Negative regulation of BZLF1 transcription may play a critical role in promoting viral latency in B cells. A number of different negative regulatory elements in the BZLF1 promoter have been identified. Of particular importance is the "ZV" motif located near the TATA box that binds to the zinc-finger protein, ZEB (Kraus *et al.*, 2001, 2003). Deletion of this site significantly enhances activation of Zp induced by B-cell receptor engagement in Akata cells (Binne *et al.*, 2002). Binding sites for the cellular YY-1 transcription factor have also been mapped (the "ZIV" elements), and shown to function as negative regulators of BZLF1 transcription (Montalvo *et al.*, 1991, 1995). A *cis*-acting sequence, ZIIR, which overlaps the ZII motif, also reportedly inhibits Zp (Liu *et al.*, 1998), although the cellular factor(s) binding to this repressor have not been identified. The cellular protein, smubp-2, binds to Zp ZI motifs and reportedly functions as a negative regulator, although it is not yet clear whether this negative regulation is mediated by direct binding of smubp-2 to Zp or acts more generally to disrupt formation of a stable TBP-TFIIA-DNA complex (Zhang *et al.*, 1999b). Finally, a series of "H-box" elements, that are similar to E-box motifs and bind to the transcription factor E2–2, have been reported to function as negative regulators of Zp in B-cells, but positive regulators in epithelial cells (Thomas *et al.*, 2003).

Regulation of Rp

Less is known about the regulation of the BRLF1 promoter (Rp) than the BZLF1 promoter. Both the BZLF1 and BRLF1 gene products activate this promoter in EBV-negative cells (Sinclair *et al.*, 1991; Ragoczy and Miller, 2001; Zalani *et al.*, 1992), and the combination of BZLF1 and BRLF1 together is more effective than either protein alone (Liu and Speck, 2003). The Rp promoter, like Zp, is activated by B-cell receptor stimulation, phorbol ester agents, and chemotherapy agents (Zalani *et al.*, 1995; Sinclair *et al.*, 1991; Feng *et al.*, 2004). There are two EGR-1 (Zif-268) binding motifs in Rp, and activation of Rp by TPA and chemotherapy requires these sites in at least some cell types (Zalani *et al.*, 1995; Feng *et al.*, 2004). Phorbol esters, chemotherapy, and B-cell receptor engagement have all been shown to increase the level of cellular EGR-1, suggesting a common mechanism by which these inducing agents might activate BRLF1 transcription. There are also several Sp1 sites in Rp (Zalani *et al.*, 1992), which are required for constitutive promoter activity as well as efficient autoactivation of Rp by its own gene product (Ragoczy and Miller, 2001; Liu and Speck, 2003). A binding site for NF1 has been reported to be a positive regulatory element in HeLa cells but not lymphoid cells (Glaser *et al.*, 1998). There are at least three BZLF1 binding sites (ZREs) in Rp, and BZLF1 activation of Rp is mediated by direct binding of BZLF1 to these ZRE sites (Sinclair *et al.*,

1991; Liu and Speck, 2003; Bhende *et al.*, 2004). Like Zp, the Rp promoter also contains binding sites for the negative regulators, YY-1 and ZEB. The two YY-1 binding motifs function as negative regulators (Zalani *et al.*, 1997) of Rp; the role of the ZEB site, if any, has not yet been defined. Potential ZI-like and ZII-like motifs in Rp exist, but their function has not been studied.

Mechanisms by which TPA and Butyrate activate IE gene transcription

TPA treatment induces lytic EBV gene transcription in some cell lines, and this effect is at least partially mediated through TPA activation of protein kinase C (Gao *et al.*, 2001; Gradoville *et al.*, 2002). Why PKC activation leads to IE gene transcription is not totally clear, but it has been shown to require both the ZI and ZII motifs in Zp (Flemington and Speck, 1990d). In the case of the ZII motif, this may reflect the ability of TPA to activate the stress map kinases (p38 and c-jun N-terminal kinase) in a PKC-dependent manner (Grab *et al.*, 2004; Krappmann *et al.*, 2001), thus leading to phosphorylation of the ATF-2 and c-jun transcription factors which bind to the ZII site. TPA increases the level of EGR-1 in cells (Krappmann *et al.*, 2001), and the Rp EGR-1 binding sites are required for TPA activation of this promoter (Zalani *et al.*, 1995).

Agents that increase histone acetylation by inhibiting histone deacetylase (HDAC) activity, including sodium butyrate, trichostatin A, and valproic acid (Davie, 2003), also induce lytic EBV gene transcription in some cell lines. These agents presumably act by increasing the histone acetylation state of the two viral IE gene promoters (Jenkins *et al.*, 2000). Butyrate-responsive cellular genes (only 2% of all genes), like Zp and Rp, often have Sp1/Sp3 binding sites (Davie, 2003). Sp1 and Sp3 interact with HDAC proteins, as does MEF2D. Thus, in the absence of HDAC inhibitors, Sp1/Sp3 and MEF2D bound to the ZI motifs in Zp may act to inhibit Zp transcription by tethering HDAC complexes to the promoter, whereas in the presence of HDAC inhibitors these transcription factors instead interact with histone acetylases and activate Zp (Gruffat *et al.*, 2002b; Davie, 2003). Unlike the inducing effect of TPA, which requires PKC, the inducing effect of histone deacetylase inhibitors is PKC-independent (Gradoville *et al.*, 2002). HDAC inhibitors alone are insufficient to induce lytic EBV infection in many cell lines (Gradoville *et al.*, 2002), presumably because additional *trans*-acting factors are required to activate BZLF1 or BRLF1 transcription, and the combination of TPA and sodium butyrate is thus required for efficient induction of lytic viral gene expression in many cell lines.

Host cell and viral factors which influence stringency of viral latency

Of note, even in the most susceptible cell lines (generally BL lines), fewer than 50% of cells ever enter the lytic form of infection even when a combination of inducing agents is used. Why a portion of cells always remain in the latent form of viral infection (Gradoville *et al.*, 1990), while others switch to the lytic form of infection, is not currently well understood. In general, we have found that lymphoblastoid cell lines (LCLs) that have been extensively passaged are much more resistant to a variety of different inducing agents than newly derived lines, which often contain a portion of cells in the lytic form of infection even in the absence of inducing agents. In contrast to extensively passaged LCLs, BL lines often retain the ability to respond to one or more lytic-inducing agents.

The tendency of certain cell lines to remain tightly latent even in the face of multiple different inducing agents may be due to either viral and/or cellular factors. Viral factors that promote EBV latency include LMP-2A expression (since LMP-2A inhibits B-cell receptor mediated activation of Zp and Rp), as well as epigenetic modifications of Zp and Rp (including DNA methylation and/or chromatin deacetylation) (Gradoville *et al.*, 1990, 2002; Paulson and Speck, 1999; Nonkwelo and Long, 1993; Szyf *et al.*, 1985). Complete resistance to lytic inducing agents occasionally reflects an integrated viral genome. In some cell lines, such as the Raji BL line, inducing agents cause an abortive lytic infection, with expression of IE and early genes but no lytic viral replication, due to the deletion of one or more essential viral replication genes. In contrast, cell lines containing a defective rearranged form of the EBV genome, dHet, as well as wild-type virus, often have particularly high levels of lytic viral replication (Taylor *et al.*, 1989). This is because the defective rearranged viral genome contains the BZLF1 gene product under the control of the constitutively active EBNA-2 latency promoter, Wp (Countryman *et al.*, 1987; Rooney *et al.*, 1988; Grogan *et al.*, 1987). There is some evidence that similar defective rearranged viral genomes occur during natural infection in humans (Gan *et al.*, 2002; Walling *et al.*, 1992).

Cellular factors contributing to EBV latency include the activated (nuclear) form of NF-KB, which directly interacts with BZLF1 and inhibits its transcriptional function (Morrison and Kenney, 2004, Gutsch *et al.*, 1994). Likewise, the retinoic acid receptor also directly interacts with BZLF1 and inhibits its function (Sista *et al.*, 1993). Nitric oxide also potently down-regulates the lytic form of EBV infection (Gao *et al.*, 1999; Kawanishi, 1995). The cellular level of ZEB, which binds to the ZV motif and inhibits Zp activity

(Krauss *et al.*, 2001, 2003), presumably also influences the stringency of EBV latency.

EBV immediate-early proteins

Introduction

Transcription of the BZLF1 and BRLF1 genes results in expression of the BZLF1 (also known at ZEBRA, Z, EB1 and Zta) and BRLF1 (R, Rta) proteins. Both BZLF1 and BRLF1 are transcription factors, and high-level expression of either BZLF1 or BRLF1 (under the control of a strong heterologous promoter) is sufficient to induce the switch from the latent to lytic form of EBV infection in some latently infected cell lines (Chevallier-Greco *et al.*, 1986; Countryman and Miller, 1985; Rooney *et al.*, 1989; Takada *et al.*, 1986; Zalani *et al.*, 1996; Westphal *et al.*, 1999; Ragoczy *et al.*, 1998). However, in many cell lines, BZLF1 is much more effective than BRLF1 for inducing lytic EBV gene expression, and in some cell lines (such as Raji cells and some lymphoblastoid lines) only BZLF1, and not BRLF1, can disrupt viral latency (Ragoczy and Miller, 1999; Zalani *et al.*, 1996; Hong *et al.*, 2004). Thus, activation of BZLF1 expression (and hence regulation of the Zp promoter) may be relatively more important in vivo for inducing lytic EBV infection than activation of BRLF1 expression. In contrast, only the BRLF1 homologue (and not the BZLF1 homologue) can induce lytic infection in latently infected KSHV cell lines.

BZLF1 transcriptional effects

BZLF1 is a homologue to c-jun and c-fos, and binds as a homodimer to AP-1 like motifs (including the consensus AP-1 site) known as Z-responsive elements (ZREs) (Chang *et al.*, 1990; Packham *et al.*, 1990; Lieberman *et al.*, 1990; Lieberman and Berk, 1990; Farrell *et al.*, 1989; Flemington and Speck, 1990a). BZLF1 transcriptionally activates immediate-early, and early, lytic EBV promoters (Urier *et al.*, 1989; Lieberman *et al.*, 1989; Rooney *et al.*, 1989; Kenney *et al.*, 1989b; Holley-Guthrie *et al.*, 1990; Zetterberg *et al.*, 2002). As shown in Fig. 25.5, the amino-terminus of BZLF1 encodes the transactivator domain (Flemington *et al.*, 1992; Deng *et al.*, 2001), as well as a region required for replication but not transcription (Sarisky *et al.*, 1996). DNA binding is mediated through a domain that is highly homologous to the basic DNA binding domains of c-jun and c-fos (Flemington *et al.*, 1994; Farrell *et al.*, 1989). Homodimerization is mediated through a bZIP domain in the carboxy-terminal portion of the protein (Flemington and Speck, 1990c; Kouzarides *et al.*, 1991). BZLF1 does

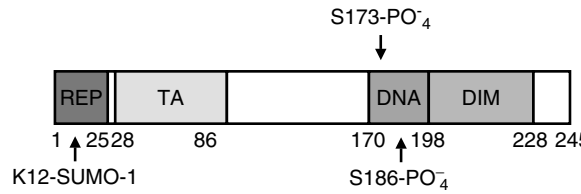

Fig. 25.5. EBV BZLF1 Immediate–early protein. Domains in the BZLF1 protein that mediate dimerization, DNA-binding and transactivation functions are shown, as well as certain phosphorylation and sumo-1 modification sites.

not heterodimerize efficiently with either c-fos or c-jun, but heterodimerizes with another cellular bZIP protein, C/EBP-alpha (Wu *et al.*, 2003), and can activate at least some promoters through C/EBP-alpha binding sites. The crystal structure of BZLF1 was recently published (Petosa *et al.*, 2006) and indicates that the bZIP domain in BZLF1 is somewhat unusual in that the carboxy-terminal region of the protein is also required to form a stable dimer.

