosphorylation of the translation elongation factor EF-1δ, an event associated with more efficient protein synthesis (Kawaguchi *et al.*, 1998). The U_L13 protein kinase is highly conserved among members of all three subfamilies of herpesviruses and studies on representative members indicate that this function of the U_L13 orthologs is also conserved (Kawaguchi *et al.*, 1999).

The third example relates to the function of ICP22, a product of the α22 gene. Mutants lacking this gene grow poorly and synthesize suboptimal amounts of a subset of late (γ_2) proteins exemplified by the U_S11, U_L38 and U_L41 proteins in primary human cell cultures and in some non-human cell lines (Purves *et al.*, 1993). ICP22 is a multifunctional protein. The functions enabling optimal synthesis of the subset of late proteins map to the carboxyl-terminal domain of ICP22 (Ogle and Roizman, 1999). At least two functions of ICP22 may account for the optimal synthesis of this subset of late viral proteins. First, ICP22 and U_L13 stabilize and activate the cyclin-dependent kinase cdc2 but enable the degradation of its partners, cyclins A and B (Advani *et al.*, 2000). cdc2 acquires a new partner, the HSV-1 DNA polymerase accessory protein encoded by U_L42 ORF (Advani *et al.*, 2001). The cdc2-U_L42 complex binds topoisomerase IIα – all in an ICP22-dependent manner (Advani *et al.*, 2003). It has been postulated that the mRNA encoding the subset of late proteins is transcribed off progeny DNA contained in massive tangles of concatemeric DNA

and that the presence of the topoisomerase enables more efficient transcription of the DNA. A second function of ICP22 and U_L13 protein kinase reported initially by Spencer and colleagues is to mediate the post-translational modification of the carboxyl-terminal domain of RNA polymerase II (RNA POL II) (Long *et al.*, 1999; Rice *et al.*, 1994, 1995). The modified RNA POL II acquires an "intermediate electrophoretic mobility" (RNA POL IIi). Recent studies in this laboratory indicate ICP22 interacts with the U_S3 protein kinase to recruit cdk9, a cyclin-dependent kinase involved in transcription (Durand *et al.*, 2005). The cdk9–ICP22 complex can phosphorylate the carboxyl-terminal domain of RNA POL II in vitro. This interaction appears to be independent of the posttranslational modification of RNA POL IIi. The presumption is that these modifications of RNA POL II enable more efficient elongation in the course of mRNA synthesis.

These are but three examples of modification of cellular structures designed to enhance the synthesis of viral gene products. Additional modifications are likely to emerge.

The objectives and general strategy of anti-host functions

A cursory review of the anti-host functions expressed by HSV indicates that they fall into four categories. In essence HSV (i) selectively blocks the synthesis of new proteins, (ii) blocks the function of preexisting cellular proteins activated after infection, (iii) selectively degrades cellular proteins (iv) blocks signaling to the host immune system indicating that the cell is infected. These functions are also expressed by other alphaherpesviruses and to a lesser extent by members of the beta- and gamma- herpesviruses. The fundamental strategy of HSV as opposed to that of members of the beta- and gamma- herpesviruses is to encode proteins that bind and subvert the function of cellular proteins. Unlike beta- and gamma-herpesviruses, HSV does not make extensive use of cellular orthologs to reinforce, substitute or block the function of cellular genes. At most, HSV encodes a short amino acid sequence related to that of a cellular protein such as the one present at the carboxyl terminal of the $\gamma_1$34.5 protein. This sequence is homologous to that of the corresponding domain of the GADD34 gene (Mohr and Gluzman, 1996).

The activation of NF-κB

On the basis of viral efforts to suppress its activation, NF-κB may well be viewed as a nemesis of viral replication and spread. Activation of NF-κB results in the synthesis of cytokines and growth factors that would lead to a potentially undesirable host response to infection (for review, see Santoro *et al.*, 2003). In HSV-1 infected cells NF-κB is activated (Amici *et al.*, 2001, Patel *et al.*, 1998), although studies on just a few products induced by activated NF-κB suggest that synthesis of NF-κB-dependent proteins may be selective (Esclatine *et al.*, 2004a,c).

In human and mouse cells tested to date, stable activation of NF-κB requires activated PKR (Taddeo *et al.*, 2003b). This protein is resident in cells and is activated by interferon and double stranded RNAs (for review, see Williams, 2001). Activated PKR phosphorylates the α subunit of the translation initiation factor 2 (eIF-2α). In turn, eIF-2α-P shuts off protein synthesis. Activated PKR could be viewed as an ancient response to infection and viruses have evolved many and diverse strategies to block its activation. Indeed HSV-1 contains a late gene: U_S11 which, when expressed early, blocks activation of PKR (Cassady *et al.*, 1998). HSV has evolved a very different but puzzling strategy to deal with PKR. Instead of blocking its activation, HSV encodes a protein, $\gamma_1$34.5, which binds the protein phosphatase 1α and redirects it to dephosphorylate eIF-2α (He *et al.*, 1997a,b, 1998). This strategy makes little sense in light of the observation that HSV-1 yields are 10- to 50-fold higher in PKR−/− cells than in sibling PKR+/+ cells (Taddeo *et al.*, 2004a). HSV requires activated PKR for some of its functions. Several lines of evidence indicate that activation of NF-κB is tied to activation of PKR. Thus, NF-κB is not activated by wild-type virus in infected PKR−/− cells. The HSV-1 mutant virus R5104 in which U_S11 was converted from a γ_2 to an early gene replicates as well as the wild-type virus but does not induce NF-κB (Taddeo *et al.*, 2003b).

A central question is why NF-κB is induced. As indicated above, wild-type HSV-1 replicated better in PKR−/− cells than in the sibling, PKR+/+ cells. In contrast, the yields of wild-type virus were at least 10-fold lower in NF-κB knockout fibroblasts, i.e. p50−/−, p65−/− and p50/p65−/− cells than in wild-type cells derived from NF-κB+/+ siblings (Taddeo *et al.*, 2004a). Currently, two hypotheses prevail. One hypothesis holds that NF-κB induces the synthesis of proteins that are required to block apoptosis (Goodkin *et al.*, 2003; Gregory *et al.*, 2004). The other hypothesis is that HSV-1 requires NF-κB-dependent proteins for its replication. This laboratory failed to find support for the first hypothesis. Indeed, HSV-1 encodes at least three proteins known to block apoptosis (see below) and p50−/−, p65−/− and p50/p65−/− cells appear to be resistant to apoptosis induced by defective HSV-1 viruses, although they are sensitive to exogenous pro-apoptotic agents

(Taddeo *et al.*, 2004a). The second hypothesis remains unproven.

Degradation of mRNA in infected cells

Studies carried out several decades ago (Roizman *et al.*, 1965; Sydiskis and Roizman, 1966, 1968) showed that cellular protein synthesis is downregulated, but the mechanisms did not become apparent until Frenkel and associates (Kwong *et al.*, 1988; Strom and Frenkel, 1987) described the role of U_L41 protein, dubbed *vhs* for virion host shutoff, in degrading mRNA (for review, see Smiley, 2004). The typical experiment designed to show the degradation involved a short labeled amino acid pulse at a time after infection. The results of these experiments showed that incorporation of amino acids into both viral and cellular proteins was diminished in wild-type virus infected cells but not in ΔU_L41 mutant infected cells. Other studies demonstrated that both viral and cellular mRNAs were degraded but that viral RNA transcripts nevertheless accumulated in infected cells, possibly as a consequence of higher rates of transcription of viral genes.

Subsequent studies reported that U_L41 interacted with the translation elongation factors eIF-4H and eIF-4B to degrade mRNA beginning at or near its 5′ terminus (Doepker *et al.*, 2004; Everly *et al.*, 2002; Karr and Read, 1999; Perez-Parada *et al.*, 2004). Moreover, consistent with the observation that U_L41 is a γ_2 structural protein made late in infection and hence if active would preclude the synthesis of viral protein, it was shown that the degradation of RNA ablated several hours after infection very likely as a consequence of the interaction of U_L41 protein with VP16 encoded by the U_L48 ORF (Smibert *et al.*, 1994). Other studies demonstrated that the shut-off of cellular protein synthesis was also the consequence of the function of ICP27. Early in infection ICP27 blocks the splicing of mRNA (Hardwicke and Sandri-Goldin, 1994). Late in infection, defined in reference to the initiation of synthesis of viral DNA, ICP27 shuttles between the nucleus and cytoplasm (Sandri-Goldin, 1998). The anti-RNA splicing functions of ICP27 do not appear to affect viral gene expression since, of the four transcriptional units that yield spliced mRNAs, three (α0, α22, α47) are expressed before the effect of ICP27 becomes apparent whereas the fourth (U_L15) is expressed at a time when ICP27 shuttles RNA. The net effect of blocking splicing is that unspliced mRNA is transported into the cytoplasm.

More recent studies (Esclatine *et al.*, 2004a,c; Taddeo *et al.*, 2003a) indicate that the degradation of cellular mRNA is a consequence of a process far more complex than that deduced from earlier studies. In essence, the degradation of mRNA and the mechanism by which this degradation is achieved appears to vary. In the case of housekeeping and constitutively expressed mRNAs (e.g., GAPDH and β-actin) the mRNAs are rapidly degraded very early after infection by an unknown mechanism in a U_L41-dependent fashion (Esclatine *et al.*, 2004c). In contrast, several mRNAs induced after infection and which normally have a relatively short half-life appear to linger even though the translation products may or may not accumulate. For example, IEX-1 mRNA is induced after infection (Taddeo *et al.*, 2002, 2003b). This mRNA contains AU-rich pentameric elements (AREs) in its 3′ untranslated region (UTR) that signal a short half-life (Bakheet *et al.*, 2003; Chen and Shyu, 1995). In mock-infected cells subject to stress this mRNA is made and then sequestered in exosomes (for review, see Butler, 2002) by members of the tristetraprolin (TTP) family (Chen *et al.*, 2001) and rapidly degraded in a 3′ to 5′ direction (Wilusz *et al.*, 2001). IEX-1 mRNA induced in ΔU_L41-infected cells is subject to a similar rapid degradation process (Esclatine *et al.*, 2004c). Unlike the situation in mock-infected cells, the mRNA appears to be stable in wild-type virus infected cells (Esclatine *et al.*, 2004c). However, a more detailed examination of the mRNA accumulating in the cytoplasm of wild-type virus infected cells indicated that this mRNA consists of full-length processed mRNA, mRNA containing the single intron of IEX-1, and finally, truncated forms of the mRNAs (Esclatine *et al.*, 2004a; Taddeo *et al.*, 2003a). The bulk of full-length mRNAs appear to be deadenylated. The truncated forms arise by 3′ to 5′ degradation and endonucleolytic cleavage at or near AREs (Esclatine *et al.*, 2004a). It is thus not surprising that IEX-1 protein is not detected beyond the first hour after infection. A similar picture is presented by mRNAs encoding IκBα and c-*fos* (Esclatine *et al.*, 2004a). Although all of these mRNAs contain AREs, not all AREs-containing mRNAs are subject to a similar fate. Thus TTP mRNA, which contains AREs in the 3′ UTR (Brooks *et al.*, 2004), is upregulated and translated to yield relatively large amounts of protein (Esclatine *et al.*, 2004a,b; Taddeo *et al.*, 2004b). Another mRNA, that of GADD45β, is also upregulated and translated (Esclatine *et al.*, 2004a). This mRNA does not contain AREs.

The model that best takes into account the available data is that HSV attempts to counter the multiple pathways of activation of stress responses by insuring that they are fully activated (e.g., specific activation of NF-κB) and then blocking those that are inimical to viral replication. Among these are responses that signal to the environment that the cell is infected or that activate pro-apoptotic pathways. A key cellular gene activated in the course of infection and which may be the basis of discrimination between mRNAs that

are degraded and those that are not is TTP. As noted above, members of the TTP family regulate the life span of AREs mRNAs (for review, see Blackshear, 2002). As yet, preliminary studies indicate that U_L41 protein interacts with components of the exosome (Esclatine *et al.*, 2004b; B. Taddeo and B. Roizman, unpublished data). Of the many issues yet unresolved is the mechanism by which some mRNAs containing AREs (e.g., TTP mRNA) are less rapidly degraded than those encoding IEX-1 or the molecular basis for the U_L41-dependent rapid degradation of GAPDH or β-actin mRNAs as compared to those of mRNAs containing AREs (Esclatine *et al.*, 2004c).

Specific degradation of cellular proteins in wild-type virus-infected cells

It could be expected that proteins with a relatively short half-life and whose mRNA is degraded after infection, as described above, would disappear and not be replenished in the wild-type virus infected cells. An example of just such a protein is Jak1, described later in the text. Analyses of a relatively small number of cellular proteins led to the discovery of several proteins that turn over in infected cells in a manner dependent on α0 rather than on U_L41 and α27 genes. The cellular proteins degraded in an ICP0-dependent manner include the promyelocytic leukemia protein (PML) SP100, the centromeric proteins (CNP) A and C, and the DNA-dependent protein kinase. In contrast to the disappearance of the proteins listed above, cyclins D3 and D1 turned over at a much slower rate or were stabilized over many hours after infection (for review, see Hagglund and Roizman, 2004).

ICP0 is a 775-residue protein translated from a spliced mRNA. The coding sequences are derived from 3 exons containing 19, 241, and 515 residues, respectively. The protein contains a RING finger located between residues 116 and 156 of exon 2. The protein was shown to interact physically with a ubiquitin specific protease (USP7), EF-1δ, the transcriptional factor BMAL and a protein of unknown function designated as p60 (for review, see Hagglund and Roizman, 2004). Early in infection ICP0 localizes in nuclear structures known as PODs, ND10, etc. Within a few hours after infection, ICP0 mediates the degradation of ND10 structures and becomes dispersed throughout the cytoplasm. After the onset of viral DNA synthesis, ICP0 is translocated into the cytoplasm. The available data indicate that ICP0 is actually retained in the cytoplasm by a β or γ_1 function until viral DNA synthesis inasmuch as in cells infected with the d120 (Δα4) mutant, ICP0 is translocated to the cytoplasm and aggregated with proteasomes after the degradation of ND10 but within a very short time after infection (Lopez *et al.*, 2001).

Three lines of investigation led to the realization that ICP0 acts as a two-sited ubiquitin ligase (for review, see Hagglund and Roizman, 2004). First, ICP0 has many features similar to that of ubiquitin ligases. Thus the RING finger is characteristic of many ubiquitin ligases and ICP0 dynamically interacts with proteasomal components. Second, the dispersal of ND10 could be directly related to the ICP0 domain encoding the RING finger. The third line of evidence emerged from studies of the interaction of ICP0 with cyclins D3 and D1. Thus, it has been shown that ICP0 could interact physically and genetically with cyclin D3, but not with cyclin D1, and independently that cdc34 was degraded in infected cells in a proteasome- and ICP0-dependent manner. The observations that both proteins did not turn over as rapidly as expected and that no new transcripts were detected suggested that ICP0 blocks their turnover possibly by degrading the ubiquitin conjugating enzyme (cdc34 or UbcH3) responsible for the degradation of cyclin D1 in uninfected cells. In vitro substrate-independent assays showed that cdc34 was polyubiquitylated in an ATP-dependent manner by sequences encoded by exon 3 rather than the expected exon 2 (Hagglund and Roizman, 2002; Hagglund *et al.*, 2002). The ubiquitylation activity was mapped to residues 621 to 624 and indeed viral mutant carrying ICP0 gene lacking these sequences did not bind or mediate the degradation of cdc34 or the stabilization of the D cyclins (Hagglund and Roizman, 2002). In addition, RING domain mutants did not affect the degradation of cdc34. The ubiquitin conjugating enzymatic site mapping in the sequences encoded by exon 3 was designated herpesvirus ubiquitin ligase 1 (HUL-1), does not resemble in sequence any of the known ubiquitin ligases and may therefore represent a new class of these enzymes.

The in vitro substrate-independent ubiquitylation assays indicated that the sequences encoded by exon 2 polyubiquitylated UbcH5A and UbcH6 ubiquitin conjugating enzymes but not a large number of others. This observation indicated that exon 2 encodes a second ubiquitin conjugating enzyme (HUL-2) (for review, see Hagglund and Roizman, 2004) and further assays using dominant negative ubiquitin conjugating enzymes established that HUL-2 employs UbcH5A to degrade PML, SP100, and the DNA-dependent protein kinase (Gu and Roizman, 2003). The context of the interaction of ICP0 with UbcH6 or the mechanism by which ICP0 mediates the degradation of CENP-C and CENP-A are not known. It is conceivable that ICP0 targets other protein for degradation.

The objectives attained by the degradation of cdc34 and PML are at least in part apparent. By degrading cdc34,

HSV precludes the degradation of cyclin D3. This protein appears to mediate the transport of ICP0 to the ND10 structure and later to the cytoplasm. A mutation that affects the binding of ICP0 to cyclin D3 affects viral replication in stationary cells and reduces the viability of the virus administered at a peripheral site from invading the central nervous system (Hagglund and Roizman, 2003). Stabilization of cyclin D3 does not drive the cell into the S phase.

PML is the organizing protein of the ND10 structures. An extensive literature attributes to ND10 numerous functions related to transactivation or repression of cellular genes (for review, see Everett, 2001; Regad and Chelbi-Alix, 2001). Ectopic overexpression of PML did not affect viral replication, although it resulted in the formation of highly enlarged ND10 structures that were not dispersed in the course of HSV-1 infection (Lopez *et al.*, 2002). Similarly, wild-type virus replicated equally well in both PML−/− and PML+/+ cells. However, on pretreatment of cells with either interferon α or γ resulted in a significantly higher decrease in viral replication in PML+/+ cells as compared to PML−/− cells (Chee *et al.*, 2003). The necessary conclusion derived from these studies is that the activation of the antiviral state is mediated through ND10 and that the objective of degrading PML and dispersal of ND10 is to preclude the potential inhibition of viral replication by exogenous interferon.

Shut down of the interferon pathways to host resistance to infection

The preceding sections cited several mechanisms by which HSV blocks interferon-mediated pathways of host resistance to infection.

(i) Both $\gamma_1$34.5 and, to a lesser, degree U_S11 proteins circumvent the consequences of phosphorylatation of eIF-2α, the former by sequestering and redirecting phosphatase 1α to dephosphorylate eIF-2α (He *et al.*, 1997a,b, 1998). The effect on the interferon pathway is apparent from the observation that $\Delta\gamma_1$34.5 mutants are highly attenuated in wild-type mice but not in mice lacking interferon receptors (Leib *et al.*, 1999, 2000).

(ii) Some of the proteins in the interferon pathways have a relatively short half life (e.g., Jak1). The U_L41-dependent RNase activity blocks the replenishment of Jak1 and possibly other proteins in the pathway (Chee and Roizman, 2004).

(iii) As noted above, absence or overexpression of PML has no effect on viral replication. The role of PML and the objective of insuring its degradation are readily apparent in interferon-treated cells. In absence of PML, the infected cells are insensitive to either α- or γ-interferon (Chee *et al.*, 2003). Thus the interferon-based activation of antiviral genes is mediated via the ND10 structures. By targeting PML for degradation, HSV pre-empts antiviral activity of exogenously produced interferon.

Consistent with the overall strategy of viral interference with host defense mechanisms, the pathways by which the HSV blocks the interferon pathways of host defense are redundant but the above list may not be exhaustive. For example, in recent studies it has been observed that the cells surface receptor for interferon γ is rapidly reduced after infection (Y. Liang and B. Roizman, unpublished data). The mechanism by which HSV causes a reduction in the amount of this receptor is not yet known. It is conceivable that as yet other anti-interferon pathways are encoded by the viral genome.

HSV blocks pro-apoptotic cellular functions

Programmed cell death or apoptosis is a mechanism by which a multicellular organism rids itself of unwanted cells. External or internal stimuli activate a cascade of proteases that degrade essential proteins and ultimately the cellular DNA. In the context of infection, apoptosis is a supreme sacrifice by cells to diminish the impact of the infection and enable the survival of the organism. While earlier studies on other viruses and human cytomegalovirus (Shen and Shenk, 1995; Zhu *et al.*, 1995) anticipated that HSV-1 would regulate apoptosis, three fundamental reports initiated an exciting excursion into the control of pro-apoptotic pathways by HSV. Thus, within a short time, three laboratories reported that HSV blocked apoptosis induced by FAS ligand (Galvan and Roizman, 1998; Jerome *et al.*, 1999, 2001; Sieg *et al.*, 1996), osmotic shock, thermal shock (Galvan and Roizman, 1998; Galvan *et al.*, 1999; Koyama and Miwa, 1997; Leopardi and Roizman, 1996), and a defective viral mutant lacking the genes encoding ICP4 (Galvan and Roizman, 1998; Sieg *et al.*, 1996; Munger *et al.*, 2001). Subsequent studies identified at least two other viral mutants capable of inducing apoptosis and at least four genes whose products block programmed cell death induced by viral gene products or by a variety of exogenous agents (Aubert and Blaho, 1999; Benetti *et al.*, 2003; Jerome *et al.*, 1999, 2001; Leopardi *et al.*, 1997a; Munger and Roizman 2001; Munger *et al.*, 2001; Murata *et al.*, 2002; Perkins *et al.*, 2002; Zhou and Roizman, 2001; Zhou *et al.*, 2000). The key issues are the mechanisms by which viral or exogenous biologic agents induced programmed cell death and the mechanisms by which the virus blocks

apoptosis. The current literature may be summarized as follows.

(i) Wild-type HSV-1 does not induce apoptosis in cultured cells in the course of productive infection. Viral mutants reported to induce apoptosis are those lacking α4 (Galvan and Roizman, 1998; Leopardi and Roizman, 1996; Munger *et al.*, 2001), α27 (Aubert and Blaho, 1999) or U_L39, the gene encoding the major subunit of ribonucleotide reductase (Perkins *et al.*, 2002). The mechanism by which these mutants induce apoptosis is not clear. There is no compelling evidence to support the argument that all viral mutants induce apoptosis by a similar mechanism. For example, the mutant lacking the α4 genes induces apoptosis in virtually all cell lines tested to date including Vero cells, whereas the mutant lacking the α27 gene induces apoptosis in some cell lines but not in Vero cells (Aubert and Blaho, 1999). Overexpression of ICP22, ICP0 or ICP27 did not lead to apoptosis in several of the cell lines tested.

(ii) Of the four viral proteins shown to block apoptosis, i.e., ribonucleotide reductase, the U_S3 protein kinase, and the glycoproteins D and J (gD and gJ), only three have been studied in some detail. Nothing is known of the mechanism of action of the U_L39 gene product other than the observation that ΔU_L39 mutants complemented by U_L39 protein do not induce apoptosis (Perkins *et al.*, 2002). It should be noted that the HSV-2 U_L39 protein encodes a kinase but the substrates of the kinase other than itself are not known.

(iii) Ectopic expression of the U_S3 protein kinase was initially reported to block apoptosis induced by the Δα4 mutant (Leopardi and Roizman, 1996). Subsequently, this protein was shown to block apoptosis induced by a variety of agents including sorbitol, ectopic expression of several pro-apoptotic genes including BAD, Bax, Bid (Benetti *et al.*, 2003; Munger and Roizman, 2001; Ogg *et al.*, 2004). Curiously, U_S3 does not appear to phosphorylate BAD contrary to the published report inasmuch as BAD protein lacking the known phosphorylation sites induces apoptosis that is blocked by the U_S3 protein kinase (Benetti *et al.*, 2003). ΔU_S3 mutants induce apoptosis albeit weakly and only in some cell lines (e.g., rabbit skin cells) but not in human or primate cells susceptible to apoptosis induction by other viral mutants. More recent studies have shown that the substrate specificity of U_S3 protein kinase is very similar to that of cyclic AMP dependent protein kinase A (PKA) (Benetti and Roizman, 2003). Thus forskolin, an inducer of PKA, blocks apoptosis induced by the Δα4 mutants, and that a specific inhibitory peptide that blocks activation of PKA reverses the effect of forskolin. U_S3 also mediates the phosphorylation of the regulatory subunit of PKA in in vitro studies. Still more recent studies place U_S3 in mitochondria (Van Minnebruggen *et al.*, 2003). The data suggest that the anti-apoptotic substrates of U_S3 protein kinase are mitochondrial proteins and that activated PKA may substitute for the U_S3 protein kinase in blocking apoptosis.

(iv) The role of gD and gJ in blocking apoptosis emerged from the observation that viral mutant stocks lacking gD in both the gene and the protein in the virion envelope (gD−/−) or viral stocks lacking the gD gene but containing the glycoprotein provided by cells ectopically expressing the protein (gD−/+) induced apoptosis that was blocked by ectopic expression of gD or gJ (Zhou and Roizman, 2001; Zhou *et al.*, 2000). The mechanisms by which the two stocks induce apoptosis differ. The model that best fits the results of the studies on gD as the blocker of apoptosis is as follows. In cells exposed to high rations of gD−/− mutant per cell, the virus enters the cells by endocytosis and triggers massive lysosomal discharge that causes cell death. Consistent with these events, chloroquine blocks apoptosis induced by gD−/− mutants (Zhou and Roizman, 2002a). To block apoptosis, gD must be either intact or consist of ectodomain and transmembrane domain linked by disulfate bonds to a transmembrane domain and a cytoplasmic domain (Zhou and Roizman, 2002b). In contrast, gD−/+ mutant stocks induce apoptosis even after infection of cells at low multiplicities of infection, chloroquine does not block apoptosis and the evidence suggests that apoptosis is induced late rather than early in infection. In this instance the etcodomain of gD is the only component of gD essential for blocking apoptosis induced by gD−/+ stocks. One hypothesis that remains to be explored in greater detail rests on an earlier report that gD interacts and colocalizes with the cation-independent mannose-6-phosphate receptor, a regulator of lysosomal enzyme transport (Zhou and Roizman, 2002a). The hypothesis predicts that, to block apoptosis induced by gD−/− mutant, the ectopically expressed gD must be translocated to the lysosomal vesicles and interact with the mannose-6-phosphate receptor. In contrast, the gD−/+ virus does not trigger apoptosis by lysosomal discharge but rather infects cells, replicates, and it is the gD−/− progeny of the gD−/+ virus that triggers apoposis during its transport through the exocytic pathway. The target of gD in this instance could be mannose-6-phosphate receptor or another as yet unidentified protein.

(v) gJ is the smallest of the glycoproteins encoded by HSV and its function until recently was largely unknown. Studies by Jerome and colleagues indicate that gJ blocks Fas ligand- or granzyme B-induced apoptosis and more important, it is involved in the protection of infected cells from CTL-induced apoptosis (Jerome *et al.*, 1998, 2001).

Conclusions

As indicated earlier in the text, the strategic objective underlying the evolution of HSV is total control of the biosynthetic and defensive pathway of the cell. This is achieved though physical interaction between viral and cellular proteins and results in the modification and diversion of the host protein to fulfill the needs of the virus. The three fundamental conclusions of the studies carried out so far are that (i) viral proteins are largely multifunctional, the function at any given time most likely determined either by the partner to which they are bound or the post-translational modification to which they are subjected; (ii) the full complement of viral protein functions remains to be discovered and (iii) HSV exhibits a functional but not sequence driven redundancy. In essence, numerous functions expressed by different viral proteins aim to modify or suppress a specific metabolic pathway, although the targeted aspects of the pathway are not identical. If HSV had the arrogance (and capacity) to express it, its motto would be "we take no chances."

Part II

Basic virology and viral gene effects on host cell functions: betaherpesviruses

Edited by Edward Mocarski

14

Comparative genome and virion structure

Andrew J. Davison and David Bhella

MRC Virology Unit, Institute of Virology, Glasgow, UK

Introduction

The two major lineages in the *Betaherpesvirinae* are the cytomegaloviruses (the *Cytomegalovirus* and *Muromegalovirus* genera, plus a number of other viruses whose taxonomy is only partially defined) and the *Roseolovirus* genus (see Chapter 1). The best characterized members of these lineages are HCMV (the prototype of the subfamily) and HHV-6, respectively. Cytomegaloviruses are present in a wide range of mammalian species, and have been termed "salivary gland viruses" because of their ease of isolation from explanted tissue. An earlier divergence of the *Betaherpesvirinae* may be represented by a herpesvirus of elephants (Richman *et al.*, 1999; Ehlers *et al.*, 2001). This chapter starts by describing the genome structures of *Betaherpesvirinae*, then examines the genetic content of HCMV and HHV-6, and finally focuses on the virion structure of HCMV.

Genome structures

The genomes of viruses in the *Roseolovirus* genus are significantly smaller, at 145–162 kbp, than those of other *Betaherpesvirinae*, at 196–241 kbp. Indeed, HCMV has the largest genome among the human herpesviruses, and thus far its closest relative, CCMV, has the largest genome of all sequenced herpesviruses. It seems likely that the ancestor of the *Betaherpesvirinae* had a genome consisting of a unique region flanked by a direct repeat (the class A genome described in Chapter 2), since this structure is characteristic of most extant members of the subfamily. Earlier studies ruled out the presence of large repeats in the genomes of MCMV (Ebeling *et al.*, 1983a; Mercer *et al.*, 1983; Marks and Spector, 1984), THV (Koch *et al.*, 1985) and RCMV (Meijer *et al.*, 1986). Later work confirmed that MCMV and RCMV have terminal direct repeats of 30 and 504 bp, respectively (Marks and Spector, 1988; Vink *et al.*, 1996). A corresponding repeat has not been detected in THV, but the genome termini have not been examined directly. GPCMV has a terminal direct repeat of about 1 kbp, and a proportion of genomes lacks one copy (Gao and Isom, 1984; McVoy *et al.*, 1997; Nixon and McVoy, 2002). RhCMV has a terminal repeat of about 500 bp that may be present in multiple copies in some genomes (Hansen *et al.*, 2003). Interestingly, this resembles the class B genome structure found in many *Gammaherpesvirinae*. Information on the genome of another monkey cytomegalovirus, SCMV, is also available (Huang *et al.*, 1978; Jeang and Hayward, 1983), but the termini have not been characterized. The most commonly studied strain of SCMV, Colburn, was isolated ostensibly from a human (Huang *et al.*, 1978). Sequences from an agent dubbed "stealth virus," which was also suggested to be of human origin, have shown that this virus is SCMV (Martin, 1999).

Cytomegaloviruses of higher primates, HCMV and CCMV, have the class E genome structure, in which two unique regions (U_L and U_S) are flanked by direct repeats (TR_L and IR_L; TR_S and IR_S) (Weststrate *et al.*, 1980; Davison *et al.*, 2003a). A copy of the terminal direct repeat of approximately 300–600 bp (the *a* sequence) is present in inverted orientation at the junction between IR_L and IR_S (Spaete and Mocarski, 1985; Tamashiro and Spector, 1986). The genomes exhibit segment inversion, which results in virions containing equimolar amounts of four genome isomers differing in the relative orientations of U_L and U_S. The genomes of two closely related herpesviruses of New World monkeys (aotine herpesviruses 1 and 3) appear to have a similar structure (Ebeling *et al.*, 1983b). However, as mentioned above, RhCMV, a virus of an Old World monkey, does not. This suggests that the class E genome structure arose in an ancestral primate cytomegalovirus from a class

A genome by duplication of fused terminal sequences at a location internally in the genome, but that this duplication was lost in the lineage represented by RhCMV. The biological reason for a class E genome structure, which is also characteristic of certain alphaherpesviruses such as HSV-1 and HSV-2 (see Chapter 5), remains unknown.

The genomes of both variants of HHV-6 (referred to as HHV-6A and HHV-6B; Martin *et al.*, 1991b; Lindquester and Pellett, 1991) and HHV-7 (Dominguez *et al.*, 1996) contain a substantial terminal direct repeat, whose size was determined by sequencing as 8.1–8.8 kbp in the former and 5.8–10.0 kbp in the latter. The ranges are due to the presence in the direct repeat of regions of variable size consisting of reiterated short sequences.

Genes

Genome sequences

Complete genome sequences are available for eight species in the *Betaherpesvirinae*, as listed in Table 2.1. These include HCMV (Chee *et al.*, 1990; Murphy *et al.*, 2003b; Dunn *et al.*, 2003b; Dolan *et al.*, 2004), MCMV (Rawlinson *et al.*, 1996), RCMV (Vink *et al.*, 2000), THV (Bahr and Darai, 2001), RhCMV (Hansen *et al.*, 2003), CCMV (Davison *et al.*, 2003a), HHV-6A (Gompels *et al.*, 1995), HHV-6B (Dominguez *et al.*, 1999; Isegawa *et al.*, 1999) and HHV-7 (Nicholas, 1996; Megaw *et al.*, 1998). Partial sequence data are also available in the literature or public sequence databases for *Betaherpesvirinae* that infect Old World primates, such as the baboon (Blewett *et al.*, 2001), drill (Blewett *et al.*, 2003), colobus monkey and orangutan, the New World primate, aotine herpesvirus 1, and members of the *Suidae* including the domestic pig (Ehlers *et al.*, 1999; Rupasinghe *et al.*, 2001; Widen *et al.*, 2001) and the warthog (Ehlers and Lowden, 2004).

Genetic content

The remainder of this section focuses on a genetic comparison of HCMV, as the most extensively characterized cytomegalovirus, with HHV-6, in the *Roseolovirus* genus. Derivation of the genetic content of HCMV has been a protracted process, because strain AD169, which was sequenced first (Chee *et al.*, 1990), lacks 15 kbp at the right end of U_L in comparison with wild-type strains (Cha *et al.*, 1996), having in place of the deleted sequence an inverted duplication of a 10 kbp region from the left end of U_L. AD169 also bears several additional mutations (Davison *et al.*, 2003a) that can vary with respect to the strain variant being used and have important functional consequences (Skaletskaya *et al.*, 2001). Also, all passaged strains examined to date are compromised in one or more genes by mutations that introduce deletions, frameshifts or termination codons (Akter *et al.*, 2003; Dolan *et al.*, 2004). The deduced gene layout in wild-type HCMV is shown in Fig. 14.1, and that of HHV-6 is shown in Fig. 14.2. The genetic content of HHV-6B appears to be the same as that of HHV-6A; nine additional small ORFs were listed by Dominguez *et al.* (1999) as unique to HHV-6B, but their protein-coding status remains unknown. HCMV and HHV-6 are currently estimated to contain 165 and 86 genes, respectively, counting duplicated genes only once. The gene content of HHV-7 is similar to that of HHV-6: all HHV-7 genes but one (U55B, which is related to U55) have HHV-6 counterparts, and all but three HHV-6 genes (U22, U83 and U94) have HHV-7 counterparts. The HHV-6 genome contains several regions consisting of complex and simple repeats (T1, T2, R1, R2 and R3 in Fig. 14.3), only one which encodes protein. In contrast, HCMV lacks such repeats, but many proteins contain quasi-repetitive regions of one or a few amino acid residues. Although infrequent in all herpesviruses, mRNA splicing is involved in transcription of at least 12 HCMV genes (7% of the total) and at least 14 HHV-6 genes (16%).

Table 14.1 details the correspondence between HCMV and HHV-6 genes, alongside functional information. HCMV and HHV-6, respectively, possess 40 and 41 of the 43 core genes inherited by the *Alpha-*, *Beta-* and *Gammaherpesvirinae* from their common ancestor (see Chapter 2), located centrally in the genomes. Both lack homologues to the genes encoding thymidine kinase and the small subunit of ribonucleotide reductase, and HCMV lacks the core gene encoding a homologue of a protein that binds to ori_{Lyt}, the origin of DNA synthesis used during productive replication. In addition, four genes common to HCMV and HHV-6 have clear homologues in the *Gamma-* but not the *Alphaherpesvirinae*. These are UL49 (related to BFRF2 and ORF66 in the *Lymphocryptovirus* and *Rhadinovirus* genera, respectively), UL79 (BVLF1 and ORF18), UL87 (BcRF1 and ORF24) and UL92 (BDLF4 and ORF31). A fifth gene, UL88, is distantly related to BTRF1 and ORF23 and positionally equivalent to a gene in the *Alphaherpesvirinae* (UL21 in HSV-1). A sixth gene, UL91, is positionally equivalent to BDLF3.5 and ORF30 in the *Lymphocryptovirus* and *Rhadinovirus* genera, respectively. These six genes are considered at present to have arisen after the lineage that led to the *Beta-* and *Gammaherpesvirinae* diverged from the *Alphaherpesvirinae*, but it is also possible that the ancestral core set included UL88 along with one or more of the others, which were lost at an early stage from the lineage giving rise to *Alphaherpesvirinae*.

UL47	U30	Tegument protein; possible role in intracellular transport; binds to UL48 protein	Baldick and Shenk (1996); Bechtel and Shenk (2002)
UL48	U31	High molecular weight tegument protein; binds to UL47 protein	Bradshaw *et al.* (1994); Gibson (1996); Ogawa-Goto *et al.* (2002)
UL48A	U32	Located on tips of hexons in capsids (SCP)	Gibson *et al.* (1996b); Baldick and Shenk (1996); Yu *et al.* (2005)
UL49	U33	Conserved in *Gammaherpesvirinae*	
UL50	U34	Inner nuclear membrane protein; role in egress of capsids from nucleus	Muranyi *et al.* (2002)
UL51	U35	Role in DNA packaging	
UL52	U36	Role in DNA packaging	
UL53	U37	Nuclear matrix protein; tegument protein; role in egress of capsids from nucleus	Muranyi *et al.* (2002); Dal Monte *et al.* (2002)
UL54	U38	Catalytic subunit of DNA polymerase; inhibited by pyrophosphate (e.g. foscarnet), nucleoside (e.g. ganciclovir) and certain non-nucleoside compounds	Heilbronn *et al.* (1987); Kouzarides *et al.* (1987); D'Aquila *et al.* (1989); [Teo *et al.* (1991)]
UL55	U39	Virion glycoprotein B (gB); component of gCI; involved in virus entry	Cranage *et al.* (1986); Boyle and Compton (1998); Boehme *et al.* (2004); [Ellinger *et al.* (1993)]
UL56	U40	Putative subunit of terminase; virion protein; binds to DNA packaging motif and exhibits nuclease activity; involved in inhibition by benzimidazole ribonucleosides and certain non-nucleoside compounds	Bogner *et al.* (1993); Bogner *et al.* (1998); Bradshaw *et al.* (1994); Krosky *et al.* (1998); Buerger *et al.* (2001); Scheffczik *et al.* (2002)
UL57	U41	Single-stranded DNA-binding protein	Kemble *et al.* (1987); Anders and Gibson (1988)
UL69	U42	Regulatory protein; tegument protein; contributes to cell cycle block; exhibits nucleocytoplasmic shuttling	Winkler *et al.* (1994); Winkler and Stamminger (1996); Hayashi *et al.* (2000); Lischka *et al.* (2001)
UL70	U43	Component of DNA helicase-primase complex; primase	McMahon and Anders (2002)
UL71	U44	Putative tegument protein	
UL72	U45	DURP family; derived from deoxyuridine triphosphatase; lacks catalytic residues and is enzymatically inactive	McGeoch and Davison (1999); McGeehan *et al.* (2001); Caposio *et al.* (2004); Davison and Stow (2005)
UL73	U46	Virion glycoprotein N (gN); component of gCII	Mach *et al.* (2000)
UL74	U47	Virion glycoprotein O (gO); component of gCIII	Huber and Compton (1997); Li *et al.* (1997); Huber and Compton (1998)
UL75	U48	Virion glycoprotein H (gH); component of gCIII; involved in entry	Cranage *et al.* (1988); Milne *et al.* (1998); [Liu *et al.* (1993); Mori *et al.* (2003b); Santoro *et al.* (2003)]
UL76	U49	Virion-associated regulatory protein	Wang *et al.* (2000); Wang *et al.* (2004)
UL77	U50	Role in DNA packaging	
UL78	U51	GPCR family; putative chemokine receptor	[Milne *et al.* (2000)]

[a] The layout here and in Fig. 14.1 is that derived by Davison *et al.* (2003a,b) and Dolan *et al.* (2004) for genes encoding functional proteins in wild type HCMV. A substantial number of additional protein-coding regions have been proposed (Chee *et al.*, 1990; Yu *et al.*, 2003; Murphy *et al.*, 2003a,b; Varnum *et al.*, 2004), and are not included because their status is considered generally less secure. The region between UL74 and UL75 may contain a small, rightward-oriented protein-coding exon (Scalzo *et al.*, 2004), and is also omitted. Homologous genes are in the same row. Blanks indicate the absence of detectable homologues. Bold font indicates HCMV genes that proved essential for growth in fibroblast cell lines in the study of Yu *et al.* (2003). Dunn *et al.* (2003b) also found that UL48, UL71, UL76, UL94 and UL96 are essential.

[b] Core genes (those inherited from the common ancestor of *Alpha-*, *Beta-* and *Gammaherpesvirinae*) are shaded, and functions take into account what is known about the homologue in the best characterized herpesvirus, which is often HSV-1 (see Chapter 2, Table 2.2). For genes conserved between HCMV and HHV-6, the information almost exclusively concerns the former. A blank indicates the absence of functional information.

[c] References primarily concern published data on gene identification and protein characterization, and are not exhaustive. Information on other aspects (e.g. dispensability, sequence variation or transcription) is generally not included. References to HHV-6 data (or, failing this, HHV-7 data) are denoted by square brackets.

[d] Positional homologue with similar functional characteristics.

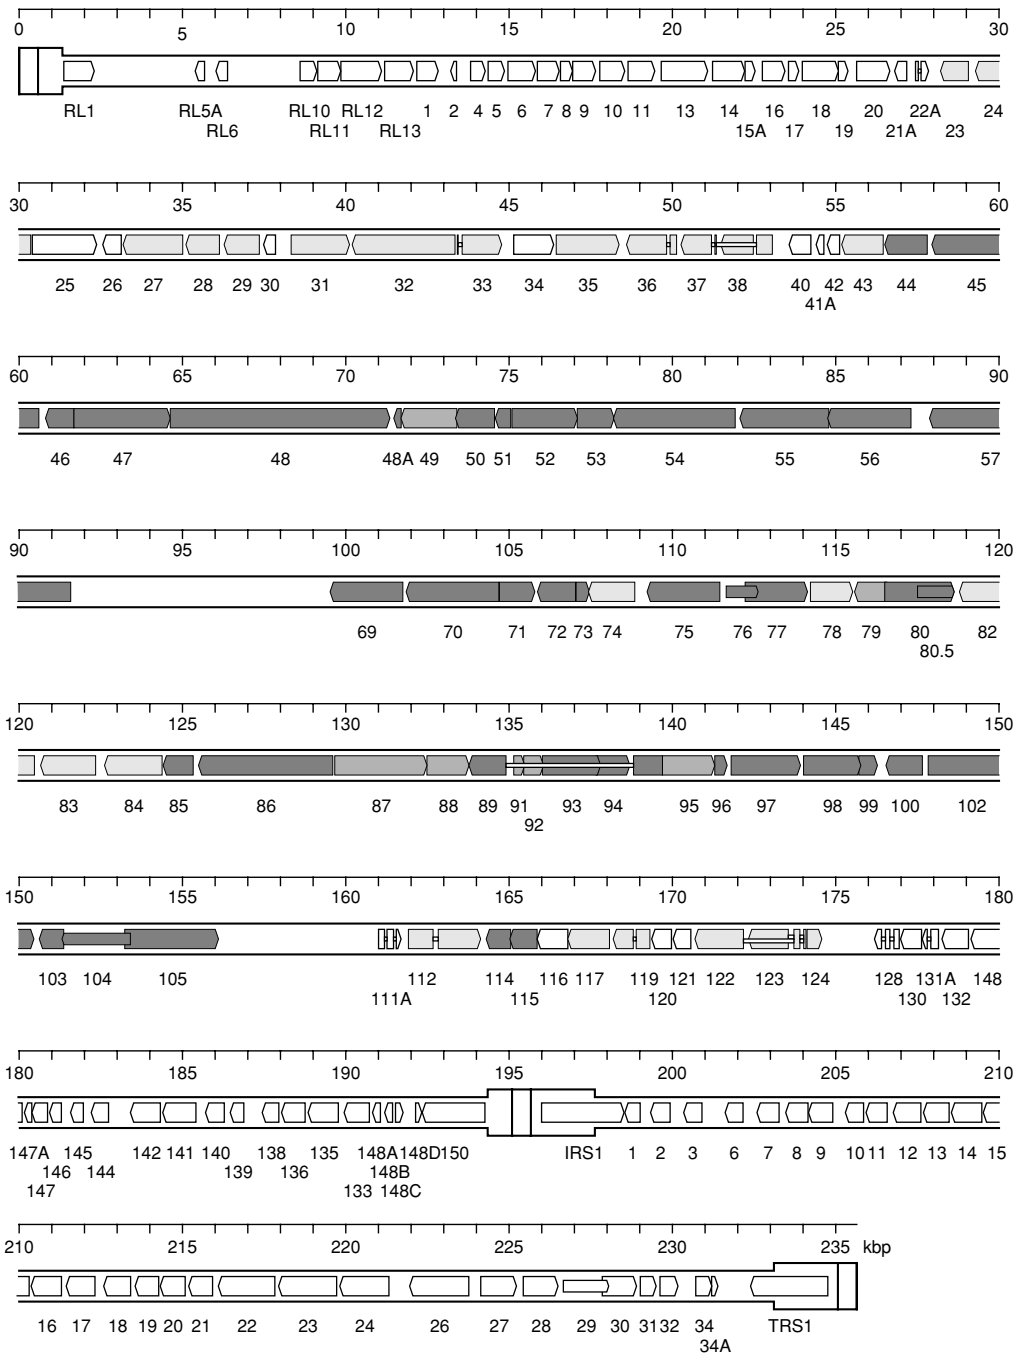

Fig. 14.1. Genetic content of wild-type HCMV, based on an interpretation of the genome sequence of strain Merlin (Dolan *et al.*, 2004), which in turn depended on analyses carried out by Chee *et al.* (1990), Cha *et al.* (1996) and Davison *et al.* (2003a, b). The inverted repeats TR_L/IR_L and TR_S/IR_S (which contain the *a* sequence depicted by a rectangle) are shown in a thicker format than U_L and U_S. Protein-coding regions are indicated by arrows, with gene nomenclature below. Introns are shown as narrow white bars. Genes corresponding to those in TR_L/IR_L and TR_S/IR_S of strain AD169 are given their full nomenclature, but the UL and US prefixes have been omitted from UL1–UL150 and US1–US34A. Core genes derived from the ancestor of *Alpha*, *Beta-* and *Gammaherpesvirinae* are shaded dark grey, additional genes derived from the ancestor of the *Beta-* and *Gammaherpesvirinae* are shaded mid grey, and other genes conserved between HCMV and HHV-6 are shaded light grey. White genes are unique to HCMV TRS1, US26 and US22 may be the counterparts of HHV-6 U95, DR1 and DR6, respectively, but are shown as unique.

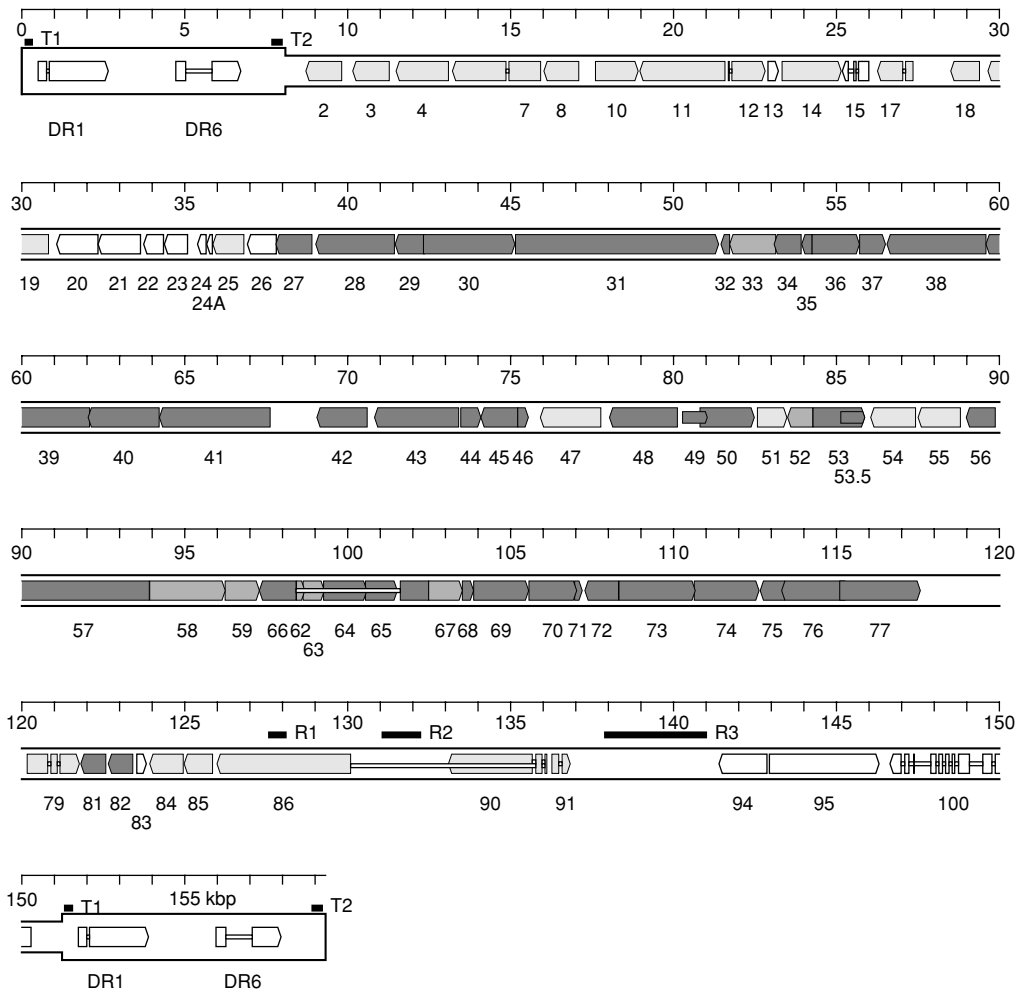

Fig. 14.2. Genetic content of HHV-6, based on strain U1102 of variant A (Gompels *et al.*, 1995) as modified by Megaw *et al.* (1998) and updated by the reintroduction of one gene (U83) and the incorporation of the splicing pattern for another (U86). The terminal direct repeat is shown in a thicker format than the unique region. Protein-coding regions are indicated by arrows, with gene nomenclature below. Introns are shown as narrow white bars. Genes in the direct repeat are given their full nomenclature, but the U prefix has been omitted from genes in the unique region. Core genes derived from the ancestor of *Alpha*, *Beta*- and *Gammaherpesvirinae* are shaded dark grey, additional genes derived from the ancestor of the *Beta*- and *Gammaherpesvirinae* are shaded light grey, and other genes conserved between HCMV and HHV-6 are shaded light grey. White genes are specific to HHV-6. U95, DR1 and DR6 may be the counterparts of HCMV TRS1, US26 and US22, respectively, but are shown as unique. Reiterated sequences T1, T2, R1, R2 and R3 are indicated by black bars.

The genes shared by HCMV and HHV-6 are collinear, probably as a result of being inherited from a common ancestor, but it is difficult to specify their number precisely. The best estimate, 73 genes, consists of 40 herpesvirus core genes, six genes inherited by the *Beta*- and *Gammaherpesvirinae*, and 27 genes specific to HCMV and HHV-6 (and HHV-7). The last class can be subdivided into 22 genes whose predicted amino acid sequences are detectably conserved (albeit weakly in some cases) in both genomes, along with the major immediate early gene (HCMV UL123) and the adjacent UL124 which lack amino acid similarity but correspond in position and orientation to HHV-6 genes (U90 and U91) with which they share properties, and three members of the US22 gene family (see below) that lack positional counterparts but have amino acid sequence counterparts elsewhere in the genome. HHV-6 U95, DR1 and

Fig. 14.3. Amino acid sequence alignments of proteins encoded by HCMV and HHV-6 genes putatively derived from a cellular OX-2 gene. (A) Conserved region in the ectodomains of human OX-2 (accession P41217), the HHV-6 and HHV-7 U85 proteins and cytomegalovirus UL119 proteins. The region includes residues 150–208 and 106–176 of the HCMV and HHV-6 proteins, respectively. Bold residues are conserved between OX-2 and one or both of the U85 proteins, or between both U85 proteins and at least two UL119 proteins. Three residues conserved throughout are indicated at the foot of the alignment. (B) Conserved residues in two regions of the primate cytomegalovirus UL120 and UL121 proteins. The entire sequence of each protein is shown. Bold residues are conserved in at least three orthologous proteins and at least one non-orthologous protein. Predicted signal and transmembrane sequences are indicated in grey and by underlining, respectively. The SCMV sequences are derived from Chang *et al.* (1995). Residues that are partially conserved between the OX-2-related proteins in (A) and the UL120 or UL121 proteins are indicated by colons.

DR6 may be the counterparts of HCMV TRS1, US26 and US22, respectively (Gompels *et al.*, 1995), but are not indicated as conserved in Figs. 14.1 and 14.2 or Table 14.1 because the precise correspondence is unclear. With these three exceptions, all of the genes inherited by HCMV and HHV-6 from their common ancestor are located between UL23 and UL124 in HCMV and U2 and U91 in HHV-6. Genes flanking this betaherpesvirus-common set are unique to each virus. Nonetheless, each virus possesses a number of genes within the conserved region that appear to be unique. These include genes lacking sequence and positional counterparts (e.g., HCMV UL116 and HHV-6 U83), genes whose positional counterparts lack sequence or functional similarities (e.g., HCMV UL34 and HHV-6 U13), and genes that are related to others and probably arose by duplication (e.g., HCMV UL25).

Gene duplication

Gene duplication has been employed widely by large eukaryotic DNA viruses and their hosts as a means of generating diversity (Prince and Pickett, 2002). Table 14.2 lists the 13 gene families that appear to have arisen in HCMV. Only four or five families have representatives, and each has fewer members, in HHV-6. The genes that have arisen by duplication appear to function in various specific aspects of the host response to infection. It is interesting to note evidence for duplication in the more recent evolution of these lineages, in the form of additional family members. For example, HHV-7 has two counterparts of HHV-6 U55 (termed U55A and U55B; Nicholas, 1996), CCMV lacks a counterpart to HCMV UL1 and has two additional counterparts of UL146 (Davison *et al.*, 2003a), and RhCMV and

Table 14.2. Gene families in HCMV and HHV-6

Family	HCMV	HHV-6	Features and putative functions
RL11	RL5A, RL6, RL11, RL12, RL13, UL1, UL4, UL5, UL6, UL7, UL8, UL9, UL10, UL11	None	Most are membrane glycoproteins; most share a putative immunoglobulin domain with certain human adenovirus E3 proteins
UL14	UL14, UL141	None	Membrane glycoproteins containing an immunoglobulin domain; UL141 is involved in NK cell evasion
UL18	UL18, UL142	None	MHC-I-related membrane glycoproteins; involved in immune evasion
US22	UL23, UL24, UL26, UL28, UL29, UL36, UL43, US22, US23, US24, US26, IRS1, TRS1	U2, U3, U7, U8, U17, U25, U95, DR1, DR6	Tegument proteins; involved in modulation of the cellular response
UL25	UL25, UL35	U14	Tegument proteins
GPCR	UL33, UL78, US27, US28	U12, U51	Chemokine receptors; some may have been captured independently
DURP	UL31, UL72, UL82, UL83, UL84	U10, U45, U54, U55 (U55A, U55B in HHV-7)	Derived from dUTPase; some are tegument proteins; multiple roles in modulating cellular responses
UL120	UL120, UL121, possibly UL119	Possibly U85	Membrane glycoproteins; possibly derived from OX-2
UL146	UL146, UL147	None	CXC chemokines
US1	US1, US31, US32	None	Related to TT virus ORF2
US2	US2, US3	None	Membrane glycoproteins; roles in immune evasion
US6	US6, US7, US8, US9, US10, US11	None	Membrane glycoproteins; roles in immune evasion
US12	US12, US13, US14, US15, US16, US17, US18, US19, US20, US21	None	Multiple transmembrane proteins

SCMV have additional members of the GPCR family corresponding to the US27 and US28 subset (Martin, 2000; Penfold *et al.*, 2003; Hansen *et al.*, 2003; Sahagun-Ruiz *et al.*, 2004). The potential for rapid evolution of gene family members is illustrated by the observation that certain examples (e.g., UL146 and some of the RL11 family) are among the most variable HCMV genes (Murphy *et al.*, 2003b; Dolan *et al.*, 2004).

It is likely that gene duplication in *Betaherpesvirinae* is more common than can be detected by amino acid sequence similarity, since it is possible for duplicated genes to diverge so extensively that similarity is obliterated. Consideration of two regions potentially in this category exemplifies the difficulties of defining evolutionary origins in such cases. In the first region, the three genes UL40-UL42 in HCMV are positionally equivalent to the six genes U20-U24A in HHV-6. Although the proteins encoded by these genes share no sequence similarity, the fact that all are predicted to be membrane-associated raises the possibility that the genes that encode them are derived from a single ancestor. It is interesting to note that one of the three HHV-6 genes (U22, U83 and U94) lacking counterparts in HHV-7 is located in this region. The analysis summarized in Fig. 14.3 sheds light on a second region, which contains the three genes UL119-UL121 in HCMV and the single gene U85 in HHV-6, all encoding putative membrane glycoproteins. The U85 protein is related to the cellular OX-2 surface glycoprotein, with greatest similarity apparent in an immunoglobulin domain (Gompels *et al.*, 1995). Atalay *et al.* (2002) also noted that an HCMV Fc-receptor encoded by HCMV UL119 contains an immunoglobulin domain. The alignment in Fig. 14.3(a) draws on data from several *Betaherpesvirinae* to support the view that U85 and UL119 are related, but with the latter diverging from OX-2 to a greater extent than the former. The alignment in Fig. 14.3(b) shows that the pair of genes adjacent to UL119 (UL120 and UL121) are distantly related to each other, and thus comprise a novel HCMV gene family. The colons between residues in Fig. 14.3(a) and Fig. 14.3(b) hint that UL120 and UL121 may be related to UL119 via the C-terminal portion of the immunoglobulin domain, although the degree of conservation is marginal. Thus, it appears that U85 and UL119 are both derived from a cellular OX-2 gene, and it is possible that UL120 and UL121 may also have arisen via duplication events involving the ancestor of UL119.

Gene capture

The simplest explanation for the presence in HCMV of genes that have counterparts in the cellular genome is that

of gene capture, a process which appears to involve insertion into the viral genome of a cDNA copy of a cellular mRNA or pre-mRNA, since most such genes lack introns. Recombination events of this sort probably occur commonly on an evolutionary scale, but few would result in viable virus, even fewer would provide a growth advantage, and even fewer still would become fixed in viral populations. The advantages of gene capture are illustrated in the case of cellular cyclo-oxygenase-2, which is involved in prostaglandin synthesis. Expression of this gene facilitates growth of HCMV (Speir *et al.*, 1998; Zhu *et al.*, 2002; Mocarski, 2002), and, unlike HCMV and CCMV, RhCMV has a copy in its genome (Hansen *et al.*, 2003). Gene capture has occurred throughout herpesvirus evolution, with ancient examples such as the dUTPase and uracil-DNA glycosylase genes common to the *Alpha-*, *Beta-* and *Gammaherpesvirinae*, more recent examples in certain of the GPCR family common to the *Betaherpesvirinae*, and even more recent examples such as the UL146 chemokine gene in primate cytomegaloviruses. Some, perhaps all, of the gene families have arisen from captured genes.

In addition to incorporating cellular genes, *Betaherpesvirinae* appear to have exchanged genetic information with other viruses. Thus, HHV-6 U94 is related to the Rep gene of *Parvoviridae*, but lacks a counterpart in HHV-7 (Thomson *et al.*, 1991). The RL11 family proteins of primate cytomegaloviruses share a putative immunoglobulin domain with a glycoprotein family encoded in the E3 region of primate *Adenoviridae* (Davison *et al.*, 2003b). A previously unreported finding concerns the primate cytomegalovirus US1 gene family, whose functions are unknown. Hijikata *et al.* (1999) noted a motif (WX_7 HX_3 $CXCX_5$ H) that is conserved near the N terminus of VP2 in a small, single-stranded DNA virus, chicken anaemia virus (CAV; *Circoviridae*). The N-terminal region of the ORF2 protein in the related TT viruses (TTVs) and TT-like viruses, which are common in humans, also contain this motif. Figure 14.4 shows that the N-terminal regions of proteins specified by the primate cytomegalovirus US1 gene family contain two copies of this motif, each of which, as suggested from the nature of the conserved residues, might coordinate a metal ion. Parenthetically, it is interesting to note that the motif is located within an extended region identified by Peters *et al.* (2002) as conserved between CAV VP2 and cellular protein-tyrosine phosphatases (PTPases). However, the significance of the relationship to PTPases is dubious, since most of the PTPase residues conserved in CAV VP2 are not conserved in the TTV ORF2 protein, and proposed catalytic residues are significantly diverged in VP2 and essentially absent from the ORF2 protein. In any case, the known PTPase catalytic residues are C-terminal to the region aligned with the proposed catalytic residues in VP2, and well outside the conserved region. It is surprising, therefore, that Peters *et al.* (2002) were able to show that VP2 and the ORF2 protein of a TT-like virus have PTPase activity.

Variation

HCMV isolates exhibit a high degree of variation in a wide range of genes (Murphy *et al.*, 2003b; Dolan *et al.*, 2004; Pignatelli *et al.*, 2004). The most variable genes potentially encode proteins that are secreted or associated with membranes, and therefore most exposed to selection by the immune system. Attempts to associate certain alleles with particular pathogenic properties have been largely unsuccessful. This may reflect the multifactorial nature of such properties, and the fact that recombination has played a part in HCMV evolution (Arav-Boger *et al.*, 2002; Rasmussen *et al.*, 2003). Limited studies of variation have also been carried out in HHV-6 (Dominguez *et al.*, 1996; Stanton *et al.*, 2003) and HHV-7 (Chan *et al.*, 2003).

Gene function

Most effort on gene function has been carried out on HCMV, but advances with other cytomegaloviruses have been substantial. Indeed, the use of the powerful bacterial articificial chromosome technology for generating mutants was innovated for MCMV (Messerle *et al.*, 1997) before it was applied to other cytomegaloviruses, including HCMV (Borst *et al.*, 1999; McGregor and Schleiss, 2001; Yu *et al.*, 2002; Chang and Barry, 2003; Murphy *et al.*, 2003b). Studies on non-human cytomegaloviruses form a vital basis for assessing the functions of genes in pathogenesis by means that cannot be applied for HCMV. The parallels are incomplete, however, as even the closest relative of HCMV that could be used practically as an animal model, RhCMV, exhibits genetic differences in comparison with HCMV. With regard to the effects of infection with *Betaherpesvirinae* on cellular transcription, several microarray analyses have been carried out (Zhu *et al.*, 1998; Kenzelmann and Muhlemann, 2000; Simmen *et al.*, 2001; Browne *et al.*, 2001). Further details on HCMV gene function are given in Chapter 15.

Virion structure

In all *Herpesviridae,* the genome is packaged within the icosahedral capsid, which is embedded in a dense proteinaceous matrix termed the tegument, and in turn surrounded by a lipid envelope extensively decorated with viral

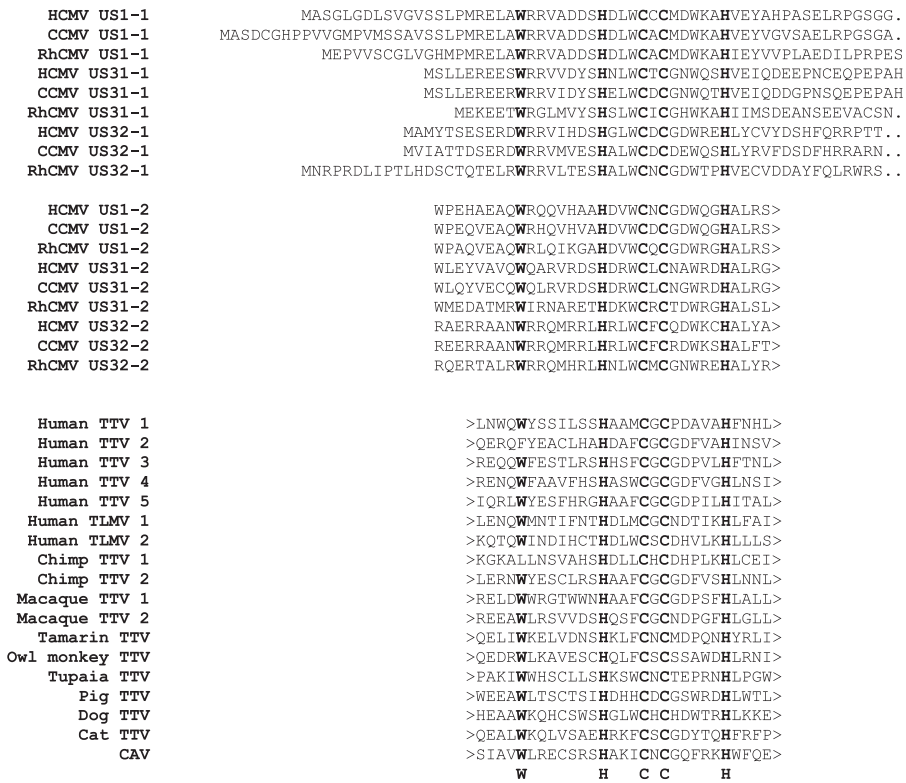

Fig. 14.4. Amino acid sequence alignments of the $WX_7HX_3CXCX_5H$ motif near the N termini of primate cytomegalovirus proteins encoded by the US1 gene family (US1, US31 and US32), the ORF2 proteins of TT viruses (TTV) of various hosts (five, two and two types for humans, chimpanzees and macaques, respectively) and TTV-like miniviruses (TLMV) of humans (two types), and VP2 of chicken anaemia virus (CAV). The cytomegalovirus sequences in the upper two panels commence at the N-terminus and proceed continuously for each virus, so that the two copies of the motif are aligned sequentially. The TTV, TLMV and CAV proteins contain a single copy of the motif. Sequences were derived via the information given in Fig. 2 in Okamoto *et al.* (2002). Arrowheads indicate that the sequences extend further towards the C terminus (cytomegalovirus proteins) or both termini (TTV, TLMV and CAV proteins). The motif is shown at the foot of the alignment.

glycoproteins (see Chapter 3). Virion morphogenesis commences in the host cell nucleus, beginning with assembly of the spherical procapsid by condensation of the capsid and scaffold proteins (see Chapter 20). By analogy with HSV-1 (Newcomb *et al.*, 1996), proteolytic maturation of the HCMV procapsid separates the scaffold from the inside surface of the capsid, giving rise to a more angular particle, while packaging of the viral genome leads to egress of the scaffold component and formation of mature C-capsids (Irmiere and Gibson, 1985). A-capsids and B-capsids are also found in great abundance in the nucleus and in mature virions (Irmiere and Gibson, 1983). A-capsids are devoid of scaffold or DNA, and are thought to be the product of aborted packaging. B-capsids are mature particles containing large or small scaffold cores that are thought to be either precursors of DNA packaging or byproducts of failed packaging (Fig. 14.5(a)). Mature capsids (A, B and C) bud out of the nucleus, and are thought to undergo a process of envelopment and de-envelopment as they traverse the nuclear membrane (see Chapter 20). The maturing virion then acquires its tegument in perinuclear compartments termed tegusomes. Finally, capsids bud into Golgi-derived cytoplasmic compartments, gaining their lipid membrane and envelope glycoproteins in the process, and exit the cell by the exocytotic pathway.

The genome

HCMV has a larger genome than members of the *Alpha-* and *Gammaherpesvirinae*, and it is consequently more tightly packaged within the capsid. However, this is not a generalized feature of the *Betaherpesvirinae,* as the genomes of HHV-6 and HHV-7 are smaller. Nonetheless, the requirement for orderly ingress and egress of the genome, through

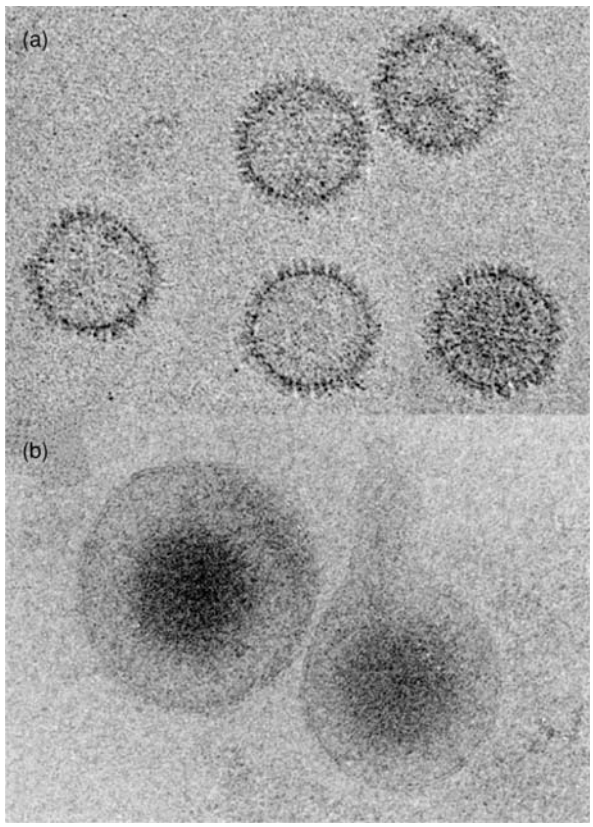

Fig. 14.5. Cryo-micrographs of (a) purified HCMV B-capsids and (b) purified HCMV virions showing the characteristic swirling pattern of the packaged genomic DNA (from Bhella *et al.*, 2000; with permission from Academic Press).

a portal complex, suggests a high degree of organization in genome packaging.

Imaging of HCMV virions by cryo-microscopy allows the packaged DNA molecule to be visualized (Fig. 14.5(b)), revealing the characteristic swirled, striated and punctate array patterns seen in many *Herpesviridae*, as well as in the double-stranded DNA bacteriophages T4, T7, λ and p22 (Bhella *et al.*, 2000). These patterns suggest a mode of packaging in which DNA enters the capsid and spools around the inner surface, winding inwards, towards the centre, in successive layers (Booy *et al.*, 1991; Zhou *et al.*, 1999). Measurements indicate that the HCMV genome is packaged in layers approximately 23 Å apart. Assuming hexagonal packing, which is the preferred conformation of DNA fibres at this packing density, this corresponds to an average interhelix spacing of 26 Å. HSV-1 virions show an interlayer spacing of 26 Å, corresponding to an interhelix distance of 30 Å. At such packing densities, the DNA would be expected to be in a liquid-crystalline state, with possible

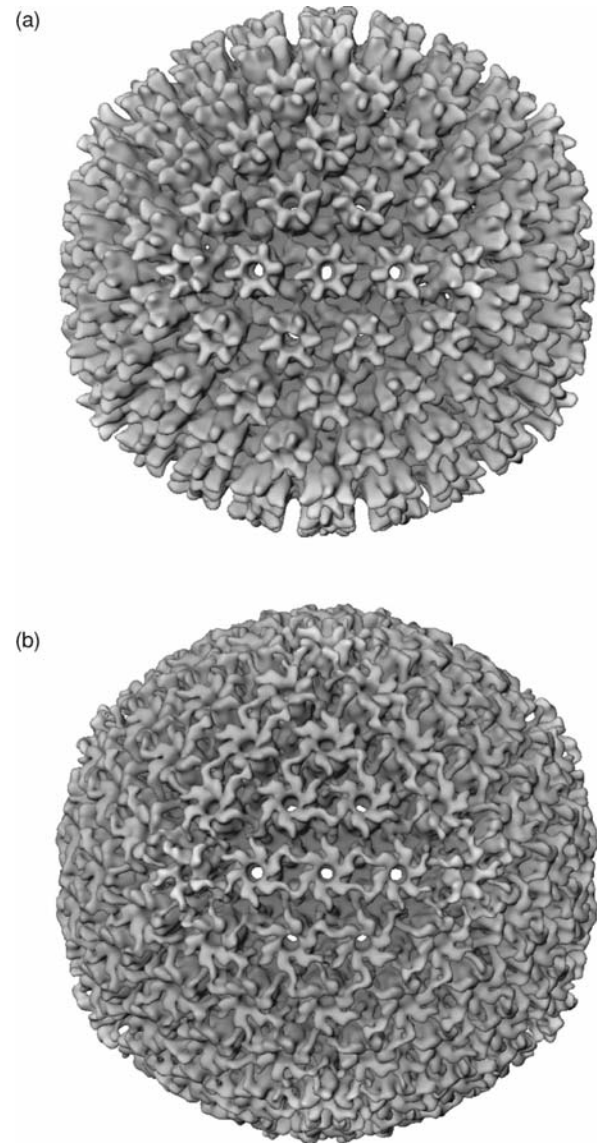

Fig. 14.6. Three-dimensional reconstructions of (a) the HCMV B-capsid (adapted from Butcher *et al.*, 1998; with permission from Academic Press), and (b) the HCMV virion (adapted from Zhou *et al.*, 1999; with permission from the American Society for Microbiology). Both structures are viewed along the icosahedral twofold symmetry axes and are radially depth-cued so that darker regions are closer to the center of the particle and lighter regions are further away. (See color plate section.)

local transitions to three-dimensional hexagonal packing in those viruses with a tighter packing density. However, curvature of the packaged DNA would prevent extensive transition to a crystalline state, suggesting that 26 Å is the upper limit of packing density achievable. In order to

package its genome, HCMV has evolved to produce a larger capsid, with a diameter of 130 nm rather than 125 nm (Butcher *et al.*, 1998).

The capsid

Investigation of B-capsid structure in HCMV strain AD169 by cryo-microscopy and image reconstruction (Fig. 14.5(a)) has revealed an architecture very similar to that of HSV-1, consisting of a hexamer-pentamer clustered T=16 icosadeltahedral shell (Butcher *et al.*, 1998). The capsid is complex, consisting of four structural proteins: the major capsid protein (MCP; encoded by UL86), the minor capsid protein (mCP; UL85), the minor capsid protein-binding protein (mC-BP; UL46) and the smallest capsid protein (SCP; UL48A) (Gibson, 1983; Irmiere and Gibson, 1985; Sedarati and Rosenthal, 1988; Gibson, 1996; Gibson *et al.*, 1996a; Gibson *et al.*, 1996b). In addition, the portal complex, which is presumed to occupy one of the fivefold vertices, is considered a capsid component.

The major structural components of the capsid are the capsomeres, termed pentons and hexons. These large, turret-like structures are composed primarily of five or six copies of the MCP, respectively. In total, there are 150 hexons occupying positions of local six-fold symmetry, and 12 pentons, located at the icosahedral five-fold symmetry axes (Fig. 14.6(a)). The hexons and pentons are 15 nm tall and have a central channel running through them that is constricted some 7.4 nm from the capsid floor, which is also composed of the MCP and appears thicker in HCMV than in HSV-1. The tips of each hexon are decorated with six copies of SCP (Yu *et al.*, 2005), a feature also found in HSV-1, in which the hexons are capped by the homologous protein, VP26 (Booy *et al.*, 1994; Trus *et al.*, 1995; Zhou *et al.*, 1995). A small capsid protein is also associated with the tips of hexons in HHV-8, but is also present at the tips of pentons (Trus *et al.*, 2001). Between the HCMV capsomeres, lying on the capsid floor at positions of local threefold symmetry, are the triplexes. These heterotrimeric structures are composed of two copies of the mCP and one copy of the mC-BP. The triplexes are critical for capsid morphogenesis, most likely linking together the capsomeres in the procapsid, directing assembly, and stabilizing the structure prior to maturation.

The tegument

Perhaps the most striking morphological difference between HCMV and HSV-1 is the extent of icosahedrally ordered tegument in the virion. Cryomicroscopy and image reconstruction have shown that in HSV-1 the only additional, icosahedrally ordered protein that is present in the virion but not the B-capsid is located at the fivefold vertices, where a single rod-like structure connects the tips of each penton MCP (VP5) subunit with the adjacent triplex and its nearest neighboring triplex (Zhou *et al.*, 1999). However, HCMV has an extensive network of icosahedral tegument that, while appearing similar to that found at the HSV-1 penton, also decorates the hexons (Fig. 14.6(b)) (Chen *et al.*, 1999). Appearing as a bridge of density, approximately 120 Å in length and 20–30 Å in diameter, the icosahedrally ordered tegument is anchored to the tip of the hexons and pentons and the top of the adjacent triplex. Investigation of the cytoplasmic B-capsids of SCMV revealed a similar pattern of tegumentation (Trus *et al.*, 1999), although independent reconstruction of lightly, moderately and heavily tegumented capsids suggests that this density is composed of at least two protein species. The first is a capsomere capping protein, which is found at the tips of both the hexons and pentons and therefore binds to the MCP rather than the SCP, which is not present on the penton. The second protein is attached to the capsomere capping protein and the adjacent triplex. The rest of the tegument appears to not be rigidly icosahedral in distribution, but this does not preclude the existence of further order.

Many tegument proteins play roles in the early stages of virus infection and are therefore packaged within the virion to ensure their presence upon infection of a new host, and many are phosphorylated (Roby and Gibson, 1986). The most abundant proteins are the basic phosphoprotein (pp150; encoded by UL32), which is O-glycosylated (Benko *et al.*, 1988) and binds directly to the capsid through its N-terminal one-third (Baxter and Gibson, 2001), the lower matrix protein (pp65; UL83), the upper matrix protein (pp71; UL82), the membrane-associated myristylated protein (pp28; UL99; Sanchez *et al.*, 2000), and the high molecular weight tegument protein (UL48) and its binding protein (UL47). The requirement to incorporate specific proteins suggests that tegument morphogenesis may involve specific interactions between individual components, leading to the formation of a structure that is at least partially ordered. This hypothesis is borne out by the finding that HCMV infections in cell culture give rise to production of many particles composed of enveloped tegument lacking a capsid (dense bodies), suggesting that the tegument can spontaneously self-assemble, possibly around aggregates of pp65 (Irmiere and Gibson, 1983). Moreover, immuno-gold labelling experiments on thin sections of virus-infected cells can reproducibly locate tegument proteins to the outer or inner regions of the tegument (Landini *et al.*, 1987). Logically, specific proteins might be expected to be located at the outer edge of the tegument, since in most enveloped viruses there is a requirement for a specific

interaction between viral matrix proteins and the cytoplasmic tail of envelope glycoproteins. Indeed, pp28 has been shown to be essential for envelopment, and may well serve this function (Silva *et al.*, 2003).

Envelope glycoproteins

Many HCMV genes encode putative membrane glycoproteins. However, few thus far have been identified as components of the virion. The most abundant protein species in the viral envelope have homologues throughout the *Herpesviridae*. These are distributed among three complexes: gCI, gCII and gCIII (Gretch *et al.*, 1988). gCI is composed of homodimers of glycoprotein B (gB; UL55), a type I integral membrane protein (Cranage *et al.*, 1986). gB is cleaved by furin into two fragments (gp55 and gp116), which remain covalently associated (Vey *et al.*, 1995). Dimerization of gB is disulfide bond dependent, and mass spectrometric analysis of proteolytic fragments of recombinant gB has revealed extensive disulfide bond formation, both between gB monomers and also between gp55 and gp116 (Eickmann *et al.*, 1998; Lopper and Compton, 2002). Along with gCII, gCI mediates cell attachment, a two-step process involving initial attachment to heparan sulfate, followed by a stabilizing interaction with another receptor (Boyle and Compton, 1998; see Chapter 16). gCII comprises two proteins: gM (UL100), a type III membrane protein, and gN (UL73), a type I membrane protein (Kari *et al.*, 1994; Mach *et al.*, 2000). gCII components are also heavily disulfide linked, although the presence of monomeric forms of these glycoproteins in the virion suggests that these bonds may not be essential for formation and function of the gCII complex (Kari *et al.*, 1990). gCIII includes a heterotrimer of gH (UL75) as well as a heterotrimer of these proteins plus a third component, gO (UL74), which lacks counterparts in *Alpha-* and *Gammaherpesvirinae* (Kaye *et al.*, 1992b; Spaete *et al.*, 1993; Huber and Compton, 1998; Li *et al.*, 1997). gCIII is involved in mediating fusion of viral and host cell membranes, in concert with gCI. In HHV-6, the third component of gCIII is gQ (U100) rather than gO (Mori *et al.*, 2003a).

In addition to glycoproteins that have counterparts throughout the *Herpesviridae*, HCMV-specific glycoproteins encoded by UL4 and RL10 have been identified as virion components (Chang *et al.*, 1989; Spaderna *et al.*, 2002). Analysis of the trafficking in cells of the RL10 protein in isolation from other HCMV proteins indicates that it may be necessary for this glycoprotein to form complexes with other membrane glycoproteins in order to facilitate incorporation into nascent virions. Similarly to the glycoproteins common to the *Herpesviridae*, the RL10 protein forms high molecular weight complexes in mature virions, possibly by disulfide bond formation.

Additional virion components

In addition to the genome, two small RNA molecules are present in the core of the virion, hybridized to the origin of DNA replication (Prichard *et al.*, 1998). These molecules may play a role in initiating DNA replication by providing a point of action for an RNase H-like enzyme, and digestion of the DNA:RNA hybrid could lead to formation of a primer in the form of the opened DNA or possibly a small fragment of the RNA. A number of mRNAs are also associated with virions, most likely located in the tegument (Bresnahan and Shenk, 2000a). The RNAs detected are specified by UL22A (also termed UL21.5) and RL13, and putative non-protein-coding regions encompassing ORFs UL106-UL109, RL2-RL5 and RL7 as defined by Chee *et al.* (1990). Translation of certain of these RNAs could ensure targeting of encoded proteins to the endoplasmic reticulum and Golgi network, before the viral genome becomes transcriptionally active. Alternatively, these molecules may be modulators of cellular immunity or structural components of the tegument. However, the biological significance of virion RNAs is questionable, since it is now known that incorporation of viral and cellular mRNAs occurs non-specifically, with the abundance of RNAs associated with the virion reflecting that in infected cells (Greijer *et al.*, 2000; Terhune *et al.*, 2004).

As there are no histone-like proteins present in herpesvirions to neutralize the charge of the packaged DNA molecule, some other mechanism must be employed. Detection of the polyamines spermine and spermidine in HCMV virions, and the finding that inhibition of polyamine biosynthesis inhibits virus growth at the level of virion assembly, has led to the suggestion that these molecules may fulfil this role (Gibson *et al.*, 1984). Other virion components contributed by the host cell include annexin II (Wright *et al.*, 1995), phospholipase A2 (Allal *et al.*, 2004), the complement control proteins CD55 and CD59 (Spear *et al.*, 1995) and β-2-microglobulin (McKeating *et al.*, 1987), which are associated with the virion envelope. β-2-microglobulin has also been detected in the tegument (Stannard, 1989), as has an actin-like protein (Baldick and Shenk, 1996). Mass spectrometric methods have recently enabled the proteins present in HCMV virions to be catalogued, including a number of viral proteins not detected hitherto and an impressive number of cellular proteins (Varnum *et al.*, 2004). However, caution needs to be exercised in assessing the biological relevance of proteins detected in low abundance by sensitive immunological or physical methods, since proving the absence of contamination with non-virion material is problematic.

Betaherpes viral genes and their functions

Edward S. Mocarski, Jr.

Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA, USA

Introduction

Despite biological divergence, human cytomegalovirus (HCMV, HHV-5), on the one hand, and the three human roseolaviruses (HHV-6A, HHV-6B, HHV-7), on the other hand, share approximately 70 evolutionarily conserved and collinear genes (italics, Table 15.1). Mammalian betaherpesviruses probably have a common ancestor dating back over 50 million years. The genomes of all betaherpesviruses vary in the regions flanking a large conserved block of genes spanning UL23 to UL124 in HCMV. There appear to be two distinct evolutionary lineages represented by cytomegaloviruses and roseolaviruses infecting primates (Chapter 14). These lineages are not preserved in lower mammals such as rodents where divergence within the cytomegaloviruses is striking. Similarity between rodent cytomegaloviruses and either primate cytomegaloviruses or roseolaviruses is about the same, and includes the same set of 70 conserved genes. Thus, despite the fact that this subgroup of herpesviruses is the most highly distributed amongst mammals, evolutionary divergence is dramatic. The betaherpesvirus-common genes are composed of 41 herpesvirus core functions discussed in Chapters 3, 4 and 14 plus approximately 30 betaherpesvirus-specific gene products that are involved in replication and cell tropism. Biological similarities include tropism for hematopoietic cells in the myeloid lineage (Kondo *et al.*, 2002a; Sissons *et al.*, 2002). In addition to the 70 conserved replication genes human betaherpesviruses HCMV and HHV-6B also have latent genes with a common structure and genomic location (Kondo *et al.*, 1996, 2002b 2003b) suggesting evolutionary conservation in this important process as well. Although little is known about their functions, homologues of several betaherpesvirus-specific genes (UL49, UL79, UL87, UL88, UL91, UL92, and possibly UL95) are common to gammaherpesviruses (see Table 14.1). Thus these two groups are more closely related to each other than to any alphaherpesviruses. Outside of the betaherpesvirus-common genes, there is considerable diversity in this virus group, including the presence of an alphaherpesvirus-like DNA replication origin and origin binding protein in roseolaviruses as well as genes that have been retained only in certain lineages, such as the presence of an adeno-associated virus *rep* gene homologue in closely related HHV-6A and HHV-6B, but not HHV-7, a gene that is conserved as well in the distant rodent betaherpesvirus, rat cytomegalovirus. The presence of specific immunomodulatory genes in only a subset of cytomegaloviruses is also striking (Mocarski, 2002, 2004). How such an array of distinct gene products entered the betaherpesvirus lineage and why they have been retained remain unresolved questions.

As discussed in Chapters 14, the betaherpesvirus-conserved genes include the herpesvirus core set. These genes are clustered towards the center of viral genomes within the unique long (U_L) genomic component of HCMV (Table 15.1). The role of HCMV genes in replication has been systematically studied in variants (*var*) of two laboratory strains Towne*var*ATCC (Dunn *et al.*, 2003b) or AD169*var*ATCC (Yu *et al.*, 2003), and five categories of growth relative to wild-type (parental) virus, have been described: (1) replication better than wild-type (temperance), (2) replication the same as wild-type, (3) complete replication deficiency, (4) severely reduced replication efficiency, (5) slightly reduced replication efficiency (Table 15.1). The host cell type dictates the category for some genes (Dunn *et al.*, 2003b; Hahn *et al.*, 2004) and varying behavior has been observed when viral mutants are studied in fibroblasts, endothelial cells and retinal pigment epithelial cells. In addition to varying behavior in different cell types, HCMV exhibits sensitivity to the cell cycle state at the time of infection (Fortunato *et al.*, 2002) and some

UL35¶	U14	U14	UL25 family; tegument phosphoprotein; interacts with UL82 protein [HHV-7 IE gene]	(Liu and Biegalke, 2002; Schierling *et al.*, 2005; Schierling *et al.*, 2004) [(Menegazzi *et al.*, 1999; Stefan *et al.*, 1997)]
	U15	U15		
UL36 × 1	U17 × 1	U17 × 1	US22 family; immediate early protein, tegument protein; inhibitor of caspase-8-induced apoptosis (vICA). [HHV-6 IE gene]	(McCormick *et al.*, 2003; Patterson and Shenk, 1999; Skaletskaya *et al.*, 2001) [(Flebbe-Rehwaldt *et al.*, 2000; Mirandola *et al.*, 1998)]
UL36 × 2	U17 × 2	U17 × 2		
UL37 × 1¶			mitochondrial inhibitor of apoptosis (vMIA) protein.	(Goldmacher *et al.*, 1999; Hayajneh *et al.*, 2001a; McCormick *et al.*, 2003; Reboredo *et al.*, 2004; McCormick *et al.* 2005)
UL37 × 3	U18	U18	Immediate early glycoprotein. [HHV-6. HHV-7 IE gene]	(Adair *et al.*, 2003; Hayajneh *et al.*, 2001b) [(Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998)]
UL38¶	U19	U19	virion glycoprotein	(Varnum *et al.*, 2004)[(Flebbe-Rehwaldt *et al.*, 2000; Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998)]
UL40			Membrane glycoprotein; signal peptide binds HLA-E to inhibit NK cell cytotoxicity	(Tomasec *et al.*, 2000; Ulbrecht *et al.*, 2000; Wang *et al.*, 2002)
	U20	U20	Putative membrane glycoprotein	[(Mirandola *et al.*, 1998)]
	U21	U21	Putative membrane glycoprotein [directs MHC class I to lysosomes]	[(Hudson *et al.*, 2001)]
	U22	U22	Putative membrane glycoprotein	
	U23	U23	Putative membrane glycoprotein	
	U24	U24	Putative membrane protein	
	U24A	U24A	Putative membrane protein	
UL41A			Virion membrane protein (also called UL41.5)	(Varnum *et al.*, 2004)
UL42			Putative membrane protein	(Dargan *et al.*, 1997; Mocarski *et al.*, 1997)
UL43	U25	U25	US22 family; tegument protein	(Adair *et al.*, 2002)
	U26	U26	Putative multiple transmembrane protein	
UL44†	U27	U27	(core) DNA polymerase processivity subunit (PPS)	(Appleton *et al.*, 2004; Loregian *et al.*, 2004a; Loregian *et al.*, 2004b) [(Agulnick *et al.*, 1993; Lin and Ricciardi, 1998)]
UL45	U28	U28	(core) Tegument; Large subunit of ribonucleotide reductase homologue (enzymatically inactive); virion protein (RR1)	(Hahn *et al.*, 2002; Patrone *et al.*, 2003) [(Sun and Conner, 1999)]
UL46†	U29	U29	(core) Component of capsid triplexes (minor capsid binding protein; TRI1)	(Gibson *et al.*, 1996)
UL47¶	U30	U30	(core) Tegument; intracellular capsid transport; binds to UL48 protein? (LTPbp)	(Bechtel and Shenk, 2002)
UL48†	U31	U31	(core) Largest tegument protein; binds to UL47 protein?; intracellular capsid transport? (LTP) [HHV-7 IE gene]	(Ogawa-Goto *et al.*, 2002) [(Menegazzi *et al.*, 1999)]
UL48A†	U32	U32	(core) Located on tips of hexons in capsids; capsid transport? (SCP) (also called UL48.5)	(Lai and Britt, 2003; Yu *et al.*, 2005)

Table 15.1. (*cont.*)

HCMV[a]	HHV-6[a]	HHV-7[a]	HCMV gene family or function[b]	Selected references[c]
UL49†	U33	U33		
UL50†	U34	U34	(core) Inner nuclear membrane protein; nuclear egress of capsids in MCMV; virion protein? (NEMP)	(Muranyi *et al.*, 2002; Varnum *et al.*, 2004)
UL51†	U35	U35	(core) DNA packaging; terminase-binding? (TERbp)	(Krosky *et al.*, 2000)
UL52†	U36	U36	(core) Capsid transport? (CNTP)	(Krosky *et al.*, 2000)
UL53†	U37	U37	(core) Nuclear matrix protein; nuclear egress of capsids in MCMV (NELP)	(Dal Monte *et al.*, 2002; Muranyi *et al.*, 2002)
UL54†	U38	U38	(core) DNA polymerase catalytic subunit (POL)	(Ihara *et al.*, 1994; Loregian *et al.*, 2004a; Loregian *et al.*, 2004b) [(Yoon *et al.*, 2004)]
UL55†	U39	U39	(core) Virion glycoprotein B (gB); homomultimers; heparan-binding, entry and signaling. [roseolavirus IE gene]	(Jarvis *et al.*, 2004; Lopper and Compton, 2004; Strive *et al.*, 2004; Wang *et al.*, 2003) [(Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998)]
UL56†	U40	U40	(core) Terminase subunit?; binds to DNA packaging motif, exhibits nuclease activity (TER2).	(Bogner, 2002; Krosky *et al.*, 1998; Scheffczik *et al.*, 2002; Scholz *et al.*, 2003)
UL57†	U41	U41	(core) Single-stranded DNA-binding protein (SSB) [roseolavirus IE gene]	(Anders and Gibson, 1988; Kemble *et al.*, 1987) [(Menegazzi *et al.*, 1999; Rotola *et al.*, 1998)]
oriLyt†	*oriLyt*	*oriLyt*	*DNA replication origin for productive infection (cis-acting) Position conserved, sequence diverged between HCMV and roseolaviruses.*	(Anders *et al.*, 1992; Masse *et al.*, 1992; Prichard *et al.*, 1998) [(Dewhurst *et al.*, 1993; Dykes *et al.*, 1997; Krug *et al.*, 2001; Stamey *et al.*, 1995; van Loon *et al.*, 1997)]
UL69¥	U42	U42	(core) Regulatory protein; tegument protein; contributes to cell cycle block; exhibits nucleocytoplasmic shuttling; tegument protein [roseolavirus IE gene]	(Hayashi *et al.*, 2000; Lischka *et al.*, 2001) [(Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998)]
UL70†	U43	U43	(core) Component of DNA helicase-primase; primase homology (HP2)	(McMahon and Anders, 2002)
UL71†	U44	U44	(core) Tegument protein; cytoplasmic egress? (CEF1)	
UL72	U45	U45	(core) Deoxyuridine triphosphatase homologue (enzymatically inactive), virion protein (dUTPase);	(Caposio *et al.*, 2004; Varnum *et al.*, 2004)
UL73†	U46	U46	(core) Virion glycoprotein N (gN); complexes with gM; entry	(Dal Monte *et al.*, 2004; Mach *et al.*, 2000; Mach *et al.*, 2005)
UL74¶	U47	U47	Virion glycoprotein O (gO); complexes with gH and gL in HCMV and roseolaviruses	(Hobom *et al.*, 2000; Huber and Compton, 1998; Theiler and Compton, 2002) [(Mori *et al.*, 2004)]
UL75†	U48	U48	(core) Virion glycoprotein H (gH); complexes with gL and gO; entry	(Baldwin *et al.*, 2000; Hobom *et al.*, 2000) [(Santoro *et al.*, 2003)]
UL76†	U49	U49	(core) Virion-associated regulatory protein	(Wang *et al.*, 2004b)
UL77†	U50	U50	(core) Portal capping protein; role in DNA packaging (PCP)	
UL78	U51	U51	GPCR family; putative chemokine receptor	(Michel *et al.*, 2005) [(Menotti *et al.*, 1999; Milne *et al.*, 2000)]
UL79†	U52	U52		
UL80†	U53	U53	(core) Protease (N terminus) and capsid assembly (scaffold) protein (C terminus) (PR) [HHV-7 IE gene]	(Gibson, 1996; Kim *et al.*, 2004; Plafker and Gibson, 1998) [(Menegazzi *et al.*, 1999; Tigue *et al.*, 1996)]
UL80.5†	U53.5	U53.5	(core) Capsid assembly (scaffold) protein (AP)	(Casaday *et al.*, 2004; Oien *et al.*, 1997; Wood *et al.*, 1997)

US23[¶]			US22 family; tegument protein	(Varnum *et al.*, 2004)
US24			US22 family; tegument protein	(Varnum *et al.*, 2004)
US26[¥]	DR6 × 1 DR6 × 2	DR6 DR7	US22 family (HHV-6 DR-6 homologue)	[(Doniger *et al.*, 1999)]
US27			GPCR family; virion glycoprotein	(Fraile-Ramos *et al.*, 2002; Varnum *et al.*, 2004)
US28			GPCR family; membrane protein; broad spectrum CC and CX3C chemokine receptor; mediates cellular activation and migration	(Billstrom *et al.*, 1999; Casarosa *et al.*, 2001; Gao and Murphy, 1994; Hertel and Mocarski, 2004; Kledal *et al.*, 1998; Melnychuk *et al.*, 2004; Neote *et al.*, 1993; Streblow *et al.*, 1999; Vieira *et al.*, 1998)
US29			Putative membrane glycoprotein, necessary in RPE cells.	
US30*			Putative membrane glycoprotein; temperance for fibroblasts	
US31			US1 family	
US32			US1 family	
US34			Putative secreted protein	
US34A			Putative membrane protein	
TRS1[¶]			US22 family; immediate early transcriptional activator; tegument protein involved in capsid assembly; blocks shut-off of translation [positional to roseolavirus U95]	(Child *et al.*, 2002; Romanowski *et al.*, 1997; Romanowski and Shenk, 1997; Stasiak and Mocarski, 1992); Child *et al.*, 2004

[a] Commonly annotated ORFs of HCMV, together with selected ORFs of HHV-6 (A or B) and HHV-7. Emphasis is on ORFs that are conserved between these viruses. General references to gene mapping, homologies and annotation (Cha *et al.*, 1996; Chee *et al.*, 1990; Davison *et al.*, 2003; Dolan *et al.*, 2004; Dominguez *et al.*, 1999b; Gompels *et al.*, 1995; Nicholas, 1996). Functional dissection of HCMV (Dunn *et al.*, 2003b; Yu *et al.*, 2003) by mutagenesis showing replication better than wild type (*), indistinguishable from wild type (normal type) or one of three broad growth deficient phenotypes: failure to replicate (bold †), very poor replication (bold ¥), slight replication defect (bold ¶) when viruses are assayed in human fibroblasts. Mutations of putative HCMV ORFs UL60 and UL61 are interpreted as disruption of HCMV oriLyt (Masse *et al.*, 1992) rather than a protein-coding ORF.

[b] Betaherpesvirus-common genes in italics, and include 40 herpesvirus core functions (see Chapters 2 and 3). Gene family, characteristics and functional information are provided for HCMV where a blank indicates the absence of functional information.

[c] References listed are to gene function where known in HCMV, with those specific to HHV-6 indicated within []; see Chapter 14 for additional references to mapping and physical characteristics. General reference for HCMV structural proteins is (Baldick and Shenk, 1996).

[d] Positional homologue.

viral mutants accentuate these effects. The herpesvirus core gene products, discussed elsewhere (Chapter 4), play roles in replication. A majority, 33, core genes (UL44, UL46, UL48, UL48A, UL50–UL57, UL70, UL71, UL73, UL75–UL77, UL80, UL80.5, UL85, UL86, UL89, UL93–UL95, UL98, UL99, UL100, UL102, UL104, UL105, UL115) are absolutely essential for HCMV replication. Mutants deficient in one (UL69) exhibit severely reduced replication efficiency (Hayashi *et al.*, 2000) and mutants in five (UL47, UL88, UL97, UL103, UL114) exhibit slightly reduced replication efficiency (Table 15.1) that for UL97 or UL114 can be dependent on the fibroblast cell cycle state (Courcelle *et al.*, 2001; Prichard *et al.*, 1996, 1999; Wolf *et al.*, 2001). Only two core genes, the ribonucleotide reductase homologue (HCMV UL45) and the dUTPase homologue (HCMV UL72), lack any detectable role in replication (Hahn *et al.*, 2002, 2003). Neither of these betaherpesvirus homologues conserve key motifs for enzymatic activity that are found in other herpesviruses leaving an open question as to function.

Many of the 30-odd betaherpesvirus-specific genes investigated individually (Bresnahan and Shenk, 2000;

Greaves and Mocarski, 1998; Marchini *et al.*, 2001) or systematically (Dunn *et al.*, 2003b; Yu *et al.*, 2003) have been found to play some role in viral replication. Ten are essential for HCMV replication in fibroblasts (UL32, UL34, UL49, UL79, UL84, UL87, UL91, UL92, UL96, UL122), six (UL28, UL82, UL112–113, UL117, UL123, US26) have a strong impact on growth and six (UL29, UL31, UL35, UL38, UL74, TRS1) have only a slight impact on growth. While the two systematic mutagenesis efforts (Dunn *et al.*, 2003b; Yu *et al.*, 2003) did not completely agree on the phenotype associated with each gene, there was a remarkable consistency given that different laboratory strains of virus were analyzed and each was completed independently. Although characterization has not continued for most genes, 11 betaherpesvirus-specific genes (UL23, UL24, UL27, UL33, UL36, UL37 × 3, UL43, UL78, UL124, IRS1, US22) play no detectable role in fibroblasts (Dunn *et al.*, 2003b). These include a tropism factor encoded by UL24, which is necessary for replication in endothelial cells (Dunn *et al.*, 2003b), as well as UL36, which encodes the viral inhibitor of caspase 8 activation (vICA), a potent cell death suppressor (McCormick *et al.*, 2003; Skaletskaya *et al.*, 2001) that influences infected cell survival in the presence of inducers of cell death. The role of the two cell death suppressors encoded by HCMV, vICA and viral mitrochondrial inhibitor of apoptosis (vMIA), appear to overlap in protection from cell death during infection (McCormick *et al.*, 2005) despite evidence that only vMIA was important in strain AD169 var ATCC (Reboredo *et al.*, 2004).

Genetic analysis has only begun in the roseolaviruses due to the relative intractability of these viruses to molecular genetic manipulation. The one insertion mutant of HHV-6B that has been reported, disrupting betaherpesvirus-specific U3-U7 (homologues of HCMV UL24, UL27 and UL28), replicates normally (Kondo *et al.*, 2003a), consistent with the behavior of individual gene mutants in HCMV homologues (Dunn *et al.*, 2003b).

One long-standing unique characteristic of the HCMV genome is the presence of gene families (Chee *et al.*, 1990; Dolan *et al.*, 2004), as described in Chapter 14, which extend to all betaherpesviruses (Dominguez *et al.*, 1999a; Gompels and Macaulay, 1995; Nicholas, 1996). The US22 family is the largest and most highly conserved of these families, and includes a great many genes that are dispensable for replication but that play roles in cell survival, cell tropism and pathogenesis (Dunn *et al.*, 2003b; McCormick *et al.*, 2003; Menard *et al.*, 2003; Skaletskaya *et al.*, 2001). HCMV encodes 13 US22 family members (Chee *et al.*, 1990) whereas roseolaviruses encode ten, nine of which are conserved in sequence or genomic location (Table 15.1). Cell tropism appears to be influenced by different members of the US22 family in different viruses. In HCMV, these are involved in tropism for particular cell types or in tempering viral replication in certain cell types (Dunn *et al.*, 2003b). For example, US22 family member UL23 has been implicated as a temperance factor for HCMV growth in fibroblasts. Other identified temperance genes (Table 15.1) are not in the US22 family and are not conserved in betaherpesviruses. The US22 family member UL24 has been implicated as a tropism factor in endothelial cells (Dunn *et al.*, 2003b) and TRS1 protein blocks activation of protein kinase R in the interferon response (Child *et al.*, 2004). Many additional genomic regions have been implicated in the control of cell tropism (Bolovan-Fritts and Wiedeman, 2002; Brown *et al.*, 1995; Cha *et al.*, 1996; Dunn *et al.*, 2003b; Gerna *et al.*, 2003; Hahn *et al.*, 2004; Hertel *et al.*, 2003; Jahn *et al.*, 1999; Kahl *et al.*, 2000; Mocarski *et al.*, 1993; Riegler *et al.*, 2000; Sinzger and Jahn, 1996; Sinzger *et al.*, 2000) but none of these has been associated with specific betaherpesvirus-conserved genes or US22 family members. Insights into tropism have been derived from studies on animal models, primarily MCMV (Brune *et al.*, 2001; Cavanaugh *et al.*, 1996; Grzimek *et al.*, 1999; Manning *et al.*, 1992; Menard *et al.*, 2003; Morello *et al.*, 1999), where evaluation in cell culture as well as in the natural host is experimentally tractable. Using MCMV, tropism for endothelial cells and macrophages has been studied in cultured cells as well as in mice and is influenced by herpesvirus core (RR1) as well as by betaherpesvirus-common (US22 family) gene products (Brune *et al.*, 2001; Hanson *et al.*, 2001; Menard *et al.*, 2003). Betaherpesvirus-conserved tegument-associated US22 family member M36, which encodes vICA similar to HCMV UL36 (McCormick *et al.*, 2003), as well as other US22 family members whose precise homologues cannot be assigned, is a specific determinant of cell tropism for macrophages but not for fibroblasts or endothelial cells (Hanson *et al.*, 2001; Menard *et al.*, 2003). The US22 family member M43 appears to influence viral growth in macrophage-like cells as well as immortalized fibroblasts, but not in primary cells of either cell type (Menard *et al.*, 2003). Unfortunately, the two US22 family members contributing to HCMV endothelial cell tropism (UL24) or temperance (UL23) (Dunn *et al.*, 2003b) have not been found to play a role in tropism for endothelial cells or macrophages when MCMV has been studied (Menard *et al.*, 2003). Also, MCMV studies have thus far not given insights into HCMV (Dunn *et al.*, 2003b; Hahn *et al.*, 2002) such that HCMV RR1 and particular US22 family members implicated in MCMV cell tropism do not exhibit a similar impact on HCMV tropism. Thus, betaherpesvirus-conserved genes have not yet been implicated in common pathways of tropism even though a large proportion of the gene products in betaherpesviruses such as HCMV as well as MCMV appear to be involved in

modulating the host response to infection (Mocarski, 2002; 2004). All betaherpesviruses encode homologues of HCMV UL33 and UL78, seven transmembrane spanning receptors as well as chemokine receptor homologues. Viruses like HCMV and MCMV immunomodulate similar cellular processes, however, these viruses often rely on evolutionarily distinct gene products to do so. Important immunomodulatory functions are therefore largely not reflected in the betaherpesvirus-conserved set of genes.

Discussion here will focus on HCMV, with presentation of betaherpesvirus-common functions in virion structure and entry, proceeding through regulation of gene expression, DNA synthesis, processing and packaging and, finally, maturation and egress. Because of apparent similarity in the genomic location and structure latent transcripts that have been mapped in HCMV (Kondo *et al.*, 1996) and HHV-6B (Kondo *et al.*, 2002b, 2003b), the chapter will conclude with a brief discussion of the molecular basis of betaherpesvirus latency.

Virion structural proteins

Virion structure is highly conserved among betaherpesviruses such that over half the betaherpesvirus-common genes encode structural proteins. As shown in Table 15.1, 23 herpesvirus core genes encode HCMV structural proteins as components of the capsid (UL46, UL48A, UL85, UL86, UL104 gene products), tegument (UL45, UL47, UL48, UL69, UL71, UL72, UL76, UL77, UL88, UL93, UL94, UL95, UL97, UL99, UL103 gene products) or envelope (UL55, UL73, UL75, UL100, UL115 gene products). Many additional core genes are involved in assembly and maturation of virions (Chapter 4). Fifteen betaherpesvirus-specific genes (UL23, UL24, UL32, UL33, UL35, UL36, UL38, UL43, UL74, UL78, UL82, UL96, IRS1, US22, TRS1) encode structural proteins, localizing to the tegument or envelope.

Betaherpesvirus capsids are composed of four major and two minor herpesvirus-conserved proteins (Chapter 4). The major capsid protein (MCP, HCMV UL86 gene product), triplex monomer and dimer proteins (TRI1 and TRI2, HCMV UL46 and UL85 gene products, respectively), and the smallest capsid protein (SCP, HCMV UL48A gene product) are prominent capsid constituents, along with the portal protein (PORT, HCMV UL104 gene product), which likely constitutes one penton used for encapsidation of viral DNA as it does in alphaherpesviruses.

Most herpesvirus core structural proteins localize to the tegument. In HCMV, all core tegument proteins (HCMV UL47, UL48, UL71, UL76, UL77, UL88, UL93–UL97, UL99, UL103 gene products) play some role in replication (Table 15.1), although four, including a protein that likely binds to the largest tegument protein, the homologue of a cytoplasmic egress facilitator, the viral serine-threonine protein kinase (VPK) and a homologue of an encapsidation and egress protein (HCMV UL47, UL88, UL97 and UL103 gene products, respectively), have only a slight impact on viral growth. VPK apparently acts in tandem with host cell cycle kinases to regulate replication events across a spectrum depending on the state of the host cell (Krosky *et al.*, 2003a; Prichard *et al.*, 1999; Wolf *et al.*, 2001) and is dispensable for replication in rapidly dividing host cells where its role is presumably redundant with host protein kinases, possibly as a cdk1 or cdk2 analogue (Kawaguchi *et al.*, 2003). The portal capping protein (HCMV UL77 gene product) is considered part of the tegument and is essential for replication. By analogy with HSV-1, UL48 may be involved in entry (Ogawa-Goto *et al.*, 2002) and others may be involved in egress (Chapter 4). UL76 protein localizes in a pattern that suggests it may be involved in regulating events immediately following infection or during maturation (Wang *et al.*, 2004b). HCMV UL99 protein (pp28) is an abundant, small myristolated tegument protein that localizes to the cytoplasm and is involved in the late stages of virion egress (Jones and Lee, 2004; Silva *et al.*, 2003). If information from alphaherpesviruses is predictive, UL99 protein may be expected to interact with other tegument proteins, such as the UL94 and UL95 gene products, as well as with the gM:gN glycoprotein complex. Investigation of tegument protein activities and capsid–tegument or tegument–envelope interactions remain important areas for experimental investigation.

A bulk of betaherpesvirus-specific structural proteins also localize to the virion tegument (Table 15.1). The most abundant include two UL82 family members, pp65 (lower matrix protein), the UL83 gene product and is the most abundant HCMV tegument protein, and pp71 (upper matrix protein), UK82 gene product, as well as pp150 (large matrix phosphoprotein), UL32 gene product, and pp28 (myristylated tegument phosphoprotein), the UL99 gene product pp65 is a major constituent of dense bodies that are produced during HCMV replication. The abundance of UL82 family members varies in other betaherpesviruses. (Gibson, 1996) as well as several minor tegument proteins. The most abundant HCMV tegument protein (pp65, upper matrix protein, UL83 gene product), a UL82 family member, is not conserved in roseolaviruses. HCMV UL82 encodes pp71, the virion transactivator (Liu and Stinski, 1992) that exhibits an MOI-dependent role in replication (Bresnahan and Shenk, 2000). A minor HCMV tegument protein encoded by UL35 interacts with the pp71 and co-stimulates transcription (Liu and Biegalke, 2002; Schierling *et al.*, 2004, 2005). HCMV UL32 encodes pp150, an essential tegument

protein (Dunn *et al.*, 2003b) that interacts with capsids (Baxter and Gibson, 2001) and localizes to nuclear and cytoplasmic compartments (Sampaio *et al.*, 2005) where it may be involved in virion assembly, maturation or egress. Conserved US22 family members (HCMV genes UL23, UL24, UL36, UL43, IRS1, US22, TRS1) all encode tegument proteins (Table 15.1). These include the UL24 tropism factor as well as UL36, cell death suppressor (McCormick *et al.*, 2003; Skaletskaya *et al.*, 2001), as discussed in Chapter 21.

The most abundant, and functionally important envelope glycoproteins found in HCMV virions, gB, gH:gL and gM:gN, are all herpesvirus core functions. Betaherpesviruses have not yet been found to encode any unique glycoproteins that control viral attachment or entry such as gD in HSV-1 or gp220/350 in EBV. In betaherpesviruses, as well as gammaherpesviruses, the gH:gL complex may be modified by a third component. These variants may influence cell type specificity as has been characterized best in the gammaherpesvirus EBV (Chapter 23). In both HCMV and roseolaviruses, a betaherpesvirus-specific protein, gO, may associate with this complex (Huber and Compton, 1998; Mori *et al.*, 2004), and, in roseolaviruses a separate glycoprotein that is not conserved in HCMV, gQ, may be a component of gH:gL complexes (Mori *et al.*, 2003b). Functional studies on gM:gN have been reported (Mach *et al.*, 2005), suggesting that this most abundant complex in virion envelopes (Varnum *et al.*, 2004) is critical for being involved in some step in entry. Other membrane proteins such as UL33, a ligand-independent seven-transmembrane-spanning signaling protein (Casarosa *et al.*, 2003), UL78, and UL38 may be associated with the virion envelope (Varnum *et al.*, 2004), but viral replication in fibroblasts is not influenced in their absence (Dunn *et al.*, 2003b).

Entry into host cells

The mechanisms of betaherpesvirus binding to the cell surface and of fusion-mediated penetration have been extensively studied but the details of these processes are still incomplete (Chapters 16 and 46). Herpesvirus core glycoproteins appear to play the critical roles in entry (Fig. 15.1), relying on gB, gH:gL and gM:gN (Chapter 4). HCMV entry into fibroblasts is via direct fusion at the cell surface (Compton *et al.*, 1992) and possibly via endocytosis in other cell types (see Chapter 16). Roseolaviruses employ direct penetration as well as endocytic pathways of entry (Mori *et al.*, 2002). Entry of betaherpesviruses appears to involve the interaction of these envelope glycoproteins with a number of distinct receptors, and is initiated by a common use of the cell surface proteoglycan heparan sulfate (Compton *et al.*, 1993; Conti *et al.*, 2000; Neyts *et al.*, 1992). The core protein gB from both HCMV (Compton *et al.*, 1993; Kari and Gehrz, 1993) and roseolaviruses (Conti *et al.*, 2000; Secchiero *et al.*, 1997) binds heparan sulfate. This initial contact is followed by interactions with additional receptors. In HCMV, a variety of cell surface proteins have been proposed to play roles in the subsequent steps in attachment (Chapter 16), although none is yet widely accepted. In addition to the role of receptors as entry mediators, HCMV binding to cells induces signaling cascades (Evers *et al.*, 2004) that activate NF-κB (Yurochko and Huang, 1999; Yurochko *et al.*, 1995), mitogen-activated protein kinase (Johnson *et al.*, 2000), phosphotidylinositol 3 kinase (Johnson *et al.*, 2001), and toll-like pathways (Compton *et al.*, 2003). gB binding seems sufficient for induction of some pathways (Boehme *et al.*, 2004; Boyle *et al.*, 1999; Wang *et al.*, 2003; Yurochko *et al.*, 1997). HCMV gB has been shown to utilize the EGF receptor as well as integrins as entry mediators (Feire *et al.*, 2004; Wang *et al.*, 2003). Signaling may play a critical role in conditioning the cell for viral replication following entry (Wang *et al.*, 2003). In HHV-6A or HHV-6B, CD46 (Santoro *et al.*, 1999) is a critical cellular receptor and interacts with gH-containing glycoprotein complexes (Mori *et al.*, 2004; Mori *et al.*, 2003b; Santoro *et al.*, 2003). Entry of HHV-7 into T cells relies on CD4 (Lusso *et al.*, 1994). Thus, except for initial contact with proteoglycan and the apparent use of core glycoproteins, betaherpesvirus attachment and entry mechanisms appear diverse at the level of current knowledge.

The same set of envelope glycoproteins (gB, gH:gL and gM:gN) have been implicated in fusion between the envelope and the cell membrane (Compton, 2004). HCMV gB and gH have been the most extensively studied for fusion (Baldwin *et al.*, 2000; Feire *et al.*, 2004; Lopper and Compton, 2004; Navarro *et al.*, 1993; Tugizov *et al.*, 1994; Wang *et al.*, 2003). HHV-6A gB is also relatively well studied (Santoro *et al.*, 2003). Recent evidence suggests core envelope glycoproteins gM and gN (gM:gN) may also be important for entry of betaherpesviruses (Mach *et al.*, 2005) despite the fact that their involvement in alphaherpesvirus entry is variable (Chapter 4). The best evidence suggests that the core envelope glycoprotein complexes formed by gB (also called gCI) or gH:gL (also called gCIII) are essential for replication in HCMV (Hobom *et al.*, 2000) because of the role these conserved glycoproteins play in fusion. The role of gH:gL modification by betaherpesvirus-specific UL74 gene product, gO (Hobom *et al.*, 2000; Huber and Compton, 1998; Theiler and Compton, 2002) remains unknown due to its relatively minor impact on viral replication (Dunn *et al.*, 2003b). In HHV-6B, gH:gL modified by either the U47 gene product gO (Mori *et al.*, 2004) or the U100 gene product gQ (Mori *et al.*, 2003a) (Table 15.1) facilitate entry into cells via CD46 (Mori *et al.*, 2003b).

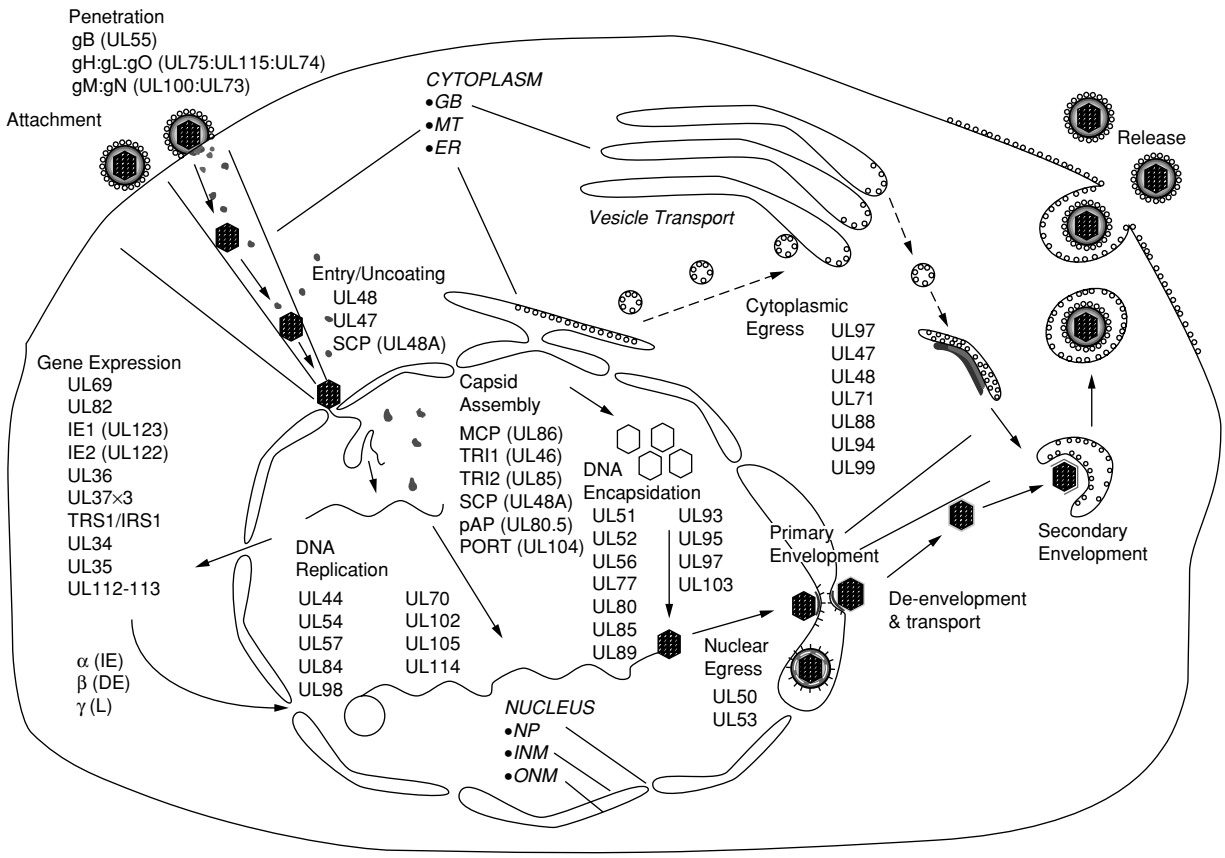

Fig. 15.1. Summary of replication functions carried out by betaherpesvirus-conserved gene products using HCMV gene designations. Major steps in productive replication are indicated along with functions (see Table 15.1) contributing to each step are listed in plain font. The entry pathway shown (black arrows) employs direct fusion at the cell surface (attachment and penetration). Entry may also follow an endocytic pathway and virion fusion with an endocytic vesicle in some betaherpesviruses (see text). Entry requires gB, gH:gL, possibly with gO, and gM:gN. HCMV UL47, UL48 and SCP gene products may mediate transport on microtubules, docking at nuclear pores and release of virion DNA into the nucleus based on work with alphaherpesviruses. One core regulatory protein (UL69) and several betaherpesvirus-specific proteins in the virion (HCMV UL82, UL36, TRS1/IRS1 gene products). expressed as IE genes (HCMV IE1, IE2, UL37 × 3 gene products) or expressed as DE genes (HCMV UL34, UL35 UL112–113 gene products) are involved in transcriptional regulation. DNA replication depends on several core proteins (HCMV UL44, UL54, UL57, UL70, UL102, UL105, UL98, UL114 gene products) as well as one betaherpesvirus-specific protein (UL84 gene product). Capsid assembly uses core functions MCP, TRI1:TRI2, SCP, PORT and pAP. Pre-formed capsids likely translocate to sites of DNA replication where several core proteins (HCMV UL51, UL56, UL77, UL80.5, UL85, UL89, UL93, UL95, UL97, UL103 gene products) are likely to be involved in encapsidation of viral DNA. Nuclear egress is likely to be controlled by HCMV UL50 and UL53 gene products, which are core proteins. Cytoplasmic egress (black arrows) and secondary (final) envelopment are controlled by core functions (HCMV UL47, UL48, UL71, UL88, UL94, UL97, UL99 gene products). Nucleocapsids are likely transported on MT and virion envelope glycoproteins follow vesicle transport to sites of final envelopment in the cytoplasm. Golgi body (GB), microtubules (MT) and endoplasmic reticulum (ER) are identified in the cytoplasm, and nuclear pores (NP), inner nuclear membrane (INM) and outer nuclear membrane (ONM) are identified in the nucleus. The cellular vesicle transport pathway from the ER to GB is also designated (dashed grey arrow). The core functions UL45 (RR1 homologue) and UL72 (dUTPase homologue) are not assigned. Functions for the betherpesvirus-common genes UL28, UL29, UL31, UL32, UL38, UL49, UL76, UL79, UL87, UL91, UL92, UL96, UL117 and US26, all of which have measurable roles in HCMV replication (Table 15.1) are not known.

The importance of the nocadozole-sensitive microtubule network in transport of HCMV nucleocapsids through the cytoplasm to the nucleus (Ogawa-Goto *et al.*, 2003) suggests that betaherpesviruses exploit normal cytoplasmic transport systems to control nucleocapsid transit through the cytoplasm. The bidirectional nature of microtubule-directed transport may allow these filaments to act as the major highways of virus particle translocation during entry as well as egress of all herpesviruses (Chapter 4). It is likely that capsid or proximal tegument proteins that are exposed following fusion mediate trafficking as well as release of the viral genome into the nucleus.

Regulation of gene expression and replication

One of the largest categories of betaherpesvirus-conserved genes encode regulatory proteins. The core homologue of the multifunctional regulator of expression found in all herpesviruses, HCMV UL69, encodes a late gene product incorporated into the tegument. This gene product regulates cell cycle progression (Hayashi *et al.*, 2000) and exhibits similarities to other herpesvirus homologues such as the capacity to shuttle between the nucleus and cytoplasm (Lischka *et al.*, 2001). In the roseolaviruses, this gene (U42) is expressed with immediate early characteristics similar to the alpha-and gammaherpesviruses (Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998), although its function has not been elucidated. Although only this one regulatory protein is included in the herpesvirus core set, a number of additional virion-associated, immediate early and delayed early gene products common to all betaherpesvirus appear to carry out regulatory processes critical to replication.

HCMV UL82 encodes pp71, a virion structural protein that localizes to the nucleus soon after infection and controls transactivation of the immediate early genes (Liu and Stinski, 1992), impacting the levels of viral infection (Bresnahan and Shenk, 2000) as well as the efficiency of viral DNA transfection (Baldick *et al.*, 1997). This gene product facilitates the interaction of viral regulatory and DNA replication proteins with nuclear domain (ND) 10 regions at the start of infection (Hofmann *et al.*, 2002; Ishov *et al.*, 2002), and may possibly control cell cycle regulation via Rb degradation (Kalejta and Shenk, 2003). The UL82 gene product interacts with another betaherpesvirus-conserved tegument protein encoded by the UL35 gene, and appears to cooperate in transactivation as well as play an accessory role in maturation (Schierling *et al.*, 2004, 2005). The roseolaviruses have only a single copy of this gene and this is most closely related to HCMV UL82. Additional UL82 family members are present in many betaherpesviruses where they encode major tegument proteins, such as the UL83 gene product (major tegument phosphoprotein) of HCMV that modulates the host cell response to infection (Abate *et al.*, 2004).

HCMV and roseolaviruses encode major immediate early nuclear proteins that have been designated IE1 and IE2 (Chapter 17). This gene cluster exhibits positional, structural and functional similarities across the betaherpesviruses although the primary amino acid sequence of these two proteins diverges dramatically. These multiply spliced gene products are abundantly made in infected cells where they are the major transactivators of viral gene expression during productive infection. In HCMV, where these gene products have been studied extensively, IE2, an 86 kDa protein, is a critical regulatory gene product responsible for activation of delayed early and late genes (Heider *et al.*, 2002; Marchini *et al.*, 2001; Pizzorno *et al.*, 1991), and IE1, a 72 kDa protein, increases the potency of IE2 in the activation of viral genes and is critical for viral replication following low MOI infection (Gawn and Greaves, 2002; Greaves and Mocarski, 1998). HCMV IE2 interacts with a variety of cellular transcription factors as an adapter or modulator of the host transcription complex to activate gene expression. IE2 is a site-specific DNA binding protein that mediates autoregulatory shut-off of IE1/IE2 region transcription at late times of infection via a specific promoter element (Chapters 17 and 18). IE1 interacts with host chromatin and cellular proteins but has not been found to directly bind DNA. IE1 (Reinhardt *et al.*, 2005) and IE2 (Pizzorno *et al.*, 1991; White *et al.*, 2004) contain distinct acidic activation domains that appear to be crucial for transactivation as well as for their critical role in viral replication.

Minor immediate early proteins are also conserved as betaherpesvirus-specific gene products (Chapter 21). HCMV immediate early proteins TRS1 and IRS1 were initially recognized as regulatory proteins working in conjunction with IE1 and IE2 in activation of delayed early and late gene expression (Iskenderian *et al.*, 1996; Stasiak and Mocarski, 1992), and although virus replication is more highly dependent on TRS1 than IRS1, neither gene product is crucial for virus replication (Blankenship and Shenk, 2002; Dunn *et al.*, 2003b). Mechanistically, the function of these proteins seems focused on the interferon response (Child *et al.*, 2004), which possibly underlies all phenotypes that have been reported.

HCMV also encodes two cell death suppressors (HCMV VICA encoded by UL36 and vMIA encoded by UL37 × 1), one of which (UL36) is more obviously conserved in all betaherpesviruses examined (McCormick *et al.*, 2003), is mutated in some strains of HCMV (Skaletskaya *et al.*, 2001) and is dispensable for replication (Patterson and Shenk,

1999). HCMV UL37 × 1 is a potent inhibitor of apoptosis (Goldmacher *et al.*, 1999) also dispensable (McCormick *et al.*, 2005), that was first thought to only be conserved amongst primate cytomegaloviruses (McCormick *et al.*, 2003). It is now clear that the MCMVm 38.5 gene functions like vMIA (McCormick *et al.*, 2005). HCMV UL37×3, which was originally designated UL37 (Chee *et al.*, 1990), is an immediate early gene product that is spliced to UL37×1 to produce a number of related gene products (Adair *et al.*, 2003). An upstream exon has not been detected in other betaherpesviruses (Table 15.1). HCMV UL37×3 does not block apoptosis when expressed without UL37×1. UL37×3 and UL37×1 are dispensable for replication (Borst *et al.*, 1999; McCormick *et al.*, 2005) UL37×3 may play some role as a transactivator of viral or cellular gene expression (Hayajneh *et al.*, 2001b), possibly in conjunction with the expression of DNA replication genes (Colberg-Poley *et al.*, 1998).

Several delayed early regulatory HCMV genes are also conserved and betaherpesvirus-specific. UL112-UL113 gene products are multiply spliced and abundant delayed early nuclear proteins (Chapter 18) critical for replication (Dunn *et al.*, 2003b; Yu *et al.*, 2003) playing roles in regulation of gene expression as well as in the initial formation of viral DNA replication compartments together with IE2 (Ahn *et al.*, 1999; Penfold and Mocarski, 1997). The conserved HCMV gene UL34 encodes a number of related regulatory gene products at early and late times during infection (Biegalke *et al.*, 2004) and is an essential replication function (Dunn *et al.*, 2003b). One activity of UL34 that has been characterized is repression of US3 expression; however, the function of UL34 that is important for viral replication must lie elsewhere because US3 is itself an immediate early immunomodulatory gene that is dispensable for replication (Chapter 62). UL84 is another nuclear delayed early protein that, in HCMV, interacts with IE2 and appears crucial for viral DNA replication (Sarisky and Hayward, 1996; Xu *et al.*, 2004a) as well as in the possible modulation of IE2 transactivation activity (Gebert *et al.*, 1997).

Viral DNA synthesis and nucleotide metabolism

Betaherpesviruses have conserved the herpesvirus core set of six DNA synthesis enzymes necessary for lytic (productive) infection as well as a number of functions that, in HCMV, play roles in the initiation of DNA replication (Chapter 19). HCMV and the roseolaviruses replicate DNA in the nucleus of the cell and have a single, positionally conserved, lytic replication origin (oriLyt), located between the genes encoding homologues of HCMV UL57 and UL69. These viruses, however, have very different *cis*- as well as *trans*-acting functions involved in the initiation of DNA replication. On the one hand, HCMV has a large, complex origin region (Anders *et al.*, 1992; Masse *et al.*, 1992) with an embedded RNA transcript (Prichard *et al.*, 1998) that apparently requires transcriptional transactivators IE2 and ppUL84 for initiation (Xu *et al.*, 2004b). The dependence of HCMV oriLyt dependent replication on UL84 or IE2 varies with assay used (Sarisky and Hayward, 1996; Reid *et al.*, 2003). Other cytomegaloviruses such as MCMV share the complex origin in a similar genomic position, but do not share any obvious sequence elements that define oriLyt functional domains (Masse *et al.*, 1992). On the other hand, HHV-6A, HHV-6B and HHV-7 have a less complex oriLyt arranged as an inverted repeat region that interacts with a viral oriBP (Table 15.1) to initiate replication (Dewhurst *et al.*, 1993; Inoue and Pellett, 1995; Krug *et al.*, 2001; Stamey *et al.*, 1995; van Loon *et al.*, 1997). Roseolavirus DNA replication likely occurs in ways analogous to alphaherpesviruses (Boehmer and Nimonkar, 2003).

UL84, together with IE2, plays an essential role in HCMV DNA replication (Pari and Anders, 1993; Sarisky and Hayward, 1996) and is conserved in other betaherpesviruses. In HCMV, an UL84:IE2 complex (Spector and Tevethia, 1994) may orchestrate the sequential association of viral proteins with ND10 regions to promotes both transcription of viral genes and development of replication centers. The stepwise addition of UL112-UL113 gene products and the six core replication proteins is likely controlled by UL84 (Ahn *et al.*, 1999; Colletti *et al.*, 2004; Penfold and Mocarski, 1997; Xu *et al.*, 2004a,b). The phenotype of a UL84 mutant is consistent with a crucial role in the intermediate events of DNA replication in a way that may be similar to the established role of IE transactivators in gammaherpesvirus lytic DNA replication (Chapter 26). One poorly understood aspect of HCMV DNA replication is the function of RNA incorporated as a triple-stranded complex associated within oriLyt (Prichard *et al.*, 1998). Active transcription from this region during infection seems to be associated with DNA replication (Huang *et al.*, 1996), although transcripts arise from several different regions across the oriLyt region.

One unexplained, but interesting twist is that, despite their genome complexity, betaherpesviruses lack ancillary nucleotide metabolism functions to the extent found in most other herpesviruses. The betaherpesviruses lack a widely conserved thymidine kinase gene. Instead, VPK (HCMV UL97 gene product) acts as the nucleoside kinase for antiviral drugs such as ganciclovir. Herpesvirus core genes with homology to ribonucleotide reductase (RR1, the HCMV UL45 gene product) or deoxyuridine triphosphatase (dUTPase, the HCMV UL72 gene product) encode enzymatically inactive proteins, based on studies of the

RR1 homologue in HHV-7 (Sun and Conner, 1999), MCMV (Lembo *et al.*, 2004), HCMV (Hahn *et al.*, 2002; Patrone *et al.*, 2003) and the dUTPase homologue in HCMV (Caposio *et al.*, 2004). In HCMV, UL84 has been assigned UTPase activity (Colletti *et al.*, 2005) although it is not yet clear how this may be related to dUTPase or other activities of this gene product in viral replication.

Capsid assembly and DNA encapsidation

The basic features of capsid maturation common to all herpesviruses appear to be preserved in the betaherpesviruses based on the conservation of genes known to be involved in this process in alphaherpesviruses (Chapter 4). Capsid assembly in the nucleus of the host cell employs the herpesvirus-conserved components of the capsid shell (MCP, SCP, TRI1 and TRI2) working in conjunction with a precursor of the assembly protein (pAP, HCMV UL80.5 gene product). A protease (PR, also called assemblin,) is also required for maturation. This protein is made as a precursor (pre-PR) consisting of PR as its amino terminus fused to a longer polypeptide that contains a region that includes the pAP sequence as its carboxyl end (HCMV UL80 gene product). PR is a serine protease that self-cleaves in prePR to release PR as well as a variant of pAP, and also processes the PR, pAP, as well as all variants of pAP (Gibson, 1996). This processing results in the production of multiple forms of pAP with identical carboxyl termini. In addition, PORT (HCMV UL104 gene product) is incorporated as one penton likely to be necessary for DNA encapsidation. During infection, pre-PR must be cleaved into PR and variant AP for encapsidation to follow capsid formation but both of these proteins, as well as AP, are absent from mature, DNA-containing capsids. Maturation is regulated by phosphorylation of the participating proteins.

Once betaherpesvirus DNA has replicated in the nucleus, encapsidation is controlled by a conserved *cis*-acting element (cleavage/packaging or *pac* site) and a series of seven herpesvirus conserved *trans*-acting functions. Functional herpesvirus-conserved *pac*1 and *pac*2 signals are located near the genomic ends of HCMV, although their arrangement appears to be unique (Bogner *et al.*, 1998; Kemble and Mocarski, 1989; Mocarski *et al.*, 1987). The processes of DNA recognition, encapsidation and cleavage are all carried out by herpesvirus core functions (Fig. 15.1). Based on systematic mutagenesis (Dunn *et al.*, 2003b; Yu *et al.*, 2003) but limited functional investigation, encapsidation of viral DNA in HCMV is likely to involve the core gene products encoded by the essential UL51, UL52, UL56, UL77, UL80, UL89, UL93 and UL95 genes (Table 15.1; Fig. 15.1), with the UL56 and UL89 gene products forming the heterodimeric, benzimidizole-sensitive terminase (TER) (Krosky *et al.*, 1998; Scheffczik *et al.*, 2002). This complex probably interacts with the PORT (UL104 gene product) penton of the capsid (Dittmer and Bogner, 2005), likely in combination with a TER-associated protein (UL51 gene product) and portal capping protein (UL77 gene product). Based on studies in other herpesviruses (Chapter 4), these five proteins mediate recognition of a *pac* site on multi-genome DNA concatamers, docking with the appropriate site on a capsid, threading viral DNA into the caspid, cleavage at a *pac* site and sealing the genome into the nucleocapsid (Fig. 15.1). Also the herpesvirus core HCMV UL52 gene product may play a role in capsid transport and the UL80 gene product, which contains the maturational protease and assembly protein, are likely to be involved in encapsidation. Phosphorylation by the VPK influences encapsidation efficiency (Wolf *et al.*, 2001), although cellular enzymes may also play a role because the requirement for VPK is relaxed in dividing cells (Prichard *et al.*, 1999; Wolf *et al.*, 2001).

Maturation

Once viral DNA has been packaged, the nucleocapsid interacts with tegument proteins together with non-structural proteins in a complex, two-stage envelopment and egress process that starts in the nucleus and leads to virion release by exocytosis at the plasma membrane (Fig. 15.1). Insights into how this process proceeds are coming from studies in HCMV and MCMV, and the functions that have thus far been implicated are encoded by herpesvirus core genes (Chapter 4). The initial envelopment event occurs at the inner nuclear membrane and favors DNA-containing nucleocapsids. In betaherpesviruses, capsids lacking DNA mature, appear in the cytoplasm and accumulate as non-infectious enveloped particles (Gibson, 1996). Correct localization in the nucleus appears critical to proper egress. Based on studies on the MCMV homologues (Muranyi *et al.*, 2002), two proteins (HCMV UL50 and UL53 gene products) appear to form a nuclear egress complex on the inner nuclear membrane to control egress from the nucleus as well as disruption of the nuclear lamina. Based on studies in alphaherpesvirurses, the nuclear egress membrane protein (HCMV UL50 gene product), likely to be a type II membrane-spanning protein, would anchor the nuclear egress lamina protein (HCMV UL53 gene product), a phosphoprotein that interacts with the nuclear lamina (Mettenleiter, 2004). Protein kinases appear to play regulatory roles in nuclear egress. In HCMV, the conserved VPK influences nuclear egress (Krosky *et al.*, 2003a), and, in MCMV, host

protein kinase C has been implicated in disruption of the nuclear lamina to allow egress (Muranyi *et al.*, 2002). The nuclear egress complex may also participate in membrane fusion events at the outer nuclear membrane that are required to deposit the nucleocapsid in the cytoplasm (de-envelopment).

Evidence for final betaherpesvirus envelopment in the cytoplasm at late endosomal or Golgi body membranes has been suspected for many years (Tooze *et al.*, 1993). Certain virion tegument proteins associate with nucleocapsids during nuclear egress, but many are added in the cytoplasm where they play essential roles in maturation (Sanchez *et al.*, 2000a). Current evidence on alphaherpesviruses and betaherpesviruses suggests that a conserved cytoplasmic egress tegument protein (HCMV UL99 gene product, pp28) plays a critical role in the secondary, or final, envelopment at cytoplasmic membranes (Britt *et al.*, 2004; Jones and Lee, 2004; Silva *et al.*, 2003). This protein is modified by myristylation and palmitylation and localizes to the cytoplasmic face of cellular membranes. In alphaherpesviruses, this homologue interacts with another herpesvirus-conserved tegument protein, a homologue of the HCMV UL94 gene product, to form a complex involved in transport (Mettenleiter, 2004). Two additional tegument proteins conserved amongst herpesviruses (HCMV UL71 and UL88 gene products) may associate with cytoplasmic membranes and be involved in egress.

A critical role in final envelopment has recently been ascribed to the major tegument phosphoprotein pp150 (encoded by UL32), a betaherpesvirus-conserved function (Aucoin *et al.*, 2006).

Thus, final envelopment occurs in the cytoplasm and, as a consequence the tegument of virions includes small amounts of cellular proteins, in particular actin (Kattenhorn *et al.*, 2004; Varnum *et al.*, 2004), as well as RNAs (Greijer *et al.*, 2003; Terhune *et al.*, 2004) that appear to represent a quantitative sampling of the cytosol. Once final envelopment has occurred, the mature virion is transported inside of a vesicle to the cell surface for release by fusion of an exocytic vesicle with the plasma membrane, a process that is likely to follow cellular vesicle trafficking pathways (Fig. 15.1).

Latency

Although there are biological differences in the pathogenesis of betaherpesviruses, infections with cytomegaloviruses and roseolaviruses appear to share a common involvement of myeloid cells, particularly in the monocyte-macrophage lineage (Kondo *et al.*, 2002a; Sissons *et al.*, 2002; Mocarski *et al.*, 2005). Persistence, latency and reactivation of these viruses exhibit similarities as well as clear differences (Chapters 42 and 47). In HCMV as well as HHV-6B, latent transcripts with a common structure and genomic location have been mapped to the major IE locus (Chapter 47). These transcripts are found in bone marrow-derived granulocyte–macrophage progenitors naturally infected with HCMV (Kondo *et al.*, 1996) or in peripheral blood monocytes naturally infected with HHV-6B (Kondo *et al.*, 2002a,b). Although the genomic region encoding these transcripts also encodes the productive phase IE1 and IE2 gene products, and IE1 is a chromatin tethering protein similar to genome maintenance functions encoded by gammaherpesviruses (Reinhardt *et al.*, 2005), the major IE gene products are not encoded during natural or experimental latent infection. In both HCMV and HHV-6B, a number of novel gene products are associated with latent transcripts (Chapter 47). In HHV-6B, these transcripts may control a stage when IE1 is needed to facilitate reactivation (Kondo, 2003). Thus far, the function of novel latent gene products has not emerged from studies using cell culture models.

This analysis of the role of betaherpesvirus-conserved gene products has attempted to evaluate data generated in a wide variety of systems such that some predictions will certainly be clarified by further investigation. This chapter is intended to provide a starting point for evaluation of data on additional betaherpesvirus-conserved functions by providing a perspective on what is known about better-studied homologues.

Early events in human cytomegalovirus infection

Teresa Compton and Adam Feire

McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, WI, USA

Introduction

All viruses must deliver their genomes to host cells to initiate infection. The plasma membrane together with cell surface constituents serve as initial barriers to entry as well as the mediators that facilitate the process. This chapter will summarize what is known about the entry pathway of human cytomegalovirus, noting certain parallels and commonalities between human cytomegalovirus (HCMV) and other betaherpesviruses (see Chapter 46 for specific pathways of HHV-6 and HHV-7 entry). The roles of HCMV envelope glycoproteins and cellular receptors that control virion attachment and membrane fusion will be summarized. This chapter will also discuss the emerging role of signaling pathways in the early events in infection and examine how virus entry and innate immune activation may be coordinated.

In the simplest context, entry requires that enveloped viruses, including HCMV, HHV-6A or B and HHV-7, use virion envelope proteins to facilitate adherence to the cell surface and fusion between the virus envelope and a cellular membrane that results in the deposition of virion components into the cytoplasm. Following delivery to the cytoplasm, capsid or tegument proteins facilitate transport through the cytoplasm to and delivery of the viral genome to the nucleus in a process known as uncoating. Tegument proteins also translocate independent of the capsid to cytoplasmic or nuclear sites. For structurally complex viruses whose envelopes contain as many as 20 proteins and glycoproteins, attachment is a multi-step process typically involving more than one envelope glycoprotein interacting with a series of cell surface receptors that serve as primary receptors and coreceptors. One consequence of these virus-cell interactions based largely on information from negative strand RNA viruses is that predicted receptor-activated conformational changes in envelope glycoproteins play roles in membrane fusion. Multiple HCMV envelope glycoproteins are required to fuse membranes. Another consequence of these initial virus–host interactions may be the formation and/or delivery of bound virions to specialized membrane domains or compartments that are optimal for fusion and for activation of signal transduction into the cell. We have also recently learned that HCMV entry is accompanied by innate immune activation. This considerably heightens the complexity of the molecular events occurring during the early events in HCMV infection.

To begin a discussion of virus entry at the cellular level, one must first consider the basis of cellular tropism since receptors involved in entry are expressed on permissive cells. In the human host, HCMV causes systemic infection and exhibits a tropism for fibroblasts, endothelial cells, epithelial cells, monocytes/macrophages, smooth muscle cells, stromal cells, neuronal cells, neutrophils, and hepatocytes (Myerson *et al.*, 1984; Sinzger *et al.*, 2000). This exceptionally broad cellular tropism in the infected host is the basis of HCMV disease manifestation by this opportunist in a variety of organ systems and tissue types in the immunocompromised host. HCMV is considered to have a restricted cell tropism in vitro, however, entry into target cells is very promiscuous, since HCMV is able to bind, fuse and initiate replication in all tested vertebrate cell types. Productive in vitro replication is supported by primary fibroblast, endothelial and certain differentiated myeloid cells as well as some astrocytoma lines (Ibanez *et al.*, 1991; Nowlin *et al.*, 1991). The ability of HCMV to enter such a wide range of cells is consistent with either one broad common receptor or a number of cell-specific multiple cell specific receptors or a complex entry pathway in which a combination of both cell specific and broadly expressed cellular receptors are utilized. By contrast, both major variants of HHV-6 and HHV-7 are predominately T-lymphotropic

although HHV-6 can infect certain cells of myeloid lineage as well. HHV-7 uses CD4, a strictly T-lymphocyte expressed molecule as a receptor while HHV-6A and B use a more broadly distributed molecule CD46 as a receptor (Lusso *et al.*, 1994; Santoro *et al.*, 1999).

Cellular receptors for HCMV

It has been known for some time that HCMV initiates infection by binding to cell surface heparan sulfate proteoglycans (HSPGs) (Compton *et al.*, 1991). Engagement of HSPGs is one relatively conserved feature of herpesvirus entry pathways and is also thought to play a role in HHV-6 and HHV-7 interactions with lymphoid cells (Conti *et al.*, 2000). At least in cell culture systems, HCMV engagement of HSPGs is thought to play a crucial role in initial stage of entry by enhancing the engagement of subsequent receptors in a cascade that ultimately leads to fusion (Compton *et al.*, 1993). This hypothesis is further supported by biochemical analysis of HCMV binding, which indicates biphasic binding properties with multiple distinct affinities (Boyle and Compton, 1998).

The ability of HCMV to bind a broad range of cell types in culture has hampered efforts to identify cellular receptors using modern molecular approaches such as expression cloning. Over the past 20 years, numerous receptor candidates have been proposed, but none has been found to be absolutely necessary for infection of all susceptible cell types. These candidate receptor molecules have been selected on the basis of solid initial criteria but none have turned out to be a general entry mediator following further investigation. It is possible that each is important only in certain cell types or tissues. It also remains possible that functional redundancy masks their individual roles.

HCMV virions were initially shown to bind β_2 microglobulin (β_2m) in urine samples (Grundy *et al.*, 1988; McKeating *et al.*, 1987; McKeating *et al.*, 1986). This observation led to binding studies showing that HCMV tegument, not envelope, binds β_2m during release from cells (Grundy *et al.*, 1987a,b; McKeating *et al.*, 1987; Stannard, 1989). This β_2m–HCMV complex was then thought to associate with the alpha chain of host cell major histocompatibility complex (MHC) class I antigens (Beersma *et al.*, 1990; 1991; Browne *et al.*, 1990; Grundy *et al.*, 1987a,b). These data led to a model in which β_2m-coated HCMV bound MHC class I molecules, displacing β_2m. However, it was later determined that β_2m expression had no correlation with in vitro entry of HCMV or in vivo spread of MCMV infectivity (Beersma *et al.*, 1991; Polic *et al.*, 1996; Wu *et al.*, 1994). The demonstration that β_2m-deficient and MHC class I-deficient mice maintain full susceptiblity to MCMV infection (Polic *et al.*, 1996) provided the last piece of evidence confounding this hypothesis.

Virus-cell overlay blots identified a cell surface protein of approximately 30 kDa whose expression correlated with cells permissive for entry, suggesting that this cellular protein may be involved in HCMV entry (Nowlin *et al.*, 1991; Taylor and Cooper, 1990). This protein was later identified as annexin II, a protein that normally binds phospholipids and calcium and has membrane bridging capabilities (Wright *et al.*, 1993, 1995). Annexin II found associated with HCMV virions (Wright *et al.*, 1994, 1995). Although annexin II binds gB and enhances HCMV binding and fusion to phospholipid-containing membranes (Pietropaolo and Compton, 1997; Raynor *et al.*, 1999), cells devoid of annexin II are fully permissive for entry and initiation of infection (Pietropaolo and Compton, 1999). The role, if any, for annexin II in HCMV entry remains unknown but this protein's membrane bridging activity may enhance entry, cell–cell spread and/or maturation and egress.

CD13, or human aminopeptidase N, is a glycosylphosphatidylinositol-linked membrane protein that has also been implicated as a receptor. This hypothesis was based on that fact only human peripheral blood mononuclear cells (PBMCs) that were CD13 positive supported productive infection (Larsson *et al.*, 1998; Soderberg *et al.*, 1993a,b). This led to a more thorough study of this possibility in which CD13-specific antibodies, and chemical inhibitors of CD13 activity were both shown to inhibit HCMV binding and entry (Soderberg *et al.*, 1993a). Excitement from this report was dampened by later reports that CD13 antibodies bind to and neutralize virus before contact with cells and by the fact that entry of HCMV into CD13 depleted cells remains normal (Giugni *et al.*, 1996). More recently, an interaction between HCMV and CD13 was shown to be important in inhibition of differentiation of monocytes into macrophages suggesting this may be a strategy for interference with cellular differentiation pathways (Gredmark *et al.*, 2004).

A consideration of HCMV-induced signaling cascades led Huang and colleagues to hypothesize a role for epidermal growth factor receptor (EGFR) as a HCMV receptor (Wang *et al.*, 2003). EGFR was reported to be phosphorylated in response to HCMV and this phosphorylation event correlated with the activation of phosphatidylinositol 3-kinase (PI-3 kinase) and Akt, as well as the mobilization of intracellular Ca^{2+}. These signaling events were blocked in the presence of EGFR antibodies. In addition, chemically cross-linked virus provided evidence for a gB–EGFR interaction. A limitation of the study, however was that there was no experimental evidence that EGFR functioned

in entry *per se* nor was it determined whether EGFR was required for the delivery of virion components across the plasma membrane. Also, conflicting results exist in the literature. Fairley and colleagues demonstrated that HCMV promoted inactivation of EGFR phosphorylation and signaling (Fairley *et al.*, 2002). In these experiments, EGFR polyclonal antibodies had no effect on HCMV entry (Soderberg *et al.*, 1993a). It is important to note that EGFR is not expressed on all HCMV susceptible cells, such as those of a hematopoeitic lineage.

Finally, an anti-idiotype antibody to viral envelope glycoprotein H (gH), identified a phosphorylated 92.5kDa cell surface glycoprotein that may be involved in the steps that follow attachment (Keay and Baldwin, 1991, 1992, 1996; Keay *et al.*, 1989, 1995). Combined, the study of HCMV entry receptors, like studies aimed at identifying entry mediators in other herpesviruses, include reports that cannot be reconciled with the ability of this virus to enter and uncoat in a broad range of cell types without invoking functional redundancy. There is continued need for data confirmation as well as further functional investigation of all receptor candidates.

Entry activated cell signaling

The first and foremost observation about HCMV biology was its namesake characteristic, cytomegaly, or cell enlargement. In vitro studies initially demonstrated a unique cytopathogenic effect (CPE) of infected cells, with HCMV infected cells appearing rounded and developing an enlarged appearance with both intracellular and intranuclear inclusion bodies late during infection (Albrecht and Weller, 1980). Infection proceeded with two waves of cell rounding, the first beginning as early as a few hours postinfection and corresponding to the impact of entry, and another starting at approximately 24 hours postinfection, when there is a distinct peak in cellular transcription and translation. The cause of this phenomenon was widely speculated upon however, and theories for HCMV-induced cell rounding included cation influx, suppression of fibronectin synthesis and integrin down-regulation (Albrecht *et al.*, 1983; Albrecht and Weller, 1980; Ihara *et al.*, 1982; Warren *et al.*, 1994).

It has been apparent for many years that cells respond to HCMV virions by activation of numerous cell signaling pathways including changes in Ca^{2+} homeostasis, activation of phospholipases C and A2, as well as increased release of arachidonic acid and its metabolites (for review, see Fortunato *et al.*, 2000). All of these changes can be triggered by UV-inactivated virions (Boldogh *et al.*, 1990, 1991b), suggesting that structural components of the virus are responsible for activation during virus-cell contact and/or virus entry. Virus–cell contact also results in the activation of transcription factors such as cfos/jun, myc, NF-κB, SP-1, as well as phosphatidylinositol 3-kinase (PI3-kinase) and mitogen-activated protein (MAP) kinases ERK1/2 and p38 (Boyle *et al.*, 1999; Kowalik *et al.*, 1993; Yurochko *et al.*, 1995, 1997; Boldogh *et al.*, 1991a; Johnson *et al.*, 2001)). These virally induced cellular physiological changes are associated with a profound effect on host cell gene expression. The levels of hundreds of host cell transcripts are altered within a few hours after exposure to virus, virus particles or soluble gB (Browne *et al.*, 2001; Simmen *et al.*, 2001; Zhu *et al.*, 1998). Thus, transcriptional changes immediately after infection do not reflect viral gene expression. These data are consistent with the interpretation that HCMV engages a cellular receptor(s) that activate signal transduction pathways culminating in reprogramming of cellular transcription.

Cellular integrins may serve as coreceptors for betaherpesviruses

Cellular integrins are ubiquitously expressed cell surface receptors that, when activated, lead to major reorganization of the cytoskeleton. Integrins exist on the plasma membrane as non-covalently linked heterodimers consisting of an α- and a β-subunit, which convey specificity in cell–cell and cell–ECM (extracellular matrix) attachment, immune cell recruitment, extravasation, and signaling (Berman and Kozlova, 2000; Berman *et al.*, 2003; Cary *et al.*, 1999). In addition, integrins have emerged as receptors for a broad range of pathogens and mediate binding of plant spores, bacteria and viruses. Feire *et al.* (2004) investigated the role that integrins play in the HCMV entry pathway. Analysis of the effects of various neutralizing antibodies implicated α2β1, α6β1, and αVβ3 integrins in entry (Feire *et al.*, 2004). Furthermore, cells devoid of β1 integrin exhibited dramatically reduced susceptibility to infection with HCMV or MCMV while entry and spread were restored when the expression of β1 integrin was re-introduced into cells. Integrin-blocking antibodies did not prevent virus attachment but specifically inhibited the delivery of a virion component, pp65, into cells suggesting that integrins function at a post-attachment stage of infection, possibly at the level of membrane fusion. The involvement of multiple integrin heterodimers is consistent with integrin biology in that many natural integrin ligands, such as extracellular matrix proteins, bind to a variety of heterodimers. Furthermore, other integrin-binding viruses are characterizd

by binding to a number of different integrin heterodimers (Stewart *et al.*, 2003).

Integrins are capable of engaging ligands through a number of identified ECM protein motifs, the most common of which contain the amino acid sequence RGD. However, there are a number of RGD-independent integrin binding motifs, including the disintegrin domain proteins of the A Disintegrin and A Metalloprotease (ADAM) family of proteins. After inspection of all HCMV structural glycoproteins, the strongest homology to an integrin-binding domain was a disintegrin-like consensus sequence (RX_{5-7} DLXXF/L) (Eto *et al.*, 2002; Stone *et al.*, 1999; Wolfsberg *et al.*, 1995) on the amino-terminus of gB. Sequence alignments confirmed that the gB disintegrin loop was more than 98% identical among 44 clinical isolates analyzed. The role of this sequence in entry was confirmed through the use of synthetic peptides that inhibited both HCMV and MCMV entry, but had no impact on entry of HSV, correlating with the lack of a disintegrin-loop in gB of this virus. Furthermore, the HCMV gB disintegrin-loop was conserved throughout much of the gamma and all of the betaherpesvirus subfamilies, but not in the alphaherpesvirus subfamily where previously identified RGD sequences appear to carry out interactions with integrins. The presence of integrin-binding sequences among conserved herpesvirus glycoproteins strongly suggests that integrins may be important for entry and signaling throughout this medically important family. EGFR has also been shown to become phosphorylated and signal indirectly, as a result of integrin activation through src family kinases or focal adhesion kinase (FAK) (Jones *et al.*, 1997; Miyamoto *et al.*, 1996; Moro *et al.*, 1998). Future work will no doubt be aimed at an analysis of the integrin-triggered signaling events and defining their roles in entry and infection.

Activation of innate immunity during entry

The cellular response to HCMV particles includes dramatic upregulation of interferon stimulated genes, including interferon β itself and inflammatory cytokines; indicators of host innate immunity (Browne *et al.*, 2001; Simmen *et al.*, 2001; Zhu *et al.*, 1998; Yurochko and Huang, 1999). Toll-like receptors (TLRs) are ancient, conserved, pathogen sensors now well appreciated to activate signal transduction pathways that lead to induction of antimicrobial/antiviral genes and inflammatory cytokines (Akira, 2001). Until recently, however, TLRs were not known to recognize virus particles. To date, members of the herpesvirus, retrovirus and paramyxovirus families have been shown to be subject to innate sensing by TLRs (Compton *et al.*, 2003; Haynes *et al.*, 2001; Kurt-Jones *et al.*, 2000; Rassa *et al.*, 2002). In particular, TLR2 on PBMCs recognize HCMV particles or virus in a comparable manner, suggesting that binding and/or entry events involve the activation of this receptor. Soluble gB is able to induce a similar pattern of innate immune gene expression and can induce an antiviral state in cells (Boehme *et al.*, 2004; Boyle, Pietropaolo and Compton, 1999). Another envelope glycoprotein (gH) activates cells (Yurochko *et al.*, 1997) and the gH/gl/gO complex may contribute to a pattern of innate immune activation as a component of entry (Netterwald *et al.*, 2004), Guerrero M. and T. Compton, unpublished observations). TLR2 stimulation results in activation of NF-κB and stimulation of inflammatory cytokine production (Compton *et al.*, 2003). A common theme has emerged implicating viral envelope glycoprotein as a specific molecular trigger for TLR activation and that viral gene expression is not required (Boehme and Compton, 2004). These studies suggest a heretofore-unknown host cell response that detects viruses during entry, prior to the onset of replication events and products such as double stranded RNA that have long been recognized as TLR ligands (Boehme and Compton, 2004). Innate sensing of viruses during entry does not result in signaling that is essential to viral replication and appears more important as a determinant of the host cell response. The interaction of envelope glycoprotein and TLR suggests that entry and innate sensing may be coordinated in some manner.

Roles of betaherpesvirus envelope glycoproteins in virus entry

The HCMV envelope is exceedingly complex and currently incompletely defined. The HCMV genome encodes ORFs to at least 57 putative glycoproteins; far more than other herpesviruses, however, the extent of transcription, translation and function of the majority of these glycoproteins remains unknown. Biochemical studies of HCMV virions have revealed that 14 structural glycoproteins; eight of which have been experimentally shown to reside in the envelope (Britt *et al.*, 2004). HCMV appears to rely on herpesvirus-common homologues for entry. These include herpesvirus-common gene products gB and gH as well as glycoproteins L (gL), O (gO), M (gM), and N (gN). A number of other structural glycoproteins (gpTRL10, gpTRL11, gpTRL12 and gpUL132, gpUS28) are HCMV-specific (Table 16.1) but so far have no role in entry.

For years, the large genome and complicated reverse genetics system have made the creation of HCMV knockout and mutant viruses difficult. Recently, a system capable of such mutations was developed whereby HCMV is

Table 16.1. Envelope proteins of CMV

ORF	Protein name	Essential	Complex partner	Role in entry
UL4	gpUL4; gp48	No	None known	None known
UL33	UL33	No	None known	None known
UL55	gB	Yes	None known	Receptor binding, fusion, Signal transduction Innate immune activation
UL73	gN	Yes	UL100; gM	None known
UL74	gO	Moderate defect in cell to cell spread	UL75;gH UL115; gL	Enhancer of cell–cell spread
UL75	gH	Yes	UL74;gO UL115;gL	Fusion, receptor binding (?)Innate immune activation
UL100	gM	Yes	UL73;gN	HSPG binding
UL115	gL	Yes	UL75;gH UL74;gO	Required for gH activity
TRL10	gpTRL10	Not determined	None known	None known
TLR12	gpTRL12	Not determined	None known	None known
US27	gpUS27	No	None known	None known
US28	gpUS28	No	None known	None known

maintained as an infectious bacterial artificial chromosome (BAC) within *Escherichia coli* (Borst *et al.*, 1999). This development has greatly hastened the process of mutating individual ORFs and will generate much information regarding both the structure and function of many envelope glycoproteins. In fact, the BAC system has demonstrated the requirement for several glycoprotein genes in the production of replication competent virus (Dunn *et al.*, 2003; Hobom *et al.*, 2000; Yu *et al.*, 2002). The HCMV glycoprotein homologues gB, gM, gN, gH, gL, have been shown to be essential for growth, while gO knockout virus remained viable with a small plaque phenotype (Hobom *et al.*, 2000). Genes for all the currently identified HCMV-specific envelope glycoproteins, including UL4 (gp48), TRL10 (gpTRL10), TRL11 (gpTRL11), TRL12 (gpTRL12), US27, UL33, UL132, have been shown to be dispensable for replication and therefore are not critical for entry (Dunn *et al.*, 2003). The HCMV-encoded chemokine receptor US28 is present in the virion envelope and has been shown to promote cell–cell fusion mediated by HIV and VSV viral proteins, however the gene has been shown to be non-essential and there is no evidence for a role for gpUS28 in either HCMV–cell or cell–cell fusion events (Dunn *et al.*, 2003; Pleskoff *et al.*, 1997, 1998).

Essential and abundant HCMV envelope glycoproteins conserved throughout the herpesviruses (including gB and gH:gL) were classified as distinct disulfide-linked high molecular weight complexes (gCI and gCIII) in HCMV-infected cells (Gretch *et al.*, 1988). The gCI complex is composed of homodimers of gB (Britt, 1984; Britt and Auger, 1986) and the gCIII complex is a heterotrimeric complex composed of gH, gL, and gO (Huber and Compton, 1997, 1998; Li *et al.*, 1997). The designation gCII has been applied to a heterodimeric complex composed of gM and gN (Mach *et al.*, 2000).

At least two glycoprotein complexes have heparan sulfate proteoglycan (HSPG) binding ability, gB and the gM component of the gM:gN complex, suggesting a critical role for cell surface proteoglycan in initial virus:cell contact (Carlson *et al.*, 1997; Kari and Gehrz, 1993). Heparin binding is a property that HCMV shares with other herpesviruses, and gB is the common glycoprotein involved in this activity. HCMV gB also appears to be the primary receptor binding protein. Soluble forms of gB exhibit biphasic binding properties and cells treated with gB are refractory to infection suggesting that gB ties up critical receptor sites used by the virus (Boyle and Compton, 1998). One of the binding sites for gB is HSPGs in that cells lacking HSPGs had a single component Scatchard plot as compared to a biphasic plot for HSPG bearing cells. As noted above, it now seems clear that a second binding partner is an integrin (Feire *et al.*, 2004) but much work remains to formally prove the disintegrin hypothesis and confirm the role of this domain in receptor engagement. The gB protein may also engage EGFR (Wang *et al.*, 2003), at least in certain cell types, however it is not yet known if this interaction requires initial interaction with integrin. The gH complex may also have a distinct receptor. Syngeneic monoclonal anti-idiotypic antibodies were created that bear the "image" of this glycoprotein complex (Keay *et al.*, 1988) and led to a putative gH receptor (Keay and Baldwin, 1989, 1991, 1992, 1996). These investigations relied heavily on

a single reagent (anti-idiotypic antibodies) and has led to only a partially sequenced receptor clone, lacking homology to known human proteins (Baldwin *et al.*, 2000; Keay and Baldwin, 1996). Thus, the identity of a HCMV gH/gL/gO receptor remains unknown. Since HCMV gH and gL are essential and infectivity can be neutralized with gH antibodies, anti-idiotypic antibodies can neutralize infectivity and the closest relative of HCMV, HHV-6, contains an analogous complex consisting of the herpesvirus-common gH and gL with the product of U100 (gQ), a complex that has been shown to interact with a candidate receptor (Santoro *et al.*, 1999). HHV-6 U47 is the homolog of HCMV UL74 (gO), and is also involved in complex formation.

Membrane fusion remains a poorly understood component of entry for any of the herpesviruses. Unlike orthomyxoviruses, paramyxoviruses, filoviruses and retroviruses that employ a single envelope glycoprotein for membrane fusion, herpesviruses appear to employ multicomponent fusion machines, with evidence that these consist of gB, gH and gL (Spear and Longnecker, 2003). Both the HCMV gB- and gH-dependent entry processes are susceptible to inhibition by neutralizing antibodies that block infection at a postattachment stage of entry, presumably at the level fusion (Bold *et al.*, 1996; Britt, 1984; Keay and Baldwin, 1991; Tugizov *et al.*, 1994; Utz *et al.*, 1989). One limitation of these conclusions, however, is the lack of a direct fusion assay and thus a role for these glycoproteins in fusion is inferred. Despite the complexity of multicomponent fusion machines, it is very likely that there are strong parallels to single component fusion proteins. Alpha helical coiled-coils critical structural domains involved in fusion that function to drive the energetic folding of membranes together. Conformational changes in fusogenic proteins bearing these coiled-coils are also a defining paradigm. Using an algorithm to detect potential structural motifs, Lopper and Compton identified heptad repeat regions in gB and gH that were predicted to form alpha helical coiled coils (Lopper and Compton, 2004). Synthetic peptides to these motifs substantially inhibit HCMV entry including virion content delivery suggesting that these motifs play a fundamental role in membrane fusion. Genetic analysis of these motifs in the context of HCMV virions will be required to further analyze the importance of alpha helical coiled coils in HCMV entry. Another fundamental question will be to determine if the gB integrin interaction is a trigger of conformational change that leads to exposure of membrane fusion domains. Intriguingly, disintegrin-bearing cellular proteins in the ADAM family are known to trigger fusion via integrin interaction in a variety of processes including sperm–egg fusion and myoblast fusion (White, 2003). Development of a reliable fusion assay is also greatly needed to begin a dissection of the biophysical properties of HCMV fusion glycoproteins.

Coordination of entry and innate immune activation

We are left with an apparent dichotomy. As HCMV enters cells to establish infection, the host recognizes the virions and activates innate immune responses. How are the two processes coordinated, or are they coordinated at all? At this time, there is no apparent role for TLRs in entry in that cell stimulation that follows this event does not contribute to replication efficiency in any observable way. It seems more likely that this is a component of the entry process where the host cell senses a pathogen-associated molecular pattern displayed on HCMV envelope glycoproteins and uses this activatation to initiate a host innate defense response. One possibility is that entry receptors such as EGFR, integrins and signaling machinery, and innate immunity sensors such as TRLs, cytoplasmic adaptors and signaling machinery, coalesce into specialized membrane microdomains with integrins playing a central ligating role. Concentration of all of these cell surface receptors into a defined platform likely facilitates cell signaling events, some of which are optimal for replication and others of which are clearly hostile to the virus. Intriguingly integrins associate with TLR2 and partition into cholesterol rich lipid rafts (Ogawa *et al.*, 2002; Triantafilou *et al.*, 2002). The complexity of events at the cell surface during the initial encounter of HCMV and cells represents an exciting opportunity to better understand the molecular underpinnings of the early virus-host interactions. The recent identification of cell surface molecules involved in the early steps in infection has greatly enhanced our knowledge of entry events in infection. Yet much remains to be done to elucidate aspects of mechanism of entry events and the corresponding innate immune activation.

Introduction

Betaherpesviruses such as human cytomegalovirus (HCMV), human herpesvirus-6A and 6B (HHV-6), and human herpesvirus-7 (HHV-7) replicate more slowly than alphaherpesviruses, are highly species-specific for infection, and establish latency in progenitor cells of the bone marrow and monocytes of the blood. HCMV has been the prototype of the betaherpesviruses for studies of gene expression and regulation. In cell culture, HCMV strains have been adapted to preferentially infect and replicate in fibroblasts. However, low passage isolates replicate well in other cell types, such as endothelial cells, macrophages and dendritic cells. In the host, HCMV replicates in macrophages, dendritic cells, colonic and retinal pigmented epithelial cells, endothelial cells, fibroblasts, smooth muscle cells, neuronal cells, glial cells, hepatocytes, and trophoblasts (Fish *et al.*, 1995, 1996; Hertel *et al.*, 2003; Ibanez *et al.*, 1991; Lathey and Spector, 1991; Maidji *et al.*, 2002; Schmidbauer *et al.*, 1989; Sinzger *et al.*, 1993, 1995, 1996). In contrast, HHV-6 and HHV-7 infect $CD4^+$ lymphocytes (Takahashi *et al.*, 1989) as well as monocyte/macrophages. Although HCMV can be transferred into and out of polymorphonuclear leukocytes via cell-to-cell contact, these cells do not permit viral replication (Grundy *et al.*, 1998; Sinclair and Sissons, 1996; Sinzger and Jahn, 1996).

Various animal betaherpesviruses have been used as models for HCMV infection. CMVs infecting seven different mammalian hosts (humans, chimpanzees, African green monkeys, rhesus macaques, guinea pigs, rats and mice) have been investigated in some level of detail. Murine CMV (MCMV) infection of mice has been the most widely used animal model. MCMV tissue tropism, virulence, latency, and reactivation exhibit similarities to those of HCMV infections (Hudson, 1979; Jordan, 1983) and many important insights have emerged from this model despite the fact that rodent and primate CMVs are evolutionarily distant relatives. Between 75 and 80 open reading frames (ORFs) of MCMV have significant sequence homology to the predicted ORFs of HCMV (Chee *et al.*, 1990; Davison *et al.*, 2003; Murphy *et al.*, 2003a,b; Rawlinson *et al.*, 1996). Rhesus CMV (RhCMV) and chimpanzee CMV (CCMV) have approximately 138 and 166 ORFs with significant homology to HCMV, respectively (Davison *et al.*, 2003; Hanson *et al.*, 2003). Current estimates suggest that HCMV has at least 165 genes, but estimates of over 190 genes have been reported, depending on the method of prediction. HCMV has 45 essential genes and 15 of them have an unknown function. The majority of the non-essential genes also have unknown functions (Dunn *et al.*, 2003). For replication in human fibroblast, 68 ORFs are completely dispensable (Dunn *et al.*, 2003). Some of the viral genes that are dispensable for replication in human fibroblast cells are required for replication in human microvascular endothelial cells or in retinal pigment epithelial cells (Dunn *et al.*, 2003). Although many of the HCMV genes are dispensable for viral growth in cell culture, studies with MCMV or RhCMV suggest that many dispensable genes are important for modulating the virus–host interaction. Approximately two-thirds of the genes of HHV-6 are collinear with the unique long (U_L) region of the HCMV genome (Chee *et al.*, 1990; Gompels *et al.*, 1995; Neipel *et al.*, 1991).

This chapter will review viral replication events, with emphasis on expression and function of the betaherpesvirus immediate early (IE) genes. Understanding betaherpesvirus replication is important for the development of better strategies to prevent and treat virus-induced disease.

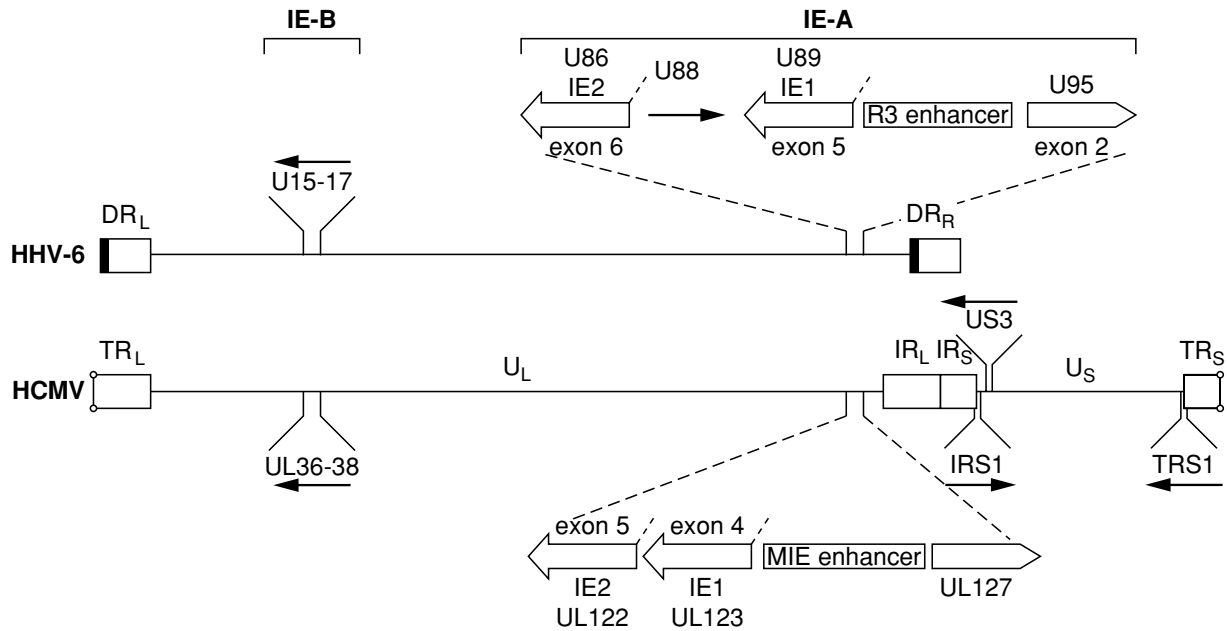

Fig. 17.1. Diagram of the immediate early (IE) genes of human cytomegalovirus (HCMV) and human herpesvirus-6 (HHV-6). The genes of the unique long (UL) components are colinear and designated alpha numerically. The unique short (US) component containing the TRS1/IRS1 and US3 genes is unique to HCMV. The unique components are flanked by either left (L) or right (R) direct repeats (DR), terminal repeats (TR), and internal repeats (IR) of the long (L) or short (S) components. Two genetically related IE loci are designated IE-A and IE-B. The major exons of the IE1 and IE2 genes in loci IE-A are designated as well as the enhancers and divergent viral gene.

Betaherpesvirus immediate early genes

The IE genes are the first viral genes transcribed after infection, and their transcription does not require *de novo* viral protein synthesis. These gene products optimize the cell for viral gene expression and replication. Figure 17.1 depicts the location of the IE gene loci on the HCMV and HHV-6 genomes. The HCMV long (L) genomic component encodes two betaherpesvirus-conserved transcription loci, the major IE genes (IE-A locus) and the IE-B locus as well as UL119-115 locus. The UL119–115 genes are not known to be involved in regulation of cellular or viral gene expression, and are not discussed in this chapter. The HCMV short (S) genomic component encodes US3 and the TRS1/IRS1 IE genes. HHV-6 lacks a region analogous to the S component of HCMV and so does not encode homologues of these HCMV genes.

The IE-A locus of HCMV encodes the major immediate early (MIE) genes and is collinear with a homologous region in HHV-6. In both viruses there is a strong transcriptional enhancer between two divergent genes (Fig. 17.1), with regulatory genes transcribed in the leftward direction designated IE1 and IE2. The function of the viral genes transcribed to the right is unknown. These viral genes and their enhancers have a major effect on productive viral replication for all betaherpesviruses where they have been studied and, consequently, they will be the focus of a majority of this chapter. For both MCMV (m128) and HCMV (UL127), the rightward transcribed viral genes in this locus are dispensable for replication in cell culture.

The IE-B locus is located in the L-component of the HCMV genome and exhibits homologous protein coding regions to HHV-6 (Flebbe-Rehwaldt *et al.*, 2000; Nicholas and Martin, 1994) (Fig. 17.1), as well as to other betaherpesviruses. The HCMV UL36–38 genes in the IE-B locus encode proteins that are required for viral growth. There are at least five transcripts from three different promoters in this region (Colberg-Poley, 1996). The products of the HCMV UL36–37 gene locus (e.g., UL37 exon 1, gpUL37, gpUL37m, and UL36) are expressed with IE kinetics and presumably serve to quickly thwart the cellular anti-viral response of apoptosis (see Chapter 21). The UL37 exon 1 unspliced RNA is abundant at IE times and remains abundant until late times after infection (Su *et al.*, 2003). HCMV oriLyt-mediated DNA replication assays are also enhanced by the UL36–38 gene products (Pari *et al.*, 1993). The HHV-6

U15–17 genes are multiply spliced in a pattern reminiscent of UL36–38 and have regulatory activities. For example, U16/17 spliced gene product activates expression from the HIV LTR promoter (Geng *et al.*, 1992).