BZLF1 activation of early lytic EBV promoters is generally mediated through direct binding of BZLF1 to ZRE motifs within the promoters (Flemington and Speck, 1990a; Urier *et al.*, 1989). BZLF1 may also activate certain cellular promoters through a non-DNA binding mechanism (Flemington *et al.*, 1994). In general, at least two ZRE sites are required for efficient activation of early viral promoters (Carey *et al.*, 1992), and these sites are usually located within a few hundred basepairs of the transcriptional start site. Once bound to DNA, the ability of BZLF1 to interact directly with histone acetylating complexes (including CBP and p300) results in acetylation of chromatin, converting it to a conformation favorable for transcription (Adamson and Kenney, 1999; Chen *et al.*, 2001a; Deng *et al.*, 2003; Zerby *et al.*, 1999). BZLF1 also interacts directly with a number of basic transcription factors, including TFIID and TFIIA (Chi and Carey, 1993; Chi *et al.*, 1995; Lieberman and Berk, 1991, 1994; Lieberman *et al.*, 1997; Mikaelian *et al.*, 1993).

In the context of the intact viral genome, all evidence to date suggests that BZLF1 activation of the BRLF1 IE promoter precedes activation of the early lytic promoters, and that both the BZLF1 and BRLF1 gene products are required for activation of most early lytic genes (Feederle *et al.*, 2000). BZLF1 may bind to the atypical ZRE sites in the BRLF1 promoter in a somewhat different manner (or perhaps conformation) than it binds to the consensus AP-1 site (El-Guindy *et al.*, 2002). This point is perhaps most clearly indicated by the phenotype of a mutant BZLF1 protein in which serine 186 in the basic DNA binding domain is altered to alanine (the residue encoded by the analogous region in c-jun and c-fos). The Z(S186A) mutant cannot bind

efficiently to either of the two ZRE sites in the BRLF1 promoter, although it binds efficiently to the consensus AP-1 site and a variety of ZRE sites within early EBV gene promoters (Adamson and Kenney, 1998; Francis *et al.*, 1997). When transfected into latently infected cells, Z(S186A) cannot induce BRLF1 transcription, and consequently is completely defective for inducing early lytic EBV gene transcription, but its lytic defect is rescued by co-transfection with a BRLF1 expression vector (Francis *et al.*, 1999; Adamson and Kenney, 1998). Serine residue 186 is phosphorylated by PKC in vitro, but whether this phosphorylation actually occurs in vivo remains controversial (El-Guindy *et al.*, 2002; Baumann *et al.*, 1998; Gradoville *et al.*, 2002; Daibata *et al.*, 1992). In lytically-infected B95–8 cells, BZLF1 is phosphorylated at residues Thr 14, Ser167, Ser173 and Ser186, and may be weakly phosphorylated at additional residues (EI-Guindy *et al.*, 2004, 2006). Phosphorylation of BZLF1 residues Ser167 and Ser173 by casein Kinase II, while not required for Z activation of early lytic genes, is required for efficient viral replication and modulates the ability of BRLF1 to regulate late gene transcription (EI-Guindy and Miller, 2004).

BZLF1 activation of methylated ZRE motifs

The EBV genome is highly methylated during the latent form of viral infection, and DNA methylation of promoters generally acts as a potent inhibitor of cellular gene transcription. However, BZLF1 was recently shown to preferentially bind to the methylated vs. unmethylated, forms of two ZRE sites in Rp (Bhende *et al.*, 2004). BZLF1 binding to the ZRE-2 site in Rp, which contains the sequence TGAGCGA, is much enhanced when the cytosine in this motif is methylated, and a previously unrecognized ZRE site in Rp, ZRE-3, which contains the sequence TTCGCGA, can only be bound by BZLF1 in the methylated form. Furthermore, BZLF1 preferentially activates the methylated form of the BRLF1 promoter in reporter-gene assays, and preferentially induces lytic EBV transcription from a methylated versus unmethylated, viral genome (Bhende *et al.*, 2004). Thus, BZLF1 is the first example of a transcription factor that preferentially activates the methylated form of a downstream target gene. This unexpected ability of BZLF1 to activate methylated lytic viral promoters reveals a novel mechanism by which EBV circumvents the inhibitory effects of viral genome methylation.

BZLF1 activation of cellular genes

Not surprisingly, BZLF1 also transcriptionally activates certain cellular genes, some of which may be important for EBV pathogenesis. The cellular genes known to be activated by BZLF1 include TGF-beta (Cayrol and Flemington, 1995), c-fos (Flemington and Speck, 1990b), the tyrosine kinase TKT (Lu *et al.*, 2000), matrix metalloproteinases 1 and 9 (Lu *et al.*, 2003; Yoshizaki *et al.*, 1999), and cellular IL-10 (Mahot *et al.*, 2003). BZLF1 activation of the immunosuppressive cytokines, TGF-beta and IL-10, could potentially dampen the host immune response during the lytic form of virus infection, whereas induction of the matrix metalloproteinases could potentially enhance metastasis of EBV-positive tumors cells expressing BZLF1. In addition, cellular IL-10 is a potent B-cell growth factor, suggesting a mechanism by which lytic EBV gene expression in a small percentage of cells could promote B-cell malignancies in a paracrine manner.

BZLF1 replication function

In addition to its essential role as a transcription factor, BZLF1 also plays a direct role in lytic viral replication. BZLF1 binds directly to a number of ZRE sites in the lytic origin of replication, oriLyt, and this binding is required for oriLyt replication (Fixman *et al.*, 1992, 1995; Hammerschmidt and Sugden, 1988; Schepers *et al.*, 1993a,b). Furthermore, a BZLF1 mutant altered at residues 12/13 is transcriptionally competent, but completely defective for mediating viral replication (Sarisky *et al.*, 1996). BZLF1 also interacts directly with some of the core viral replication proteins (Zhang *et al.*, 1996; Takagi *et al.*, 1991; Gao *et al.*, 1998). Together, these results suggest that BZLF1 acts as an essential oriLyt binding protein during lytic EBV replication, and that this binding may promote formation of the initial replication complex.

The BZLF1-knockout virus is less efficient in promoting lymphoproliferative disease in SCID mice

The phenotype of a BZLF1-deleted EBV has been recently described (Feederle *et al.*, 2000) in 293 cells and primary B cells. As expected, this mutant cannot undergo the lytic form of EBV replication unless the BZLF1 gene product is expressed in trans. In 293 cells infected with the BZLF1-knockout virus, expression of the BZLF1 gene product induces expression of the IE protein, BRLF1, as well as the complete complement of early and late lytic genes. In contrast, expression of the BRLF1 gene product in 293 cells infected with BZLF1-knockout virus does not result in expression of the majority of early or late genes. The BZLF1-knockout virus is not reported to be defective in immortalizing B cells. The phenotype of the BZLF1-knockout virus confirms that both BZLF1 and BRLF1 transcriptional

functions are required for the induction of many (but not all) lytic EBV genes in the context of the intact viral genome.

Surprisingly, however, recent findings suggest that early-passage lymphoblastoid cell lines (LCLs) derived from either BZLF1 -deleted, or BRLF1-deleted, viruses are less efficient than lines derived using wild-type virus in regard to their ability to form lymphoproliferative disease in SCID mice (Hong *et al.*, 2005a,b). LCLs containing the BZLF1-deleted virus secrets less of the two B-cell growth factors, cellular IL-6 and cellular IL-10, and less of the potent angiogenesis factor, VEGF, than LCLs from the same donor containing wild-type EBV. These results suggest that a small number of lytically infected cells may contribute to the growth of some EBV-associated tumors in vivo through the release of paracrine growth factors or angiogenesis factors.

BZLF1 effects on the host cell environment

In addition to its essential roles as a transcription factor and viral replication protein, BZLF1 alters the host cell environment in numerous different ways that presumably act together to enhance the efficiency of lytic viral replication. As the first viral protein expressed during lytic reactivation (and primary lytic infection), BZLF1 is ideally situated to protect the virus from a variety of different host defenses, including cellular apoptosis and the host innate immunity, and to regulate the host cell cycle.

BZLF1 cell cycle effects

There is increasing evidence that herpesviruses usurp the host cell cycle control mechanisms to assure adequate substrates for lytic viral DNA replication. However, the cell cycle effects of BZLF1 appear to be cell-type dependent. BZLF1 produces a profound G1/S block in some cell types, including primary fibroblasts (Rodriguez *et al.*, 1999, 2001a; Cayrol and Flemington, 1995, 1996a,b; Mauser *et al.*, 2002b; Wu *et al.*, 2003). In cell types susceptible to this G1/S block, BZLF1 decreases expression of cyclin A and c-myc (Mauser *et al.*, 2002b; Rodriguez *et al.*, 2001b), and increases p21 expression (Wu *et al.*, 2003; Cayrol and Flemington, 1996b). BZLF1 activates p21 expression through a C/EBP-alpha binding site in the p21 promoter, an effect that involves the direct interaction between BZLF1 and C/EBP-alpha (Wu *et al.*, 2003). In other cell types, such as HeLa cells, BZLF1 induces both a G2 and mitotic block (Mauser *et al.*, 2002a; Cayrol and Flemington, 1996a). The G2 block results from decreased cyclin B, while the mitotic block is associated with a defect in chromosome condensation (Mauser *et al.*, 2002a).

Nevertheless, the cell types in which BZLF1 induces cell cycle blocks are either not normally infected by EBV (fibroblasts), and/or are likely to be deficient in normal cell cycle regulation controls (tumor cells). In sharp contrast to the results in fibroblasts and tumor cell lines, in telomerase-immortalized, as well as primary, keratinocytes, BZLF1 actually enhances expression of a number of S-phase dependent cellular proteins, and increases the level of E2F-1, cyclin E and cyclin A (Mauser *et al.*, 2002b). Likewise, inducible BZLF1 expression in the EBV-immortalized marmoset B-cell line, B95–8, results in enhanced activity of cyclin-dependent kinases, although cellular DNA replication is blocked (Kudoh *et al.*, 2003). Most importantly, agents that inhibit the activity of cyclin-dependent kinases also inhibit lytic EBV gene expression (Kudoh *et al.*, 2004), although it is not currently understood why cyclin-dependent kinases are required for efficient lytic EBV replication. These results suggest that a "pseudo-lateG1/S-phase" environment, in which certain late G1/S-phase restricted cellular proteins are expressed, but cellular DNA does not actually replicate, may be the ideal host cell environment for lytic EBV replication. Inhibition of cellular DNA replication presumably decreases competition between the virus and host cell DNA for limiting substrates involved in DNA replication, while the expression of certain G1/S-phase restricted cellular proteins, such as E2F-1, may be required for viral replication.