The US3 gene is transcribed at IE times to yield three alternatively spliced transcripts (Colberg-Poley, 1996). IE gene expression is controlled at multiple levels. Upstream of the US3 promoter is two sequence repeats designated R2 and R1 (Weston, 1988). R2 is a NF-κB containing enhancer that promotes a high level of US3 transcription. R1 has 19 repetitions of a 5'-TRTCG-3' pentanucleotide arranged as direct repeats, inverted repeats, and variably spaced single pentanucleotides. Although R1 was reported to silence expression from the US3 promoter in transient transfection assays (Chan *et al.*, 1996; Thrower *et al.*, 1996), R1 enhances expression of the flanking US3 and US6 genes by an unknown mechanism when assayed in the context of viral infection (Bullock *et al.*, 2001, 2002). The US3 and US6 viral gene products disrupt the process of cellular HLA presentation of viral antigens at the cell surface and, consequently, they likely contribute to evasion of the host immune response (see Chapter 62). Between the start site of transcription and the TATA box of the US3 promoter is a *cis*-acting repressor element that binds the viral protein encoded by the essential HCMV UL34 gene (Dunn *et al.*, 2003; LaPierre and Biegalke, 2001). Mutation of the *cis*-acting element causes a high level of expression of the US3 gene at early and late times after infection (Lashmit *et al.*, 1998). The positive regulation of US3 gene expression may trap viral antigens introduced into the cell upon virus entry or expressed *de novo*. The negative regulation may prevent the toxic consequences of continued trapping of cellular HLA molecules on the membranes of the endoplasmic reticulum. US3 expression is repressed at late times after infection when the viral proteins encoded by US2, US6, and US11 contribute to immune evasion (see Chapter 62).

Because their transcription initiates in repeats flanking the U_S region, the TRS1/IRS1 genes are controlled by identical promoter elements. This arrangement results in proteins with identical N-terminal domains and divergent C-terminal domains, given the 3′-end, of their transcripts arise from different unique sequences in the U_S region (Fig. 17.1). TRS1 and IRS1 proteins are packaged into the virion as tegument components and, therefore, these viral proteins are introduced into cells in advance of IE gene expression (Romanowski *et al.*, 1997). Viruses lacking IRS1 replicate normally. However, mutation of TRS1 together with IRS diminishes the yield of infectious virus and the mutant viral particles sediment abnormally in gradients, suggesting defective viral assembly (Blankenship and Shenk, 2002). In transient assays, TRS1/IRS1 gene products activate expression of early viral promoters in cooperation with the viral MIE gene products (Romanowski and Shenk, 1997) and are necessary components for HCMV oriLyt-dependent DNA replication (Pari *et al.*, 1993). An amino terminal truncated IRS1 gene product ($pIRS1^{263}$) controlled by a downstream promoter in the unique region antagonizes the activation function of the IRS1 and TRS1 viral proteins (Romanowski and Shenk, 1997). Recent work has suggested that both TRS1 and IRS1 encode functions that evade interferon response in HCMV-infected cells (Child *et al.*, 2004). These HCMV gene products appear to be RNA-binding proteins that prevent activation of host cell protein kinase R (PKR) pathways, thereby averting shut off of protein synthesis (Hakki and Geballe, 2005). It remains possible that all of the activities previously ascribed to these IE proteins are due to this central control of the cellular response to infection as has been found for PKR inhibitors encoded by other DNA viruses.

Betaherpesvirus transcriptional enhancers upstream of the MIE genes

Transient transfection and transgenic mouse experiments with the HCMV enhancer-containing MIE promoter driving expression of an indicator gene suggest that the activity of this enhancer is influenced by the cell type and the state of cell differentiation (Baskar *et al.*, 1996a,b). However, additional transgenic mice studies yielded different data failing to show such correlation expression patterns. During infection, viral IE gene expression is first affected by attachment and entry requirements, and then, by cellular signal transduction pathways induced by the virus or other external stimuli. Serum and virion components increase MIE promoter activity at low multiplicity of infection (MOI). The relative importance of individual enhancer *cis*-acting sites may vary depending on the type of cell and external stimulus. In addition, it is not known which *cis*-acting elements in the MIE enhancer are important in a given cell type. For example, the NF-κB sites may be important in the hepatocytes under conditions of inflammation, when pro-inflammatory factors activate the transcription factor NF-κB (Prosch *et al.*, 1995). The function of the MIE enhancers of betaherpesviruses is important to understand because the enhancers likely play a pivotal role in regulating viral latency, reactivation, and pathogenesis.

Figure 17.2 compares the known consensus binding sites for eukaryotic transcription factors in enhancer elements upstream of the MIE genes of human, chimpanzee, simian, murine, and rat (England and Maastricht strains) CMVs. Uncharacterized *cis*-acting elements may emerge from

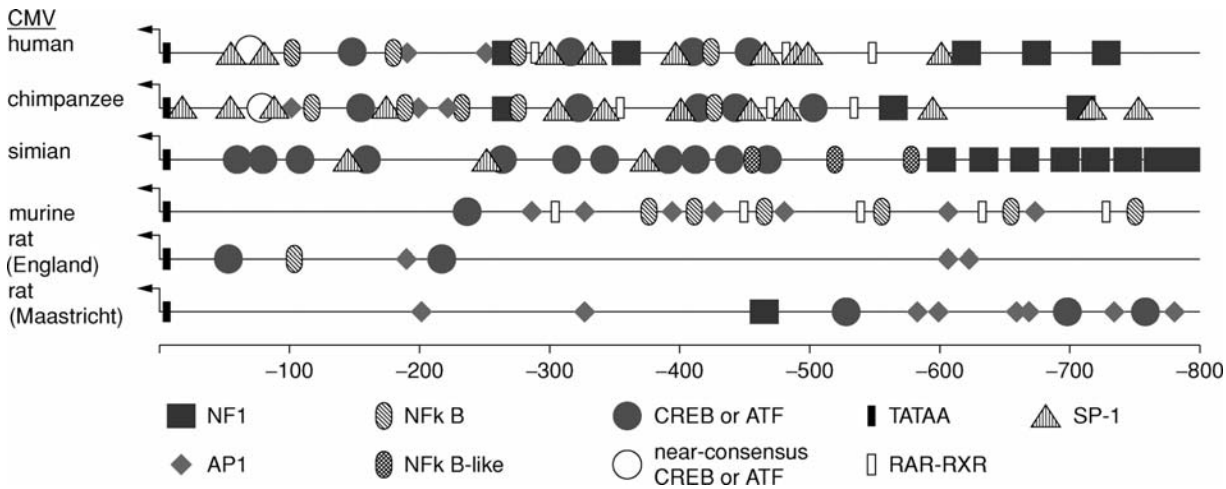

Fig. 17.2. Comparison of the enhancers of cytomegaloviruses. The known consensus binding sites of cellular transcription factors in the major immediate early enhancers are designated.

further studies seeking an impact on viral replication. CMV MIE enhancer elements have an array of *cis*-acting sites that bind cellular transcription factors (Angulo *et al.*, 1996, 1998a; Beisser *et al.*, 1998; Chang *et al.*, 1990; Davison *et al.*, 2003; Dorsch-Hasler *et al.*, 1985; Meier and Stinski, 1996; Sandford and Burns, 1996; Stinski, 1999; Thomsen *et al.*, 1984; Vink *et al.*, 2000; Meier and Stinski, 2006). Many of these binding sites are repetitive, but their arrangement and numbers vary among the different species-specific viruses. HCMV, ChCMV, SCMV, and MCMV share common regulatory elements that are functional binding sites for NF-κB, CREB/ATF, AP-1, and RAR-RXR (Angulo *et al.*, 1995, 1996, 1998a). RCMV (England strain) is unusual in that it contains fewer *cis*-acting elements than other viruses. The HCMV enhancer also has functional binding sites for serum response factor, Elk-1, Sp-1, CAAT/enhancer binding protein and gamma-interferon activating sequence (Meier and Stinski, 1996; Netterwald *et al.*, 2005). Binding sites for other cellular transcription activators are also present in this enhancer, but their significance is unknown. In transient transfection assays, the different *cis*-acting elements act individually or cooperatively to attract the RNA polymerase II transcription initiation complex to the MIE promoter (Hunninghake *et al.*, 1989).

The betaherpesvirus MIE enhancer elements are considered important because they may also serve as a target for reactivation from latency. The original hypothesis was that the MIE enhancer contributed to a quick and robust expression of the MIE genes, and evidence supporting this remains strong when expression of viruses carrying mutations in this region are studied in cell culture (Meier and Pruessner, 2000). Substitution of the enhancer of HCMV with the MCMV IE enhancer generates a virus with reduced expression and growth in culture (Isomura and Stinski, 2003), whereas subsitution of the MCMV with the HCMV MIE enhancer generates a virus that can replicate in culture or in mice (Grzimek *et al.*, 1999) with characteristics that indicated a role for the enhancer in increasing the number of cells expressing IE gene products in specific infected host tissues.

Figure 17.3 compares the enhancers of HCMV and HHV-6. Although these viruses share little common sequence, the enhancers are positioned similarly between divergent promoters upstream of the IE1 and IE2 genes (Lashmit *et al.*, 2004; Lundquist *et al.*, 1999; Takemoto *et al.*, 2001). The HHV-6 enhancer is characterized by repeat elements of 104 to 107-bp which contain polyomavirus enhancer A binding protein (PEA3) sites, NF-κB binding sites, some AP-2 binding sites (not identified in Fig. 17.3). The only obvious common elements shared by the two enhancers are NF-κB sites. The HHV-6 enhancer cannot substitute for the HCMV enhancer (H. Isomura and M. F. Stinski, unpublished data). While the HCMV enhancer influences IE1 and IE2 gene transcription, the HHV-6 enhancer has an effect on the divergent IE U95 gene transcription and is only speculated to have an effect on transcription of the IE1 and IE2 genes (Takemoto *et al.*, 2001). The HCMV MIE region has two repressor elements, one that binds IE2 proteins located immediately upstream of the IE1/IE2 transcription start site that likely represses gene expression when IE2 levels rise at early times of infection (Cherrington *et al.*, 1991; Liu *et al.*, 1991; Pizzorno and Hayward, 1990) and one that binds a cellular protein immediately upstream of the TATA box of the divergent UL127 gene and blocks expression

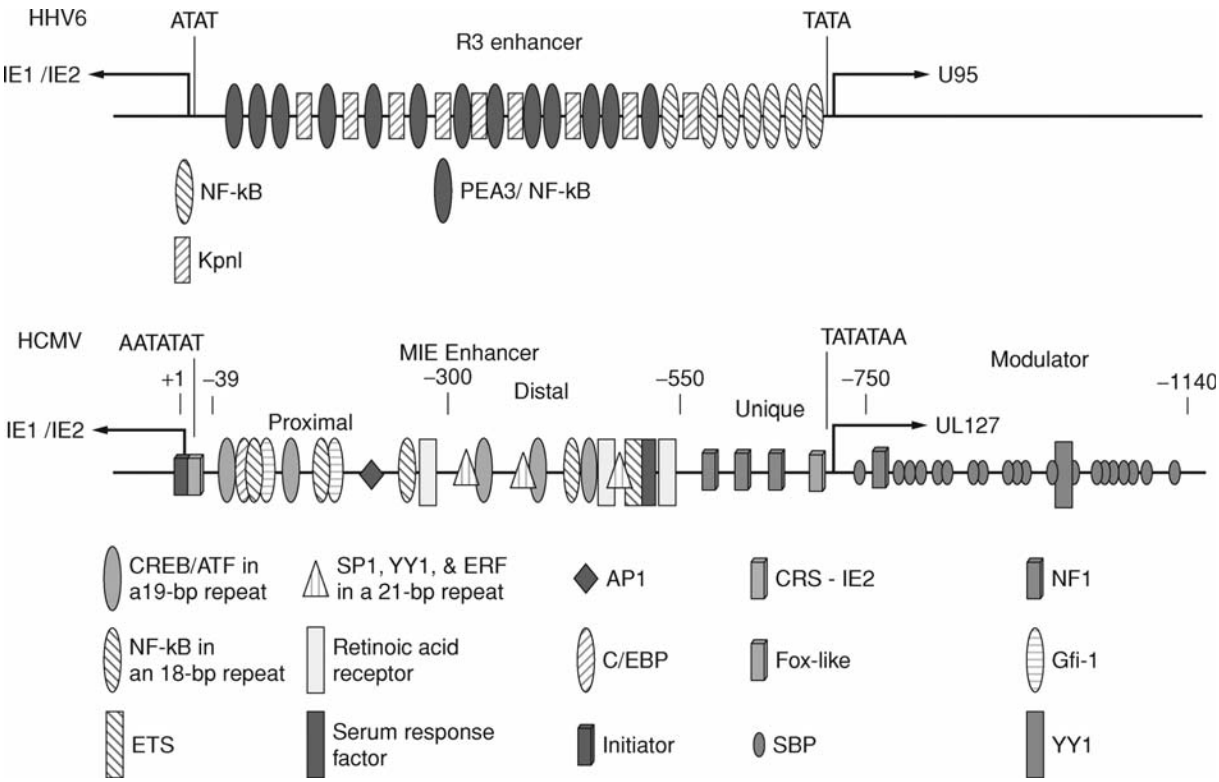

Fig. 17.3. Comparison between the HCMV major immediate early (MIE) and the HHV-6 R3 enhancer. Viral genes and promoter/transcription start sites are designated by an arrow. The HCMV also has a unique region and a modulator discussed in the text. The various transcription factor binding sites identified for HCMV and HHV-6 are designated. The AP-2 sites in the R3 enhancer are not identified. (See color plate section.)

throughout infection (Angulo *et al.*, 2000b; Lashmit *et al.*, 2004; Lundquist *et al.*, 1999). Additionally, silencing of the MIE enhancer appears to occur through a variety of cellular transcription factors in certain cell types, particularly when the cells are undifferentiated. Murine CMV has a similar arrangement of enhancer, MIE gene and divergent gene, but transcriptional repression signals have not been found. As far as has been determined, the IE1 and IE2 homologues are important in replication but the divergent genes of the betaherpesviruses are non-essential for replication in cell culture and their function is not known. The U94 gene of HHV-6, of interest because it is similar to the *rep* gene of adeno-associated virus (AAV), is located in the intron of the viral U95 gene and is transcribed in the opposite direction of U95 (Takemoto *et al.*, 2001). The AAV *rep* gene product is a DNA binding protein with ATPase and helicase activity and is required for AAV DNA replication. The HHV-6 U94 gene product is found in very low abundance during productive HHV-6 infection but shares some of these properties (see Chapter 47).

Function of the betaherpesvirus major immediate–early enhancers

Thus far, two approaches have been used to study the function of betaherpesvirus MIE enhancers during viral infection: (i) mutation of enhancer components, and (ii) substitution of the enhancer from one species with that from a different species. Mutational analysis in the context of the viral genome demonstrated that the HCMV enhancer has two functional components referred to as the distal enhancer (−580 to −300) and the proximal enhancer (−300 to −39) relative to the transcription start site (+1) (Fig. 17.3). The distal enhancer is dispensable at high MOIs in cultured cells but has a significant effect on the efficiency of viral replication at low MOIs (Meier and Pruessner, 2000). Without the distal enhancer, the virus has a small plaque phenotype. The distal enhancer is composed of multiple *cis*-acting elements. Deletion of −300 to −347 or −347 to −579 has little to no effect on MIE promoter-dependent transcription, but deletion of the entire region (−580 to −300) has

a significant effect (Meier *et al.*, 2002). The distal enhancer functions in *cis* and is orientation-independent relative to the transcription start site. The hypothetical ORFs in the distal enhancer are not important for viral replication in cell culture because insertion of stop codons at −300 or −345 had no effect on IE gene expression or virus titer (Meier *et al.*, 2002). The proximal enhancer upstream of −39 also determines the efficiency of virus replication in cell culture (Isomura *et al.*, 2004). Deletion of the proximal enhancer affects IE and early viral gene expression, viral DNA synthesis, and the rate of viral growth (Isomura *et al.*, 2004). Which elements in the distal or proximal enhancer are required for virus replication in various cell types is currently unknown. Despite the commonality of NF-κB sites in betaherpesvirus enhancers, the minimal enhancer element for HCMV appears to be an Sp-1 binding site (Isomura *et al.*, 2004, 2005).

Mutation of the CREB/ATF binding sites in the entire enhancer had little to no effect on HCMV replication in human fibroblast (HF) or in NTera2-derived neuronal cells at high or low MOIs (Keller *et al.*, 2003). Likewise, mutation of the NF-κB sites in the entire enhancer had little to no effect on viral replication at high or low MOIs in HF cells (Benedict *et al.*, 2004). Since MCMV and HCMV replicate efficiently in cells where the NF-κB activation pathway has been inhibited (Benedict *et al.*, 2004; Melnychuk *et al.*, 2003), the NF-κB transcription factor may not always be necessary for replication in cell culture. The requirement for particular HCMV MIE enhancer elements has not yet been assessed using viral mutants.

Enhancer substitution experiments have also demonstrated that CMV MIE enhancers affect viral replication. Recombinant with the rat CMV (England) MIE enhancer substituted with the MCMV MIE enhancer was deficient in replication in rat fibroblasts and in the infected rat, with greatly reduced levels of viral replication in the salivary glands (Sandford and Burns, 1996). While recombinant HCMV with the MIE enhancer substituted by the SCMV (Colburn) MIE enhancer replicated as well as wild-type virus (H. Isomura and M. F. Stinski, unpublished data), recombinant HCMV with the enhancer substituted with the MCMV enhancer replicated slower and to lower levels in HF cells (Isomura and Stinski, 2003). Consistent with this, the plaques of the enhancer substituted HCMV recombinant virus had a small plaque phenotype. When a recombinant MCMV substituted with the HCMV MIE enhancer was made, the recombinant MCMV replicated in mouse fibroblast (Angulo *et al.*, 1998b) and in mouse liver at levels similar to wild-type virus, but there was a decrease in the infection at other sites in the mouse (Grzimek *et al.*, 2001). While the MCMV enhancer is not essential for replication in cultured murine fibroblasts at high MOI, this region is required for cytopathic effects in culture and disease in the mouse (Angulo *et al.*, 1998b). Taken together, these observations suggest that CMV enhancers are not always functionally equivalent and suggest one role they play is to optimize the efficiency of viral replication in various cell types with which the virus normally interacts. The *cis*-acting elements in the betaherpesvirus enhancers have evolved over millions of years for each of the species-specific viruses.

Silencing of the immediate-early genes

Betaherpesvirus MIE genes are regulated in a cell type- and differentiation-dependent manner. The viral genomes may be organized into a nucleosome-array like latent genomes of herpesviruses in other subfamilies (Deshmane and Fraser, 1989; Dyson and Farrell, 1985). Conditionally permissive cell lines have been used to investigate silencing and reactivation of HCMV. In the undifferentiated cell, the MIE enhancer-containing promoter is silent, and the cells are non-permissive for viral replication. In the differentiated cell, the MIE enhancer-containing promoter is active, and the cells are permissive for viral replication. For example, HCMV fails to replicate after penetration into NTera2 cells, an undifferentiated embryonic carcinoma line (Gonczol *et al.*, 1984). This postentry block corresponds to silencing of the MIE promoter-dependent transcription (LaFemina and Hayward, 1986; Meier, 2001; Nelson and Groudine, 1986). Inactivity of the MIE promoter appears to be a feature of natural HCMV latency (Taylor-Wiedeman *et al.*, 1994; Kondo *et al.*, 1994, 1996; Slobedman and Mocarski, 1999). The MIE promoter of MCMV is generally inactive during viral latency, except in a rare subset of cells where spontaneous reactivation appears to be occurring (Grzimek *et al.*, 2001; Hummel *et al.*, 2001; Koffron *et al.*, 1998; Kurz *et al.*, 1999; Kurz and Reddehase, 1999).

Transient transfection studies identified the HCMV 21-bp-repeats, the unique region, and the modulator as *cis*-acting sites that confer repression of transcription in the undifferentiated monocytic THP-1 and embryonal NTera2 cell lines (Fig. 17.3) (Huang *et al.*, 1996; Kothari *et al.*, 1991; Liu *et al.*, 1994; Nelson *et al.*, 1987; Shelbourn *et al.*, 1989; Sinclair *et al.*, 1992). Three copies of the 21-bp-repeats are located in the distal MIE enhancer, whereas the unique region and modulator forms the 5′-extent of the MIE regulatory region. The following cellular repressors of transcription have also been proposed to act through one or more elements in the modulator, the unique region, or the enhancer: silencing binding protein (SBP) (Thrower *et al.*, 1996), modulator recognition factor (Huang *et al.*, 1996),

PDX1 (Chao *et al.*, 2004), Yin Yang-1 (YY1) (Liu *et al.*, 1994), methylated DNA-binding protein (Zhang *et al.*, 1995), growth factor independence-1 (Gfi-1) (Zweidler-McKay *et al.*, 1996), and the ETS2-repressor factor (ERF) (Wright *et al.*, 2002). While eliminating any one of these sets of negative *cis*-acting elements increases the MIE promoter activity in transient transfection experiments, their selective removal from the HCMV genome results in a completely different outcome. Silencing in the context of the viral genome is not alleviated by removal of the 21-bp-repeats, the modulator, the unique region, or both 21-bp-repeats and modulator in either undifferentiated monocytic THP-1 or embryonal NTera2 cells (Meier, 2001). Site-specific mutation of the Gfi-1 sites has no effect in undifferentiated monocytic THP-1 cells (R. Schnetzer and M. F. Stinski, unpublished data). Thus, silencing occurs in the context of viral infection, and its regulatory mechanism differs quantitatively from that observed in transfected cells. It remains possible that redundancy of negative *cis*-acting elements explains these differences, but studies have not yet provided any evidence of this. Nonetheless, the findings suggest that the HCMV MIE promoter becomes silenced in undifferentiated cells, but this process depends on factors that remain to be identified.

In the embryonal NTera2 cell culture model, a portion of quiescent HCMV genomes have a super-coiled structure (Meier, 2001), which appears similar to CMV latency in blood monocytes of healthy subjects (Bolovan-Fritts *et al.*, 1999). The super-coiled structure would be expected to package into nucleosomes as is the case for gammaherpesviruses. The HCMV MIE enhancer of the quiescent viral genomes is inactive even when positive-acting transcription factors NF-κB and RAR-RXR are activated (Meier, 2001). However, inhibition of cellular histone deacetylase (HDAC) reactivates transcription from the MIE promoter. These data suggest that betaherpesvirus MIE promoter silencing may involve HDAC-based modification of viral chromatin. Murphy *et al.* (2002) showed that the silent HCMV MIE promoter is associated with less acetylated histone H4 as compared to an active MIE promoter. Acetylated H4 was also less abundant on silent MIE promoters in experimentally infected blood monocytes compared to active MIE promoters in permissive monocyte-derived macrophages (Murphy *et al.*, 2002). In addition, the cellular HP1 protein, which selectively binds methylated histone H3 at lysine 9 in cellular heterochromatin (Jenuwein and Allis, 2001), is preferentially associated with the repressed MIE promoters (Murphy *et al.*, 2002). While MCMV MIE promoter reactivation can also be achieved in latently infected murine tissue (Hummel *et al.*, 2003), direct evidence for CMV DNA silencing via chromatin components is lacking at this time. The combined findings imply that chromatin may condense on the betaherpesvirus genomes in non-permissive and undifferentiated cells to restrict MIE promoter activity.

Reactivation of the immediate–early genes

Reactivation of betaherpesviruses is observed commonly in the setting of immunosuppression, particularly where allogeneic stimulation and proinflammatory cytokines are present and stimulate monocyte differentiation (Cook *et al.*, 2002; Fietze *et al.*, 1994; Hahn *et al.*, 1998; Hummel *et al.*, 2001; Mutimer *et al.*, 1997; Soderberg-Naucler *et al.*, 1997b; Soderberg-Naucler *et al.*, 2001). Proinflammatory cytokines, such as those released during allogeneic transplantation, AIDS, sepsis, or myelosuppressive chemotherapy, induce the MIE promoter-dependent transcription.

For MCMV, the effect of MIE promoter reactivation can be dampened by a mechanism that prohibits the production of the alternatively spliced ie3 RNA (Grzimek *et al.*, 2001; Kurz *et al.*, 1999), which is the functional equivalent of the HCMV IE2 gene. HCMV MIE promoter reactivation may also be subjected to further regulation in infected monocytes, as certain stimuli only reactivate production of spliced RNA for IE1, but not IE2 (Taylor-Wiedeman *et al.*, 1994). Stimuli sufficient to induce differentiation of these cells into a monocyte-derived macrophage or dendritic cell phenotype, enables completion of the HCMV reactivation program (Soderberg-Naucler *et al.*, 1997b 2001).

The molecular mechanisms that trigger and sustain CMV reactivation are largely unknown. Transgenic mice and transient transfection experiments implicate NF-κB and CREB/ATF as important mediators in stimulus-induced MIE promoter reactivation (Hummel *et al.*, 2001; Prosch *et al.*, 1995; Stein *et al.*, 1993). TNF-α potently induces NF-κB activity and reactivates MCMV's MIE promoter in latently infected lung tissue, but is not alone sufficient to sustain the reactivation process (Hummel *et al.*, 2001). HCMV reactivation from monocytes in cell culture induced by allogeneic stimulation does not require TNF-α, but instead, depends on the combination of interferon-γ and other unidentified factors (Soderberg-Naucler *et al.*, 2001). The mechanism(s) by which these cytokines or other factors stimulate HCMV reactivation is unknown. In the embryonal NTera2 cell model, forskolin stimulation of the cyclic AMP signaling pathway and inhibition of HDAC induce HCMV MIE promoter reactivation. The reactivation is dependent on CREB/ATF-binding sites within the enhancer (M. Keller and J. Meier, unpublished data). Taken together, it appears that betaherpesvirus reactivation from

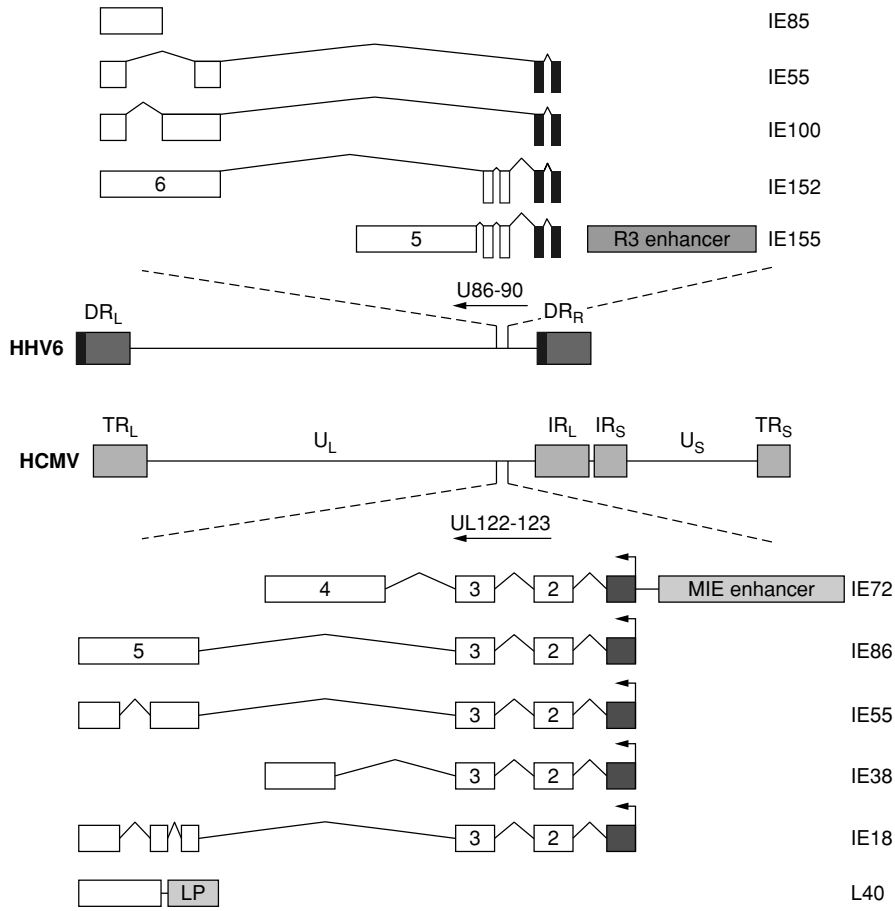

Fig. 17.4. Comparison of the IE1 and IE2 genes and their isomers for HCMV and HHV-6. The exons with ORFs for the IE1 and IE2 genes are designated as open boxes. The isomers of the IE1 and IE2 genes are designated according to apparent molecular weight. A HCMV late (L) isomer and late promoter (LP) are designated.

latency may entail multiple regulatory mechanisms for orchestrating both derepression and activation of the viral IE gene expression.

Betaherpesvirus major immediate–early genes

All betaherpesviruses have CpG dinucleotide suppression in the major immediate early (MIE) locus. The significance of CpG dinucleotide suppression is unknown, but it suggests that these genes are regulated by host methylation in a certain setting such as latency. Downstream of the betaherpesvirus enhancer-containing MIE promoter are two regulatory genes designated IE1 and IE2 in HCMV and HHV-6 as well as most other betaherpesviruses. Importantly, in MCMV, they are designated ie1 and ie3, respectively. In all betaherpesviruses, multiple gene products are encoded by these two genes through differential mRNA spicing and promoter usage throughout infection. For the CMVs, the single MIE promoter directs transcription of three small exons that are spliced alternatively to either exon 4 or exon 5 of the precursor IE RNA followed by cleavage and polyadenylation (Fig. 17.4) (Nicholas, 1994 Stenberg *et al.*, 1984, 1985). An initiation codon in exon 2 and a termination codon in either exon 4 or exon 5 gives rise to the major proteins encoded by IE1 and IE2, respectively, at IE times (Fig. 17.4). In HHV-6, the first four exons of a precursor RNA are spliced alternatively to either exon 5 or exon 6 (Fig. 17.4) (Nicholas, 1994; Schiewe *et al.*, 1994). An initiation codon in exon 3 and a termination codon in either exon 5 or exon 6 give rise to the proteins encoded by IE1 and IE2, respectively. The viral proteins encoded by HCMV are designated according to their apparent molecular weight and have amino acids in common at the amino terminus, with the exception of a late viral protein, designated L40 that arises from a unique promoter element within the exon 5

region (Fig. 17.4). HHV-6 also generates multiple forms of the IE1 and IE2 proteins by alternate splicing between and within exons. The HHV-6 MIE proteins are also designated according to their apparent molecular weight (Fig. 17.4) (Papanikolaou *et al.*, 2002).

Functions of the major immediate–early viral proteins

While it is assumed that the proteins encoded by betaherpesvirus IE1 and IE2 genes have similar functions, these proteins exhibit dramatic evolutionary divergence in amino acid sequence. These differences may have evolved to meet the regulatory needs for broadly different species-specific and cell-specific herpesviruses represented by this subgroup. The functions of the major HCMV IE1 and IE2 gene products, IE72 and IE86, have been investigated extensively, and minor products IE38, IE55, and IE18 isomers have received less attention. During the two hours after HCMV infection of HFs, the mRNA for the IE2 gene is expressed predominantly, and this is followed by a period when the mRNA for the IE1 gene predominates (Stamminger *et al.*, 1991). In contrast, the expression of HHV-6 IE1 precedes that of IE2 (Papanikolaou *et al.*, 2002). Relative to the mRNAs for HCMV IE72 and IE86 proteins, the amount of mRNA for IE55 or IE38 is low in fibroblasts. The mRNA for IE18 is lower in HFs than in macrophages (Stenberg, 1996). The IE2 protein of HCMV negatively autoregulates the expression of the IE1 and IE2 genes, but there is no evidence to date that HHV-6 IE2 protein negatively autoregulates (Cherrington *et al.*, 1991; Liu *et al.*, 1991; Pizzorno and Hayward, 1990). The IE86 protein of HCMV binds to the minor groove of the MIE promoter that contains a *cis*-repression sequence (crs) between −13 and −1 relative to the transcription start site (+1) (Lang and Stamminger, 1994). The late 40 kDa protein (L40) of the IE2 gene can also bind to the crs and negatively autoregulate transcription of the MIE genes (Plachter *et al.*, 1993; Puchtler and Stamminger, 1991; Stenberg *et al.*, 1989). While the IE1 and IE2 gene products are discussed separately below, they seem to work synergistically in executing their functions during viral infection.

The IE1 proteins

The IE1 proteins of CMVs have only a few regions of homology and a characteristic acidic acid residue cluster towards the C-termini. The IE1 genes of human and MCMV are dispensable for viral replication at high MOIs (1 to 5 PFU/cell). When the IE1 gene is deleted, the efficiency of viral replication is reduced at low MOIs (0.001 to 0.05 PFU/cell) (Greaves and Mocarski, 1998; Mocarski *et al.*, 1996). After infection at low MOI with recombinant HCMV containing an IE1 gene deletion, there are insufficient levels of early viral gene expression required for viral DNA replication (Gawn and Greaves, 2002). At high MOIs, virion-associated proteins present in infectious and non-infectious particles may compensate for the absence of functional IE1.

After synthesis in the cytoplasm, IE72 is transported to the nucleus and targeted to nuclear bodies known as promyelocytic leukemia (PML) oncogenic domains (PODs) or nuclear domain 10 (ND10). The viral protein is modified by conjugation of SUMO-1 or SUMO-2 (small ubiquitin-like modifier) at lysine residue 450. The apparent molecular weight of IE72 following modification is approximately 92 kDa (Spengler *et al.*, 2002; Xu *et al.*, 2001). Although sumoylation may be important for the efficiency of viral replication, a recombinant virus with lysine residue 450 mutated is replication competent in HFs (Lee *et al.*, 2004). Recombinant virus with lysine residue 450 mutated expresses lower levels of IE2 RNA and IE86 protein (Nevels *et al.*, 2004). With or without SUMO conjugation, IE72 displaces the ND10 presumably by binding to its associated proteins, such as PML, SP100, and hDaxx. The central hydrophobic region of IE72 binds to PML (Lee *et al.*, 2004) and inhibits the accumulation of sumoylated forms of PML. A PML-associated transcriptional repressor, HDAC-2, is inactivated (Ahn and Hayward, 1997; Ahn *et al.*, 1998a; Wilkinson *et al.*, 1998) and, consequently, the basal transcription initiation complex is activated (Muller and Dejean, 1999; Tang and Maul, 2003; Xu *et al.*, 2001). Early after infection, the viral DNA and transcripts are detected in the nucleus, and RNA polymerase and mRNA spliceosome assembly factors are juxtaposed to the ND10 (Ishov *et al.*, 1997). HHV-6 IE1 protein is also localized to ND10 and modified by SUMO-1 at lysine residue 802, but the IE1 protein does not dispense PML (Gravel *et al.*, 2002). The reason for this significant difference in the function of these betaherpesvirus IE1 proteins is not known; however, disruption of ND10 is not a requisite for HCMV replication. The multiple functions of the betaherpesvirus IE1 proteins are not fully understood. One function of the HCMV IE72 protein may be to counter the innate immune response in cells by down-regulation of virus-induced interferon-like response (Singh and Compton, 2004) and another may block apoptosis (Zhu *et al.*, 1995), promoting conditions for viral replication in the host cell.

IE38 (IE19) is reported to be an HCMV IE1 gene product that lacks amino acids 88 to 404 of IE72 (Fig. 17.4). A radioactive probe to the 5 end of IE1 detected a cDNA of 0.65 kb that could code for IE38 (Shirakata *et al.*, 2002). An antibody to a peptide between amino acids 383 and 420 detected both IE72 and IE38 (Kerry *et al.*, 1995). Others have not detected IE38 and suggest it may represent an

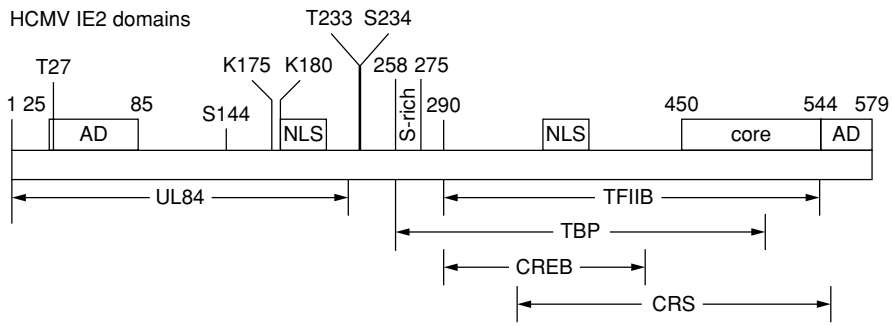

Fig. 17.5. Domains of HCMV IE86 encoded by the IE2 gene. The domains are demarcated according to amino acid residue. Transcription activation domains (AD) are located at the amino and carboxyl termini. There are serine-rich (S-rich) domains and two nuclear localization signals (NLS). There is an essential region designated the core domain. Regions of the viral protein that interact with another viral gene product (UL84), cellular transcription factors, or the *cis* repression sequence (crs) of the MIE promoter are designated.

N-terminal cleavage product of IE72 (Awasthi *et al.*, 2004). Transient transfection experiments suggested that IE38 functions synergistically with IE72 (Shirakata *et al.*, 2002). Whether or not these functions of IE38 occur in the virus-infected cell remains to be determined.

It is unclear how IE72 (or IE38) activates cellular promoters, but an association of IE72 with TATA box-associated factors (TAFs) and transcription factors (Sp-1, E2F-1, CTF-1) has been proposed (Hayhurst *et al.*, 1995; Lukac *et al.*, 1997; Margolis *et al.*, 1995). In transient transfection experiments, IE72 moderately activates the viral MIE promoter and the cellular DNA polymerase α, c-fos, c-myc and dihydrofolate reductase promoters (Cherrington and Mocarski, 1989; Hagemeier *et al.*, 1992b; Sambucetti *et al.*, 1989; Wade *et al.*, 1992). The mechanism by which IE72 protein activates promoters may be related to inhibition of HDAC-2 activity (Tang and Maul, 2003).

It has been proposed that HCMV IE72 has intrinsic protein kinase activity (Pajovic *et al.*, 1997). The related protein, IE38 does not have the proposed protein kinase domain. The Rb family members p107 and p130, the E2F transcription factor family members, and PML are phosphorylated by the IE72 protein (Ippolito *et al.*, 2003; Pajovic *et al.*, 1997). Phosphorylation of the Rb family members would dissociate the repressor from E2F and activate the E2F cellular transcription factor. The leucine zipper region of IE72 can bind the N-terminus of p107, alleviate the repressive effect of p107 and, consequently, activate cyclin dependent kinase-2 (cdk2)/cyclin E activity (Zhang *et al.*, 2003). Therefore, IE72 induces cycle cell progression, but the effect of the viral protein is more demonstrable in a p53 negative cell than in a p53 positive cell (Castillo *et al.*, 2000). An active p53 pathway should increase levels of p21 cyclin-dependent kinase inhibitor even in the presence of activated E2F transcription factors, but p21 is decreased in the HCMV-infected cell (Chen *et al.*, 2001; Noris *et al.*, 2002). HCMV infection affects p53 because the cellular protein is sequestered in the nucleus in viral replication centers (Fortunato and Spector, 1998).

The IE2 proteins

The betaherpesvirus proteins encoded by the IE2 gene exhibit amino acid similarity across their C-terminal regions. The HCMV IE2 gene and its functional homologue in MCMV (ie3) are absolutely essential for the cascade of viral gene expression (Angulo *et al.*, 2000a; Marchini *et al.*, 2001). Recombinant viruses with deletion of the HCMV IE2 gene or the MCMV ie3 gene are unable to activate early viral gene expression, and, consequently, viral DNA synthesis and late gene expression are also affected. The betaherpesvirus IE2 proteins have N- and/or C-terminal domains that activate viral gene expression and are considered a master regulator of productive infection. The IE2 gene of HCMV has been studied in detail. It regulates activation of transcription from viral and cellular promoters, negatively auto-regulates the MIE promoter, and induces cell cycle progression. Figure 17.5 is a diagram of the functional domains of the HCMV IE2 protein IE86. IE86 is also targeted to ND10 in the nucleus and modified by conjugation with SUMO-1 or SUMO-2 at lysine (K) residues 175 or 180. The apparent molecular weight of the modified protein is 105 kDa (Ahn *et al.*, 2001; Hofmann *et al.*, 2000); however, sumoylation of IE86 is not required for viral growth (Lee and Ahn, 2004).

Unlike IE72, IE86 does not disperse ND10. However, IE86 remains adjacent to ND10 where a portion of the input viral DNA is also located (Ishov *et al.*, 1997). Modification of IE86 by SUMO may facilitate interaction with the basal transcription machinery and/or with cellular or viral transcription factors. In transient transfection experiments, IE86 mutated at lysine residues 175 and 180 autoregulates the

MIE promoter, but fails to efficiently activate early viral promoters (Hofmann *et al.*, 2000). A recombinant virus with deletion of amino acid residues 136 to 290 still down-regulates transcription from the MIE promoter, but the mutant exhibited lower levels of late gene (UL83 and UL99) expression (Sanchez *et al.*, 2002). Late gene expression is also disrupted by deletion of four amino acids from 356 to 359 (White *et al.*, 2004). This mutation would disrupt a region where IE86 interacts with the basal transcription factors TFIIB and TBP (Fig. 17.5). IE86 has a serine-rich region from amino acids residues 258 to 275. Mutation of the serine residues from 258 to 264 or 266 to 269 delays viral growth, but mutation from 271 to 275 accelerates viral growth (Barrasa *et al.*, 2005). These serine residues are in a region of the protein that can bind TBP (Fig. 17.5). IE86 is also modified by phosphorylation at amino acid residues T27, S144, T233, and S234 (Harel and Alwine, 1998) (Fig. 17.5). Differences in phosphorylation may have significant effects on the function of the viral protein.

Data indicate that mutation of amino acids between 427 to 435 and 505 to 511 caused a loss of auto-regulation of the MIE promoter by IE86 (White *et al.*, 2004). Mutation of histidines 446 and 452 generates a protein that cannot bind to the crs and negatively autoregulates the MIE promoter in an in vitro transcription assay (Macias and Stinski, 1993). Therefore, the carboxyl region of the IE86 protein is critical for auto-regulation of the MIE promoter (Fig. 17.5). Autoregulation of the MIE promoter by the IE86 protein at early times is likely due to the blockage of RNA polymerase II and transcription initiation factors at the transcription start site (Macias *et al.*, 1996). At late times after infection the IE86 protein was found to be associated with repressive chromatin (Reeves *et al.*, 2006). With murine CMV, the M112/113 gene product co-localizes with and binds ie3 protein (the equivalent of human CMV IE86) to inhibit the repressive effect on the MIE promoter and promotes continued MIE gene expression (Tang *et al.*, 2005).

In transient transfection assays, multiple regions of IE86 are reported to be important for promoter activation. Two activation domains (AD) are located at amino acid 25 to 85 and 544 to 579 (Fig. 17.5). Amino acid residues 1 to 98, 169 to 194, 175 to 180, and multiple regions in the carboxyl terminal half of the protein are also important for viral promoter activation (Malone *et al.*, 1990; Pizzorno *et al.*, 1991; Sommer *et al.*, 1994; Stenberg, 1996; Yeung *et al.*, 1993). Other important regions of IE86 are amino acid residues 388 to 542, and 463 to 513, which encompass a dimerization region and a helix–loop–helix region, respectively (Ahn *et al.*, 1998b; Macias *et al.*, 1996; Macias and Stinski, 1993; Waheed *et al.*, 1998). There is a core region between amino acids 450 and 544. Mutations in this region affect most of the activities of this protein (Fig. 17.5) (Asmar *et al.*, 2004).

IE86 interacts with a wide variety of cellular transcription factors (Bryant *et al.*, 2000; Lang *et al.*, 1995; Lukac *et al.*, 1994; Yoo *et al.*, 1996). These factors include TBP, TFIIB, and TAF4 as well as histone acetyl-transferase (Bryant *et al.*, 2000; Caswell *et al.*, 1993; Fortunato and Spector, 1999; Hagemeier *et al.*, 1992a; Lukac and Alwine, 1997; Spector, 1996). IE86 may serve as a link between various upstream sequence-specific DNA binding regulators of transcription and the basal transcription initiation complex. The protein also interacts with an early viral protein encoded by the UL84 gene of HCMV (Colletti *et al.*, 2004; Samaniego *et al.*, 1994; Spector and Tevethia, 1994). Over-expression of UL84 prior to viral infection will antagonize activation of early viral promoters by IE86 protein (Gebert *et al.*, 1997). The UL84 gene is essential for viral DNA synthesis and growth (Xu *et al.*, 2004b). The UL84 protein interacts with itself and with the IE86 protein which is essential for oriLyt-dependent viral DNA synthesis (Colletti *et al.*, 2004; Sarisky and Hayward, 1996). DNA synthesis is initiated by the activation of a oriLyt bidirectional promoter by IE86 and UL84 viral proteins (Xu *et al.*, 2004a). The other HCMV IE genes, IE1, UL36–38, and IRS1/TRS1, have a stimulatory effect on ori-Lyt-mediated DNA replication in HF cells (Anders and McCue, 1996).

The IE86 protein also interacts with cellular proteins that control cell cycle progression. Several types of biological assays indicate that IE86 physically binds Rb (Fortunato *et al.*, 1997; Hagemeier *et al.*, 1994; Sommer *et al.*, 1994). The release of the cellular E2F transcription factor from Rb, as a consequence of this interaction, is considered to be one of the key HCMV mechanisms for induction of cell cycle progression. As many as 4-fold more serum-starved glioblastoma U373 or 293T cells are induced into S phase by wild type IE86 compared to a mutant protein (Murphy *et al.*, 2000). IE86 blocks cell division by arresting p53 wild type cells at G_1/S (Murphy *et al.*, 2000; Song and Stinski, 2002; Wiebusch and Hagemeier, 1999; Wiebusch *et al.*, 2003). In p53 mutant U373 cells or p53 null Saos-2 cells, IE86 does not inhibit cell cycle progression at G_1/S (Song and Stinski, 2005). These cells synthesize cellular DNA and cell cycle progression stops at the S phase for U373 cells or the G2/M-phase for Saos-2 cells (Murphy *et al.*, 2000; Song and Stinski, 2005). In p53 null Saos-2 cells, a block in cell cycle progression at the G_2/M-phase by the IE86 protein correlates with an aberrant increase in cyclin B and cdk1 levels (Song and Stinski, 2002). IE86 likely prepares the cell for DNA synthesis by activating cellular genes that regulate the cell cycle, enzymes for DNA precursor synthesis, and proteins for initiation of cellular DNA synthesis (Song and Stinski, 2002). For example, production of mRNAs for cyclin E, cdk-2, E2F-1, DNA polymerase α, and MCMs is significantly increased by IE86 (Song and Stinski, 2002). Preparation

for DNA synthesis is critical for the virus because CMVs typically infect terminally differentiated cells in the G_o/G_1 phase of the cell cycle when the pool of dideoxynucleotide triphosphates and biosynthetic enzyme levels are low. HCMV IE86 is an unusual regulatory protein in comparison to regulatory proteins of adenovirus, SV40, or papilloma DNA viruses because it pushes the p53 wild type cell from G_o/G_1 to the G_1/S transition, yet blocks further cell cycle progression (Murphy *et al.*, 2000; Wiebusch and Hagemeier, 2001). Both of the IE 72 and IE86 proteins stabilize p53, which is associated with phosphorylation of p53 at serine residue 15 (Castillo *et al.*, 2005; Song and Stinski, 2005). The IE86 protein induces the degradation of cellular mdm2 and thereby prevents ubiquitination and proteasome degradation of p53 (Zhang *et al.*, 2006). Recombinant virus with a mutant IE86 protein that fails to block cell cycle progression at the G1/S interface and allows for cellular DNA synthesis, replicates slowly relative to wild type virus (Petrik *et al.*, 2006). The IE86 protein may block rather than promote apoptosis (Zhu *et al.*, 1995).

One of the functions of cellular p53 tumor suppressor protein is to ensure termination of cells that have lost the ability to regulate growth. Even though the HCMV IE86 protein binds to p53 (Bonin and McDougall, 1997; Speir *et al.*, 1994), p53 is not inactivated by the IE86 protein and, as a result, cdk inhibitor p21 increases in relative amount (Shen *et al.*, 2004; Song and Stinski, 2002). However, in the HCMV infected cell the levels of p21 decrease (Chen *et al.*, 2001; Noris *et al.*, 2002). In the p53 wild type HF cell, IE86 induces senescence that is manifested in continued cellular metabolism, production of plasminogen activator inhibitor type I, and neutral β-galactosidase activity (Noris *et al.*, 2002).

While the viral IE86 protein acts by a different mechanism to activate cellular gene expression, it acts to favor virus survival by inhibiting cellular beta-interferon, cytokine, and pro-inflammatory chemokine expression by an unknown mechanism (Taylor and Bresnahan, 2005, 2006).

Factors that stimulate betaherpesvirus immediate–early gene expression

Cellular signal transduction events

Infection of HF cells with HCMV triggers activation of multiple signal transduction pathways. There is an activation of the phosphatidylinositol 3-kinase (PI3K), the mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK), and the p38 MAPK signal transduction pathways (Johnson *et al.*, 2000, 2001; Rodems and Spector, 1998). Inhibitors of these signal transduction pathways suppress HCMV replication, which implies that the signal transduction pathways are necessary for efficient viral replication. The PI3K pathway is activated by virion components immediately upon entry. An activated PI3K pathway induces production of secondary messengers like phosphotidyl inositol and diacylglycerol (Albrecht *et al.*, 1990, 1991; Wang *et al.*, 2003) and increases in cyclic AMP, GMP, and intracellular stores of calcium. The MAPK/ERK and p38 MAPK pathways are activated early after infection and sustained until late times (Johnson *et al.*, 2000; Rodems and Spector, 1998). The PI3K, MAPK/ERK, and p38 MAPK pathways have major effects on the activation of a variety of cellular transcription factors. This activation often results from phosphorylation of the transcription factors and, consequently, up-regulates both cellular and viral gene expression. HCMV early promoters are suppressed by inhibitors of signal transduction pathways (Chen and Stinski, 2002). Therefore, activation of signal transduction pathways is an important step in the efficient replication of betaherpesviruses.

Prostaglandins and reactive oxygen species (ROS) also serve as secondary messengers that elicit multiple responses in betaherpesvirus-infected cells (Zhu *et al.*, 2002). Virions of HCMV up-regulate cellular cyclooxygenase-2 (cCOX-2) (Zhu *et al.*, 2002). The rhesus CMV encodes a viral COX-2 (vCOX-2), which is required for efficient viral replication in endothelial cells (Hanson *et al.*, 2003; Rue *et al.*, 2004). Prostaglandin E2, a product of COX-2, activates the HCMV MIE enhancer-containing promoter (Kline *et al.*, 1998). HCMV infection generates ROS partly through a COX-2-dependent pathway. ROS also activates the HCMV MIE promoter and augments viral replication. Inhibition of cCOX-2 or scavenging of ROS decreases HCMV IE gene expression and viral replication (Speir *et al.*, 1998; Zhu *et al.*, 2002). Treatment with prostaglandin E2 reverses the inhibitory effects on HCMV replication.

Lastly, proinflammatory cytokines induce various signaling pathways that stimulate MIE gene expression and viral replication. This outcome is observed, for example, in HCMV-infected macrophages or granulocyte–macrophage progenitors treated with tumor necrosis factor-α or interferon-γ (Soderberg-Naucler *et al.*, 1997a; Hahn *et al.*, 1998).

Virion components

A wide variety of virion components are involved in activating betaherpesvirus IE gene expression. Engagement of HCMV or viral glycoprotein gB with epidermal growth factor receptor activates the PI3K-mediated signaling pathway (Wang *et al.*, 2003). HCMV glycoproteins also have a role

in stimulating the release of pro-inflammatory cytokines mediated by the CD14 and Toll-like receptor 2 molecules on the cell surface (Compton *et al.*, 2003). These cytokines may act on signaling pathways, which in turn, activate cellular transcription factors.

HHV-6 U54 is similar in amino acid sequence to HCMV UL82. The HCMV UL82 gene and the UL35 gene, which encode viral tegument proteins, have a profound positive impact on the efficiency of viral replication (Bresnahan and Shenk, 2000; Dunn *et al.*, 2003; Schierling *et al.*, 2004). These viral tegument proteins are transported to the nucleus of the infected cell where they are targeted to the ND10 (Schierling *et al.*, 2004). UL82 (pp71) protein interacts with a cellular repressor of transcription, hDaxx, and may disrupt or inactivate the hDaxx-histone deacetylase (HDAC) complex (Cantrell and Bresnahan, 2006; Hensel *et al.*, 1996; Hofmann *et al.*, 2002; Ishov *et al.*, 1997, 2002). The viral pp71 tegument protein induces proteasome dependent degradation of hDaxx and thereby neutralizes an intrinsic immune defense mechanism of the cell (Saffert and Kalejta, 2006). In cells deficient in hDaxx, UL82 protein is not targeted to the ND10. The viral MIE promoter and early promoters are activated by UL82 protein (Baldick *et al.*, 1997; Bresnahan and Shenk, 2000; Liu and Stinski, 1992). Heterologous promoters, like herpes simplex virus IE promoters, are also activated by UL82 protein (Homer *et al.*, 1999). The mechanism involves interaction with cellular repressors of transcription and reduction of HDAC activity. The UL82 protein also has effects on cell cycle progression. It stimulates quiescent cells to re-enter the cell cycle and accelerates cells through G_1 (Kalejta and Shenk, 2003a). The UL82 protein binds to members of the retinoblastoma (Rb) protein family and induces proteosome-dependent Rb family degradation (Kalejta and Shenk, 2002, 2003b). A release of the Rb family of repressors from E2F responsive cellular promoters increases cellular cyclins, cdks, and biosynthetic enzymes for DNA synthesis. UL82 protein increases the infectivity of HCMV in HF cells (Baldick *et al.*, 1997).

HHV-6 U42 is the homologue of HCMV UL69. Deletion of the HCMV UL69 gene, which also encodes a tegument protein, causes a delay in viral DNA replication and late gene expression (Lu Hayashi *et al.*, 2000). At low MOI, virus mutated in the UL69 gene replicate slower and take longer to reach peak levels of infectious virus (Lu Hayashi *et al.*, 2000). The UL69 protein is transported to the nucleus where it may interact with proteins that regulate chromatin structure such as hSPT6 (Winkler *et al.*, 1994). The UL69 protein enhances transcription from the viral MIE promoter in transient transfection assays (Winkler *et al.*, 1994). It also affects cell cycle progression by blocking G_1/S transition (Lu Hayashi *et al.*, 2000).

Members of the betaherpesvirus family also have structural homologues of seven transmembrane G-protein-coupled receptors (GPCRs) (Chee *et al.*, 1990; Gompels *et al.*, 1995; Gruijthuijsen *et al.*, 2002; Nicholas, 1996; Rawlinson *et al.*, 1996; Vink *et al.*, 2000; Waldhoer *et al.*, 2002). Recombinant viruses with deletions of the GPCR genes replicate less efficiently in certain cell types. For example, recombinant murine or rat CMV with M33, R33, or M78 genes deleted replicate less efficiently in macrophages and are unable to disseminate to the salivary gland of the animal (Beisser *et al.*, 1999; Davis-Poynter *et al.*, 1997). Several of the viral GPCRs have been shown to initiate ligand-independent constitutive signaling through the G protein phospholipase C (PLC) pathway. Human and rhesus CMV US28 GPCRs induce intracellular signaling following binding of ligands such as fractalkine and CC chemokines. Although HCMV has a sequence homologue (UL33), US28 has been proposed to act in a manner similar to MCMV M33 in that both result in activation of the PLC pathway and activation of CREB and NF-κB. Betaherpesvirus GPCRs are postulated to have a role in the early re-programming of the host cell to favor viral replication. Their activation of cellular transcription factors may enhance IE and early gene transcription.

Infection and dysregulation of the cell cycle by betaherpesviruses

Although betaherpesviruses encode a viral DNA polymerase, processivity factor, single-stranded DNA binding protein and helicase/primase complex for viral DNA synthesis, the viruses depend on many host cell enzymes for this process. The betaherpesviruses do not encode many of the enzymes for synthesis of DNA precursors. Permissive HF cells are typically in the G_0/G_1 phase of the cell cycle and have low amounts of dideoxynucleotide triphosphates and biosynthetic enzymes of DNA precursors at the time of infection. Infection of mouse fibroblasts by MCMV or HF cells by HCMV stimulates production of cellular enzymes of DNA precursor synthesis, e.g., thymidylate synthetase, ribonucleotide reductase, deoxycytidylate deaminase, and dihydrofolate reductase (Gribaudo *et al.*, 2000; Hertel and Mocarski, 2004; Song and Stinski, 2002). Upon HCMV infection, there is a 30-fold increase in the size of the thymidylate triphosphate pool (Biron *et al.*, 1986). In addition, cells are primed for cellular DNA synthesis when the virus induces production or activities of select cellular cyclins and cdks, which are required for cell cycle progression. For example, cyclin E and cdk2, which are necessary for the G_1/S transition, are highly activated after HCMV infection of HF cells

(Bresnahan *et al.*, 1997; Jault *et al.*, 1995; McElroy *et al.*, 2000; Salvant *et al.*, 1998). In contrast, cyclin D, which is necessary for G_1 phase, and cyclin A, which is necessary for the S phase, are not induced by HCMV in HF cells (Zhu *et al.*, 1998). Betaherpesviruses appear to activate the cell differently from that of mitogenic stimulation where the cyclins are activated in a cascade fashion.

The cdks phosphorylate Rb family members and activate the E2F family of transcription factors (Nevins, 1992; Weinberg, 1995). E2F expression is increased after HCMV infection (Salvant *et al.*, 1998; Song and Stinski, 2002), which, along with cyclin E, comprises a feed-forward loop allowing amplification of signals that promote cell cycle progression from G_1 to S phase. However, with HCMV-infected HF cells, the majority of the cells are blocked at the G_1/S transition point (Bresnahan *et al.*, 1996; Dittmer and Mocarski, 1997; Lu and Shenk, 1996). Progression into S phase interferes with efficient HCMV replication because there is little to no IE gene expression during S phase (Fortunato *et al.*, 2002; Salvant *et al.*, 1998). Cellular proteins might be involved in suppressing IE gene expression during S phase, because an inhibitor of cellular proteosome activity allows for a higher level of IE gene expression (Fortunato *et al.*, 2002). In general, the G_1/S compartment of the cell cycle is the most favorable environment for betaherpesvirus gene expression, but the S phase is unfavorable.

An increase in cyclins and cdk activity is likely important for HCMV because cdk inhibitors like roscovitine and olomoucine affect splicing of the IE mRNAs (Sanchez *et al.*, 2004) and inhibit infectious virus production (Bresnahan *et al.*, 1997). In addition, inhibitors of cellular enzymes involved in DNA precursor synthesis (e.g., thymidylate synthetase and deoxycytidylate deaminase) can block HCMV and MCMV replication (Gribaudo *et al.*, 2000). The combination of inactivation of the repressor proteins such as Rb and the activation of proteins involved in movement of the cell cycle such as cyclin E and cdk2 induce an environment most favorable for betaherpesvirus DNA replication. IE proteins of betaherpesviruses play an important role in this stage of the viral replication cycle.

Summary

Betaherpesviruses infect multiple cell types in the host. In general, the productive infection ensues in cells that are terminally differentiated and in the G_o/G_1 phase of the cell cycle. Expression of the IE genes is tightly regulated because these gene products are required for viral replication and have a potential detrimental impact on viral latency. The virions contain components that stimulate both cellular and viral genes. Viral glycoproteins, tegument proteins, and GPCRs can stimulate signal transduction pathways that activate cellular transcription factors and enhance the efficiency of viral replication. The MIE gene products directly activate early viral genes and further stimulate the cell for efficient early and late viral gene expression. Both viral tegument proteins and the MIE proteins cause dysregulation of the cell cycle. The cell is pushed from the G_0/G_1 phase to the G_1/S transition point, with concomitant activation of cellular proteins for DNA precursor synthesis, cell cycle progression, and DNA initiation and synthesis. In the HCMV-infected cell, the level of phospho-serine15-p53 is increased, which stabilizes p53. In p53 wild type cells, the cell cycle stops at the G_1/S transition. The HCMV UL69 tegument protein also prevents transition into S phase. Replication of betaherpesviruses appears to be best in a cell that progresses to the G_1/S transition point, but is prevented from entering the S phase. The betaherpesviruses include both human and animal pathogens for which there are no vaccines, and the available antiviral therapies are fraught with limited efficacy and high rates of adverse effects. A better understanding of betaherpesvirus replication and pathogenesis is needed for developing novel strategies to prevent disease by these opportunists.

Early viral gene expression and function

Elizabeth A. White and Deborah H. Spector

Department of Cellular and Molecular Medicine and Center for Molecular Genetics, University of California, San Diego, La Jolla, CA, USA

Introduction

Viral early genes are defined by two criteria: they require prior *de novo* synthesis of viral immediate-early (IE) and cellular proteins for their transcription, and this expression is insensitive to inhibitors of viral DNA synthesis such as phosphonoformate, ganciclovir, cidofovir, and phosphonoacetate. Close inspection of the kinetics of synthesis of this class of genes reveals multiple subgroups (for review, see Fortunato and Spector, 1999). The earliest of the early gene transcripts appear and accumulate to their highest levels by 8 hours postinfection (h p.i.) (e.g., the HCMV 2.2 kb family of transcripts – UL112–113), while the latest of the early transcripts cannot be detected until just prior to the onset of viral DNA replication (e.g., the HCMV 2.7 kb major early transcript – $\beta_{2.7}$ or TRL4) and accumulate to highest levels much later during infection when viral DNA replication is allowed to proceed. (Mocarski and Courcelle, 2001) Levels of a third subgroup increase at late times (e.g., the abundant HCMV 1.2 kb RNA – TRL7) and are partially blocked by inhibitors of viral DNA synthesis. This subgroup may be further divided into genes that are referred to as early–late or leaky–late.

This review will describe the viral factors and cellular environment required for the expression of the viral early genes, the function of the early genes with respect to viral replication, and the subversion of host cellular processes and modulation of host immune responses that are associated with the expression of these genes. Selected examples of early genes will be used to illustrate different mechanisms controlling this complex class of genes. The focus is on human cytomegalovirus (HCMV) and its replication in fibroblasts, the most extensively studied betaherpesvirus. A separate section at the end of the review is devoted to human herpesvirus 6 (HHV-6) and human herpesvirus 7 (HHV-7).

The host cell range of HCMV permissivity in vivo is broad. The major targets of infection are cell types such as epithelial and endothelial cells as well as peripheral blood leukocytes in the myelomonocytic lineage. Infection also extends to specialized parenchymal cells such as neurons and astrocytes in the brain and retina, smooth muscle cells, and hepatocytes (Sinzger and Jahn, 1996). Infection is restricted, however, when the virus is grown in tissue culture cells. Primary human fibroblasts have been used for virus isolation as well as for most studies on the cellular and molecular biology of HCMV. Fresh clinical isolates of this virus retain the ability to replicate in cultured epithelial cells and macrophages. This is not a property of laboratory propagated strains. It should be kept in mind that the rules governing early gene expression and the functional importance of the gene products might be quite different in other cell types than in fibroblasts.

Identification of HCMV early genes

The initial identification of HCMV early genes was based on studies that measured the rate of accumulation of viral transcripts. Pulse-labeled whole cell, nuclear, or cytoplasmic RNA was hybridized to cloned subgenomic fragments or viral DNA cleaved with restriction endonucleases and fractionated by gel electrophoresis (DeMarchi, 1981; DeMarchi, 1983; DeMarchi *et al.*, 1980; McDonough and Spector, 1983; Wathen and Stinski, 1982; Wathen *et al.*, 1981). In complementary experiments, the size and abundance of various RNAs were determined by hybridization of radiolabeled viral DNA or cloned subgenomic fragments to dot blots or Northern blots of RNA isolated at various times in the infection (DeMarchi, 1983; McDonough and Spector, 1983; Wathen and Stinski, 1982). Two important points emerged from these studies. First, there is no clustering of

RNA transcripts in the genome according to their temporal expression. Furthermore, some HCMV early expression appeared to be subject to post-transcriptional controls that governed either the transport of RNA from the nucleus to the cytoplasm or the stability of the RNA in the cytoplasm. These early studies provided information on the relative abundance, size, and temporal expression of about 30% of the RNAs (Chambers *et al.*, 1999; Mocarski and Courcelle, 2001) and served as the framework for more detailed analysis of individual transcription units.

More recently, additional studies have used PCR analysis, gene arrays, and large-scale mutagenesis to classify each of the predicted HCMV ORFs as IE, early, or late and to characterize these as essential or dispensable for growth in tissue culture cells (Chambers *et al.*, 1999; Dunn *et al.*, 2003; Yu *et al.*, 2003). In one study (Chambers *et al.*, 1999), infected cell RNA was hybridized to a DNA microarray carrying oligonucleotides corresponding to the majority of the strain AD169 ORFs and four ORFs present in the Towne strain. IE transcripts were isolated from cells infected in the presence of the protein synthesis inhibitor cycloheximide and harvested at 13 h p.i., while cells treated with ganciclovir for 72 h were the source of RNAs transcribed with early kinetics. Late RNA was isolated from untreated cells at 72 h p.i., and differential sensitivity to ganciclovir was the basis for further characterization of these transcripts as early–late or late. The expression of selected transcripts not previously characterized was confirmed by further hybridization analysis. In agreement with the initial studies, there was no clear correlation of kinetic class with location or polarity of the ORF in the genome, although the majority of the US region ORFs were expressed with early kinetics.

HCMV-mediated changes in the cellular environment prior to early gene expression

Examination of the viral growth cycle reveals intricate interactions between HCMV and the host cellular machinery that optimize the environment for viral replication and prevent recognition of the infected cell by the immune system. The details of these events are discussed in depth in Chapters 16, 19, 20, 21, 58, and 59. Because early gene products are important in many aspects of infection, a brief summary is provided here.

Events triggered by the binding of the virus to the host cell

The initial contact of the virus with the cell membrane triggers physiological changes and activates signaling pathways that in many ways resemble the interferon response or the second messenger-type response that occurs during regulation via hormones and growth factors (for review, see Chapter 16 and Fortunato *et al.*, 2000). For example, there is hydrolysis of phosphatidylinositol(4,5)-biphosphate, stimulation of arachidonic acid metabolism, a transient influx of calcium, upregulation of the transcription factors Sp1 and NF-κB, and activation of the mitogen activated protein kinases (ERK1/2 and pp38) and the phosphatidylinositol 3-kinase pathways (Albrecht *et al.*, 1991; Johnson *et al.* 2000, 2001a,b; Rodems and Spector, 1998). Also associated with this immediate activation of the host cell is the induction of a subset of RNAs encoding genes induced by alpha or beta interferon (IFN-α/β) in uninfected cells (Boyle *et al.*, 1999; Browne *et al.*, 2001; Navarro *et al.*, 1998; Zhu *et al.*, 1997, 1998). The HCMV-associated induction occurs in the absence of any detectable IFN-α/β or *de novo* protein synthesis and appears to require simply the exposure of the cell to virions, non-infectious enveloped particles, or dense bodies. The up-regulation of the interferon-responsive genes, however, is tempered by the viral matrix protein pp65 as well as by one or more viral gene products or cellular factors that are expressed during the first few hours of the infection (Abate *et al.*, 2004; Browne and Shenk, 2003; Browne *et al.*, 2001). It has recently been shown that the IE1 and IE2 genes encode at least two of the proteins responsible for the downregulation of this IFN-α/β-mediated signaling response. IE2 86 kDa protein blocks the production of IFN-β and several chemokines (Taylor and Bresnahan, 2005; Taylor and Bresnahan, 2006), while IE1 72 acts further downstream to block type I interferon-mediated signaling and the induction of multiple interferon-responsive genes (Paulus *et al.*, 2006).

ND10 are sites of genome deposition and IE transcription

Upon infection of cells with a variety of DNA viruses, the morphology of nuclear structures referred to variously as ND10 (nuclear domain 10), PODs (PML oncogenic domains), or PML bodies is rapidly altered (for review, see Chapter 17). While infection with adenovirus 5 (Ad5) results in these punctate structures acquiring a reticular appearance, both HCMV and herpes simplex virus type 1 (HSV-1) infections disrupt ND10 sites and disperse associated proteins. In uninfected cells, a number of proteins including the growth suppressors promyelocytic leukemia protein (PML), Sp100, HP1, and Daxx are localized to ND10 domains, and many of these are interferon inducible. As is the case for Ad5 and HSV-1, a subset of HCMV genomes are

deposited at ND10 sites immediately following infection, and it is these genomes that provide the template for early transcription (Ishov and Maul, 1996; Ishov *et al.*, 1997). Transcripts produced at these sites are consequently in close proximity to spliceosome assembly factor SC35 domains, which may further aid in rapid expression of IE genes following infection.

Once the major HCMV IE proteins, IE1 72 and IE2 86, are expressed during the infection, these first localize to ND10 sites. While the punctate pattern of IE2 86 expression persists for a longer time, between 3 and 6 h p.i. both IE1 72 and ND10-associated proteins, including PML, become completely dispersed throughout the nucleus (Ahn and Hayward, 1997; Ishov *et al.*, 1997; Kelly *et al.*, 1995; Korioth *et al.*, 1996). Further studies involving either transfection of IE1 or IE2 expression vectors or infection with a recombinant virus unable to express IE1 72 indicate that IE2 86 protein is able to localize to ND10 sites in the absence of IE1 72, but disruption does not occur (Ahn *et al.*, 1998a; Ahn and Hayward, 1997; Ishov *et al.*, 1997). IE1 72 is required for disruption of the ND10 sites, but since the IE1 deletion mutant virus replicates well under high multiplicity conditions, this event appears not to be required for the infection to proceed. Modification of IE1 by SUMO-1 is also not required for HCMV-mediated ND10 dispersal or for viral replication, although a virus with a mutation in the IE1 sumoylation site grows more slowly (Lee *et al.*, 2004; Nevels *et al.*, 2004; Xu *et al.*, 2001). The observation that IE1 abrogates sumoylation of PML and Sp100 suggests that this is at least one element of the mechanism by which ND10 associated proteins are dispersed during the infection (Muller and Dejean, 1999).

A growing body of evidence suggests that even after IE1 72 has caused dispersal of ND10 sites, these locations remain important for viral replication. Between 3 and 8 hours p.i., aggregates of cyclin dependent kinase (cdk) 9 and cdk 7 appear in the nuclei of HCMV-infected cells. Input viral genomes and IE1 and IE2 proteins are also present at some, but not all, of these sites (Tamrakar *et al.*, 2005). When cells are infected with the IE1 72 deletion mutant virus, ND10 structures are maintained and the cdk 9 aggregates can be visualized at the periphery of the PML-containing ND10 sites. In addition, the UL112–113 early gene proteins appear to colocalize with IE2 86 at the periphery of the original ND10 sites beginning about 6 h p.i., and these nucleate viral DNA replication compartments that form later during infection (Ahn *et al.*, 1999a).

Finally, a series of studies suggest that an interaction between the HCMV tegument protein pp71 and the ND10-associated Daxx is the basis of a mechanism by which early events in the viral life cycle are initiated at ND10 sites (Hofmann *et al.*, 2002; Ishov *et al.*, 2002; Marshall *et al.*, 2002). Work using recombinant viruses has shown that the Daxx-binding ability of pp71 is required for efficient HCMV replication and IE gene expression during low, but not high, multiplicity infections (Cantrell and Bresnahan, 2005; Cantrell and Bresnahan, 2006; Saffert and Kalejta, 2006). When Daxx expression is reduced, the activity of the major IE promoter increases in transient transfection assays. Knockdown of Daxx expression also alleviates the reduced IE gene expression observed in pp71 deletion mutant virus-infected cells (Cantrell and Bresnahan, 2006; Preston and Nicholl, 2006). These findings are further explained by the observation that pp71 is required for the proteasome-mediated degradation of Daxx that begins 2 h p.i. in HCMV-infected cells. This degradation is required for efficient IE gene expression and is thought to increase gene activity by eliminating Daxx-mediated histone deacetylase recruitment to promoters (Saffert and Kalejta, 2006).

Inhibition of apoptosis

Two viral IE proteins from the UL36–38 region of the genome serve to prevent the host cell from undergoing apoptosis (for review see Chapter 21). One (vMIA) is the protein product of UL37 exon 1, and the second (vICA) is encoded by UL36. vMIA, which is essential for viral replication, travels from the endoplasmic reticulum (ER) to the Golgi and finally to mitochondria. Its expression in transiently transfected HeLa cells blocks apoptosis induced by either anti-Fas antibody plus cycloheximide or by TNF-α, and in stably transfected HeLa clones, it appears to act at a stage between activation of caspase 8 and cytochrome c release into the cytoplasm (Goldmacher *et al.*, 1999; McCormick *et al.*, 2003b). Recently, it was found that vMIA sequesters the pro-apoptotic protein Bax in the mitochondria, thus suppressing mitochondrial permeabilization (Arnoult *et al.*, 2004). The half-life and localization pattern of vICA in infected cells vary depending on the strain of virus used in the infection (Patterson and Shenk, 1999). Like vMIA, vICA is involved in preventing apoptosis in infected cells, but it acts further upstream to block cleavage of procaspase 8 and its subsequent activation (Skaletskaya *et al.*, 2001). Either protein appears to be dispensable for growth in culture so long as the other is retained. Many laboratory-adapted viral strains express non-functional UL36 (Skaletskaya *et al.*, 2001). The high degree of UL36 and UL37 exon 1 conservation across the cytomegalovirus family indicates that both contribute critical functions to replication of the virus in the host organism (McCormick *et al.*, 2003a; McCormick *et al.*, 2005).

Functions of viral early genes

Many early gene products are required for successful viral replication. In libraries of HCMV BACs constructed to disrupt each unique ORF (Dunn *et al.*, 2003; Yu *et al.*, 2003) 41–45 of the ORFs examined appear essential for replication in fibroblasts; 117 are not required but when deleted, give rise to phenotypes ranging from growth like wild type to severe impairment of viral replication. Interestingly, some of these dispensable ORFs (UL24, UL64, and US29) are required for viral growth in cell types other than fibroblasts. In addition, four of the mutants with non-essential genes deleted (UL10, UL16, US16, and US19) grow significantly better than the wild type in cell types other than fibroblasts. Early gene products constitute a significant proportion of essential loci, given that 23 to 25 essential and augmenting genes were characterized as early or early–late in the study by Chambers *et al.* (1999).

Most of the viral early genes function in one of two ways. A subset of the early products required for growth in tissue culture are directly involved in viral DNA synthesis, cleavage and packaging of the viral genome, and assembly of the virus particles (see Chapters 19 and 20). A second group of genes functions to create a cellular and extracellular environment that is optimal for viral gene expression and replication, either by modulating factors involved in the control of cellular DNA synthesis or by altering the host organism's immune response to the virus.

Genes involved directly in viral replication

The majority of the proteins required for synthesis and processing of the viral DNA are expressed with early kinetics, as are many of the factors involved in the initial stages of viral particle assembly. In conjunction with some of the IE and late viral proteins, these products provide the central functions of the viral life cycle.

Initial studies on the replication of the viral DNA identified 11 loci required for origin of lytic replication (*ori*Lyt)-dependent DNA replication (Pari and Anders, 1993; Pari *et al.*, 1993) (Chapter 19). These were conducted as complementation assays in which cloned fragments of the HCMV genome were tested for their ability to support replication of a vector containing *ori*Lyt sequences. Six of the required genes are predicted to function directly in DNA replication and are homologous to factors required for herpes simplex virus type 1 (HSV-1) DNA replication. The products of these genes are pUL54, the viral DNA polymerase; ppUL44, the polymerase processivity factor; ppUL57, a single-stranded DNA binding protein; and three proteins that comprise a helicase-primase complex: pUL70, pUL102, and pUL105. Each of these genes is expressed with early or delayed early kinetics (Chambers *et al.*, 1999; Smith and Pari, 1995). Two additional early loci, UL112–113 and UL84, were identified in the complementation assays and are required together with UL122–123, IRS/TRS1, and UL36–38, three IE loci with regulatory functions that are discussed elsewhere in this chapter.

The functions of several viral early proteins have been closely examined in subsequent work. Viable viruses with point mutations in the UL54 gene, selected on the basis of reduced sensitivity to ganciclovir and cidofovir, tend to grow more slowly than parental virus (Cihlar *et al.*, 1998; Smith *et al.*, 1997). The DNA polymerase processivity factor encoded by UL44 forms a complex with the viral polymerase and binds to double-stranded DNA, thereby stabilizing interactions with the template (Ertl and Powell, 1992; Hwang *et al.*, 2000; Weiland *et al.*, 1994). Recently, residues in the C-terminus of the polymerase have been shown to be required for the ppUL44–pUL54 interaction (Loregian *et al.*, 2004; Loregian *et al.*, 2003). The function of the UL57 gene product has not been examined directly, but by analogy to its homologous HSV-1 counterpart ICP8, this protein is predicted to bind the single-stranded DNA unwound by the helicase–primase complex (Kiehl *et al.*, 2003). The UL102 and UL105 genes have been characterized (Smith *et al.*, 1996; Smith and Pari, 1995), and biochemical studies demonstrating interactions between their protein products and the product of the UL70 gene further support the idea that, as in HSV-1, these three factors function together as the HCMV helicase-primase (McMahon and Anders, 2002).

The product of the UL84 gene is essential for viral DNA synthesis and productive infection (Dunn *et al.*, 2003; Xu *et al.*, 2003, 2004; Yu *et al.*, 2003). The protein localizes to replication centers in the nuclei of infected cells (Lischka *et al.*, 2003; Xu *et al.*, 2002), interacts with IE2 86 (Spector and Tevethia, 1994), and can promote *ori*Lyt-dependent DNA replication when core replication proteins from Epstein-Barr virus are supplied (Sarisky and Hayward, 1996). Recent studies with a BAC defective for the expression of UL84 suggest that it may regulate some of the functions of IE2 86 as well as contribute to the early formation of the replication centers. Interpretation of the results with this mutant BAC, however, is complicated by the observation that the UL84 protein provided in trans does not complement viral growth (Xu *et al.*, 2004). There is also evidence that the UL112–113 proteins localize to viral replication centers early in their formation and may play a role in the recruitment of additional factors to these sites (Ahn *et al.*, 1999b; Iwayama *et al.*, 1994; Penfold and Mocarski, 1997).

UL114 is an early gene that, although not identified in these complementation assays, appears to contribute to

efficient replication of viral DNA (Courcelle *et al.*, 2001; Prichard *et al.*, 1996). The UL114-encoded uracil-DNA glycosylase is not strictly required for growth in fibroblasts, but a mutant lacking this gene is delayed in the initiation of DNA replication.

Following synthesis, viral DNA is cleaved into genome-length segments and packaged into preformed capsids (Chapter 19). Early proteins involved are introduced only briefly here. Four early–late products (major capsid protein, minor capsid protein, minor capsid binding protein, and small capsid protein) contribute to capsid formation and are the products of the UL86, UL85, UL46, and UL48.5 genes, respectively (Gibson, 1996). Capsid formation also relies on the assemblin precursor UL80.5 and the proteinase precursor UL80a. UL89 and UL56 early gene products play roles in DNA cleavage (Buerger *et al.*, 2001; Krosky *et al.*, 2003; Underwood *et al.*, 1998), and by homology to HSV-1 proteins at least four HCMV products, most expressed with early kinetics, are predicted to be involved in packaging cleaved DNA into progeny capsids. These four proteins are encoded by the HCMV UL51, UL52, UL77, and UL104 genes and are predicted to have functions including transport of the capsids to sites of DNA packaging and formation of a structure through which DNA enters the capsid. Recently, it has been shown that the TRS1 protein also may be involved in packaging at a step that occurs after the cleavage of the DNA (Adamo *et al.*, 2004).

Preparing the cell for viral DNA replication

In a cell that is permissive for the viral infection, the expression of the early genes is associated with a cascade of events that results in the stimulation of host cell genes, particularly those encoding proteins that are required for host cell DNA synthesis and proliferation. Early studies revealed a marked increase in the levels of the enzymes ornithine decarboxylase, thymidine kinase, DNA polymerase alpha, and dihydrofolate reductase following HCMV infection (Boldogh *et al.*, 1991; Estes and Huang, 1977; Hirai and Watanabe, 1976; Isom, 1979; Wade *et al.*, 1992). More recent DNA microarray analyses show that the viral infection leads to upregulation of multiple DNA synthesis and cell cycle genes at the level of transcription (Browne *et al.*, 2001). In part, this may follow HCMV-induced hyperphosphorylation of the retinoblastoma family of proteins (Jault *et al.*, 1995; McElroy *et al.*, 2000), which likely releases the inhibition that these proteins confer to the E2F/DP transcription factors that regulate the transcription of many of these same genes (Dyson, 1998). The tumor suppressor protein p53 is stabilized in HCMV-infected cells and is sequestered in viral replication centers (Fortunato and Spector, 1998; Jault *et al.*, 1995). Other proteins that are sequestered in the viral replication centers are PCNA and RPA, which are both essential for the elongation phase of host cell DNA synthesis and may play some role in viral DNA synthesis (Dittmer and Mocarski, 1997; Jault *et al.*, 1995).

HCMV also induces elevated levels of cyclin E and cyclin B and their associated kinase activities (Bresnahan *et al.*, 1996; Jault *et al.*, 1995; McElroy *et al.*, 2000; Salvant *et al.*, 1998; Sanchez *et al.*, 2003). Cyclin E transcription is induced, and this up-regulation requires the expression of viral early genes (McElroy *et al.*, 2000; Salvant *et al.*, 1998). In contrast, multiple posttranscriptional pathways are used in the activation of Cdk1/cyclin B1 complexes (Sanchez *et al.*, 2003). The accumulation of the cyclin B1 subunit is the result of increased synthesis and reduced degradation of the protein via the ubiquitin-proteasome pathway. In addition, the active catalytic subunit of the complex, Cdk1, accumulates in virus-infected cells. This is due partially to the down-regulation of the expression and activity of the Cdk1 inhibitory kinases Myt1 and Wee1 and the accumulation of the Cdc25 phosphatases that remove the inhibitory phosphates from Cdk1. Modulation of these pathways appears to require at least some early gene expression (Sanchez *et al.*, 2003).

During this early period in the infection, HCMV also inhibits selective host cell functions, presumably to ensure that viral replication is favored over that of the host. These events lead the cell to a fully "activated" state, but it is clear that the virus primes the cell for its own DNA replication at the host's expense and has sufficiently dysregulated the cell cycle and signaling pathways to ensure that cellular DNA synthesis and cell division is blocked (Bresnahan *et al.*, 1996; Dittmer and Mocarski, 1997; Jault *et al.*, 1995; Lu and Shenk, 1996; Salvant *et al.*, 1998). In contrast to the activation of cyclins E and B, the expression of cyclin A and its associated kinase activity is inhibited by infection with HCMV (Jault *et al.*, 1995). Although the failure to induce cyclin A in the virus-infected cells probably plays a role in the blockage of cellular DNA synthesis, it has recently been found that viral early gene products also affect key steps in this process prior to the requirement for cyclin A. Briefly, DNA synthesis in eukaryotic cells is precisely regulated such that genomic DNA doubles only once during each cell cycle (Diffley, 2001; Fujita, 1999; Lei and Tye, 2001). The first step involves the assembly of prereplication complexes (pre-RC) at the replication origins. The origin recognition complex (Orc), a multisubunit complex, binds to the origins of cellular DNA replication and remains bound during most of the cell cycle (Quintana and Dutta, 1999; Tatsumi *et al.*, 2000; Vashee *et al.*, 2001). Cdc6 and Cdt1 are recruited to the complex and facilitate the loading of the family of six Mcm proteins on to DNA (Maiorano *et al.*, 2000; Nishitani *et al.*, 2000, 2001; Rialland *et al.*, 2002). Cdt1 itself is regulated by

a protein called geminin that normally accumulates during S-phase and ensures that each origin is used only once. Analysis of this process has revealed that there is a delay in the expression of the Mcm proteins in infected cells. The greatest effect is observed with Mcm5, whose levels remain low until after 32 h p.i. The loading of the Mcm proteins onto the DNA pre-RC complex is also defective in the virus-infected cells and is associated with the premature accumulation of geminin (Biswas *et al.*, 2003; Wiebusch *et al.*, 2003b). Interestingly, as is the case with cyclin B, the increased levels of geminin results from decreased levels of proteasome-mediated degradation (J. W. Choi and D. H. Spector, unpublished results).

Although there is evidence from transient expression systems that the IE1 and IE2 proteins and the virion constituent proteins UL69 and UL82 contribute to the virus-mediated alteration in cell growth control (Bresnahan *et al.*, 1998; Castillo *et al.*, 2000; Kalejta *et al.*, 2003; Kalejta and Shenk, 2003; Lu and Shenk, 1999; Murphy *et al.*, 2000; Sinclair *et al.*, 2000; Song and Stinski, 2002; Wiebusch *et al.*, 2003a; Wiebusch and Hagemeier, 1999, 2001), studies in the context of viral infection show that early gene products are also required (McElroy *et al.*, 2000; Sanchez *et al.*, 2003). A challenge remains to determine which viral genes are involved and elucidate the mechanisms governing their activity. Given the large number of early genes, most of which have not yet been studied, the task is not trivial.

Modulation of host immune responses

In addition to subversion of the intracellular machinery, HCMV needs to deal early in the infection with its survival in its human host and evasion of the immune response. This topic is discussed in detail in Chapters 58 and 59, and so is only briefly summarized here (for other reviews, see (Mocarski, 2002, 2004)). Optimization of in vivo pathogenesis and viral persistence is accomplished by effects on intracellular processes, the release of soluble factors, and regulation of cellular receptors that are involved in modulation of innate, inflammatory, and adaptive immune responses. The number of viral genes that are known to play a role in these processes is still small, and all of these have proven to be dispensable for productive infection in tissue culture. The general consensus, however, is that the large block of "non-essential" early genes in the U_S region whose functions have yet to be determined are key players in viral pathogenesis.

One well-studied mechanism of viral immune evasion involves interference with MHC class I antigen presentation by at least four gene products (US2, US3, US6, and US11) (Ploegh, 1998) (Chapter 58). At early times in the infection, HCMV also disarms the interferon-mediated branch of the host's antiviral defense. The cells become refractory to IFN-α/β-mediated stimulation of MHC class I, IRF-1, MxA, and 2′–5′-oligoadenylate synthetase gene expression, transcription factor activation, and signaling (Miller *et al.*, 1999). Viral genes that have been implicated in these events include UL83 and TRS1/IRS1 (Abate *et al.*, 2004; Browne and Shenk, 2003; Child *et al.*, 2004). In addition, there is repression of IFN-γ-mediated signal transduction, and thus cells do not respond to the presence of IFN-γ by upregulating the expression of MHC class II genes (Miller *et al.*, 1998; Sedmak *et al.*, 1994). The viral US2, and possibly US3, proteins can also downregulate HLA-DRα and DMα, two proteins that are involved in MHC class II antigen presentation (Tomazin *et al.*, 1999).