BZLF1 effects on p53

Activation of p53 in host cells serves as an important host defense mechanism, since p53 induces cellular apoptosis and hence limits viral replication. Not surprisingly, therefore, many viruses, including herpesviruses, encode proteins that inhibit various aspects of p53 function. The effects of BZLF1 on p53 in the host cell are quite complex. Somewhat paradoxically, in some (but not all) cell types, the presence of BZLF1 results in a rather dramatic increase in the level of total p53, and induces a number of post-translation modifications of p53 (including a series of activating phosphorylations and acetylations) that are usually associated with enhanced p53 transcriptional function (Mauser *et al.*, 2002c). BZLF1 also increases the amount of p53 binding in some cell types (Mauser *et al.*, 2002c). This activation of p53 that occurs in BZLF1-expressing cells may represent an attempt by the host cell to limit EBV replication. Nevertheless, the majority of evidence suggests that BZLF1 quite efficiently inhibits p53 transcriptional function (Zhang *et al.*, 1994; Mauser *et al.*, 2002c). BZLF1 inhibition of p53 may be due in part to the previously observed direct interaction between the BZLF1 and p53 proteins (Zhang *et al.*, 1994). In addition, BZLF1 significantly reduces the level of the basic transcription factor, TATA-binding protein (TBP), in host cells, and restoration

of this protein partially reverses the ability of BZLF1 to inhibit p53 transcriptional function (Mauser *et al.*, 2002c). Finally, as discussed below, BZLF1-mediated dispersion of nuclear PML bodies in host cells may also decrease p53 function, since optimal p53 transcriptional function requires PML bodies. In any event, given that p53 is an important cellular mediator of apoptosis, the ability of BZLF1 to inhibit p53 function likely plays a crucial role in protecting the virus from apoptosis during the earliest timepoints of lytic infection.

BZLF1 dispersion of PML bodies

Promyelocytic leukemia (PML) bodies, also known as nuclear domain 10 (ND-10) bodies, are nuclear structures which contain a number of different cellular proteins, including CREB-binding protein (CBP), Sp100, Rb, Daxx, ISG20, and the small ubiquitin-related modifier, sumo-1 (Bernardi and Pandolfi, 2003; Salomoni and Pandolfi, 2002). Only the PML protein is absolutely essential for formation of PML bodies, and the PML protein must be covalently modified by sumo-1 in order to form these bodies. Although the exact function(s) of PML bodies is somewhat mysterious, the fact that the formation of these bodies is dramatically enhanced by both type I and type II interferons, and that a number of different viruses encode proteins capable of dispersing PML bodies, suggests that these bodies have an antiviral function (Chee *et al.*, 2003; Bernardi and Pandolfi, 2003; Salomoni and Pandolfi, 2002). PML bodies have been proposed to be important for certain types of apoptosis, MHC class I presentation, efficient acetylation of p53, interferon effects, and for the stability and function of an important cellular DNA repair complex, Mre11/Rad50/NBS1 (Bernardi and Pandolfi, 2003; Salomoni and Pandolfi, 2002; Chee *et al.*, 2003). As each of these proposed functions would be expected to reduce viral replication, it is perhaps not surprising that many viruses attempt to inhibit the formation of PML bodies.

High level BZLF1 expression in EBV-negative cells is sufficient to disperse PML bodies, and this effect is correlated with the ability of BZLF1 to inhibit sumo-1 modification of the PML protein (Bell *et al.*, 2000; Adamson and Kenney, 2001). BZLF1 itself is efficiently modified by sumo-1 over lysine 12, and the ability of BZLF1 to inhibit PML protein sumo-1 modification may be at least partially due to competition between BZLF1 and PML for limiting amounts of sumo-1 in the host cell (Adamson and Kenney, 2001). A BZLF1 mutant altered at residues 12 and 13 is transcriptionally competent, but defective in mediating lytic replication (Sarisky *et al.*, 1996). Thus, sumo-1 modification of BZLF1 may be primarily important for its replicative, rather than transcriptional, function.

In the context of the intact virus, lytic EBV infection in cells results in the release of proteins such as Sp100 and Daxx from ND10 bodies, followed by the release of PML (Bell *et al.*, 2000). Lytic viral replication commences after dispersion of the Sp100 and Daxx proteins, but prior to the onset of PML dispersion, and lytic viral replication complexes are often closely associated with dispersed PML protein aggregates (Bell *et al.*, 2000). These findings suggest that reorganized PML complexes may play a role in promoting lytic EBV replication.

BZLF1 effects on the host immune response

BZLF1 plays a key role in attenuating the host immune response to lytic viral infection. PML bodies are required for an efficient antiviral effect of interferon alpha in herpes simplex virus 1 infection (Chee *et al.*, 2003), suggesting that BZLF1-mediated dispersion of PML bodies may protect lytic EBV infection from interferon alpha. BZLF1 also strongly inhibits transcription of the gene encoding an essential component of the interferon gamma receptor, and thereby abrogates interferon gamma signaling in host cells (Morrison *et al.*, 2001). This ability of BZLF1 to inhibit interferon gamma signaling is likely important not only for protecting the virus from the immunostimulatory effects of interferon gamma (including induction of MHC class II and IRF-1), but may also be required for epithelial cell-derived virus to efficiently infect B cells. Virus produced in cells expressing MHC class II, which would normally be induced by gamma interferon in infected epithelial cells if BZLF1 did not prevent this, preferentially infects epithelial cells, whereas virus produced in cells not expressing MHC class II preferentially infects B cells (Borza and Hutt-Fletcher, 2002). In addition to preventing interferon gamma signaling, BZLF1 was recently shown to directly interact with, and inhibit the function of, IRF7 (Hahn *et al.*, 2005). AS IRF7 augments production of type I interferons, the interaction between BZLF1 and IRF7 no doubt helps the virus to attenuate the antiviral effects of interferon alpha and beta in lytically infected cells.

Tumor necrosis factor alpha (TNF-alpha) is another important antiviral cytokine inhibited by BZLF1 expression in host cells. TNF-alpha not only activates expression of a number of important inflammatory genes (through its effects on NF-KB), but also induces cellular apoptosis. As TNF-alpha production is an immediate, and important component of the host immune response to viral infection, not surprisingly many viruses encode proteins that limit the effects of TNF-alpha in the infected host cell. In the case of lytic EBV infection, BZLF1 dramatically inhibits the activity of the promoter for the gene encoding the major

TNF-alpha receptor (TNF-R1) (Morrison *et al.*, 2004). Since TNF-R1 is a fairly short-lived protein, this reduction in TNF-R1 transcription results in dramatically decreased expression of the TNF-R1 protein. Thus, TNF-alpha cannot activate transcription of important downstream target genes such as ICAM-1 in BZLF1-expressing cells, and is also unable to induce cellular apoptosis (Morrison *et al.*, 2004). The exact mechanism(s) by which BZLF1 inhibits transcription of the genes encoding the TNF-R1 and interferon gamma receptors has not yet been defined.

Complex interactions between BZLF1 and the NF-KB transcription factor are also involved in inhibiting expression of many different NF-KB dependent cellular genes involved in the host immune response. BZLF1 interacts directly with the p65 component of NF-KB, and this interaction inhibits the transcriptional function of BZLF1 (Gutsch *et al.*, 1994; Hong *et al.*, 1997). However, recent evidence suggests that BZLF1 also potently inhibits NF-KB-dependent activation of promoters (Keating *et al.*, 2002; Morrison and Kenney, 2004), and decreases NF-KB binding to promoters in the context of the intact cellular genome (Morrison and Kenney, 2004). Thus, the IL-1 cytokine cannot activate NF-KB-responsive cellular genes in the presence of BZLF1, even though the upstream components of the IL-1 signaling pathway appear to be unaffected by BZLF1 (Morrison and Kenney, 2004). Somewhat paradoxically, however, since one of the NF-KB responsive genes inhibited by BZLF1 is I-kappa B (IK-B) (Morrison and Kenney, 2004), and the IK-B protein normally acts to retain NF-KB in the cytoplasm in an inactive form, BZLF1-expressing cells actually have a very high level of nuclear NF-KB (Morrison and Kenney, 2004). This BZLF1-mediated translocation of NF-KB into the nucleus may act to negatively regulate BZLF1 transcriptional function and hence promote viral latency in situations where BZLF1 expression is limiting relative to the amount of nuclear NF-KB.

Finally, BZLF1 also regulates cellular cytokine expression in ways that would be anticipated to protect the virus. As discussed previously, BZLF1 stimulates expression of both TGF-beta, and IL-10 (Cayrol and Flemington, 1995). Both TGF-beta and IL-10 have immunomodulatory effects that would be expected to attenuate the cytotoxic T cell response directed against the virus. In addition, BZLF1 inhibits expression of MHC class I on cells (Keating *et al.*, 2002; Mahot *et al.*, 2003). This latter effect may be at least partially mediated through BZLF1 effects on NF-KB, although other pathways appear to be involved, as well (Keating *et al.*, 2002). The immunomodulatory effects of BZLF1 are summarized in Fig. 25.6.

The role of BRLF1 in lytic induction

Expression of the EBV immediate–early protein, BRLF1, also induces lytic EBV infection in a subset of latently infected cell lines (Feederle *et al.*, 2000; Ragoczy *et al.*, 1998; Zalani *et al.*, 1996; Westphal *et al.*, 1999). Interestingly, the BRLF1 homologue in KSHV (ORF50) is the major inducer of lytic infection for this virus. Even in cell lines (such as the Raji Burkitt lymphoma line) where BRLF1 expression by itself is not sufficient to disrupt viral latency, it is clear that BRLF1 expression is required (in concert with BZLF1) to activate many early lytic genes, including BMRF1 (Feederle *et al.*, 2000; Ragoczy and Miller, 1999). Consistent with this, the BRLF1 gene product is essential for lytic viral replication (Feederle *et al.*, 2000). Like BZLF1, BRLF1 also binds directly to the EBV oriLyt (Gruffat and Sergeant, 1994; Hammerschmidt and Sugden, 1988). In contrast to the importance of certain oriLyt ZRE sites, the BRLF1 binding sites in oriLyt are not absolutely essential for oriLyt replication, at least in plasmid-based replication assays (Fixman *et al.*, 1992).

The primarily nuclear BRLF1 gene product is a transcriptional activator that contains an amino-terminus DNA binding domain and homodimerization domain (Manet *et al.*, 1991) and a carboxy-terminal transcriptional activation domain (Hardwick *et al.*, 1988, 1992) (Fig. 25.7). The transcriptional activator domain of BRLF1 interacts directly with TBP and TFIIB (Manet *et al.*, 1993). BRLF1 also interacts directly with the histone acetylase, CREB-binding protein (CBP) (Swenson *et al.*, 2001). BRLF1 activates lytic EBV gene promoters through at least two different mechanisms. BRLF1 binds directly to a GC-rich motif (consensus $GGCCN_7GTGGTG$) which is present in the promoters of at least three early EBV genes, SM (formerly called BMLF1), BHRF1, and BMRF1 (Gruffat *et al.*, 1990; Gruffat *et al.*, 1992; Gruffat and Sergeant, 1994; Kenney *et al.*, 1989a; Quinlivan *et al.*, 1993). In the case of the BHRF1 and SM promoters, the BRLF1-binding motifs function as powerful enhancer elements in the presence of the BRLF1 protein (Kenney *et al.*, 1989a; Cox *et al.*, 1990; Chevallier-Greco *et al.*, 1989). In the case of the BMRF1 promoter, BRLF1 by itself induces little activation, but cooperates with BZLF1 to produce efficient activation of this promoter (Holley-Guthrie *et al.*, 1990; Quinlivan *et al.*, 1993).

In contrast, BRLF1 activates its own promoter (Rp) and the BZLF1 promoter (Zp) through mechanisms that do not involve direct DNA binding of BRLF1 to these promoters. BRLF1 stimulation of its own promoter requires the Rp Sp1 motifs (Ragoczy and Miller, 2001; Liu and Speck, 2003), although it is not yet known exactly how (or if) BRLF1 regulates cellular factors binding to the Sp1 motif. BRLF1

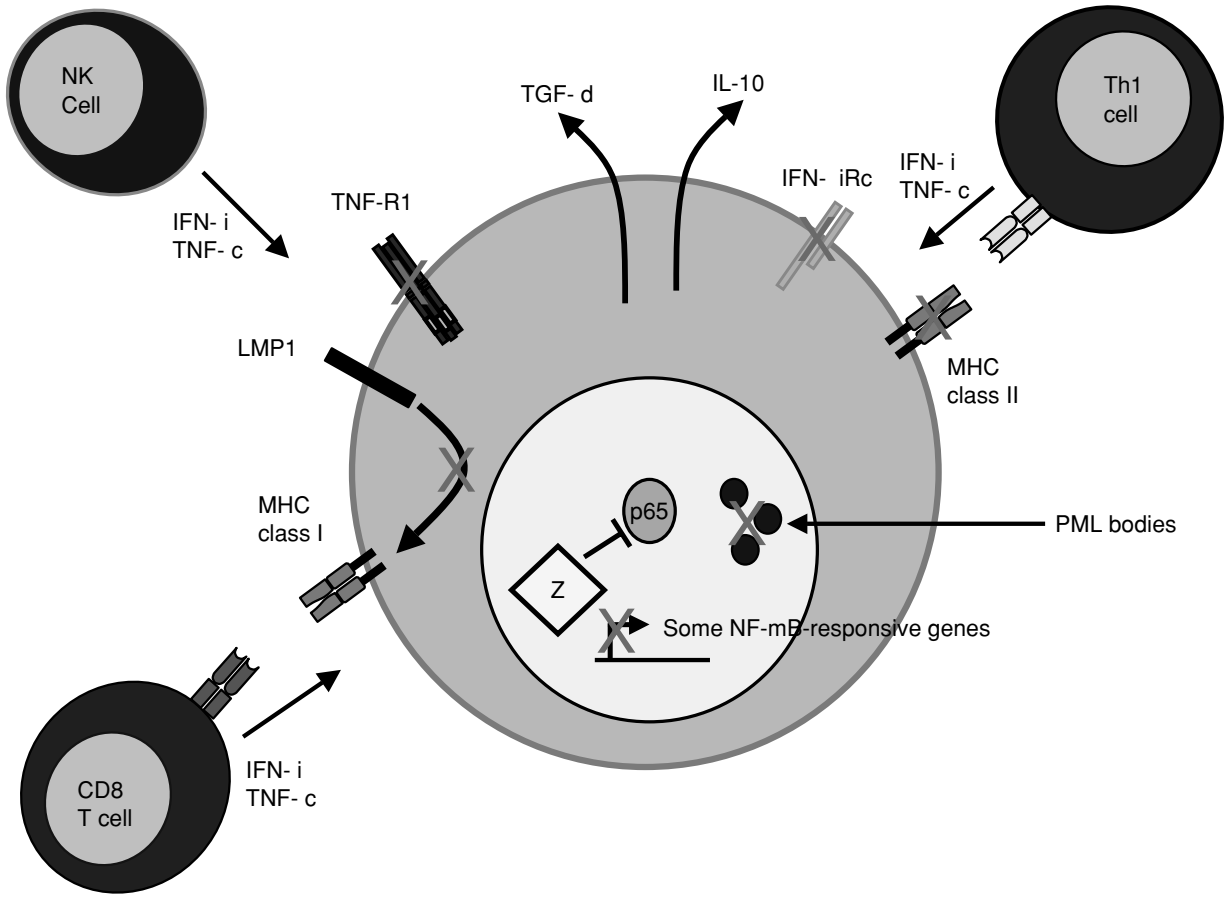

Fig. 25.6. Inhibitory effects of BZLF1 on host immunity. BZLF1 activates transcription of the immunosuppressive cytokines, TGF-beta and IL-10, while decreasing transcription of the receptors for interferon gamma and TNF-alpha. BZLF1 inhibits the transcriptional activity of the p65 component of NF-kappa B and abrogates MHC class I induction by LMP1. BZLF1 also mediates dispersion of PML bodies, which are important for MHC class I expression and response to alpha interferon.

stimulation of the Zp promoter requires the ZII motif, and is likely mediated by BRLF1 activation of the c-jun and ATF-2 transcription factors (Adamson *et al.*, 2000). BRLF1 expression in cells activates the stress Map kinases (p38 and c-jun N-terminal kinase) (Adamson *et al.*, 2000), as well as PI3 kinase (Darr *et al.*, 2001), and inhibition of either p38 stress Map kinase, or PI3 kinase, activity abolishes the ability of BRLF1 to activate BZLF1 transcription, or disrupt viral latency (Adamson *et al.*, 2000; Darr *et al.*, 2001). BRLF1 stimulation of the viral DNA polymerase promoter is also mediated through an indirect mechanism, involving USF and E2F-1 binding motifs (Liu *et al.*, 1996).

The inability of BRLF1 expression by itself to induce fully lytic gene expression in certain cell lines, such as Raji, primarily reflects the inability of BRLF1 to activate BZLF1 transcription in these cell lines (Zalani *et al.*, 1996). In Raji cells, BRLF1 by itself efficiently activates an early promoter (SM promoter) that is directly bound by BRLF1, but cannot activate Zp, or an early viral promoter, BMRF1, which requires the combination of BZLF1 and BRLF1 for activation (Ragoczy and Miller, 1999). Why BRLF1 induces BZLF1 transcription in some latently infected cell lines, but not others, is not currently understood.

BRLF1-knockout virus phenotype

A BRLF1-deleted knockout virus has been made and its phenotype studied in 293 cells as well as primary B cells (Feederle *et al.*, 2000). As is the case for the BZLF1- knockout virus, the BRLF1-knockout virus immortalizes primary B cells with efficiency similar to wild-type virus, but early-passage B cell lines obtained with BRLF1-deleted virus

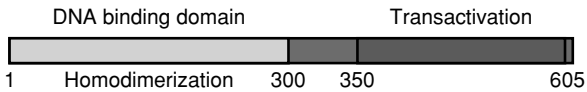

Fig. 25.7. EBV BRLF1 immediate–early protein. Domains in the BRLF1 protein that mediate dimerization, DNA-binding and *trans*-activation functions are shown.

are impaired for producing lymphoproliferative disease in SCID mice (Feederle *et al.*, 2000; Hong *et al.*, 2005a,b). In 293 cells, the BRLF1-knockout virus is unable to enter the lytic form of infection, or express the BZLF1 immediate–early gene, unless the BRLF1 gene product is supplied in trans. These results confirm that the BRLF1 gene product is an important and essential activator of the Zp IE promoter, and that many early viral promoters require both BZLF1 and BRLF1 functions for activation in the context of the intact viral genome. As discussed later, this particular BRLF1-knockout virus was subsequently discovered to be unable to express an early EBV gene product, BRRF1. The phenotype of the "BRLF1-knockout" virus in certain cell types is also partially due to the loss of BRRF1 expression, which cooperates with BRLF1 to activate transcription of BZLF1 (Hong *et al.*, 2004). Nevertheless, it is clear that the BRLF1 gene product is essential for fully lytic EBV gene expression, as well as lytic viral replication, in all cell lines tested to date (Feederle *et al.*, 2000; Hong *et al.*, 2004).

There is emerging evidence that BRLF1 may be able to activate transcription of a subset of late viral genes even in the absence of viral replication. In 293 cells containing the BZLF1-knockout virus, BRLF1 induces expression of a subset of "late" genes, although the virus cannot replicate due to the lack of BZLF1 expression (Feederle *et al.*, 2000). BRLF1 also activates some late genes in Raji cells, in which the viral genome is unable to replicate (Ragoczy and Miller, 1999). The exact mechanism by which BRLF1 activates late genes has not been well defined. Assuming that BRLF1 also activates certain late genes when expressed at a physiologic level in the context of the intact viral genome, the regulation of EBV late gene transcription may be fundamentally different from that of late viral genes in the alpha herpesviruses. The ability of BRLF1 to activate certain viral late genes is modulated by the BZLF1 protein (EI-Guindy and Miller, 2004).

BRLF1 activation of the cellular fatty acid synthase gene

Recent evidence suggests that BRLF1 activation of the cellular gene, fatty acid synthase (FAS), may be an essential component in BRLF1-mediated induction of lytic EBV infection (Li *et al.*, 2004). The FAS enzyme is required for the synthesis of many different lipids, including palmitate, and high-level expression of FAS is normally restricted to fat cells and liver cells. BRLF1 robustly activates FAS gene expression in host cells, and this effect is lost in the presence of p38 kinase inhibitors. Of potential therapeutic interest, agents known to specifically inhibit the FAS enzyme (cerulenin and C75) also inhibit the ability of transfected BRLF1 to induce the lytic form of EBV gene expression, including induction of BZLF1 transcription (Li *et al.*, 2004). In contrast, FAS inhibitors do not affect the ability of transfected BZLF1 (driven by a strong heterologous promoter) to induce lytic EBV gene expression. These results suggest cellular FAS activity is required for BRLF1 activation of the BZLF1 promoter (Zp). Exactly why this is the case remains unknown, but may reflect the fact that palmitoylation of proteins is often required for entry of these proteins into lipid rafts, and the ability of these proteins to initiate signal transduction cascades. Since FAS inhibitors also repress anti-IgG induction of lytic EBV in Akata cells, and the constitutively lytic EBV infection which occurs in AGS (gastric carcinoma) cells (Li *et al.*, 2004), they could potentially be developed as a completely novel approach for inhibiting the earliest aspects of lytic EBV infection in patients.

BRLF1 cell cycle effects

Like BZLF1, BRLF1 also profoundly affects the regulation of the host cell cycle. BRLF1 expression results in an increased number of cells in S-phase in both primary human fibroblasts and HeLa cells, and this effect is associated with dramatically increased E2F-1 expression (Swenson *et al.*, 1999). In addition, since BRLF1 activates the promoter of the viral DNA polymerase gene through an E2F-1 site (rather than a direct binding mechanism) (Liu *et al.*, 1996), the ability of BRLF1 to increase the level of E2F-1 in the host cell may be required for efficient transcription of the viral DNA polymerase (and consequently efficient lytic viral replication). BRLF1 also interacts directly with the tumor suppressor protein, Rb (Zacny *et al.*, 1998). Since Rb plays an essential role in regulating the host cell cycle, the interaction between Rb and BRLF1 may be a mechanism by which BRLF1 activates cell cycle progression.