Another mechanism that HCMV uses to interfere with immune surveillance is modulation of extracellular host factors (i.e., interleukins and chemokines) that are involved in inflammatory reactions and function to activate and recruit T cells, NK cells, neutrophils, and monocytes to the sites of infection. HCMV also encodes several chemokines, cytokines, and receptors that likely play a role in the inflammatory response and in the dissemination of the virus. One factor, cmvIL-10 (UL111A), is a functional homologue of IL-10 that has been proposed to downregulate macrophage and T cell responses and hence have an anti-inflammatory role (Kotenko *et al.*, 2000; Spencer *et al.*, 2002). Another is a functional alpha chemokine, vCXCL-1 (UL146), that attracts neutrophils via CXCR2 (Penfold *et al.*, 1999). HCMV also encodes four glycoproteins with homology to G-protein-coupled seven-TM receptor proteins (UL33, UL78, US27, and US28) (Chee *et al.*, 1990a). One of these (US28) serves as a specific receptor for the CX3C chemokine fractalkine and can also bind many other CC chemokines (Gao and Murphy, 1994; Kuhn *et al.*, 1995; Mizoue *et al.*, 2001). The observation that expression of US28 in vascular smooth muscle cells causes the cells to exhibit enhanced migration towards inflammatory cytokines has led to the hypothesis that US28 may not only facilitate viral dissemination, but also contribute to the progression of vascular diseases. (Streblow *et al.*, 1999).

Transactivating functions of the major IE proteins

Since viral immediate–early (IE) gene products are the primary regulators of HCMV early gene expression, it is important to introduce these proteins and their functions. This topic is covered in detail in Chapters 17, and only the salient points are discussed here. The main sites of IE transcription are the UL122–123 (major immediate early, MIE), UL36–38, US3, and IRS1/TRS1 open reading frames (Fig. 18.1).

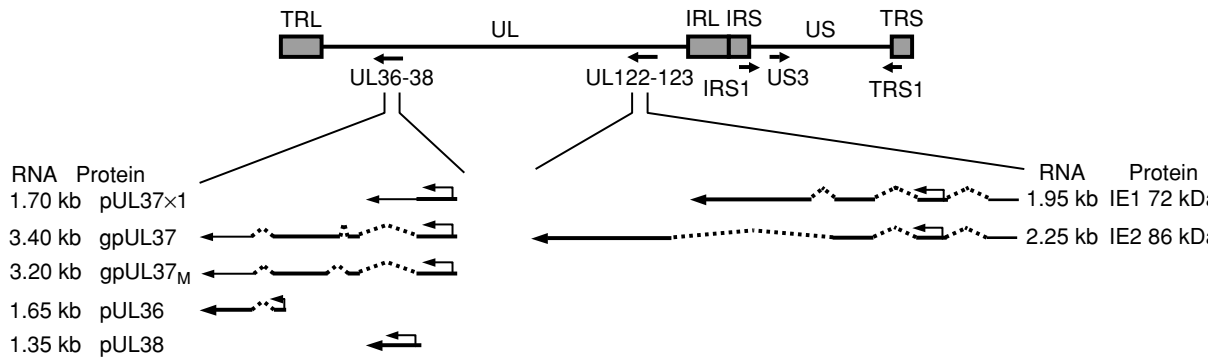

Fig. 18.1. Sites of IE transcription in the HCMV genome. Relative positions in the genome of the IE loci encoding regulatory proteins are shown. The splice patterns of the four IE transcripts expressed from the UL36–38 region and of the two major IE transcripts expressed from the UL122–123 region are indicated. Also shown is the early UL38 transcript.

The predominant and best-characterized members of this group are the products of the major IE region: the IE1 72 and IE2 86 kDa proteins and related products.

Structure and function of the IE1 72 and IE2 86 kDa proteins

The tight control and remarkably strong transactivating capacity of IE1 and IE2 proteins have caused significant effort to be directed towards understanding how they control the progression of the infection. A single, five-exon transcript from the major IE region is differentially spliced to give two predominant products the IE1 72 kDa protein (exons 1–4) and IE2 86 kDa protein (exons 1–3 and 5). Translation of each mRNA initiates in exon 2, and the two proteins share 85 amino acids (aa) at their amino termini (Stenberg *et al.*, 1984, 1985; Stinski *et al.*, 1983). IE1 72 has modest transactivating effects, including the ability to transactivate the major immediate early promoter (MIEP). Both the regions unique to IE1 and to IE2 encode additional, minor transcripts, some of which are cell-type specific (Awasthi *et al.*, 2004; Jenkins *et al.*, 1994; Kerry *et al.*, 1995; Puchtler and Stamminger, 1991; Shirakata *et al.*, 2002; Stenberg *et al.*, 1989).

IE2 86 is thought to transactivate and repress transcription via protein-protein and protein-DNA interactions. IE2 86 binds to itself, to the UL84 gene product, and to a number of cellular proteins. These host factors include components of the basal transcription complex TBP, TFIIB, and multiple TBP-associated factors (TAFs), Rb, p53, and transcription factors including Sp1, Tef-1, c-Jun, JunB, ATF-2, NF-κB, protein kinase A-phosphorylated delta CREB, p300, CBP, P/CAF, Nil-2A, CHD-1, Egr-1, and UBF (Bonin and McDougall, 1997; Bryant *et al.*, 2000; Caswell *et al.*, 1993; Chiou *et al.*, 1993; Choi *et al.*, 1995; Fortunato *et al.*, 1997; Furnari *et al.*, 1993; Gebert *et al.*, 1997; Hagemeier *et al.*, 1992, 1994; Jupp *et al.*, 1993; Lang *et al.*, 1995; Lukac *et al.*, 1994, 1997; Schwartz *et al.*, 1994, 1996; Scully *et al.*, 1995; Sommer *et al.*, 1994; Spector and Tevethia, 1994; Speir *et al.*, 1994; Wara-Aswapati *et al.*, 1999; Wu *et al.*, 1998; Yoo *et al.*, 1996) (F. Ruchti and D. H. Spector, unpublished results). While interactions between IE1 72 and cellular proteins including p107 (Johnson *et al.*, 1999) have also been demonstrated, the IE1 product does not bind to DNA. IE2 86 binds to specific DNA sequences through interactions that are thought to involve the minor groove (Lang and Stamminger, 1994; Waheed *et al.*, 1998), a notable example being its site-specific binding to the 14 bp *cis*-repression signal (*crs*) located between the TATA box and transcription start site in the major immediate–early promoter (MIEP). It has been shown that this interaction with DNA is the mechanism by which IE2 86 negatively regulates its own transcription (Cherrington *et al.*, 1991; Huang and Stinski, 1995; Lang and Stamminger, 1994; Liu *et al.*, 1991; Macias and Stinski, 1993; Pizzorno and Hayward, 1990). In addition, IE2 86 binds to similar 14 bp sites upstream of the TATA box in early promoters including the UL112–113 (2.2kb RNA), TRL7 (1.2 kb RNA), and UL4 promoters (Arlt *et al.*, 1994; Chang *et al.*, 1989; Huang and Stinski, 1995; Schwartz *et al.*, 1994; Scully *et al.*, 1995).

Multiple studies have aimed to define motifs and domains of IE2 86 that are required for both protein–protein and protein–DNA interactions as well as to identify amino acids that are likely to be post-translationally modified. The ability of IE2 86 to interact with other proteins maps broadly to the region not shared with IE1 72, amino acids 86–542 (Chiou *et al.*, 1993; Sommer *et al.*, 1994). A subset of this region, aa 388–542, is required for IE2 86 dimerization (Ahn *et al.*, 1998b; Chiou *et al.*, 1993; Furnari *et al.*, 1993). The DNA-binding capability of IE2, which controls regulation of early promoters and autoregulation, is also the result of sequences present in the C-terminal half of the

protein between residues 290–579 (Chiou *et al.*, 1993; Lang and Stamminger, 1993; Schwartz *et al.*, 1994). Regions spanning the full length of the protein appear to be important for IE2 86 transactivation of promoters, including HCMV early promoters, with the critical regions located between aa 1–98 and 170–579 (Hermiston *et al.*, 1990; Malone *et al.*, 1990; Pizzorno *et al.*, 1991; Scully *et al.*, 1995; Sommer *et al.*, 1994; Stenberg *et al.*, 1990; Yeung *et al.*, 1993). Activation of different viral promoters may require different IE2 86 domains, such as the requirement of sequences from aa 26–85 and aa 290–579 to transactivate the UL112–113 promoter and the additional requirement for aa 86–135 for activation of the 1.2 kb RNA promoter (Scully *et al.*, 1995; Sommer *et al.*, 1994).

The extensive posttranslational modifications of the major IE products suggest that they may be important for the functions of the proteins. Both IE1 72 and IE2 86 are phosphorylated and modified by sumoylation (Ahn *et al.*, 2001; Heider *et al.*, 2002a, b; Hofmann *et al.*, 2000; Spengler *et al.*, 2002; Xu *et al.*, 2001). Although a virus with a mutation in the IE1 sumoylation site grows slightly more slowly than the wild type, mutation of the IE2 sumoylation sites has no effect on viral replication (Lee and Ahn, 2004; Nevels *et al.*, 2004). In vitro and in vivo studies show that IE2 86 is phosphorylated on multiple residues (Harel and Alwine, 1998). When the consensus MAP kinase motifs at amino acids 27, 144, 233–234, and 555 are mutated to alanine, some of the resulting proteins have a stronger capacity to transactivate in transient expression assays than wild type IE2 86. However, in the context of the viral genome, these mutations have no effect on viral replication in fibroblasts (Heider *et al.*, 2002b). In contrast, mutations of the multiple serines in the region between amino acids 258 and 275 have complex effects on viral growth, with some mutations accelerating and others inhibiting the infection (Barrasa *et al.*, 2005). The fact that these major differences in growth rate are associated with only modest effects of the mutations on the transactivation function of IE2 86 in transient expression assays underscores the difficulty of extrapolating results from transient expression assays to events that occur in the context of viral infection.

In vitro and transient expression assays demonstrating the transactivating functions of the major IE proteins

Numerous studies have shown that the major IE proteins function together and separately to activate their own promoter as well as a wide range of heterologous viral and cellular promoters. Studies have been conducted primarily using transient transfection of effector plasmids expressing IE proteins and target plasmids expressing reporters driven by a range of viral promoters. In particular, these include the 1.2 and 2.7 kb RNA and UL112–113 (2.2 kb RNA) early promoters and sequences driving expression of genes involved in viral DNA replication (Colberg-Poley *et al.*, 1992; Klucher *et al.*, 1993; Schwartz *et al.*, 1994; Scully *et al.*, 1995). The results of these studies indicate that IE2 86 makes the greatest contribution to activation and in some cases, increases the level of reporter expression 40- to 80-fold over expression in the absence of IE1 72 or IE2 86. IE1 72 alone is a relatively weak transactivator, and only affects a limited number of promoters that have been tested. The transient assay function that best accounts for the growth defects exhibited by mutant viruses lacking IE1 72 is cooperation with IE2 86 in the activation of early promoters (Gawn and Greaves, 2002; Greaves and Mocarski, 1998).

Mutational analysis of the major IE products in the viral genome

The above studies laid the groundwork for elucidating the critical domains and functions of the major IE products. The recent studies that have used recombinant viruses with mutations in the UL122–123 ORFs, however, are more biologically relevant. A human fibroblast cell line expressing IE1 72 allowed the propagation of a mutant virus lacking UL123 exon 4 that was unable to express full-length IE1 72 (Mocarski *et al.*, 1996). While our laboratory and others have attempted the construction of a similar cell line expressing the IE2 86 protein, to date none has been isolated. In the absence of a complementing cell line, it is difficult to propagate recombinant viruses with mutations in essential genes like IE2 86; however, the advent of bacterial artificial chromosomes (BACs) as vectors for the cloning of herpesvirus genomes has largely allowed this problem to be circumvented (for review see Adler *et al.*, 2003). Since the majority of the viral genome is present in the BAC, mutations can be made and characterized entirely in bacteria regardless of the viability of the resulting virus. Reconstitution of virus from the clone is achieved by transfecting the altered genome and a construct expressing pp71 into cells permissive for HCMV infection (Baldick *et al.*, 1997).

Several groups have since used this approach to construct HCMV IE2 86 mutants. A recombinant virus with most of the unique region of the IE2 gene (ORF UL122) deleted is defective in early gene expression and does not produce infectious progeny, providing additional evidence that IE2 86 is required for the activation of early genes and for viral replication (Marchini *et al.*, 2001). Members of our group generated a viable mutant with a deletion spanning IE2 86 residues 136–290 and showed that this virus expresses IE and early genes and replicates its DNA

comparably to the wild type but is delayed in expression of a subset of late genes (Sanchez *et al.*, 2002).

Smaller mutations introduced into the IE2 86 gene in the viral genome have also been used to define specific regions of the protein required for the activation of early promoters. Members of our laboratory have constructed recombinants with internal deletions of amino acids 356–359, 427–435, or 505–511 (White *et al.*, 2004). These mutations were selected on the basis of the IE2 86 domain mapping and functional studies discussed above and are located in the C-terminal region important for protein–protein interactions and DNA binding. Each deletion results in a nonviable virus. The IE2 86Δ356–359 mutation removes amino acids implicated in the activation of the UL112–113 and UL54 promoters (Stenberg *et al.*, 1990) and results in a clone that is able to support limited early gene expression but not replication of viral DNA. The IE2 86Δ427–435 and IE2 86Δ505–511 mutations disrupt the zinc finger and helix-loop-helix motifs present in the protein, and the resulting recombinants do not support early gene expression. All are defective in *crs*-mediated autorepression of the major IE promoter, although the degree of this defect varies with the mutant. Similarly, a temperature-sensitive IE2 86 mutant virus that contains the point mutation C509G (C510G in AD169) is able to transactivate the UL112–113 promoter at 32.5°C, but not at 39.5°C (Heider *et al.*, 2002a). This mutant also exhibits increased transcription from immediate early loci consistent with a defect in autoregulation.

The use of other recombinant viruses has helped elucidate the contributions of IE2 86 to host cell cycle dysregulation during HCMV infection. A virus with a deletion of the majority of exon 3 of the major IE region expresses altered forms of both IE1 72 and IE2 86 proteins and is viable, but severely growth impaired (White and Spector, 2005). It is defective both in the activation of viral early promoters and in altering the expression of certain cellular proteins including cyclin E. Neither of these defects can be fully complemented by growth in the presence of wild type IE1 72 protein. C-terminal sequences of IE2 86 are also required for host cell cycle dysregulation, as infection with a virus carrying a glutamine-to-arginine point mutation at aa 548 does not arrest the host cell cycle and does allow host DNA replication to proceed (Petrik *et al.*, 2006).

Fewer HCMV mutants with disruptions in the IE1 72 coding region have been isolated and characterized, but an existing mutant constructed by deleting exon 4 of the major IE region gives important information about the role of this protein in regulation of the infection. The recombinant is viable, exhibiting minimal growth defects in cells infected at a high multiplicity but exhibits striking replication deficiency at low MOIs (Gawn and Greaves, 2002; Greaves and Mocarski, 1998; Mocarski *et al.*, 1996). Fibroblasts infected with 0.4 pfu/cell of IE1 mutant virus express IE2 86 about as frequently, and to similar levels, as wild-type infected cells, but by immunostaining, deletion mutant-infected cells express delayed early proteins, including ppUL44, ppUL57, and pUL69, much less frequently or to lower levels than wild-type infected cells. This effect on protein expression is apparent at the transcriptional level as well, with decreased accumulation of delayed early RNAs in cells infected at low multiplicity with the mutant. UL112–113 expression is supported to an intermediate degree, with fewer mutant-infected cells staining positively for these proteins than for IE2 86, but more than stained positive for ppUL44. Apparently, while high levels of IE2 86 or another factor are able to compensate for the loss of IE1 72 during a high multiplicity infection, efficient activation of early genes in cells infected at low multiplicity requires IE1 72. A further study used constructs expressing wild type or mutant forms of IE1 72 to complement the IE1 deletion mutant virus in *trans* (Reinhardt *et al.*, 2005). This work showed that aa 476–491 tether IE1 72 to chromatin but are not required for complementation, while aa 421–475 comprise an acidic domain necessary for complementation and restoration of wild type titers during low multiplicity growth.

Additional immediate early proteins have regulatory roles

In addition to UL122–123, the UL36–38 and IRS1/TRS1 families and the US3 locus encode IE proteins with regulatory functions. Knockout mutants constructed to date suggest that either UL37 exon 1 or UL36 are necessary for progression of the infection (Blankenship and Shenk, 2002; Borst *et al.*, 1999; Dunn *et al.*, 2003; Patterson and Shenk, 1999; Yu *et al.*, 2003; McCormick *et al.*, 2005). The IRS1 and TRS1 ORFs encode three proteins: two expressed from a promoter located in the repeated region flanking the US segment of the genome with an ORF continuing into the unique region, and a third, smaller, protein designated pIRS1^{263} which is expressed from an internal promoter in the unique region of the IRS1 gene (Romanowski and Shenk, 1997). In transient expression assays, either the IRS1 or TRS1 protein can complement HCMV origin-dependent DNA replication and modestly upregulate transcription from the MIEP or cooperate with IE1 72 and IE2 86 in activation of other viral promoters (Pari and Anders, 1993; Romanowski and Shenk, 1997). None of these three gene products is essential for viral replication in tissue culture, since recombinant viruses lacking the unique regions of the IRS or TRS1 open reading frames are viable (Blankenship

and Shenk, 2002; Jones and Muzithras, 1992). The mutant lacking the IRS1 products grows normally, whereas the TRS1 deletion mutant exhibits a multiplicity-dependent growth phenotype. The amount of virus released from cells infected with the TRS1 deletion mutant at a low MOI is reduced drastically compared to that released from wild-type infected cells, but cells infected at a high MOI produce only slightly less virus than the wild type. TRS1 mutant virus replication proceeds normally through DNA replication, and appears to be defective in packaging the viral DNA at a step that occurs after the cleavage of the DNA (Adamo *et al.*, 2004). Two studies have investigated TRS1 and IRS1 protein function using recombinant vaccinia or herpes simplex type 1 viruses that lack the normal ability to block host cell protein synthesis shutoff upon infection (Child *et al.*, 2004; Cassady, 2005; Hakki and Geballe, 2005). TRS1 and IRS1 proteins were able to restore this ability in both cases, either after transient expression in the vaccinia virus-infected cell or from the HSV-1 recombinant. TRS1 protein also binds dsRNA via an N-terminal domain distinct from the C-terminal region that contributes to the evasion of the shutoff of translation (Hakki and Geballe, 2005).

The UL36–38 gene products were also identified in the study that identified eleven loci required for complementation of DNA replication (Pari and Anders, 1993), and are individually dispensable for growth in culture (Dunn *et al.*, 2003; Yu *et al.*, 2003; McCormick *et al.*, 2005). Four of five transcripts from this region are expressed with IE kinetics, three from the UL37 promoter and one coding for the UL36 product (Fig. 18.1) (Chee *et al.*, 1990b; Goldmacher *et al.*, 1999; Kouzarides *et al.*, 1988). The 3.4 kb spliced transcript from the UL37 promoter is present only at IE times and encodes an integral membrane glycoprotein, gpUL37 (Kouzarides *et al.*, 1988; Tenney and Colberg-Poley, 1991a,b). An alternative splice of this transcript generates the 3.2 kb mRNA coding for gpUL37$_M$ (Goldmacher *et al.*, 1999; Colberg-Poley *et al.*, 2000), and these proteins traffic from the ER to mitochondria. While gpUL37 is able to transactivate the hsp70 promoter in transient assays, and UL37 exon 2 or exon 3 sequences are required for this activity, deletion of these exons does not affect the ability of the virus to replicate in culture (Borst *et al.*, 1999; Colberg-Poley *et al.*, 1998; Goldmacher *et al.*, 1999; Tenney *et al.*, 1993; Zhang *et al.*, 1996). The conservation of the UL37 exon 1 sequence in clinical isolates and high-passage laboratory strains, as well as in other primate CMVs, and in rodent CMVs (McCormick *et al.*, 2003b, 2005) suggest that the anti-apoptotic functions of vMIA homologues are important in response to the stress of infection. In transient transfection assays, a construct expressing UL37 exon 1 can also activate the UL54, UL44, and other early viral promoters. Although this activation is observed when constructs expressing IE1 72 and IE2 86 are used in this assay (Colberg-Poley *et al.*, 1998), adding UL37 exon 1 and IE1/IE2 expression vectors together results in a synergistic activation effect. The final IE transcript from the UL36–38 region is the UL36 RNA, which encodes a protein (vICA) that is also involved in preventing apoptosis in infected cells (Skaletskaya *et al.*, 2001). The fifth transcript from this region is the product of the UL38 gene and is expressed with early kinetics.

A third region transcribed with IE kinetics is the US3 gene, which specifies at least three alternatively spliced RNAs coding for related proteins. It is the target of complex positive and negative regulatory control (Biegalke, 1995, 1997, 1998, 1999; Chan *et al.*, 1996; Thrower *et al.*, 1996) and like much of UL36–38, is dispensable for growth in culture (Jones and Muzithras, 1992). Proteins generated from this region help the virus to evade the host immune response by keeping MHC class I molecules retained in the ER and unable to traffic to the plasma membrane (Ahn *et al.*, 1996; Jones *et al.*, 1996). US3 transcripts are abundant during the first three hours of infection and decrease by five h p.i. Transcription is regulated by a combination of elements located near the promoter including a silencer, enhancer, and transcriptional repressive element (tre) which shares sequence similarity with the *crs* element involved in control of major IE region expression (Biegalke, 1998; Bullock *et al.*, 2001, 2002; Chan *et al.*, 1996; Lashmit *et al.*, 1998; Thrower *et al.*, 1996). The product of the UL34 gene binds the tre element and represses transcription of US3 (LaPierre and Biegalke, 2001). The US3 proteins seem to possess limited intrinsic transactivating capability, as they have only been shown to induce the cellular hsp70 promoter in transient assays (Colberg-Poley *et al.*, 1992; Tenney *et al.*, 1993; Zhang *et al.*, 1996).

UL112–113 transcription is differentially controlled at early and late times

Many of our current views on the regulation of early gene expression are derived from studies on the UL112–113 region of the HCMV genome (Fig. 18.2). The UL112–113 ORFs encode a family of phosphoproteins of 84, 50, 43, and 34 kDa that share a common amino terminal domain. The initial evidence for the importance of these gene products came from the studies of Pari and Anders, who identified the locus encoding them as one of the eleven required for the replication of a plasmid containing the HCMV origin of DNA replication *ori*Lyt (Pari and Anders, 1993). As noted above, the UL112–113 proteins were found to be among

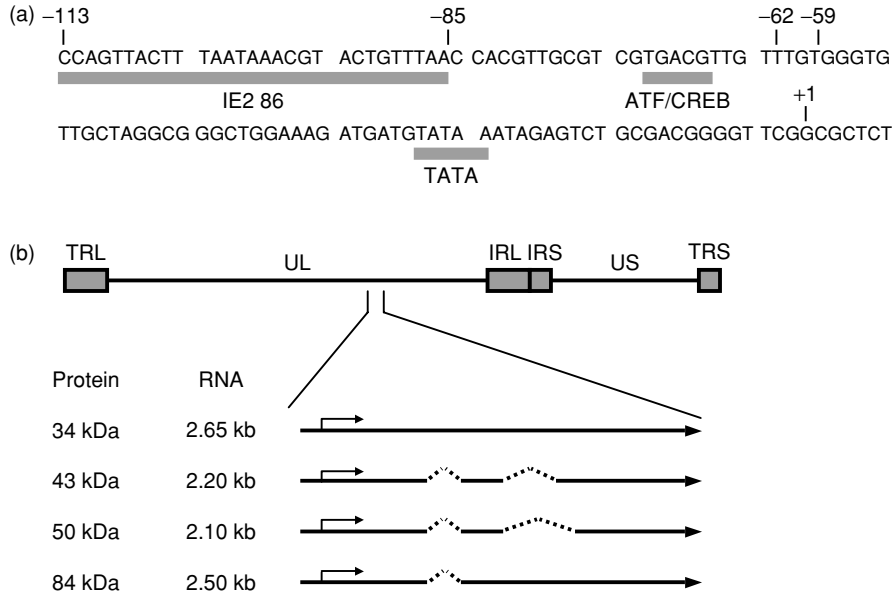

Fig. 18.2. Structure of the HCMV UL112–113 region. (a) The UL112–113 promoter from nt −113 to +7 relative to the early transcription start site, +1. The IE2 86 binding site located between −113 and −85, the consensus ATF/CREB site, and the late transcription start site at −62 are indicated. Sequences between −84 and −59 are required for IE2 86-mediated activation of the UL112–113 promoter. (b) Four transcripts from the UL112–113 region encode phosphoproteins with common N-termini. Splice patterns and sizes of the transcripts and corresponding proteins are indicated. The 2.1 and 2.2 kb RNAs are expressed by 8 h p.i., while the 2.5 and 2.65 species increase in abundance later.

the first to colocalize with IE2 86 at the periphery of the original ND10 sites and appeared to form the initial nucleation sites for subsequent viral DNA replication (Ahn *et al.*, 1999a). Transient expression assays also have shown that they can cooperate with the UL36–38 and IRS1/TRS1 ORFs to augment the stimulation of several early gene promoters by the IE1 and IE2 proteins. Although the recent studies with mutant recombinant viruses that do not express these proteins indicate that the gene products are not absolutely essential for the viral infection, the resulting viruses are severely debilitated in their ability to replicate (Dunn *et al.*, 2003; Yu *et al.*, 2003). The molecular and cellular mechanisms underlying their function, however, are still unknown.

Transcription from the UL112–113 locus begins as early as 8 h p.i. and continues for the duration of the infection, although the relative abundance of members of the family changes as the infection progresses (Staprans *et al.*, 1988; Staprans and Spector, 1986). Two spliced RNAs of 2.1 and 2.2 kb are expressed by 8 h p.i. and encode 50 kDa and 43 kDa phosphoproteins, respectively (Staprans *et al.*, 1988; Staprans and Spector, 1986; Wright and Spector, 1989; Wright *et al.*, 1988). These transcripts are coterminal at both 5′ and 3′ ends and share identical 5′ and internal exons, but use different splice acceptor sites in the 3′ exon to generate the two species, which encode proteins with different carboxyl termini. Later in the infection, transcription from the early start site decreases and initiation of transcription occurs at a site further upstream at nt −62. Two RNAs of 2.5 and 2.65 kb also increase in abundance as the infection proceeds, with the 2.5 kb transcript having spliced out only the first intron and encoding an 84 kDa phosphoprotein and the unspliced 2.65 kb transcript specifying a 34 kDa phosphoprotein (Staprans and Spector, 1986; Wright and Spector, 1989; Wright *et al.*, 1988).

In initial studies, transiently transfected UL112–113 promoter-CAT reporter constructs were used to determine that the region located at −113 to −59 relative to the transcription start site is required for activation of this promoter during the infection. These assays utilized 5′ and internal promoter deletion mutants to show that these sequences were required for activation by IE2 86; this region also contained one of four binding sites for IE2 86, at −113 to −85 (Schwartz *et al.*, 1994; Staprans *et al.*, 1988). Further work indicated that although this IE2 86 binding site contributes to full activation of the UL112–113 promoter, it is in fact sequences between −84 and −59 that are strictly required for full activation of this promoter by IE2 86 (Arlt *et al.*, 1994; Schwartz *et al.*, 1996). A consensus ATF/CREB site is located between nt −71 to −66, suggesting that a member of the ATF/CREB family of transcription factors contributes significantly to IE2 86-mediated promoter activation

(Staprans *et al.*, 1988). Additional mutational analyses of the region indicate that this contribution is modulated by interactions with factors bound to other regions of the promoter.

Further work used a series of gel shift analyses to establish that CREB is the major ATF-related protein in uninfected U373 MG cells that binds to this site (Schwartz *et al.*, 1996). Three bands were observed following incubation of wild-type UL112–113 promoter sequences from −84 to −59 with nuclear extracts from U373 MG cells, and two of these were reduced or eliminated when wild type sequences from −72 to −61 were mutated. A complex comigrating with one of the bands also formed when a DNA fragment containing a consensus ATF/CREB site was used as the probe instead of the UL112–113 promoter. The majority of this consensus probe-protein complex was supershifted by the addition of anti-CREB antibody, as was most of the corresponding band in the UL112–113 promoter-protein complexes. The other two bands were less affected by the addition of anti-CREB antibody, but also were not supershifted in the presence of either anti-ATF-2 or anti-ATF-4.

Subsequent studies from our laboratory have used recombinant viruses to define the promoter elements controlling UL112–113 expression in the infected cell (Rodems *et al.*, 1998). In these viruses, a cassette containing the UL112–113 promoter driving expression of the CAT reporter was inserted between the US9 and US10 loci in the viral genome. Reporter expression from this ectopic location authentically reproduced the kinetics of UL112–113 expression, in particular the switch from the +1 to the −62 transcription start site late in the infection (Staprans and Spector, 1986). The family of viruses was constructed based on the observations discussed above and comprised recombinants containing the wild type UL112–113 promoter or one of a series of IE2 86 and/or ATF/CREB binding site mutations in the promoter. As in transient assays, deletion of the ATF/CREB site in the virus resulted in a severe reduction in reporter activity early in the infection, but by 72 h p.i. wild type and ATF/CREB deletion mutants differed in reporter activity by less than twofold. Deletion of the ATF/CREB site also resulted in a shift of the late transcription start site downstream by the number of residues deleted. Consistent with data from transient transfection assays, when the IE2 86 binding site between −113 and −85 was deleted, the level of transcription from the mutant promoter was reduced to half of wild-type promoter levels at early times. Later in the infection, this level was not sustained, and extracts from IE2 86 binding site mutant-infected cells exhibited 15-fold less CAT activity than extracts from wild-type promoter virus-infected cells. These results support a model in which transcription from the UL112–113 promoter is differentially controlled at early and late times postinfection, with the ATF/CREB site providing significant regulatory control at early times and little to none at late times. The IE2 86 binding site, in contrast, modulates UL112–113 transcription at early times but is even more important for the maintenance of elevated transcript levels late in the infection.

Further mutational analysis of the UL112–113 promoter was used to define the sequences between −113 and −85 involved in the control of late transcription. Insertion of 5- or 10-nt sequences into the promoter and a corresponding shift in the late transcription start site suggest that sequences in this region direct late transcription from the UL112–113 promoter with distance-dependent characteristics (D. Kim and D. H. Spector, unpublished results). This complex control of transcription from the UL112–113 region reinforces the idea that, while overall expression of a given viral gene may appear to change little as the infection progresses, this steady-state level is achieved through a series of temporally distinct regulatory mechanisms.

In addition to the above controls operating at the level of transcription, analysis of the pattern of expression of the four RNAs and their corresponding proteins revealed that there were additional mechanisms being used to regulate the level of the proteins (Wright and Spector, 1989). The high levels of the 43 kDa UL112–113 protein at early times correlated well with the abundance of the 2.2 kb RNA at this time. The kinetics of synthesis of the 84- and 34-kDa proteins also correlated well with those of their corresponding RNAs. In contrast, the level of the 2.1 kb RNA was only slightly lower than that of the 2.2 kb RNA at all times during the infection, but the 50 kDa protein did not accumulate until later in the infection. Interestingly, the level of the 50 kDa protein was most sensitive to inhibition of viral DNA replication, suggesting that its accumulation at late times might be coupled to ongoing viral DNA replication. The mechanism for this post-transcriptional regulation is still unknown. It does not appear to be related to stability of the full-length protein, as in pulse-chase experiments at early times in the infection, the 50 kDa protein showed similar kinetics of decay as the 43 kDa protein. Other possibilities are that there is some block to efficient translation of the RNA or that the protein is transiently unstable during translation.

Multiple *cis*-acting sequences regulate UL54 expression

UL54, the ORF encoding the HCMV DNA polymerase, is a prototypical early–late gene whose regulation has been studied both in the context of the viral genome and in numerous transient expression and in vitro assays

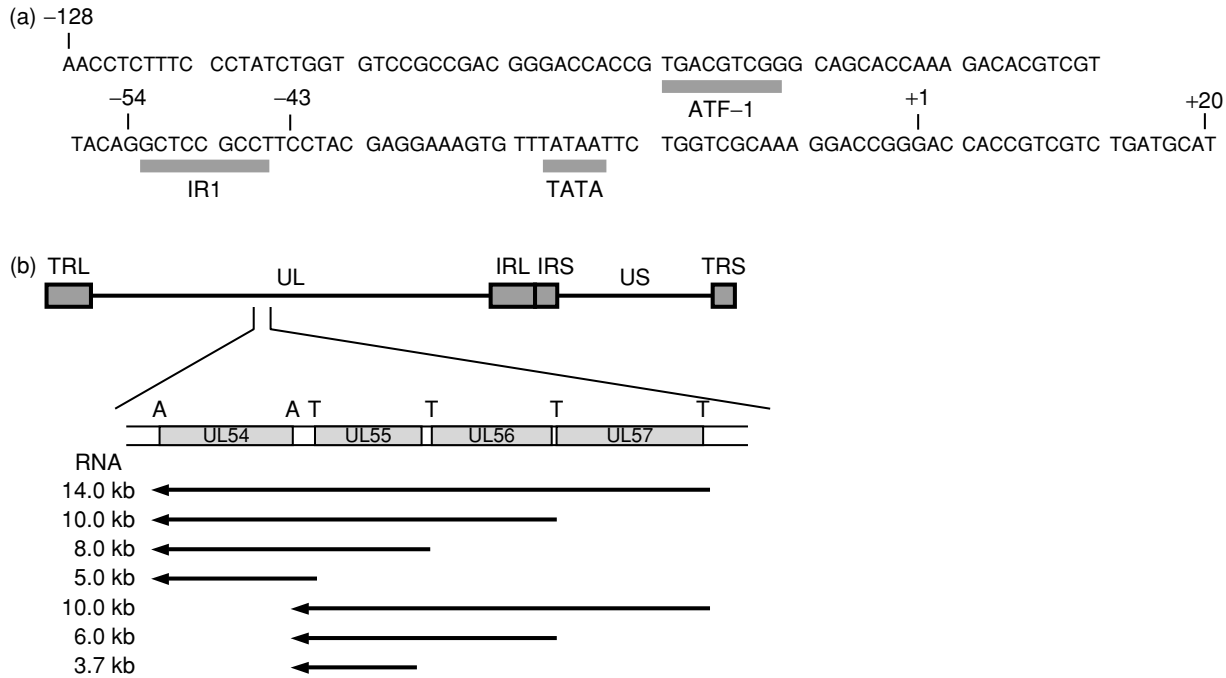

Fig. 18.3. Structure of the HCMV UL54 region. (a) The minimal UL54 promoter from nt −128 to +20 relative to the transcription start site, +1. The IR1 element located between −53 and −45 and the ATF-1 binding site from −88 to −80 are indicated. Sequences between nt −54 and −43 are required for IE protein-mediated promoter activation. (b) Transcripts expressed from the UL54-UL57 region. At least seven RNAs resulting from transcription from four start sites (predominant TATA elements, T) and polyadenylation at two sites (predominant poly A sites, A) are expressed from this region.

(Fig. 18.3). Seven transcripts resulting from initiation at four sites and polyadenylation at two sites in the UL54–57 region are expressed from this cluster of genes. The first RNA transcripts containing UL54 sequences are detectable as early as 8–12 h p.i., but in contrast to the UL112–113 family of transcripts, their level increases significantly at later times (Smuda *et al.*, 1997).

Initial transient expression studies on the regulation of the UL54 promoter indicated that IE2 86 was required for its activation and that other IE and early products including IE1 72, TRS/IRS1, and the UL112–113 proteins cooperated to further activate transcription from the promoter (Kerry *et al.*, 1996). These experiments also identified promoter elements required for activation in transient and in vitro assays, defining the minimal polymerase promoter as the region from −128 to +20 relative to the transcription start site and demonstrating that an 8 bp inverted repeat element at −53 to −45, IR1, was required for activation of the polymerase promoter by viral IE proteins in transient transfection assays (Kerry *et al.*, 1994, 1996). A second copy of the IR1 element is present at −225, but did not contribute significantly to activation of the polymerase promoter in these assays (Kerry *et al.*, 1996). IR1 was found to bind cellular factors found in nuclear extracts prepared from infected cells. If the IR1 element was mutated, the cellular factors failed to bind and activation of the promoter by IE proteins was decreased threefold (Kerry *et al.*, 1994). A pair of studies identified the transcription factor Sp1 as one of the cellular proteins that could bind the IR1 element. In one study (Luu and Flores, 1997), scanning mutagenesis of the promoter from −270 to +200 confirmed the requirement of the −54 to −43 region for IE mediated activation of the promoter. Using a 30 bp DNA probe and uninfected HeLa cell extracts, the authors demonstrated that Sp1 bound to this region. In the other study (Wu *et al.*, 1998), a shorter IR1-containing DNA probe also bound Sp1 in extracts of U373 cells overexpressing IE2 86, but not in parental U373MG cells or in HeLa cells. The complex could be supershifted by the addition of antibody specific to IE2 86, but the presence of IE2 86 in this complex did not seem to require DNA binding activity since addition of an unlabeled DNA probe containing the *crs* did not reduce complex formation. In addition, an Sp1 binding oligonucleotide competed away this complex in the IE2 86-expressing U373 cells. Based on these results, the authors proposed that an inhibitory factor present in HeLa cells prevents the Sp1-UL54 promoter interaction from occurring.

Numerous differences in experimental design prevent further direct comparison of these studies, and the role of Sp1 in control of UL54 expression in infected cells has not yet been examined.

Another regulatory domain in the UL54 promoter was localized to between nt −88 to −80 (Kerry *et al.*, 1994, 1997). A 40 bp DNA probe from this region bound nuclear proteins from infected human fibroblasts, with DNA binding activity particularly strong in 48–72 h p.i. extracts and weaker at earlier times or when DNA replication was inhibited by the addition of phosphonoacetate (PAA). Supershift analyses confirmed that one protein present in this complex is ATF-1. Since recombinant ATF-1/DNA complexes migrate differently than those present in infected cell nuclear extracts, it is possible that an additional protein is involved in this interaction or that ATF-1 is differentially modified during the infection.

Analysis of the UL54 promoter in the context of the viral genome began with the characterization of this promoter driving a CAT reporter in a construct inserted between ORFs US9 and US10 (Kohler *et al.*, 1994). Subsequent studies used similar recombinant viruses to better define the role of the IR1 element in UL54 promoter activation. A family of viruses was constructed in which either the full-length polymerase promoter (−425 to +20), the full length promoter with a mutation in the IR1 site, or the minimal activation domain (−128 to +20) drove expression of the CAT reporter (Kerry *et al.*, 1996). Based on CAT activity and RNA levels by Northern blot, UL54 promoter activity at early times was three- to fourfold lower than the wild-type when the IR1 element was mutated. In contrast, deleting the upstream promoter region and including only the minimal promoter resulted in a slight increase in promoter activity. This was consistent with the increase in promoter activity observed in transient assays when the −425 to −128 region was deleted, but the effect was smaller in the context of the viral genome. At late times, the IR1 element appears to be less important to the activation of this promoter, since the virus carrying the IR1 mutation exhibited only a slight reduction in both RNA levels and CAT activity by 72 to 96 h p.i. The ATF site in the UL54 promoter was similarly examined by constructing recombinant viruses (Kerry *et al.*, 1997). In contrast to the IR1 element, the ATF binding site appears to control UL54 promoter activity both at early and late times p.i. Mutation of the ATF site in a UL54 promoter-CAT reporter virus resulted in five- to sixfold decreases in both mRNA expression and CAT activity over a range of times, from 24–96 h p.i.

Finally, recent work has attempted to use regulation of the UL54 promoter to understand the species specificity of HCMV (Garcia-Ramirez *et al.*, 2001). These experiments examined the activity of the HCMV polymerase promoter following HCMV infection of murine NIH 3T3 cells transiently or stably transfected with a yeast artificial chromosome (YAC) clone containing much of the HCMV genome. The authors found that mutating the IR1 element in this context reduced reporter activity and interpreted these results to invoke similar cellular factors in both 3T3 and human cells, suggesting that species specific cellular factors do not underlie activation of the UL54 promoter. Given the many differences between murine and human fibroblasts, it is difficult to put these findings in context. A complete characterization of the UL54 promoter-reporter YAC construct in human cells to understand the consequences of promoter mutations in the natural context might help understand any work across species barriers.

UL4 expression is controlled at the transcriptional and translational levels

UL4 is an example of an early gene whose expression is regulated by unique mechanisms operating at both the transcriptional and translational levels (Fig. 18.4). Three unspliced transcripts are expressed from the UL4 locus, with 1.4 and 1.5 kb RNAs present at early times and a 1.7 kb product detectable later. These encode an incompletely characterized membrane glycoprotein, gp48, which is a virion component that is completely dispensable for viral growth in tissue culture (Hobom *et al.*, 2000).

Transcriptional control of the UL4 gene was first analyzed in a series of transient transfection assays demonstrating that the UL4 promoter is responsive to IE2 86 and that there are two *cis*-acting sites in the UL4 promoter upstream of the TATA box (Chang *et al.*, 1989; Huang *et al.*, 1994). The first site, a CCAAT box with inverted dyad symmetry between −88 and −98 relative to the transcription start site, appeared to be a positive regulatory element that could bind the transcription factor NF-Y in vitro (Huang *et al.*, 1994). Gel shift analyses demonstrated the formation of two complexes that were inhibited by the addition of a competing oligonucleotide containing the NF-Y target sequence or supershifted by the addition of antibody to NF-Y. Neither could be supershifted by the addition of IE2 86-specific antibody. One complex was present in both uninfected and infected cells; the second was only detected in infected cells. When phosphatase was added, the second complex decreased in abundance while the first increased, suggesting that NF-Y may be differentially phosphorylated in HCMV-infected cells.

A second regulatory region located between −169 and −139 in the UL4 promoter, site 2, bound a cellular factor in

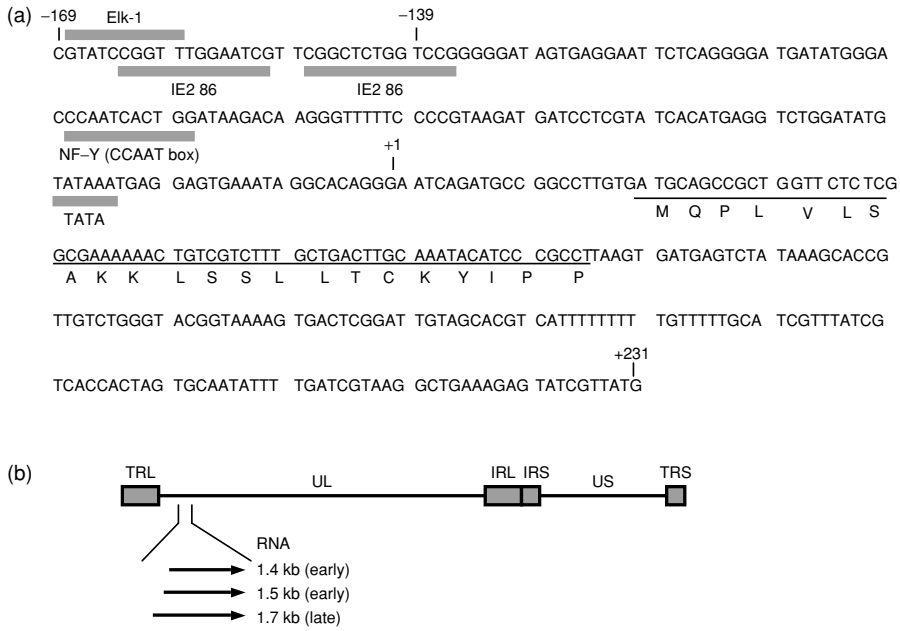

Fig. 18.4. Structure of the HCMV UL4 region. (a) The UL4 promoter and transcript leader sequences from nt −169 to the start site of gp48 (pUL4) translation. Sequences are representative of HCMV Towne strain and are numbered relative to the start site of 1.5 kb RNA transcription, +1. Site 2 is located between −169 and −139 and contains two putative IE2 86 binding sites and the Elk-1 site. The CCAAT box binds NF-Y. uORF2, which encodes the *cis*-acting repressor of UL4 transcription, is underlined, and the sequence of the 22 aa peptide is indicated. (b) Transcripts expressed from the UL4 region. Three 3′ coterminal transcripts with different 5′ ends are produced. Two RNAs of 1.4 and 1.5 kb are present at early times, with the 1.5 kb transcript expressed more abundantly. The 1.7 kb transcript is present later in the infection.

vitro, as indicated by DNA footprinting and gel shift assays, and negatively influenced transcription (Huang *et al.*, 1994; Huang and Stinski, 1995). The importance of IE2 86 in the activation of this promoter was suggested by the following observations: first, the negative effect on the promoter was relieved when an IE2 86 expression vector was cotransfected with the UL4 promoter–CAT reporter construct; second, a truncated version of IE2 86 containing amino acids 290 to 579 bound site 2 in vitro (Huang and Stinski, 1995). These results led to the hypothesis that IE2 86 binds to a specific negative regulatory region (which is 65% homologous to the *crs* element in the major IE promoter) and in the process displaces a bound cellular factor, thus allowing activation of the UL4 promoter. Mutation of the putative zinc finger region of IE2 86 resulted in a protein that could no longer interact with the promoter, lending further support to this idea.

Recent studies examining transcriptional control of the UL4 promoter in the context of the viral genome confirm some, but not all, of these initial findings and demonstrate important differences between control of viral gene expression in transient assays and in the infected cell. A series of HCMV recombinants containing the CAT reporter cassette driven by a wild type or mutant UL4 promoter inserted into the viral genome between US7 and US12 were derived (Chen and Stinski, 2000). In this ectopic location, the CAT transcript was expressed with kinetics much like those of the native UL4 transcript, but to slightly lower overall levels. Here, a mutation in the UL4 promoter NF-Y binding site did not alter CAT transcript levels, leading to the conclusion that in the virus, the NF-Y binding site contributes little or nothing to control of UL4 transcription. In contrast, site 2 mutants displayed altered reporter expression. Site 2 contains two putative (but non-consensus) IE2 86 binding sites and a predicted Elk-1 binding site that together appeared to be required for maximal expression in the context of viral infection (Chen and Stinski, 2000). In a later study, however, disruption of the Elk-1 site alone was sufficient for the effect, indicating that it is likely Elk-1 or a related cellular factor and not the IE2 86 binding sites that play the critical regulatory role (Chen and Stinski, 2002). Elk-1 binding to this site is supported by EMSA data in which a consensus Elk-1 site competes for cellular factor binding and an Elk-1 antibody partially supershifts the UL4 promoter-cellular factor complex (Chen and Stinski, 2000).

Transcriptional upregulation of UL4 expression has been used to demonstrate the importance of the MAPK/ERK and p38 MAPK pathways in HCMV replication. Peak activation of these signal transduction cascades occur at 4 and 8 h p.i., respectively, and appears to be important to the progression of productive infection via efficient expression of early and late genes (Johnson *et al.*, 2001a; Rodems and Spector, 1998). In one study (Chen and Stinski, 2002), the requirement for these pathways was analyzed in the context of UL4 transcription using the MAPK/ERK kinase (MEK) inhibitor UO126 and the p38 MAPK inhibitor FHPI. Cells infected with one of the recombinant viruses expressing the CAT gene from wild-type or mutant UL4 promoters were treated with an inhibitor and assayed for CAT activity. Strikingly, inhibition of MEK with the chemical inhibitor UO126 caused UL4 promoter activity to drop by 70%–80% for all promoters tested, with approximately equivalent loss of expression when the wild-type UL4 promoter was used as well as when site 2 or the NF-Y or Elk-1 binding sites were disrupted. The effect of the inhibitor FHPI was very similar, with no effect on UL4 promoter constructs when used at a low concentration and a 50%–80% reduction of both wild type and mutant promoter activity at a higher concentration. These data suggest that the UL4 promoter is responsive to both MAPK/ERK and p38 MAPK pathways and that the minimal responsive element is the TATA, not one of the other transcription factor binding sites that have been analyzed. This effect, however, was less prominent when endogenous UL4 RNA expression was examined, and the possibility of general inhibition of viral transcription or downregulation of other upstream factors in the presence of these inhibitors has not yet been addressed.

Novel post-transcriptional controls also distinguish the regulation of UL4 expression. Three small ORFs are located in the UL4 transcript upstream of the gp48 transcription start site. The largest of these, uORF2, encodes a 22 aa product which acts in *cis* to repress translation of the authentic UL4 transcript (Degnin *et al.*, 1993). Interestingly, this repression is amino acid- (but not nucleotide-) sequence dependent and is particularly sensitive to mutations in codons near the C-terminus of uORF2. In transient transfection-superinfection assays, missense mutation or deletion of the terminal amino acid, a proline, resulted in significantly elevated expression of reporter protein while the level of UL4 promoter-driven transcript remained unchanged. Changes in the N-terminal leader sequence also had an effect, with missense mutations at codons 7 and 8 reducing the ability of uORF2 to block translation. A further series of modified primer extension assays showed that ribosomes are stalled on the RNA at the uORF2 termination codon. These data have led to the following hypothesis regarding the mechanism of inhibition of downstream translation by uORF2. A ribosome translates through the uORF2 sequence until it reaches the final proline codon. Here, the nascent uORF2 peptide remains covalently linked to the peptidyl-tRNA and bound to the ribosome on the transcript. A possible interaction between this complex and the release factor eRF1, mediated by C-terminal prolines at positions 21 and 22 in the uORF2 peptide and a GGQ motif in eRF1, stabilizes the intermediate and prevents hydrolysis of the peptidyl-tRNA bond (Cao and Geballe, 1996, 1998; Janzen *et al.*, 2002). Ribosomes stall before they are able to reach the gp48 translation start site, resulting in uORF2-dependent repression of gp48 translation.

The above model is supported by results from recombinant viruses as well. When the uORF2 initiation codon in the UL4 region was mutated, there was a significant upregulation of gp48 protein expression by the mutant relative to the wild-type virus (Alderete *et al.*, 2001). In vivo, ribosomes were also stalled at the uORF2 termination codon in wild-type but not mutant-infected cells. The relatively normal expression of other early proteins indicates that it is not a general upregulation of translation in mutant-infected cells that accounts for this phenotype. Curiously, it appears that there is a slight delay in the accumulation of the UL4 transcript in mutant infected cells, with the UL4 RNA detectable by Northern blot 24 h p.i. in cells infected with the parental wild-type virus, but not until 48 h p.i. in uORF2 mutant-infected cells.

Since neither loss of nor overexpression of UL4 appears detrimental to viral replication in cultured fibroblasts (Alderete *et al.*, 2001; Hobom *et al.*, 2000), it seems likely that this complex regulation is important in the infected host where gp48 may have a cell type-specific role. Control of its transcription and translation remain interesting illustrations of the diverse methods used by the virus to regulate gene expression.

Human herpesviruses 6 and 7

Human herpesvirus 6 is distinguished by its ability to grow in T-lymphocytes. There are two variants: HHV-6A (GS and U1102-like isolates) and HHV-6B (Z-29 and HST-like isolates). Although the variants have approximately 90% nucleotide sequence identity and share many properties, they differ with respect to their epidemiology, cell tropism, interaction with the host cell, and in vivo pathogenesis. HHV-6B infection is very common in early childhood and is associated with exanthem subitum (roseola infantum), a mild illness that lasts only a few days (Yamanishi

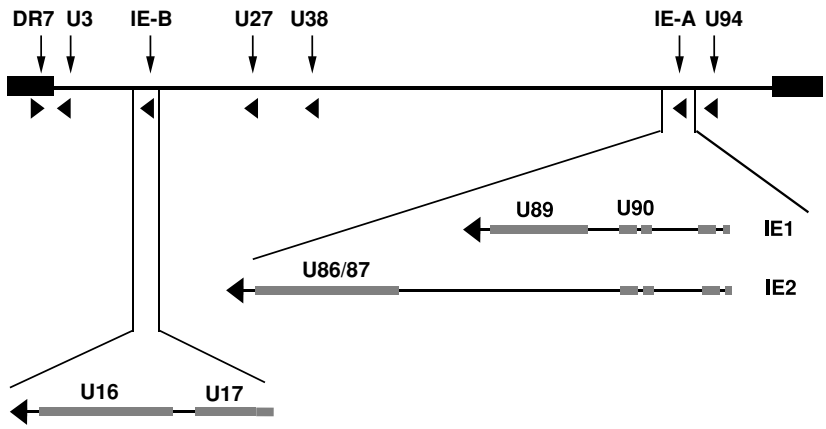

Fig. 18.5. HHV-6A Genome. The HHV-6 gene products with regulatory activities – DR7, U3, IE-B, U27 (DNA polymerase processivity factor), IE-A, and U94 – are shown on the map. The location of the U38 (DNA polymerase) ORF is also shown. The solid arrowheads indicate the direction of transcription. An expanded view of the IE transcripts encoded by the IE-A and IE-B loci is shown below the genome. The dark boxes are coding exons, the lighter boxes are non-coding exons, and the thin lines between the boxes are introns.

et al., 1988). HHV-7 is biologically similar to the two HHV-6 variants and is less frequently associated with this illness (Dominguez *et al.*, 1999; Isegawa *et al.*, 1999; Megaw *et al.*, 1998; Nicholas, 1996; Tanaka *et al.*, 1994). The DNA genomes of HHV-6 and HHV-7 are smaller than that of HCMV, with the length 159 kbp for HHV-6A, 161–170 kbp for HHV-6B, and 145–153 kbp for HHV-7 DNA. The genome of all of these viruses consists of a long unique segment bounded by direct repeats (Dominguez *et al.*, 1999; Gompels *et al.*, 1995; Isegawa *et al.*, 1999; Lindquester and Pellett, 1991; Martin *et al.*, 1991b; Megaw *et al.*, 1998; Nicholas, 1996)). In general, the genes of these viruses are collinear with those of human cytomegalovirus U_L region (see Chapter 14).

Analysis of the molecular biology of HHV-6 and HHV-7 has been limited by poor growth and low yields in cultured cells. Thus, the elucidation of the regulation of gene expression is not well advanced and has relied almost exclusively on transient assays that are known to be relatively poor predictors of behavior in the context of viral infection. The overall pattern of gene expression (IE, early, and late) resembles that of HCMV and other herpesviruses, but the assignment of many of the individual genes to a particular class is still tentative and has been influenced by the sensitivity of the assay applied, the specific strain of virus, and cell line used in the analysis. The reader is referred to Chapters 42 and 43 as well as the following papers for the details: Menegazzi *et al.* (1999); Mirandola *et al.* (1998); Oster and Hollsberg (2002); Rapp *et al.* (2000). For the purposes of this review, only HHV-6 IE genes that appear to have some regulatory functions and two early genes whose regulation has been studied in greatest depth – the HHV-6 DNA polymerase (U38) and the DNA polymerase processivity factor (U27) (Fig. 18.5) – will be discussed.

HHV-6 IE gene products with regulatory activities

The HHV-6 regulatory proteins that have been studied are encoded by the IE-A and IE-B loci, DR7, U3, U27, and U94. The IE-A and IE-B loci of both HHV-6 and HHV-7 are the major sites of IE gene expression (Fig. 18.5). The IE-A region (U86 to U90) is collinear with the major immediate early region of HCMV that encodes the IE1 and IE2 proteins (UL122–123), and the IE-B region (U16 to U19) is collinear with the HCMV IE ORFs UL36 to UL38 (see Chapter 17).

These putative viral regulatory proteins have only been studied with promoters from cellular genes and genes from heterologous viruses. Because HHV-6 has been proposed to be a cofactor in the progression of AIDS, many of these studies have used the HIV-1 LTR promoter (for review, see Lusso and Gallo, 1995). The HIV-1 LTR has been found to be activated by regions of the HHV-6A genome corresponding to the IE-B locus (Chen *et al.*, 1994; Garzino-Demo *et al.*, 1996; Geng *et al.*, 1992; Horvat *et al.*, 1991), the IE-A locus (Gravel *et al.*, 2003; Martin *et al.*, 1991a; Papanikolaou *et al.*, 2002; Stanton *et al.*, 2002), DR7 (Kashanchi *et al.*, 1994; Thompson *et al.*, 1994a), U3 (Mori *et al.*, 1998), and U27 (Zhou *et al.*, 1994). The IE-A locus also transactivates the CD4 promoter (Flamand *et al.*, 1998) and adenovirus E3 and E4 promoters (Martin *et al.*, 1991a), and the IE-B locus activates HPV 16 and 18 promoters (Chen *et al.*, 1994). Some of the regulatory proteins also appear to have negative effects. For example, U94 negatively regulates HIV-1 and H-ras promoters (Araujo *et al.*, 1995), and DR7 negatively regulates

promoters that are responsive to p53 (Kashanchi *et al.*, 1997).

IE-A

HHV-6A and HHV-6B exhibit a different organization in the IE-A region (Dominguez *et al.*, 1999; Isegawa *et al.*, 1999). The HHV-6A IE-A locus consists of two genetic units that are referred to as IE1 and IE2 (Chapter 17). Although this region is collinear with the HCMV major IE locus UL123 (IE1 72) and UL122 (IE2 86), it shares no nucleotide or protein sequence homology. The IE1 region encodes a 3.5 kb transcript that consists of 4 small 5′ exons and a large 3′ exon (Fig. 18.5) (Schiewe *et al.*, 1994). Translation begins in exon 3, yielding a major protein of approximately 150 to 170 kDa that contains ORFs U90 and U89 (Papanikolaou *et al.*, 2002). The corresponding region of HHV-6B shares only 62% identity at the amino acid level and encodes a major IE protein of approximately 150 kDa (Gravel *et al.*, 2002; Takeda *et al.*, 1996). The proteins are phosphorylated and conjugated to the ubiquitin-like protein SUMO-1 (Chang and Balachandran, 1991; Gravel *et al.*, 2002). The sequence divergence of the HHV-6A and HHV-6B IE1 protein is reflected in their function in that the HHV-6A IE1 protein is a stronger activator of heterologous promoters in transient expression assays than the corresponding HHV-6B protein (Flamand *et al.*, 1998; Gravel *et al.*, 2002; Martin *et al.*, 1991a).

Both HHV-6A and HHV-6B IE1 proteins are able to traffic to the ND10 sites (PODs). However, in contrast to other herpesviruses, interaction of the ND10 domains with IE1 does not lead to their dispersal, and IE1 maintains a stable interaction with ND10 throughout the infection (Gravel *et al.*, 2002; Stanton *et al.*, 2002). By immunostaining, the highest number of individual IE1 bodies can be detected at 12 h p.i., when they begin to coalesce into 1–3 larger bodies. It is likely that other viral proteins are needed to generate the larger bodies, since when the IE1 proteins were individually expressed, they colocalized with PML and SUMO-1 but the ND10 sites did not coalesce. Thus as is the case for HCMV, dispersal of ND10 domains is not a prerequisite for productive infection.

Recently, a full-length cDNA encoding the HHV-6A IE2 protein was isolated (Gravel *et al.*, 2003); it contains ORFs U90 and U86/87, the positional homologues of the HCMV ORF encoding IE2 86 (Fig. 18.5). The 5.5 kb IE2 mRNA is expressed in the absence of *de novo* protein synthesis with kinetics that are somewhat delayed relative to the IE1 transcript. The IE2 mRNA is also less abundant, but it continues to increase throughout the infection while the IE1 mRNA reaches maximal levels by 12 h p.i. At later times, larger transcripts that have not been characterized and may initiate from upstream sites appear. The processed IE2 mRNA consists of 5 exons; 4 small exons located upstream of U89 are shared with IE1 and the fifth exon corresponds to the IE2 specific ORF U86/87. The sequence of the HHV-6A IE2 transcript diverges from that encoded by the HHV-6B variant, with only 64% identity at the amino acid level. The HHV-6A IE2 protein is also 167 amino acids shorter. By Western blot analysis with an antibody specific for the IE2 region, it appears that the major IE2 protein is approximately 220 kDa. At later times in the infection, additional smaller proteins of 100, 85 and 55 kDa have also been observed (Gravel *et al.*, 2003; Papanikolaou *et al.*, 2002). Analogous to the HCMV IE2 86 protein, the full-length HHV-6A IE2 protein functions in transient expression assays as a promiscuous activator of multiple promoters, including minimal promoters containing only a TATA box (Gravel *et al.*, 2003; Papanikolaou *et al.*, 2002). Recently, deletion analysis showed that both the N- and C-terminal domains of this protein are required for full function (Tomoiu *et al.*, 2006). Interestingly, the HHV-6A IE2 protein does not appear to downregulate its own promoter, possibly because it does not contain the HCMV *cis*-repression signal.

IE-B

The HHV-6 IE-B region consists of the ORFs U16, U17, U18, and U19 and is collinear with the HCMV region containing the UL36–38 ORFs. As shown for the HCMV UL36–38 region, transcription from the HHV-6 IE-B region is complex (Flebbe-Rehwaldt *et al.*, 2000; Mirandola *et al.*, 1998). In HHV-6A (GS strain), the U17 and U16 ORFs are positional homologues of HCMV UL36 and yield a spliced IE RNA (Fig. 18.5) (Flebbe-Rehwaldt *et al.*, 2000; Mirandola *et al.*, 1998). HCMV UL36 also consists of 2 exons, with exon 2 corresponding to HHV-6A U16 (Tenney and Colberg-Poley, 1991a, b). In addition to the HHV-6 transcripts that contain the U17/U16 ORFs, there are also transcripts that include the U16 and U15 ORFs (U15 is unique to HHV-6). The HHV-6A and HHV-6B U17/U16 RNAs first appear at IE times and are maintained throughout the infection. The other U16 containing transcripts are expressed primarily as early RNAs, although a low level of transcription can be detected at IE times.

The HHV-6 U18 and U19 ORFs are transcribed as multiply spliced early RNAs. These are positional homologues of the HCMV UL37 and UL38 genes, respectively, but may not be functional homologues. With the caveat that all of the functional assays have been performed with transient assays and plasmid constructs, the ORFs do not correspond to their HCMV homologues with respect to their potential role as transactivators. In HHV-6, the ORFs that can

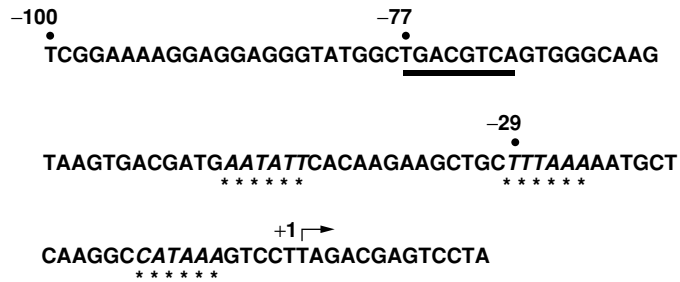

Fig. 18.6. HHV-6A DNA polymerase (U38) promoter. Sequences that could potentially serve as TATA boxes are italicized and marked with asterisks. The arrow at position +1 shows the transcription start site. The consensus ATF/CREB binding site is underlined.

transactivate the HIV-1 LTR promoter are U17/U16, not U18/U19 (Chen *et al.*, 1994; Garzino-Demo *et al.*, 1996; Geng *et al.*, 1992; Horvat *et al.*, 1991). UL37 exon 1, which has no apparent homologue in HHV-6 or HHV-7, serves as a cell death suppressor and transactivator of HCMV early gene promoters in transient assays (Colberg-Poley *et al.*, 1998; Patterson and Shenk, 1999; Goldmacher *et al.*, 1999).

U94

U94 is encoded by HHV-6A and HHV-6B and is a homologue of the adenovirus associated virus 2 (AAV-2) rep gene (Thomson *et al.*, 1991). Although not conserved in primate CMVs, a homologue is found in rat CMV (Vink *et al.*, 2000). In AAV-2, the rep68 gene encodes a site-specific ATP-dependent endonuclease and helicase that is involved in the site-specific integration of AAV into chromosome 19. U94 can serve as a helper for AAV-2 replication and can complement an AAV-2 virus with a mutation in the rep gene (Thomson *et al.*, 1994). The role of the U94 protein is yet to be elucidated, but it may play a role in latency and modulation of the infection. Relevant to this are the data showing that cell lines expressing HHV-6B U94 cannot be infected by HHV-6A and that the U94 transcript can be detected during latency in PBMC (Rotola *et al.*, 1998). U94 was also found to suppress H-ras and BPV-1 transformation (Araujo *et al.*, 1997) and transcription from H-ras and HIV-1 LTR promoters (Araujo *et al.*, 1995). HHV-7 does not encode a U94 homologue.

cis-acting sequences within HHV-6 early promoters

DNA polymerase (U38)

Analogous to HCMV, the HHV-6 DNA polymerase gene has been used as a prototypical early gene for examining *cis*-acting regulatory sequences on the promoter (Fig. 18.6). Based on the position of the RNA start site, standard transient expression assays with promoter-CAT reporter genes have been used to identify and characterize the major regulatory region for transcription (Agulnick *et al.*, 1994). The data showed that expression of CAT from a construct containing sequences −524 to +115 relative to the transcription start site was below the limit of detection in uninfected HSB-2 human T cells, but was highly up-regulated in infected cells. By mutational analysis, the cis-acting sequences for activation were localized to the sequences between −78 and +13. The major regulatory element within this region was a consensus ATF/CREB binding site located at nt −77 to −70. Further support for this domain serving a regulatory role was the observation that in gel shift assays, this site bound to two protein complexes in both infected and uninfected nuclear extracts. The ATF/CREB site, however, is not required for activation of this promoter by the HHV-6A IE2 protein in transient assays (Tomoiu *et al.*, 2006).

The U38 promoter does not contain a consensus TATA element in the –30 region, although there are several AT-rich domains located at positions −48 to −43, −29 to −24, and −11 to −6. When point mutations were introduced into each of the domains individually, there was no effect on the promoter, leading the authors to conclude that the promoter is TATA-less (Agulnick *et al.*, 1994). However, the start site for transcription was not identified for any of the mutants in the transient expression assays, and thus the possibility that the elements might be able to compensate for one another, albeit with a change in start site, cannot be excluded. As has been the case for all herpesvirus promoters, conclusions cannot be drawn from transient assays alone and each promoter must be assessed in the context of the viral genome. It would seem likely that the ATF/CREB site is the major regulatory element, as this sequence is located in a similar position in the promoter of the HCMV DNA polymerase gene and its function has been confirmed in the context of the HCMV genome (Kerry *et al.*, 1994, 1996, 1997).

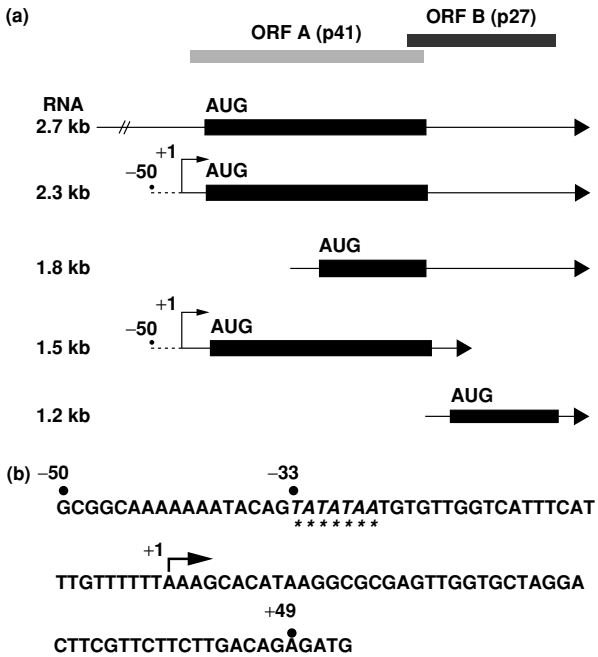

Fig. 18.7. HHV-6A DNA polymerase processivity factor (U27). (a) The early–late transcripts from the U27 region are shown. ORF A encodes the 41-kDa DNA polymerase processivity factor. The dark boxes represent the putative protein product. (b) Promoter for the 1.5 kb and 2.3 kb U27 RNAs. The sequence that could potentially serve as a TATA box is italicized and marked with asterisks. The arrow at position +1 shows the transcription start site. The translation initiation codon at nt +49 is also indicated.

DNA polymerase processivity factor (U27)

U27 encodes a 41 kDa nuclear phosphoprotein that is the homologue of the HCMV UL44 gene encoding DNA polymerase processivity factor (Fig. 18.7) (Agulnick *et al.*, 1993; Chang and Balachandran, 1991). The U27 region actually includes two ORFs, ORF A and ORF B. ORF A corresponds to a 41 kDa protein, and the downstream ORF B could encode a 27 kDa protein (Zhou *et al.*, 1997). The transcription pattern of this gene is similar for both the variant A HHV-6 GS strain and the variant B HHV-6 Z29 strain. At least five early–late unspliced RNA species ranging in size from 1.2 to 2.7 kb (1.2, 1.5, 1.8, 2.3, and 2.7 kb) map to this locus, with the 2.3 kb RNA being the most abundant (Agulnick *et al.*, 1993; Zhou *et al.*, 1997). Four of the RNAs (2.7, 2.3, 1.8, and 1.2 kb RNAs) are 3′ co-terminal. The 1.5 kb RNA utilizes the same start site as the 2.3 kb RNA but terminates upstream of the other four RNAs. The 2.3 kb and 1.5 kb RNAs have the potential to encode the p41 protein in ORF A, and the 1.2 kb RNA could specify a protein of about 17 kDa within ORF B. Although the 2.7 kb RNA includes ORF A, the presence of several AUGs before ORF A makes it unlikely that it encodes p41. Likewise, the 1.8 kb RNA has several AUGs with short ORFs before ORF B, but it could be translated into a truncated version of ORF A.

Regulation of the promoter for the 1.5 kb and 2.3 kb U27 RNAs was studied for the HHV-6A GS strain in HSB-2 human T-cell line (Thompson *et al.*, 1994b). The transcription start site, which is 48 bp upstream of the translation initiation codon AUG, is preceded by a TATA sequence starting at nt −33 relative to the RNA start site. Using mutant promoter-CAT constructs in transient expression assays, an essential regulatory element that was activated in the infected cells was localized between nt −73 and −52. Within this region were a putative binding site for the transcription factor C/EBP (CAAT enhancer-binding protein) and two other repeat sequences. The activity of this site was both distance and orientation dependent relative to the TATA sequence.

Mobility shift assays indicated that there were four complexes that bound to this region. The two that were present in both uninfected and infected cells (C1 and C2) did not appear to contain C/EBP factors. Point mutations within these sites that eliminated binding also inactivated the promoter. Two of the binding complexes were only present in uninfected cells (C3 and C4) and they could be competed by an oligonucleotide containing a consensus C/EBP site. The construction and use of a HHV-6 BAC will greatly facilitate further studies on the regulation of this and other promoters during the viral life cycle.

Conclusions

The studies presented here highlight the central role that early gene expression plays in the viral life cycle. It is the middleman in the relay race leading to the production of infectious virus. Events precipitated by the initial contact of the virus with the host cell and the synthesis of IE gene products set the stage for early gene expression. The products of these early genes not only provide the component parts for the factories devoted to viral DNA synthesis, cleavage and packaging of the viral genome, and assembly of the virus particles, but also serve to commandeer the host cell machinery and signaling pathways to create a cellular environment that is optimal for viral gene expression and DNA replication. Although dispensable for growth in tissue culture, a cadre of the early genes must also establish a blockade to the host's immune response and prepare routes of escape for viral dissemination. Analogous to the control of host cell genes, viral early gene expression is regulated at multiple levels by mechanisms operating at the initiation of transcription, RNA processing and transport, translation,

and mRNA and protein stability. The development of BACs as vectors for the cloning of herpesvirus genomes has revolutionized the field so that the function of viral genes and the regulation of their expression can be studied in the biologically relevant context of the viral infection. These techniques coupled with the rapidly moving fields of genomics and proteomics will greatly enhance our ability to elucidate the cellular and molecular mechanisms governing the interaction of the virus with its host.

Overview

Much of the current understanding of betaherpesvirus DNA synthesis is based on studies with the cytomegaloviruses and is further shaped by comparison with prototypic alpha- and gammaherpesviruses. As for all herpesviruses, betaherpesvirus DNA synthesis occurs in the nucleus and relies on a core set of virus-coded proteins composing the replication fork machinery (detailed later) working together with *trans*-acting functions that promote initiation on a genetically defined, *cis*-acting replicator, called *ori*Lyt. DNA synthesis initiates in the vicinity of *ori*Lyt as soon as essential virus coded proteins appear, producing high molecular weight replication intermediates whose structure has not been fully characterized. Onset of viral DNA synthesis licenses transcription of a subset of the late class of viral genes, many of which encode proteins that assemble and constitute the complex virion. Subsequently, replication intermediates are resolved, and the progeny genomes are packaged into preformed capsids and mature ends are formed by the encapsidation machinery. Because these replication functions are essential for viral replication and pathogenesis, and differ from host counterparts, they have been candidate targets for the development of antiviral drugs. Moreover, further study of DNA replication and encapsidation may provide new insights about cellular components that contribute to these processes. Our goals in this chapter are to provide an up-to-date summary of betaherpesvirus lytic-phase replication machinery, to highlight emerging contrasts to other herpesviruses, and to consider how DNA synthesis-dependent late gene expression is regulated.

Soon after nuclear entry, a fraction of the input linear cytomegalovirus genomes circularizes by a process that does not require *de novo* protein synthesis, and these circular forms have been considered the likely template for subsequent transcription and replication events. In this model concatemeric products are generated from a rolling circle intermediate in much the same way this process is envisioned for other herpesviruses (Chapter 4). Unfortunately, the lack of any cell-free replication systems has left the process of DNA replication in any of the herpesviruses poorly understood. Consistent with a rolling circle model is the finding that *ori*Lyt-containing circular plasmids are replicated in virus-infected cells to form head-to-tail concatemers. Some models posit an initial theta form mode, but evidence is scant and there is no published evidence to support this possibility for any betaherpesvirus. Authentic HCMV replication intermediates contain very few circles and have structural characteristics consistent with the rolling circle model, but the majority are not readily resolved in monomeric form by digestion with unique-cutting restriction enzymes, arguing that more complex – probably branched – structures predominate, rather than simple concatemers or circles (McVoy and Adler, 1994). The observed abundance of apparently complex products might arise from redundant initiation, from the presence of recombination intermediates, or from strand invasion; however, unambiguous evidence for any of these mechanisms is lacking. Interestingly, HHV-6 produces concatemers with relatively little branching (Severini *et al.*, 2003), suggesting that whatever event(s) contributes to the complex replication intermediates seen in cytomegaloviruses and many other herpesviruses are not a requisite component of roseolovirus replication.

Recent, well-received evidence employing HSV-1 regulatory gene mutants supports a model for viral DNA synthesis beginning on linear genomes, and proceeding via branched intermediates rather than via circularization and rolling circle mechanisms. This work implies that circularization may actually suppress replication and promote establishment of latency (Jackson and DeLuca, 2003).

Available data do not exclude such a model for HCMV, because the inhibition of DNA synthesis by drug treatment from the time of infection results in the persistence of both circular and nuclease-sensitive linear HCMV genomes (McVoy and Adler, 1994). Given that circular genomes are associated with HCMV latency (Bolovan-Fritts *et al.*, 1999), these certainly appear to serve as templates for initiation of DNA synthesis upon reactivation. The extent to which the high molecular weight cytomegalovirus replication intermediates observed following infection of permissive cells arise preferentially by a rolling circle mechanism from circular templates or by some other mechanism will require further study.

Despite biological similarities between cytomegaloviruses and roseolaviruses, initiation of DNA replication proceeds with distinct mechanisms. The genomic location of the *cis*-acting element, *ori*Lyt is similar, being positioned between genes encoding the homologues of HCMV UL57 and UL69; however the sequence elements are very different. HCMV has a highly complex *ori*Lyt region that spans over a kilobase of DNA, whereas roseolaviruses rely on a simpler *ori*Lyt with structural similarities to alphaherpesviruses DNA replication origins (Chapter 10). Likewise, the *trans*-acting functions are distinct, with HCMV relying on transcriptional transactivators and roseolaviruses relying on an origin binding protein homologous to those encoded by alphaherpesviruses.

Betaherpesvirus replication proteins

A cotransfection–replication assay has enabled the identification of the subset of betaherpesvirus proteins required for origin-dependent DNA replication. In this assay, cloned viral genes are transfected along with a plasmid containing *ori*Lyt. When all *trans*-acting functions are included, amplification of the *ori*Lyt-containing plasmid occurs. Amplification of *ori*Lyt is detected using the restriction enzyme *Dpn* I, which removes bacterially propagated plasmid DNA due to cleavage specificity for methylated adenine. Input, nonreplicated DNA, is thereby removed and subsequent DNA blot hybridization detects specifically replicated DNA. This assay identified HSV-1 replication proteins (Wu *et al.*, 1988) and eleven essential loci contributing to the amplification of HCMV *ori*Lyt (Pari and Anders, 1993). The genes and their protein designations are listed in Table 19.1. HCMV DNA replication requires the same set of core replication proteins as HSV-1. Later studies, performing cotransfections using plasmids encoding the replication proteins under the control of strong constitutively active promoters, showed that one subset of these genes was directly involved in the enzymatic activity of DNA synthesis whereas other genes had roles in gene regulation or cell death suppression (Sarisky and Hayward, 1996). It was determined that one protein, UL84, appeared to be unique among the HCMV replication proteins together with a requirement IE2 in human fibroblast cells (Pari and Anders, 1993; Sarisky and Hayward, 1996).

Table 19.1. HCMV genes required for *ori*Lyt-dependent DNA replication

HCMV genes	HHV6 genes	Proposed function
UL44	U27	Polymerase accessory protein
UL54	U38	Polymerase
UL57	U41	Single-stranded DNA binding protein
UL70	U43	Primase
UL84		Early protein with UTPase and nucleic and binding activity
UL102	U74	Primase-associated factor
UL105	U77	Helicase
IE2		Transactivator; along with UL84 activates *ori*Lyt promoter
UL36–38		Auxiliary functions
UL112–113		Auxiliary functions
IRS1/TRS1		Auxiliary functions

HCMV DNA replication has characteristics that distinguish it from HSV-1, as well as from the roseolaviruses. Divergence includes a distinct type of origin binding protein (OBP) for each type of virus. HSV-1 encodes an OBP (Olivo *et al.*, 1988; Wu *et al.*, 1988) that initiates DNA synthesis by interacting with specific DNA sequences within *ori*Lyt (Chapter 10) and has associated enzymatic activities consistent with a role in initiation such as helicase activity (Bruckner *et al.*, 1991; Hazuda *et al.*, 1991). Both HHV-6B and HHV-7 encode an OBP that may function similar to that encoded by the alphaherpesvirus HSV-1. Roseolaviruses have *ori*Lyt sequences with OBP sites and other apparent similarities (Dewhurst *et al.*, 1994; Krug *et al.*, 2001) to HSV-1, including a role in transient replication (Dewhurst *et al.*, 1994; Dykes *et al.*, 1997). These origins are not similar in any way to HCMV *ori*Lyt or replication origins of other cytomegaloviruses. HCMV relies on IE2 and UL84 as apparent OBPs and both are betaherpesvirus-conserved proteins (Chapter 15); however, testing a role in cytomegalovirus replication awaits development of a suitable assay. What follows is a description of each HCMV replication protein and the current status with respect to proposed function.

Helicase–primase complex (UL105, UL70 and UL102)

As in all herpesviruses the HCMV helicase–primase is a heterotrimeric complex composed of a helicase subunit

(UL105), a primase subunit (UL70) and a linking subunit (UL102). In vitro assays determined that the three proteins interact as a complex (McMahon and Anders, 2002). The proposed helicase for HCMV was first identified as the homologue for HSV-1 UL5. The UL105 gene encodes a 3.4 kb transcript that is present in infected cells as early as 24 hours post-infection and a 110 kDa protein was detected using UL105 specific antiserum (Smith *et al.*, 1996). With respect to UL102, initial controversy regarding sequence data suggested that UL102 was a spliced transcript. Subsequent studies involving the identification of the UL102 mRNA isolated from an HCMV cDNA library indicated that UL102 is an unspliced 2.7 kb transcript which encodes an 873 codon ORF (Smith and Pari, 1995). The UL70 ORF encodes a 945 amino acid protein that is the proposed homologue for HSV-1 UL52. Like the HSV-1 primase, pUL70 contains a putative DXD motif that is common to the metal binding site found in prokaryotic primases and family B DNA polymerases (Dracheva *et al.*, 1995; Ilyina *et al.*, 1992; Li *et al.*, 1993). To date, no published study has demonstrated helicase or primase activity using recombinant HCMV proteins or betaherpesvirus homologues.

DNA polymerase (UL54) and polymerase accessory protein (UL44)

The HCMV polymerase and the polymerase accessory protein are among the most well-characterized HCMV proteins. Contrary to many herpesvirus proteins, the polymerase and its accessory protein appear to be easily purified as recombinant proteins and retain native function in in vitro assays. Using purified UL54 from insect cells, this protein was shown to synthesize DNA from a variety of templates. In addition, the polymerase accessory protein, the gene product of UL44, stimulated DNA polymerase activity in a template dependent manner (Ertl and Powell, 1992). In infected cells the HCMV DNA polymerase associates with the UL44 gene product (Ertl and Powell, 1992). UL54 along with UL44 were efficiently expressed in an in vitro-coupled transcription/translation reticulocyte lysate system and the activity of the enzymes was comparable to what was observed from the native infected cell purified proteins (Cihlar *et al.*, 1997). This method established a simple protocol for the expression and purification of the recombinant proteins. Homologous domains of ppUL54, with significantly conserved sequences and similar enzymatic properties in HSV and other herpesviruses have been identified (Coen, 1996). The expression of ppUL54 is controlled by multiple regulatory elements during viral infection. ppUL54 is resistant to high salt concentrations and is sensitive to particular deoxyribonucleoside and pyrophosphate analogue antiviral agents (Freitas *et al.*, 1985; Huang, 1975; Wahren *et al.*, 1985). Proteins expressed from both UL112–113 and IRS1/TRS1 loci in association with the major immediate–early (MIE) proteins, were implicated as *trans*activators of UL54 expression (Kerry *et al.*, 1996, 1997). These studies implicated cellular factors as one of the major factors involved in control of UL54 expression. Since UL54, along with the product of another conserved gene, UL97 (viral protein kinase), are targets of many antiviral compounds, many studies have focused on the genetic changes occurring in these genes in drug-resistant HCMV isolates. Several of these studies have shown that the main mechanism conferring drug resistance is through point mutations within the DNA polymerase gene locus (Cihlar *et al.*, 1998 a,b; Eckle *et al.*, 2000; Eizuru, 1998; Mousavi-Jazi *et al.*, 2001). One drug in particular, foscarnet (PFA), induced specific point mutations in a conserved region of the polymerase gene likely to be associated with pyrophospate release (Mousavi-Jazi *et al.*, 2003). Studies involving the use of siRNA demonstrated that UL54 inhibition by this method can be as efficient as conventional drug therapies (Wiebusch *et al.*, 2004).

The polymerase accessory protein, ppUL44 (originally designated ICP36) (Mocarski *et al.*, 1985), is an abundant, nuclear phosphorylated DNA-binding protein with an approximate molecular weight of 52 kDa that partitions into viral replication compartments (Anders and McCue, 1996; Gibson, 1983, 1984; Gibson *et al.*, 1981; Ho, 1991; Mocarski *et al.*, 1985). UL44 protein can be detected in infected cells during the early phase of viral infection and accumulates in the nuclei of infected cells until, and throughout, the late phase (Ho, 1991). UL44 was shown to be a substrate for UL97 protein kinase demonstrating that the phosphorylation of UL44 may be controlled by both viral encoded and cellular kinases (Krosky *et al.*, 2003). In addition, the requirement for UL44 in the transient replication assay, studies using the expression of antisense RNA to the UL44 transcript also demonstrated UL44 as being an essential protein in the context of the viral genome in virus infected cells (Ripalti *et al.*, 1995). It was shown that transactivation of the UL44 promoter depends on a gene product(s) encoded by the TRS1 segment of the genome in conjunction with IE1 and IE2 immediate–early proteins (Stasiak and Mocarski, 1992).

Because UL54 and UL44 represent significant drug targets recent studies have focused on the interaction of these two proteins. In vitro analysis determined that the C-terminal end of UL54 was essential for interaction with UL44. A small peptide, corresponding to residues 1161–1242 of UL54, effectively interfered with the interaction of the two proteins (Loregian *et al.*, 2003). Further studies indicated that specific point mutations within the UL54 protein in amino acid residues Leu1227 and Phe1231, were

sufficient to impede the interaction of UL54 with UL44, as well as affecting the ability of the enzyme complex to synthesis long chain DNA (Loregian *et al.*, 2004).

Single-stranded DNA binding protein (UL57)

The single-stranded DNA (ssDNA) binding protein has similar size and biochemical properties to the HSV-1 single-stranded DNA binding protein encoded by the UL29 gene (Anders and Gibson, 1988; Anders *et al.*, 1986, 1987; Kemble *et al.*, 1987). The HSV-1 ssDNA binding activity is essential for viral DNA replication (Lee and Knipe, 1985; Ruyechan, 1983) and exhibits a helix-destabilizing activity but can also catalyze the renaturation of complementary single strands of DNA (Dutch and Lehman, 1993). Recent studies indicate that this protein exhibits RNA binding and R-loop formation in addition to functioning as a recombinase (Boehmer, 2004; Reuven *et al.*, 2004). HSV ssDNA binding protein interacts with several other viral DNA replication proteins including DNA polymerase and the OBP, and binding may stimulate the activities of DNA polymerase, OBP helicase, and helicase–primase (Boehmer *et al.*, 1993; Boehmer and Lehman, 1993a,b; Chiou *et al.*, 1985; Falkenberg *et al.*, 1997; Hamatake *et al.*, 1997; Hernandez and Lehman, 1990; Tanguy LeGac *et al.*, 1998).

HCMV ssDNA binding protein is encoded by UL57 as a 140 kDa protein that localizes to intranuclear DNA replication compartments by 48 h post-infection and accumulates in characteristic prereplicative sites when DNA synthesis is inhibited by treatment with drugs that inhibit viral DNA synthesis (Anders *et al.*, 1987; Penfold and Mocarski, 1997).

UL84

The requirement for the core replication proteins: polymerase, polymerase processivity factor, trimeric helicase-primase and ssDNA binding protein is common among all herpesviruses. One additional protein, the UL84 gene product (ppUL84) is necessary for replication. ppUL84 is a 586aa polypeptide present in infected cells as early as 2.5 hpi (He *et al.*, 1992) and is a nuclear-localizing phosphoprotein. UL84 colocalizes with UL44 and IE2 (580 aa) in the nucleus and is a component of viral replication compartments in infected and transfected cells (Xu *et al.*, 2002). UL84 stably interacts with IE2 in infected cells (Samaniego *et al.*, 1994; Spector and Tevethia, 1994) and overexpression of UL84 decreases IE2-mediated transient transactivation (Gebert *et al.*, 1997). ppUL84 nuclear localization can either use a signal similar to the SV40 T antigen nuclear localization signal (Xu *et al.*, 2002) or a non-conventional importin alpha protein-dependent process (Lischka *et al.*, 2003). ppUL84 probably dimerizes (Colletti *et al.*, 2004). The self-interaction domain is localized to a highly charged region of the protein. UL84 is the only HCMV function needed to facilitate replication of HCMV *ori*Lyt by the six Epstein–Barr virus replication-fork proteins in Vero cells (Sarisky and Hayward, 1996). Although there were different HCMV-encoded factors required in human fibroblasts versus Vero cells, UL84 was the only auxiliary component that could not be omitted (Sarisky and Hayward, 1996). Other laboratories have observed cell type dependent requirements for HCMV replication proteins, indicating that replication may proceed by different mechanisms depending on cellular factors present (Reid *et al.*, 2003). The UL84 ORF is essential for virus growth as evidenced by the generation of recombinant viruses with insertions or replacement in UL84 (Dunn *et al.*, 2003; Xu *et al.*, 2004). Interestingly, all kinetic classes of viral transcripts are made in cells transfected with recombinant UL84 deficient viral bacmid DNA (Xu *et al.*, 2004), despite the fact that UL84-defective BACs fail to accumulate any viral DNA.