Early lytic EBV gene regulation

The expression of the two immediate–early proteins, BZLF1 and BRLF1, allows the subsequent expression of viral early genes. In the context of the intact viral genome, transcriptional activation of many early promoters, such as BMRF1, requires that both the BZLF1 and the BRLF1 gene products be expressed (Feederle *et al.*, 2000; Cox *et al.*, 1990). The most extensively studied early lytic EBV promoter is the BMRF1 gene promoter. This promoter contains two BZLF1 binding motifs, as well as one BRLF1 binding site (Holley-Guthrie *et al.*, 1990; Quinlivan *et al.*, 1993). In reporter gene assays in EBV-negative cells, BZLF1 alone efficiently activates the BMRF1 promoter (an effect which requires that both of the ZRE sites be present), whereas the BRLF1 gene product by itself at most modestly activates the BMRF1 promoter. In some cell types, but not others, the combination of BZLF1 and BRLF1 together is significantly more effective than BZLF1 alone at activating BMRF1 reporter gene plasmids (Holley-Guthrie *et al.*, 1990). In cells containing the latent form of EBV infection, all data to date suggest that the combination of both BZLF1 and BRLF1 is required for significant activation of BMRF1 transcription, regardless of cell type (Adamson and Kenney, 1998; Feederle *et al.*, 2000; Ragoczy and Miller, 1999; Zalani *et al.*, 1996).

Nevertheless, the relative importance of the BZLF1 versus BRLF1 gene products for activation of early gene transcription in the context of the intact viral genome appears to be promoter-specific. The early SM promoter, which contains at least one BZLF1 binding motif, as well as a BRLF1 binding site, can be activated by transfected BRLF1 in a cell line (Raji) where BRLF1cannot induce BZLF1 expression from the endogenous viral genome (Ragoczy and Miller, 1999; Swenson *et al.*, 2001). Thus the SM early promoter can be activated by BRLF1 alone, even in the context of the intact viral genome. Two other early promoters, BHLF1 and BHRF1, which are divergent promoters contained within the lytic EBV origin of replication, oriLyt, have been extensively studied in vitro, but much less so in the context of the intact virus. There are two strong BRLF1 binding sites located between the BHLF1 and BHRF1 promoters in oriLyt (Gruffat and Sergeant, 1994); in reporter gene assays, the BHRF1 promoter appears to be more responsive to BRLF1 than the BHLF1 promoter (Hardwick *et al.*, 1988; Cox *et al.*, 1990). Both the BHLF1 and BHRF1 promoters have two or more BZLF1 sites and are activated by BZLF1 alone in reporter gene assays (Hardwick *et al.*, 1988). The relative importance of BZLF1 vs. BRLF1 for BHLF1 vs. BHRF1 transcriptional activation in the context of the intact virus has not been well studied.

Early lytic EBV gene products

Replication proteins

Many of the early lytic EBV gene products are directly involved in mediating the lytic form of viral replication. The six core viral replication proteins which mediate lytic viral replication include the catalytic component of the viral DNA polymerase (BALF5), the DNA polymerase processivity factor (BMRF1), the single-stranded DNA binding protein (BALF2), helicase (BBLF4), primase (BSLF1), and primase-associated protein (BBLF2/3)(Fixman *et al.*, 1992). In addition, some early EBV genes encode enzymes involved in deoxynucleotide metabolism, including the viral thymidine kinase gene (BXLF1) (Littler *et al.*, 1986), the viral dUTPase gene (Fleischmann *et al.*, 2002) and viral ribonucleotide reductase (BORF2 and BARF1). From the results of studies performed on the analogous genes in HSV-1, it is likely that these early EBV gene products are required for efficient production of nucleotide substrates in non-replicating cells. In addition, the EBV-encoded thymidine kinase (TK) function may be required for the therapeutic effect of the antiviral drug, acyclovir, as the EBV TK is a deoxypyrimidine kinase that phosphorylates a broad range of nucleoside analogues (such as acyclovir) not recognized efficiently by the cellular TK (Littler and Arrand, 1988).

Transcription factors

There are at least two viral transcription factors encoded by early lytic EBV genes. Interestingly, the BMRF1 gene product (Cho *et al.*, 1985) functions not only as the viral DNA polymerase-processivity factor (Tsurumi *et al.*, 1993, 1994), but also as a transcription factor (Zhang *et al.*, 1997, 1999a). BMRF1 activates transcription of the oriLyt promoter, BHLF1, and the BMRF1-responsive region of this promoter is contained within a GC-rich domain (the downstream essential domain) that is also essential in *cis* for oriLyt replication (Zhang *et al.*, 1997). The exact mechanism by which BMRF1 activates oriLyt transcription is not yet known. The transcriptional function of BMRF1 requires its carboxy-terminal domain (Zhang *et al.*, 1999a), which is not required for DNA polymerase-processivity function in vitro (Kiehl and Dorsky, 1991; 1995).

Another early lytic viral transcription factor is the BRRF1 gene product (Hong *et al.*, 2004). The BRRF1 gene is encoded by the opposite strand of the first intron of the BRLF1 immediate–early gene (Segouffin-Cariou *et al.*, 2000). BRRF1 enhances the transcriptional function of c-jun, and activates the BZLF1 immediate–early promoter

through the CRE ("ZII") motif (Hong *et al.*, 2004). BRRF1 activation of c-jun transcriptional function is associated with increased c-jun phosphorylation, although the precise mechanism for this effect is not yet known. Although BRRF1 expression alone is not sufficient to activate BZLF1 transcription from the latent viral genome, BRRF1 function is required for efficient BRLF1-mediated activation of Zp in some latently infected cell lines (Hong *et al.*, 2004). A knockout virus originally thought to specifically delete the BRLF1 gene product (Feederle *et al.*, 2000) was subsequently shown to be defective in BRRF1 transcription, and rescue of the fully lytic phenotype of this virus requires both the BRLF1 and BRRF1 gene products in trans (Hong *et al.*, 2004). KSHV contains a gene that is homologous to BRRF1 in the analogous position of the viral genome and has a similar function (Gonzalez *et al.*, 2005).

SM: a protein that regulates RNA transport and stability

In contrast to the latent and IE genes of EBV, the early and late genes often contain no introns. RNA derived from intronless genes is often unstable in cells. The early lytic gene product, SM (previously known as BMLF1) (Cook *et al.*, 1994), is an RNA-binding protein which plays an important role in increasing the stability of intronless lytic viral transcripts, as well as promoting the transport of such messages from the nucleus to the cytoplasm (Kenney *et al.*, 1989c; Gruffat *et al.*, 2002a; Hiriart *et al.*, 2003a,b; Boyle *et al.*, 1999, 2002; Buisson *et al.*, 1989, 1999; Chen *et al.*, 2001b; Farjot *et al.*, 2000; Ruvolo *et al.*, 1998, 2001, 2004; Semmes *et al.*, 1998). The SM protein thus acts to create a cellular environment in which viral lytic (intronless) messages are preferentially expressed over cellular (intron-containing) messages. Recent studies of an SM-knockout virus confirm that the SM gene product is essential for efficient viral replication and virion production (Gruffat *et al.*, 2002a). Another recently described function of the SM protein is its ability to inhibit PKR activation (Poppers *et al.*, 2003), which appears to be distinct from its effect on RNA. PKR inhibition by SM would presumably allow the virus to escape the inhibitory effect of PKR activation on protein translation. In contrast, SM actually enhances the expression of STAT1 (Ruvolo *et al.*, 2003); it is as yet unclear how this activation benefits the virus.

Proteins that inhibit cellular apoptosis and immune evasion

EBV also encodes an early lytic gene product, BHRF1, which inhibits cellular apoptosis. BHRF1 is a homologue of the cellular anti-apoptosis gene, BCL-2, and like BCL-2 inhibits apoptosis in response to a number of different stimuli (Henderson *et al.*, 1993; Tarodi *et al.*, 1994). The ability of BHRF1 to prevent cellular apoptosis very likely increases the efficiency of lytic EBV viral replication by preventing the death of the host cell prior to the completion of replication.

The BARF1 early gene encodes a soluble receptor for colony-stimulating factor 1 (Strockbine *et al.*, 1998). BARF1 inhibits the differentiating and proliferative effects of this cytokine on monocytes/macrophages (Strockbine *et al.*, 1998), and decreases alpha-interferon secretion from monocytes/macrophages (Cohen and Lekstrom, 1999). Thus, BARF1 may be important for protecting the virus from antiviral effects mediated through monocytes and macrophages.

A viral kinase

The BGLF4 early gene encodes a viral kinase (EBV-PK) which is homologous to the UL97 gene product of cytomegalovirus. In addition to autophosphorylation, at least two other EBV proteins, BMRF1 and the EBNA Leader protein, are phosphorylated by the BGLF4 kinase (Kato *et al.*, 2001, 2003; Chen *et al.*, 2000; Gershburg and Pagano, 2002), although the effect of this phosphorylation on BMRF1 and EBNA Leader protein function is not currently defined. In addition, like the CMV (UL97) and HSV (UL13) homologues, BGLF4 also phosphorylates the cellular protein, translation elongation factor 1 delta (Kato *et al.*, 2001). To date the kinase motifs recognized by the BGLF4 and homologous proteins encoded by CMV and HSV appear to be similar to cdc2 kinase motifs (Kawaguchi *et al.*, 2003). Although the exact function of the BGLF4 kinase during lytic EBV replication has not yet been clearly defined, as is the case with the CMV (but not HSV) homologue, BGLF4 expression in cells results in phosphorylation of the antiviral nucleoside analogue, ganciclovir, converting it to the active form (Marschall *et al.*, 2002). Thus, ganciclovir (as well as acyclovir) can be used to inhibit lytic EBV replication.

Viral replication

Lytic EBV replication probably occurs through a rolling-circle mechanism and involves the formation of head-to-tail concatamers of the genome. Lytic EBV replication requires the lytic origin of replication (oriLyt) in cis, and the viral core replication proteins (BALF5, BMRF1, BBLF2, BBLF4, BSLF1, and BBLF2/3) in trans (Fixman *et al.*, 1992,

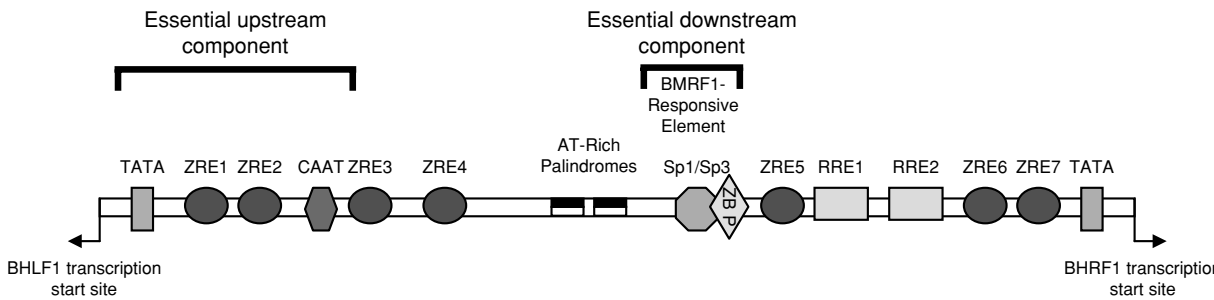

Fig. 25.8. *Cis*-acting elements of oriLyt. OriLyt overlaps the divergent promoters of two early genes, BHLF1 and BHRF1. The locations of BZLF1 (ZRE) and BRLF1 (RRE) binding sites, as well as the binding sites of cellular transcription factors ZBP-89, Sp1, and Sp3, are shown. The localization of two essential elements in oriLyt that are absolutely required for replication in indicated.