Recent evidence showed that ppUL84 acts in concert with IE2-p86 to activate a *cis*-acting element within *ori*Lyt suggesting that a ppUL84-IE2-p86 interaction may supply a "trigger" for viral DNA synthesis. Therefore, ppUL84 appears to have a dual function in HCMV DNA replication. The first is either as a coactivator of transcription along with IE2 or a repressor of IE2-mediated transcriptional activation. Activation of a promoter within *ori*Lyt may provide an essential signal for initiation of DNA synthesis. The second function may involve an as yet undefined enzymatic activity such as a helicase. This is based on the observation that the amino acid sequence of UL84 has a significant homology to the DExD/H box family of RNA helicases. Consistent with this possibility, HCMV UL84 shows UTPase activity (Colletti *et al.*, 2005). These proteins may act as either coactivators or repressors of transcription in a promoter-specific manner (Wilson *et al.*, 2004). New electromobility shift assay (EMSA) data from the Pari laboratory show that UL84 can interact with both DNA and RNA in vitro. This interaction appears to be non-specific but a higher affinity for RNA sequences that form a stem-loop suggests that UL84 may bind to these structures within *ori*Lyt. Moreover, chromatin immunoprecipitation (ChIP) assays using either infected-cell DNA or DNA contained within purified virus showed that UL84 is associated with the HCMV genome. UL84 binding was localized to three distinct regions within *ori*Lyt.

HCMV UL84 homologues are found in all betaherpesviruses (Chapter 15) but have highest DNA sequence similarity in closely related chimpanzee or baboon CMV (Davison *et al.*, 2003). This is in contrast to UL84 homologues found within MCMV and GPCMV, or in the roseolaviruses where the UL84 ORF retains little similarity to

the HCMV counterpart. This lack of sequence homology also appears to translate to a functional distinction between primate CMVs and other species since it was demonstrated that the UL84 ORF is non-essential for virus growth in both MCMV and GPCMV (Morello *et al.*, 2002) (M. Schleiss and A. McGregor, personal communication).

Origin binding proteins in roseoloviruses

Initiator proteins for HHV6 and HHV7 appear to have close homology to OBP of HSV-1. These proteins, the gene product of U73 for both HHV6 and HHV7, each interact with two sites within the *ori*Lyt for both viruses. These sequences are equivalent to Box I and Box II of HSV-1 *ori*Lyt, flank AT-rich sequences and exhibit other similar sequence characteristics. Other DNA replication proteins within HHV6 and HHV7 have been assumed based on nucleotide sequence homology to the HSV-1 and HCMV functions. They include: U38 (DNA polymerase), U27 (polymerase accessory protein), U43, U74 and U77 (helicase–primase complex) and U41 (ssDNA binding protein).

Immediate–early protein IE2–580aa

As is summarized in Chapter 17, IE2 encodes an 86-kDa nuclear immediate–early phosphoprotein that is essential for lytic replication in tissue culture (Heider *et al.*, 2002; Marchini *et al.*, 2001). IE2-p86 is thought to be the major transcription-activating protein of HCMV and is also responsible for negative autoregulation of the major immediate–early promoter (MIEP) (Mocarski, 2001). IE2 has been implicated in multiple protein–protein interactions including the formation of dimers, association with ppUL84 and several transcription factors, for example CREB, CBP, SP-1, and c-Jun (Chiou *et al.*, 1993; Furnari *et al.*, 1993; Lang *et al.*, 1995; Lukac *et al.*, 1994; Schwartz *et al.*, 1996; Scully *et al.*, 1995; Wara-aswapati *et al.*, 1999).

The role of IE2 with respect to DNA replication is less well understood. It has been shown that IE2-p86 interacts with ppUL84 to activate a responsive promoter within *ori*Lyt (Xu *et al.*, 2004). However, the requirement for IE2 in origin-dependent DNA replication is apparently cell type dependent. The *ori*Lyt promoter is constitutively active in Vero cells, thereby enabling amplification of *ori*Lyt in the absence of IE2 (Xu *et al.*, 2004).

UL36–38

Although these genes were identified as being required for DNA replication (Pari and Anders, 1993), they appear to play an auxiliary role (Sarisky and Hayward, 1996). In addition, in a human fibroblast cell line immortalized with the catalytic subunit for telomerase (hTERT), the gene products of UL36–38 are no longer necessary for origin-dependent DNA replication (Xu *et al.*, 2004). These proteins may function to facilitate a more favorable cellular environment for transient DNA replication. The UL36–38 locus encodes at least five transcripts from three different transcriptional promoters: the UL36, UL37, UL37$_M$, UL37×1 and UL38 RNAs (Goldmacher *et al.*, 1999; Kouzarides *et al.*, 1988; Tenney and Colberg-Poley, 1991a,b; Wilkinson *et al.*, 1984). Despite being initiated at the same IE promoter, three UL37 RNAs, UL37×1, UL37, UL37$_M$, are generated by differential RNA splicing and polyadenylation and show dramatically different temporal expression during HCMV infection. The UL37×1 unspliced RNA is expressed abundantly at IE times and remains abundant until late times of infection. In contrast, the other two UL37 RNAs, which are spliced, are expressed at low abundance during IE times and encoding two UL37 glycoproteins (gpUL37 and gpUL37$_M$) that are dispensable for replication. Only pUL37×1 is required for viral replication (Reboredo *et al.*, 2004) possibly via its anti-apoptotic activity (Goldmacher *et al.*, 1999; Hayajneh *et al.*, 2001).

Betaherpesvirus replication origins

Cytomegalovirus *ori*Lyt

Several lines of evidence show that a unique HCMV origin of lytic DNA synthesis, called *ori*Lyt, lies near the middle of U$_L$, between the UL57 and UL69 ORFs. First, this region directs virus-mediated replication of plasmids in transient replication assays (Anders and Punturieri, 1991). Such assays allowed the mapping of functional replicator sequences (Anders *et al.*, 1992; Masse *et al.*, 1992; Zhu *et al.*, 1998); see below). Second, evidence from an inhibitor study indicates that DNA synthesis initiates in or near this region of the virus genome during productive infection of permissive cells (Hamzeh *et al.*, 1990). Third, although poorly conserved at the nucleotide sequence level, the position of *ori*Lyt next to the single-stranded DNA binding protein gene is conserved in all other cytomegaloviruses studied to date, and the corresponding regions confer replication competence in the transient assay (Masse *et al.*, 1997; Vink *et al.*, 1997). Finally, in contrast to the lytic replicators of many other herpesviruses, cytomegalovirus *ori*Lyt appears to be single-copy, because it is not duplicated in the genomes of either laboratory or clinical isolates, and recombinant HCMV BACs deleted for *ori*Lyt fail to produce virus or replicate their genomes (Dunn *et al.*, 2003; D. G. Anders, unpublished results; Borst and Messerle, 2005). This is consistent with previous findings that no other

segment of the viral genome has replicator activity in the transient assay. Therefore, *ori*Lyt is thought to be essential for lytic replication in the host. Because it is essential and may play an important regulatory role in the virus–host relationship, we provide a complete summary of work-to-date.

Cytomegalovirus *ori*Lyt structure

Cytomegalovirus *ori*Lyt is distinguished from most other herpesvirus replicators, including those of the roseoloviruses, in that it is large and complex. Some structural features are shared with gammaherpesvirus *ori*Lyt sequences. Deletions to define the external borders established a minimal *ori*Lyt region containing essential elements, and showed that sequences spanning more than 2.5 kbp can contribute to replicator activity in transient assays (Anders *et al.*, 1992; Masse *et al.*, 1992). Kanamycin cassette insertion studies defined a similar core region, roughly nt 91 750 to 93 300, within which the insertions either eliminated or greatly impaired replicator function (Zhu *et al.*, 1998). This minimal oriLyt core region does not support efficient replicator activity, at least in transient assays, in the absence of left or right flanking sequences. The flanking sequences independently contribute to *ori*Lyt activity with relaxed position dependence, in that insertions do not significantly compromise activation of the *ori*Lyt core, and therefore they have been referred to as "auxiliary" sequences.

Two notable features characterize the cytomegalovirus *ori*Lyt region. First, it contains a high density of direct and inverted repeats (Masse *et al.*, 1992). Several of these appear virus specific, including multiple copies of a 10-bp motif similar to the known binding site for the UL34 protein clustered in the left auxiliary region, and 13- (also known as FspI/SphI) and 19-bp directly repeated sequences within the core region. Reiterated sequences similar to the 10-bp and 13-bp motifs are present at corresponding positions in other cytomegaloviruses. Two large, but imperfect inverted repeats are present on the right side of the *ori*Lyt core region; similar structures are present at the corresponding positions of all known CMV *ori*Lyt sequences. Interestingly, these can be variably reiterated in laboratory strains (Prichard *et al.*, 1998). Other repeated elements include a variety of consensus host transcription factor recognition sequences, most notably clusters of potential Sp1 and CREB sites. Which of these reiterated motifs contribute to replicator activity, how and under what circumstances, remains to be determined. A second characteristic feature of CMV *ori*Lyt is its overall base composition asymmetry. Most of the *ori*Lyt region approximates the overall GC content of the viral genome, but AT-rich segments lie on the left side, and a very GC-rich region on the right. The imperfect inverted repeats lie in the GC-rich region. EBV *ori*Lyt shows a similar organization. The roles of AT-rich and GC-rich segments are not understood, but the AT-rich segment in the leftward minimal activating sequence contributes to activation of the core replicator in transient assays (Kiehl *et al.*, 2003).

A series of overlapping 200-bp deletions spanning the *ori*Lyt core region were made and tested for activity in the transient replication assay to search for essential elements (Zhu *et al.*, 1998). All except one of the core deletions reduced replicator activity from about 20- to greater than 100-fold, suggesting that elements contributing to replicator activity are scattered throughout the core region, or that spatial relationships of distant elements are important. Two regions critical for replicator activity were identified by this approach. One of these, extending from nt 92 400 to 92 573, includes the only known individually essential element, a pyrimidine (Y)-rich tract followed by a purine (R)-rich tract of nucleotides, referred to as a "Y-block." Y·R elements are present in all other CMV *ori*Lyt sequences as well as in EBV *ori*Lyt, but are absent from origins that characterize HHV-6, HHV-7 and alphaherpesviruses that interact with an origin binding protein (Huang *et al.*, 1996). Nucleotide substitutions in this element eliminate replicator activity in the transient assay. The other essential segment spans nt 92 887 to 93 145, and contains the cluster of Sp1 consensus sites and overlaps the vRNA-2 region. A 405 bp deletion starting at starting at 92 574, which was less than threefold reduced in activity relative to the wild type in the transient replication assay, identified the only dispensable sequence in the *ori*Lyt core region. Lastly, because the core region alone has minimal activity in the transient assay, auxiliary sequences probably play an important role in activating *ori*Lyt. A minimal *ori*Lyt activating sequence overlapping the UL57 promoter was defined by reconstitution, providing a model to study how auxiliary sequences enhance core replicator function (Kiehl *et al.*, 2003).

Finally, there are two important caveats to conclusions regarding functional elements of CMV *ori*Lyt. First, they were drawn on the basis of transient assays. Specific sequence requirements for *ori*Lyt function in the context of the virus genome have yet to be investigated. Second, most of this work was done in permissive fibroblasts; comparative studies in other cell types important in the infected host, in which different sets of cellular regulatory proteins predominate, may reveal distinct sequence requirements. Indeed, the HCMV *ori*Lyt bidirectional promoter $ori\text{Lyt}_{PM}$ is constitutively active in Vero cells, but requires both IE2 and UL84 for activity in fibroblasts (Xu *et al.*, 2004).

*ori*Lyt open reading frames and transcripts

The HCMV *ori*Lyt region includes predicted ORFs UL58-UL61, and a newly described ORF 3 lies at the right boundary (Murphy *et al.*, 2003a). In addition, the *ori*Lyt region is actively transcribed and several transcripts have been characterized. However, the predicted proteins are not conserved in other cytomegaloviruses including chimpanzee CMV and moreover, with the exceptions of UL59 and to a lesser extent ORF3, the *ori*Lyt ORFs are not conserved amongst clinical isolates, suggesting that they may not represent authentic protein-coding genes (Murphy *et al.*, 2003b; see Chapter 14).

The UL59 ORF is interesting in that it is absent in other other CMV genomes sequenced to date, and appears to have been recently acquired as an insertion between the organizationally conserved *ori*Lyt core and leftward auxiliary regions. It is better conserved among clinical isolates than the other potential *ori*Lyt coding sequences, and a corresponding late transcript of 0.4–0.7 kb is made. However, it is not known whether the predicted protein is expressed. The segment upstream of UL59, extending about 900 bp to Y·R element, is rich in consensus transcription factor binding site sequences, and contains an apparently bidirectional promoter, *ori*Lyt$_{PM}$, that is regulated by IE2 and UL84 (Xu *et al.*, 2004). Transcripts spanning UL59 initiate from several sites in this region. Deletion of the UL59 ORF does not affect HCMV growth in fibroblasts, but tests of growth in other cell types have not been reported (Dunn *et al.*, 2003).

Recombinant HCMV BACs carrying an insertion in either the UL60 or UL61 ORF or a deletion of the UL60 ORF failed to replicate, but these mutations would be predicted on the basis of previous findings to inactivate *ori*Lyt, and therefore more subtle mutations would be needed to determine whether these ORFs are essential (Dunn *et al.*, 2003; Yu *et al.*, 2003). A second, late transcript of around 6.5 kb that has the same orientation and is 3 co-terminal with the UL59 transcript crosses *ori*Lyt from right-to-left, but the complete structure of that transcript is not known.

Three other *ori*Lyt RNA species have been described. The first, called the small replicator transcript, is a roughly 250 nt early, non-polyadenylated species with a single 5′ end and a variable 3′ end that overlaps the essential "Y-block" element (Huang *et al.*, 1996). It lies within the UL60 ORF. An upstream promoter for the small replicator transcript is active in transient assays, but studies to confirm this in the genome context have yet to be done. Two other RNAs, called virus-associated or "vRNAs," were found to be covalently associated with progeny DNA at least partly in RNA–DNA hybrid form, and present in virions (Prichard *et al.*, 1998). vRNA-1 localizes between nt 93 799 and 94 631, and vRNA-2 between nt 92 636 and 93 513. Nothing is known about how these transcripts are expressed or how they function. The apparently non-coding nature of the small replicator transcript and the vRNAs, the timing of their expression, their unusual properties and their association with genetically defined segments essential for *ori*Lyt activity have led to suggestions that they may participate in initiation of DNA synthesis.

The mechanism of initiation

Initiation of CMV DNA synthesis is not understood. Based on the information available from a variety of DNA replication systems that have been studied, initiation can be predicted to require several steps, including (i) an initial strand separation followed by unwinding, and (ii) assembly of replication fork proteins to form an active complex at the site of initiation. In SV40, T-antigen binds to specific origin sequences to form a complex that, in cooperation with certain structural features of the origin, untwists and subsequently, with an intrinsic helicase activity, unwinds the origin duplex. In addition, it directs polymerase alpha/primase association. The alphaherpesviruses origin-binding protein (e.g., HSV-1 UL9), as well as the homologous HHV-6 and HHV-7 proteins, are thought to play an analogous role, using an essential intrinsic helicase activity to provide the initial unwinding in cooperation with the single-strand DNA binding protein. However, as noted above, the cytomegaloviruses lack a UL9 homologue. Therefore, it is not clear how initial unwinding occurs or how the replication fork proteins may be directed to load. One frequently discussed possibility is that RNA–DNA hybrids formed during transcription may produce open regions that could be used to load the helicase–primase complex. This suggestion is supported by the synthesis of candidate RNAs and the observation of residual RNA-DNA hybrids, the vRNAs, in replicated viral DNA at sites critical to *ori*Lyt activity. This could explain, at least in part, the complexity of CMV *ori*Lyt, as this mechanism requires not only the transcript itself, but also control regions for transcription and elements to direct assembly to the replication fork complex. However, there are many other possibilities including co-opting the cellular initiation machinery, as EBV does for latent phase DNA synthesis. Initiation remains one of the most interesting areas for investigation of CMV DNA synthesis.

Roseolovirus replication origins

Human herpesviruses 6 and 7 lytic-phase replicators were identified using a transient replication assay (Dewhurst

et al., 1993; van Loon *et al.*, 1997). The roseolovirus lytic origins are located adjacent to the single-stranded DNA binding protein gene, U41, a position that is similar to CMV *ori*Lyt; however, the structure of roseolovirus *ori*Lyt exhibits similarity to that of the alphaherpesviruses. As is the case for cytomegalovirus, HHV-6 and HHV-7 *ori*Lyt sequences are thought to be unique, although this has not been fully tested. The HHV-6 *ori*Lyt region is unusually AT rich, and includes a large, imperfect directly repeated (IDR) sequence. In contrast, HHV-7 *ori*Lyt is more compact and is missing the IDR region and adjacent sequences that contribute to HHV-6 replicator activity. Both are smaller and less structurally complex than cytomegalovirus *ori*Lyt, and include comparatively fewer potential transcription factor recognition sequences. Plasmids carrying HHV-6 *ori*Lyt were replicated following introduction into either HHV-6- or HHV-7-infected cells, although HHV-7 *ori*Lyt was only replicated in HHV-7-infected cells (van Loon *et al.*, 1997).

In striking contrast to HCMV *ori*Lyt, the roseolovirus replicators are characterized by the presence of at least two binding sites for a virus-coded protein, U73, homologous to the alphaherpesvirus OBP. As noted above (see Chapter 15), OBP homologues are not found in the cytomegaloviruses. As detailed earlier, the roseolovirus OBP homologues bind specifically to defined oriLyt sites in vitro (Inoue *et al.*, 1994; Inoue and Pellett, 1995; Krug *et al.*, 2001), and mutation of either site, or of the spacer region separating them, inactivates the replicator when tested in the transient assay (Dewhurst *et al.*, 1994; Dykes *et al.*, 1997). Therefore, OBP binding to the *ori*Lyt sites is probably essential for lytic viral replication, and mechanistically the roseolovirus replicators appear to resemble alphaherpesvirus counterparts rather than those of the cytomegaloviruses. Nevertheless, it is noteworthy that, although the HHV-6 minimal replicator spans only about 400 bp including the OBP sites, flanking sequences boost replicator activity in the transient assay suggesting that they may play an important role in regulating activity in the context of the virus genome. The minimal efficient origin includes the IDR region, which greatly enhances activity by an unknown mechanism (Dewhurst *et al.*, 1993). The IDR spans the most A+T rich segment, which may serve as a "DNA unwinding element." Comparison of the HHV-6A and B strain *ori*Lyt sequences revealed that they are more than 95% identical over the minimal essential region including the OBP binding sites, but considerably divergent in the auxiliary flanking regions, particularly beyond the IDR sequences. HHV-6A strains contain three copies of the imperfect direct repeat, whereas HHV-6B carries two copies. Interestingly, a sequence similar to the experimentally defined HHV-6 minimal efficient origin was reiterated in some cultured lineages of HHV6B, presumably by homologous recombination, and the reiterated *ori*Lyt enhanced replicator activity in the transient assay (Dewhurst *et al.*, 1994; Stamey *et al.*, 1995). This is reminiscent of the reiterations seen in HCMV *ori*Lyt laboratory strains. Specific elements within the auxiliary regions contributing to replicator activity have not been identified and, aside from the OBP binding sequences, little is known about the functional elements regulating the roseolovirus replicator.

Latent phase replication

EBV and other herpesviruses that establish latency in replicating cell types have a separate origin (*ori*P) that is responsible for maintenance and replication of the viral genome during latency. However, no latent phase origin has been identified in the cytomegalovirus genome. Indeed, a latent origin may not be required if the primary sites of latency are in non-dividing cells, particularly if the latency reservoir is replenished by cycles of reactivation as the latency hosts are stimulated to differentiate and divide. Nevertheless, little is known about the molecular aspects of betaherpesvirus latency, and the existence of a latency maintenance element cannot be excluded.

Late gene expression

Replication of the viral genome provides an essential activating event for the expression of high levels of the betaherpesvirus late genes. It is widely understood that late genes encode for proteins required for virus assembly and egress. These genes can be divided into two broad classes. The gamma 1 or leaky-late class are expressed at very low levels at early times after infection and are dramatically upregulated at late times. In contrast, the gamma 2 or "true" late genes are expressed exclusively after and are dependent upon viral DNA replication. The mechanism that restricts late gene activation to after DNA replication has not yet been determined, although at least two general possibilities have been considered. First, the restriction may be related to DNA structure, or possibly DNA modifications that are altered immediately post replication. Alternatively, binding of viral or cellular proteins to repressor elements within late promoters may inhibit late gene expression, with subsequent displacement or titration of the repressors being accomplished by DNA replication.

Our understanding of late gene regulation in the betaherpesviruses lags far behind that of early gene regulation (Chapter 17). Only a handful of late gene promoters have been analyzed in detail. One of the primary reasons for this has been the difficulty in recapitulating the appropriate kinetic regulation of late genes in transient

transfection/superinfection assays. Initial studies of betaherpesviruses late promoters in this type of assay system revealed that upon superinfection, promoter activity could be detected at early times after infection (Depto and Stenberg, 1992; Rudolph *et al.*, 1990). Thus, it was assumed that transient assays would not provide complete information regarding the necessary promoter components required to restrict viral gene expression to late times, requiring the assessment of these promoters in the context of the viral genome. In this respect, the recent development of the bacterial artificial chromosome (BAC) system to rapidly generate viral mutants will likely facilitate the analysis of late gene regulation.

However, even though a limited subset of late genes have been analyzed to date, some general features associated with their regulation have been identified. Typically, late promoters seem to require a TATA element but no further upstream sequences for transcriptional activation (Depto and Stenberg, 1989, 1992; Kohler *et al.*, 1994; McWatters *et al.*, 2002; Wing *et al.*, 1998). Similar findings have been observed for late gene promoters of herpes simplex virus, where the TATA box and downstream elements are sufficient to direct late gene activation (Flanagan *et al.*, 1991; Homa *et al.*, 1986; Weir, 2001). This is in contrast to the betaherpesviruses early promoters, where specific upstream sequence elements capable of binding to cellular transcription factors are critical for promoter activation. The most extensive studies on late gene regulation published to date have examined the human cytomegalovirus UL99 gene encoding the virion tegument protein pp28 (Depto and Stenberg, 1992; Kerry *et al.*, 1997; Kohler *et al.*, 1994). This gene, which is expressed as a gamma 2 late gene, requires only sequences from -40 relative to the cap site to restrict expression to late times (Kohler *et al.*, 1994). In order to accurately replicate appropriate promoter kinetics, these studies were performed by introducing the promoter construct regulating the CAT reporter gene into an alternate, transcriptionally inert site in the HCMV genome. This type of study led to the hypothesis that late promoters are relatively simple promoters consisting primarily of a TATA element and downstream sequences and lacking a requirement for multiple transcriptional regulatory elements.

Despite some limitations, transient assays have yielded important information about the minimal promoters of a number of late genes. (Depto and Stenberg, 1989; McWatters *et al.*, 2002; Wing *et al.*, 1998). For example, in the analysis of the HCMV UL75 promoter, which controls expression of the envelope glycoprotein gH, sequences from −38 to +15 relative to the cap site were sufficient to activate this promoter (McWatters *et al.*, 2002). However, although additional regions of the promoter were not essential for activation, closer examination of those sequences revealed a much more complex mode of regulation (McWatters *et al.*, 2002). Specifically, sequences downstream of the UL75 cap site appeared to function as a dominant regulatory element. In the absence of this region, both activation and repressor elements were identified in the upstream sequences. (McWatters *et al.*, 2002). Similarly, analysis of the HCMV UL94 late promoter identified a dominant regulatory element downstream of the cap site that functioned as a derepressor (Wing *et al.*, 1998). In the absence of this downstream element, deletion of the upstream sequences enhanced promoter activity, suggesting the presence of an upstream negative regulatory element. This negative regulatory element contained two p53 binding sites that were important, although not sufficient for the repressive effects (Wing *et al.*, 1998). These studies suggest that the regulation of late gene expression may be more complex than previously thought, with additional sequences allowing the binding of viral and/or cellular proteins that may influence the regulation of late promoters. However, it remains to be determined if these elements truly play a role in late gene regulation in the context of a normal viral infection, or if these are artifacts resulting from the assay system.

Studies suggesting a more complex model for late promoter activation are intriguing, given that a number of HCMV late promoters have been identified in the midst of both immediate early and early gene regions (Leach and Mocarski, 1989; Leatham *et al.*, 1991; Puchtler and Stamminger, 1991). In fact, in some cases, specific late transcripts with alternate TATA elements and start sites have been identified within HCMV early promoters (Jones and Muzithras, 1991; Leach and Mocarski, 1989). Thus it might be expected that adjacent regulatory elements or enhancers within the promoter context could influence the activation or kinetics of expression of such late transcriptional units. In this context, it is important to note that analyses of late promoter regulation in the context of the viral genome have been performed in a transcriptionally inert region (Kohler *et al.*, 1994), and the association of repressors and activators may be critical for restricting viral late gene expression within their natural genomic context. Thus, a more complex model of late promoter regulation emerges, with a possible role for multiple repressor and activator proteins influencing the kinetics of gene expression.

Some efforts have been made to identify specific regulatory proteins that are involved in the activation of HCMV late promoters. With respect to cellular transcription factors, analysis of the UL75 promoter indicated a role for a cellular PEA3-related protein in transcriptional activation (McWatters *et al.*, 2002). Inversely, a role for p53 in transcriptional repression of the UL94 promoter has been identified (Wing *et al.*, 1998). Some recent studies suggest

that the NF-κB transcription factor may also be involved in activating viral late gene expression (DeMeritt *et al.*, 2006). Other studies have identified sequence elements involved in late promoter activation, although the specific proteins required for activation remain to be identified (Depto and Stenberg, 1989, 1992). Intriguingly, a more global analysis of the putative promoter regions of HCMV late genes revealed a palindromic GC-rich sequence (CCGCGGGCGCGG) in the promoters of 17% of viral late genes (Chambers *et al.*, 1999). The significance of this sequence element in late gene regulation remains to be determined.

In addition to cellular proteins, there is evidence for the role of viral factors in the activation of late promoters. The fact that late kinetics are not conserved when the promoters are relieved of the constraints of the viral genome suggests that the viral factors required for activation are present at early times of infection. Indeed, the HCMV immediate–early proteins can activate some late promoters, although to minimal extents (Depto and Stenberg, 1989, 1992; Wu *et al.*, 2001). Other HCMV proteins, such as trs1 may also play a role in activating late promoters (Romanowski and Shenk, 1997; Stasiak and Mocarski, 1992). The finding that the IE proteins of HCMV may be involved in regulating viral late gene expression is interesting in the light of recent studies examining the role of IE2 during viral infection (Sanchez *et al.*, 2002; White *et al.*, 2004). Deletion of IE2 sequences from amino acids 136 to 290 resulted in reduced amounts of IE2 in infected cells but had minimal impact on viral DNA replication (Sanchez *et al.*, 2002). Interestingly, two viral late proteins, pp65 and pp28 were found to be expressed at reduced levels. Likewise, UL83 mRNA levels that encode the pp65 gamma 1 late protein were reduced (Sanchez *et al.*, 2002). Small internal deletions in IE2 from amino acids 356–359, 427–435, and 505–511 and one substitution mutant of IE2 were also assessed using the same strategy (White *et al.*, 2004). The deletion of amino acids 356–359 and the substitution mutant were both defective in late gene expression. In contrast, deletion of amino acids 427–435 and 505–511 resulted in an IE2 protein that did not activate early gene expression, but expressed certain gamma 1 and gamma 2 genes at early times after infection. Sequence analysis located a potential IE2-binding site within the promoter region of one of these genes, suggesting that IE2 may be involved in transcriptional repression of late genes (White *et al.*, 2004). These findings suggest that IE2 plays a hitherto unrecognized role in directly regulating late gene expression in both a positive and a negative manner.

A role for IE2 in late promoter regulation would appear to be in conflict with the kinetics of expression of this protein. One possibility is that IE2 is differentially modified at late times after viral infection. IE2 can be modified by both phosphorylation and sumoylation, and differential modification through the course of infection could influence the ability of IE2 to regulate gene expression (Heider *et al.*, 2002; Hofmann *et al.*, 2000; Lee *et al.*, 2003). Alternatively, an IE2-related protein, p40 corresponding to amino acids 242–580 of IE2 (Plachter *et al.*, 1993) has been characterized that is expressed via an alternate promoter at late times. This protein has been demonstrated to function as a transactivator, but its specific role during infection has not been defined (Jenkins *et al.*, 1994). The possibility exists that the p40 protein is involved in the activation of late promoters. Indeed, the IE2 deletion from amino acids 136 to 290 that exhibits defects in late gene expression removes the start codon for the p40 late gene product from the IE2 region (Sanchez *et al.*, 2002). Thus, IE2 or IE2-related proteins may play a differential role in transcriptional activation of viral promoters at multiple stages of viral infection. Recent studies have identified a gammaherpesvirus gene, ORF18 that is essential for late gene expression (Arumugaswami *et al.*, 2006). While a direct role for the betaherpesvirus homolog of ORF18, UL79 in late gene activation has yet to be assessed, it is highly likely that additional viral proteins will be found to be important for the regulation of late promoters.

To date, there has been only one study addressing the direct role of DNA replication in stimulating late gene transcription. In this analysis, the HCMV TRL7 gene that is expressed with gamma 1 kinetics was assessed in the context of a plasmid containing the HCMV *ori*Lyt region (Wade and Spector, 1994). This approach restored the dependence on DNA replication for high levels of the TRL7 promoter-directed transcript in transient assays. While the plasmid itself did replicate upon superinfection with HCMV, the level of replication appeared to be insufficient to explain the increased transcription rates. In addition, enhanced transcription of the gamma 1 gene at late times did not appear to be related to methylation differences, or dependent on specific upstream promoter elements. One intriguing possibility discussed by the authors is that factors required for replication may play a dual role in both replication and transcriptional activation, with replication providing a mechanism for bringing such factors into proximity of the promoter, and thereby providing for enhanced transcription, based on a model originally identified in the bacteriophage T4 (Herendeen *et al.*, 1989, 1992).

In addition to transcriptional events, there is evidence that post-transcriptional regulation may play a critical role in controlling the appearance of viral late gene products. Analysis of the HCMV UL99 5' untranslated region revealed that these sequences influenced translational regulation, via a putative stem–loop structure (Kerry *et al.*, 1997). While

the mechanism of this regulation has not yet been characterized, recent analysis of IE2 mutants revealed that this protein may be involved, suggesting that the influence of IE2 on late gene expression is at multiple levels (White *et al.*, 2004). Post-transcriptional regulation has also been identified as a potential influence on the expression of late genes in the other betaherpesviruses, HHV-6 and -7. For these two viruses, specific splice variants that are restricted to the late phase of viral infection have been identified (Menegazzi *et al.*, 1999; Mirandola *et al.*, 1998). Thus, post-transcriptional control of gene expression at the late stages of viral infection may be a common mechanism in the betaherpesviruses to control the function and time of appearance of viral proteins. Post-transcriptional mechanisms also play an important role in the regulation of late gene expression during herpes simplex virus infection (McCormick *et al.*, 1999; Perkins *et al.*, 2003), suggesting that this may represent a common theme in the control of late gene expression throughout the herpesviruses.

In summary, although minimal sequences may be sufficient to restrict expression to late times in a transcriptionally inactive environment, a more accurate picture of the complexity of betaherpesvirus late gene regulation is now emerging. A role for viral and cellular transcriptional regulators, both positive and negative, has been identified, although definitive studies to truly assess late promoter requirements in a natural genomic environment remain to be performed. In addition, post-transcriptional events likely play a critical role in controlling the time of appearance of viral late proteins. Such strict control over the expression of late proteins is likely to be key for the appropriate assembly and egress of new virion particles.

Introduction

The assembly of betaherpesviruses, specifically cytomegaloviruses, is a topic of considerable interest to virologists and structural biologists. These viruses are among the largest and most complex animal viruses and encode a large number of proteins. Some clinical isolates of human cytomegalovirus (HCMV) have been predicted to contain as many as 250 ORFs (Chee *et al.*, 1990; Murphy *et al.*, 2003), while other authors have suggested that the coding capacity of HCMV may actually be on the order of 165 ORFs (see Chapter 14). Although the number of virus-encoded proteins that are incorporated into the infectious particle is unknown, estimates from several laboratories suggest that it could approach 100 proteins (Varnum *et al.*, 2004). In addition, the particle also contains an unknown number of host cell proteins, some that may have functional significance in the replicative cycle of these viruses (Varnum *et al.*, 2004). Thus, the complexity of virus assembly rivals that of some cellular organelles. Furthermore, CMVs do not arrest host cell protein synthesis even at late phases of replication as do the alphaherpesviruses and therefore during their assembly can either compete with host cell protein synthetic and targeting pathways or more likely, express viral specific functions that modulate host cellular pathways to optimize viral protein synthesis and transport. Identification of these virus-specified host cell modifications together with their interactions with virion proteins will aid in the understanding of the assembly of this virus. Similar approaches have provided a reasonably detailed view of the assembly pathways of bacteriophages and eukaryotic RNA viruses, including HIV-1, and these studies have in some instances served as templates for investigations of DNA virus assembly. However, herpesviruses encode vastly more virion proteins compared to RNA viruses, and assembly takes place in both nuclear and cytoplasmic compartments. Definitive studies of capsid assembly have been carried out in alphaherpesviruses and have been extended to include in vitro, cell free assembly of the herpes simplex viral (HSV) capsid (Newcomb *et al.*, 1994). Many of the capsid proteins of CMVs and other betaherpesviruses share extensive structural and functional homology with HSV capsid proteins and cryoelectron microscopic analysis of the HCMV capsid suggests similar, but not identical, capsid structure (Butcher *et al.*, 1998; Chen *et al.*, 1999; Trus *et al.*, 1999; Zhou *et al.*, 1999, 2000). The most structurally diverse region of the herpesvirus virion appears to be the tegument which is composed of a great many betaherpesvirus- and CMV-unique proteins. Although proteins with homologous functions localized to this region of the virus can be readily identified for many different herpesviruses, only a limited number of these proteins exhibit significant structural homologies (Mocarski and Tan Courcelle, C., 2001). Despite these similarities, a large number of structural proteins appear to be unique for each subfamily of herpesviruses and in some cases, such as HCMV, several tegument proteins have no counterparts in alphaherpesviruses (Mocarski and Tan Courcelle, C., 2001). Together, these findings suggest that, although common themes likely exist for herpesvirus assembly, it is almost certain that distinct aspects of the assembly pathway of each of these viruses will be identified and these differences in the assembly of different herpes viruses could point to key features of the infectious cycle of these viruses.

Early studies of the assembly of alphaherpesviruses including HSV suggested that virion envelopment occurred at the nuclear membrane (Campadelli-Fiume *et al.*, 1991; Johnson and Spear, 1982). This concept was extended to other herpesviruses including HCMV, even though early studies utilizing electron microscopy suggested major differences between the morphogenesis of these two viruses, both within the infected cell and in the

overall appearance of extracellular virions (Smith and DeHarven, E., 1973). Subsequent studies of alphaherpesviruses provided evidence for nuclear envelopment–de-envelopment followed by envelopment at cytoplasmic membranes (Granzow *et al.*, 1997; Jones *et al.*, 1988; Whealy *et al.*, 1991). These reports provided clear evidence that perinuclear virions contained a different subset of tegument and envelope proteins than mature virions, findings that support acquisition and then loss of an immature envelope by perinuclear virions (Brack *et al.*, 1999; Granzow *et al.*, 1997, 2001; Klupp *et al.*, 2000). These results have been further supported by more recent studies of viruses with deletion mutations in genes encoding both virion envelope and tegument proteins (Brack *et al.*, 1999; Fuchs *et al.*, 2002; Kopp *et al.*, 2003). The elegant studies of pseudorabies virus (PRV) have provided definitive evidence of cytoplasmic virion envelopment and served as a guide for studies of the envelopment of β-herpesviruses (Mettenleiter, 2002). The envelopment of CMVs, specifically HCMV, also appears to take place within a cytoplasmic compartment based on studies of tegument protein trafficking and incorporation into the virion particle (Britt *et al.*, 2004; Sanchez *et al.*, 2000a; Silva *et al.*, 2003). Major gaps remain in the understanding of capsid tegumentation, capsid egress from the nucleus, and cytoplasmic assembly of the mature, infectious HCMV particle. The development of bacterial artificial chromosome (BAC) technology that allows the maintenance of HCMV as infectious clones coupled with the application of techniques of recombinant prokaryotic genetic manipulation has accelerated experimental studies in HCMV assembly (Adler *et al.*, 2003; Borst *et al.*, 1999; Messerle *et al.*, 2000; Smith and Enquist, L. W., 1999). Together with other technologies such as mass spectrometry and cryoelectron microscopy, current studies should provide more definitive understanding of this complex process. In the following review, the focus will be on the assembly of HCMV as a model for betaherpesvirus assembly because the majority of studies have been carried out in systems utilizing HCMV or the related virus, murine CMV (MCMV). When possible, studies of other betaherpesvirus will be discussed.

Assembly of the capsid

Structural studies of the HSV capsid have indicated that structural and functional protein homologues of HSV capsid proteins are present in the capsid of HCMV, HHV-6, and HHV-7 (Table 20.1). Cryoelectron microscopic analysis of the capsids of HCMV and HSV have revealed near identical structures, albeit with slight differences in the floor of the capsid, perhaps because of the larger size of the HCMV genome (Butcher *et al.*, 1998; Chen *et al.*, 1999; Trus *et al.*, 1999; Zhou *et al.*, 2000). Because of this structural conservation, it has been assumed that the assembly of the HCMV capsid as well as capsids of other β-herpesviruses follow a very similar assembly pathway as that of HSV (Steven *et al.*, 1997; Grunewald *et al.*, 2003). The size of the HCMV particle is approximately 2000 angstroms. The nucleocapsid is approximately 1300 angstroms and is of iscosahedral $T = 16$ symmetry (Butcher *et al.*, 1998; Chen *et al.*, 1999). As noted in Table 20.1, there are six identified protein components of the mature HCMV capsid present in the infectious particle (Gibson, 1996). Interestingly, the capsid proteins from both HSV and HCMV share considerable structural and biochemical characteristics and, in the case of MCP, even express cross-reactive antibody binding sites (Rudolph *et al.*, 1990).

The HCMV capsid is composed of 162 capsomeres consisting of 150 hexons and 12 pentons (Butcher *et al.*, 1998; Chen *et al.*, 1999). The most abundant protein components of the capsid is the major capsid protein (MCP, UL86) and the smallest capsid protein (SCP, UL48–49), with 960 and 900 copies respectively present in each capsid. Two copies of the minor capsid protein (MnCP, UL85; triplex dimer or TR-2) combined with a single copy of the minor capsid binding protein (MnCP-bp; triplex monomer or TR-1) UL46 form the triplexes that are located between adjacent pentons and hexons (Fig. 20.1) (Butcher *et al.*, 1998; Chen *et al.*, 1999; Gibson, 1996; Gibson *et al.*, 1996; Trus *et al.*, 1999). The capsid pentons and hexons are assembled entirely from the major capsid protein. Each hexon is decorated on each vertex with the smallest capsid protein (Yu *et al.*, 2005). The smallest capsid protein of HSV, Vp26, has been shown to be dispensable for capsid assembly in cell culture, whereas deletion of the HCMV homologue results in the loss of infectivity, presumably by preventing the assembly of infectious virions (Borst *et al.*, 2001). A cartoon depicting the assembly pathway is detailed in Fig. 20.1.

Protein interactions and capsid assembly

As noted above, evidence from transmission electron microscopy and cryo-EM, combined with the conservation of capsid protein function, suggests that the capsid assembly of HCMV and other betaherpesviruses closely follows that of HSV (Beaudet-Miller *et al.*, 1996; Gibson, 1996, Gibson *et al.*, 1996, 1990, 1993; Welch *et al.*, 1991a,b; Wood *et al.*, 1997; Grunewald *et al.*, 2003). Yet several unique features of the HCMV capsid such as the role of the smallest capsid protein in production of infectious virions suggest that there are differences in the assembly of capsids of these two viruses. Although the atomic structure of HCMV capsid proteins has not been determined, several reports have characterized some of the more relevant protein–protein

Table 20.1. Proteins of the capsid of β-herpesviruses: comparison with HSV

Protein	HSV	HCMV[1]	HHV-6; HHV-7[2]
Major capsid protein	Vp5 (UL119)	MCP (UL86)*	U57
Small capsid protein	Vp26 (UL35)	SCP (UL48A)*	U32
Minor capsid protein[3]	Vp 23(UL18)	MnCP (UL85)*	U56
Minor capsid protein[3]	Vp19c (UL38)	MnCP-bp (UL46)*	U29
Assembly protein	Vp 22a (UL26.5)	Assembly protein (UL80.5)	–
Assembly protein precursor	Vp21(UL26)	Assemblin precursor$_{COOH}$ (UL80a)	U53
Assembly protein precursor	Vp24 (UL26)	Assemblin (UL80a)*	–
Portal protein	Vp (UL6)	UL104	U76

[1] The * indicates capsid proteins that have been demonstrated in infectious virions. Pre-B capsids are thought to contain products of both the UL80a and UL80.5 orfs, mature virions have also been shown to contain products of the UL80a orf, but not UL80.5. Modified from Gibson (Gibson, 1996)

[2] Homologous orf from HHV-6 and HHV-7 based on published nucleotide sequence (Dominguez *et al.*, 1999; Gompels *et al.*, 1995; Nicholas, 1996)

[3] The MnCP (UL85) is also referred to as the triplex dimer protein or TR-2 and the MnCP-bp is referred to as the triplex monomer protein or TR-1.

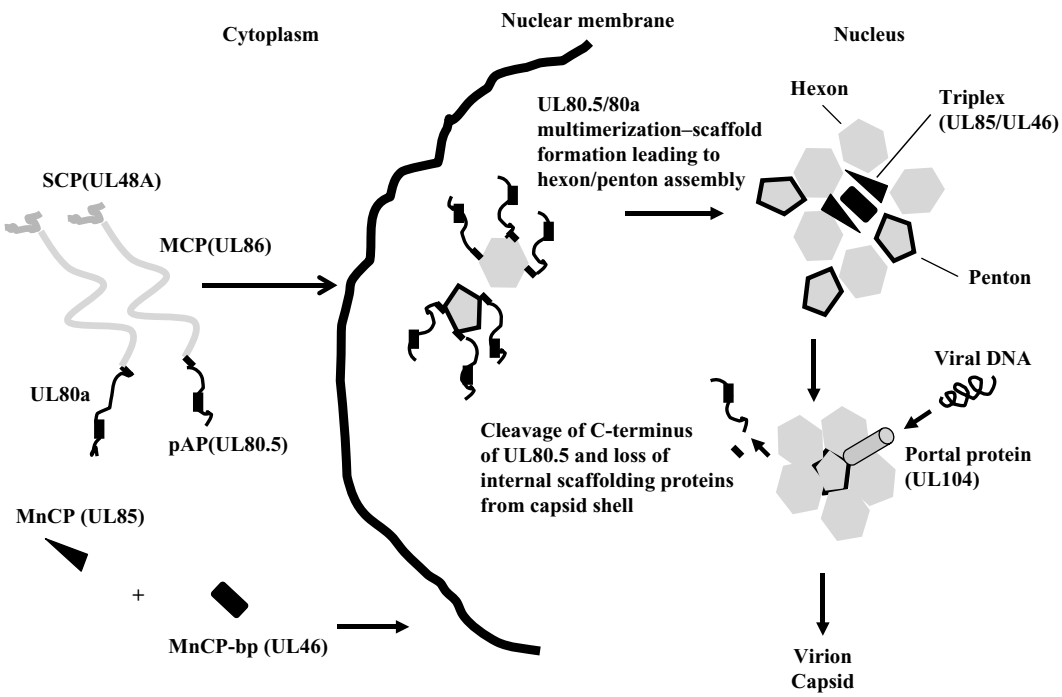

Fig. 20.1. Model of HCMV encapsidation. (1) The capsid proteins MCP, SCP, and products of the UL80a and UL80.5 orf that contain a MCP binding domain are thought to interact in the cytoplasm and are then translocated into the nucleus of the infected cell. The MnCP (UL85) and MnCP-bp (UL46) are also translocated into the nucleus but not as part of the SCP/MCP/UL80a,80.5 complex. (2) Once in the nucleus, self-interaction domains in the products of the UL80a (assemblin precursor) or the UL80.5 (assembly protein) lead to formation of pentons and hexons and the generation of the capsid scaffold. These structures then interact with the triplex formed between MnCP and MnCP-bp and pre-capsid shells form. (3) Unit length viral DNA is inserted into the capsid shell by proteins of the packaging/terminase complex including the proteins encoded by the UL89 and UL56 orfs through the capsid portal formed by the products of the UL104 orf. Coupled with the entry of viral DNA is the extrusion of the assembly protein (and forms of the assembling precursor secondary to cleavage at the carboxyl domain of these proteins). Nomenclature and model adapted from Gibson (Gibson 1996).

interactions that appear to be required for HCMV capsid assembly. The identity of participating cellular proteins and in many cases the temporal order of protein–protein interactions that lead to capsid formation remain undefined. The template for HCMV capsid assembly can be derived from the pioneering studies of HSV capsid assembly from several laboratories (Heymann *et al.*, 2003; Newcomb *et al.*, 1994, 1996, 1999, 2001; Oien *et al.*, 1997; Tatman *et al.*, 1994; Zhou *et al.*, 2000).

The initial steps of capsid assembly involve formation of a scaffold for the generation of the capsid subunit and the pre-capsid structures, protein interactions between the MCP and UL80a and UL80.5, and possible interactions between MCP and SCP. The scaffolding protein(s) of HCMV has been identified as gene products of UL80a and UL80.5 ORFs (Welch *et al.*, 1991a, b). These genes are organized as nested, in-frame 3-coterminal genes that give rise to four transcripts and four gene products with common carboxyl termini (Welch *et al.*, 1991a). The largest transcript is derived from UL80a and encodes the proteinase precursor which includes the HCMV proteinase in the amino terminal half of the precursor and the assembly protein in the carboxyl terminal half (Welch *et al.*, 1991a,b). Self-cleavage of UL80a by the proteinase function leads to generation of the assemblin and a COOH terminal fragment that overlaps with UL80.5 (Welch *et al.*, 1991b). The role of this protein in capsid assembly appears to be analogous to that reported for the HSV scaffolding protein, VP24 (Liu and Stinski, 1992b; Preston *et al.*, 1992, 1994; Tatman *et al.*, 1994). A second protein, the assembly protein, is the product of UL80.5, a nested ORF collinear with the carboxyl terminus of UL80a. The proteins encoded by the longest ORF, UL80a, and the UL80.5 ORF both express a conserved domain (CCD) at the extreme carboxyl terminus that has been shown to interact with the HCMV MCP (Gibson, 1996; Wood *et al.*, 1997). This interaction is required for nuclear translocation of the MCP (and presumably SCP) because the MCP lack a nuclear localization signal and its mass of 150 kDa would exclude it from passive nuclear entry. Consistent with this prediction is the finding that expression of MCP in the absence of other viral proteins results in cytoplasmic localization (Beaudet-Miller *et al.*, 1996; Lai and Britt, W. J., 2003; Nicholson *et al.*, 1994). Because a conserved functional nuclear localization signal is present in the C-terminal domain of UL80.5 as well as some forms of UL80a, interaction between these proteins and MCP results in the nuclear translocation of MCP (Beaudet-Miller *et al.*, 1996) as depicted in Fig. 20.1. An amino-terminal conserved domain (ACD) can be found in the amino terminal domain of UL80.5 and the corresponding cleavage product of UL80a. This domain promotes self-interaction and has been suggested to lead to the generation of UL80a and UL80.5 multimers (Beaudet-Miller *et al.*, 1996; Gibson, 1996; Wood *et al.*, 1997). The self-interaction, together with interactions with MCP, is thought to catalyze the association of MCP into multimers leading to the formation of intranuclear hexons and pentons (Fig. 20.1) (Gibson, 1996). Interestingly, the SCP has also been shown to interact with the MCP in the absence of other viral proteins (Lai and Britt, W. J., 2003). The sequences of SCP that are responsible for this interaction have been mapped but the functional significance of this interaction has not been studied in the context of replicating virus (Lai and Britt, W. J., 2003). The interaction between these two abundant and essential components of the capsid raises several important questions, including if the observed interaction between the SCP and MCP is critical for structural events leading to capsid assembly or for a downstream event in virion assembly such as capsid/tegument interactions required for capsid tegumentation and virion assembly. Interactions between the products of the UL85 and UL46 have also been demonstrated by two-hybrid systems (Gibson *et al.*, 1996). This interaction is required for the formation of the triplexes of the capsid and presumably results in a conformational change that allows their positioning between capsomeres. The interacting sequences of this set of capsid proteins have not been unequivocally mapped, perhaps as a result of the limited solubility of the protein products of UL46 and their aggregation by heating (Gibson *et al.*, 1996).

Capsid maturation and DNA packaging

Once the immature shell of the capsid is formed, viral DNA must be packaged into this immature capsid or precapsid to generate a mature nucleocapsid. In studies of HSV the packaging of unit length viral DNA takes place in a well described pathway in which capsid maturation and DNA packaging appear to be coupled (Heymann *et al.*, 2003; Steven and Spear, 1997). However, capsid assembly and most aspects of capsid maturation can take place in the absence of viral DNA as evidenced by HSV capsid formation in a virus-free and in an in vitro cell free system (Newcomb *et al.*, 1994; Tatman *et al.*, 1994). The final step in HCMV capsid maturation, based on models of HSV capsid assembly, involve proteolytic cleavage of the carboxyl terminal MCP binding domain (M domain) of UL80.5 and M domain containing forms of UL80a in the shells of the immature B-capsids and including any full length UL80a that may be present in these precapsid forms (Gibson, 1996). The loss of the UL80 encoded scaffolding structures appears to be coupled to viral DNA packaging (Gibson, 1996; Lee *et al.*, 1988). Unit length viral DNA enters the maturing

capsid presumably through an asymmetric site of the capsid structure that based on the HSV model, contains a portal protein. In the case of HCMV, the portal protein has been proposed to be encoded by the UL104 product (Komazin *et al.*, 2004). Entering viral DNA is thought to lead to extrusion of the cleavage products of the UL80 from the virion capsid (Gibson, 1996). It is likely that fragments of UL80a or 80.5 remain in the capsid; however, their role in the maintenance of the structure of the virion capsid is unclear.

The packaging of viral DNA is mediated through virus-encoded protein recognition of two conserved sequence motifs, the *pac-1* and *pac-2* sequences, that are located in the *a* sequence at each end of the viral genome (Mocarski and Tan Courcelle C., 2001). The virus proteins mediating packaging comprise the viral terminase complex that consists of at least two proteins, the products of the UL56 and UL89 orfs, that function together with the UL104 portal protein (Bogner *et al.*, 1998; Giesen *et al.*, 2000; Scheffczik *et al.*, 2002; Scholz *et al.*, 2003). The product of UL56 is a 130 kDa protein that has been shown to bind to AT rich sequences in the *pac* sequences and also to have nuclease activity, both activities that suggest its role in packaging as well as cleavage of viral DNA (Bogner *et al.*, 1998; Scholz *et al.*, 2003). More recently, studies from this same laboratory have suggested that the product of the UL89 ORF, a 75 kDa protein, is actually responsible for the DNA cleavage activity that has been assigned to the terminase complex (Scheffczik *et al.*, 2002). Interestingly, the activity of several members of a group of antiviral drugs that have in common a benzimidazole core structure has been shown to map to UL89 and UL56 (Krosky *et al.*, 1998). Although these two proteins are essential for the recognition and packaging of unit length viral DNA, several unexpected findings in studies of the mechanism of action of the benzimidazole antiviral drugs, including maribavir, have suggested that other virus-encoded proteins could be present in this cleavage-packaging complex.

Nuclear tegumentation and nuclear egress

Reports from several laboratories in the early 1990s resolved several inconsistencies in the literature of alphaherpesvirus envelopment. These studies lead to a model in which virion capsids are initially enveloped at the nuclear envelope and following a de-envelopment step at the outer nuclear membrane are delivered to the cytoplasm for final envelopment at cytoplasmic membranes (Brack *et al.*, 1999; Jones and Grose, C., 1988; Skeppner *et al.*, 2001; Wang *et al.*, 2000; Whealy *et al.*, 1991; Zhu *et al.*, 1995). These studies of capsid egress from the nucleus of HSV (or PRV, VZV) infected cells have been illuminating, but differences in cellular tropism, replication, virion protein composition and virion morphology between betaherpesviruses and alphaherpesviruses suggest that virion assembly distal to the nuclear events of encapsidation could be significantly different. Furthermore, more recent studies have demonstrated that a significant number of tegument proteins encoded by HCMV lack sequence homologues in HSV, and in some cases virion tegument proteins of one betaherpesvirus (HCMV) do not have homologues in other betaherpesviruses, including other cytomegaloviruses. Finally, the changes in the size and morphology of the nucleus that are observed in HCMV infected primary fibroblasts are characteristic of the cytopathic effect of this virus and distinct from changes in cells infected with HSV or PRV. As a result, investigators studying the assembly of HCMV and other betaherpesviruses have postulated models for nuclear egress and envelopment that could be specific to this group of viruses.

Perhaps the most poorly understood aspect of the assembly of herpesviruses is the tegumentation of virion particle. In addition to the undefined number of proteins in the tegument, it remains to be determined whether the essential function of individual tegument proteins is regulatory such as pp71 (UL82), interference with host responses such as pp65 (UL83), structural such as pp28 (UL99), or in some cases multifunctional (Baldick *et al.*, 1997; Browne *et al.*, 2003; Kalejta and Shenk, T., 2003; Liu and Stinski, 1992a; Silva *et al.*, 2003). Thus, genetic deletions affecting ORFs encoding tegument proteins that result in loss of infectivity could be ascribed to several possible mechanisms other than a block in the assembly of an infectious particle secondary to the loss of an essential structural protein. Furthermore, the trafficking of nuclear tegument proteins that eventually are incorporated into the infectious particle remains almost completely unstudied. Examples of the different distribution of HCMV tegument proteins are illustrated in Table 20.2. The most striking aspect of the differing cellular localization of this subset of tegument proteins is that virus assembly presumably requires organization of the tegument to insure ordered incorporation of tegument proteins as well as maintenance of essential protein–protein interactions.

This can be readily explained by a radial distribution of tegument proteins in the particle and by the sequential addition of these proteins during nucleocapsid transit from the nucleus through cellular compartments that are used for final assembly. However, cryoelectron microscopic analysis of the virion structure, although consistent with the sequential acquisition of tegument proteins, has not provided definitive evidence for such a pathway leading to tegument assembly (Chen *et al.*, 1999; Trus *et al.*, 1999).

Table 20.2. Cellular localization of a subset of HCMV tegument proteins

		Cellular localization in productive infection		
ORF	Protein	Nucleus	Cytoplasm	Nucleus and cytoplasm
UL25	ppUL25	−	+	−
UL26	ppUL26	+	−	−
UL32	pp150	+[2]	+	−
UL48	pp200	+	−	−
UL50	p35	+	−	−
UL53	pp38	+	−	+[1]
UL69	ppUL69	+	−	−
UL82	pp71	+	−	?
UL83	pp65	+	−	+[1]
UL94	pp36	+	−	−
UL99	pp28	−	+	−

[1] This set of tegument proteins remains localized exclusively to the nucleus until late in the replication cycle and then can be found in both the nucleus and cytoplasm.
[2]Nuclear localization of pp150 can be demonstrated with different conditions of fixation.

Thus, the assembly of the tegument layer of HCMV remains unclear and may involve nuclear tegumentation and de-tegumentation as has been proposed for PRV (Fuchs *et al.*, 2002; Granzow *et al.*, 1997, 2001). Studies of the alphaherpesvirus PRV have demonstrated that nuclear viral capsids are essentially free of detectable tegument proteins and acquire tegument entirely in the cytoplasm (Granzow *et al.*, 1997, 2001). From a combination of elegant electron microscopic analyses and studies of viral deletion mutants, Mittenleiter and colleagues have proposed compelling arguments that the PRV capsid interacts with non-structural virus-encoded nuclear proteins that facilitate capsid envelopment and de-envelopment at the nuclear envelope (Fig. 20.2) (Mettenleiter, 2002). The virus-encoded proteins UL31 and UL34 of PRV are thought to be essential for nuclear egress and have been shown to be localized to the nucleus of infected cells but cannot be detected in the virion (Fuchs *et al.*, 2002). The viral and/or cellular proteins that participate in these nuclear fusion events, other than UL31 and UL 34, have not been identified. Although this model of PRV nuclear egress is consistent with a number of observations from these and other investigators, other examples of tegument protein trafficking fail to fit precisely with this model. An example is the HSV tegument

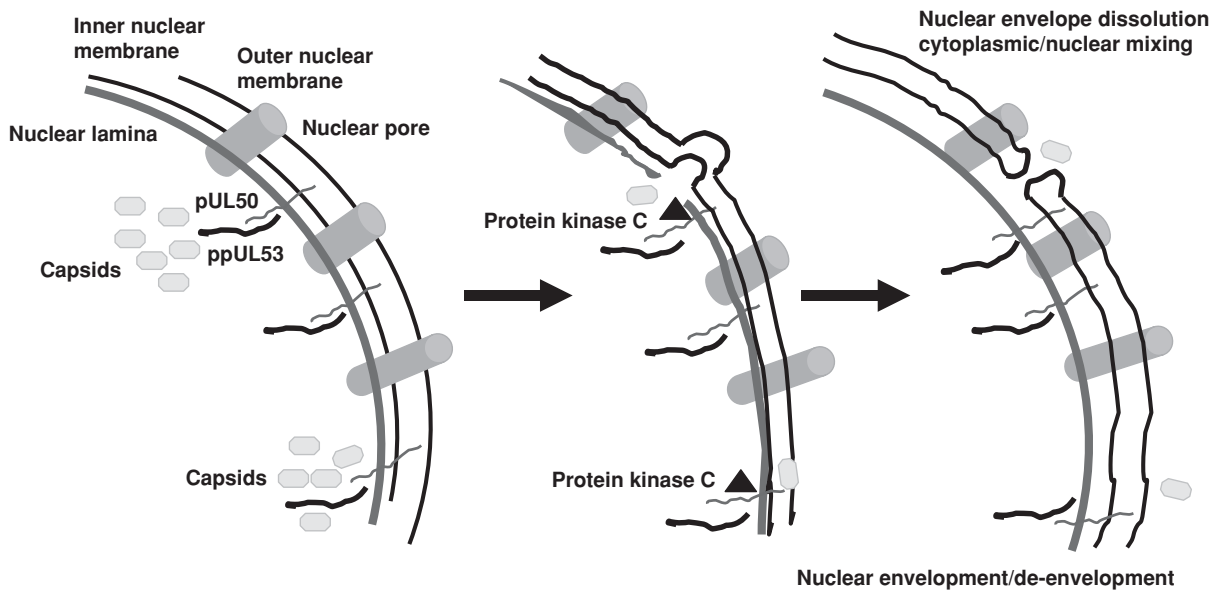

Fig. 20.2. Two models of nuclear egress of the HCMV capsid. The structure of the bi-leaflet nuclear envelope and underlying nuclear lamina is shown. Nuclear pore complexes are depicted as cylinders. Focal accumulation of intranuclear capsids adjacent to inner nuclear membrane domains containing viral proteins encoded by UL50 and UL53, with UL50 shown inserting into inner nuclear membrane. In the top model, nuclear lamina dissolution secondary to lamin phosphorylation associated with localization of protein kinase C activity leads to nuclear envelope herniation, nuclear cytoplasmic mixing and eventual capsid release into the cytoplasm (Muranyi *et al.*, 2002). The nuclear envelope rapidly reseals resulting in only transient nuclear/cytoplasmic mixing. In the bottom model, the focal accumulation of capsids and their interaction with as yet unidentified cellular or virus-encoded proteins leads to a fusion with the inner nuclear envelope protein, translocation into intranuclear space and a second event leading to budding into the cytoplasm. Note the second mechanism of capsid egress is also postulated to require nuclear lamina dissolution.

protein Vp22 (UL49) that has been shown localized to the nucleus of the infected cell and cannot be detected on immature perinuclear capsids, yet it is eventually incorporated into the virion as a tegument protein, presumably during cytoplasmic tegumentation (del Rio *et al.*, 2002). Early electron microscopic findings indicated that the cytoplasmic forms of HCMV contained a considerably thicker tegument as compared to HSV (and presumably PRV) and it is well known that numerous HCMV nuclear tegument proteins are present in the virion. Thus, it is likely that nuclear egress of the HCMV capsid is more complex than the models proposed for alphaherpesviruses. This HCMV pathway of nuclear egress could involve nuclear tegumentation, de-tegumentation, and a final tegumentation that would incorporate virion tegument proteins that localize to the nucleus, or even more simply, both nuclear and cytoplasmic tegumentation.

Early studies of HCMV egress noted that virion structural proteins could be localized to the nuclear matrix of virus infected cells (Sanchez *et al.*, 1998). The nuclear matrix of eurkaryotic cells can be viewed as the cytoskeleton of the nucleus. This nuclear structure has been shown to be a site of transcription and DNA replication, including for DNA viruses (Pombo *et al.*, 1994; Schirmbeck *et al.*, 1989). Major components of the nuclear matrix include the nuclear lamins, a group of cellular proteins that represent the intermediate filaments of the nucleus (Stuurman *et al.*, 1998). Nuclear lamins are known to play an important role in the integrity of the nuclear envelope and have been shown to link the nuclear matrix with the inner membrane of the nuclear envelope through their interactions with a number of integral membrane proteins in the inner nuclear membrane, thus creating what is referred to as the nuclear lamina. The finding of a specific interaction of HCMV virion tegument proteins with the nuclear matrix, and in particular lamin B, raised the possibility that this interaction could represent a pathway of nuclear egress of tegumented capsids (Sanchez *et al.*, 1998). Studies have demonstrated that nuclear lamin phosphorylation and dephosphorylation can be coupled with loss of lamin structure and, in some cases, the disruption of the nuclear envelope (Steen *et al.*, 2000; Stuurman *et al.*, 1998). Lamin phosphorylation has been demonstrated in HCMV infected cells and it was initially suggested that either an intrinsic kinase activity of an HCMV encoded protein or a cellular kinase activity localized to regions adjacent to the nuclear envelope could account for phosphorylation of nuclear lamins (Muranyi *et al.*, 2002; Radsak *et al.*, 1991). The focal loss of nuclear envelope integrity has been suggested to contribute to the nuclear egress of the HCMV capsid (Gallina *et al.*, 1999; Sanchez *et al.*, 1998). However, it should be noted that loss of lamin structure alone cannot account for loss of nuclear membrane integrity.

Consistent with proposed mechanisms of egress of HCMV that include a focal loss of nuclear membrane integrity have been studies of the Vpr protein of HIV-1. Expression of this virus-encoded protein has been shown to be associated with the focal loss of nuclear membrane integrity and mixing of cytoplasmic and nuclear proteins (de Noronha *et al.*, 2001). A recent study utilizing murine CMV as a model system reported similar findings by demonstrating that two non-structural nuclear proteins encoded by m50 and m53 could localize host protein kinase C activity to an area adjacent to the nuclear envelope (Muranyi *et al.*, 2002). The redistribution of protein kinase C activity resulted in the phosphorylation of lamins A and C at levels that could be associated with loss of structural integrity of the inner nuclear membrane (Muranyi *et al.*, 2002). The m50 and m53 are sequence homologues of the alphaherpesvirus UL34 and UL31, respectively, and are believed to represent the functional homologues of these proteins. Similar to the alphaherpesvirus UL34 protein, the m50 product is a type II membrane protein that contains motifs with limited homology with known integral membrane proteins of the nuclear envelope (Muranyi *et al.*, 2002). Because both m50 and m53 encode essential functions for virus replication, this finding suggests that nuclear egress of CMVs could require focal disruption of the nuclear lamins leading to the loss of the integrity of the inner nuclear membrane. The homologous proteins of HCMV, pUL50 and ppUL53, have also been shown to be essential for virus replication and interestingly, ppUL53 can be detected in the virion tegument, suggesting that it has an additional role in virus assembly other than its proposed function in facilitating nuclear egress (Dal Monte *et al.*, 2002). Studies of ppUL53 trafficking indicate that, in the absence of other virus-encoded proteins, it is expressed only in the nucleus but that it can be detected in both the nucleus and the virus assembly compartment in virus infected cells late in infection (Dal Monte *et al.*, 2002) (W. Britt, unpublished data). Thus, in contrast to findings in the PRV, one of the essential nuclear virus-encoded proteins that is thought to be required for modification of the nuclear envelope is also found within the tegument of the mature virion. It is unclear if HCMV pUL50 is present in the virion tegument. Expression of the abundant HCMV virion tegument protein pp65 (UL83) is also restricted to the nucleus of infected cells secondary to a functional bipartite nuclear localization signal until late in infection when it is distributed in the cytoplasm and can be detected predominantly in the assembly compartment (Sanchez *et al.*, 2000a). These findings would indicate that either HCMV

virions are partially tegumented in the nucleus or that nuclear tegument proteins have trafficking pathways to sites of tegument assembly in the cytoplasm.

Other models of nuclear egress have been proposed yet insufficient data is available to determine their validity. In studies of HHV-7, Frenkel and co-workers described an intranuclear, cytoplasmic vacuole or invagination that appeared to be a site of nuclear budding of the mature capsid (Roffman *et al.*, 1990). This structure designated a tegusome and was identified by electron microscopic analysis of infected cells (Roffman *et al.*, 1990). This structure provided an explanation consistent with the incorporation of virus-encoded nuclear proteins into the tegument of the mature particle. Similar structures have not been identified in other betaherpesviruses.

A pathway of egress of herpesvirus capsids from nucleus that unifies available data has yet to be described. However, it is clear that these viruses have devoted at least some of their genomic information to encode proteins that can either directly modify key structures of the nuclear envelope or recruit cellular functions to the nuclear membrane. These findings would suggest that immature capsids (and possibly tegumented capsids) could exit the nucleus through focal herniations of nuclear membrane as proposed for the function of Vpr of HIV. Alternatively, translocation of the capsid across the nuclear envelope into the cytoplasm of the infected cell could require a membrane fusion event, a mechanism that is favored by the bulk of the literature describing alphaherpesvirus assembly.

Cytoplasmic tegumentation and envelopment

Final tegumentation and envelopment of the infectious betaherpesvirus particle appear to occur exclusively in the cytoplasm of the infected cell. Studies that have described the trafficking of virion tegument and envelope proteins have led to several proposed models of cytoplasmic assembly of the infectious virion. Two studies of HCMV utilizing cryoelectron microscopy indicated that the tegument layer adjacent to the capsid exhibited aspects of iscosahedral symmetry and, from estimates of the mass of the presumed tegument protein that occupied this layer, one group of investigators argued that the protein adjacent to the capsid was pp150 (UL32) (Trus *et al.*, 1999); however, the identity of the protein was not pursued either biochemically or immunologically. The suggestion that the tegument protein pp150 was adjacent to the capsid raised the possibility that this virion protein was acquired during nuclear egress of the capsid. The distribution of pp150 within infected cells was initially proposed to be nuclear and cytoplasmic, although a subsequent study that employed a larger number of viral and cell markers suggested that pp150 was expressed only in the cytoplasm of infected cells (Hensel *et al.*, 1995; Sanchez *et al.*, 2000a). In this latter study, pp150 was used to define an isolable cellular compartment that was designated as the assembly compartment (Sanchez *et al.*, 2000a). This compartment was shown to be localized to a juxtanuclear site that was in close proximity to the microtubular organizing center (MTOC) of infected cells (Sanchez *et al.*, 2000a). Subsequent studies from other laboratories have also identified this cytoplasmic structure (Dal Monte *et al.*, 2002; Silva *et al.*, 2003). A number of both nuclear and cytoplasmic localized tegument proteins have been shown to localize to the assembly compartment, including many of the proteins listed in Tables 20.2 and 20.3. Isolation of this compartment by centrifugation of cell lysates over density gradients allowed the identification of both tegument and envelope proteins, including processed glycoprotein B (gB, UL55) within in this compartment, consistent with this compartment being a site of virus envelopment and assembly. The trafficking and accumulation of virion proteins and subviral structures to this site is not understood; however, recent studies of tegument protein trafficking coupled with a greater understanding of glycoprotein trafficking are beginning to suggest model pathways for its formation within infected cells and may represent a cytoplasmic inclusion identified in early studies of HCMV morphogenesis.

Tegument protein trafficking and incorporation into the particle

Although it is likely that understanding the trafficking of virion tegument proteins will be key to understanding the assembly of the infectious particle, little is known about the localization of these proteins to the assembly compartment. One structural tegument protein for which some features of its intracellular trafficking are known is pp28 (UL99). Studies demonstrated that this small (191 amino acid) myristylated protein is membrane associated and when expressed in the absence of other viral proteins, is retained in the ER/Golgi intermediate compartment (ERGIC) (Sanchez *et al.*, 2000b). In virus infected cells, pp28 is transported to the assembly compartment, where it localizes with envelope glycoproteins and with other tegument proteins including pp150 (Sanchez *et al.*, 2000a; Silva *et al.*, 2003). Recombinant viruses in which the gene encoding UL99 has been deleted, the reading frame has been interrupted, or the protein mistargeted in the infected cell by deletion of the myristylation site are non-infectious and non-enveloped particles were observed in the cytoplasm of cells infected with the mutant pp28 deletion virus (Britt

Table 20.3. HCMV envelope glycoproteins

Glycoprotein	Orf[1]	Complex formation	Essential for infectivity	Proposed function
gB	UL55(U39)	oligomer	Yes	Attachment/fusion
gH	UL75 (U48)	gH/gL/gO	Yes	Fusion/penetration
gL	UL115(U82)	gH/gL/gO	Yes	Fusion/penetration
gO	UL74(U100[2])	gH/gL/gO	Yes	Fusion/penetration
gM	UL100(U72)	gM/gN	Yes	Unknown
gN	UL73(U46)	gM/gN	Yes	Unknown
gpTRL10	TRL10	Unknown	No	Unknown
gpUL132	UL132	Unknown	No	Unknown

[1] Homologous orf from HHV-6 and HHV-7 based on published nucleotide sequence are shown in parentheses (Dominguez *et al.*, 1999; Gompels *et al.*, 1995; Nicholas, 1996).
[2] Note the HHV-6 functional homologue of HCMV gO has been identified as the glycoprotein encoded by HHV-6 orf U100 and has been designated gQ (Mori *et al.*, 2003).

et al., 2004; Jones and Lee, 2004; Silva *et al.*, 2003). Interestingly, the virion assembly compartment was formed in cells infected with the UL99 deletion mutant, indicating that this protein was not required for trafficking of other tegument and presumably envelope proteins to this cytoplasmic compartment. The trafficking of other tegument proteins, including nuclear tegument proteins, to the assembly compartment has not been studied in sufficient detail to allow investigators to develop a model of HCMV tegument assembly.

Envelope glycoprotein trafficking and envelopment of the particle

Similar to the uncertainties that surround the structure and composition of the tegument, the envelope of HCMV remains poorly defined. Although the analysis of the coding sequence of HCMVs suggest that as many as 50 ORFs could encode proteins with N-linked carbohydrate modification, to date, some eight experimentally defined virus specific glycoproteins have been shown to be present in the virion envelope (Table 20.3). At least six of these have been shown to exist as disulfide-linked oligomers (gB, gH/gL/gO; gM/gN) in the virion, a characteristic of CMVs that at first glance appears unique in the herpesvirus family. Formation of these disulfide-linked oligomers takes place in the ER prior to transport of these complexes through the secretory pathway. When expressed in the absence of other viral proteins, glycoproteins (gB) or complexes of glycoproteins (gH/gL/gO; gM/gN) listed in Table 20.3, with the exception of gpTRL10, traffic to Golgi and post-Golgi compartments.

Many of these glycoproteins have been shown to contain well-described signals within their cytoplasmic domains that enable them to utilize the cellular secretory pathway for intracellular trafficking. Examples of these signals include phosphorylated amino acid residues and acidic amino acid clusters that are recognized by cellular adaptor proteins including PACS-1 that localize proteins to the TGN, tyrosine and di-leucine signals that promote glycoprotein retrieval from the cell surface and possibly from other cellular membranes through their interactions with cellular adaptor proteins, and likely other motifs that facilitate interactions with tegument proteins (Crump *et al.*, 2003; Jarvis *et al.*, 2002, Tugizov *et al.*, 1999). Although the role of these various signals on individual glycoproteins has been shown in many cases to function in intracellular trafficking as predicted based on studies of similar signals on other viral glycoproteins, it remains unclear what role these signals play in the assembly and infectivity of the mature virion. As an example, it has been argued that gB in the envelope of infectious virus was derived from cell surface gB retrieved from the cell surface by endocytosis and targeted to the TGN, a presumed site of virus assembly (Radsak *et al.*, 1996; Tugizov *et al.*, 1999). Yet recent studies have shown that mutation of this targeting signal in gB has no effect on the phenotype of the mutant virus when compared to wild-type virus (Jarvis *et al.*, 2002). This latter finding raises several possible interpretations such as a redundancy of targeting signals in the cytoplasmic domain of HCMV virion glycoproteins or that additional intracellular pathways are operative in cells infected with this virus that enable the virion glycoproteins to localize in the assembly compartment. However, it is important to note that several of these glycoproteins have very conventional targeting motifs that are conserved in their cytoplasmic domains, a finding that suggests that well-described cellular pathways of viral

glycoprotein localization are utilized during virion assembly. A complete discussion of the intracellular trafficking of these proteins is beyond the scope of this section but, because of the potential cooperativity between proteins and redundancy of function, many of the observations made in the study of individual HCMV glycoproteins in isolation from virus infection could be of limited value in definition of their role in assembly and function in the mature virion. The development of recombinant systems that enable investigators to insert specific mutations should help address these aspects of HCMV envelopment.

The mechanisms leading to final envelopment of the infectious HCMV or other betaherpesvirus particles have not been described. In fact, localizing the virion tegument proteins and envelope glycoproteins to an isolable cellular compartment suggests that envelopment takes place after tegumentation of the nucleocapsid. The recent findings that described unenveloped particles in the cytoplasm of cells infected with the UL99 (pp28) deletion virus supports a working model of envelopment that includes budding of a tegumented capsid through a membrane that contains viral envelope glycoproteins (Silva *et al.*, 2003). The source of the membrane structure and the mechanisms that localize the large number of glycoproteins to this single membrane have not been well described but recent studies of the trafficking of HCMV UL33 and UL27 have suggested that virions were wrapped in membrane tubules as well as budding into multivesicular bodies, structures connected with the endosomal system (Fraile-Ramos *et al.*, 2001). The location of these membranous structures in a juxtanuclear compartment and the differentiation of this compartment from Golgi and TGN are consistent with previous studies of the virus assembly compartment identified in virus infected cells (Fraile-Ramos *et al.*, 2001; Sanchez *et al.*, 2000a; Homman-Londiyi *et al.*, 2003). Previous studies also suggested that HCMV was enveloped in an endosomal compartment (Tooze *et al.*, 1993). Other enveloped viruses, most notably retroviruses, have been shown to utilize a pathway that includes budding into late endosomal compartments during their assembly (Amara *et al.*, 2003; Pelchen-Matthews *et al.*, 2003). If such cellular structures are ultimately shown to be a site of HCMV envelopment (budding), it could follow that HCMV exits the infected cell by a similar exocytic pathway (Gould *et al.*, 2003).

Viral modulation of the host response to infection

A. Louise McCormick and Edward S. Mocarski, Jr.

Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford CA

Betaherpesviruses such as HCMV dramatically affect host cell physiology and encode a wide variety of functions that modulate the infected host cell as well as the immune response (Mocarski, 2002, 2004). Major structural and nonstructural proteins modulate host cell transcriptional repression (Saffert and Kalejta, 2006, Tavalai *et al.*, 2006), cell-intrinsic responses (Abate *et al.*, 2004; Goldmacher, 2004), responses to interferon (Child *et al.*, 2004; Khan *et al.*, 2004) and natural killer (NK) lymphocytes (Lodoen and Lanier, 2005), and adaptive antibody or T-lymphocyte immunity (Chapter 62). The host immune components that are targets of modulation by HCMV are the same host functions that are important in suppressing virus infection, suggesting that the balance between host clearance and viral escape mechanisms dictates many aspects of viral pathogenesis. By reducing the overall impact of antiviral defenses, HCMV seems to be able to escape the full brunt of host innate and adaptive immunity, thereby allowing the virus to persist. It now appears that an overwhelming majority of viral gene products are dedicated to modulation of host cell and immune modulation (Chapter 15). The overwhelming majority (~100 gene products) may be implicated in modulation because they are dispensable for replication in cultured fibroblasts (Dunn *et al.*, 2003; Yu *et al.*, 2003).

During infection, HCMV and other cytomegaloviruses have a striking impact on cellular gene expression, cell cycle progression, and cellular behavior. More limited information suggests that roseolaviruses, HHV-6A, HHV-6B, and HHV-7 have a similar impact on cells (Chapters 18 and 47). In HCMV several major phases of cellular modulation occur. An interferon-like stimulation of host cells immediately follows virus entry due to the effect of virus particles (see Chapter 16) even though cellular alarm systems involved in IRF-3 and apoptosis are defused. Activation of viral gene transcription by derepression of histone deacetylase activity underlies expression of viral gene products (see Chapters 17 and 18). A dysregulation of cell cycle progression follows early viral gene expression (see Chapter 18) and extends through a pseudo-S phase, and can culminate in pseudomitosis (a property that varies among viral) (Hertel and Mocarski, 2004). A poorly understood process results in the death of the host cell following several days of productive replication. All of these likely vary with host cell type and susceptibility, and all of these may impact replication efficiency. Modulation of host cell and host cell behavior is also a factor in pathogenesis, possibly mediating important stages and cell type specific events during acute and chronic disease in the infected host. Thus, specific HCMV-encoded proteins have been shown to modulate interferon regulated factor (IRF)-3, host cell susceptibility to apoptosis, induction and activity of host cytokines and interferons, stability and cell surface expression of both classical and non-classical major histocompatibility complex (MHC) proteins, and many key processes involved in host cell signaling, gene expression, and metabolism (Mocarski, 2002, 2004; Mocarski and Courcelle, 2001). Together, these broad modulatory capabilities likely contribute to the success of the betaherpesviruses as ubiquitous pathogens. Although many interface with known cellular growth control points in ways that are better studied in the gammaherpesviruses, little evidence supports an oncogenic role for this group of viruses. The impact of HCMV on cells has reinforced the notion that the virus may be involved in acute and chronic diseases affecting the vasculature, and is supported by experiments with rodent cytomegaloviruses. This chapter will focus on viral modulation of the cellular response to betaherpesvirus infection, focusing primarily on HCMV due to the information available.

Modulation of histone deacetylase activity

HCMV replication is stimulated when permissive cells are treated with inhibitors of histone deacetylases (Murphy *et al.*, 2002) or when virus is propagated in cells in which expression of histone deacetylases has been inhibited (Tavalai *et al.*, 2006). Two viral gene products have been implicated in derepression. One major tegument protein, ppUL82 (pp71), also known as the virion transactivator, appears to inactivate Daxx (Cantrell *et al.*, 2005; Everett, 2006; Hofmann *et al.*, 2002; Ishov *et al.*, 2002; Staffert and Kalejta, 2006). The major immediate early protein, IE1-p72, long known to disrupt nuclear domain 10 (ND-10) sites early after infection (Korioth *et al.*, 1996), has been ascribed a role in inactivate a family of promyelocytic leukemia protein (PML) proteins, that also act as repressors of viral gene expression (tavalai *et al.*, 2006).

Modulation of IRF–3

HCMV entry into cells is associated with a dramatic induction of NF-κB (Yurochko *et al.*, 1997a) that is likely to drive the interferon-like response of cells exposed to infectious virus, viral particles, or soluble envelope glycoprotein gB (Simmen *et al.*, 2001; Yurochko *et al.*, 1997a; Zhu *et al.*, 1997, 1998). Although the interferon β transcript is induced in virus-infected cells, even following high MOI infection, interferon itself is only produced in cell cultures subjected to low MOI infection (Rodriguez *et al.*, 1987; Zhu *et al.*, 1997). Several investigators, have described the induction of IRF-3 immediately after infection of permissive fibroblasts (Boehme *et al.*, 2004; Browne and Shenk, 2003; Navarro *et al.*, 1998; Preston *et al.*, 2001), using a variety of viral strains and infection conditions. Induction has been associated with the appearance of a novel IRF-3 complex (Navarro *et al.*, 1998). In contrast, experiments that included both uniform high MOI and use of a monoclonal antibody to detect IRF-3 demonstrated that wild type strains of HCMV fail to induce IRF-3 (Abate *et al.*, 2004), a property that may be shared by rhesus CMV (DeFilippis and Fruh, 2005). Experimental differences in MOI and time post infection, as well as in choice of viral strains and strain variants, may contribute to differences in IRF-3 activation and level of inhibition by pp65 (ppUL83) during infection. Virion pp65 reduces the level of activation of IRF-3 immediately following infection and pp65 expression independent of viral infection is sufficient to inhibit IRF-3 activation by a variety of signals (Abate *et al.*, 2004). In the presence of pp65, there appears to be a transient activation of IRF-3 (Yang *et al.*, 2005) that does not exhibit kinetics consistent with the dramatic impact of virus infection on cells. NF-kB, which has been a topic of study for many years (see below), may also be a target of pp65 depending on experimental conditions (Browne *et al.*, 2003). Even though IRF-3 activation that occurs within 2 h postinfection is likely to be dependent on preformed cytoplasmic protein, the ability of IRF-3 siRNA to increase expression of certain IRF-3 responsive genes and decrease HCMV replication levels has been reported (DeFilippis *et al.*, 2006). The mechanism of IRF-3 regulation over the first few hours of infection will emerge from further mechanistic studies.

Activation of NK-κB and interferon response genes

A classical NF-κB response occurs in two distinct phases following HCMV infection of fibroblasts (Johnson *et al.*, 2001a; Kowalik *et al.*, 1993; Sambucetti *et al.*, 1989; Yurochko *et al.*, 1995). The first phase follows as early as 5 minutes after exposure of cells to virus or virus particles and apparently results from the release of preformed NF-κB mediated by the binding and postattachment events (Boyle *et al.*, 1999; Yurochko *et al.*, 1997a; Netterwald *et al.*, 2004). This initial NF-κB activation may underlie the virion-induced interferon-like response (Browne *et al.*, 2001; Zhu *et al.*, 1997, 1998) and enhance expression of immediate early (IE) genes through the enhancer (DeMeritt *et al.*, 2004). Based on studies with MCMV, the NF-κB sites in the enhancer region may not be essential in all settings (Benedict *et al.*, 2004). NF-κB activation requires phosphorylation-dependent degradation of an inhibitor of NF-κB (IκB), and this degradation is activated in response to infection and continues throughout the infection cycle (Kowalik *et al.*, 1993). Phosphorylation is dependent on a three subunit IκB kinase (IKK) that is both activated and, based solely on the use of chemical inhibitors, required for initiation of viral replication (Caposio *et al.*, 2004) in quiescent fibroblasts. Activation is not critical in actively growing astrocytoma cells (Eickhoff and Cotten, 2005). Deletions made through the enhancer reduce viral replication efficiency in a pattern that suggests a possible role of NF-κB as well as other transcription factor binding sites (Isomura *et al.*, 2004). Another phase of NF-κB activation due to the initiation of NF-κB transcription, allowing continued expression throughout infection (Kowalik *et al.*, 1993; Yurochko *et al.*, 1997b). A physiological role for activation is masked by the relative complexity of events as well as the activities of viral regulatory gene products (Castillo *et al.*, 2000).

The interferon-like and likely NF-kB-dependent activation of cellular gene expression begins within a few hours after virus particle contact with cells (Browne *et al.*, 2001; Simmen *et al.*, 2001) and the response includes a wide range of signaling pathways in addition to those that activate NF-κB (Albrecht *et al.*, 1992; Boldogh *et al.*, 1990, 1991, 1997; Evers *et al.*, 2004; Wang *et al.*, 2003). The production of interferon β itself during HCMV infection is inversely associated with MOI (Rodriguez *et al.*, 1987). Levels of this interferon sufficient to influence the behavior of cells is only induced following exposure of cells to low MOIs or to inactive virus particles (Boehme *et al.*, 2004; Compton, 2004). There is little detectable interferon in the medium or associated with virus particles following high MOI infection (Abate *et al.*, 2004; Rodriguez *et al.*, 1987; Zhu *et al.*, 1997). Interferon has long been known to be relatively ineffective against this group of viruses, whether tested in culture (Holmes *et al.*, 1978) or in patients (Cheeseman *et al.*, 1977). HCMV infected cells do not support interferon receptor signaling or the translation of interferon β transcripts but viral functions that carry out these activities remain to be identified. HCMV deflects major interferon regulated pathways through the action of the closely related viral TRS1 and IRS1 gene products (Child *et al.*, 2002, 2004; Cassady, 2005). These can replace either the vaccinia dsRNA binding protein E3L or the herpes simplex virus-1 (HSV-1) γ34.5 gene product and suppress both protein kinase R (PKR) and the 2–5 oligoadenylate (2–5OAS) synthetase/RNase L system. Despite the lack of obvious motifs, pTRS1 binds dsRNA and includes an unconventional dsRNA-binding domain conserved in pIRS1; however, this domain is not sufficient to rescue E3L mutant virus (Hakki and Geballe, 2005). Thus, TRS1 primarily, but IRS1 secondarily, impede PKR-mediated inactivation of eukaryotic intiation factor 2 as well as the activation of RNase L by products of 2–5A synthetases and the resultant degradation of mRNA and rRNA. IRS1 mutants are fully growth proficient, but growth of TRS1 mutants is reduced (Blankenship and Shenk, 2002; Dunn *et al.*, 2003) and impacts virion assembly (Adamo, *et al.*, 2004).

Impact on the host cell cycle

Betaherpesvirus genomes are transcribed and replicated within the nucleus, the same cellular compartment that regulates the cell cycle and controls apoptosis following DNA damage or aberrant protooncogene expression. Cellular DNA is damaged, the cell cycle is dysregulated, and protooncogene expression is increased following cytomegalovirus infection. DNA damage induced by HCMV includes both randomly distributed and specific chromosomal breaks and gaps (AbuBakar *et al.*, 1988; Deng *et al.*, 1992; Fortunato *et al.*, 2000a). It is not evident that any of these processes requires viral replication.

Cell cycle dysregulation occurs during HCMV productive infection and gives the impression of progression into S phase and mitosis, although cellular DNA synthesis and cell division are blocked. Initial reports of a G2/M arrest, defined by presence of what appeared to be a 4N chromosomal peak (Jault *et al.*, 1995; Lu and Shenk, 1996) were clarified by further work showing host cell DNA content does not increase in infected cells (Bresnahan *et al.*, 1996; Dittmer and Mocarski, 1997; Salvant *et al.*, 1998). Specific inhibition of viral and cellular DNA replication showed that this increase was due to the accumulation of viral DNA (Dittmer and Mocarski, 1997]. Interestingly, viral replication is delayed in cells infected during S phase until after the cell cycle has progressed at least to G2/M, and the majority of cells must apparently cycle to G1 prior to the initiation of viral gene expression (Salvant *et al.*, 1998; Fortunato *et al.*, 2002). It remains possible that the CMV-induced block to cellular DNA synthesis and dysregulation of the cell cycle will vary with each differentiated cell type tested, as detailed studies have not been undertaken in relevant cell types such as endothelial cells, myeloid cells, or epithelial cells. It is notable that studies in MCMV have suggested that induction of apoptosis as a result of viral infection is cell type dependent and that viral inhibitors of apoptosis show cell type specificity (Brune *et al.*, 2001, 2003; Menard *et al.*, 2003).

The structural proteins that modulate host cells most dramatically include two relatively abundant viral tegument proteins, ppUL82 (pp71) (Bresnahan and Shenk, 2000; Kalejta and Shenk, 2002) and pUL69 (Hayashi *et al.*, 2000; Lu and Shenk, 1999). Both are introduced into cells during viral entry. In addition, the IE2 p86 regulatory protein encoded immediately following entry (Murphy *et al.*, 2000; Song and Stinski, 2002) has a dramatic impact on the cell. All three have been characterized for their impact on cell cycle independent of viral replication. pUL69 and IE2 p86 inhibit cell progression past G1 and S, respectively, and pUL82 (pp71) induces quiescent cells to enter the cell cycle. The impact of any of these during viral infection remains poorly understood, but ppUL82 (pp71) may act through derepression of HDACs (Cantrell *et al.*, 2005; Hofmann *et al.*, 2002; Ishov *et al.*, 2002; Saffert and Kalejta, 2006). The situation is complicated by the fact that virus-infected cells do not remain at any distinct stage of the cell cycle but can have characteristics that extend from resting, Go-like to a pseudomitotic state (Hertel and Mocarski, 2004). HHV-7 infection apparently promotes accumulation of polyploid cells with enlarged single cells that have a

polylobated nucleus and >4N genome content (Secchiero *et al.*, 1998).

HCMV and HHV-7 grossly alter cyclin and other cell cycle regulatory protein expression patterns (Fortunato *et al.*, 2000b; Hertel and Mocarski, 2004), as described in Chapter 18. Cell cycle dysregulation is accompanied by increases in cyclin E and cdk2 (Bresnahan *et al.*, 1996; Jault *et al.*, 1995) as well as cdk2 translocation to the nucleus (Bresnahan *et al.*, 1997). Additionally, infected cells accumulate hyperphosphorylated pRB (Jault *et al.*, 1995), consistent with induced E2F-specific gene transcription (Song and Stinski, 2002). Proteins that are normally involved in cellular DNA replication, including PCNA (Dittmer and Mocarski, 1997; Mate *et al.*, 1998) and RPA (Fortunato and Spector, 1998), increase and accumulate within sites of viral DNA replication in the nucleus. Increases in cyclin B and cdc2 activity were first demonstrated in infected cells that appeared to have progressed to the G2/M boundary based on DNA content (Jault *et al.*, 1995), but cyclin B levels clearly increase in fibroblasts arrested by CMV at a G1/S-like boundary (Dittmer and Mocarski, 1997). Despite the presence of regulatory factors required for transition through S phase, cellular DNA synthesis is restricted through virus-specific inhibition of licensing factors (Biswas *et al.*, 2003; Wiebusch *et al.*, 2003). All of these studies provide clear evidence of severe dysregulation by HCMV. Although less well characterized, HHV-7 will likely differ from CMV since cdc2 activity decreases after HHV-7 infection. Similar to CMV, cyclin B increases in HHV-7 infected cells despite a G1/S-like arrest. In conjunction with cell cycle alterations, HCMV infection increases expression of the protooncogenes c-jun, c-fos, c-myc (Boldogh *et al.*, 1990), and the tumor suppressor p53 (Jault *et al.*, 1995; Speir *et al.*, 1994). p53 is a transcription factor that promotes growth arrest or apoptosis in response to cell stress (Haupt *et al.*, 2003) or other regulators of intrinsic cell death such as oncogene activation, nucleotide depletion, hypoxia, redox modulation, and loss of normal cell contacts (Giaccia and Kastan, 1998). p53-induced cell death is primarily due to *trans*-activation of specific apoptosis regulators including several proapototic Bcl-2 family members that promote mitochondria membrane permeability transition. The outcome of p53 activity, growth arrest or induction of apoptosis, depends on many factors including p53 expression levels, p53 co-activators, cell type, and type of stress (Haupt *et al.*, 2003). p53 levels are controlled via Mdm2 (mice) or Hdm2 (humans), which direct degradation via the proteasome. Early during HCMV infection, p53 levels increase due to a decrease in protein turnover (Jault *et al.*, 1995; Muganda *et al.*, 1998; Speir *et al.*, 1994). Further, specific coactivators of p53, such as myc, are induced but apoptosis is not induced, possibly due to accumulation in discrete subnuclear regions colocalizing with the viral DNA polymerase processivity factor, ppUL44 (Fortunato and Spector, 1998), a marker of viral DNA replication compartments (Penfold and Mocarski, 1997). A direct physical interaction with IE2 p86 may inhibit p53-mediated transactivation (Speir *et al.*, 1994). One reported interaction of IE2 p86 and p53 (Bonin and McDougall, 1997), however, was carried out in cells that expressed a non-functional IE2 p86 (Murphy *et al.*, 2000), such that this area needs additional investigation. IE2 p86-deficient viruses fail to replicate at all (Heider *et al.*, 2002; Marchini *et al.*, 2001), and a variety of deletions have been made within the protein coding sequences to delineate regions that are necessary for viral replication (Sanchez *et al.*, 2002; White *et al.*, 2004), as described in Chapter 18. In addition to sequestration of the protein, HCMV may have additional means of negating p53 activity, including the increased expression of inhibitory proteins in the p53-family. p53-mediated transcription of apoptotic genes is influenced by the presence of p73 (Flores *et al.*, 2002). In p53 deficient astrocytoma cells, the presence of p73 confers sensitivity to DNA damaging agents such as cisplatin, and HCMV infection alters sensitivity to such agents (Allart *et al.*, 2002) and increases the expression of a cellular dominant negative isoform of p73 that may interfere with both p53- and p73-dependent activities.

Suppression of apoptosis

Apoptosis is an evolutionarily conserved cellular process that removes cells during infection, development, or homeostasis. Apoptosis is initiated by intrinsic stress or DNA damage within the cell that accompanies infection by obligate intracellular parasites and viruses (Ferri and Kroemer, 2001; Polster *et al.*, 2004). Death of the cell early after viral infection prevents the production of progeny, and such mechanisms would exert a strong impact on the slow growing betaherpesviruses. This evolutionarily ancient host defense strategy may be induced in mammals through intrinsic signals, as a consequence of cell stress induced by virus infection, or extrinsic signals through the engagement of death receptors on the cell surface or other immune effector mechanisms. Apoptotic bodies and cellular debris from dead cells are cleared by professional phagocytic cells, such as MΦ and DCs, which carry out critical roles priming the adaptive immune response. A wide range of cellular sensors may be triggered by viral infection, including alterations of the cellular tumor-suppressor p53 or other cell cycle regulators, alterations in mitochondrial function, nuclear changes resulting from DNA damage and repair, modification of endoplasmic reticulum, and

activation of PKR (Everett and McFadden, 1999, 2001). A wide range of antiapoptotic proteins encoded by DNA and RNA viruses have been recognized (Cuconati and White, 2002; Polster *et al.*, 2004), and many target the mitochondrion (Boya *et al.*, 2004). These inhibitors suppress cell death resulting from the intrinsic impact of virus infection or from extrinsic inducers or stimuli that accompany the host immune response. The consequence of keeping cells alive is enhancement of viral replication levels that increase the chances of a virus gaining a foothold in the host.

Betaherpesviruses rely on a variety of virus-encoded regulators that prevent cells from showing molecular or morphological hallmarks of apoptosis (Allart *et al.*, 2002; Brune *et al.*, 2003; Goldmacher *et al.*, 1999; Reboredo *et al.*, 2004; Skaletskaya *et al.*, 2001), as depicted in Fig. 21.1. Two HCMV genes, UL37x1 (Goldmacher *et al.*, 1999; Reboredo *et al.*, 2004), which encodes the viral mitochondrial localized inhibitor of apoptosis (vMIA), and UL36 (Skaletskaya *et al.*, 2001), which encodes the viral inhibitor of caspase 8 activation (vICA), inhibit apoptosis through clearly defined mechanisms. The major IE gene products have also been suspected of blocking apoptosis but little mechanistic insights have been gained. Four MCMV gene products inhibit apoptosis, with one (M36) being homologous to HCMV UL36 (McCormick *et al.*, 2003a; Menard *et al.*, 2003), one (m38.5) being a positional and functional homolog of vMIA (McCormick, 2005) and two (m41 and M45) functioning differently than any known HCMV gene product (Brune *et al.*, 2001, 2003; Hahn *et al.*, 2002; Patrone *et al.*, 2003). HHV-6B infected CD4+ cultures include apoptotic cells and virus-positive cells are more resistant to apoptosis than neighboring cells (Inoue *et al.*, 1997), suggesting that this virus also encoded genes that are antiapoptotic. The homologue of UL36 is the most likely candidate. There is also evidence that apoptosis may occur following exposure of non-permissive cells to betaherpes-viruses or in non-infected cells in productively infected cultures. Thus, all evidence is consistent with a role for betaherpesvirus gene products regulating apoptosis to prolong the life of the infected cell or make it resistant to host immune defense mechanisms. A role for suppression of apoptosis in species specificity of MCMV replication has also been demonstrated by converting human cells to a susceptible state using HCMV vMIA (Jurak and Brune, 2006).

vMIA (pUL37x1)

The genomic region of HCMV encoding the ORFs UL36, UL37, and UL38 is transcriptionally complex (Fig. 21.2). Sequence analysis combined with transcription and in vitro translation studies (Kouzarides *et al.*, 1988; Tenney and Colberg-Poley, 1990, 1991a, 1991b) indicated the presence of two immediate–early transcripts that include UL37x1. The larger transcript, 3.2–3.4 kb in length, is present only at immediate early times, encodes the glycoprotein gpUL37, and terminates at a polyadenylation signal located between UL36 and UL35. The more abundant, 1.7kb transcript, encoding pUL37x1, is present at immediate early times as well as throughout the remainder of infection. This transcript terminates at a polyadenylation signal located between UL38 and UL37x2. A splice variant encoding gpUL37$_M$ includes UL37x1, UL37x2, and a portion of UL37x3 (Goldmacher *et al.*, 1999). Transcription and translation in vitro predicted apparent molecular weights of 58 kDa and 24 kDa, respectively for gpUL37 and pUL37x1 (Tenney and Colberg-Poley, 1990). More recently, cDNA cloning has revealed that transcription through this region may produce as many as 11 spliced and unspliced transcripts (Adair *et al.*, 2003), including all those that had been previously identified. HCMV-induced alterations to the cellular splicing machinery apparently ensures the continued production of the unspliced transcript encoding pUL37x1 throughout infection (Su *et al.*, 2003).

The fact that UL37x1-containing gene products provide antiapoptotic activity emerged from transient expression of viral DNA fragments and functional analyses of pUL37x1, gpUL37 and gpUL37M clones in a cell death suppression assay (Goldmacher *et al.*, 1999). The name vMIA is reserved for the most potent of these, pUL37x1. vMIA prevents cell death induced by TNF, Fas ligand (Goldmacher *et al.*, 1999), TRAIL (Skaletskaya *et al.*, 2001), E1B19K deficient adenovirus (Goldmacher *et al.*, 1999), HIV Vpr (Roumier *et al.*, 2002), doxorubicin (Goldmacher *et al.*, 1999), nitric oxide, peroxynitrite, 4-hydroxynonenal (Vieira *et al.*, 2001), hydroxychloroquine (Boya *et al.*, 2003a), ionidamine, arsenite, the retinoid derivative CD437 (Belzacq *et al.*, 2001), propionibacterial short chain fatty acids (Jan *et al.*, 2002), *N*-(4-hydroxyphenyl)retinamide (Boya *et al.*, 2003b), and macroautophagy (Boya, 2005). vMIA increases the susceptibility of human cells to MCMV productive infection (Jurak and Brune, 2006). vMIA mediates protection at the level of the mitochondria and prevents release of cytochrome c and subsequent downstream events (Fig. 21.1), but does not prevent upstream events including cleavage of either procaspase-8 or Bid (Goldmacher, 1999). vMIA can be immunoprecipitated with adenine nucleotide transporter, a component of the mitochondria membrane pore that interacts with Bax and other Bcl-2 family members but for vMIA, this interaction is non-specific. vMIA also interacts with Bax in cells (Arnoult *et al.*, 2004; Poncet *et al.*, 2004), and Bax also localizes to mitochondria during MCMV infection (Andoniou *et al.*, 2004). More recently an interaction with growth arrest and DNA damage 45 alpha (GADD45α) was established

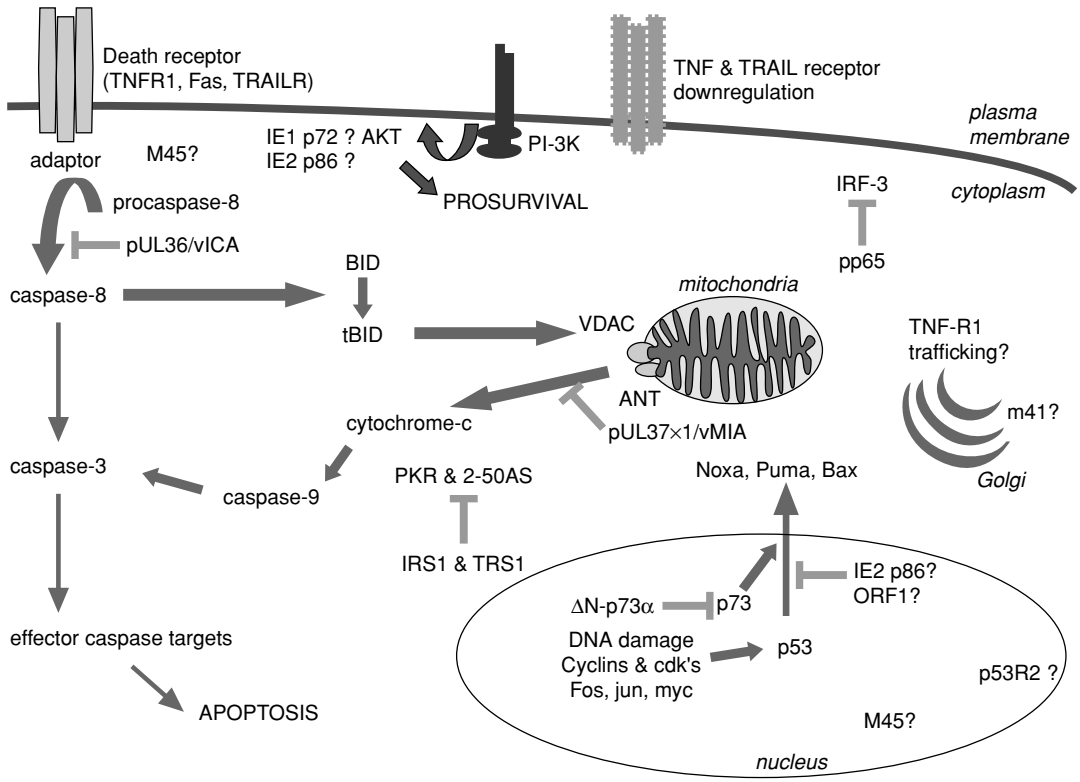

Fig. 21.1. Betaherpesvirus inhibition of apoptosis and interferon response. Grey arrows represent proapoptotic pathways while black arrows indicate prosurvival pathways and black lines indicate interruption of proapoptotic pathways. Cellular functions are listed in grey font and viral functions are indicated in black font. Plasma membrane, cytoplasm, nucleus, mitochondria, and Golgi, are depicted in italics. Bold black text indicates viral inhibitors with known or suspected mechanisms. Question marks indicate possible points of interference by viral proteins.

through yeast two hybrid and significantly, this interaction was shown to be critical for cell-death protection since addition of any GADD45 family member (alpha, beta, or gamma) enhanced survival and function was impaired by siRNA-mediated GADD45 family reduction. vMIA lacks the BH domains that characterize Bcl-2 family members and Bax also localizes to mitochondria during MCMV infection (Andoniou *et al.*, 2004). Rather this, protein is composed of an amino terminal region, aa 5–34, that is important for localization to mitochondria and a carboxyl terminal region, aa 118–147, that is critical for anti-apoptotic activity (Hayajneh *et al.*, 2001). This domain also mediates the interaction with GADD45 family members that facilitates vMIA activity (Smith *et al.*, 2005).

vMIA does not exhibit sequence variation in HCMV (Hayajneh *et al.*, 2001) and sequence homologs can only be found in primate CMVs. The regions of highest sequence conservation are coincident with regions defined by mutational studies to be required for vMIA activity (McCormick *et al.*, 2003b). "In fact, a minimal 69 aa protein that includes amino acids 1–34 and 112–147 of vMIA retains full activity (Hayajneh *et al.*, 2001) and is very similar to homologues in monkey CMVs (McCormick *et al.*, 2003b)." At a positionally conserved location in the viral genome, MCMV and rat CMV retain a functional homolog which despite limited sequence homology, functions in cell death assays (McCormick *et al.*, 2005). A UL37x1 homolog has not been identified in other betaherpesviruses, although all betaherpesviruses carry a gene homologous to UL37x3, which as the largest exon, has been annotated as UL37 in most betaherpesviruses but that lacks independent anti-apoptotic activity (Chapter 15; McCormick *et al.*, 2003b). UL37x1 is not essential for viral replication in Towne*var*ATCC, a strain carrying a functional vICA (McCormick *et al.*, 2005). In contrast, transposon mutants disrupting HCMV UL37x1 fail to produce infectious virus, in AD169*var*ATCC, a strain carrying a mutant UL36 (Reboredo *et al.*, 2004). Other, independently derived UL37x1 deletion mutants made in AD169*var*ATCC had also suggested that vMIA is required for viral replication (Brune *et al.*, 2003; Dunn *et al.*, 2003; Yu *et al.*, 2003). Thus, vMIA is dispensable unless other mutations are present which render the virus

	vICA	gpUL37	gpUL37$_M$	vMIA

Fig. 21.2. Presence of functional antiapoptotic genes in HCMV strains. (top) Depiction of the commonly used laboratory strains AD169, Towne, and Toledo genomes. Rectangles represent repeated *ab* - *b′a′* sequence flanking the unique long (U_L) and the c′a - *ac* sequences flanking the short (U_S) genome components. An expansion of the region including nucleotides 47,000–54,000 is depicted with a representation of ORFs (open rectangles) in the UL36-UL37 region. Splicing patterns relevant to proteins with demonstrated antiapoptotic function are indicated by lines connecting ORFs and polyadenylation sites are indicated by arrowheads. The presence (+) or absence (–) of vICA, gpUL37, gpUL37$_M$, and vMIA in AD169*var* ATCC, AD169*var* DE, Towne*var* ATCC, Towne*var* RIT and Toledo (passage 8) is indicated below the ORF diagram (Dunn *et al.*, 2003; Skaletskaya *et al.*, 2001).

dependent on the gene to prevent apoptosis. (Dunn *et al.*, 2003; Brune *et al.*, 2003; Reboredo *et al.*, 2004; Yu *et al.*, 2003; Skaletskaya *et al.*, 2001). Consistent with this conclusion and in contrast to the caspase-dependent cell death noted for strains that require vMIA, premature death in Towne*var*ATCC mutant virus is caspase-independent (McCormick *et al.*, 2005).

vICA (pUL36)

This betaherpesvirus-conserved anti-apoptotic gene product is dispensable for HCMV replication in cultured fibroblasts and is mutated in many common laboratory strains (Patterson and Shenk, 1999; Skaletskaya *et al.*, 2001), as depicted in Fig. 21.2. Evidence that UL36 encodes the anti-apoptotic protein vICA first emerged from transient expression of viral DNA fragments in a cell death suppression assay (Skaletskaya *et al.*, 2001). Caspase 8, the target of pUL36, is also known as FLICE. vICA is mechanistically similar to the viral and cellular FLICE inhibitory proteins (v-FLIP and c-FLIP), but lacks any sequence similar to death effector domains typical of this class of protein. Like FLIPs, vICA prevents cleavage by binding to the pro-domain of procaspase-8 and provides protection from apoptosis initiated by death receptors TNFR, TRAILR, or Fas that require caspase 8 activation. vICA only slightly delays cell death induced by E1B19K deficient adenovirus or doxorubicin. The presence of vICA correlates with an increased resistance of HCMV to inducers of extrinsic cell death (Skaletskaya *et al.*, 2001). Mutants of the MCMV homologue M36 show a reduced growth phenotype in macrophages (IC-21, J774-A1, and peritoneal exudate cells) but not in fibroblasts or endothelial cells, but this behavior does not appear to extend to the HCMV gene product (Dunn *et al.*, 2003). M36 mutant infected cells are, however, more susceptible to induction of apoptosis by the Fas pathway similar to HCMV viruses defective in UL36 (Skaletskaya *et al.*, 2001).

UL36 homologs and vICA function are widely conserved among betaherpesviruses and sequence conservation includes regions outside the boundaries of the US22-family domains (McCormick *et al.*, 2003a). The homolog is an immediate early gene in MCMV, while the rhesus macaque CMV homolog is an early gene similar to vMIA in that virus. The homologs of UL36 in HHV-6A and HHV-7 are each encoded by a spliced transcript. The HHV-6A is regulated as an immediate–early gene (Flebbe-Rehwaldt *et al.*, 2000), whereas the HHV-7 spliced RNA seems to be regulated as an early gene (Menegazzi *et al.*, 1999).

Other cell death suppressors

Ribonucleotide reductases convert ribonucleoside diphosphates to deoxyribonucleoside diphosphates and are generally important for DNA synthesis and repair. While alphaherpesviruses and gammaherpesviruses encode both ribonucleotide subunits RR1 and RR2 and make an active enzyme, the betaherpesviruses only encode a homolog of the RR1 subunit that lacks enzymatic activity (Chapter 15). Viral mutants of MCMV M45, but not the HCMV homolog UL45, show cell-type dependent growth properties (Brune *et al.*, 2001; Hahn *et al.*, 2002). Insertional mutants of M45 grow similar to wild-type viruses in cultured fibroblasts, bone marrow stromal cells, and hepatocytes but fail to grow in either endothelial cells or macrophages (Brune *et al.*, 2001), which enter apoptosis by about 1 day post-infection. Cell to cell spread is thus severely restricted. The alphaherpesvirus HSV-2 RR1 subunit prevents cell death upstream of caspase 8 activation due to an amino-terminal extention relative to other RR1 homologs (Langelier *et al.*,

2002) in addition to being a component of an active ribonucleoside reductase enzyme. It is possible that M45 has preserved such an antiapoptotic function, although there is little sequence similarity to guide how the two may be related. Cell-type restricted growth and induced apoptosis are not observed in HCMV UL45 mutants, which grow poorly and are less efficient at cell-to-cell spread (Patrone *et al.*, 2003), but do not exhibit cell type specific defects in fibroblasts, macrophages, or endothelial when used at high MOIs (Hahn *et al.*, 2002). Mutant HCMV is somewhat reduced compared to wt in ability to withstand Fas-induced apoptosis (26% survival vs. 50% survival), however; HCMV UL45 is unable to independently block cell death in the absence of viral infection.

MCMV mutant defective in m41 prematurely kills cells and replicates to reduced levels compared to parental virus (Brune *et al.*, 2003). Caspase inhibition reduces but does not eliminate cell death, suggesting that apoptosis may underlie the process. Expression of epitope-tagged m41 during viral infection shows localization to Golgi. The mechanism of protection remains to be elucidated.

HCMV IE1 p72 and IE2 p86 are nuclear proteins that regulate transcription of cellular and viral genes (Chapters 17 and 18) and each can associate with cellular proteins. Cellular transcription factor E2F is modulated by IE1 p72 interaction with the Rb-pocket protein p107 (Poma *et al.*, 1996) or by IE2 p86 interaction with pRB (Hagemeier *et al.*, 1994). Regulation of E2F1 is mediated by binding to IE1 p72 (Margolis *et al.*, 1995). IE1 p72 and IE2 p86 suppress apoptosis induced by TNF or E1B19K defective adenovirus (Zhu *et al.*, 1995) and anti-apoptotic activity maps to disparate sequences without any hint of mechanism. Importantly, fibroblasts constitutively expressing IE1 p72 that have been used to complement growth of IE1 p72 mutant viruses do not exhibit any obvious altered cell cycle progression or susceptibility to apoptosis. In transient assays, a genomic clone including IE1 p72 and IE2 p86 rescues a temperature sensitive derivative of $TAF_{II}250$ mutant cells (*ts* 13) from transcriptional repression and apoptosis but not cell cycle arrest (Lukac *et al.*, 1997). Further analysis indicated either IE2 p86 or IE1 p72 activates the PI3 kinase pathway and AKT as a consequence (Yu and Alwine, 2002) similar to the response of these prosurvival pathways to infection (Johnson *et al.*, 2001b), but the role of IE1 p72 and IE2 p86 as suggested by the $TAF_{II}250$ mutant cells has not been extended to natural infection. IE2 p86 but not IE1 p72 protects from overexpression of p53 in smooth muscle cells (Tanaka *et al.*, 1999). In contrast IE2 p86 but not IE1 p72 expression in endothelial cells induces apoptosis (Wang *et al.*, 2000). Control of cell-intrinsic responses is the suggested mechanism for HCMV IE1 facilitation of MCMV replication in human cells (Tang and Maul, 2006). These data may suggest that any potential protective role includes both an induction-specific and a cell-type specific component.

Alteration of extrinsic cell death pathways during infection

TNF-R1 surface expression levels decrease following HCMV infection of macrophage or astrocytoma cell lines (Baillie *et al.*, 2003) as well as following MCMV infection of bone marrow derived macrophages (Popkin and Virgin, 2003). Although the viral factors required for the down-regulation have not been identified, either virus seems to employ a post-transcriptional mechanism. Uninfected fibroblasts insensitive to TRAIL mediated apoptosis become sensitive to TRAIL following HCMV infection (Sedger *et al.*, 1999). Infection increases expression of death-inducing TRAIL-R1 and TRAIL-R2, but not decoy receptors TRAIL-R3 and TRAIL-R4. Analysis of HHV-7 revealed downregulation of TRAIL-R1 but not TRAIL-R2, TNF-R1, TNF-R2, or Fas during infection of CD4 cells (Secchiero *et al.*, 2001). Infections by other betaherpesviruses maintain the Fas receptor available for activation. Fibroblasts infected by HCMV and MCMV are susceptible to Fas-mediated apoptosis (Chaudhuri *et al.*, 1999; Goldmacher *et al.*, 1999; Menard *et al.*, 2003; Skaletskaya *et al.*, 2001) and some, but not all, strains of HCMV may increase Fas receptor surface expression (Chaudhuri *et al.*, 1999; Chiou *et al.*, 2001).

HCMV encodes a potential TNF-receptor homolog (Benedict *et al.*, 1999), although this protein has not been assigned any role in blocking apoptosis. UL144 encodes a glycoprotein consisting of a leader peptide, cysteine-rich domains (CRD), membrane extension region, transmembrane domain, and a short cytoplasmic tail. UL144 exhibits dramatic strain-to-strain sequence variability (Bale, 2001; Lurain, 1999), although the protein has highly conserved transmembrane and cytoplasmic domains. UL144 is the closest known relative of the cell surface herpesvirus entry mediator (HVEM; Chapter 7) protein, whose normal function is as a cognate ligand for the B- and T-lymphocyte attenuator (Sedy *et al.*, 2005). UL144 binds B and T lymphocyte attenuator (BTLA) and inhibits T-cell proliferation.

Summary

The betaherpesviruses all appear to alter cell cycle and to block rather than promote apoptosis during infection. Cytomegaloviruses prevent cellular DNA synthesis whereas roseolaviruses allow continued cellular DNA

synthesis during productive infection, although cell division is blocked in all of these viruses. While none of the betaherpesviruses has been implicated in malignancy, such an impact on the host cell has raised interest of persistent betaherpesvirus infection in certain chronic diseases. These viruses encode a wide variety of functions that modulate the cellular environment, including functions that modulate cell cycle progression and that derail apoptosis induced by either intrinsic or extrinsic mediators.

Part II

Basic virology and viral gene effects on host cell functions: gammaherpesviruses

Edited by Patrick Moore

22

Introduction to the human γ-herpesviruses

Richard Longnecker[1] and Frank Neipel[2]

[1]Feinberg School of Medicine, Northwestern University Medical School, Chicago, IL, USA
[2]Institute for Clinical and Molecular Virology, University of Erlangen, Germany

Introduction

This chapter will provide a brief background into the γ-herpesviruses family in comparison to other members of the herpesvirus family; but the primary focus of this chapter will be to recount the discovery of the two human γ-herpesviruses (EBV and KSHV) and the diseases associated with infection of each virus, a brief introduction into their life cycles, and finally a description of the genome characteristics of the viruses including a description of their respective genomes. In many ways, the discovery and association with human diseases for both EBV and KSHV have many parallels despite almost three decades separating their discoveries and association with human disease.

The γ-herpesvirus family

The γ-herpesviruses are a subfamily of herpesviruses that were first distinguished by their cellular tropism for lymphocytes. Subsequent molecular phylogenetic analyses have confirmed the close relationship among these viruses that is distinct from the α- and β-herpesviruses subfamilies (Fig. 22.1). *Gammaherpesvirinae* is currently divided into two genera, *Lymphocryptoviridae* which includes human Epstein–Barr virus (EBV or HHV4) and *Rhadinoviridae*, which includes human Kaposi's sarcoma-associated herpesviru*s* (KSHV or HHV8). Recent studies suggest that primate rhadinoviruses can be further subdivided in KSHV-like viruses, a second closely related but distinct lineage of Old World primate viruses related to the rhesus rhadinovirus (RRV), and the New World monkey rhadinoviruses represented by herpesvirus saimiri (HVS). A more detailed analysis of the non-human γ-herpesviruses will be discussed in Chapters 60 and 61.

Although the best-studied members of the γ-herpesviruses are EBV and KSHV, γ-herpesviruses are parasites of a broad range of mammals from mice (murine herpesvirus-68 and related viruses) to cows and horses (bovine herpesvirus 4 and equine herpesvirus 2), as well as primates. Surprisingly, γ-herpesviruses of lower mammals most closely resemble the rhadinoviruses, and exhibit extensive molecular piracy of host regulatory genes that is not found in EBV and related viruses. Interestingly, the lymphocryptoviruses have been found only in primates and humans. The γ-herpesviruses share a similar genomic structure that the 172 kilobase pair, linear double-stranded DNA genome of the B95–8 EBV strain serves as the prototype since it was the first γ-herpesvirus that was sequenced (Baer *et al.*, 1984). The large central region of the genome contains most of the coding capacity for the viruses, including blocks of highly conserved genes that are shared among the herpesviruses (Fig. 22.2). The ends of the molecule are capped by variable numbers of direct repeat sequences that are the sites for genome circularization during latency. Unlike the α-herpesviruses (Chapter 10), the γ-herpesviruses do not undergo genomic isomerization and only linearize and recircularize in their terminal repeat regions, although the numbers of terminal repeats can be highly variable.

The γ-herpesviruses also share a number of characteristics in common with the α- and β-herpesviruses, particularly related to lytic viral replication. During lytic replication, the γ-herpesviruses genome is packaged as a linear molecule in a proteinaceous capsid, which is then enveloped by a lipid bilayer prior to release from the cell. This process starts when viral transactivators initiate viral genome-wide transcription through a series of orderly transcriptional cascades. Different classes of viral genes (immediate–early, early and late) are transcribed resulting in the production of infectious virions. As with other

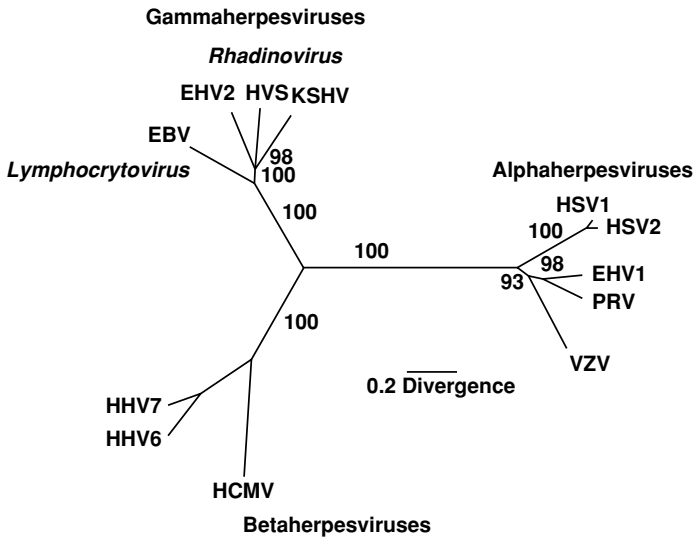

Fig. 22.1. Phylogenetic tree for selected herpesviruses. Phylogenetic trees are based on comparison of aligned amino acid sequences between herpesviruses for the MCP gene. The comparison of MCP sequences was obtained by the NJ method and is shown in unrooted form, with branch lengths proportional to divergence (mean number of substitution events per site) between the nodes bounding each branch. The number of times (of 100 bootstrap samplings) that the division indicated by each internal branch was obtained is shown next to each branch; bootstrap values below 75 are not shown. Figure adapted from Fig. 2A from reference (Moore *et al.*, 1996). Used with permission of American Society of Microbiology.

herpesviruses, γ-herpesviruses lytic replication is thought generally to cause cell death. While specific mechanisms for lytic replication differ between the herpesviruses, and even among the γ-herpesviruses, they all broadly share similar capsid structures and have similar overall mechanisms for lytic replication. As would be expected, genes involved in lytic replication and viral capsid production tend to be highly conserved across the herpesvirus subfamilies, including the γ-herpesviruses.

The γ-herpesviruses differ the most dramatically from each other and from other herpesviruses during the latent portion of their lifecycle. Unlike the other human herpesviruses, both EBV and KSHV latency can be established and manipulated in vitro, providing an important experimental system that is unavailable for other viruses. Latency occurs after infection of a cell and transport of the capsid to the nucleus where the genome is released. The viral genome, still a linear DNA fragment, then circularizes by ligation of terminal repeat sequences and replicates as an episome using the host cell replication machinery.

A key feature of the γ-herpesviruses is their common capacity to induce lymphoproliferation and cancers. Tumors caused by EBV and KSHV include lymphoproliferative diseases and lymphomas, but also include tumors from other tissue-types, such as smooth muscle cells and endothelial cell origin. In some cases, tumorigenesis occurs when viruses cross species such as bovine infection by the wildebeest γ-herpesviruses, alcelaphine herpesvirus 1, in Africa (Ensser *et al.*, 1997). In other cases, tumorigenesis is a rare occurrence among infected individuals, except when the host is specifically susceptible through immunosuppression or through a rare familial mutation altering normal immune function.

EBV was the first human tumor virus discovered and has been a rich source of information for tumor biologists as well as a tool for immortalizing cell lines for use as reagents. As shown by the Henles in 1967, EBV has the unusual property of immortalizing primary B lymphocytes in culture (Henle *et al.*, 1967). Continuous cell lines that result from this immortalization are termed lymphoblastoid cell lines (LCLs) reflecting their activated phenotype. These LCLs contain EBV episomes and express a very limited number of viral genes and have served as an important model of EBV latent infection and transformation as will be further discussed in Chapter 24. These latently infected cell lines, as shown in 1978 by zur Hausen and colleagues can be induced to lytic replication by treatment with phorbol esters (zur Hausen *et al.*, 1978). Interestingly, similar treatment of cell lines harboring KSHV causes induction of lytic replication (Arvanitakis *et al.*, 1996; Renne *et al.*, 1996).

KSHV, more recently discovered, provides a unique tumor virus model since it has incorporated cellular proto-oncogenes and serves as a rosetta stone between cancer biology and tumor virology. The natural lifecycles of EBV and KSHV are well studied and experimentally tractable allowing for the careful examination of oncogenes from these viruses not only in terms of their capacity to induce cell transformation but also in terms of their roles in the natural viral life cycle.

The discovery of Epstein–Barr virus (EBV)

Although there was considerable evidence to indicate the role of viruses in human cancers from animal studies dating from the early 1900s, it was not until the identification of Burkitt's lymphoma and the subsequent identification of EBV in this unusual tumor that a clear role of viruses in human cancers became apparent. The first key to the puzzle of a human virus being associated with a human

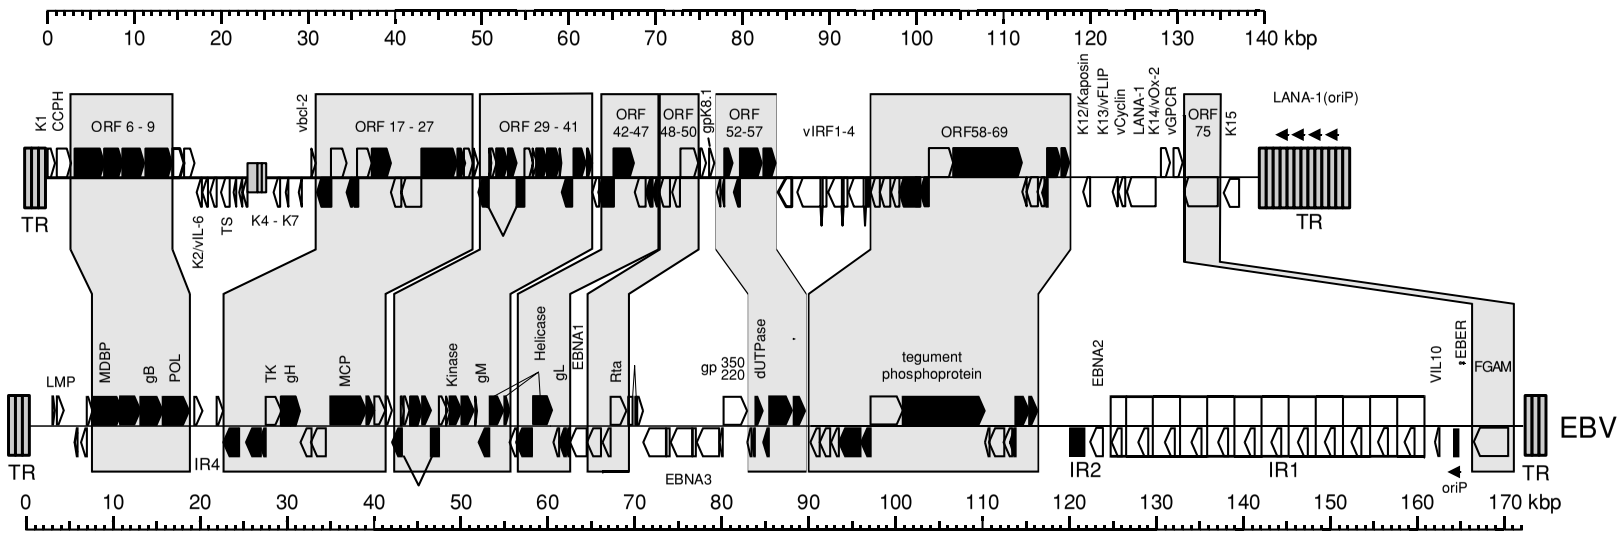

Fig. 22.2. Colinearity of the genetic maps of KSHV (top) and EBV (bottom). Schematic representation of the genomes of KSHV and EBV were drawn to scale based on the sequences by Russo *et al.* (PNAS 93, 14862–14867, 1996; Genbank acc. no. U75698) and the inverted sequence of EBV strain B95–8 (Baer *et al.*, *Nature* **310** (5974), 207–211 (1984), Genbank acc. no. NC001345), respectively. According to Russo *et al.*, protein coding regions (open reading frames, ORF) of KSHV that are conserved amongst KSHV and herpesvirus saimiri are numbered from 1 to 75. KSHV ORFS without detectable homology to herpesvirus saimiri genes are numbered with the prefix "K" or from K1 to K15. Open arrows symbolize herpesvirus genes not conserved amongst all human herpesvirus groups (alpha, beta, and gamma), whereas "core" herpesvirus genes that share homology detectable by BLAST amongst all groups of human herpesviruses are represented by arrows filled in black. The names of a few hallmark-genes are given above the EBV genome. Essentially, conserved genes are localized in five (seven) major blocks on the genomes of KSHV and EBV, linked here by trapezoid boxes. Most genes of the lytic replication cycle (virion proteins, DNA-replication proteins) are found here. These blocks of core herpesvirus genes are interspersed by areas coding for more strain- or virus-specific genes. In the case of KSHV, these are usually the "K"-genes that are frequently homologous to genes of the host cell. In the case of EBV, the Epstein-Barr virus nuclear antigens (EBNA 1–3) and latent membrane proteins (LMP1–2) are present at these positions. In addition, two major envelope glycoproteins of KSHV and EBV, gpK8.1 and gp350–220, respectively, are not conserved amongst the viruses. However, both genes are located at comparable positions close to the center of the coding regions.

Abbreviations: CCPH, complement control protein homologue; MDBP, major DNA binding protein; gB, glycoprotein B; pol, DNA polymerase; vIL-6, viral IL-6 homologue; vbcl-2, viral bcl-2; TK, thymidine kinase; gH, glycoprotein H; MCP, major capsid protein; gM, glycoprotein M; gL, glycoprotein L; Rta: R-transactivator of transcription; vIRF1–4: interferon regulatory factors 1–4; vFLIP: viral flice-inhibitory protein; vCyclin: viral cyclin-D homologue; vOx-2: viral Ox-2 (CD200) homologue; LANA-1: latent nuclear antigen 1; vGPCR: viral G-protein coupled receptor homologue; FGAM: formyl-glycin-amid transferase homologue; vIL10: viral interleukin 10 homologue; EBER: EBV-encoded small RNAs; TR, terminal repeat; IR: internal repeat; oriP: plasmid origin of replication.

tumor resulted from the interest of Denis Burkitt with a malignancy in children in Africa.

Denis Burkitt was born in 1911 and lived in Lawnkilla near Enniskillen, County Fermanagh, Ireland. He received his medical training at Trinity College in Dublin with his clinical training at Adelaide Hospital. Following graduation and after working in hospitals in his native Ireland and military service as army surgeon in the Royal Army Medical Corps, Burkitt embarked on a career of medical service in Africa due in part to his strong religious convictions and interest in service in the third world. In 1957, after being in Kampala, Uganda, for 10 years, he was asked by Hugh Trowell, a colleague in Kampala, to see a young boy with swellings on both sides of his upper and lower jaws that proved to be a lymphoma. The tumor was a very common cancer in African children, was fast growing causing grotesque disfigurement, and was fatal upon metastasis to other parts of the body.

Burkitt's fascination and interest in the tumor led him to carefully examine hospital records and to send out a questionnaire to government and mission hospitals throughout Africa. He also embarked on what he would call his long safari to document the incidence of this lymphoma. From this trip, which took 10 weeks, covered 10 thousand miles, journeyed through 12 countries, and stopped at 57 hospitals; Burkitt found a definite pattern of distribution with the lymphoma confined to a region 10 degrees north and 10 degrees south of the equator following closely the pattern of distribution of mosquito borne diseases such as malaria and yellow fever. These initial results were published in the *British Journal of Surgery* in 1958 (Burkitt, 1958). But it was not until 1961 after publication of a more detailed version in *Cancer* with a pathologist Greg O'Conor (Burkitt and O'Conor, 1961) and an invitation to give a lecture at Middlesex Hospital in London in March of 1961 that allowed the next step in the identification of EBV to fall into place.

In the audience of Burkitt's talk at Middlesex Hospital was Anthony Epstein who immediately developed an interest in the Burkitt's tumor. Epstein, who had worked on the Rous sarcoma virus, had developed an interest in the role of viruses in cancer and he was fascinated with Burkitt's description of his findings. Rous sarcoma virus was shown in 1911 by Peyton Rous at the Rockefeller Institute in New York to be responsible for a sarcoma that was transmissible in chickens. Epstein and Burkitt immediately began to collaborate. Biopsies were flown from Kampala to Epstein's laboratory in London, but it was not until 1963 after Yvonne Barr and Bert Achong joined the hunt that herpesvirus-like particles were observed in February 1964 from a cell line established from a biopsy delivered from Africa early in December of 1963 (Epstein *et al.*, 1964). Interestingly, both Achong and Barr were graduates of schools in Ireland. Achong graduated from University College Dublin and Yvonne Barr was a graduate of Trinity College Dublin.

Human disease associated with EBV infection

Considerable interest has focused on EBV since its discovery and its link with Burkitt's lymphoma. Along with KSHV, as we will learn also in this chapter, EBV is the only other herpesvirus with an etiological role in human malignancies. As described above, EBV is a causative agent in endemic Burkitt's lymphoma, but since the link of EBV with this lymphoma, EBV has also been shown to be important for a large number of additional diseases in humans.

Shortly after the description of EBV association with Burkitt's lymphoma, the Henles, a husband and wife team at the Children's Hospital of Philadelphia obtained a set of cell cultures from Epstein. Werner and Gertrude Henle were both born and educated in Germany. Werner emigrated to the United States in 1936 finding an instructorship position at the University of Pennsylvania. Werner's grandfather, Jacob Henle, was of Jewish descent, making his further training and livelihood in question because of the increased power of the Nazi regime in Germany and the approaching war. It had become "increasingly clear" to Werner that he could "not stay in Germany and pursue a career to his liking." In 1937, Gertrude Szpingier, who was Werner's fiancée, joined Werner in Philadelphia. They had met at the University of Heidelberg and were married the day after Gertrude's arrival in the United States. They spent their entire careers at the University of Pennsylvania making not only important discoveries in regard to EBV, but also other aspects of virology, immunology, and viral oncology.

With the cultures in hand from Epstein, the Henles began to explore the presence of antibodies directed against the new virus. By analyzing the immune response, Gertrude and Werner demonstrated that the EBV was widespread in the human population (Henle and Henle 1966; Henle *et al.*, 1969). As expected, they found antibodies to EBV in children with Burkitt's lymphoma, but also in the serum of healthy African children. Also, as may have been expected, the antibody titers in Burkitt's lymphoma patients were much higher that in healthy children. More surprising, was the finding that antibodies were found in most serums from children tested all over the world indicating that the virus was ubiquitous within the human population. Burkitt's lymphoma cell lines in culture were also used at this time by Lloyd Old and his colleagues at the Memorial Sloan–Kettering Cancer Center in New York to make the initial

connection of EBV infection and nasopharyngeal carcinoma (Old *et al.*, 1966).

Because antibodies to EBV were so ubiquitious, the Henles suspected that infections with EBV were common and were generally self-limited in nature. Interestingly, this has been a common observation in regard to most of the herpesviruses that were subsequently discovered. At the time of the discovery of EBV, only three other human herpesviruses were known. These were herpes simplex virus (HSV), varicella-zoster virus (VZV), and cytomegalovirus (CMV). All of these viruses caused overt symptoms as in the case for HSV and VZV, or were associated with serious congenital defects. As will be discussed in other chapters and this chapter, HHV6, HHV7, and KSHV cause little disease in immune competent individuals. It is only when the immune host immune system is compromised that overt symptoms typically appear with infection of these viruses.

As is the case for many discoveries, serendipity led to the discovery of the association of EBV with infectious mononucleosis. Late in 1967, a technician working in the Henle laboratory developed classical symptoms of infectious mononucleosis (Henle *et al.*, 1968). Prior to her symptoms, she had shown no antibodies to EBV, but with her symptoms, antibodies appeared to EBV. As will be reviewed in the later chapters, we will learn that, along with the association of EBV with Burkitt's lymphoma, NPC, and infectious mononucleosis, EBV has now been found to be involved in a much wider range of human disease. It is generally accepted that EBV is involved with several other malignancies of lymphocyte origin such as some types of Hodgkin's lymphoma, and epithelial origin such as gastric carcinoma. Table 22.1 contains a list of diseases with known EBV etiology. Each of these disease associations will be expanded in later chapters and specific references can be found in these chapters. EBV is also a factor in a variety of other human malignancies including some T and NK cell lymphomas.

The association of EBV with other diseases, such as breast carcinoma and hepatocellular carcinoma, remain controversial and will likely only be resolved in the coming years with additional research. In immunosuppressed patients, EBV causes a variety of proliferative disorders including oral hairy leukoplakia in AIDS patients, immunoblastic lymphomas, and an unusual tumor of muscle origin in children with AIDS or who are under immune suppression for liver transplantation. In young boys with X-linked immunodefiencies, EBV causes severe mononucleosis that results in death.

Evidence is accumulating that the EBV may also be associated with immune mediated diseases. In particular, there is a variety of auto-immune diseases that appear to have an infectious agent as a cofactor such as multiple sclerosis, rheumatoid arthritis, and diabetes. For each of these autoimmune diseases, it has been suggested that EBV may have an involvement in causing deregulation of the normal immune response to self-antigens. But, since EBV is so ubiquitous, many of these studies are also controversial. The linking of EBV infection to autoimmune disease and controversial malignancies such as breast carcinoma and hepatocellular carcinoma may await the development of an effective vaccine against EBV which will be discussed in Chapter 72. By preventing primary infection, an effective vaccine would offer convincing proof of a disease association due to absence of a particular disease or malignancy in those vaccinated for EBV. This may allow the true appreciation of the wide variety of disease associated with EBV infection in humans.

EBV life cycle

Infection with EBV usually occurs early in childhood, resulting in an asymptomatic infection. The virus is spread through saliva. If primary infection occurs later, B-cell proliferation and the resulting immune response results in infectious mononucleosis. After primary infection, most individuals will harbor the virus for the remainder of their life, and carriers develop cellular immunity against a variety of both lytic and latency associated proteins that will be more discussed later in this chapter as well as in Chapter 51. By adulthood, the majority of the human population (upwards of 90%) is infected with EBV. Periodically, virus is shed from latently infected individuals by the induction of lytic replication in B lymphocytes. The true site of latent infection has not been determined, but the virus likely resides in B lymphocytes. Recent studies have shown that EBV can be detected in circulating peripheral blood lymphocytes in carriers of EBV latent infections by PCR (both for viral DNA and viral mRNA) (Tierney *et al.*, 1994; Chen *et al.*, 1995; Babcock *et al.*, 1999; Qu *et al.*, 2000) and virus isolation and outgrowth of immortalized cell lines by culturing peripheral lymphocytes (Yao *et al.*, 1985). It has not been determined if this is the true site of latency. Other potential sites of EBV latency may include bone marrow, lymph nodes, or other lymphoid organs.

Early experiments suggested that latency is not maintained by constant re-infection of circulating B-lymphocytes as evidenced in patients treated with acyclovir (Yao *et al.*, 1989). Acyclovir, a nucleoside analogue that can inhibit lytic replication in the oral epithelium had no effect on the number of B-cells in the peripheral blood population that harbor the virus. More recent experiments have shown

Table 22.1. EBV associated pathologies in the human host

Pathology	Sub-type	Percent EBV +	Notes
Burkitt's lymphoma			
	Endemic	95–100%	Africa and New Guinea
	Sporadic	20–30%	Outside endemic region
Infectious mononucleosis		100%	
Chronic active EBV infection		100%	
Nasopharyngeal carcinoma		100%	Near 100% association with Type II and Type III, Type I frequently associated with EBV in endemic regions (South East Asia and North Africa)
Hodgkin's disease			90% in children in Latin America
	Mixed cell, lymphocyte depleted	60–80%	
	Nodular schlerozing	20–40%	
Fatal IM/X-linked lymphoproliferative syndrome		100%	
Immunocompromised disorders			
	Post-transplant Lymphoproliferative disorder	80%	
	Burkitt's lymphoma	30–50%	
	Diffuse large cell lymphoma – Centroblastic	30%	
	Diffuse large cell lymphoma – Immunoblastic	90%	
	Primary CNS lymphoma	100%	
	Non-Hodgkin's lymphoma	30–50%	
	Leiomyosarcoma	100%	Unusual muscle tumor found primarily in children
	Oral Hairy leukoplakia	100%	
T-Cell lymphoma			
	Nasal T/NK lymphomas	100%	EBV Infected B cells detected along with the lymphoma. T/NK cells can be infected with EBV.
	Angioimmunoblastic lymphadenopathy with dysproteinemia	30%	
Gastic carcinoma			
	Undifferentiated carcinoma of nasopharyngeal type	100%	
	adenocarcinoma	5–15%	

that viral gene expression may be greater than may have previously been thought in lymphoid organs such as the tonsil suggesting that the virus may manipulate normal B-cell development and survival to insure continued latency by the expansion of infected cells without lytic replication (Miyashita *et al.*, 1997; Babcock *et al.*, 1998, 2000; Babcock and Thorley-Lawson, 2000; Joseph *et al.*, 2000a,b; Thorley-Lawson, 2001; Hochberg *et al.*, 2004a,b). This will be more fully discussed in later chapters.

Further evidence of the hematopoetic site of EBV latency comes from engraftment of bone marrow cells that can result in the loss of the resident virus or the appearance of a new virus strain from donor lymphocytes (Gratama *et al.*, 1989). Lytic replication is presumed to occur when EBV infected B lymphocytes traffic through and transmit infection to oral epithelium providing a source for infection of other individuals. Interestingly, recent studies have suggested different virus strains are present within different compartments in humans with EBV latent infection such as peripheral blood and the oral cavity suggesting that epithelial infection may be more important than previously thought (Sitki-Green *et al.*, 2003). Understanding the complex interplay in EBV latency in the human host and the importance of viral gene expression requires the careful

analysis of EBV gene function which will be the topic of other chapters.

The discovery of Kaposi's sarcoma-associated herpesvirus (KSHV)

The discovery of KSHV or human herpesvirus 8 (HHV8), has many parallels with the discovery of Epstein–Barr virus. Like Dennis Burkitt, Patrick Moore and Yuan Chang, were intrigued by the appearance of a new cancer in the United States, but rather than appearing in very young children, the disorder was appearing in young healthy gay men (Jaffe *et al.*, 1983). This disorder was Kaposi's sarcoma (KS). KS was originally described as idiopathic purplish pigmented sarcoma of the skin by Moriz Kaposi in 1872 (Kaposi, 1872). Kaposi, born Moriz Kohn in Kaposvar, Hungary, obtained his MD in Vienna in 1861 and worked with Ferdinand Hebra, the founder of a renowned School of Viennese Dermatology. He would later become Hebra's son-in-law in 1869 and his successor in 1881. Also in 1869, Kaposi wrote the initial description of lupus erythematosus with a more comprehensive description published in 1872. He also described xeroderma pigmentosum. In 1871, two years after converting from Judaism to Roman Catholic and marrying Hebra's daughter, he changed his name to reflect his birthplace. In contrast to the frequent surname Kohn, Kaposi was certainly unique in Vienna, thus avoiding being mixed-up with others. In addition, this name change may have guarded against the harsh anti-semitism during the rule of Emperor Franz-Josef. Like his more comprehensive description of lupus erythematosus, it was also in 1872 that Kaposi published his description of the sarcoma that now bears his name. KS was a relatively rare, indolent, pigmented growth typically found on the skin of elderly men. Initially, Kaposi reported on the clinical features of six cases, including one of a young boy, but the remaining cases were all in men over 40 years of age. He reported that the disease was incurable and often resulted in death within two years after the disease appeared. In the 1960s, before the AIDS epidemic, it was realized that KS was not as rare as initially thought. The incidence in equatorial tropical Africa or sub-Sarahan African is much greater as will be more fully discussed below.

Following the outbreak of AIDS in the 1980s, in which there was a dramatic increase of KS in AIDS patients, there was considerable interest in the further study of this unusual malignancy and in particular the association of KS with infection with a human pathogen. Like Burkitt's lymphoma, a role for a virus was suspected in KS lesions long before the onset of HIV infection and the resulting AIDS epidemic. As early as 1972, herpesvirus-like particles were found in electron microscopic analysis of KS biopsies (Giraldo *et al.*, 1972). This virus was determined to be cytomegalovirus (CMV), a herpesvirus that is ubiquitous in the human population. By the early 1990s, a number of other pathogens had also been found in KS lesions by a variety of investigators. Typically, these agents were not found in all the lesions and in many cases they were ubiquitous agents in the human population and were subsequently dismissed as having a role in KS. Like Burkitt's lymphoma, there was epidemiological data that suggested the role of an infectious agent in the development of KSHV. But before the identification of KSHV, it was thought that HIV may be the critical factor in the development of AIDS-associated KS. However, the uneven distribution of KS among different transmission groups for the human immunodeficiency virus (HIV) resulted in the hypothesis that an environmental factor or a transmissible agent other than HIV was involved in KS pathogenesis (Beral *et al.*, 1990). Most notably, whereas more than 20% of homosexual and bisexual AIDS patients developed KS, only 1% of age- and sex-matched men with hemophilia suffered from this uncommon tumor, suggesting transmission of a KS-related virus by sexual practice.

The first real break that led to the discovery that a herpesvirus was linked to KS came in 1993 when Yuan Chang moved to Columbia University to take up a position in neuropathology. Chang received her medical degree from the University of Utah College of Medicine. Patrick Moore married Yuan Chang and in 1989 he left his job at the Centers for Disease Control to follow Chang to New York. Moore received a MS from Stanford in 1980, his MD from the University of Utah School of Medicine in 1985, and his MPH from the University of California, Berkeley in 1990. Once in New York, Moore was unable to find an appropriate academic position, so he joined the New York City Health Department. Both Moore and Chang were interested in identifying new pathogens without in vitro culture since this was a question that Moore was interested in from his work at the Centers for Disease Control. A recent publication from Michael Wiglers' laboratory at Cold Spring Harbor detailed a new technique called representational difference analysis (RDA). This technique, which was developed by the Lisitsyns, used PCR to identify DNA sequences present in one sample but not a control sample. On the surface, this looked ideal for the identification of unique infectious agents. The paper describing this technique was published in *Science* (Lisitsyn *et al.*, 1993). It was not used to detect unique pathogen, but only the feasibility of using this technique was demonstrated using lambda or adenovirus DNA. Barry Miller, a colleague of Patrick Moore at the Centers for Disease Control, suggested that Moore and Chang apply this technique in their pathogen discovery.

With a single KSHV lesion and control tissue, the husband and wife team began to perform RDA. The initial experiments were performed by Chang and Melissa Pessin. Pessin was a pathology resident on a research rotation at Columbia. Moore helped in the evenings after finishing his duties at the New York City Health Department. The initial amplifications resulted in four prominent bands. Two KS lesions were positive for two of the four bands by Southern hybridization, but surprisingly, a control tissue from an AIDS patient was also positive. The control tissue was from an unusual lymphoma found in AIDS patients. This lymphoma, characterized by pleural, pericardial, or peritoneal lymphomatous effusions, is referred to as primary effusion lymphoma (PEL) or body-cavity based lymphoma and would also be shown to be positive for the new herpesvirus that Chang and Moore identified as will be detailed later.

Testing a larger panel tissue, Moore and Chang found that virtually all of the KS lesions were positive while none of the controls showed the same number of positives. From sequencing the RDA products, they developed internal PCR primers for one of the sequences that allowed a simple PCR based screen for analysis of additional tissues. Surprisingly, when the initial sequences were compared to sequences available in the current databases, no homologous sequences were identified. This suggested an unknown pathogen. Moore quit the Health Department in January 1994 so that he could devote his efforts full-time to the project at Columbia. Chang made an important contact working in the spring of 1994 with Frank Lee and Janice Culpepper at the DNAX Institute for molecular biology. Lee, working with newly developed BLAST sequence alignment algorithms, was able to show that DNA fragments isolated by RDA from KS lesions unambiguously belonged to a new herpesvirus, similar to but distinct from known herpesviruses. With this data in hand, a paper was submitted to *Science* and was accepted for publication in December of 1994, identifying a new herpesvirus (Chang *et al.*, 1994). Both Moore and Chang have recently moved to the University of Pittsburgh School of Medicine, where Chang is a Professor of Pathology and Moore is a Professor of Molecular Genetics and Biochemistry and Director of the Molecular Virology Program at the University of Pittsburgh Cancer Institute.

KSHV life cycle

Like EBV, KSHV requires intimate contact for transmission. At least in regions endemic for KS, all evidence points to similar modes of transmission in young children as has been described for EBV (Mayama *et al.*, 1998; Martro *et al.*, 2004). Primary infection likely occurs from contact via saliva with parents, siblings, playmates, and close relatives at a very early age. Similarly, in adult populations close intimate contact is also required. Interestingly, in comparison to EBV the infection rates of KSHV within the human population can vary dramatically throughout the world population based on serology. In endemic regions such as Africa, infections rates are well over 50%, whereas in Northern Europe and the United States, infection rates range from 1–6% (Gao *et al.*, 1996; Kedes *et al.*, 1996; Simpson *et al.*, 1996). Southern Europe, which like Africa, has a higher incidence of KS, also has a higher rate ranging from 10%–30% when compared to infection rates in the United States and Northern Europe (Schatz *et al.*, 2001). As might be expected, infection rates measured by serology are higher in homosexual men than in the general population in western countries, ranging from 20%–40% in homosexual men not suffering from KS (Martin *et al.*, 1998). In immunocompromised KSHV infected individuals, a wide assortment of cells and tissues has been shown to harbor KSHV. Most frequently, peripheral B cells have been reported to carry the KSHV genome (Ambroziak *et al.*, 1995). But T-cells, monocytes, and endothelial cells have also been found positive for KSHV DNA (Henry *et al.*, 1999; Blackbourn *et al.*, 2000). In contrast, the site of latency in immunocompetent individuals is essentially unknown. Difficulties in detecting viral DNA in seropositive, healthy individuals may reflect a low frequency of spontaneous KSHV reactivation, which would in turn result in the scarceness of KSHV positive cells and relatively low KSHV transmission rates at least in North America, Northern Europe and most parts of Asia. As a consequence, sites of persistence and the overall strategy of KSHV latency in the human host have been difficult to determine as of this date. The supposedly low rate of spontaneous reactivation in immunocompetent individuals is also reflected by low and declining antibody titers (Martro *et al.*, 2004). The latter has made it difficult initially to estimate the seroprevalence of KSHV in the general population (Pellett *et al.*, 2003), as will be detailed in Chapter 54.

Human disease associated with KSHV infection

Symptoms related to primary infection with KSHV have only recently been described (Andreoni *et al.*, 2002). Like EBV, it would appear that symptoms in immunocompetent individuals are very modest with primary infection being largely asymptomatic. In children, this primary infection may be associated with a febrile maculopapular skin rash (Andreoni *et al.*, 2002). Reports have indicated that primary infection in adults undergoing immune suppression for organ transplantation have experienced bone marrow failure, splenomegaly, and fever (Luppi *et al.*, 2002). There

is also evidence that KSHV may be transmitted by solid organ transplants, eventually resulting in the development of rapidly progressing KS (Barozzi *et al.*, 2003; Marcelin *et al.*, 2004). However, at present it is not clear whether screening of organ donors for KSHV infection is beneficial.

Despite the only recent identification of KSHV, remarkable progress has been made in the identification of pathological consequences of infection with KSHV. Along with EBV, as described above, KSHV is also associated with proliferative disorders in both immune competent and immune deficient humans. In endemic regions of Africa, KS is a common debilitating cancer among men, women, and children. Following the establishment of this link, KSHV has also been shown to be important for a number of other diseases in the human population as will be described.

Classical KS, as originally identified by Kaposi, was typically seen in elderly Mediterranean patients, was indolent in nature, and affected the skin of the lower limbs. In endemic KSHV infection in Africa, before the HIV epidemic hit, KSHV infection presents as four distinct clinical syndromes: relatively benign, nodular cutaneous disease which is very similar to classical KS, aggressive cutaneous disease which invades both bone and localized soft tissue, florid visceral and mucocutaneous disease, and finally lymphadenopathic disease that can rapidly disseminate to lymph nodes and visceral organs (quite often in the absence of cutaneous disease). The final syndrome typically occurs in children. KS associated with immune suppression either from HIV infection or organ transplantation commonly presents multifocally and symmetrically and may arise quickly. These lesions will often undergo spontaneous remission with improving immune status.

As discussed earlier, there were early indications that another proliferative disorder observed in HIV patients might also be related to KSHV infection. Early work by Chang and Moore found that an unusual lymphoma in patients with AIDS was also positive for KSHV DNA (Chang *et al.*, 1994). The lymphoma was confined primarily to body cavities and grows as an effusion. Hence the names primary effusion lymphoma (PEL) or body-cavity based lymphoma. Daniel Knowles and Ethel Ceserman working with Moore and Chang established that these tumors are also uniformly positive for KSHV (Cesarman *et al.*, 1995). Interestingly, the vast majority of these tumors are also positive for EBV.

The final disease in human associated with KSHV infection is multicentric Castleman's disease (MCD). MCD was first described by Castleman in 1956 and is an unusual lymphoproliferative disorder that is characterized by lymphadenopathy, fever, and splenic infiltration (Castleman *et al.*, 1956). KSHV is present in nearly all the cases of MCD in AIDS patients as originally shown by Soulier and colleagues in 1995 and about half of the cases in HIV-negative patients (Soulier *et al.*, 1995). MCD is considered to be a semi-malignant lymphoproliferative disorder, associated with IL-6 hyperproduction and inflammatory symptoms. In the context of MCS, however, a highly aggressive plasmablastic non-Hodgkin-lymphoma may arise which is also KSHV positive and likely to have arisen from monoclonal "microlymphomas" detectable in some MCD lesions (Dupin *et al.*, 2000).

Finally, there have been reports of the potential association of KSHV infection with sarcoidosis (Di Alberti *et al.*, 1997) and multiple myeloma (Rettig *et al.*, 1997), but as is the case with EBV association with liver and breast cancer, the linkage of KSHV infection with these two pathologies requires additional confirmation before a definitive link is established. In 2003, C. D. Cool *et al.* detected DNA and antigen of KSHV in lung tissues of 10 out of 16 patients with severe primary pulmonary hypertension (Cool *et al.*, 2003). It is fascinating to note that, like MCD, PEL, and KS, primary pulmonary hypertension is frequently associated with HIV-1 infection. However, several follow-up studies were not able to confirm this intriguing finding (Henke-Gendo *et al.*, 2004 and reviewed in D. Rimar *et al.*, July 2006). But C. D. Cool and coworkers argue, that in contrast to their initial work most follow-up studies were based on serological assays. In fact, only two of the studies used DNA-PCR and/or histochemistry Katano *et al.*, 2005; Daibata *et al.*, 2004), and these were performed on patients from Japan, were KSHV prevalence is very low. Thus, further work is needed before a link between PPH and KSHV infection can be considered shown.

Phylogenetic relationship between EBV, KSHV, and non-human γ-herpesvirus genomes

The γ-herpesviruses are split into two subfamilies: the γ1-herpesviruses and the γ2-herpesviruses. The two human γ-herpesviruses include the recently identified KSHV, and EBV, which are distinguished by their latent infection of lymphoblastoid cell lines either of T- or B-cell origin. EBV is the only human member of the genus γ1-herpesvirus also termed lymphocryptovirus. A number of related viruses have been identified that infect both New World and Old World primates (Wang, 2001; Wang *et al.*, 2001). These viruses serve as important models to investigate the pathogenesis of the lymphocryptoviruses in vivo (see Chapters 60 and 61). KSHV is a member of the γ2-herpesviruses or rhadinoviridae and like EBV has important related viruses that infect New and Old World primates. Herpesvirus saimiri (HVS), which infects squirrel monkeys, has been well studied and also provides an important model of KSHV in vivo pathogenesis (Fickenscher and Fleckenstein, 2001).

Following the discovery of KSHV in man, several studies were undertaken to detect additional Old-World primate rhadinoviruses. By searching for antibodies cross-reactive with KSHV, the group of Ronald Desrosiers at the New England Primate Research Centre isolated the rhesus monkey rhadinovirus (RRV) (Desrosiers *et al.*, 1997). The complete genomic sequence of RRV clearly showed that this virus is more closely related to KSHV than herpesvirus saimiri (Searles *et al.*, 1999). In particular, most genes not conserved between KSHV and herpesvirus saimiri, the so-called "K" genes, do have homologues in RRV. In contrast to HHV-8, RRV can be readily propagated in cell culture. While RRV was discovered at the East Coast, Timothy M. Rose and Marnix Bosch were sleepless in Seattle. They studied tissue specimens from rhesus monkeys suffering from retroperitoneal fibromatosis (RF) at the Washington Regional Primate Research Centre. RF has been identified as an infrequent disease syndrome occurring in immunosuppressed macaques (Giddens *et al.*, 1985). RF lesions somewhat resemble KS: they consist of an aggressively proliferating fibrous tissue with a high degree of vascularization, and transmission studies indicated that an infectious agent may be involved in RF pathogenesis. By using a degenerated PCR technique, fragments of a herpesvirus DNA polymerase gene were identified in RF tissues from two macaque species, *Macaca nemestrina* and *Macaca mulatta* (Rose *et al.*, 1997). Sequence comparisons indicated that, at least the DNA polymerase genes of these two novel rhadinoviruses, tentatively termed RFHVMm and RFHVMn, are more closely related to KSHV than the DNA polymerase genes of RRV. In addition, the LANA gene of RVHVmn is closely related to KSHV in structure and sequence. A role of RFHVMn in the pathogenesis of RF is suggested by the finding that RF spindle cells are highly positive for RFHVMn LANA (Burnside *et al.*, 2006). However, attempts to isolate these viruses on cultured cells have not been successful so far. Several rhadinoviruses have been discovered since then in various Old World primates, including chimpanzees, gorillas and orang-utans. Phylogenetic analysis clearly showed that these Old Word primate rhadinoviruses form two clades. KSHV is the prototype of one clade, and RRV the prototype of the second clade. The thrilling point here is: most Old World primate species seem to harbor representatives of both clades. The search for a second rhadinovirus in man has not been successful to date, however.

Human γ-herpesviruses genomes

At least two EBV types have been identified in human populations and these were formerly designated EBV type A and type B (Zimber *et al.*, 1986) but have recently been designated EBV-1 and EBV-2 to parallel the HSV-1 and HSV-2 nomenclature. The majority of EBV isolates in western communities are type 1, while type 2 EBV isolates appear to be largely restricted to equatorial Africa and Papua New Guinea. Unlike HSV-1 and HSV-2, there is extensive nucleotide homology and restriction endonuclease site conservation throughout most of the EBV-1 and EBV-2 genomes. However, there are important differences in the sequence of key EBV genes such as EBNA2 and the EBNA3 family of genes (Dambaugh *et al.*, 1984; Sample *et al.*, 1990). But, overall, the two types of EBV are considerably more closely related to each other than are HSV-1 and HSV-2 (Lees *et al.*, 1993). Related to the differences in key EBV genes, the EBV-1 strains transform lymphocytes more readily and to faster growing cell lines than do EBV-2 strains (Rickinson *et al.*, 1987).

EBV has a linear double-stranded genome of approximately 172 kilobase pairs (kb) and has a base composition of 59% guanine plus cytosine. It was the first large DNA virus whose complete sequence was determined (Baer *et al.*, 1984). Subsequent to the sequencing of the EBV genome, the VZV, HSV, CMV, HHV6, and KSHV genomes were cloned and sequenced. The EBV genome sequenced, designated B95–8, was from an EBV-infected marmoset cell line partially permissive for lytic replication (Miller *et al.*, 1972). Upon further analysis, it was determined that this virus isolate contained a deletion of approximately 12 kb relative to other EBV strains. Sequence analysis of Raji EBV strain revealed the 12 kb region deleted from B95–8 contained three potential open reading frames (Parker *et al.*, 1990). The sequence analysis to date predicts around 85 to 95 open reading frames (Table 22.3, Fig. 22.2). The nomenclature for each identified gene in the sequence is based on the BamHI fragment in which the reading begins. This is followed by an "L" or an "R," depending on the whether the reading frame is leftward or rightward. The reading frames in each BamHI fragment are then numbered. As is apparent from the Table 22.2, many of the reading frames also have another name based on the prior identification of the gene product or homology to well described genes or gene products described in other herpesviruses.

The KSHV genome is a linear, double-stranded DNA of approximately 160 kbp and has the overall structure typical for rhadinoviruses (Fig. 22.2) (Russo *et al.*, 1996). A complete rhadinovirus genome is usually termed M genome, as it is of intermediate density (M-DNA). The γ2-herpesviruses were termed "rhadino" viruses utilizing the ancient greek word for fragile, because this M-DNA tends to split into two fractions of DNA molecules with highly different density, the L-DNA containing genes (low density, low G+C content) and the terminal repetitive H-DNA (high density, high G+C content). The latter is, as far as

Table 22.2. KSHV associated pathologies in the human host

Pathology	Sub-type	Percent KSHV Positive	Notes
Kaposi's sarcoma	Classical	100%	
	African endemic	100%	
	iatrogenic immunosuppression	100%	
	AIDS-associated	100%	
Primary effusion lymphoma		~100%	50% of PEL are also positive for EBV
Multifocal Castleman disease	HIV-associated	90%–100%	
	Non-HIV associated	~40%	
	Plasma cell variant	50–100%	50% in HIV-negative, up to 100% in HIV positive patients
	Hyaline vascular variant	Usually negative	
Primary pulmonary hypertension		60%	unconfirmed report

known until today, without coding capacity. The L-DNA contains at least 89 open reading frames, 67 of which have homologues in the closely related γ2-herpesvirus prototype herpesvirus saimiri. The overall amino acid sequence identity of these 67 KSHV reading frames to homologues identified in herpesvirus saimiri ranges from 22.4 to 66% (average: 42%). Conserved genes are usually found in a comparable genomic position and orientation. Thus, KSHV genes that share homology with herpesvirus saimiri are numbered from left to right according to their position on the herpesvirus saimiri genome. Open reading frames which do not share recognizable amino acid homology with genes in herpesvirus saimiri are numbered with the prefix "K" (Table 22.4). Until today, 19 genes have been identified which are not clearly homologous to genes identified in herpesvirus saimiri (K1 – K15, K4.1, K4.2, K8.1, K10.5). Frequently, these "K" genes are strikingly homologous to known cellular genes. They code for proteins interfering with the immune system, for enzymes of the nucleotide metabolism, and for putative regulators of cell growth (Table 22.4).

Despite enormous differences in base composition, it is apparent that herpesvirus genomes have many open reading frames in common. Many products of EBV genes can be predicted on the basis of their amino acid homology with HSV genes and genes from other herpesvirus genes such as KSHV. The predictions and known functions are shown in Tables 22.3 and 22.4. These similarities between proteins encoded by the different herpesviruses, such as HSV-1, KSHV, and EBV underscores the relationships between the various herpesviruses. The homologous genes are primarily limited to genes required for the cleavage and packaging of the viral genome and infection of susceptible host cells. Included among the conserved genes are virion structural proteins, enzymes involved in DNA replication, some regulators of gene expression, and glycoprotein genes. Lytic gene function has been primarily described in HSV, because lytic replication is easily observed in tissue culture systems allowing gene function studies. In contrast, EBV and KSHV, which are largely latent in tissue culture systems, have been less amenable to studies of lytic gene function.

Characteristics of the γ-herpesvirus virion

Morphologically, the EBV and KSHV virions are very similar to other herpesvirus virions, consisting of an envelope containing viral glycoproteins (Epstein *et al.*, 1964, 1965). A tegument layer is found between envelope and nucleocapsid. The envelope contains viral transmembrane glycoproteins that mediate attachment and entry, either via fusion or endocytosis. Most glycoproteins of EBV and KSHV are conserved amongst the different herpesvirus families (gB, gH, gL, gM and gN). However, the most abundant envelope glycoproteins of EBV and KSHV are not found in more distant herpesviruses. These are termed gp350/220 and gpK8.1, respectively (Hutt-Fletcher, 1995; Raab *et al.*, 1998). The EBV and KSHV capsids are similar to those of other herpesviruses. The icosahedral capsid shells are composed of 162 capsomers (12 pentons, 150 hexons). It contains the linear, double stranded DNA molecule wrapped around a toroid-like protein core. The three-dimensional structure of the KSHV capsid has been determined by cryo electron-microscopy using viral particles produced from cultured primary effusion lymphoma (PEL) cells at a resolution of 22 – 24A (Wu *et al.*, 2000).

Conclusions

There has been dramatic progress in the understanding the molecular biology and disease associations of oncogenic

Table 22.3. EBV genes

EBV gene	HSV gene	KSHV gene	EBV Name	Known or proposed function
BNRF1		ORF75		Tegument protein, putative phosphoribosylformylglycinamidine synthase
EBER1,2				*Cell survial factor*
BCRF1				IL-10 homologue – host immune modulator
BCRF2				
BWRF1			*EBNALP*	*Regulator of latent viral gene Transcription (EBNA5)*
BYRF1			*EBNA2*	*Major regulator of viral gene Transcription*
BHRF1		ORF16		Bcl-2 homologue
BHLF1				
BFLF2	UL31	ORF69		Associates with nuclear matrix
BFLF1	UL32	ORF68		Virion protein – DNA cleavage/packaging
BFRF1	UL34	ORF67		Virion protein – capsid assembly
BFRF2		ORF66		
BFRF3	UL35	ORF65		Capsid protein
BPLF1	UL36	ORF64		Virion phosphoprotein – DNA release
BOLF1	UL37	ORF63		Cytoplasmic phosphoprotein
BORF1	UL38	ORF62		Capsid assembly – binds DNA
BORF2	UL39	ORF61		Ribonucleotide reductase (large subunit)
BaRF1	UL40	ORF60		Ribonucleotide reductase (small subunit)
BMRF1	UL42	ORF59		Polymerase associated processivity factor
BMRF2	*UL43*	ORF58		Transmembrane glycoprotein, 53/55kDa
BSLF2/ BMLF1	UL54	ORF57		Post-transcriptional regulator of viral gene expression
BSLF1	UL52	ORF56		DNA replication – helicase/primase complex
BSRF1	*UL51*	ORF55		
BLRF1		ORF53		gN
BLRF2		ORF52		p23 capsid antigen
BLLF1a			gp350	Virion binding to CR2 (CD21)
BLLF1b			gp220	Virion binding to CR2 (CD21)
BLLF3	UL50	ORF54		dUTPase
BLRF3-BERF1		*EBNA3C*		*Regulator of latent viral gene Transcription (EBNA6)*
BERF2a,b		*EBNA3B*		*Regulator of latent viral gene Transcription (EBNA4)*
BERF3-BERF4		*EBNA3A*		*Regulator of latent viral gene Transcription (EBNA3)*
BZLF2			gp42	Complexes with gp25 and gp85 – binds HLA Class II
BZLF1				Z transactivator
RAZ				Z regulator
BRLF1		ORF50		R transactivator
BRRF1		ORF49		Transcription factor
BRRF2		ORF48		
BKRF1			*EBNA1*	*Maintenance of viral episome*
BRKF2	UL1	ORF47	gp25	gL – complexes with gp42 and gp85
BKRF3	UL2	ORF46		Uracil-DNA glycosylase
BKRF4	*UL3*	ORF45		Nuclear phosphoprotein
BBLF4	UL5	ORF44		DNA replication – helicase/primase complex
BBRF1	UL6	ORF43		Virion protein – DNA packaging
BBRF2	UL7	ORF42		
BBLF3	UL8	ORF41		DNA replication – helicase/primase complex
BBLF2	UL9	ORF40		DNA replication – helicase
BBRF3	UL10	ORF39		gM
BBLF1	UL11	ORF38		Myristylated virion protein
BGLF5	UL12	ORF37		exonuclease
BGLF4	UL13	ORF36		Virion protein kinase

Table 22.3. (*cont.*)

EBV gene	HSV gene	KSHV gene	EBV Name	Known or proposed function
BGLF3	UL14	ORF34		Putative virion tegument protein, anti-apoptotic
BGLF3.5		ORF35		
BGRF1	UL15	ORF29a		DNA packaging protein
BGLF2	UL16	ORF33		Capsid maturation/assembly protein
BGLF1	UL17	ORF32		Capsid maturation/DNA packaging
BDLF4		ORF31		
BDRF1	UL15	ORF29b		DNA packaging protein
BDLF3		*ORF28*	gp150	Enhances epithelial infection
BDLF3.5		*ORF30*		
BDLF2		ORF27		
BDLF1	UL18	ORF26		Minor capsid protein

Raji LF2		ORF11		
Raji LF1				Part of BILF1

Note: Genes in italics in the "EBV" column are expressed in EBV latent infections. In the "HSV" and "KSHV" columns, the homology of the genes in italics with EBV is statistically not significant when standard blast comparisons are made. However, due to positional analogy, it is likely that the genes are evolutionary related. Based on the sequence data published in references (Baer *et al.*, 1984; McGeoch *et al.*, 1985, 1988; Parker *et al.*, 1990; Russo *et al.*, 1996).

γ-herpesviruses like EBV and KSHV. Many years of research on lymphomas induced by EBV and herpesvirus saimiri have identified viral factors that are critical for the proliferative disorders observed with these viruses. Upon infection of naïve B- or T-cells, respectively, differentiation and proliferation are induced in an antigen-independent manner, most likely to expand the pool of virus -infected or -infectable cells. To achieve this goal, both EBV and herpesvirus saimiri make use of transmembrane proteins mimicking constitutively active signaling receptors. In the case of EBV, the latent membrane proteins 1 and 2A are likely essential for the differentiation and expansion of latently infected cells observed in vivo. In herpesvirus saimiri, these latent transmembrane proteins are STP (saimiri transforming protein) and a second protein termed TIP (tyrosine kinase interacting protein) that is found in some strains of herpesvirus saimiri. Usually, this process does not result in the development of malignant disease, but is likely important for the establishment of latency. However, other circumstances can occur which may result

Table 22.4. KHSV genes

KSHV gene	HSV gene	EBV gene	KHSV name	Known or proposed properties and function
K1			K1	Transmembrane glycoprotein, signaling protein
ORF04			CCPH	Complement binding protein
ORF06	UL29	BALF2		ssDNA binding protein
ORF07	UL28	BALF3		DNA cleavage/packaging
ORF08	UL27	BALF4		gB – virus maturation
ORF09	UL30	BALF5		DNA polymerase
ORF10				
ORF11		Raji LF2		
K2			*vIL-6*	*viral interleukin-6, direct binding to gp130*
ORF02			DHFR	Dihydrofolate reductase
K3			IE-1B	Downregulates MHC I
ORF70				Thymidylate synthase
K4			vMIP-II / vMIP-1a	Viral macrophage inflammatory protein (chemokine)
K4.1			vMIP-III / vMIP-1b	Viral macrophage inflammatory protein (chemokine)
K4.2				
K5			IE-1A	Downregulates MHC I
K6			vMIP-I / vMIP-1a	Viral macrophage inflammatory protein (chemokine)
K7				partially overlaps w. non-translated T1.1RNA (=Nut-1, PAN RNA)
ORF16		BHRF1		Bcl-2 homologue
ORF17	UL26	BVRF2		Serine protease
ORF18				
ORF19	UL25	BVRF1		Virion protein

ORF57	UL54	BSLF2/ BMLF1		Transactivator/repressor
K9			vIRF-1	Viral interferon regulatory factor
K10			vIRF-4	Viral interferon regulatory factor
K10.5			*vIRF-3, LANA-2*	*Viral interferon regulatory factor, latent nuclear Antigen 2*
K11			vIRF-2	Viral interferon regulatory factor
ORF58	*UL43*	BMRF2		Putative integral membrane glycoprotein
ORF59	UL42	BMRF1		Polymerase associated processivity factor
ORF60	UL40	BaRF1		Ribonucleotide reductase (small subunit)
ORF61	UL39	BORF2		Ribonucleotide reductase (large subunit)
ORF62	UL38	BORF1		Capsid assembly – binds DNA
ORF63	UL37	BOLF1		Cytoplasmic phosphoprotein
ORF64	UL36	BPLF1		Virion phosphoprotein – DNA release
ORF65	UL35	BFRF3		Capsid protein
ORF66		BFRF2		
ORF67	UL34	BFRF1		Virion protein – capsid assembly
ORF67.5	UL33	BFRF4		DNA packaging
ORF68	UL32	BFLF1		Virion protein – DNA cleavage/packaging
ORF69	UL31	BFLF2		Associates with nuclear matrix
K12			*Kaposin A,B,C*	
K13			*vFLIP*	*Anti-apoptotic viral flice inhibitory protein*
K14			*vCyclin*	*Cyclin-D homologue*
ORF73			*LANA*	*Latent nuclear antigen, maintenance of latent viral genome,* functional analogue to EBV EBNA 1
K14			vOx-2	Viral Ox-2 homologue, immunomodulatory protein
ORF74			vIL8R, vGPCR	viral interleukin-8 receptor, viral G-protein coupled receptor; constitutively active, KS-like lesions in transgenic mice
ORF75		BNRF1		Tegument protein, putative Phosphoribosylformylglycinamidine synthase
K15				Signaling protein

Note: Genes in italics in the "KSHV" column are expressed in KSHV latent infections. In the "HSV" and "EBV" columns, the homology of the genes in italics with KSHV is statistically not significant when standard blast comparisons are made. However, due to positional analogy, it is likely that the genes are evolutionary related. Based on sequence data published in references (McGeogh *et al.*, 1985, 1988; Parker *et al.*, 1990; Russo *et al.*, 1996).

in overt malignant disease such as accidental infection of a foreign host, immunosuppression, or infection with malaria. Each of these increases the risk of development of disease associated with viral infection. In addition, genetic changes may occur in infected cells within the host that may also be important for the development of malignant disease. This may be quite rapid as seen in Burkitt's lymphoma or have a lengthy latency period as seen in Hodgkin's lymphoma. Besides the latent membrane proteins, other EBV viral proteins such as EBNA1 (Wilson *et al.*, 1996; Drotar

et al., 2003) and the virally encoded small RNAs called the EBERs (Komano *et al.*, 1999; Ruf *et al.*, 2000) may also have a role in EBV-associated malignant diseases in the human host. This will be more fully covered in later chapters.

Several lines of evidence indicate that KSHV plays an essential role in KS pathogenesis: the virus is invariably present in KS, KSHV infection precedes KS-development, the virus is present in the tumor cells themselves, and it is rather infrequently found outside the population at risk of KS (see Chapters 50 and 54). Research on KSHV pathogenesis is hampered by the lack of a cell culture system for transformation and animal models for KSHV proliferative diseases. Studies using rodents transgenic for single KSHV genes have been more successful, but results from such experiments should still be interpreted with caution, no matter how tempting the resemblance of lesions in mice transgenic for vIL8R to KS may be (Yang *et al.*, 2000).