1995). Each of these core replication proteins is absolutely essential for the lytic form of replication, and a number of these core replication proteins directly interact with one another, presumably allowing formation of a large replication initiation complex (Daibata and Sairenji, 1993; Fujii *et al.*, 2000; Gao *et al.*, 1998; Liao *et al.*, 2001). In addition, the BZLF1 IE protein is absolutely required for replication, even when the core replication proteins are expressed under strong constitutive heterologous promoters. BZLF1 interacts directly with the core replication proteins, BMRF1 and BBLF4 (Zhang *et al.*, 1996; Liao *et al.*, 2001).

EBV DNA polymerase activity is mediated by the catalytic component of the enzyme (BALF5) in conjunction with the polymerase processivity factor (BMRF1). The catalytic component of the polymerase also has 3′-to 5′ proofreading exonuclease activity (Tsurumi *et al.*, 1993). The EBV polymerase, in contrast to cellular polymerase, is active in high-salt (100 mM ammonium sulfate) (Tsurumi *et al.*, 1993).

There are usually two copies of oriLyt in the EBV genome, although viral strains that contain only one copy of oriLyt (such as B95–8) seem to replicate equally well. The minimal oriLyt contains the divergent promoters of two EBV early genes, BHRF1 and BHLF1, as well as binding sites for the two EBV immediate-early proteins, BZLF1 and BRLF1 (Hammerschmidt and Sugden, 1988) (Fig. 25.8). Two domains of oriLyt are absolutely essential for replication. The "upstream " essential domain contains two binding sites for BZLF1, and BZLF1 binding to these sites is required for replication (Schepers *et al.*, 1993a,b, 1996). The "downstream" essential domain is a GC-rich sequence bound by the Sp1, Sp3 and ZBP-89 cellular transcription factors (Baumann *et al.*, 1999; Gruffat *et al.*, 1995; Schepers *et al.*, 1993b), and this region also mediates BMRF1 transcriptional effects (Zhang *et al.*, 1997). ZBP-89 binding appears to be particularly important for oriLyt replication, and ZBP-89 over-expression in cells enhances replication of an oriLyt containing plasmid (Baumann *et al.*, 1999). In addition, the ability of the downstream essential domain to form a triple helix DNA structure may be required for oriLyt replication (Portes-Sentis *et al.*, 1997).

Once replication is completed, the virus is clipped within the terminal repeat region of the genome into a linear, unit-length genome and then packaged into virion particles. The EBV terminal repeats are sufficient to allow packaging of plasmids in *cis* (Zimmermann and Hammerschmidt, 1995); however, the viral proteins that mediate the cleavage and packaging functions have not been identified.

Late viral gene regulation

Late EBV genes are traditionally defined as genes that are expressed after the onset of viral replication; expression of late genes is inhibited by agents that prevent viral DNA replication. Relatively little is known about the regulation of late EBV promoters. Unlike the early viral promoters, the late promoters do not usually contain BZLF1 or BRLF1 binding sites. Assuming that EBV late viral gene promoters are regulated in a similar manner as the late viral gene promoters in herpes simplex virus, it would be anticipated that EBV late promoters are primarily activated in cis by viral replication, and that this effect requires only a small region of the upstream promoter sequences. However, recent studies using the BZLF1- and BRLF1- knockout viruses have indicated that the requirement for viral replication may not be as absolute for late gene expression in gamma herpesviruses as it appears to be the case for alpha herpesviruses. For example, expression of the BRLF1 immediate-early protein in cells containing the BZLF1-knockout virus induces expression of a subset of "late" genes in the absence of viral replication (Feederle *et al.*, 2000). BRLF1 can also activate some late genes in Raji cells in the absence of viral replication (Ragoczy and Miller, 1999). In reporter gene assays, certain late promoters are

also activated in a replication-independent manner (Serio *et al.*, 1997, 1998).

Late viral proteins

Many late genes encode structural viral proteins, including the nucleocapsid proteins that make up the virion particle. The viral glycoproteins which mediate EBV binding and fusion to the cellular receptor and co-receptor (gp350/220, gp85, gp42, gp25) are also encoded by late genes and are further discussed in Chapter 23. In addition, EBV encodes at least one late viral gene product, vIL-10 (BCLF1), that is likely important for protecting the virus from the host immune response. The vIL-10 gene product is a homologue of cellular IL-10 (Hsu *et al.*, 1990) and shares its ability to potently repress the cytotoxic T-cell response. Therefore, secretion of viral IL-10 from lytically infected cells would be expected to protect the virus from this response (Salek-Ardakani *et al.*, 2002). In addition, as both cellular and viral IL-10 function as B-cell growth factors, the lytically infected pool of EBV-positive B cells could potentially support the growth of the latently infected pool through a paracrine mechanism involving the release of viral IL-10 (Miyazaki *et al.*, 1993; Stuart *et al.*, 1995; Rousset *et al.*, 1992). An EBV mutant virus deleted in the viral IL-10 gene was not found to be defective in B-cell transformation in vitro or lymphoma formation in mice (Swaminathan *et al.*, 1993); however, the lack of an obvious phenotype in this mutant virus may reflect the finding that BZLF1 induces cellular IL-10, and that the functions of cellular and viral IL-10 are redundant. Perhaps not surprisingly, one or more late viral gene products also appear to inhibit apoptosis, suggesting that prevention of cellular apoptosis is important for efficient EBV infection throughout the lytic replication cycle (Inman *et al.*, 2001). A late viral protein which has homology to the anti-apoptotic cellular Bcl-2 protein is encoded by the BALF1 gene, but whether this protein inhibits or activates apoptosis remains controversial (Marshall *et al.*, 1999; Bellows *et al.*, 2002).

Viral assembly and egress

At the end of the lytic replication cycle, the structural proteins involved in initiation of infection must be reassembled into the mature virion. Current models of herpesvirus assembly and egress propose that capsids are first built around a scaffold in the nucleus, that the scaffold is then lost to make room for packaging of the genome, and that the completed nucleocapsids, associated with at least some of the tegument proteins, bud through the inner nuclear membrane into the perinuclear space, acquiring a first envelope in the process. De-enveloped nucleocapsids are then delivered to the cytoplasm by fusion with the outer nuclear membrane or that of the endoplasmic reticulum. The final envelope and additional or different tegument proteins are acquired during rebudding into a cytoplasmic compartment, probably the trans-golgi network, that puts the virus back into a later stage of the exocytic pathway for release by exocytosis (for review see Mettenleiter, 2002). This model has been developed primarily from the study of alphaherpesviruses. However, the probability that EBV follows a similar envelopment, de-envelopment, reenvelopment pathway is supported by observations of the B-958 strain of EBV where higher levels of glycoprotein gB are seen in the nuclear membrane of cells producing virus than in mature enveloped virions and there is a reverse distribution of the major virion glycoprotein gp350/220 (Gong and Kieff, 1990). This is, in turn, dependent on a second soluble nuclear protein, BFLF2 (Gonella *et al.*, 2005; Lake and Hutt-Fletcher, 2004). These two proteins are conserved throughout the herpesvirus family and appear to have similar functions in each. In addition, however, the EBV glycoprotein gB also plays a role in nuclear egress (Herrold *et al.*, 1995). This function is not shared by the gB homologs of the alpha and betaherpesviruses. One possibility is that gB, known to be essential for glycoprotein-mediated cell fusion (Haan *et al.*, 2001), is required for the fusion of the first virus envelope with the outer nuclear membrane. Acquisition of the second and final envelope requires a complex of glycoproteins gN and gM (Lake and Hutt-Fletcher, 2000), but little more is known about the process aside from the provocative finding that loss of the transforming protein LMP1 severely impairs virus release (Ahsan *et al.*, 2005). These final and critical stages in EBV replication remain poorly understood.

Treatment of lytic EBV infection

Lytic EBV infection is inhibited by both acyclovir and ganciclovir (Lin and Machida, 1988; Datta *et al.*, 1980; Lin *et al.*, 1987; Meerbach *et al.*, 1998). The nucleoside analogues, acyclovir and ganciclovir, are phosphorylated to their active forms in lytically infected cells, presumably due to the effects of the two viral kinases, EBV thymidine kinase and BGLF4 (Lin *et al.*, 1986; Moore *et al.*, 2001; Marschall *et al.*, 2002). As acyclovir is less toxic than ganciclovir in patients, acyclovir is the preferred agent for treating the one disease that is definitely due to lytic EBV infection, oral hairy leukoplakia. The antiviral drug foscarnet, which inhibits the viral DNA polymerases of all known herpesviruses and effectively inhibits lytic EBV replication in vitro (Datta and

Hood, 1981), could also theoretically be used to treat lytic EBV infection in patients. However, as foscarnet is quite toxic, and there is no evidence to date that EBV strains resistant to acyclovir or ganciclovir are a clinical problem, foscarnet is not currently used to treat lytic EBV infection in patients. There is no convincing evidence that inhibition of lytic EBV infection in immunocompetent patients with infectious mononucleosis shortens or ameliorates this illness (Torre and Tambini, 1999). Whether acyclovir or ganciclovir treatment is useful in treating early polyclonal EBV-associated lymphoproliferative disease in post-transplant patients is somewhat controversial (Cohen, 2000; Oertel *et al.*, 1999). As lytic EBV gene products are not currently thought to be required for immortalization and growth of B cells in vitro (Feederle *et al.*, 2000), it is not clear that preventing this form of infection in vivo would slow the growth of EBV-immortalized B cells in patients. There is more convincing evidence suggesting that anti-viral prophylaxis reduces the subsequent development of EBV-associated lymphoproliferative disease in transplant recipients (Farmer *et al.*, 2002; Malouf *et al.*, 2002; Green *et al.*, 2001; Fong *et al.*, 2000; McDiarmid *et al.*, 1998; Darenkov *et al.*, 1997). In this case, inhibition of lytic EBV infection presumably reduces the pool of latently infected B cells, thereby decreasing the probability that one or more of these cells eventually becomes malignant.