At least two concurring models exist for the role of KSHV in oncogenesis. The "cytokine model" emphasizes the role of inflammatory cytokines induced or produced by KSHV. A closer look at clinical course and histopathology of KS raises doubts about the relevance of "classical," transforming genes for the pathogenesis of this peculiar tumor. The peculiar pathology of KS hints at a more complex, indirect mechanism of pathogenesis. Based on clinical observations and data derived from cell culture systems, models of KS pathogenesis were developed before KSHV was discovered. Several groups agreed upon the notion that KS develops as an interplay of inflammatory cytokines and angiogenic factors (Ensoli and Stürzl, 1998), although the cytokines focused on varied in different reports. Interestingly, KSHV encodes or induces several cytokines with intriguing similarity to the cellular factors shown to be required for in vitro models of KS. An example is VEGF that is secreted by cells expressing the constitutively active vIL-8R. This leads to a model of KS pathogenesis, where increased secretion of both viral and cellular cytokines, the latter in part induced by KSHV, promote inflammatory infiltrates (vMIP, vIL-6), angiogenesis (vMIP, vIL-8R), and enhance spindle cell proliferation (vIL-6, vIL-8R via VEGF).

The reliable presence of KSHV in the spindle cells may point to additional factors beyond those induced through the 1%–3% productively infected cells, voting for a role more compatible with a typical "oncogenic transformation" model by latently expressed viral genes. Starting from the close relationship to EBV and herpesvirus saimiri, it is intriguing to assume that transmembrane proteins mimicking constitutively active receptors mechanisms, similar to those identified in EBV and herpesvirus saimiri, might be relevant for KSHV pathogenesis. At first sight, KSHV genes K1 and K15 might fall into this category. However, attempts to detect expression of these genes in latently infected tumor cells remain unsuccessful.

Thus, KS may result from a complex interplay of both viral and cellular cytokines and angiogenic factors, induced by a sustained inflammatory reaction initiated by up to 3% productively infected cells. Perhaps the viral cyclin and other latency-associated proteins such as LANA-1 might further enhance the proliferation of KS cells and favor the development of truly malignant cells by indirect means, e.g., the reduced control of accidental DNA damage. As KS is an unusual malignancy, resembling hyperplastic, angioproliferative inflammatory changes rather than true sarcoma, such a multistep/multifactorial model might be more compatible with KS pathogenesis than classical transformation models by viral oncogenes, as described for EBV, herpesvirus saimiri, and possibly for KSHV-associated B-cell malignancies (PEL).

Acknowledgments

R. L. is a Stohlman Scholar of the Leukemia and Lymphoma Society of America and supported by the Public Health Service grants CA62234, CA73507, and CA93444 from the National Cancer Institute and DE13127 from the National Institute of Dental and Craniofacial Research. Gammaherpesviruses entry and early events during infection

Bala Chandran[1] and Lindsey Hutt-Fletcher[2]

[1]Rosalind Franklin University, North Chicago, IL, USA
[2]Louisiana State University, Shreveport, LA, USA

The two human gammaherpesviruses, Epstein–Barr virus (EBV), a gamma 1 lymphocryptovirus and Kaposi's sarcoma associated virus (KSHV), a gamma 2 rhadinovirus, have many features in common. They share an architecture that is typical of all members of the herpesvirus family, they share an ability to establish latency in lymphocytes, and they are both initiators or potentiators of human tumors. For the virologist some of the challenges they present are the same, in particular the relative dearth of fully permissive, easily manipulated cell culture systems for study. In this respect the many years of work on EBV provided an initial roadmap to accelerate study of KSHV. However, the strategies that the viruses use for cell infection and replication provide not only interesting reflections of common ancestry, but also interesting contrasts in adaptation to unique cellular niches in their human hosts.

Target cells for EBV

EBV can infect a variety of cell types under different circumstances, including T-cells, NK-cells, smooth muscle cells and possibly follicular dendritic cells (Rickinson and Kieff, 2001). However, B-lymphocytes and epithelial cells are its two major targets. B-cells are the primary reservoir of virus in persistently infected individuals and it is likely, although not certain, that the first cell infected in vivo is an epithelial cell. There has been some controversy over whether EBV normally infects epithelial cells during the courses of a primary infection or whether the virus infects epithelial cells only in the context of oncogenesis (nasopharyngeal carcinoma) or extreme immune dysfunction (oral hairy leukoplakia). Detection of EBV in epithelial tissue of healthy donors or patients with acute infectious mononucleosis has not always been consistent (Anagnostopoulos *et al.*, 1995: Frangou *et al.*, 2005; Lemon *et al.*, 1977; Niedobitek *et al.*, 1989; Pegtel *et al.*, 2004; Sixbey *et al.*, 1984; Venables *et al.*, 1989). However, the preponderance of findings and the characteristics of virus shed in saliva of healthy carriers support a role for epithelial cells in amplification of virus during primary and persistent infection (Jiang *et al.*, 2006). The clear association of the virus with significant epithelial pathology and its ability to infect epithelial cells in vitro either as free virus (Tugizov *et al.*, 2003; Turk *et al.*, 2006) or as B-cell associated virus (Imai *et al.*, 1998, Shannon-Rowe *et al.*, 2006) also reinforce the position that failures to detect virus may represent technical difficulties rather than reality.

B cells have been most extensively studied because the immortalizing effects of virus are so striking in this cell type, because B-cells are easier to isolate and because, after EBV infection, they are extremely easy to grow as latently infected cells. They retain episomes well in culture and are the best source of cell-free virus. Reactivation occurs spontaneously in a small subpopulation of some semipermissive B cell lines and can be induced in larger numbers of cells by agents such as phorbol esters, sodium butyrate or by cross-linking of immunoglobulin on the cell surface (Kieff and Rickinson, 2001). Epithelial cells typically lose episomes in vitro, but recent derivation of recombinant viruses that carry drug resistant markers has allowed selection of cells that can support episomal maintenance. The degree of lytic replication that occurs in epithelial cells varies from cell line to cell line. In many cell lines virus remains latent unless reactivated by treatment with inducing agents, but there is a recent report of extensive lytic replication in two polarized cell lines (Tugizov *et al.*, 2003).

Target cells for KSHV

The in vivo host cell range of KSHV is not yet fully characterized, but appears to be broad in that KSHV viral DNA and

transcripts have been detected in B-cells from the peripheral blood, B-cells in primary effusion lymphomas (PEL) or body-cavity based B-cell lymphomas (BCBL) and multicentric Castleman's disease (MCD), flat endothelial cells lining the vascular spaces of Kaposi's sarcoma (KS) lesions, typical KS spindle cells, CD45+/CD68+ monocytes in KS lesions, keratinocytes, and epithelial cells (Antman and Chang, 2000; Dourmishev *et al.*, 2003; Ganem, 1998; Sarid *et al.*, 1999; Schulz *et al.*, 2002). KSHV DNA is present in a latent form in the vascular endothelial and spindle cells of KS tissues and expresses the latency associated LANA1 (ORF 73), cyclin D (ORF72), vFLIP (ORF 71) and K12 genes. However, virus DNA is lost within a few passages of cells cultured from the KS lesions. This is reminiscent of the loss of EBV episomes from nasopharyngeal carcinoma cells in tissue culture and the reason for it is not currently known. KSHV DNA is found in the CD19+ peripheral blood B cells of KSHV seropositive individuals and the detection of both lytic and latent forms in B- cells of KS patients suggests that CD19+ B-cells may be a primary reservoir for persistent infection (Antman and Chang, 2000; Dourmishev *et al.*, 2003; Schulz *et al.*, 2002).

Cell lines with B-cell characteristics such as BC-1, HBL-6, JSC, BCBL-1 and BC-3 have been established from PEL tumors (Dourmishev *et al.*, 2003). The BC-1, HBL-6 and JSC cells carry KSHV and EBV genomes, while BCBL-1 and BC-3 cells carry only KSHV genome. KSHV exists in a latent state in these BCBL cells and expresses the latency associated ORF73, ORF72, K13, K12, K15 and ORF 10.5 genes. In parallel with EBV, spontaneous reactivation and expression of lytic cycle proteins occurs in 1% to 5% of BCBL cells. The lytic cycle can also be induced in about 20% to 30% of cells by phorbol esters, sodium butyrate and the lytic cycle switch protein known as RTA encoded by KSHV ORF 50 (Antman and Chang, 2000; Dourmishev *et al.*, 2003; Liao *et al.*, 2003; Schulz *et al.*, 2002)

KSHV also has a much broader in vitro tropism than EBV. The virus can infect human B, lymphocytes, endothelial, epithelial, and fibroblast cells, as well as a variety of animal cells such as owl monkey kidney cells, baby hamster kidney fibroblast cells, Chinese hamster ovary (CHO) cells, and mouse fibroblasts (Akula *et al.*, 2001b; Bechtel *et al.*, 2003; Blackbourn *et al.*, 2000; Ciufo *et al.*, 2001; Dezube *et al.*, 2002; Lagunoff *et al.*, 2002; Moses *et al.*, 1999; Naranatt *et al.*, 2003; Renne *et al.*, 1998; Vieira *et al.*, 2001). Unlike EBV, infection of primary B-cells by KSHV does not result in immortalization. However, like EBV in vitro infection by KSHV is characterized by the expression of latency associated genes and the absence of productive lytic replication. After activation with phorbol esters or ORF 50 protein, lytic replication is supported by many cells including primary human microvascular dermal endothelial cells (HMVEC-d), human umbilical vein endothelial cells (HUVEC), human foreskin fibroblast cells (HFF), human endothelial cells immortalized by telomerase (TIME) or the E6/E7 proteins of human papilloma virus, monkey kidney cells and mouse fibroblasts (Bechtel *et al.*, 2003).

Detection of KSHV latency associated nuclear antigen (LANA-1) encoded by ORF 73 after 2 days post-infection has led to the notion that the establishment of latency is the default pathway of infection (Bechtel *et al.*, 2003; Lagunoff *et al.*, 2002; Schulz *et al.*, 2002; Tomescu *et al.*, 2003). However, in vitro KSHV latent infection in primary fibroblasts, endothelial cells, or non-adherent B-cells is unstable, and viral DNA is not efficiently maintained (Tomescu *et al.*, 2003). Even during primary infection of endothelial and other cells, the proportion of KSHV-infected cells decreases over time (Grundhoff and Ganem, 2004). Loss of genomes begins approximately 4 days after infection and by 3 weeks fewer than 15% of the cells remain positive for LANA1 (Tomescu *et al.*, 2003). Whether the wild-type KSHV from the saliva of infected individuals or KSHV isolates from Africa have similar properties and tropisms remains unknown at the present time.

Virion structure

The virions of EBV and KSHV are at least superficially very similar to those of other herpesviruses. Each consists of a linear double stranded genome, an icosahedral capsid surrounded by an amorphous layer of tegument proteins and a lipid envelope carrying multiple unique glycoprotein species.

The KSHV genome is made up of a unique long region (LUR) of about 145kb flanked by varying numbers of terminal repeats. A large region of the KSHV genome is conserved among herpesviruses, and is colinear with both the gamma 1 EBV and the gamma 2 herpesvirus saimiri (HVS) (Neipel *et al.*, 1997; Russo *et al.*, 1996). It encodes more than 90 open reading frames (ORFs), designated ORFs 4 to 75 for their homology to those of HVS (Neipel *et al.* 1997; Russo *et al.*, 1996). Divergent regions in-between the conserved gene blocks contain more than 20 KSHV unique genes which are designated with the prefix K.

The EBV genome is slightly larger than that of KSHV at approximately 180 kb. However, it includes a large, internal, tandemly reiterated 300 kb repeat known as IR1, a number of smaller internal repeats (IR2-IR4) and 500 bp terminal repeats arranged in tandem, all of which can vary in number in different strains of viruses. The more than 90 ORFs of

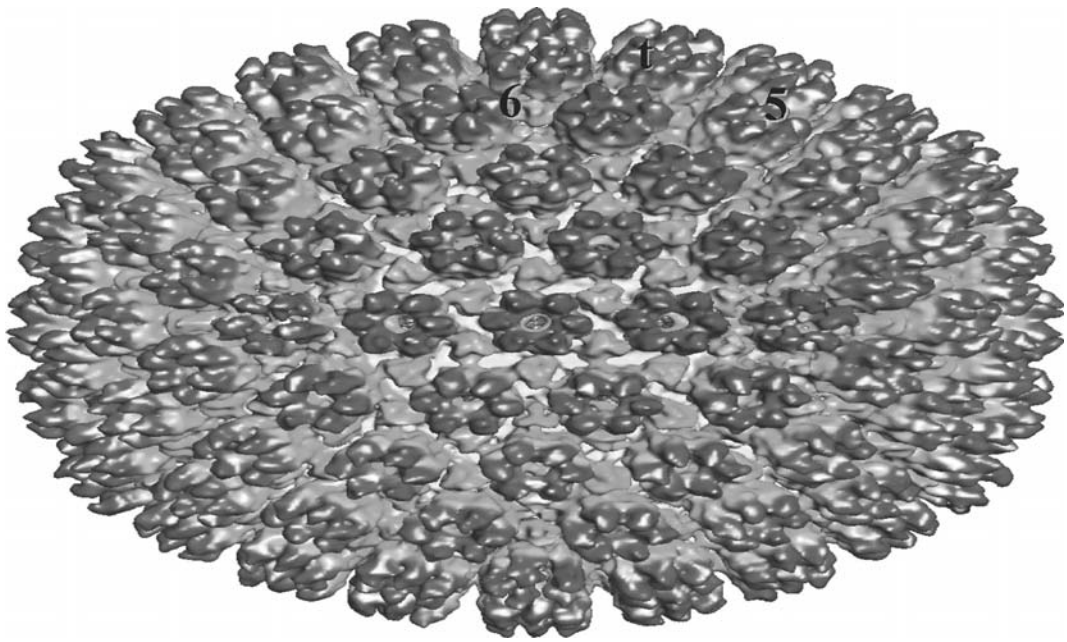

Fig. 23.1. 3D structure of the KSHV capsid at 24-Å resolution by electron cryomicroscopy. The capsid is shown as shaded surface color-coded according to particle radius. The three structural components of the capsid are indicated, including 12 pentons ("5"), 150 hexons ("6") and 320 triplexes ("t"). (Wu *et al.*, 2000 with permission). (See color plate section.)

EBV are named for the fragment within the original *Bam*H 1 restriction map of the B95–8 genome (Baer *et al.*, 1984) in which they originate and their direction of transcription. The BALF4 ORF, for example, is the fourth leftward reading ORF originating in the *Bam*H 1 A fragment.

Cryoelectron microscopy analyses reveal that KSHV capsid has the same $T = 16$ triangulation number, capsid architecture, structural organization and size as herpes simplex virus (HSV) and the human cytomegalovirus (HCMV) (Lo *et al.*, 2003; Trus *et al.*, 2001; Wu *et al.*, 2000) (Fig. 23.1). As in other herpesviruses, the capsids have a typical icosahedral shell and are composed of four structural proteins encoded by KSHV ORFs 25, 26, 62 and 65. The major capsid protein encoded by ORF 25 forms the hexameric and pentameric capsomers. The capsid floor between the hexons and pentons is formed by the heterotrimeric complexes composed of one molecule of the ORF62 protein and two molecules of the ORF26 protein. Both these proteins show significant amino acid sequence homology to the capsid proteins of alpha- and betaherpesviruses. The fourth protein, ORF65, is a small basic and highly antigenic protein, lacks significant sequence homology with its structural counterparts from the other subfamilies; however, similar to the small basic capsid protein VP26 of HSV, KSHV ORF 65 decorates the surface of the capsids. Lytic replication of KSHV leads to the formation of at least three capsid species, A, B, and C, and the A capsids are empty, B capsids contain an inner array of a fifth structural protein, ORF17.5, and C capsids contain the viral genome (Lo *et al.*, 2003; Trus *et al.*, 2001; Wu *et al.*, 2000).

No similar detailed analyses of the EBV capsid have yet been done, although transmission electron microscopy reveals a structural organization and size similar to other herpesviruses. Very little is known about the individual capsid proteins and assignments of ORFs as encoding capsid proteins have been made until recently only by homology with known HSV capsid proteins. Even less has been hypothesized about the composition of the tegument as few EBV ORFs have homology to any of the known HSV tegument proteins. The only EBV protein, which has been consistently described as a tegument protein is p140, which is thought to be encoded by the BNRF1 ORF (Hummel and Kieff, 1982). This ORF is described as having homology with *N*-formylglycinamide ribotide amidotransferases of *Eschericia coli* and *Drosophila melanogaster* (Russo *et al.*, 1996), but the significance of the homology is unknown. The first proteomic analysis of the proteins in the virion particle promises to stimulate new research in this understudied area (Johannsen *et al.*, 2004).

Virus structural proteins involved in entry

In contrast, considerable effort has been expended on analysis of the biochemistry and function of the envelope

Table 23.1. Genes encoding membrane proteins that are expressed only in the lytic cycle

EBV protein/gene	KSHV protein/gene	EBV function	KSHV function
gp350/220/BLLF1	—	attachment to B cell receptor CR2	—
gH/BXLF2	gH/ORF22	virus cell fusion; attachment to epithelial cell receptor/coreceptor; complexes with gL	virus entry; complexes with gL
gL/BKRF2	gL/ORF47	chaperone for gH	chaperone for gH
gp42/BZLF2	—	interaction with B cell coreceptor HLA class II	—
gB/BALF4	gB/ORF8	assembly/exit/fusion	attachment to cells via heparan sulfate; interacts with integrins; virus entry; egress
gN/BLRF1	gN/ORF53	codependent on gM for processing; complex of gNgM required for production of enveloped virions	complexes with gM
gM/BBRF3	gM/ORF39	complexes with gN; complex required for production of enveloped virions	codependent on gN for processing; complex inhibits cell fusion
BMRF2	—	interacts with integrins; important to infection of polarized epithelial cell lines	—
gp150/BDLF3	—	unknown	—
p38/BFRF1		homologue of alphaherpesvirus UL34 proteins	
	?ORF67	interacts with BFLF2 protein (UL31 homologue) localizes to the nuclear rim, facilitates nuclear egress	?
gp78/BILF2	—	unknown	—
BILF1	—	constitutively active G protein-coupled receptor	—
—	gpK8.1A/K8.1	—	attachment to cells via heparan sulfate; virus entry
—	gpK8.1B/K8.1	—	unknown
—	OX-2/K14	—	adhesion of infected cells
—	K1/K1	—	signal induction
—	K15/K15	—	signal induction

proteins. These are the proteins that are critically needed to mediate attachment, entry, assembly and egress of virus and the majority of them are glycoproteins. The different tropisms of herpesviruses are potentially due to unique complements of these glycoproteins as well as subtle differences among those that are conserved.

The precise number of EBV membrane proteins that are exclusively expressed during the lytic cycle is not yet known, but there is evidence for at least twelve (Table 23.1). Five of these are glycoproteins that have homologues in all herpesvirus studied to date and are now commonly referred to by the naming system originally developed for the prototype alphaherpesvirus, herpes simplex virus. They are gB gH, gL, gM, and gN (Hutt-Fletcher, 2002). The remaining seven proteins are named for their apparent mass or referred to by the name of the open reading frame (ORF) that encodes them. One, p38, the product of the BFRF1 gene (Farina *et al.*, 2000) is also conserved among all the herpesvirus families and is the homolog of the most widely studied alphaherpesvirus UL34. It is not glycosylated and is not found in the virion particle (Farina, 2004; Johannsen *et al.*, 2004). It interacts with the BFLF2 gene product, the homolog of alphaherpesvirus UL31 (Gonella *et al.*, 2005; Lake and Hutt-Fletcher, 2004) and like its homologs in other herpesviruses its major role is probably to facilitate exit of the newly formed EBV nucleocapsid from the nucleus (Farina *et al.*, 2005). The remaining six are glycoproteins that are unique to the gammaherpesviruses. Glycoproteins gp150 (Kurilla *et al.*, 1995; Nolan and Morgan, 1995), gp78 (Mackett *et al.*, 1990) and the product of the BILF1 gene, which is glycoprotein with an apparent mass of approximately 50 kDa (Paulson *et al.*, 2005), have counterparts only in lymphocryptoviruses (Rivailler *et al.*, 2002). Glycoproteins gp350/220 (Hummel *et al.*, 1984), gp42 (Li *et al.*, 1995) and the BMRF2 protein (Tugizov *et al.*, 2003) have counterparts in lymphocryptoviruses (Rivailler *et al.*, 2002) and in certain of the rhadinoviruses (Russo *et al.*, 1996; Telford *et al.*, 1995; Virgin *et al.*, 1997). Glycoproteins gp350/220, gp42 and the BMRF2 protein, together with the conserved glycoproteins gB, gH and gL, are all involved in virus entry

as described below. It also is possible that complexes of gN and gM may play a role in this process although their major role is probably in envelopment and egress of newly made virus as described in Chapter 25 (Lake and Hutt-Fletcher, 2000). The phenotype of a virus that lacks gp150 is little changed from wild type virus, except that its ability to infect epithelial cells is very slightly enhanced (Borza and Hutt-Fletcher, 1998). The BILF1 gene product functions as a constitutively active G protein-coupled receptor. It is not found in the virion (Johannsen *et al.*, 2004), but may play a role in modulating intracellular signaling pathways (Beisser *et al.*, 2005). Nothing is known about possible functions of gp78.

KSHV also expresses the five conserved herpesvirus glycoproteins. (Table 23.1). Open reading frames 8, 22, 47, 39 and 53 encode glycoproteins gB, gH, gL, gM and gN, respectively (Akula *et al.*, 2001a; Baghian *et al.*, 2000; Naranatt *et al.*, 2002; Neipel *et al.*, 1997; Russo *et al.*, 1996). HHV-8 also encodes for additional glycoproteins such as gpK8.1A, gpK8.1B, K1, K14 and K15 that are expressed during lytic replication (Birkmann *et al.*, 2001; Chandran *et al.*, 1998; Neipel *et al.*, 1997; Russo *et al.*, 1996). Studies have shown that gB, gH/ gL, gM/gN and gpK8.1A are virion-envelope associated glycoproteins (Akula *et al.*, 2001a; Baghian *et al.*, 2000; Koyano *et al.*, 2003; Naranatt *et al.*, 2002; Neipel *et al.*, 1997; Russo *et al.*, 1996; Zhu *et al.*, 1999).

Virus attachment

Entry of enveloped viruses into cells involves at least two events, attachment to the cell surface and penetration through the cell membrane. Herpesviruses, not unexpectedly given the large number of different proteins found in a herpesvirus envelope, use multiple different proteins to complete the entry process. Increasingly, in recent years it has also become apparent not only that multiple proteins are involved in entry, but also that the complement of proteins that is used can vary considerably when different cells are the target of infection and different molecules are available for interaction with the virus.

Attachment of EBV

Attachment of EBV to B-cells has been known for many years to be mediated by a high affinity (Moore *et al.*, 1989) protein–protein interaction between the virus glycoprotein gp350/220 and the complement receptor type 2, CR2 or CD21 (Fingeroth *et al.*, 1984; Frade *et al.*, 1985; Nemerow *et al.*, 1985). Glycoprotein gp350/220 is an abundant, highly glycosylated type 1 membrane protein and has a dual nomenclature because its gene is expressed in two alternatively spliced forms with masses of approximately 350 and 220 kDa (Beisel *et al.*, 1985; Hummel *et al.*, 1984). The splice maintains the reading frame of the protein and results in the loss of residues 500 to 757 of the full-length 907 amino acid form which contain three repeats of a 21 amino acid motif with amphipathic characteristics. The splice does, however, retain the CR2 binding domain at the amino terminus of the molecule. Although not definitively mapped, this binding site is thought to include a short sequence of 21 amino acids that is very similar to the proposed binding sequence of the natural ligand of CR2, the C3d component of complement (Lambris *et al.*, 1985; Nemerow *et al.*, 1989; Tanner *et al.*, 1988). The functional significance of the existence of the two spliced forms of the EBV protein, if any, is unclear. However, the initial interaction between gp350/220 and CR2 tethers the virus approximately 50 nm from the B -cell surface (Nemerow and Cooper, 1984) so one possibility is that exchange of the larger for the smaller form might bring the virus a little closer to the cell membrane.

CR2 is a type 1 membrane protein and a member of a large family of proteins involved in tissue repair, inflammation and the immune response that is characterized by structural modules known as short consensus repeats (SCR). The EBV binding site has been very precisely mapped to the amino terminal SCR-1 and SCR-2 (Martin *et al.*, 1991). The tandem repeats, which comprise the entire extracellular domain of CR2, are 60–75 amino acids in length each forming discrete structural units (Moore *et al.*, 1989) that probably provide some segmental flexibility to the molecule (Weisman *et al.*, 1990) and that may also be important to positioning the virus for entry.

The ligand/receptor pair that is responsible for attachment of EBV to an epithelial cell is much less clear. Early models proposed that epithelial cells were infected when B-cells fused with epithelial membranes, but there are no data that either refute or confirm this possibility (Bayliss and Wolf, 1980). Some epithelial cell lines express at least low levels of CR2 (Fingeroth *et al.*, 1999; Imai *et al.*, 1998) and stable expression from a cDNA clone of CR2 renders a significant proportion of the cells permissive to infection (Li *et al.*, 1992). However, the physiological relevance of this is uncertain. Identification of CR2-expressing epithelial cells in vivo has been confounded by the fact that the monoclonal antibodies used to make the determinations cross-react with an unrelated epithelial cell protein (Young *et al.*, 1989). Cells that carry the polymorphic IgA receptor can be infected with virus that is coated with IgA specific for gp350/220 (Sixbey and Yao, 1992). This may be particularly relevant to infection of cells at the basolateral surface in an immune host, although in polarized cells virus was transported intact from the basolateral to the apical surface

so it may be more important for virus shedding than virus infection (Gan *et al.*, 1997).

Epithelial lines also express an as yet unidentified molecule that facilitates virus binding via a complex of gH and gL (Molesworth *et al.*, 2000; Oda *et al.*, 2000). Virus lacking gHgL loses the ability to bind to these lines and soluble forms of gHgL can be shown to attach specifically (Borza *et al.*, 2004). However, infection rates are low and it is possible that this interaction represents inefficient use, in the absence of a primary attachment receptor, of a coreceptor that is more important for penetration (see below). Most recently, an interaction between the BMRF2 protein and $\alpha 5\beta 1$ integrins on the basolateral surfaces of polarized epithelial cells has been reported to lead to high levels of infection and lytic replication in vitro (Tugizov *et al.*, 2003). This observation is particularly compelling since polarized epithelial cells are probably closer to the environment encountered by virus in vivo. The BMRF2 protein is predicted to span the membrane many times and one of the predicted extracellular loops contains an RGD motif. Further work will be necessary to determine whether use of this motif is most relevant to attachment or penetration of virus, but it may provide parallel to the use of an RGD sequence in KSHV gB (see below) for entry. Unlike KSHV and many other herpesviruses, discussed in the next section, EBV is not known to encode any heparan sulfate binding proteins.

Attachment of KSHV

The broad cellular tropism of KSHV which binds to a variety of target cells such as human B, endothelial and epithelial cells, and monocytes (but not T and NK cells), as well as a variety of animal cells (Akula *et al.*, 2001b; Dezube *et al.*, 2002) may be in part due to its interaction with the ubiquitous cell surface heparan sulfate (HS) (Akula *et al.*, 2001b). The initial virus–cell interactions of many other herpesviruses including herpes simplex types 1 and 2, pseudorabies virus, bovine herpesvirus 1, human cytomegalovirus, human herpesvirus 7 and bovine herpesvirus 4 also involve binding to HS. The first indication that HS might be involved in KSHV infection of target cells came from the serendipitous observation that infection of primary HMVEC cells was difficult in the presence of the heparin that is used in the growth medium of these cells. Further analyses showed that KSHV infection can be inhibited in a dose-dependent manner by soluble heparin, a glycosaminoglycan closely related to HS, but not by chondroitin sulfates A and C (Akula *et al.*, 2001b). Infectivity is reduced by enzymatic removal of cell surface HS with heparinase I and III, virus binding is blocked or displaced by soluble heparin and binding is drastically reduced on CHO cells that are deficient in HS (Akula *et al.*, 2001b). The interaction with HS may be the first set of ligand-receptor interactions that concentrates KSHV on the cell surface where it can subsequently bind to one or more additional host cell molecules that are essential to the entry process.

Two consensus motifs for the heparin binding domain (HBD) of polypeptides have been proposed, XBBXBX and XBBBXXBX, where B is a positively charged basic amino acid (lysine, arginine or histidine) flanked by an additional positively charged residue separated by hydrophobic amino acids "X" (Akula *et al.*, 2001a). Heparin-binding proteins often contain more than one of these sequences, and analysis of HBD of several proteins suggest that the negatively charged sulfate or carboxylate groups on heparin may interact via electrostatic interactions with positively charged cationic residues in a protein or peptide (Akula *et al.*, 2001a). Predictive analysis of KSHV sequences revealed putative HBD in the extracellular domains of HHV-8 gB and gpK8.1A. KSHV-gB contains the BXXBXBBXBB (^{108}HIFKVRRYRK^{117}) type HBD, which is conserved throughout the $\gamma 2$ herpesviruses (Akula, 2001a), and gpK8.1A possess two possible, although atypical heparin-binding motifs, gpK8.1A-H1 (^{150}SRTTRIRV^{157}, XBXXBXBX) and gpK8.1A-H2 (^{182}TRGRDAHY^{189}, XBXBXXBX) (Wang *et al.*, 2001).

The KSHV K8.1 gene is positionally colinear to glycoprotein genes in other members of the gammaherpesvirus subfamily including the EBV gene encoding gp350/gp220, the gp150 gene of murine gamma herpesvirus 68, the ORF 51 gene of HVS, and the BORFD1 gene of bovine herpesvirus 4 (Neipel *et al.*, 1997; Russo *et al.*, 1996). The K8.1 gene (genomic nucleotide position 76 214 bp – 76 808 bp) encodes a 197-aa long ORF with a predicted molecular weight of about 22 kDa, with a N-terminal signal sequence and five putative *N*-glycosylation sites, but without any transmembrane sequence. Screening of a cDNA library from TPA induced BCBL-1 library with a HIV+KS+ serum identified two cDNAs encoded by the gpK8.1 gene (Chandran *et al.*, 1998). Analyses of these cDNAs show that the gpK8.1 gene encodes two ORFs, designated gpK8.1A and gpK8.1B, from spliced messages. The larger cDNA is 752 bp long (76 214 – 76 941 bp) and utilizes the polyadenylation signal sequence (AATAAA) at position 77 013 bp. The 228-aa long encoded protein is designated gpK8.1.A which contains a signal sequence, transmembrane domain, and four *N*-glycosylation sites.

The first 142 amino acids encoded by the gpK8.1A cDNA are identical to the genomic gpK8.1 ORF sequence. This cDNA is derived from a transcript with a 95bp sequence spliced out [CAG/(GT)GTAT donor site and TCTAC(AG)/G

acceptor site] and ends at the genomic nucleotide position 76 941 bp, which is 187bp beyond the end of genomic gpK8.1 ORF. This has resulted in the generation of a transmembrane domain not seen in the genomic gpK8.1 ORF. The smaller 569 bp long cDNA encodes the gpK8.1B, with a 183-bp sequence spliced out. The splice acceptor site for the ORF gpK8.1B transcript is the same as the gpK8.1A ORF; however, the splice donor site [CGA/(GT)GAGT] for the gpK8.1B cDNA is upstream of the splice donor site of the gpK8.1.A cDNA resulting in frame deletion of 61 amino acids in the smaller ORF. The resulting 167 aa long ORF is a typical class I glycoprotein with a cleavable signal sequence, a transmembrane domain, three putative *N*-glycosylation sites and is predicted to code for a protein of about 18.5 kDa. Except for an amino acid change near the splice site (S to R), the gpK8.1B shares identical amino acid sequences with the gpK8.1.A. Both gpK8.1A and gpK8.1B contain N- and O-linked sugars, and gpK8.1A is the predominant form detected within the infected cells and the virion envelopes (Chandran *et al.*, 1998; Neipel *et al.*, 1997; Zhu *et al.*, 1999). Both are immunogenic proteins (Zhu *et al.*, 1999).

The 845 amino acid KSHV-gB ORF includes a predicted signal sequence between residues 1–23, a predicted transmembrane domain between amino acids 710–729 and 13 potential *N*-glycosylation sites. There is a potential proteolytic cleavage site (RKRR/S) at amino acid position 440–441, and cleavage at this site would result in two proteins with predicted masses of about 48 and 45 kDa (Akula *et al.*, 2001a; Baghian *et al.*, 2000). Experimentally the protein has been shown to be expressed on the surface of the infected cell and in virion envelopes (Akula *et al.*, 2001a; Baghian *et al.*, 2000). It is synthesized as a 110 kDa precursor protein, undergoes cleavage and processing, and the envelope-associated form consists of 75 and 54 kDa polypeptides that form disulfide-linked heterodimers and multimers (Akula *et al.*, 2001a).

Several lines of evidence indicate that KSHV-gB and gpK8.1A bind to cell surface HS molecules (Akula *et al.*, 2001a; Birkmann *et al.*, 2001; Wang *et al.*, 2001). Binding of soluble forms of the proteins made in baculovirus is saturable and can be blocked by soluble heparin (Wang *et al.*, 2001, 2003). Full-length gB and gpK8.1A in the virion envelope specifically bind heparin-agarose, and can be eluted by high concentrations of soluble heparin, but not by chondroitin sulfates (Akula *et al.*, 2001a; Wang *et al.*, 2001). KSHV-gpK8.1A binds to heparin with an affinity comparable to that of glycoproteins B and C of herpes simplex virus (Birkmann *et al.*, 2001) and the gpK1A binds more strongly than gB (Wang *et al.*, 2003). Even though the involvement of KSHV-gB residues 108–117 and gpK8.1A residues 150–157 in binding to HS-like moieties has been convincingly demonstrated, it is also possible that other weak and/or high affinity HBDs may appear in HHV-8 gB and gpK8.1A in their native quaternary structures if basic amino acids separated linearly are juxtaposed, forming a typical HBD. The presence of two or more heparin-binding glycoproteins within a single virus is not unprecedented, since the well-studied human α-and β-herpesviruses contain at least two HS binding glycoproteins e.g. gB and gC for herpes simplex 1 and 2, gB and gCII for human cytomegalovirus, and gB and gp65 for human herpesvirus 7. The presence of two-HS binding proteins in KSHV re-emphasizes the importance of cell surface HS for attachment of many, although not all, herpesviruses.

Penetration

Penetration of any enveloped virus into a cell involves fusion of the virion envelope with the membrane of the cell and can occur either at the cell surface or after endocytosis. Endocytosis affords a convenient and often rapid system of transit across the plasma membrane and through the cytoplasm for delivery of viral cargo to the vicinity of the nucleus (Sieczkarski and Whittaker, 2002; Whittaker, 2003). The best understood paradigm for virus cell fusion is provided by the RNA viruses such as the human immunodeficiency virus, which fuses at the cell surface, and influenza virus, which fuses with the endocytic vesicle. The virus glycoproteins that mediate fusion are made as single type 1 membrane proteins, but are cleaved during processing to create two species which reassociate in a metastable state (Colman and Lawrence, 2003). The fragment that retains the transmembrane domain includes a hydrophobic sequence or "fusion peptide" that can be triggered by conformational changes to insert into an opposing cell membrane and initiate formation of a fusion pore. The conformational change in the human immunodeficiency virus is triggered by interaction with coreceptors, the conformational change in the influenza virus fusion protein is triggered by exposure to the low pH of the endosome. However, no clear-cut paradigm has yet been identified for any herpesvirus. Fusion appears to require cooperation between several unique protein species, none of which include readily identifiable "fusion peptides" and the site at which fusion occurs varies from virus to virus and even cell type to cell type.

Penetration by EBV

Penetration of EBV into B cells and epithelial cells is significantly different both in terms of the virus and cell proteins

involved and in terms of the routes that are used. Attachment of EBV to the B cell surface via CR2 stimulates endocytosis of virus into thin-walled non-clathrin coated vesicles (Nemerow and Cooper, 1984; Tanner *et al.*, 1987) and fusion occurs in a low pH environment. Exposure to low pH is not an essential requirement, but endocytosis does appear to be necessary as virus fails to fuse with B cells treated with the endocytosis inhibitors chlorpromazine and sodium azide. In contrast, fusion with an epithelial cell occurs at neutral pH and is resistant to treatment with either chlorpromazine or sodium azide (Miller and Hutt-Fletcher, 1992).

Fusion of the EBV envelope with the B cell requires at least three and probably four virus glycoproteins, gB, gH, gL and gp42. EBV gB is a 857-residue protein that shares some structural, although little sequence homology with its counterparts in other herpes viruses (Gong *et al.*, 1987). The positions of many of the cysteine residues in gB are conserved. Like gB of HHV-8 it undergoes cleavage to produce two polypeptides of approximately 56 and 80 kDa that are linked by disulfide bonds (Johannsen *et al.*, 2004; C. M. Lake and L. M. Hutt-Fletcher, unpublished data). Although some strains of EBV carry very little gB in the virion (Gong and Kieff, 1990) and, as discussed in Chapter 25, EBV gB plays a very important role in virus assembly (Lee and Longnecker, 1997), recent work in which different combinations of virus proteins were expressed and examined for their abilities to fuse cell membranes indicates that EBV gB is also an essential part of the fusion machinery (Haan *et al.*, 2001).

The remaining three proteins that are known to be required for fusion with B cells, gH, gL and gp42, form a non-covalently linked complex in virus (Li *et al.*, 1995). Liposomes that contain all virus envelope proteins, except gH, gL and gp42, bind to receptor positive cells but fail to fuse (Haddad and Hutt-Fletcher, 1989) and recombinant virus that lacks all three can bind to but cannot penetrate B cells (Molesworth *et al.*, 2000). Glycoprotein gH, the largest of the three is a 708 residue type 1 membrane protein with five potential *N*-linked glycosylation sites and it carries about 10 kDa of *N*-linked sugar (Baer *et al.*, 1984; Heineman *et al.*, 1988; Oba and Hutt-Fletcher, 1988). Although members of the gH family of proteins share little sequence homology, if aligned at a conserved *N*-linked glycosylation site at the carboxyterminus they show a co-linearity of cysteine residues that suggests a conservation of secondary structure (Klupp and Mettenleiter, 1991). Each member is also dependent on the smaller membrane protein, gL, for folding and transport through the cell. The EBV gL is a 137-residue glycoprotein of approximately 25 kDa that remains anchored in the envelope by an uncleaved signal sequence (Li *et al.*, 1995; Yaswen *et al.*, 1993). Because of the dependence of gH on gL and because EBV in which expression of the gH gene is interrupted phenotypically lacks gL as well (Molesworth *et al.*, 2000), there are only few instances in which the functions of the two proteins can be separated.

Glycoprotein gp42, the third member of the complex required for penetration of a B cell, is not dependent on gHgL for processing and does not have counterparts in most herpesviruses (Li *et al.*, 1995). The gHgL complex in both human cytomegalovirus and human herpes virus 6 also include a third component known, respectively, as gO and gQ (Huber and Compton, 1998; Mori *et al.*, 2003), but these latter proteins, have no obvious homology to gp42. Only in the gammaherpesviruses are similar proteins predicted (Rivailler *et al.*, 2002; Telford *et al.*, 1995). EBV gp42 is a 223 residue type 2 membrane glycoprotein that has weak similarity to a C-type lectin (Spriggs *et al.*, 1996). The predicted signal sequence and transmembrane anchor lie between residues 7 and 28, the region of the molecule that is responsible for the interaction with gHgL lies between residues 40 and 58 (Wang *et al.*, 1998; Ressing *et al.*, 2005) and the carboxyterminal domain of the protein interacts with the variable region of the β chain of HLA class II (Spriggs *et al.*, 1996).

Several lines of evidence indicate that the interaction between gp42 and HLA class II is essential to B-cell infection. A monoclonal antibody to gp42 that blocks the interaction with HLA class II inhibits virus cell fusion (Miller and Hutt-Fletcher, 1988) and a monoclonal antibody to HLA class II that blocks gp42 binding neutralizes virus infection (Li *et al.*, 1997). A soluble form of gp42 in which the transmembrane domain is replaced with the Fc domain of human immunoglobulin competes with gp42 in virus for binding to HLA class II and blocks infection and B-cells that lack HLA class II cannot be infected unless HLA class II expression is restored (Li *et al.*, 1997). Finally, a recombinant virus that lacks gp42 fails to infect B-cells unless cells and bound virus are fused with polyethylene glycol (Wang and Hutt-Fletcher, 1998), or a soluble form of gp42 which lacks a transmembrane domain but which retains the ability to bind to gH and gL is added in *trans* (Wang *et al.*, 1998). Binding shows some allelic specificity (Haan and Longnecker, 2000) and the crystal structure of HLA class II bound to gp42 reveals that gp42 binds peripherally to the variable domain of the β-chain (Mullen *et al.*, 2002). A current minimalist model of B cell penetration would then suggest that, following attachment of virus via gp350 and CR2, gp42 interacts with HLA class II and that this event leads to triggering of the fusion machinery, gHgL and gB.

Fusion of virus with epithelial cells requires only gB and gHgL (McShane and Longnecker, 2004) and residues required for fusion can be distinguished from those

required for fusion with B cells (Omerovic *et al.*, 2005; Wu *et al.*, 2005). However, epithelial cells do not express HLA class II constitutively, and recombinant virus that lacks gp42 infects epithelial cells as well as wild-type virus. Not only is gp42 dispensable for infection of epithelial cells, its presence is also inhibitory. Stoichiometric analysis of wild-type virus demonstrates the presence of much larger amounts of gHgL than gp42 in the virion, implying that some complexes naturally lack or are low in gp42. Saturation of the complexes by addition of soluble gp42 in *trans* blocks epithelial infection. In addition infection of epithelial cells, but not B cells, can be blocked by antibodies that interact with gHgL or gH alone (Wang *et al.*, 1998). These findings have been interpreted to mean that there is a coreceptor on epithelial cells that can substitute for HLA class II and with which gHgL interacts in the absence of gp42. Soluble forms of gHgL bind saturably to epithelial cells. Scatchard analysis indicates the presence of as many as 200 000 high affinity receptors per cell with a K_D of approximately 5×10^{-9} M (L. Chesnokova, A. Morgan and L. Hutt-Fletcher, unpublished data). Whether or not this receptor is the same as that which can be used to attach virus to epithelial cells is not yet known. However, a minimal model of penetration of an epithelial cell suggests that following attachment an interaction of gHgL alone with a coreceptor triggers the activity of the fusion machinery.

The observation that gp42 is essential for B-cell infection but dispensable for epithelial infection suggested that changes in the stoichiometry of the gHgLgp42 complex would influence tropism of EBV for the two cell types and comparisons of virus made in HLA class II positive B-cells and HLA class II negative epithelial cells support the hypothesis that such changes might occur in vivo (Borza and Hutt-Fletcher, 2002). Virus made in HLA class II-negative epithelial cells can be as much as two logs more infectious for B-lymphocytes than the same amount of virus produced by an HLA class II-positive B-cell. Virus originating from either cell type binds equally well to CR2 on the B-cell surface, but virus made in the B-cell enters less efficiently. This appears to reflect the fact that in a class II-positive virus-producing cell some complexes containing gp42 interact with class II during biosynthesis and are targeted to the class II trafficking pathway where they are vulnerable to degradation. The resulting loss of three-part complexes from virus reduces the efficiency of class II-dependent entry. Such a loss does not occur in a class II-negative epithelial cell where virus has a relative increase in gp42 and an increased efficiency for class II-dependent entry and induction of HLA class II expression can reverse the phenotype. The levels of gp42 in virus also impact infection of epithelial cells via the class II-independent pathway. B cell virus is on average fivefold better at infecting epithelial cells than epithelial virus. These findings suggest that gp42 may function as a switch of virus tropism that might be relevant to spread of virus between tissues in vivo (Borza and Hutt-Fletcher, 2002) (Fig. 23.2). However, since the effects on B-cell infection are by far the most striking,

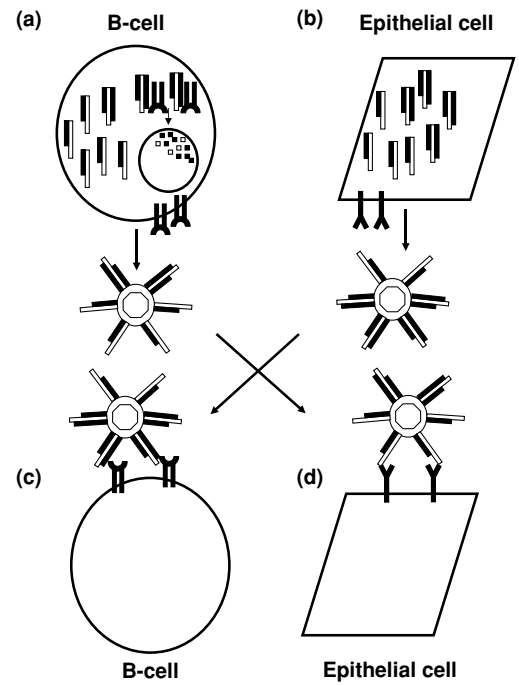

Fig. 23.2. Glycoprotein gp42 can function as a switch of EBV tropism. (a) EBV makes both three part gHgLgp42 complexes and two part gHgL complexes. When virus is made in a B-cell, some of the three-part gHgLgp42 complexes bind to HLA class II within the cell and as a result traffic along the same exocytic pathway as that followed by HLA class II. This includes passage through a vesicle rich in proteolytic enzymes which normally digests exogenous protein for presentation by HLA class II. The gHgLgp42 complexes bound to HLA class II are proteolytically digested in this compartment and as a result fewer of the three-part complexes are available for incorporation into virus. (b) In an epithelial cell which does not express HLA class II a larger number of three part complexes are available for incorporation into virus. (c) Entry into a B-cell requires an interaction between gp42 and HLA class II. The relative increase of gp42 in virus derived from an epithelial cell thus increases the ability of virus to infect a B-cell. (d) Infection of an epithelial cell requires an interaction with a gHgL coreceptor. Interaction of the gHgL complex with this coreceptor is blocked by gp42. The relative reduction of gp42 in virus derived from an HLA class II positive B-cell thus increases the ability of this virus to infect an epithelial cell. gHgL; gHgLgp42; HLA class II; gHgLR.

the biological effects may primarily be to drive into the B-cell pool any virus that initiates infection by replicating in an epithelial cell.

The events that occur concurrent with, and following, fusion of the virus and cell membrane that are necessary to facilitate transport, uncoating and delivery of the genome to the nucleus are largely unknown and currently can only be guessed at, based on what little is understood for other herpesviruses. There are, however, hints that additional envelope proteins may be involved in efficient delivery of infectious virus. Loss of the complex of gM and gN not only severely compromises envelopment and egress of EBV, as described in Chapter 25, but also leads to a defect in infection that cannot be rescued by treating bound virus with exogenous mediators of fusion. One possible explanation for this finding is that there is a defect in dissociation of envelope and tegument necessary for movement of virus toward the nucleus (Lake and Hutt-Fletcher, 2000).

Penetration by KSHV

KSHV enters the B-cell line BJAB (Akula *et al.*, 2001a), HFF (Akula *et al.*, 2003), the human epithelial line 293 (Inoue *et al.*, 2003; Liao *et al.*, 2003) and endothelial cells (Akula *et al.*, 2002) by endocytosis. HHV-8 virions can be visualized in endocytic vesicles of BJAB (Akula *et al.*, 2001b, 2003) within 5 min of infection where they fuse with the vesicle wall (Akula *et al.*, 2003), and viral capsids are found in the vicinity of nuclear membranes by 15 minutes after infection. Anti-KSHV- gB antibodies colocalize with virus-containing endocytic vesicles. In HFF cells, KSHV infection is significantly inhibited by the preincubation of cells with chlorpromazine HCl, which blocks endocytosis via clathrin-coated pits, but not by nystatin and cholera toxin B, which block endocytosis via caveolae and induce the dissociation of lipid rafts, respectively. Infection is also inhibited by blocking the acidification of endosomes by NH_4 Cl and bafilomycin A in HFF and 293 cells (Akula *et al.*, 2003; Liao *et al.*, 2003). These findings suggest that penetration of KSHV occurs in and requires a low pH intracellular environment. Further work is required to determine if virus takes the same route into other cell types.

The KSHV gHgL complex consists of a 120 kDa protein (gH) and a 41–42 kDa protein (gL) linked by non-covalent bonds and found both on the surface of the cell and in virions (Naranatt *et al.*, 2002). As in other herpesviruses, KSHV-gL is required for gH processing and intracellular transport and the complex is required for entry. Anti-gH and anti-gL antibodies neutralize KSHV infectivity, individually and more efficiently together, without having any effect on virus binding to target cells (Naranatt *et al.*, 2002). Deletion of 58 amino acids in the cytoplasmic tail of KSHV-gB removed the putative endocytosis signals (YXXΦ). Expression of this truncated KSHV-gB (gBMUT), but not the full length gB, can be detected on the surface of CHO cells (Pertel, 2002). Co-expression of KSHV- gBMUT, gH, and gL resulted in the fusion of CHO cells with 293 cells (Pertel, 2002). Further work is necessary to determine the role of KSHV gB, gH and gL mediated fusion in entry of target cells, but at this point it seems likely that the minimal fusion machinery of both KSHV and EBV comprises gB, gH and gL.

Much more is known about the involvement of KSHV gpK8.1 and gB in post binding events. Although these proteins are involved in the interaction with the cell surface HS molecules, even high concentrations of rabbit polyclonal and monoclonal anti-gB and anti-gpK8.1A antibodies which neutralize infection do not block the binding of KSHV to target cells (Akula *et al.*, 2001a; Zhu *et al.*, 1999). This implies a role for the proteins after attachment has occurred; possibly as a result of interaction with additional cell surface molecules. Among all the gB homologues sequenced to date, only KSHV-gB possesses an integrin-binding RGD motif at amino acids 27 to 29 which is predicted to be immediately adjacent to the putative signal sequence of the protein (Akula *et al.*, 2002). The RGD motif is the minimal peptide region of many extracellular matrix (ECM) proteins known to interact with subsets of host cell surface integrins. KSHV infectivity of fibroblasts and endothelial cells is neutralized by RGD peptides, by antibodies to α3 and β1 integrins, and by soluble α3β1 integrin (Akula *et al.*, 2002) and anti-gB antibodies immunoprecipitate a complex of virus and α3β1. At the same time, RGD peptides, anti-integrin antibodies and soluble integrins fail to block virus binding to adherent target cells such as human endothelial and fibroblast cells suggesting that KSHV uses the a3β1 integrin as one of the cell receptors or coreceptors for entry (Akula *et al.*, 2002). Expression of human α3 integrin also increases the infectivity of virus for CHO cells (Akula *et al.*, 2002).

Additional studies suggest that infection of fibroblasts or endothelial cells can also be neutralized by soluble αVβ3 and αVβ5 integrins with higher levels of neutralization with soluble α3β1 integrin. Virus binding and viral DNA internalization studies suggest that αVβ3 and αVβ5 integrins also play roles in KSHV entry and may expand the in vivo target cells for KSHV. Using an RTA-dependent reporter 293-T cell line (Inoue *et al.*, 2003) reported the inability of soluble α3β1 integrin and RGD peptides to block the infectivity of KSHV. However,

in this study virus was centrifuged with cell in the presence of polybrene which may account for the apparent discrepancy. Polybrene is a positively charged cation which can complex with the virus envelope and may bypass the need for a receptor. This property of polybrene is the basis for its use to increase the infectivity of many viruses and to deliver nucleic acid for gene therapy. The nature of other receptor(s) recognized by KSHV and the glycoproteins involved need to be evaluated further.

KSHV also utilizes the dendtric cell-specific ICAM-3 grabbing nonintegrin (DC-SIGN; CD209) as a receptor for infection of myeloid DCs and macrophages (Rappocciolo *et al.*, 2006). DC-SIGN was required for virus attachment to these cells and DC-SIGN-expressing cell lines. KSHV binding and infection were blocked by anti-DC-SIGN monoclonal antibody and soluble DC-SIGN, and mannan, a natural ligand for DC-SIGN. The residual level of KSHV binding and infection in cells pretreated with anti-DC-SIGN antibodies in these studies were attributed to additional receptors for KSHV on these cells. Expression of DC-SIGN on B-lymphoblastoid cell lines (LCL) and K562 cells which are normally resistant to KSHV rendered them susceptible to KSHV infection (Rappocciolo *et al.*, 2006). Since neither of these cells expressed $\alpha 3\beta 1$ on their surface, this suggested that other molecules such as DC-SIGN may be involved in infection of these target cells.

Another recent study showed that KSHV also utilizes the 12-transmembrane transporter protein xCT for entry into adherent cells (Kaleeba and Berger, 2006). The xCT molecule is part of the cell surface 125 kDa disulfide linked heterodimeric membrane glycoprotein CD98 (4F2 antigen) complex containing a common glycosylated heavy chain (80kDa) and a group of 45 kDa light chains. The xCT molecule involved in glutamate/cystine exchange is one of the light chain (Kaleeba and Berger, 2006). Expression of recombinant xCT rendered otherwise not susceptible target cells permissive for both KSHV cell fusion and virion entry. Antibodies against xCT blocked KSHV fusion and entry with naturally permissive target cells such as the adherent target cells of human and nonhuman cell types. However, xCT mRNA was not detected in human CD19 primary B cells isolated from fresh peripheral blood mononuclear cells (Kaleeba and Berger, 2006). These studies further suggest that like EBV, KSHV may possess alternative receptor(s) in adherent and non-adherent cells and other molecules besides xCT may be involved in infection of B cells. It is interesting to note that the CD98 complex usually associates with $\beta 1$ integrin and has been shown to be involved in membrane clustering and $\beta 1$ integrin-mediated signal cascades (Fenczik *et al*,. 2001; Feral *et al.*, 2005).

Cell surface signaling during entry

The interactions of eukaryotic cells with their extracellular environments are largely mediated by ligand-induced signaling molecules exposed at the cell surface. The ensuing multitudes of biological processes are mediated by highly inter-linked networks of signaling pathways. Ligand mimicry is an opportunistic mechanism by which microbes, including viruses, subvert host signaling molecules for their benefit (Virji, 1996). By evolving to use cell surface molecules for attachment or entry into a cell, viruses have also evolved to take advantage of the events triggered by signaling to facilitate intracellular transport, to manipulate cell defense mechanisms, or to induce the pattern of cellular gene expression that is most conducive to establishment of latent or productive infection. Understanding virus induced signaling and its consequence is emerging as an important area of virology.

Signaling by EBV during the early stages of infection

The B cell receptor for EBV, CR2, can function as a signal transducer both independently and as a part of a signal transduction complex. This complex, composed of CR2, CD19 and CD81, modifies cell surface immunoglobulin-mediated signaling. CR2-transduced signaling is not required for infection of tumor derived cell lines by EBV (Martin *et al.*, 1994), which suggests that it is not required for intracellular transport or uncoating of virus, but several studies suggest that it may be critical for transformation of a resting B cell. Binding of EBV to CR2 stimulates capping of both CR2 and immunoglobulin and leads to increased blast formation, cell adhesion, surface CD23 expression and increased RNA synthesis (Gordon *et al.*, 1986; Tanner and Tosato, 1992). Interleukin 6, which is a paracrine or autocrine growth factor for EBV immortalized B cells (Tanner and Tosato, 1992), is activated by purified gp350/220 by a pathway that is sensitive to inhibitors of protein kinase C and tyrosine kinases and probably occurs as a result of downstream activity of NFκB (D'Addario *et al.*, 2001). Activation of NFκB increases transcription from the EBV Wp promoter which is responsible for initiation of latent gene expression and inhibition of NFκB inhibits transformation (Sugano *et al.*, 1997). Interaction of gp350/220 with CR2 also induces tyrosine phosphorylation of CD19 and activation of phosphatidylinositol 3-kinase (PI 3-K). Inhibition of these pathways inhibits expression of essential transforming genes (Sinclair and Farrell, 1995).

It is unlikely that signal transduction by EBV structural components and cell proteins is limited to the interaction between gp350/220 and its effects on gene expression, but

potential effects of other virus proteins have yet to be studied. The interactions between gp42 and HLA class II and between the BMRF2 protein and integrins, which, as discussed in detail below, play important roles in HHV-8 infection, appear to be very promising avenues for future exploration.

Signaling by KSHV during the early stages of infection

The integrins with which KSHV gB interacts are part of a large family of heterodimeric receptors containing noncovalently associated transmembrane α and β glycoprotein subunits (Giancotti, 2000; Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000). There are 17 α and 9 β subunits, generating more than 24 known combinations of αβ cell surface receptors. Each cell expresses several combinations of αβ integrins, and each αβ combination has its own binding specificity and signaling properties (Giancotti, 2000; Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000). Integrin interactions with ECM proteins provide robust signals for host-cell gene expression and mediate a variety of cell functions such as activation of cytoskeleton elements, endocytosis, attachment, cell cycle progression, cell growth, apoptosis, and differentiation (Giancotti, 2000; Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000). FAK is a non-receptor protein-tyrosine kinase that localizes in focal adhesions with vinculin, and FAK activation is the first step necessary for the outside–in signaling of integrins (Calderwood *et al.*, 2000; Giancotti, 2000; Sastry and Burridge, 2000). Within 5 minutes of infection, KSHV induces the integrin-mediated activation of FAK in endothelial and fibroblast cells, and co-localizes with the focal adhesion component vinculin (Akula *et al.*, 2002). Soluble gB, but not soluble gpK8.1A, induces FAK, which also colocalizes with pakillin (Wang *et al.*, 2003). FAK activation is inhibited by the pre-incubation of virus or gB with soluble α3β1 integrin or anti-gB antibodies, and is not activated by a soluble form of gB in which the RGD sequence had been mutated (Akula *et al.*, 2002; Wang *et al.*, 2003). The ability of anti-integrin antibodies and soluble integrin to neutralize virus infection without affecting virus entry suggests that integrin and the associated signaling pathways have a role to play in KSHV entry and infection of target cells.

Studies with FAK knockout mouse fibroblasts Du3 ($FAK^{-/-}$) and parental Du17 ($FAK^{+/+}$) cells confirm that FAK plays a key role in HHV-8 infection (Naranatt *et al.*, 2003). Since activation of FAK is central to many paradigms of outside-in signaling by integrins, actin assembly, and endocytosis, KSHV may be taking advantage of these signaling pathways both to promote entry and to produce a cellular state that facilitates infection.

KSHV induced the phosphorylation of FAK in FAK-positive Du17 mouse embryonic fibroblasts early during infection. The absence of FAK in Du3 ($FAK^{-/-}$) cells resulted in about 70% reduction in the internalization of KSHV DNA, suggesting that FAK plays a role in KSHV entry. Expression of FAK in Du3 ($FAK^{-/-}$) cells via an adenovirus vector augmented the internalization of viral DNA. Expression of the FAK dominant-negative mutant FAK-related non kinase (FRNK) in Du17 cells significantly reduced the entry of virus. Reduced quantity of virus entry in Du3 cells, delivery of viral DNA to the infected cell nuclei (Krishnan *et al.*, 2006), and expression of KSHV genes suggested that in the absence of FAK, another molecule(s) may be partially compensating for FAK function. Infection of Du3 cells induced the phosphorylation of the FAK-related proline-rich tyrosine kinase (Pyk2) molecule, which has been shown to complement some of the functions of FAK. Expression of an autophosphorylation site mutant of Pyk2 in which Y402 is mutated to F (F402 Pyk2) reduced viral entry in Du3 cells, suggesting that Pyk2 facilitates viral entry moderately in the absence of FAK. These results suggest a critical role for KSHV infection-induced FAK in the internalization of viral DNA into target cells (Krishnan *et al.*, 2006). One of the important downstream effectors of FAK that is activated directly or through Src kinase via Ras is PI 3-K, a member of a family of lipid kinases (Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000) that act as second messengers for a number of cell functions including the activation of Rho-GTPases and anti-apoptotic pathway Akt molecule (Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000). KSHV induces PI 3-K within 5 min of infection which decreased after 15 min (Naranatt *et al.*, 2003). The response can be inhibited by pre-incubating KSHV with integrin and by the PI 3-K inhibitors wortmannin and LY294002. Another hallmark of integrin interaction with ligands is the reorganization and remodeling of actin cytoskeleton. This is controlled by the Rho family of small GTPases, such as Rho, Rac, and Cdc42, and the morphological changes induced by Rho, Rac and Cdc42 activation are downstream effects of PI 3-K activation (Hall and Nobes, 2000). Immediately following KSHV infection, target cells exhibit morphological changes and cytoskeletal rearrangements such as filopodia, lamellipodia and stress fibers. This together with the phosphorylation of PI 3-K by KSHV at early time infection suggests the induction of RHo-GTPases and the associated signal pathways (Naranatt *et al.*, 2003).

FAK represents a point of convergence from activated integrins and initiates a cascade of intracellular signals that eventually activate the mitogen activated protein kinase (MAPK) pathways (Giancotti and Ruoslahti, 1999;

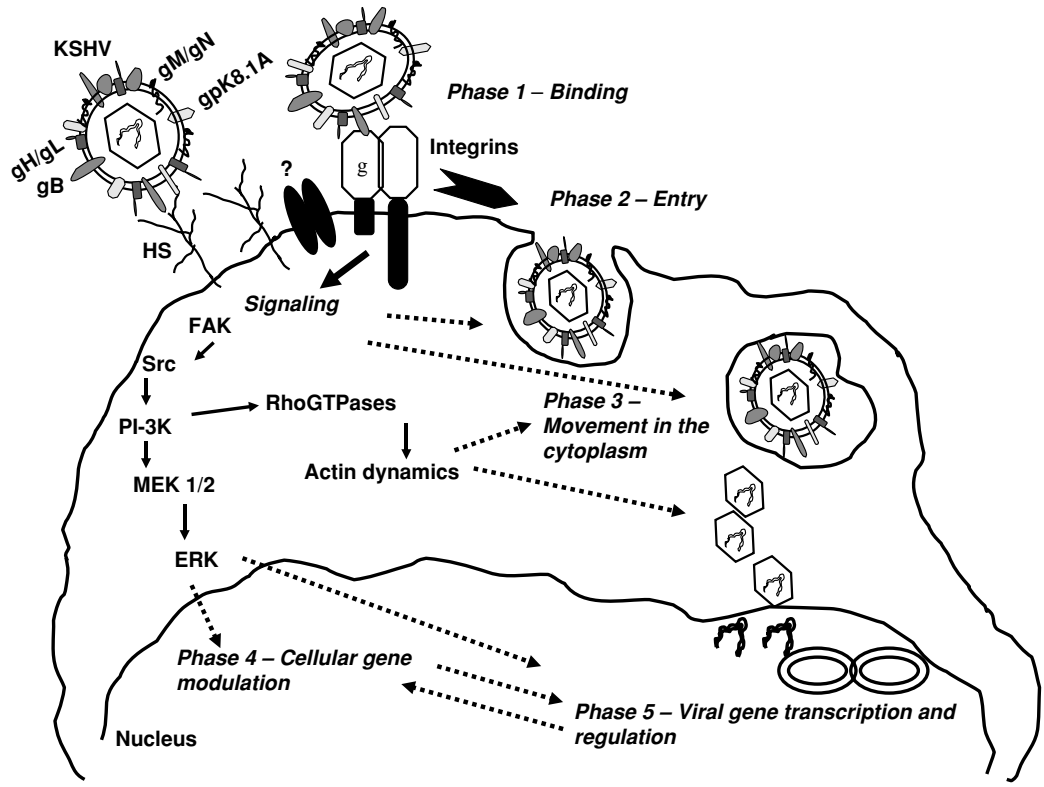

Fig. 23.3. Model for early events of KSHV infection of target cells. Early events of KSHV infection are depicted in overlapping dynamic phases. In phase 1, KSHV binds to the cell surface via its interactions with heparan sulfate proteoglycans (HSPGs) and integrins and possibly to other yet to be identified molecule(s). In phase 2, virus enters into the target cells, overlapping with the induction of host cell signal pathways. In phase 3, viral capsid/tegument moves in the cytoplasm, probably facilitated by the induced signal pathways, and probably overlaps with phase 4, the induced host cell gene transcription and expression. In phase 5, viral DNA enters into the nucleus followed by the viral gene expression. Solid arrows depict the KSHV-induced host cell signaling events that have been so far characterized. The dotted lines depict the potential stages of virus entry and infection at which the induced signaling events may have a role based on the known functions of these signaling events.

Sastry and Burridge, 2000). MAPK pathways exist in all eukaryotes and control fundamental cellular processes such as proliferation, differentiation, survival and apoptosis (Giancotti and Ruoslahti, 1999; Sastry and Burridge, 2000). As early as 5 minutes postinfection, KSHV activates the MEK (MAPK/ERK kinase) and extracellular-signal-regulated kinase (ERK) (Naranatt *et al.*, 2003) (Fig. 23.3). Focal adhesion components PI 3-K and protein kinase C-ζ (PKC-ζ) are recruited as upstream mediators of the HHV-8 induced ERK pathway.

Antibodies to KSHV-gB that neutralize infection and soluble α3β1 integrin inhibit the virus-induced ERK signaling pathways. Early kinetics of the cellular signaling pathway and its activation by UV-inactivated KSHV suggest a role for virus binding or entry, but not viral gene expression, in this induction. Studies with human α3 integrin transfected CHO cells, and FAK negative mouse DU 3 cells suggest that the α3β1 integrin and FAK play critical roles in the KSHV mediated signal induction (Naranatt *et al.*, 2003). Inhibitors specific for PI 3-K, PKC-ζ, MEK and ERK significantly reduce virus infectivity without affecting virus binding to the target cells. Examination of entry of viral DNA supports a role for PI 3-K in KSHV entry and a role for PKC-ζ, MEK and ERK at a stage after entry (Naranatt *et al.*, 2003). PI 3-K is involved in the activation of Rho-GTPases. These in turn are critical for the activation of Rac, Rho, Cdc42 and Rab5 which are involved in the modulation of actin dynamics, formation of endocytic vesicles and the fission of endocytic vesicles. Furthermore, viral capsid movement in the cytoplasm probably depends upon the microfilaments and microtubules, which are controlled by the RhoGTPases. Since KSHV induces the RhoGTPases, it is reasonable to speculate that these inductions serve a vital role in the infectious process. The interaction of KSHV with

cells induces the polymerization of cortical actin filaments (Naranatt *et al.*, 2003). Further detailed analyses are essential to decipher the link between these pathways and their potential roles not only in KSHV entry into target cells but also the release and movement of capsids in the cytoplasm and delivery of viral DNA into the nucleus.

Besides playing an important role in the entry of viral nucleic acid into the nucleus of the infected cells, KSHV interactions with HS, integrins and other host cell surface molecules may also dictate the outcome of an infection by creating an appropriate intracellular environment facilitating infection. For example, there are many obstacles that viruses have to overcome during the early and late stages of infection of target cells in the host. They include external threats to infected cells from the innate and adaptive immune systems as well as internal obstacles such as transcriptional blocks and cellular apoptosis that may be triggered by virus binding and entry. To establish a successful infection, herpesviruses must have developed many ways to manipulate and overcome these obstacles early during infection. In this respect, stimulation of PI 3-K by KSHV, which may influence the Akt induced anti-apoptotic pathway, and modulation of interferon response factors by the virion associated tegument protein ORF 45 protein (Zhu and Yuan, 2003) are of considerable interest.

Cytoplasmic trafficking, delivery of viral genome into the nucleus

After release into the cytoplasm, the EBV and KSHV capsid/tegument must traffic through the cell in order for viral DNA to be delivered into the nucleus. HSV-1 utilizes dynein motors and microtubules for this purpose and the activation by KSHV of RhoGTPases, which are important to control of microtubules, is consistent with a similar mechanism of transport for this virus.

Similar to HSV, KSHV utilizes the dynein motors in the cytoplasmic trafficking and delivery of viral DNA to the nucleus (Narranat *et al.*, 2005). Microtubules play important roles in KSHV infection since depolymerization of microtubules even though did not affect KSHV binding and internalization, it inhibited the nuclear delivery of viral DNA and infection (Narranat *et al.*, 2005). The interesting aspect is that KSHV induced the acetylation of microtubules, an essential step for the microtubule aggregation, which are mediated by the host cell pre-existing signals induced by KSHV binding an entry steps. The inactivation of Rho GTPases by Clostridium difficile toxin B significantly reduced the microtubular acetylation and the delivery of viral DNA to the nucleus (Narranat *et al.*, 2005). Activation of Rho GTPases by *Escherichia coli* cytotoxic necrotizing factor significantly augmented the nuclear delivery of viral DNA. Activation of RhoA-GTP-dependent diaphanous 2 was observed, with no significant activation in the Rac- and Cdc42-dependent PAK1/2 and stathmin molecules. The nuclear delivery of viral DNA increased in cells expressing a constitutively active RhoA mutant and decreased in cells expressing a dominant-negative mutant of RhoA. Like in HSV-1, KSHV capsids colocalized with the microtubules, and the colocalization was abolished by the destabilization of microtubules with nocodazole and by the PI-3K inhibitor affecting the Rho GTPases. These results suggest that KSHV induces Rho GTPases, modulates microtubules and promotes the trafficking of viral capsids and the establishment of infection (Narranat *et al.*, 2005). These studies demonstrated for the first time modulation of the microtubule dynamics by virus-induced host cell signaling pathways to aid in the trafficking of viral DNA to the infected cell nucleus. These data strongly suggest that KSHV manipulates the host cell signaling pathway to create an appropriate intracellular environment that is conducive to the establishment of a successful infection.

No studies of EBV have directly addressed this issue, although the observation that at least in epithelial cells the EBV BMRF2 protein interacts with integrins is provocative (Tugizov *et al.*, 2003). In primary B cells transcription from incoming EBV DNA can be detected within 10–12 h post infection and since circularization of the genome requires host protein synthesis (Sinclair and Farrell, 1995), whereas initiation of transcription from the viral genome does not (Hurley and Thorley-Lawson, 1988), it can be inferred that transcription initiates from the incoming linear genome. Transcription is unaffected by inhibitors of tyrosine kinases and PI 3-K, but synthesis of virus proteins is reduced implying that stimulation of kinases is not required for transport of virus to the nucleus, as it may be for KSHV, but for a later stage in the infection process (Sinclair and Farrell, 1995). Circular episomes have been detected by 16 h post infection and their formation may require that the cell move from G0 to G1 (Alfieri *et al.*, 1991; Hurley and Thorley-Lawson, 1988). De novo protein synthesis is probably necessary for circularization and a cellular protein complex that includes Sp1 and binds to the recombination junctions within the terminal repeats of the genome may be involved in the process (Sun *et al.*, 1997). Early studies have suggested that amplification of the first formed episome does not occur in primary B cells until more than one week after infection (Hurley and Thorley-Lawson, 1988). No similar studies have yet been reported for KSHV, although the virus is found in episomal form in PEL cells (Ballestas *et al.*, 1999). Clearly much more needs to be known about the events between entry and early transcription from the incoming genome for both KSHV and EBV.

Summary

The importance of EBV and KSHV as oncogenic viruses has appropriately focused efforts on understanding the ways in which they influence cell survival and growth. An unintended consequence has been that information about productive replication of both viruses has been less forthcoming. Recent progress, particularly in understanding the early events that initiate entry, has been promising, but many important gaps remain to be filled. The determinants of tropism remain incompletely defined for both EBV and KSHV and although the perennial problem of how herpesviruses mediate virus cell fusion is not unique to either EBV or KSHV, it is still largely unsolved. The effect of entry on cell signaling pathways is proving to be an extremely fertile area of study, not just for understanding how viruses establish a suitable intracellular milieu for gene expression and DNA replication, but also for understanding how viruses are transported to the nucleus after the cell membrane has crossed. Progress with KSHV has been particularly interesting in this regard. It already appears likely that infection of endothelial cells by KSHV and infection of B cells by EBV may follow different pathways. However, whether this reflects fundamental differences in virus strategy, or adaptation to different host cells will require study of the viruses in more than one of the cell types that each infects. As important as a comprehensive understanding of lytic replication is to understanding the pathogenesis of disease as a whole, for EBV and KSHV it remains a distant goal.

Maintenance and replication during latency

[2]University of Florida, Gainesville, FL

Introduction

The human gammaherpesviruses Epstein–Barr Virus (EBV) and Kaposi's sarcoma-associated herpesvirus (KSHV) are associated with a variety of malignancies involving cells of various lineages.

After primary infection and initial viral propagation in epithelial and lymphoid cells, both viruses establish latency in a subset of CD19 positive B-cells. In this often lifelong asymptomatic stage, in which EBV genomes are detectable primarily in resting memory B-cells, the number of infected cells is extremely low and virus load is tightly controlled by the host cellular and humoral immune response.

Loss of this balance leads to an increase in viral load, which often precedes the onset of malignant diseases. Both tissue involvement and histopathology are highly variable between EBV- and KSHV-associated malignancies and involve either lymphoid (Burkitt's lymphoma and primary effusion lymphoma), epithelial (nasopharyngeal carcinoma), or endothelial (Kaposi's sarcoma) tissues.

However, common to all gammaherpesvirus-associated tumors is that the majority of tumor cells are latently infected, and harbor extrachromosomal circularized viral genomes called episomes that are replicated and segregated by the host cellular replication machinery indefinitely. This ability to maintain long-term latent infection in quiescent and proliferating cells may be a defining property shared by both the lymphocryptoviruses (LCV, represented by EBV) and the rhadinoviruses (RDV, represented by KSHV).

This chapter aims to summarize our current understanding of the underlying mechanisms by which EBV and KSHV achieve long-term episomal maintenance in latently infected cells, which conceptually can be viewed as a two step process: replication of the viral genome and faithful segregation to daughter cells (Fig. 24.1).

Before going into the details about viral DNA replication, episomal maintenance and their *cis*- and *trans*-requirements, it is important to note that much less is known about the molecular events that precede the establishment of stable latency after primary infection. Initially, KSHV, like most herpesvirus virions, attaches to heparin sulfate prior to interactions with its receptor. On B-cells KSHV binds to members of the alpha integrin family which may serve as receptor or coreceptor (Akula *et al.*, 2001, 2002). However, EBV does not encode a heparin binding protein and directly binds to the high affinity receptor CD21 which is highly expressed on B-cells (Ahearn *et al.*, 1988; Li *et al.*, 1992). Attachment, binding and internalization, which for both viruses are believed to be dependent on endocytosis, are discussed in detail in Chapter 23. Virion binding to cell surface receptors also triggers signal transduction pathways, which may facilitate viral entry. The concurrent steps: transport of capsids through the cytoplasm and delivery of the linear viral genome to the nucleus have not been studied in great detail for either EBV, or KSHV. It is believed that circularization of viral genomes occurs early after infection prior or concurrent with the onset of viral mRNA synthesis (Hurley and Thorley-Lawson, 1988; Alfieri *et al.*, 1991). Recent studies on KSHV show that DNA is detectable in infected cells as early as 5 min post-inoculation. Furthermore, first viral transcripts are detectable by 30 min post-infection. Surprisingly, one study on KSHV found that many of the genes expressed after *de novo* infection were early lytic genes rather than latency-associated genes. However, after latency-associated genes were detectable, a marked down-regulation of lytic gene expression was noted (Naranatt *et al.*, 2004). This new finding suggests that early lytic genes contribute the establishment of latency by providing auxiliary functions such as perturbing immune recognition of infected cells. The

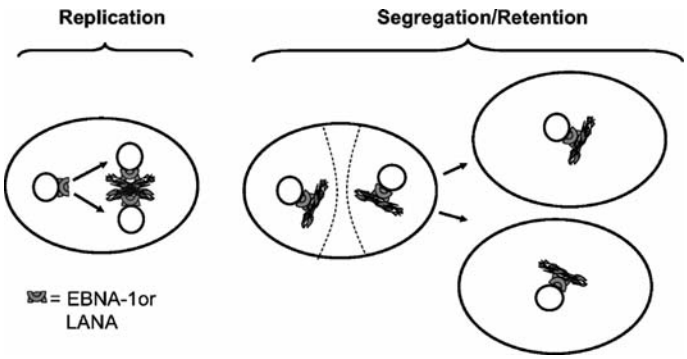

Fig. 24.1. Plasmid maintenance model for EBV and KSHV. EBNA1 and LANA tether viral genomes to cellular chromosomes. This tethering can occur through numerous chromosome-associated proteins and appears to be sufficient for stable plasmid maintenance.

question about how latency is established is also discussed in Chapter 23 which is specifically focused on early events after infection. The focus of this chapter, however, is how the viral episome is maintained in cells in which latency has been established.

During latency, viral gene expression is limited to a small subset of genes dedicated to viral genome maintenance and host-cell accommodation. Although many genes required for lytic replication and virion structure are highly conserved among the herpesvirus family, those genes required for the establishment and maintenance of latency are quite distinct even within the gammaherpesviruses. EBV encodes a total of eight different latency-associated genes whose expression differences among lymphoid malignancies gave rise to the classification of three latency programs. While some Burkitt's lymphomas express only a single latent antigen (Epstein–Barr virus nuclear antigen 1, EBNA1), rare immunoblastic lymphomas may express all EBNAs in addition to the latent membrane proteins (LMP 1 and 2). For KSHV, gene expression analysis showed that tumor cells in KS lesions and PEL-derived cell lines also express only a small number of genes. Although viral gene expression during latency may differ between KS and PEL, PEL-derived cell lines have been instrumental for the identification and characterization of so far five KSHV latency-associated genes. These are the latency-associated nuclear antigens (LANA and LANA2), vCyclin, vFLIP, and Kaposin A and B.

With the exception of LANA and EBNA1, which both play an important role in viral DNA replication and genome maintenance during latency, there is little conservation between the latency-associated genes of lymphocryptoviruses and rhadinoviruses. The functions and roles of these gene products in the biology of KSHV and EBV will be discussed elsewhere in this volume and have recently been subject to a number of excellent review articles (Boshoff and Weiss, 2002; Herndier and Ganem, 2001).

Both LCV and RDV family members encode origin binding proteins (EBNA1 and LANA) and possess genetic elements (origins) dedicated to viral genome maintenance and replication during latent infection in proliferating cells. The specific protein interactions and detailed mechanisms used by LCV and RDV have evolutionarily diverged, but many of the underlying strategies of viral persistence are quite similar. A review of the properties of the latent viral genome and the mechanisms of DNA replication, maintenance, and segregation during latency should highlight important differences and essential similarities among the gammaherpesviruses.

EBV (Lymphocryptovirus)

A number of excellent reviews address the biology of EBV replication and plasmid maintenance during latency (Leight and Sugden, 2000; Sugden and Leight, 2001). Most of this section will focus on the molecular biology of Epstein–Barr nuclear antigen 1 (EBNA1) and its interactions with the origin of plasmid replication (*OriP*). It is this interaction that is primarily responsible for EBV genome stability during latency. However, other aspects of the viral chromosome will be considered, including the importance of DNA methylation status, chromatin organization, and nuclear matrix attachment.

Properties of the episomal latent viral genome

The prototypical latent gammaherpesvirus exists as multicopy (5–100) covalently closed circular genomes that can be separated from chromosomal DNA by density gradient centrifugation (Adams and Lindahl, 1975; Nonoyama and Tanaka, 1975) and by gel electrophoresis using the Gardella gel system (Gardella *et al.*, 1984). However, integrated forms of the virus can be detected, and numerous cell lines have been described that have complete and partial EBV genomes integrated into the cellular chromosome (Adams and Lindahl, 1975; Nonoyama and Tanaka, 1975; Andersson-Anvret and Lindahl, 1978; Lindahl *et al.*, 1978; Koliais, 1979; Anvret *et al.*, 1984; Lawrence *et al.*, 1988; Popescu *et al.*, 1993; Kripalani-Joshi and Law, 1994; Wuu *et al.*, 1996; Ohshima *et al.*, 1998; Chang *et al.*, 2002). In the prototypical latent infection, EBV circularizes rapidly after

initial infection through an annealing event at the terminal repeats (Kintner and Sugden, 1979; Laux *et al.*, 1989; Cheung *et al.*, 1993; Zimmermann and Hammerschmidt, 1995). The circular form is thought to be essential for reactivation of the lytic cycle and production of progeny virus. Circularization is also required for the expression of the terminal repeat transcript LMP2a that may contribute to the stability of the latent state by inhibiting B-cell receptor mediated reactivation signals (Laux *et al.*, 1989; Miller *et al.*, 1994).

Chromatin organization of the latent episome

Packaging of cellular DNA into nucleosomal chromatin is essential for its protection and stability throughout much of the cell cycle. This holds true for viral episomal DNA, as well. During latency, the viral episome is associated with nucleosomes in arrays that are indistinguishable from bulk cellular DNA (Shaw *et al.*, 1979; Dyson and Farrell, 1985). Micrococcal nuclease laddering assays revealed that the majority of the EBV latent genome is organized in nucleosome arrays (Dyson and Farrell, 1985), with the exception of the region covering *OriP* (Wensing *et al.*, 2001). Nucleosomes were also disorganized in the adjacent sequences encompassing the EBERs, which are two genes constitutively transcribed by RNA polymerase III during most forms of latency (Sexton and Pagano, 1989; Wensing *et al.*, 2001). Consistent with these findings, biochemical studies revealed that EBNA1 can displace a mononucleosome positioned over an EBNA1-binding site in vitro, suggesting that EBNA1 binding to *OriP* is sufficient for displacing an ordered array of nucleosomes from this region of the latent genome (Avolio-Hunter *et al.*, 2001).

In contrast to the latent genome, EBV DNA found in the virion or after lytic replication appears to be nucleosome free (Shaw *et al.*, 1979; Dyson and Farrell, 1985). Nucleosome assembly on newly synthesized lytic DNA might inhibit DNA insertion into the nucleocapsid, and thus might inhibit infectious virion production. It is not clear what mechanism prevents nucleosome assembly during lytic infection; nucleosome assembly on newly synthesized cellular DNA is coupled to DNA replication proteins, and these cellular enzymes do not participate in viral lytic replication. Alternatively, viral encoded proteins may actively prevent nucleosome assembly on the viral genome during lytic replication by an as yet unknown mechanism.

Nucleosome positioning and histone modification may also contribute to the gene regulation during latent infection. Lytic gene promoters are transcriptionally repressed during latent infection. Inhibitors of histone deacetylases, like sodium butyrate and trichostatin A, are potent activators of lytic cycle gene expression (Saemundsen *et al.*, 1980; Jenkins *et al.*, 2000). The positioned nucleosome contributes to transcriptional repression of the immediate early gene, but it is not clear how the nucleosome is positioned in the viral genome. Nucleosome positioning may be affected by at least two mechanisms including nucleosome positioning elements inherent in DNA sequence, and sequence specific binding proteins that recruit nucleosome modifying activities. Histone deacetylases associated with DNA binding proteins MEF2D and RBP-Jk are known to maintain repressive chromatin at the EBV BZLF1(Liu *et al.*, 1997; Speck *et al.*, 1997; Gruffat *et al.*, 2002) and EBNA2 Cp (Hsieh *et al.*, 1999; Alazard *et al.*, 2003) promoters. In addition to restricting gene expression, chromatin structure and histone modifications may protect the viral genome from DNA damage during latency. Nucleosome position and remodeling may also play a role in the regulation of plasmid replication during latency of both EBV and KSHV (Stedman *et al.*, 2004; Zhou *et al.*, 2005).

DNA methylation of latent EBV

DNA methylation is an epigenetic mark associated with transcriptional silence (Bird, 1986; Jones and Wolffe, 1999). The EBV genome is highly methylated during latency (Saemundsen *et al.*, 1983) and there is evidence that virion DNA is also hypermethylated (Diala and Hoffman, 1983). DNA methylase inhibiting drugs, like 5-aza-cytidine, can induce lytic gene expression from latently infected cells (Ben-Sasson and Klein, 1981). DNA methylation has also been found to play a critical role in regulating LMP1 and EBNA2-6 transcription (Ernberg *et al.*, 1989; Masucci *et al.*, 1989; Allday *et al.*, 1990; Hu *et al.*, 1991; Minarovits *et al.*, 1994; Robertson *et al.*, 1996; Robertson and Ambinder, 1997; Schaefer *et al.*, 1997; Falk *et al.*, 1998; Ambinder *et al.*, 1999; Robertson, 2000) and thus contributes to the transition between various latency programs.

Like nucleosome phasing, DNA methylation is not uniform throughout the viral genome. DNA methylation is generally spared from sequence elements of *OriP* (Falk and Ernberg, 1993; Salamon *et al.*, 2001). EBNA1 binding to *OriP* contributes to the sparing of DNA methylation, but the mechanism preventing DNA methylation is not known (Hsieh, 1999; Lin *et al.*, 2000; Salamon *et al.*, 2000). EBNA1 bound to *OriP* can also affect transcription of LMP1p (Gahn and Sugden, 1995) and Cp (Reisman and Sugden, 1986; Puglielli *et al.*, 1996; Nilsson *et al.*, 2001), and it is possible that effects on DNA methylation and chromatin structure

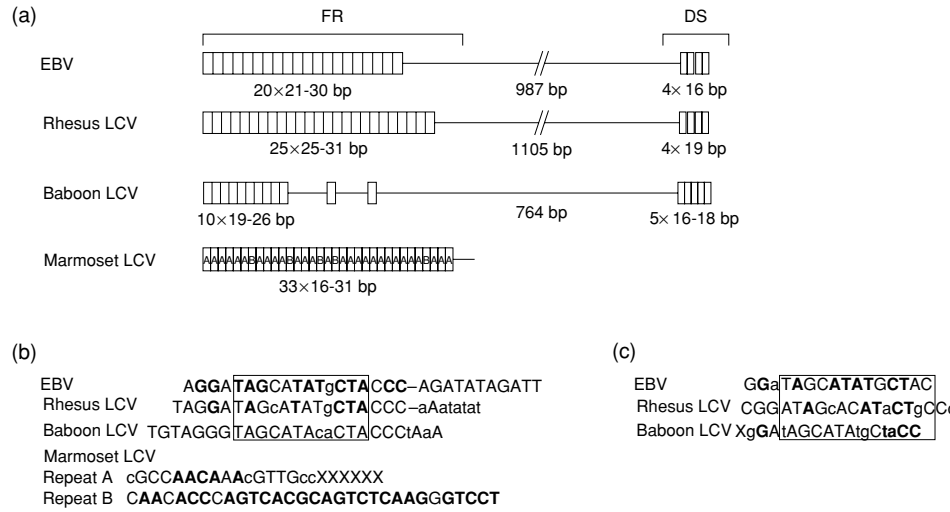

Fig. 24.2. Comparative *OriP* structure of lymphocryptoviruses. (a) Family of repeat (FR) and dyad symmetry elements of human and primate viruses. (b) and (c) Alignment of EBNA1 binding sites within FR and DS elements (courtesy of Rivaillier *et al.* (2002).

at *OriP* contribute to latent cycle transcription. In this respect, *OriP* may be a significant control element determining gene expression patterns in the various types of EBV latency.

Molecular biology of *OriP*

The genetic elements responsible for plasmid maintenance and DNA replication were identified through the elegant experiments of Yates and Sugden (Yates *et al.*, 1984, 1985; Reisman *et al.*, 1985). In these experiments, plasmid subclones of the B95-8 genome were tested for their stable maintenance in EBV positive cell lines and only one region (nucleotides 7000 and 9258 in EBV coordinates) possessed clear plasmid maintenance and DNA replication activity (Yates *et al.*, 1984). This region is referred to as the origin of plasmid replication (*OriP*) and consists of two functional domains, the family of repeats (FR) and the Dyad symmetry (DS) region (Fig. 24.2) (Lupton and Levine, 1985; Reisman *et al.*, 1985; Yates *et al.*, 1985; Chittenden *et al.*, 1989; Wysokenski and Yates, 1989). The Epstein–Barr virus nuclear antigen 1 (EBNA1), which is expressed in most forms of viral latency, binds directly to the 30 bp repeat elements found in FR and DS in *OriP* (Rawlins *et al.*, 1985). EBNA1 is the only viral protein required for episomal maintenance and replication of *OriP*-containing plasmids (Yates and Camiolo, 1988; Wysokenski and Yates, 1989).