Lytic induction as a strategy for treating EBV-positive tumors

Finally, the purposeful induction of lytic EBV infection in EBV-positive tumor cells is increasingly being explored as a potential way to selectively kill EBV-infected tumor cells (Gutierrez *et al.*, 1996; Israel and Kenney, 2003; Westphal *et al.*, 1999). Theoretically, EBV-positive tumors containing the latent forms of viral infection could be switched to the lytic form of infection by either inducing expression of the EBV immediate–early genes from the endogenous viral genome in tumors, or by using gene delivery methods to express either of the EBV immediate–early proteins in tumor cells. When adenovirus vectors expressing either the BZLF1 or BRLF1 gene products are injected directly into EBV-positive nasopharyngeal carcinoma tumors grown in nude mice, tumor growth is inhibited, whereas control adenovirus vectors have no effect (Feng *et al.*, 2002b). In addition, certain cytotoxic therapies, including some chemotherapy agents and gamma irradiation, have been found to induce lytic EBV gene transcription in at least a portion of tumor cells (Feng *et al.*, 2002a, 2004; Roychowdhury *et al.*, 2003; Westphal *et al.*, 2000). Lytic induction by cytotoxic agents is mediated through activation of the two EBV immediate-early promoters and requires the PI3 kinase, p38 kinase, and MAP kinase pathways (Feng *et al.*, 2002a, 2004). Specific transcription factor binding sites in both the BZLF1 promoter (ZI and ZII), and the BRLF1 promoter (EGR-1) are also required (Feng *et al.*, 2004). Agents that inhibit histone deacetylases (such as butyrate compounds) have also been shown to enhance the amount of lytic EBV infection in some mouse tumor models (Westphal *et al.*, 2000).

Lytic induction strategies are most effective for inhibiting tumor growth when combined with the antiviral drug, ganciclovir (Mentzer *et al.*, 1998; Feng *et al.*, 2002a, 2004; Faller *et al.*, 2001; Roychowdhury *et al.*, 2003; Westphal *et al.*, 2000). In cells containing the lytic (but not latent) type of EBV infection, virally encoded kinases (BGLF4 and the viral thymidine kinase) are expressed which phosphorylate the nucleoside analogue, ganciclovir, converting it to its active cytotoxic form (Moore *et al.*, 2001). Phosphorylated ganciclovir inhibits not only viral DNA replication, but also inhibits the host cell DNA replication, and is thus cytotoxic. Furthermore, phosphorylated ganciclovir can be transferred into nearby cells that are unable to phosphorylate ganciclovir (i.e., tumor cells with latent EBV infection), and thus induce "bystander" killing. As chemotherapy and irradiation induce lytic infection in only a portion of tumor cells, the combination of these agents with ganciclovir is much more effective than either agent alone for treating EBV-positive tumors in mouse models (Feng *et al.*, 2002a, 2004). Whether ganciclovir will be effective in combination with lytic induction strategies for treating EBV-positive human tumors is currently being investigated (Faller *et al.*, 2001; Mentzer *et al.*, 2001).

Unresolved issues for the future

The discovery in 1985 that BZLF1 activates lytic EBV expression in latently infected cells was a true milestone in our understanding of lytic EBV gene regulation. Since then, many further advances have been made. However, many questions remain. For example, numerous EBV-encoded microRNAs were recently discovered, including microRNAs which overlap the lytic BHRF1 (anti-apoptosis) and BALF5 (viral DNA polymerase) genes (Shen and Goodman, 2004; Pfeffer *et al.*, 2004) as well as multiple microRNAs located in the introns of the latent BART gene (Cai *et al.*, 2006). Since microRNAs generally promote gene silencing by targeting homologous mRNAs for degradation, the EBV-encoded microRNAs may serve to promote the latent form of viral infection. However, at this point relatively little is

known regarding the regulation of microRNA formation during EBV infection, and whether these microRNAs do indeed regulate viral gene expression. Furthermore, will EBV, like a growing list of other viruses, encode a mechanism for preventing the effect of host genome-derived, antiviral microRNAs?

We still know very little about the nature of the proteins comprising the viral tegument. Does EBV, like other herpesviruses, have a viral tegument protein which serves to transcriptionally activate the viral IE promoters during primary lytic infection? The availability of modern proteomic techniques should allow us to determine the cellular and viral protein composition of the virion, as well as how lytic EBV infection affects cellular proteins. A proteomic analysis of the virion particle was recently published (Johannsen *et al.*, 2004)

It remains unclear which viral proteins confer sensitivity to commonly used antiviral drugs, including acyclovir and ganciclovir. Are these drugs activated primarily by the viral thymidine kinase, or the viral protein kinase (BGLF4)? Alternatively, is the combination of both of these viral proteins required for nucleoside analogue activation in EBV-infected cells? Can we develop new drugs (potentially fatty acid synthase inhibitors) that would inhibit lytic EBV infection at its earliest step, i.e., expression of the viral immediate-early proteins. If we could completely prevent lytic EBV infection in patients (such as organ transplant recipients) who are highly prone to the development of EBV-associated malignancies, would this reduce the number of EBV-induced tumors?

These are only a few of the many questions that will need to be answered by future investigators. What remains certain is that EBV will remain an important and fascinating pathogen for many years to come.

Acknowledgment

Many thanks to Lindsey Hutt-Fletcher, who wrote the "Viral assembly and egress" section in this chapter.

Overview: goals of lytic replication

Herpesviruses are extremely successful pathogens that have coevolved with their mammalian hosts over the past 60–80 million years (McGeoch and Davison, 1999). This success likely is attributable to the ability of the Herpesviridae to establish lifelong latent infections of their host. Latently infected cells provide a perpetual reservoir from which progeny viruses can be amplified for dissemination within the host and transmission between hosts. Herpesvirologists have traditionally used the term "lytic reactivation" to describe the biological events that begin with emergence of a virus from latency and end with lysis of the host cell and release of progeny virions. Clinico-epidemiologic studies suggest that lytic reactivation of KSHV is an essential pathogenic step in multiple human diseases. The goal of this chapter is to review the host–virus interactions that are critical for regulating induction of KSHV from latency, subsequent progression through the lytic cycle, replication of the viral genome, and assembly of mature viral particles.

Lytic reactivation of KSHV is a critical pathogenic step in development of KS and other human diseases

Numerous epidemiologic studies unanimously agree that reactivation of KSHV from latency is a critical pathogenic step during the progression to KS. Serologic assays (Gao *et al.*, 1996a; Kedes *et al.*, 1996; Martin *et al.*, 1998; Simpson *et al.*, 1996) demonstrate that primary infection by KSHV typically occurs at least 10 years prior to clinically apparent KS in AIDS patients (Martin *et al.*, 1998). During progression of AIDS-KS, seroconversion precedes the first occurrence of detectable viral DNA in peripheral blood (Gao *et al.*, 1996b; Martin *et al.*, 1998; Moore *et al.*, 1996; Whitby *et al.*, 1995), and detection of viral DNA is associated with the appearance of new KS lesions (Cannon *et al.*, 2003). The incidence of KS is tenfold higher in KSHV seropositive patients who have PBMC viremia vs. those without virus in the peripheral blood (Engels *et al.*, 2003; Keller *et al.*, 2001; Moore *et al.*, 1996; Whitby *et al.*, 1995). Furthermore, following KS diagnosis, the amount of KSHV DNA in PBMCs increases with the increased severity of KS staging (Campbell *et al.*, 2000), while lower viral burden in the peripheral blood is associated with a more positive clinical prognosis (Quinlivan *et al.*, 2002). Individual studies of HIV-negative forms of KS (African, Classic or iatrogenic) also concur that KSHV reactivation precedes KS, and viral replication increases during the progression to more severe KS stages (Beyari *et al.*, 2003; Campbell *et al.*, 2003; Cattani *et al.*, 1999; Vitale *et al.*, 2000; Mantina *et al.*, 2001; Boneschi *et al.*, 2001). During KS development, the infection of endothelial cells in skin appears to temporally follow the rise in peripheral blood virus, suggesting that the dermal lymphatics are not a major reservoir for the virus prior to KS (discussed further below).

Lytic replication of KSHV has also been implicated in the pathogenesis of a number of Human diseases other than KS. In AIDS patients with multicentric Castleman's disease (MCD), KSHV viremia in PBMCs fluctuates over a 1 to 2 log range, with peaks corresponding to symptomatic episodes (Oksenhendler *et al.*, 2000; Grandadam *et al.*, 1997). In patients with hemophagocytic lymphohistiocytosis (HL), the peripheral blood load of KSHV is increased at least one order of magnitude during HL events, and frequently precedes these events (Fardet *et al.*, 2003). Methylation of the viral genome that represses the lytic cycle during latency seems to be relieved in patients with KS, MCD, or primary

effusion lymphoma (PEL; described below) (Chen *et al.*, 2001).

The successful treatment of KS patients with drugs that block herpesviral DNA replication suggests that ongoing viral replication is required not only for initiation of KS but for maintenance of the disease. Two such antivirals are: Ganciclovir, a nucleoside analogue that slows the elongation of nascent DNA chains by competitive inhibition of herpesviral DNA polymerase proteins (Field *et al.*, 1983), and Foscarnet, a pyrophosphate analogue that interferes with pyrophosphate exchange between the herpesviral polymerases and deoxynucleoside triphosphates (Wahren *et al.*, 1985). Both drugs reduce KSHV replication in PEL models of infection (Kedes and Ganem, 1997). Independent clinical studies have demonstrated that treatment of high-risk patients with either Ganciclovir (Martin *et al.*, 1999) or Foscarnet (Jones *et al.*, 1995) reduces KS risk, and both drugs slow KS progression if administered subsequent to diagnosis (Robles *et al.*, 1999). Ganciclovir and Foscarnet may cause regression of AIDS-KS without clearance of detectable KSHV from blood (Humphrey *et al.*, 1996), suggesting that viral persistence in the absence of lytic replication is not sufficient to promote KS; however, other treatments have been reported that lead to KS regression accompanied by clearance of peripheral blood viremia (Monini *et al.*, 2001). MCD has also been treated successfully with Ganciclovir, with accompanying reductions in KSHV viremia (Casper *et al.*, 2004a).

The immune system tempers lytic reactivation of KSHV and KS development

The inverse relationship between immunocompetence and the development of KS is most clearly observed in studies of solid organ transplant recipients. More than 50% of KSHV-positive, immunosuppressed organ recipients develop tumors (Farge *et al.*, 1999), and post-transplant KS typically regresses upon cessation of immunosuppression (for review see Hengge *et al.*, 2002). The majority of post-transplant KS patients are KSHV seropositive prior to transplantation, suggesting that reactivation of latent virus is etiologically responsible for the disease (Weigert *et al.*, 2004; Parravicini *et al.*, 1997; Cattani *et al.*, 2001; Andreoni *et al.*, 2001).