OriP consists of at least two functional elements that are separated by a non-essential 1 kb spacer region (Fig. 24.2). The family of repeats (FR) consists of 20 × 30 bp repeats each containing a 16 bp EBNA1 binding site. The DS element consists of four lower affinity EBNA1 binding sites that are organized as two functional pairs. The minimal replicator for *OriP* consists of one functional pair of EBNA1 binding sites spaced precisely 21 nucleotides from the center of each site (Yates *et al.*, 2000). The DS element of EBV consists of two minimal replicators, and mutagenesis shows that at least one intact pair is essential for replication function (Harrison *et al.*, 1994; Koons *et al.*, 2001). DS also consists of three nine base pair repeat elements, referred to as nonamer repeats, which are positioned adjacent to each pair of EBNA1 sites (Niller *et al.*, 1995; Vogel *et al.*, 1998). Mutations of the nonamer sites have 2–5 fold effects on replication and plasmid maintenance, but appear not to be absolutely essential for minimal replicator activity (Vogel *et al.*, 1998; Yates *et al.*, 2000; Koons *et al.*, 2001; Deng *et al.*, 2002, 2003). The nonamer sites are identical to telomere repeats, and were found to interact directly with the telomere repeat binding factors TRF1 and TRF2 (Deng *et al.*, 2002).

An *OriP*-like structure is conserved in sequence and position in all lymphocryptovirus family members, although there is considerable variation in the number, spacing, and sequence of EBNA1 binding sites (Rivailler *et al.*, 2002) (Fig. 24.2). The rhesus EBV (CalHV-3) contains an unusual family of repeats that consists of two repetitive sequences that diverge considerably from consensus EBNA1 sites. This observation is surprising since the DNA binding domain of the rhesus EBNA1 protein is strongly conserved.

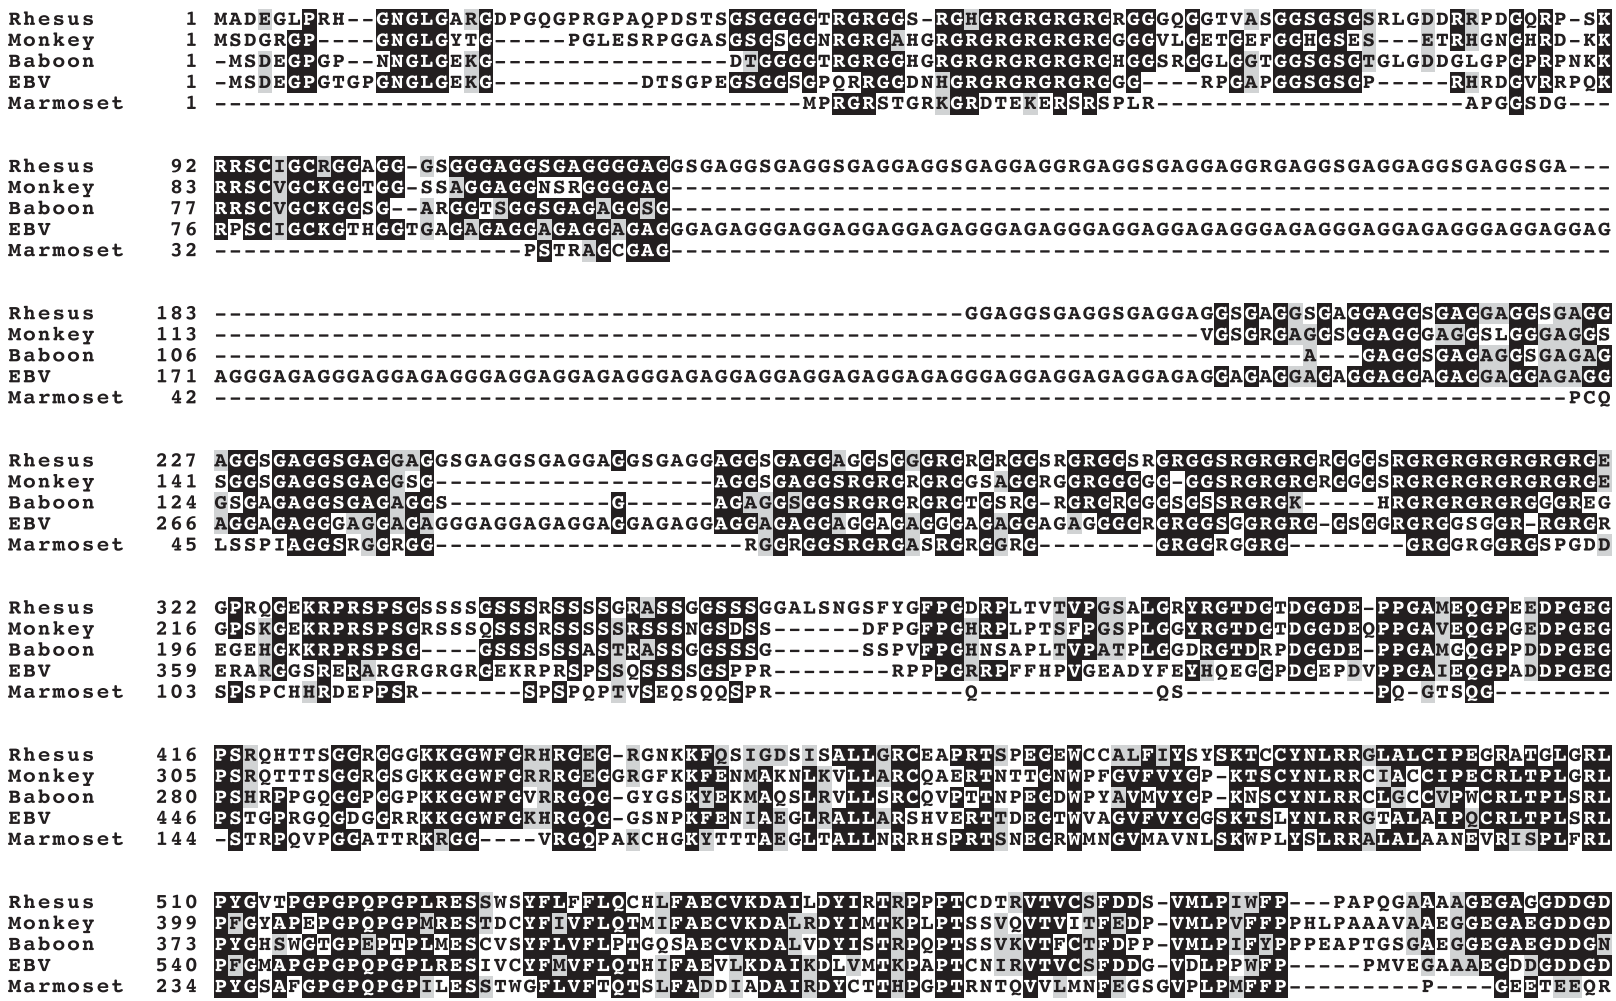

Fig. 24.3. EBNA1 proteins are highly conserved among lymphocryptoviruses. Amino acid alignment demonstrating that the N- and C-terminus of EBNA1 from all five viruses are conserved. Only Rhesus and EBV contain the immune modulatory GA repeats.

Interestingly, no apparent DS element could be identified at the correct position in the rhesus genome (Rivailler *et al.*, 2002). A recent study has shown that the 14 bp spacing (found in EBV) is optimal for plasmid maintenance, while the 10 bp spacing (found in HVP) functions better in transcription enhancement (Hebner *et al.*, 2003). Earlier studies indicated that at least 7-8 EBNA1 binding sites were required for FR function in plasmid maintenance assays, and this seems to vary depending on the spacing of these sites (Lupton and Levine, 1985; Chittenden *et al.*, 1989; Hebner *et al.*, 2003). The spacing between EBNA1 sites in the DS appear to be more highly conserved, and these spacing constraints are likely to be critical for replication initiation function (Bashaw and Yates, 2001)

Properties of EBNA1

All of the known members of the lymphocryptovirus family have a protein with homology to EBNA1, including those found in the rhesus (cercopithicine HV 15), marmoset (callitrichine herpesvirus 3), baboon (herpesvirus papio), and squirrel monkey (cynomolgus herpesvirus A4) (Fig. 24.3). Human Epstein–Barr virus EBNA1 has been most intensively studied, and is necessary and sufficient for *OriP*-dependent DNA replication and plasmid maintenance (Yates *et al.*, 1984, 1985). EBNA1 deletion mutants fail to establish episomal latent infection (Lee *et al.*, 1999) indicating that EBNA1 is required in the context of the intact genome. In addition to its role in DNA replication, EBNA1 can activate transcription from a synthetic plasmid containing multiple EBNA1 binding sites upstream of simple viral promoter (Wysokenski and Yates, 1989). *OriP* bound EBNA1 can function as a transcriptional enhancer for the LMP1 promoter and EBNA2–6 Cp promoter 2–10 kilobase pair away. EBNA1 may also possess additional activities associated with B-cell immortalization since EBNA1 deletion leads to a dramatic decrease in immortalization efficiency (Humme *et al.*, 2003) and its overexpression inhibits apoptosis (Kennedy *et al.*, 2003).

EBNA1 can be divided into several functional domains, with the C-terminal domain (aa 450–620) encoding the DNA binding and dimerization activity essential for interaction with DS, FR, and BamHI Q binding sites (Fig. 24.4) (Rawlins *et al.*, 1985; Ambinder *et al.*, 1990, 1991; Chen *et al.*, 1993, 1994; Goldsmith *et al.*, 1993; Ceccarelli and Frappier, 2000; Cruickshank *et al.*, 2000; Wu *et al.*, 2002). This domain has been crystallized with and without DNA (Fig. 24.5) (Bochkarev *et al.*, 1995, 1996), and shows a remarkable similarity to the structural fold of the DNA binding domain of bovine papilloma virus E2 protein, suggesting that these viral proteins share common ancestral precursor involved in plasmid-based replication. The papillomavirus E2 protein binds the papillomavirus DNA replication origin and helps to load the viral encoded helicase, E1 (Edwards *et al.*, 1998). E2 also has important function in papillomavirus transcription regulation and, like EBNA1, is involved in both positive and negative regulation of gene expression (Desaintes and Demeret, 1996).

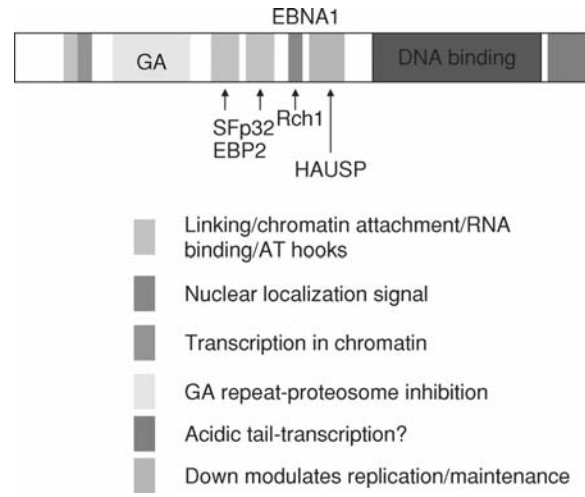

Fig. 24.4. Functional protein domains of EBNA1. Amino acid residues are indicated for the boundaries of protein domains for DNA binding, dimerization, chromosome binding sites (CBS), nuclear localization (NLS), or protein–protein interactions (as indicated). (See color plate section.)

C-terminal DNA binding domain

A detailed analysis of the X-ray crystal structure of the EBNA1 DNA binding domain reveals a fascinating and unique DNA interaction interface, with extensive protein DNA contacts in both the major and minor grooves of the DNA helix (Fig. 24.5) (Bochkarev *et al.*, 1996). The structures reveal that EBNA1 can introduce a strong bend in bound DNA, and provides some insight into the likely contacts between critically phased dimer binding sites in the DS minimal replicon. EBNA1 has been shown to induce permanganate sensitivity upon thymine residues of one strand on the two outermost binding sites in DS (sites 1 and 4) (Hearing *et al.*, 1992). Structural studies revealed that permanganate sensitivity is not a result of duplex breathing caused by single stranded DNA formation, but rather resulted from an unusual helical distortion of a thymine residue on one strand of the EBNA1 binding sites in DS (Summers *et al.*, 1997; Bochkarev *et al.*, 1998). The amino acid residues 461 to 469 that make contact with the minor groove of the EBNA1 binding site were shown to be essential for inducing the permanganate sensitivity (Summers *et al.*,

1997). The functional significance of this distorted thymine structure on DNA replication function remains unclear.

N- terminal domain linking activity

The amino terminal domains of EBNA1 possess genetically distinct activities essential for DNA replication, plasmid maintenance and transcription (Yates and Camiolo, 1988; Wu *et al.*, 2002). Multiple regions amino terminal to the DNA binding domain contribute to DNA replication and plasmid maintenance activity (Fig. 24.4). The amino terminal regions of EBNA1 have no obvious sequence homology to other known proteins, but do contain three RGG-rich domains that were first recognized for their similarity to RGG-elements found in hnRNP RNA binding proteins (Burd and Dreyfuss, 1994). The RGG motifs (aa 34–56, and 339–377) were found to confer some RNA binding ability on EBNA1, but the biological significance of EBNA1 RNA binding has not been elucidated (Snudden *et al.*, 1994). These RGG-rich regions in the amino terminal domain also confer intramolecular "linking" between EBNA1-DNA complexes as revealed by the formation of large non-resolved complexes in electrophoresis mobility shift assay (EMSA) (Frappier *et al.*, 1994; Mackey *et al.*, 1995). Electron microscopy revealed that EBNA1 can induce DNA looping between FR and DS (Su *et al.*, 1991; Middleton and Sugden, 1992), and the aa 350–361 were shown to be responsible for DNA looping in both electron microscopy studies and ligation enhancement assays (Frappier *et al.*, 1994). The linking domains (aa 40–89, 331–361, and 372–391) were also found to be important for EBNA1 replication and transcription activity (Mackey and Sugden, 1999). The precise mechanistic contribution of these RGG-rich linking domains remains unclear, but are likely to be involved in the protein-protein interactions and metaphase chromosome binding properties of EBNA1.

Metaphase chromosome attachment

EBNA1 can also associate with metaphase chromosomes through amino acids that appear to overlap the linking domains, and are essential for plasmid maintenance function (Marechal *et al.*, 1999). EBNA1 attachment to metaphase chromosome has been mapped to three domains that correlate well with the ability of EBNA1 to confer plasmid maintenance (Marechal *et al.*, 1999; Kanda *et al.*, 2001; Wu *et al.*, 2002). EBNA1 has also been shown to colocalize with DNA replication compartments even in the absence of viral DNA (Ito and Yanagi, 2003), suggesting that the association with interphase chromatin is independent of viral DNA sequences. Intriguingly, substitution of the amino terminal domain of EBNA1 with the HMG I/Y or histone H1 chromatin binding folds was sufficient to reconstitute efficient plasmid maintenance (Hung *et al.*, 2001),

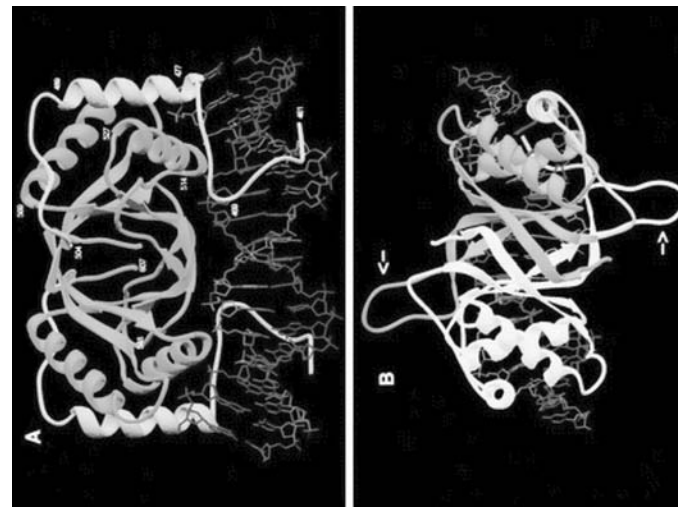

Fig. 24.5. X-ray crystal structure of EBNA1 dimer bound to a consensus DNA recognition site (courtesy of Bocharev *et al.*, *Cell* in press). (a) Ribbon diagram showing the core domain (residues 504–607) from each monomer, in blue. Flanking domains are shown in yellow. (b) View down the non-crystallographic axis showing one monomer in white and the other in the same color scheme as used in (a). Proline loops are indicated by arrows. (See color plate section.)

suggesting that chromosome attachment is both necessary and sufficient for plasmid maintenance. One recent finding indicates that the chromosomal attachment sites of EBNA1 have AT-hook activity, and can bind to AT-rich DNA (Sears *et al.*, 2003, 2004). This suggests that the linking-activity involves weak DNA binding through the amino terminal domain of EBNA1. These data would also account for why this region of EBNA1 can be substituted with HMG I/Y and histone H1, which have AT-hook domains and DNA binding activity.

Transcription regulation

The transcription regulatory properties of EBNA1 have also been investigated. As mentioned above, EBNA1 can stimulate transcription of Cp and LMP1 during latency (Sugden and Warren, 1989; Wysokenski and Yates, 1989; Puglielli *et al.*, 1996; Nilsson *et al.*, 2001). The amino terminal domain of EBNA1 is required for this activity, and can be distinguished from the DNA replication and plasmid maintenance properties by mutational analysis (Yates and Camiolo, 1988; Wu *et al.*, 2002). Transcription activation of chromatin integrated templates required the conserved amino terminal sequence (aa 65–89), which was not essential for activation of transient plasmid based genes (Kennedy and Sugden, 2003). EBNA1 can also function as a transcription repressor, and can down-regulate

transcription of its own mRNA initiating at the F promoter (Sung *et al.*, 1994). In this autoregulatory loop, EBNA1 competes with E2F binding sites necessary for the cell cycle regulation of EBNA1. The detailed mechanisms of EBNA1 transcription activation and repression have not yet been characterized.

Proteosome inhibition by GA repeats

EBNA1 also has a variable length ~200 residue glycine-alanine repeat from aa 100 to 325 using the B95-8 strain. Deletion of the GA repeat has no apparent effect on DNA replication, plasmid maintenance, or transcription regulation. However, the GA repeats inhibit ubiquitin-dependent/proteosomal processing of EBNA1 (Levitskaya *et al.*, 1995, 1997). The GA repeats reduce peptide processing and HLA class I presentation, and are responsible for the limited cytotoxic T-cell response to EBNA1 protein in latently infected cells (Blake *et al.*, 1997). The GA repeats can also inhibit proteosome processing on foreign molecules, and may represent a general strategy for viral proteins to escape immune cell recognition (Levitskaya *et al.*, 1997; Leonchiks *et al.*, 2002). In addition to the effect on protein stability, the GA repeats inhibit EBNA1 translational efficiency, thus contributing to the low, but stable EBNA1 protein expression levels in latently infected cells (Yin *et al.*, 2003).

Cellular proteins that interact with EBNA1

Yeast two hybrid assays and biochemical isolation have identified several cellular proteins that interact with EBNA1. The two hybrid assay isolated SFp32/TAP/hyaluronectin (Wang *et al.*, 1997), importins α and β (Fischer *et al.*, 1997; Kim *et al.*, 1997; Ito *et al.*, 2000), and EBP2 (Shire *et al.*, 1999), while biochemical purifications isolated SFp32(Chen *et al.*, 1998; Van Scoy *et al.*, 2000), and HAUSP (Holowaty *et al.*, 2003). SFp32/TAP binds to two independent regions of EBNA1, aa 40–60 and aa 325–376, which overlaps the RGG motifs and linking domains (Wang *et al.*, 1997) (Fig. 24.4). Overexpression of SFp32 inhibited EBNA1 transcription activation (Wang *et al.*, 1997), and interacts with *OriP* by chromatin immunoprecipitation assay (Van Scoy *et al.*, 2000). SFp32 has also been isolated as a binding partner with the herpesvirus simiri ORF73 LANA protein (Hall *et al.*, 2002) and HIV-1 Tat (Fridell *et al.*, 1995; Yu *et al.*, 1995). SFp32 is thought to have a primary function in oxidative phosphorylation at the mitochondrial membrane (Muta *et al.*, 1997), but may also have a role in the nucleus when shuttled with nuclear binding partners, like EBNA1 (Matthews and Russell, 1998).

EBP2 was also isolated in a two hybrid assay (Shire *et al.*, 1999) and the interaction domain was mapped to the aa 325–376 which overlap with the DNA linking activity that is essential for plasmid maintenance. The yeast EBP2 orthologue has a role in ribosome biogenesis, and has a nucleolar localization (Huber *et al.*, 2000). The most compelling evidence for a role of EBP2 has been in the reconstitution of *OriP* plasmid maintenance in budding yeast (Kapoor *et al.*, 2001). In this system, *OriP* confers centromeric plasmid segregation activity only when EBNA1 is coexpressed with human EBP2. EBP2 and EBNA1 colocalize when expressed in yeast and human cell lines, and EBP2 has been shown to bind to metaphase chromosomes (Wu *et al.*, 2000). EBP2 has been proposed to function in mediating EBNA1 interaction with metaphase chromosomes, and provide EBNA1 with a chromosome attachment and plasmid partitioning function required for stable plasmid maintenance (Wu *et al.*, 2000, 2002).

HAUSP/USP7, along with nucleosome assembly protein (Nap1), template activating factor Ib/SET, protein-kinase CKII, and protein arginine methylase PRMT5, were identified by mass spectrometry analysis of EBNA1 associated proteins (Holowaty *et al.*, 2003). HAUSP/USP7 has also been found to associate with HSV-1 ICP0 (Everett *et al.*, 1999) and this binding correlates with ICP0 transcription activation function. Mutations in EBNA1 that disrupt HAUSP/USP7 binding caused a fourfold increase in plasmid maintenance activity of EBNA1, although no change in EBNA1 protein stability could be detected. EBNA1 binding to HAUSP/USP7 did affect the stability of p53 by blocking its binding and deubiquitylation by HAUSP/USP7. These studies are especially exciting since they provide a mechanism for the anti-apoptotic function of EBNA1 during B-cell immortalization (Saridakis *et al.*, 2005). The functional characterization of other EBNA1-associated proteins has not yet been reported.

Cellular proteins that interact with *OriP*

Cellular factors that interact with *OriP* have also been characterized. A cellular factor, OBP-1/Kid, binds to and competes for the EBNA1 binding sites in *OriP* (Wen *et al.*, 1990; Zhang and Nonoyama, 1994). OBP-1/Kid has kinesin-like motor activity and localizes to metaphase chromosomes and the mitotic spindle (Tokai *et al.*, 1996). A specific role for OBP-1/Kid in *OriP* function has not been apparent, especially since OBP-1 competes for EBNA1 and EBNA1 is thought to bind *OriP* constitutively through most of the cell cycle (Hsieh *et al.*, 1993). The region of EBV encompassing *OriP* and the EBERs associates with the nuclear matrix

(Jankelevich *et al.*, 1992), and it is likely that this binding is dependent upon EBNA1.

Telomere repeat binding factors also bind to *OriP* in association with EBNA1 (Deng *et al.*, 2002). These host-cell proteins include TRF1 and TRF2, as well as hRap1, tankyrase, and poly-ADP ribose polymerase (PARP1). Both tankyrase and PARP1 have poly-ADP ribose polymerase activity, and EBNA1 can be poly-ADP ribosylated in vitro. TRF1 and TRF2 have identical binding specificity for the nonamer repeats in DS, but have opposing activities in DNA replication assays (Deng *et al.*, 2003). TRF2 associates with DS throughout most of the cell cycle, while TRF1 binding peaks in G2/M and its overexpression inhibits *OriP* replication (Deng *et al.*, 2003). The precise function of these telomeric factors and their potential role in EBNA1 modification is under investigation.

Mechanism of *OriP*- DNA replication

OriP can function as a plasmid origin of replication, and the initiation site for replication has been mapped by a two-dimensional gel electrophoresis assay to a region within or quite close to DS (Gahn and Schildkraut, 1989). In contrast, DNA replication pauses or arrests at FR, suggesting that the bulk of DNA replication occurs in a rightward direction initiating at DS (Gahn and Schildkraut, 1989). Earlier studies also demonstrated that *OriP* is subject to cell cycle restricted replication using heavy-light and heavy-heavy strand density gradient isolation (Adams, 1987; Yates and Guan, 1991), as well as by using Mbo1 and Dpn1 restriction enzyme analysis (Shirakata *et al.*, 1999; Hirai and Shirakata, 2001). Early studies demonstrated that EBV genomes replicate once and only once in the early S phase of the cell cycle (Adams, 1987). Subsequently, it was shown that plasmids carrying *OriP* also replicate only once per cell division cycle in EBNA1 positive cells (Yates and Guan, 1991).

DNA replication at cellular origins requires the assembly of pre-replication licensing factors that include the origin recognition complex (ORC), the minichromosome maintenance (MCM) complex, CDC6, Geminin, and CDT1 (Bell and Dutta, 2002). Components of the ORC complex were shown to associate with *OriP* in vivo using chromatin immunoprecipitation assays (Chaudhuri *et al.*, 2001; Dhar *et al.*, 2001; Schepers *et al.*, 2001). Further genetic evidence that *OriP* is regulated by cellular origin components was demonstrated by a failure of *OriP* to replicate in cells haploinsufficient for ORC2 (Dhar *et al.*, 2001). Futhermore, EBNA1 coimmunoprecipitates with ORC2 and overexpression of geminin inhibited *OriP* replication (Dhar *et al.*, 2001). EBNA1 can also interact with purified replication protein A, the cellular single stranded DNA binding protein required for stabilizing the replication fork (Zhang *et al.*, 1998). From these studies, it is apparent that cellular proteins involved in the regulation of chromosomal replication also control *OriP* replication (Fig. 24.6). A recent study demonstrated that TRF2 can bind a subunit of ORC, and stimulate OriP replication (Atanasiu *et al.*, 2006). Despite these many protein interactions, the precise mechanism of ORC recruitment and DNA polymerase loading at OriP remain to be elucidated.

Mechanism of viral chromosome replication

In the context of the complete genome (Little and Schildkraut, 1995; Norio and Schildkraut, 2001) or plasmid containing large chromosomal DNA inserts (Krysan *et al.*, 1989; Krysan and Calos, 1991), replication may initiate at locations other than DS. Consistent with this, DS can be deleted from EBV genomes without disrupting episomal maintenance of the viral genome (Norio *et al.*, 2000). An alternative replicator sequence, referred to as Rep*, was identified between nt 9370 and 9668 in the EBV genome (Kirchmaier and Sugden, 1998). The Rep* can partially restore plasmid maintenance and DNA replication activity to FR plasmids lacking DS. Rep* does not contain any detectable EBNA1 binding sites by sequence analysis or by direct DNA binding assays, suggesting cellular initiation factors may bind to this region in the absence of EBNA1.

OriP and EBNA1 suffice for the reconstitution of DNA replication and plasmid maintenance on transfected plasmid DNA. However, in the context of the episomal viral genome, it appears as if *OriP* is only used a fraction of the time to initiate DNA synthesis during latency (Little and Schildkraut, 1995). Single molecule analysis of replicated DNA (SMARD) also indicated that *OriP* was not the primary site for initiation of DNA replication in Raji Burkitt

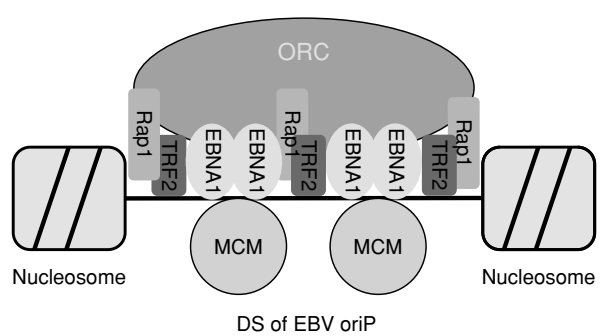

Fig. 24.6. Model for *OriP* of EBV. Indicated are protein–protein and protein DNA interactions that are required for the initiation of DNA synthesis at *OriP*. (See color plate section.)

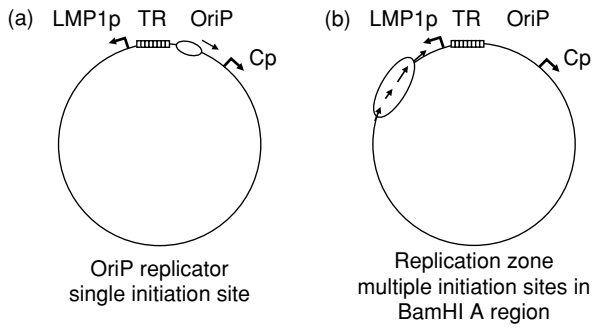

Fig. 24.7. Replication zone versus *OriP*. While in plasmid-based assays DNA synthesis starts at a discrete site near *OriP* (a) in EBV infected cells ori activity is dispersed over a replication zone (b).

lymphoma cell lines, and that the majority of replication initiated from a diffuse zone centered near a PAC1 site in the Bam HI A region (B95-8 coordinates 153, 637) (Little and Schildkraut, 1995; Norio *et al.*, 2000; Norio and Schildkraut, 2001). Initiation of replication in higher eukaryotes may be determined by higher order chromatin domains, rather than discrete replicators, like DS (Gilbert, 2001). EBV appears to have at least two mechanisms for initiating DNA replication, from the discrete DS replicator, or from the broader Bam HI A centered domain of the genome (Fig. 24.7). The possibility that Bam HI A has a replication initiation zone function is particularly intriguing since this region of the genome is transcriptionally active in most forms of EBV latency, and encodes a number of small RNA transcripts (Sadler and Raab-Traub, 1995). The alternative use of replication zones would explain why DS is dispensable for episomal maintenance of the EBV genomes during latency (Norio *et al.*, 2000). It is also likely that the large fragments of cellular DNA that substituted for DS in cosmids also possessed replication initiation zone activity (Krysan *et al.*, 1989; Krysan and Calos, 1991).

Mechanisms of plasmid segregation

Regardless of the flexibility in the site of replication initiation, EBNA1, and presumably FR, are essential for stable episomal maintenance (Lee *et al.*, 1999). EBV lacking EBNA1 can not establish latent episomal genomes (Lee *et al.*, 1999; Humme *et al.*, 2003). Tethering of *OriP* to metaphase chromosomes is thought to be the primary mechanism of plasmid maintenance (Fig. 24.1). The interactions with metaphase chromosome components appears to be highly flexible since substitution of the HMG I/Y and histone H1 chromosome binding regions with EBNA1 linking domains can rescue plasmid maintenance (Hung *et al.*, 2001). Chromosome tethering appears to be mediated by several factors, including the chromatin associated-EBP2 and the AT-hook activity found in the EBNA1 linking domains. Additionally, telomeric factors that bind adjacent to and cooperatively with EBNA1 at DS, contribute to *OriP* plasmid maintenance (Deng *et al.*, 2002). Although the precise role of telomere repeat factors at DS is unclear, recent studies suggest that they contribute to the establishment of a replication and maintenance competent plasmid, perhaps by contributing to the organization of chromatin structure on *OriP*-containing plasmids and facilitating metaphase chromosome attachment.

KSHV (Rhadinovirus)

Shortly after the discovery of KSHV DNA by representational display analysis in KS lesions (Chang *et al.*, 1994), gene expression analysis by *in situ* hybridization and RT-PCR showed that KSHV in KS-lesions are predominantly latently infected (Zhong *et al.*, 1996). Similarly, PEL-derived cell lines are latently infected and, analogous to EBV-infected Burkitt's lymphoma lines, can be induced to enter the lytic replication cycle (Cesarman *et al.*, 1995; Renne *et al.*, 1996a,b). Like BL cell lines for EBV, PEL-derived cell lines have been instrumental for cloning and characterization of the KSHV genome and for the identification of the latency-associated genes.

The KSHV episome in latently infected cells

KSHV episomal viral genomes have been detected by Gardella gel analysis in KS lesions and PEL-derived cell lines (Renne *et al.*, 1996a). Different PEL cell lines contain varying copy numbers (25 to several 100) that are stably maintained over time (Cesarman *et al.*, 1995; Renne *et al.*, 1996b; Cannon *et al.*, 2000). While deletions and duplications have been detected in PEL cells, no integration events have been reported for KSHV. The fact that sodium butyrate, a potent histone deacetylase inhibitor induces lytic replication in PEL cells suggests that nucleosome organization limits lytic cycle gene expression. Lu *et al.* demonstrated that a deacetylated nucleosome positioned over the transcriptional initiation sites of the ORF50 immediate early promoter and its acetylation and remodeling correlated with transcriptional activation and initiation of lytic cycle gene expression (Lu *et al.*, 2003). Similar to EBV, DNA methylation might play a role in the regulation of latency; recent studies suggest methylation of the ORF50 promoter during latency (Chen *et al.*, 2001).

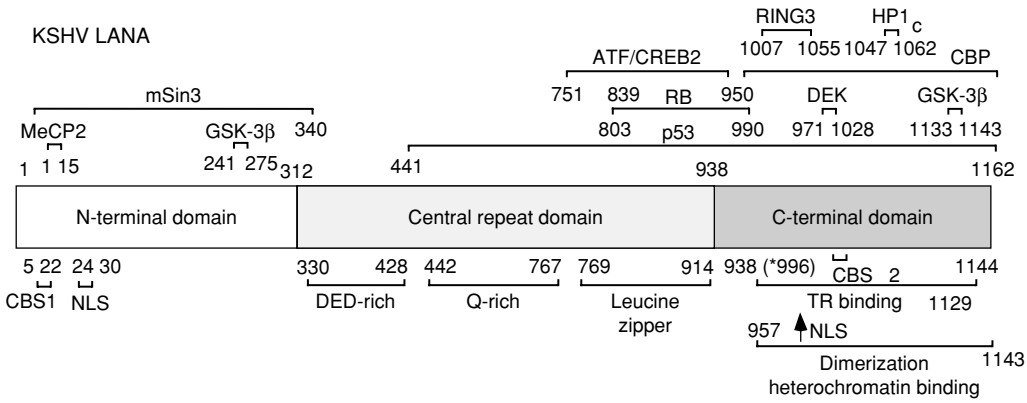

Fig. 24.8. Functional domains of LANA. Amino acid residues are indicated for the boundaries of protein domains for DNA binding, dimerization, chromosome binding sites (CBS), nuclear localization (NLS), or protein-protein interactions (as indicated). LANA amino acid numbering is based on the sequence published by Russo *et al.*, 1996. (* 996 denotes the N-terminus of the core DNA binding domain mapped by Komatsu *et al.*, 2004).

Further evidence that KS lesions harbor episomal DNA comes from the finding that KS spindle cells upon explantation lose viral genomes after only few passages in culture (Dictor *et al.*, 1996). Telomerase-immortalized microvascular endothelial cells can be infected with PEL-derived cell-free virions but lose the viral genome upon cultivation; similar results have recently been shown for a variety of cell lines. These data suggest that the establishment of stable latency at least in the context of *de novo* infection in vitro occurs with low frequency (Lagunoff *et al.*, 2002; Grundhoff and Ganem, 2004). In contrast to cultured cells from KS lesions, PEL cells cultivated in vitro, efficiently maintain KSHV genomes over a long time at a stable copy number (Renne *et al.*, 1996b; Cannon *et al.*, 2000; Cesarman *et al.*, 1995).

Properties of the latency-associated nuclear antigen (LANA)

The first evidence of a latency-associated gene product came from the fact that sera from KS patients contain antibodies that stain PEL cells in a specific nuclear speckled pattern by immunofluourescence assay. This then "unknown" antigen was termed LANA for latency-associated nuclear antigen (Gao *et al.*, 1996; Kedes *et al.*, 1996). Using Northern blot analysis and expression cloning it was subsequently shown that LANA is encoded by ORF73 of KSHV (Kedes *et al.*, 1997; Kellam *et al.*, 1997; Rainbow *et al.*, 1997). *In situ* hybridization studies revealed that nearly all cells in KS lesions express ORF73 mRNA (Dittmer *et al.*, 1998; Talbot *et al.*, 1999) and LANA protein is consistently detected by immunohistochemistry in all malignancies associated with KSHV (Rainbow *et al.*, 1997; Dupin *et al.*, 1999). The ORF73 gene is located in a cluster of four latency-associated genes and is expressed from a poly-cistronic singly spliced mRNA of 5.7 kb that also encodes ORF72, a viral cyclinD homologue, and ORF71, a v-Flip protein (Dittmer *et al.*, 1998; Talbot *et al.*, 1999). Furthermore, this latency-associated region of KSHV contains the Kaposin gene (Zhong *et al.*, 1996; Sadler *et al.*, 1999). The functions and roles of these additional latency-associated gene products in the biology of KS will be discussed elsewhere in this volume and have recently been subject to a number of excellent review articles (Ganem, 1997; Schulz, 1998; Herndier and Ganem, 2001; Boshoff and Weiss, 2002). Adding to the complexity of this region, a cluster of microRNAs, that may modulate host cellular and/or viral gene expression, was recently identified between ORF71 and the Kaposin gene (Cai *et al.*, 2005; Pfeffer *et al.*, 2005; Samols *et al.*, 2005).

Modular domain structure of LANA

LANA can be divided into three major domains: a proline- and serine-rich N-terminal region (312 aa), a central region variable in length between viral isolates (Gao *et al.*, 1999) that is composed of several acidic repeats including a leucine zipper motif, and a conserved C-terminal domain, containing both a proline-rich region and a region rich in charged and hydrophobic amino acids (Fig. 24.8). A comparison of LANA proteins across the rhadinovirus family revealed significant sequence homologies only within the C-terminal domain. While there is some limited

homology within the N-termini, which differ dramatically in size between proteins, there is no conservation for the central domain – indeed this domain is often missing or reduced to a small number of acidic residues (Russo *et al.*, 1996; Grundhoff and Ganem 2003; Alexander *et al.*, 2000; Searles *et al.*, 1999). Although there is only limited amino acid sequence homology between LANA and EBNA1, computer-assisted folding predictions for the LANA C-terminus revealed structural relatedness to the DNA binding domains of EBNA1 and the papillomavirus E2 protein whose structures have been solved (Bochkarev *et al.*, 1996; Grossman and Laimins, 1996; Grundhoff and Ganem, 2003).

Transcriptional regulation and signaling properties of LANA

Two hybrid screens have identified LANA interactions with transcriptional coactivators RING 3 and ATF/CREB (Platt *et al.*, 1999; Lim *et al.*, 2000) and co-repressor mSin3 (Krithivas *et al.*, 2000). Gene expression profiling and transient transcription assays have identified cellular and viral genes that are modulated by LANA (Krithivas *et al.*, 2000; Hyun *et al.*, 2001; Knight *et al.*, 2001; Renne *et al.*, 2001; An *et al.*, 2005). LANA, like EBNA1, transcriptionally activates its own synthesis in part by binding to a low affinity site in its promoter LANAp (Jeong *et al.*, 2001; Renne *et al.*, 2001). On the other hand, Gal4/LANA fusion proteins can repress expression from a Gal4 binding site-containing reporter (Krithivas *et al.*, 2000; Schwam *et al.*, 2000). These results indicate that LANA is a complex transcription regulatory protein that can both activate and repress transcription, by direct DNA binding or indirectly through protein interactions, perhaps also depending on cellular and chromosomal environment. More recently, LANA has also been implicated in early steps that lead to the establishment of latency after *de novo* infection. First, Krishnan *et al.* analyzed viral transcription pattern at very early time points post entry and showed that the earliest gene detectable was ORF50, the viral transactivator which regulates the switch from latent to lytic replication (Krishnan *et al.*, 2004). Next, the expression of LANA was detectable and there was an inverse relation between LANA expression and ORF50 expression. Subsequently, it was demonstrated that LANA inhibits ORF50-dependent transactivation (Lan *et al.*, 2004) and furthermore this inhibitory effect appears to be disrupted by the acetylation of LANA (Lu *et al.*, 2006). These data strongly suggest that LANA expression levels determine the outcome of *de novo* infection. This novel aspect of LANA-dependent regulation of latency and other signaling events that occur early after virus entry are discussed in Chapter 23 of this volume.

LANA also has profound effects on cellular growth regulation and cell cycle control. LANA interacts with p53, and down-regulates p53-dependent transcription (Friborg *et al.*, 2000). LANA was also shown to bind the retinoblastoma tumor suppressor (pRB), and modulates E2F-dependent transcription of cell cycle control genes. Furthermore, ectopic LANA expression can transform RF cells in combination with H-ras (Radkov *et al.*, 2000). Recently, LANA has been shown to promote S-phase entry by targeting the APC/wnt/β-catenin signaling pathway through inactivation with GSK3-beta in primary effusion lymphomas. This pathway is altered in many human malignancies (Fujimuro and Hayward, 2003; Fujimuro *et al.*, 2003). Consistent with these findings, LANA prolongs the passage number of primary human umbilical vein endothelial cells (HUVEC) when introduced by retroviral transduction (Watanabe *et al.*, 2003). However, no experimental system could demonstrate that LANA alone can transform primary cells. In summary, LANA targets key signaling pathways including cell cycle, apoptosis, and chromatin re-modeling and it is, therefore, intriguing to speculate that LANA may contribute to immortalization and/or transformation.

Latent DNA replication and segregation

Ballestas *et al.* first demonstrated through long-term maintenance assays that LANA plays a role in episomal maintenance. Cosmid clones spanning the entire KSHV genome were assayed for their ability to establish plasmid maintenance in BJAB cells in a LANA-dependent manner. Using a selectable marker, resistant cell clones were analyzed for the presence of episomal DNA by Gardella gel analysis. In these assays, a cosmid containing the left end of the genome including terminal repeat (TR) sequences was maintained only in LANA expressing cells. These data unambiguously identified LANA as the only viral protein required in trans for episomal long-term maintenance (Ballestas *et al.*, 1999); these data demonstrated that with respect to its role in episomal maintenance, KSHV LANA is a functional homologue of the EBV origin binding protein EBNA1.

Mechanism of episomal segregation and chromosome tethering

Confocal microscopy demonstrated colocalization of LANA with both viral episomes and mitotic chromosomes suggesting that LANA, like EBNA1, contributes to

long-term maintenance by tethering viral genomes to chromosomes (Ballestas *et al.*, 1999). The association of LANA with heterochromatin during interphase, and mitotic chromosomes during mitosis, has since been demonstrated by several laboratories, and data from Cotter et al demonstrating LANA/Histone H1 interaction first suggested protein-protein interaction as the underlying mechanism for chromosome tethering (Cotter and Robertson, 1999; Szekely *et al.*, 1999; Schwam *et al.*, 2000; Viejo-Borbolla *et al.*, 2003). By preparing a panel of LANA/GFP fusion proteins, Piolot *et al.* identified an 18 amino acid long chromosome binding site (CBS) within the N-terminus of LANA (aa 5 to 22) that confers chromatin association to GFP (Piolot *et al.*, 2001). Most recently, Barbera *et al.* reported a detailed analysis of the N-terminal CBS and provided biochemical and elegant genetic evidence that LANA tethers episomes to mitotic chromosomes through direct interactions with core histones H2A/B. The N-terminal chromosome attachment domain was found to be both critical and sufficient for the histone interaction, which was confirmed further by structural analysis and modeling (Barbera *et al.*, 2006).

Krithivas *et al.* further proved that LANA attaches to chromatin via protein-protein interactions by identifying two chromatin-associated cellular proteins that interact with LANA by two-hybrid screen and immunoprecipitation. MeCP2 is a methyl CpG binding protein and interacts with LANA through the N-terminal chromosome binding domain, referred to as CBS1. The second protein, DEK, interacts with CBS2 located in the C-terminus of LANA (aa 971–1028) (Fig. 24.8). Convincing evidence that two LANA domains are mediating chromosome attachment, binding to MeCP2 and DEK respectively, came from the observation that LANA does not bind to chromosomes in murine cells which are negative for both proteins. However, transfection of MeCP2 and/or DEK encoding cDNAs restored LANA/chromatin co-localization in mouse cells (Krithivas *et al.*, 2002). Although LANA interactions with MeCP2 and/or DEK are highly specific, it is important to note that for episomal maintenance the association of viral episomes and chromatin is sufficient. This was demonstrated by Shinohara et al who replaced the N-terminus of LANA, containing CBS1, with histone H1. The resulting fusion protein was able to co-localize with mitotic chromosomes and, moreover, as shown for a similar EBNA-1/HMG-Y fusion protein, functions in long-term maintenance assays (Hung *et al.*, 2001; Shinohara *et al.*, 2002; Sears *et al.*, 2003). Together, these data strongly suggest that LANA contributes to episomal long-term maintenance by tethering the viral genomes to chromatin (Fig. 24.1).

Mapping LANA's DNA binding motif and DNA binding domain

The long unique region (LUR) of KSHV is flanked on both sides by about 40 copies of terminal repeats which are believed to be important for circularization of the linear virion DNA after viral entry. Each TR unit of KSHV is 801 bp and 89% GC-rich (Lagunoff and Ganem, 1997). Scanning of the 140 kbp LUR did not reveal any repeats or sequence elements reminiscent of homology to the *OriP* of EBV. Instead, Cotter *et al.* provided the first evidence that LANA binds to the TR sequences of the viral genome. Radio-labeled cosmid clones harboring sequences from both ends of the genome were immunoprecipitated with LANA specific antibodies after DNA was incubated with lysates from LANA expressing cells (Cotter and Robertson, 1999).

Direct evidence that LANA could bind to TR DNA was generated with in vitro translated (Ballestas, 2001) or vaccinia virus expressed LANA proteins (Garber *et al.*, 2001, 2002). Electrophoresis mobility shift assays (EMSA) identified a 18 bp long GC rich sequence motif within TR that is bound by LANA (Ballestas, 2001; Garber *et al.*, 2001). Weaker binding sites within TR and one site outside of TR at the left end of the genome have been described but no further functional data for these sites have been reported (Cotter *et al.*, 2001).

Mutational analysis in combination with EMSA mapped the DNA binding domain to the C-terminus of LANA (residues 938 to 1144) (Cotter *et al.*, 2001; Garber *et al.*, 2001). Recently, additional studies have suggested a core DNA binding domain to a 143 amino acid long peptide that encompass residues 996 to 1129 (Komatsu *et al.*, 2004) (Fig. 24.8).

Identification of a DS-like element within TR

After identifying the DNA binding domain within the LANA C-terminus, quantitative EMSA in combination with DNA footprinting revealed that LANA binds to two adjacent sites within TR. When increasing amounts of purified LANA-C protein were incubated with a radio-labeled probe, a second complex with slower mobility was observed at high protein concentrations and its intensity further increased while the first complex seemed unchanged. In vitro DNaseI footprinting assays verified the presence of a second binding site. A re-examination of the TR sequence revealed that the 17 bp imperfect palindrome of LANA binding site 1 (LBS1) is separated by a 5 bp spacer from a second site (LBS2) with only three nucleotide changes, compared to LBS1. Mutation analysis revealed a cooperative binding mechanism by which the high affinity LBS1 permits

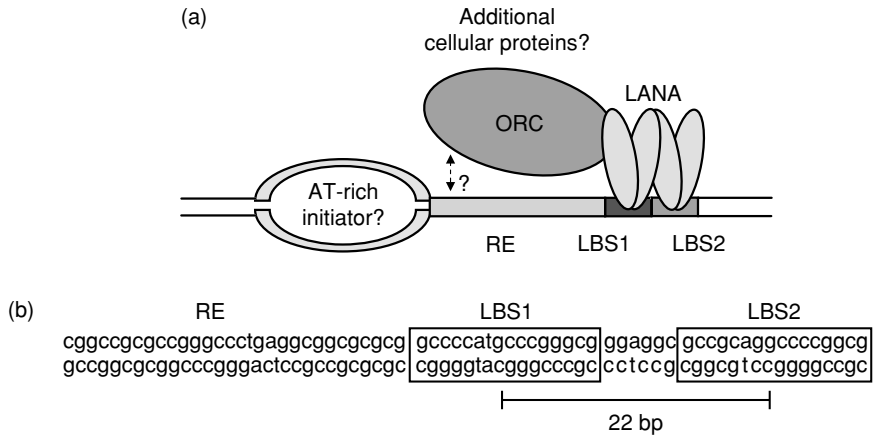

Fig. 24.9. Functional elements of KSHV origin within TR. (a) Model of latent KSHV ori. LBS1/2 and the RE element. LANA binds as dimmers to both sites and the RE element is required for function. ORC LANA and/or TR interaction have been shown both in vitro and in vivo. The AT-rich region may function as initiator element. (b) High (LBS1) and low affinity site (LBS2) are spaced by 22 bps. While this spacing is conserved to DS element of EBV *OriP* there is no sequence homology in binding sites.

loading of LANA onto LBS2 (the Kd for LBS1 was determined to be 1.4 nM) (Garber *et al.*, 2002) (Fig. 24.9).

The presence of both a high and low affinity site and the spacing of 22 bp from center to center within the TR of KSHV is reminiscent of the dyad symmetry element in the EBV *OriP* (21 bp spacing) which is bound by EBNA1 in a cooperative manner. Based on these data and the observation by Schwam et al that the C-terminal DNA binding domain of LANA forms dimers in solution (Schwam *et al.*, 2000), a model is proposed in which two LANA dimers bind to LBS1 and LBS2 in a cooperative fashion, comparable in stoichometry and affinity to EBNA1 binding to *OriP* (Yates *et al.*, 2000).

The TR functions as LANA-dependent plasmid origin

Long-term maintenance of viral DNA in latently infected cells can be divided into two different steps. First, viral DNA needs to be replicated by the cellular replication machinery; second, viral genomes have to be faithfully segregated during mitosis. Ballestas *et al.* showed that plasmids containing two copies of TR sustain LANA-dependent long-term maintenance in lymphoid cell lines (Ballestas *et al.*, 1999)

Short-term replication assays allow the detection of newly synthesized DNA 48 to 72 hours post transfection by its resistance to DpnI digestion, a restriction enzyme that digests only dam methylated DNA. Using this assay several laboratories tested TR-containing plasmids for their ability to replicate in the presence and absence of LANA in primate cells of epithelial, endothelial, and lymphoid lineage. These data established that LANA, in addition to its role in episome segregation, also supports viral DNA replication during latency and that, at least in the context of plasmid replication, all necessary cis-elements are located within the TR sequences (Hu *et al.*, 2002; Lim *et al.*, 2002; Grundhoff and Ganem, 2003). Furthermore, deletion analysis yielded a TR subfragment of 105 bp that replicates as well as plasmids containing one or two copies of TR in the presence of LANA (Hu *et al.*, 2002). Within a TR element, both LANA binding sites contribute to DNA replication since the replication efficiency of mutant TR sequences is directly proportional to their affinity to LANA (Garber *et al.*, 2002).

Further detailed deletion mapping of the minimal replicator within TR revealed that the origin requires LBS1 and LBS2, reminiscent of a dyad symmetry element, and a 29 to 32 bp long GC-rich element upstream. This novel sequence element was termed replication element (RE) since a TR deletion mutant lacking RE does not replicate in the presence of LANA (Hu and Renne, 2005) (Fig. 24.9).

Trans-requirements for LANA and interaction with cellular ORC proteins

Mutational analysis of LANA revealed that the DNA binding domain is required for DNA replication of TR-containing plasmids (Hu *et al.*, 2002) while removal of the central domain has no effect. The C-terminal DNA binding domain of LANA (215 aa) has residual replication activity (25%), and its activity is greatly increased when fused to the N-terminus. This observation is consistent with a model by which the chromosome binding sites located in the N- and C-terminus of LANA contribute to both DNA replication

and segregation (Piolot *et al.*, 2001; Krithivas *et al.*, 2002; Mattsson *et al.*, 2002).

Lim *et al.* has recently demonstrated that the C-terminus of LANA interacts with ORC 2, 3, 4, and 5 in an ATP dependent manner (Lim *et al.*, 2002). These promising in vitro GST pull-down results have been confirmed by in vivo interaction studies demonstrating ORC2 binding to TR in a LANA-dependent manner (Stedman *et al.*, 2004). Thus, in order to support DNA replication both EBNA1 and LANA bind to DS elements in their respective origin and recruit cellular licensing factors (Figs. 24.6 and 24.9).

Summary

All the reported data strongly suggests that the KSHV origin of latent replication is located within the TR sequences of KSHV – as a result, KSHV has many putative origins of replication. However, no genetic studies on KSHV have been reported that address the role of the TR sequences and LANA in the context of the viral genome. For HVS, a related rhadinovirus, it was shown that both the TR sequences and a functional ORF73 gene are required for the establishment of long-term episomal maintenance (Collins *et al.*, 2002). These results further suggest that rhadinoviruses do not contain an *OriP* element within the LUR.

Considerable progress has been made to analyze KSHV latent DNA replication and segregation in plasmid-based assays – many more studies are required to address the question of where DNA replication initiates within the context of the viral episome in vivo.

EBV and KSHV origins and origin binding proteins: conserved and diverged?

EBNA1 and LANA are functional homologues. Both proteins support latent DNA replication by specifically binding to their respective origins of replication and by recruiting host cellular ORC proteins (Figs. 24.6 and 24.9). In addition, EBNA1 and LANA promote long-term episomal maintenance by tethering viral genomes to chromatin.

There is no sequence homology between EBNA1 and LANA binding sites within the DS element of *OriP* and the TR of KSHV. However, there is significant similarity in the structural organization of the minimal replicator elements. Both proteins bind as dimers in a cooperative manner to two sites that have nearly identical spacing from center to center (21 bp for EBV and 22 bp for KSHV). This conserved binding mechanism induces structural changes on DNA such as bending towards the major groove that may directly contribute to origin activity and the formation of pre-replication complexes. LANA binding to TR bends DNA by 57 degrees and 110 degrees when both LBS1 and LBS2 are occupied (Bashew and Yates, 2001; Wong and Wilson, 2005). While for EBV a minimal replicator consists of only two EBNA1 binding sites, the KSHV origin requires a second GC-rich element outside of the LANA binding sites (Fig. 24.10). Additionally, EBNA1 and LANA can both interact with ORC proteins that are likely to be essential for the initiation of DNA replication. It is also likely that EBNA1 and LANA DNA binding domains are structurally similar, and share features with the papillomavirus E2 replication protein.

To facilitate genome segregation and maintenance, both proteins tether episomal viral DNA to cellular chromosomes through protein–protein interactions via multiple domains that target a variety of cellular proteins. Surprisingly, there is little overlap in the set of cellular interacting proteins that mediate attachments to cellular chromosomes for EBNA1 and LANA. The simplest interpretation, that chromosomal attachment can occur in a non-specific manner, has experimentally been supported by the observation that EBNA1 and LANA fusion proteins with known chromatin binding proteins support genome maintenance.

The genomic organization of the maintenance elements in EBV and KSHV appear to have diverged considerably (Fig. 24.10). The 1.2 kbp *OriP* is located within the unique long region of the EBV genome. *OriP* has evolved into two functionally different sequence elements that each contain multiple EBNA-1 binding sites: (i) the dyad symmetry (DS) element, required for EBNA1-dependent DNA replication and (ii) the family of repeats (FR), which are required for long-term maintenance. All lymphocryptoviruses have some *OriP*-like element with conserved genome positioning, although even among the lymphocryptoviruses there is considerable variation on the number and spacing of EBNA1 binding sites, and the requirement for a DS-like element may not exist in the cynomolgous herpesvirus (Fig. 24.2).

The structure of the origin of latent replication within the TRs of the rhadinovirus family is different in that each TR represents a putative origin that contains two LANA binding sites but no distinguishable elements comparable to DS and FR in *OriP*. The repetitive nature of the TRs may reflect some aspects of the EBV FR element; this notion is supported by the observation that more than one copy of TR is necessary for efficient long-term maintenance while a single TR is sufficient for DNA replication. Notably, the EBNA1 repetitive sites within FR are spaced 14 bp, while the LANA binding sites between TR are spaced ~800 bp. Whether this reflects an inherent difference in their mechanism of plasmid maintenance will be interesting to determine.

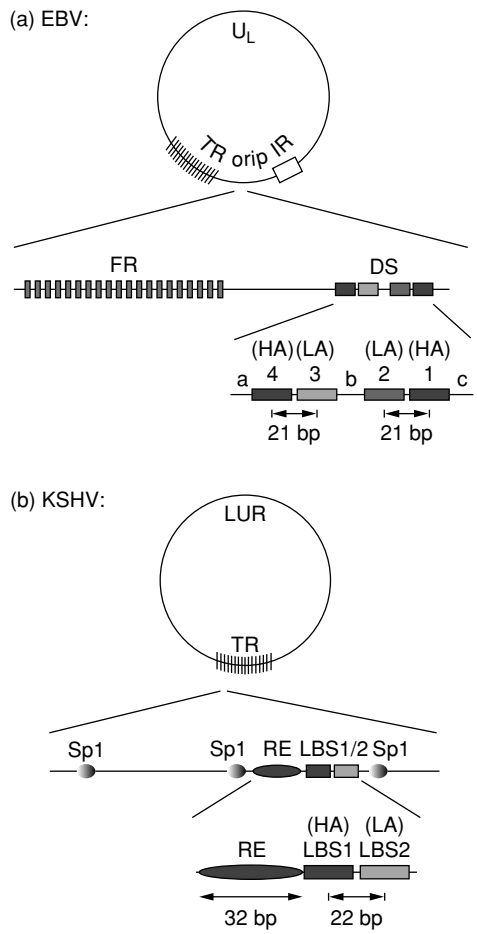

Fig. 24.10. Comparison between genomic structure and positioning of EBV and KSHV. (a) EBV: one *OriP* which contains two functionally different elements that are bound by EBNA1. The DS element contains four EBNA1 binding sites, two sites serve as minimal replicator. To ensure long-term maintenance the FR confer EBNA1-dependent chromatin tethering. (b) KSHV: many putative origins located within TR. Two LANA binding sites resemble DS-like element and together with RE compromise the minimal replicator. The array of TRs may provide tethering function analogous to FR.

The maintenance elements created by repetitive EBNA1 and LANA binding sites are also efficient origins of replication, but these may not be the only replication origins in the large genomes of these viruses. Based on DS deletion studies and single molecule replication data from EBV (Norio *et al.*, 2000; Norio and Schildkraut, 2001), it is likely that both viruses can utilize alternative DNA replication initiation zones in the intact viral genome (Fig. 24.7). The mechanisms governing the utilization of alternative replication initiation sites in EBV or KSHV has not been explored in detail. Nor is it known if the repetitive origins found in the TRs of KSHV function coordinately or selectively to ensure cell cycle restricted genome duplication.

The transcription regulatory properties of EBNA1 and LANA may also be related to their ability to establish replication origins and maintenance elements. Both EBNA1 and LANA may have effects on local chromatin structure which may contribute to the transcription and replication activity at adjacent and distal regions of the genome. The association of LANA with histone modifying complexes and chromatin-associated proteins suggests that much of its activity is directed to altering the chromatin environment.

Some of the growth stimulating activities of LANA, that are not seen in EBNA1, may be attributed to its transcription regulatory and chromatin modulating activities. A similar genomic study of cellular gene expression changes induced by EBNA1 has not been reported, and may reveal unanticipated properties of EBNA1 that are reminiscent of LANA. LANA effects on cell cycle control that can be attributed to the interactions with cellular checkpoint proteins like p53 and Rb, are almost definitely lacking in EBNA1, but perhaps equivalent to the EBNA3 family of interactions. Similarly, LANA's interaction and alteration of the GSK-3β kinase activity and β-catenin signaling pathway may be more equivalent to the activities of EBV transforming proteins encoded by LMP1 and BARTs. This suggests that in addition to their similar but not identical mechanisms for latent DNA replication and genome maintenance, both EBV and KSHV have evolved common strategies to modulate cellular environment in latently infected cells. While in EBV these functions are distributed over an entire family of EBNA proteins, KSHV has evolved a multifunctional protein that has acquired many of the described EBNA activities.

It may also be important to note that both LANA and EBNA1 have a non-essential central linker domain characterized by stretches of copolymeric amino acids. The Gly–Ala repeats in EBNA1 have been shown to have an important function in reducing proteosomal processing and therefore limiting presentation of viral peptide on HLA surface molecules. Recently, a similar immune evasion mechanism was revealed for the highly acidic ED and QP repeats within the central domain of LANA. LANA-GFP fusion proteins containing an ovalbumin epitope are not efficiently presented to cytotoxic T cells. Like the EBNA1 Gly-Ala repeats the LANA central domain conveys reduced antigen presentation in cis (Zaldumbide *et al.*, 2006). Hence, although the sequences of these repeats are not related, this represents yet another example of functional homology between the origin binding proteins of lymphocrypto- and rhadinoviruses.

Reactivation and lytic replication of EBV

Shannon C. Kenney

University of Wisconsin,
Madison, WI, USA

Viral pathogenesis

The lytic form of EBV infection is required for the production of progeny virus, and is thus essential for cell-to-cell spread of the virus, as well as transmission from host to host. Unfortunately, there is currently no cell culture system in vitro that is permissive for efficient primary lytic EBV infection. Although a recent report suggests that allowing the virus to first attach to the surface of primary B cells greatly facilitates EBV infection of epithelial cells in vitro (Shannon-Lowe *et al.*, 2006), even this system of infection still does not result in efficient horizontal spread of virus from cell to cell. Thus, lytic EBV infection in vitro has been studied by reactivating the lytic form of infection from latently infected cell lines using a variety of inducing agents, including phorbol esters, butyrate, calcium ionophores, and B-cell receptor stimulation.

During primary infection, EBV probably initially infects oral epithelial cells in a lytic form, and then subsequently infects B-cells, where the virus usually assumes one of the latent forms of infection. In contrast to alpha and beta herpesviruses, which cause human diseases during the lytic form of viral infection but are essentially innocuous while in the latent form of infection, most illnesses attributable to EBV infection are associated with the latent forms of infection. During primary EBV infection, some individuals, particularly adolescents, develop the syndrome infectious mononucleosis (IM) approximately 1 month after being infected (Cohen, 2000; Jenson, 2000). The EBV-positive B-cells in patients with IM contain primarily the latent form(s) of infection, and the symptoms associated with this illness are attributable to the onset of a vigorous cytotoxic T-cell response against the virally infected B-cells (Cohen, 1999; Jenson, 2000; Andersson *et al.*, 1987; Cohen, 2000). Lytic EBV infection (in either oral epithelial cells or B-cells) presumably precedes the onset of clinical IM, as IM patients have an extremely robust CD8 T-cell response directed against lytic viral protein epitopes (Steven *et al.*, 1997; Hislop *et al.*, 2002). Nevertheless, it has been difficult to document primary lytic EBV infection in patients, presumably due to the long asymptomatic incubation period for IM (Cohen, 1999, 2000).

Following recovery from IM, it is often difficult or impossible to find any lytically-infected cells in immunocompetent individuals (Herrmann *et al.*, 2002), although the preponderance of evidence suggests that reactivated lytic EBV infection most commonly occurs in tonsillar plasma cells as well as in tonsillar B-cells (Laichalk *et al.*, 2005; Pegtel *et al.*, 2004; Niedobitek *et al.*, 1997, 2000; Faulkner *et al.*, 2000). Nevertheless, the only human disease that is unequivocally due to lytic EBV infection, oral hairy leukoplakia (OHL), occurs in epithelial cells on the lateral aspect of the tongue (Lau *et al.*, 1993; Walling *et al.*, 2001, 2003b; Greenspan *et al.*, 1985; Resnick *et al.*, 1990). This hyperproliferative lesion is observed only in highly immunocompromised patients and is easily treated by antiviral agents such as acyclovir that inhibit the lytic form of EBV infection. Interestingly, the lytic (but not latent) form of EBV infection was also recently found in the malignant breast epithelial cells, as well as normal breast cells, in some cases of breast cancer (Huang *et al.*, 2003), suggesting that the breast may also be a site for lytic EBV replication.

The lytic form of EBV infection is clearly required for transmission of the virus from host to host, and thus is an essential aspect of viral pathogenesis. The saliva from immunocompetent hosts often contains infectious EBV (Shu *et al.*, 1992; Lucht *et al.*, 1995; Ikuta *et al.*, 2000; Ling *et al.*, 2003; Walling *et al.*, 2003a), indicating that lytically infected cells in or near the oral cavity must exist, even if they are difficult to detect in the presence of a vigorous cytotoxic T-cell response (Tao *et al.*, 1995). Thus it is not surprising that the great majority (90% or more) of the human

population ultimately becomes infected with this virus. EBV has also been reported to be present in both male and female genital secretions, suggesting that this virus could in some instances be sexually transmitted (Israele *et al.*, 1991; Sixbey *et al.*, 1986).

Activation of lytic EBV infection

Lytic viral gene cascade

EBV lytic genes are expressed in a temporally regulated manner. In many cell lines the two immediate–early genes, BZLF1 and BRLF1, are the first viral genes expressed following lytic induction stimuli, and both BZLF1 and BRLF1 transcription occurs even in the presence of protein synthesis inhibitors (Biggin *et al.*, 1987; Flemington *et al.*, 1991; Takada and Ono, 1989). In some cell lines, such as the Burkitt lymphoma line, Akata, BZLF1 expression may precede BRLF1 expression (Yuan *et al.*, 2006). Once activated, the IE gene products function as transcription factors and together activate transcription of the early viral genes. Early viral genes are defined as genes that are transcribed prior to lytic viral replication (and thus are not inhibited by viral replication inhibitors), but are not transcribed in the presence of protein synthesis inhibitors. Early viral genes encode the viral replication proteins, including the virally encoded DNA polymerase. Following viral replication, the late viral genes are transcribed; late gene transcription is repressed by viral replication inhibitors. Many late genes encode structural proteins that make up the virion particle.

Stimuli that induce lytic EBV infection

In the human host, it is likely that differentiation of B cells into plasma following B-cell receptor stimulation by antigen (Laichalk and Thorley-Lawson, 2005) as well as differentiation in epithelial cells, both activate the lytic form of EBV infection (Tovey *et al.*, 1978; Young *et al.*, 1991). In cell culture systems in vitro, agents such as the phorbol ester, 12-0-tetradecanoyl phorbol-13-acetate (TPA), sodium butyrate, and calcium ionophores are commonly used to induce the lytic form of EBV infection (Faggioni *et al.*, 1986; zur Hausen *et al.*, 1978). Ultimately, what each of these various lytic EBV inducing stimuli shares is the ability to activate transcription of the two EBV IE genes, BZLF1 and BRLF1, from the latent viral genome. Lytic induction stimuli induce BZLF1 and BRLF1 transcription with similar kinetics (Biggin *et al.*, 1987; Flemington *et al.*, 1991; Takada and Ono, 1989), and many stimuli activate both the BZLF1 and BRLF1 promoters in EBV-negative cells (Zalani *et al.*, 1995; Shimizu and Takada, 1993; Feng *et al.*, 2004; Flemington and Speck, 1990d). Thus, other than possibly Akata cells, there is no firm evidence that one IE promoter is more important than the other for mediating lytic induction, and it may be that simultaneous activation of both promoters is required for efficient lytic induction. Once made, the BZLF1 and BRLF1 proteins function as transcription factors which activate their own promoters, as well as one another's promoters (Liu and Speck, 2003; Adamson *et al.*, 2000; Flemington *et al.*, 1991; Ragoczy and Miller, 2001; Sinclair *et al.*, 1991; Speck *et al.*, 1997; Zalani *et al.*, 1996), and thus greatly amplify the inducing effect of the initial lytic stimulus.

Of the various methods used in the lab to induce lytic EBV gene transcription, engagement of the B-cell receptor may be the most physiologic. B-cell receptor activation is accomplished using antibody directed against human IgG or IgM, depending upon which immunoglobulin is produced by the B-cell line. Akata Burkitt lymphoma cells are particularly responsive to this treatment, with up to 50% of cells converting to the lytic form of infection in a synchronous manner. Viral IE gene expression occurs very rapidly (30 minutes or less) after B-cell receptor engagement, followed a few hours later by early gene transcription (Takada and Ono, 1989; Mellinghoff *et al.*, 1991; Flemington *et al.*, 1991). Induction of lytic EBV infection by B-cell receptor engagement requires the activation of calcium-dependent signaling pathways (Chatila *et al.*, 1997; Liu *et al.*, 1997b), as well as the activation of numerous other signaling pathways (Adamson *et al.*, 2000; Bryant and Farrell, 2002; Darr *et al.*, 2001; Iwakiri and Takada, 2004; Mellinghoff *et al.*, 1991). The potential mechanism(s) leading from B-cell receptor engagement to EBV IE gene activation are outlined in Fig. 25.1. The LMP-2A viral latency protein helps to maintain viral latency by preventing the ability of antigen to activate B-cell receptor stimulated signaling pathways (Miller *et al.*, 1994a,b, 1995).

Certain cytokines, particularly TGF-beta, can also induce lytic viral infection in a subset of Burkitt lymphoma lines in vitro, and could potentially reactivate EBV in vivo (Fahmi *et al.*, 2000; Adler *et al.*, 2002). The interaction between CD4 T cells and EBV-infected B cells has also been reported to induce lytic infection (Fu and Cannon, 2000). Finally, there is increasing evidence that severe host cell stress in response to many different toxic stimuli (including chemotherapy and irradiation) can induce lytic EBV infection (Feng *et al.*, 2002a, 2004; Westphal *et al.*, 2000; Roychowdhury *et al.*, 2003).

In oral epithelial cells, lytic EBV infection is normally confined to differentiated cells. In OHL lesions, the EBV genome, and expression of lytic viral proteins, are only found in the more differentiated epithelial cell layers

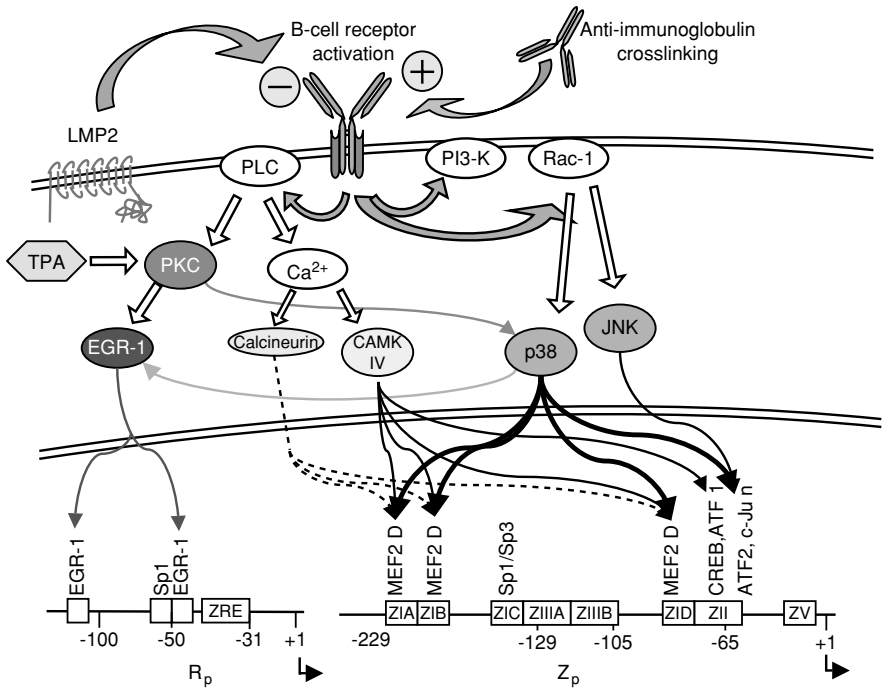

Fig. 25.1. Pathways leading to EBV reactivation in the host cell. Signal transduction pathways that are activated by B-cell receptor (BCR) engagement at the surface of the B-cell, or by phorbol ester (TPA) treatment of cells, are indicated. Promoter motifs in the two EBV IE promoters (Rp and Zp) that are activated by the signaling pathways are shown, as well as the transcription factors that bind to these motifs. Anti-immunoglobulin cross-links and activates the BCR, leading to activation of phosphotidylinositol 3-kinase (PI3K), Ras-family GTPases including Rac1, and phospholipase C gamma-2 (PLC). This is followed by activation of additional downstream pathways as indicated, including protein kinase C (PKC), calcium-dependent factors calcineurin and calcium/calmodulin-dependent kinase type IV (CAMK-IV), and stress MAP kinases (p38 and c-jun N-terminal kinase (JNK)). The EBV LMP-2 protein inhibits activation through the BCR. TPA activates PKC.

(Greenspan *et al.*, 1985; Young *et al.*, 1991). In vitro, differentiation of at least some EBV-positive epithelial lines induces the lytic form of EBV infection (Karimi *et al.*, 1995; Li *et al.*, 1992).

Many of the stimuli used to activate lytic EBV infection in vitro share the ability to activate a variety of signal transduction pathways, including PI3 kinase, p38 kinase, ERK kinase, and protein kinase C, and these kinases have been shown to be essential for induction of lytic EBV transcription by a number of different stimuli (Hayakawa *et al.*, 2003; Mansouri *et al.*, 2003; Fahmi *et al.*, 2000; Fan and Chambers, 2001; Dent *et al.*, 2003; Iwakiri and Takada, 2004; Furukawa *et al.*, 2003; Ionescu *et al.*, 2003; Gao *et al.*, 2001; Satoh *et al.*, 1999; Mellinghoff *et al.*, 1991). In the case of anti-immunoglobulin treatment, activation of calcium-dependent signaling pathways also plays an essential role in lytic viral induction. Two different calcium-dependent proteins activated by B-cell receptor engagement, the calcium/calmodulin-dependent phosphatase, calcineurin, and the calcium/calmodulin-dependent protein kinase type IV/Gr, are required for lytic EBV induction by anti-IgG in Akata cells (Goldfeld *et al.*, 1995; Chatila *et al.*, 1997). Cyclosporin, an immunosuppressive drug that inhibits calcineurin, prevents anti-IgG induction of lytic EBV (Bryant and Farrell, 2002; Goldfeld *et al.*, 1995). The relative importance of each particular signal transduction pathway may vary somewhat depending upon the nature of the stimulus and the cell type.

Organization of the IE gene region of EBV

The organization of the various transcripts and proteins derived from the EBV IE gene region is shown in Fig. 25.2. The immediate–early transcripts that encode BZLF1 and BRLF1 are derived from two different immediate–early promoters, Zp and Rp. The BRLF1 protein is encoded by messages initiating from Rp. These transcripts are bicistronic and could potentially make both the BRLF1 and BZLF1 gene products (Manet *et al.*, 1989). There is some evidence that translation of the BZLF1 protein from the Rp-derived

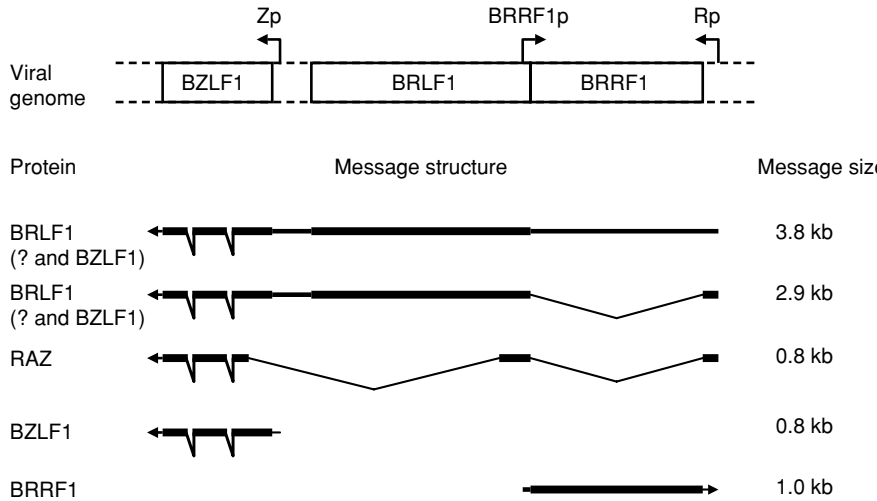

Fig. 25.2. Transcription of the EBV immediate-early gene region. The location of the two immediate-early (IE) genes, BZLF1 and BRLF1, the two IE promoters, Zp and Rp, and the BRRF1 early gene and promoter is shown. Rp directs transcription of a bicistronic message that encodes the BRLF1 and BZLF1 proteins. An alternatively spliced message encodes the RAZ protein, which may function as a negative regulator of BZLF1. The Zp-derived message is the major source of the BZLF1 protein. The BRRF1 promoter directs transcription of the early BRRF1 gene from the opposite DNA strand.

transcripts occurs in vivo, and that the BRLF1 protein is required for this process (Chang *et al.*, 1998; Chang and Liu, 2001). However, the great majority of BZLF1 protein is probably derived from the BZLF1 transcript that initiates from the Zp promoter. A spliced message which contains parts of both BRLF1 and BZLF1 (referred to as RAZ), initiated from Rp, is transcribed later in infection and its gene product may serve as a negative regulator of BZLF1 transcriptional function (Furnari *et al.*, 1994; Manet *et al.*, 1989; Segouffin *et al.*, 1996). The BRRF1 transcript, derived from the BRRF1 promoter and encoded by the opposite strand of the BRLF1 intron (Manet *et al.*, 1989; Segouffin-Cariou *et al.*, 2000), produces an early protein that was recently shown to be a transcriptional activator (Hong *et al.*, 2004) important for efficient lytic EBV gene expression under certain circumstances.

Initial steps in viral reactivation

The promoters driving BZLF1 and BRLF1 transcription, Zp and Rp, are inactive in B-cells containing the latent form of EBV infection (Flemington *et al.*, 1991; Zalani *et al.*, 1992; Biggin *et al.*, 1987; Takada and Ono, 1989; Mellinghoff *et al.*, 1991). Epigenetic modifications such as DNA methylation and histone deacetylation likely contribute to inhibition of IE gene transcription in the context of the intact viral genome (Szyf *et al.*, 1985; Paulson and Speck, 1999; Nonkwelo and Long, 1993; Falk and Ernberg, 1999; Ambinder *et al.*, 1999; Paulson *et al.*, 2002; Bhende *et al.*, 2004; Jenkins *et al.*, 2000; Gruffat *et al.*, 2002b). Nevertheless, even "naked" DNA reporter gene constructs driven by the Zp and Rp promoters are essentially inactive in many EBV-negative B-cell lines (Feng *et al.*, 2004; Kenney *et al.*, 1989b; Sinclair *et al.*, 1991; Zalani *et al.*, 1995), but can be activated by lytic inducing stimuli such as TPA and B-cell receptor stimulation. Thus, the inactivity of the Zp and Rp promoters in unstimulated B cells must reflect the lack of *trans*-acting transcription factors, which positively regulate the two IE promoters, and/or the relative excess of cellular factors which negatively regulate the two IE promoters.

Cellular factors which activate Zp

Cellular transcription factors that positively and negatively regulate the Zp and Rp promoters are shown in Figs. 25.3 and 25.4. Regulation of the Zp promoter has been much more extensively studied than regulation of the Rp promoter. The region of Zp between –233 and +12 contains the *cis*-acting sequences required for Zp activation by lytic-inducing agents. Two types of *cis*-acting motifs, the "ZI" and "ZII" motifs, are critical for activation of Zp by a variety of different lytic-inducing stimuli. The four ZI motifs (ZIA, ZIB, ZIC, and ZID) are AT-rich sequences that have dual roles as both negative, as well as positive, regulators of Zp transcription (Borras *et al.*, 1996; Daibata *et al.*, 1994, Flemington and Speck, 1990a,b; Binne *et al.*, 2002). In the absence of lytic-inducing agents, these elements down-regulate constitutive Zp activity in B cells. However,

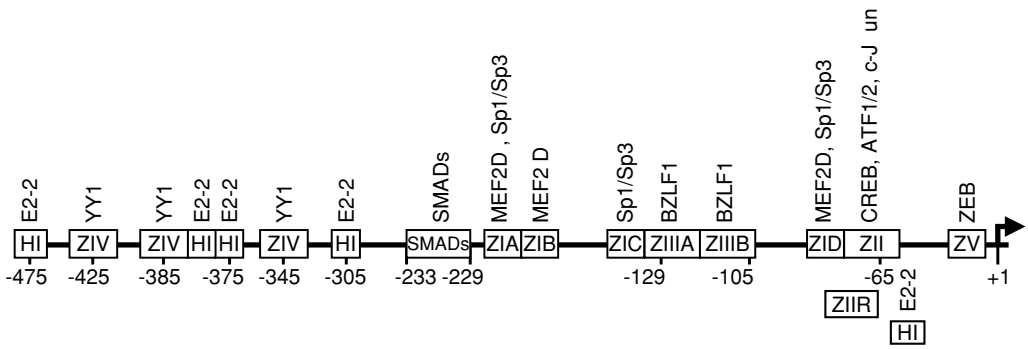

Fig. 25.3. Regulation of the EBV immediate–early BZLF1 promoter. Regulatory motifs in the BZLF1 (Zp) promoter are shown. Cellular and viral proteins known to bind to each motif are indicated.

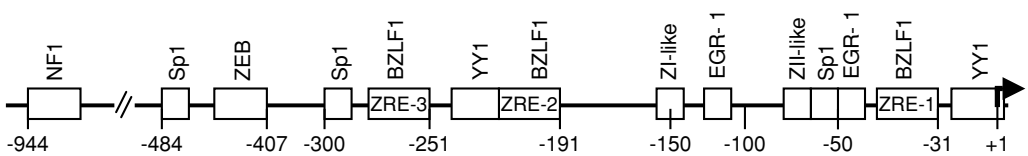

Fig. 25.4. Regulation of the EBV immediate–early BRLF1 promoter. Regulatory motifs in the BRLF1 (Rp) promoter are shown. Cellular and viral proteins known to bind to each motif are indicated.

the ZI elements are also essential for Zp activation by a variety of different inducing stimuli, including TPA, anti-immunoglobulin, calcium ionophores, and chemotherapy (Feng *et al.*, 2004; Binne *et al.*, 2002). Three of the four ZI motifs (ZIA, ZIB, ZID) bind to the transcription factor, MEF2D (Liu *et al.*, 1997b). ZIA, ZIC and ZID also bind weakly to Sp1 and Sp3 (Liu *et al.*, 1997a). This dual role of the ZI motifs as both negative, as well as positive, regulators of Zp transcription may reflect a preferential interaction of MEF2D with histone deacetylating complexes during viral latency (hence acting to inhibit Zp transcription), which is switched to a preferential interaction with acetylating complexes by lytic inducing stimuli (Gruffat *et al.*, 2002b). The phosphorylation status of MEF2D may play an essential role in determining if it represses, versus activates, Zp transcription. Interestingly, calcium/calmodulin-dependent protein kinase type IV/Gr indirectly activates MEF2D by preventing the association between MEF2D and HDAC proteins, whereas MAP kinases directly activate MEF2D by phosphorylating the transcriptional activator domain and enhancing its function (McKinsey *et al.*, 2000). Nevertheless, phosphorylation of other sites in MEF2D may inhibit its function (Li *et al.*, 2001). Cross-linking the B-cell receptor in Akata Burkitt lymphoma cells results in rapid dephosphorylation of the MEF2D in a cyclosporine-sensitive manner, suggesting that calcineurin is involved in dephosphorylating (and perhaps activating) MEF2D (Bryant and Farrell, 2002).

The "ZII" motif is also essential for induction of BZLF1 transcription by most stimuli (Binne *et al.*, 2002; Flamand and Menezes, 1996; Feng *et al.*, 2004; Flemington and Speck, 1990d; Daibata *et al.*, 1994; Chatila *et al.*, 1997). The "ZII" motif is a slightly atypical CREB-responsive element (CRE) that binds CREB, ATF-1, the ATF-2/c-jun heterodimer, and possibly the c-jun/c-fos ("AP1") heterodimer as well (Flamand and Menezes, 1996; Flemington and Speck, 1990d; Liu *et al.*, 1998; Adamson *et al.*, 2000; Wang *et al.*, 1997). The cellular factors which bind to CRE motifs are constitutively expressed in many cell lines, but cannot function as efficient transcriptional activators unless they are phosphorylated over specific residues by certain kinases. The c-jun N-terminal kinase (JNK) is the major activator of c-jun transcriptional function, while the stress Map kinase p38 phosphorylates and activates ATF-2. Many of the stimuli that induce lytic EBV infection in vitro (including B-cell receptor engagement, BRLF1-mediated induction, and certain chemotherapy agents) are known to activate the p38 and JNK kinases, and conversely, inhibitors of p38 and JNK kinases reduce the effectiveness of a number of lytic-inducing stimuli (Adamson *et al.*, 2000; Feng *et al.*, 2002a, 2004). Thus, the activated (phosphorylated) form of an ATF-2/c-jun heterodimer appears to be important for activation of BZLF1 transcription by a number of different stimuli.

Lytic induction may also be mediated through ATF-1 or CREB binding to the ZII motif (Wang *et al.*, 1997), as

the activated (phosphorylated) forms of these transcription factors activate Zp in reporter gene assays. Consistent with a role for ATF- 1 and CREB in at least some cell types, activation of the Zp promoter induced by epithelial cell differentiation is associated with increased binding of ATF-1 and CREB to the Zp CRE motif (Karimi *et al.*, 1995; MacCallum *et al.*, 1999). In addition, engagement of the B-cell receptor results in calcium mobilization and activation of the calcium/calmodulin-dependent protein kinase type IV/Gr, which phosphorylates and activates CREB (Matthews *et al.*, 1994). Both ATF-1 and CREB phosphorylation are observed transiently following anti-IgG treatment of Akata cells (Bryant and Farrell, 2002).

The BZLF1 promoter sequences –233 to –229 bind to Smad3/Smad4, which mediate signaling by the TGF-beta cytokine, and this region of the promoter is required for the TGF-beta activation of Zp that occurs in certain BL lines (Fahmi *et al.*, 2000; Liang *et al.*, 2002). In addition, TGF-beta activation of Zp requires the ZII motif (Liang *et al.*, 2002). C-jun bound to the ZII motif interacts directly with Smad3/4 bound to the Smad binding site in Zp, perhaps explaining the need for both elements (Liang *et al.*, 2002).

BZLF1 autoregulation

There are two ZRE sites in Zp (ZIIIA and ZIIIB), and BZLF1 activates Zp transcription in reporter gene assays (Binne *et al.*, 2002; Flemington and Speck, 1990a). The Zp promoter (in the context of a stable oriP-containing episomal vector) cannot be efficiently activated by anti-IgG signaling in Akata cells when the ZIIIA site of Zp is deleted (Binne *et al.*, 2002). These results suggest that the ability of Z to autoactivate its own transcription may be an essential component for induction of lytic EBV infection. However, it has been suggested that the ZIIIA site in Zp may also bind cellular factors required for induction of BZLF1 transcription by anti-Ig prior to the onset of BZLF1 binding to this site. Since BZLF1 activates TGF-beta transcription (Cayrol and Flemington, 1995), and TGF-beta activates the BZLF1 promoter in at least some cell lines, the TGF-beta pathway may serve as another potential mechanism by which BZLF1 activates its own promoter. Nevertheless, whether BZLF1 actually activates the Zp promoter in the context of the intact genome during viral reactivation remains controversial. A number of published reports suggest that it may not (Binne *et al.*, 2002; Zalani *et al.*, 1996; Le Roux *et al.*, 1996).

Negative regulatory elements in Zp