Similarly, AIDS-related immunosuppression appears to be a key facet of the contribution of HIV coinfection to KS development and progression. Although KSHV prevalence was 24.6% in 1978 prior to the emergence of HIV infection in San Francisco (Osmond *et al.*, 2002), KS incidence remained low until the AIDS epidemic took hold (Eltom *et al.*, 2002). Detection of KSHV DNA increases, and KS severity worsens, as CD4+ cell counts drop (Keller *et al.*, 2001; Martin, *et al.*, 1998; Min and Katzenstein, 1999; Tedeschi *et al.*, 2001; Whitby *et al.*, 1995). T-cell proliferative responses to KSHV are also reduced, in HIV-1+ and not HIV-1-men and may decrease prior to reduction in CD4+ cell numbers (Strickler *et al.*, 1999). Independent of CD4+ cell count (or HIV-1 infection), antibodies that neutralize KSHV infection are also reduced in KSHV+ people who have KS, as compared to those who are KSHV+ but do not have KS (Kimball *et al.*, 2004). Immune suppression also appears to play a critical role in development of Classic KS (Iscovich *et al.*, 2000; Brenner *et al.*, 2002); however, such patients may live many decades with latent KSHV before KS strikes (if at all) (Cerimele *et al.*, 2000). For example, 13.2% of Sardinian (Italian) children between the ages of 6 and 14 were seropositive for KSHV (Serraino *et al.*, 2000), yet Classic KS is associated with advanced age, with the highest risk for those at least 50 years old (Santarelli *et al.*, 2001).

Immune restoration in AIDS patients treated with highly active antiretroviral therapy (HAART) also implicates the control of KSHV replication by the immune system as a key factor in KS incidence. The introduction of HAART has resulted in recent annual declines of KS of 8.8% to 39% in the USA and Europe (Jones *et al.*, 2000; Mocroft *et al.*, 2004). HAART also decreases progression of AIDS-KS to visceral disease (Nasti *et al.*, 2003), and increases the median time of survival (Tam *et al.*, 2002). During successful HAART, regression of KS and decreasing KSHV detection is accompanied by restoration of numbers and functions of CD4+ cells (Casper *et al.*, 2004b; Lebbe *et al.*, 1998; Mocroft *et al.*, 2004; Wilkinson *et al.*, 2002; Jones *et al.*, 2000; Cattelan *et al.*, 2001; Pellet *et al.*, 2001), CD8+ cells (Bourboulia *et al.*, 2004; Wilkinson *et al.*, 2002), or NK cells (Sirianni *et al.*, 2002). Conversely, HAART non-responders fail to clear KSHV from PBMCs (Sirianni *et al.*, 2002; Cattelan *et al.*, 2001).

However, the success of HAART in ameliorating KS likely is attributable not only to immune restoration, but also to the concomitant reduction in HIV-1 load (Cattelan *et al.*, 2001; Lebbe *et al.*, 1998; Wilkinson *et al.*, 2002). Many studies have documented an increased risk of KS (Cannon *et al.*, 2001; Jacobson *et al.*, 2000) and increased detection of KSHV viremia (Gill *et al.*, 2002; Mantina *et al.*, 2001; Tedeschi *et al.*, 2001) with higher viral loads of HIV-1. Some HAART-treated populations show regression of AIDS-KS that corresponds with decreased HIV-1 loads independently of CD4+ levels (Gill *et al.*, 2002). HIV-1-infected cells produce a soluble factor that induces reactivation of latent KSHV in culture (Varthakavi *et al.*, 1999; Mercader *et al.*, 2000), and

HIV-1 infection of cultured PEL cells also reactivates KSHV (Merat *et al.*, 2002; Varthakavi *et al.*, 1999; Huang *et al.*, 2001). The HIV-1 Tat and Vpr proteins can independently promote lytic cycle induction and replication of KSHV in culture (Huang *et al.*, 2001; Harrington *et al.*, 1997; Merat *et al.*, 2002). HIV protease inhibitors may also block KS independently of the immune system by inhibiting KS cell invasion of the extracellular matrix, in part by blocking matrix metalloproteinase-2 activity (Sgadari *et al.*, 2002).

MHV-68 is a model for immune control of gamma-herpesvirus reactivation from latency

There is currently no small animal model for KSHV infection that recapitulates KS, so it is not possible to scientifically test the host immune response to KSHV infection and the pathogenic consequences in a disease-specific fashion. However, murine gammaherpesvirus (MHV)-68 provides the most compelling experimental evidence of the requirement for a functioning immune system in controlling gammaherpesviral replication, reactivation, and pathogenesis. MHV-68 shares extensive colinearity and conserves many genes with KSHV (Virgin *et al.*, 1997). Intranasal infection of immunocompetent mice leads to primary replicaton in alveolar epithelial cells, followed by establishment of latency in splenic B-cells (Sunil-Chandra *et al.*, 1992a,b). The B-cell reservoir for MHV-68 is CD19+ (Weck *et al.*, 1999a), as is a reservoir of KSHV infection (Dittmer *et al.*, 1999; Ambroziak *et al.*, 1995). A small fraction of latently infected immunocompetent mice proceed to develop lymphoproliferative disease (LPD), but the incidence of LPD can be strongly amplified by treatment of the mice with cyclosporine A (Sunil-Chandra *et al.*, 1994), a calcineurin inhibitor commonly used in humans as an immunosuppressant to prevent rejection of solid organ transplants (for review see Kaufman *et al.*, 2004). This observation has provided the basis for experimental evaluation of MHV-68 pathogenesis in mice with underlying immunodeficiencies generated by various gene-specific knockouts of critical immune effectors.

Mice from many of the respective immunodeficient lines, notably type I interferon null mice (Weck *et al.*, 1997), die during primary, acute MHV-68 infection, before pathogenic analyses of latency and reactivation can be assessed (for review see Simas and Efstathiou, 1998; Speck and Virgin, 1999). However, in mouse lines that do not succumb to the initial viral challenge, both cellular and humoral immunity have been implicated in controlling various characteristics of MHV-68 latency and reactivation. In CD8+ deficient mice, the pool of latently infected cells in the spleen and peritoneum is enlarged, and reactivation efficiency is increased (Tibbetts *et al.*, 2002; Weck *et al.*, 1996; Cardin *et al.*, 1996). Among effector molecules that can be produced by CD8+ T cells, IFNγ and perforin control reactivation efficiency, and the number of latently infected cells, in the peritoneum and in the spleen, respectively (Tibbetts *et al.*, 2002). In mice deficient for major histocompatibility class (MHC) II, MHV-68 establishes a progressive, productive infection, suggesting that CD4+ cells may steer the early infection towards latency (Cardin *et al.*, 1996). Repression of latency can be rescued in this model by treatment of mice with an agonistic antibody to CD40, whose ligand is normally expressed by CD4+ cells in providing help to the antiviral CD8+ cytolytic function (Sarawar *et al.*, 2001). CD4+ cells can also function later during MHV-68 pathogenesis to cause regression of MHV-68 induced B-cell tumors when prestimulated and adoptively transferred to nude mice (Robertson *et al.*, 2001).

Mice that are B-cell deficient as a result of the μ-immunoglobulin knockout (μ-MT) can nonetheless be infected by MHV-68, with latency established most prominently in non-B-cells in the peritoneum (Weck *et al.*, 1999b). In this model, the virus reactivates more efficiently than in healthy mice, and sustains reactivation for greater than 100 days following initial infection, escaping the control of reactivation that normally occurs in healthy mice at 3–4 weeks postinfection (Stewart *et al.*, 1998; Weck *et al.*, 1996, 1999b). The ability of MHV-68 to establish latency in B-cell-depleted mice led to the discovery of a second major reservoir for the virus in macrophages, and therefore to the suggestion that bone marrow may be a source of latently infected macrophages continually available to replenish the periphery (Weck *et al.*, 1999b).

The humoral response to MHV-68 infection also influences latency and reactivation of the virus. CD28-null mice have normal levels of CD4+ and CD8+ T-cells, and B-cells, but their humoral immunity is deficient due to defective T/B-cell collaboration (Shahinian *et al.*, 1993). T-cell depletion by injection of anti-T-cell antibodies in these mice results in reactivation of latent MHV-68, which can be prevented by the prior passive transfer of antiviral immune serum (Kim *et al.*, 2002). In B-cell deficient mice, passive transfer of antilytic cycle antibody, but not antilatent cycle antibody, reduces the frequency of cells harboring latent virus, and the frequency of lytic reactivation of the virus (Gangappa *et al.*, 2002). Combined with the finding that the antiviral drug cidofavir also reduces the frequency of latently infected cells, this suggests that lytic reactivation is required for maintenance of viral persistence (Gangappa *et al.*, 2002).

Experimental infection by MHV-68 has also proven powerful for differentiation of true latent infection from chronic/persistent infection, a distinction that is very difficult to ascertain in natural Human infections by gammaherpesviruses. MHV-68-specific immunoglobulin (Ig) G remains elevated after peaking 2 weeks following infection (Stevenson and Doherty, 1998), perhaps as a result of intermittent reactivation of latent virus (Simas *et al.*, 1999). A similar elevation of virus-specific antibodies has been described for KSHV that is sustained for many years following seroconversion in HIV+ and HIV− men (Gao *et al.*, 1996a; Biggar *et al.*, 2003), suggesting that intermittent reactivation from latency, or persistent replication of KSHV, may occur in certain hosts. Chronic replication of MHV-68 primarily leads to smooth muscle infection of large vessels and arteritis, which occurs with different frequencies in mice lacking an interferon gamma response (type II interferon), functional B-cells, functional CD4+ cells, or MHC II (Dal Canto *et al.*, 2002; Weck *et al.*, 1997).

Sites of latency and reservoirs for viral amplification in vivo

All of the gammaherpesviruses can infect lymphoid cells, and all can produce disease in that lineage. KSHV can also establish latency in non-lymphoid cells, but each site appears to make unique contributions to KSHV pathogenesis, and not all sites appear to be significant long-term reservoirs of amplifiable virus.

As described earlier in this chapter, after a KSHV-infected individual seroconverts, the titer of viral DNA in peripheral blood varies in direct proportion to the speed of progress to KS and severity of subsequent disease. The peripheral blood reservoir for KSHV has been unanimously identified as CD19+ B-cells, both prior to, or during, KS and in MCD patients. (Ambroziak *et al.*, 1995; Bigoni *et al.*, 1996; Blackbourn *et al.*, 1997; Harrington *et al.*, 1996; Kikuta *et al.*, 1997; Whitby *et al.*, 1995). Infected B-cells have also been localized to lymph nodes (Dupin *et al.*, 1999; Schalling *et al.*, 1995), and can support both latent and lytic gene expression (Polstra *et al.*, 2003). Virus has also occasionally been detected in peripheral T-cells and other monocytes (Blasig *et al.*, 1997; Harrington *et al.*, 1996; Kikuta *et al.*, 1997; Sirianni *et al.*, 1997), and monocytes can maintain the viral infection if cultured in vitro in the presence of inflammatory cytokines (Monini *et al.*, 1999b). CD19 negative, cultured PEL specimens also support latent and lytic infection; moreover, PEL cells release mature virus that can infect primary CD19+ cells in culture (Renne *et al.*, 1998), and that can establish long-term latency in CD19+ B-cells in human thymus/liver (thy/liv) tissue implanted into mice with severe-combined immunodeficiency (SCID) (Dittmer *et al.*, 1999). Thus B-cells are regarded as one site of long-term KSHV latency that can serve as a reservoir of virus for subsequent dissemination throughout the body.

Endothelial cells are a second site of latency for KSHV, and are associated with a much higher frequency of pathology than other cells infected by the virus. In KS tumors, the KSHV-infected cell is a CD34+ endothelial cell with characteristic spindloid morphology (Boshoff *et al.*, 1995; Staskus *et al.*, 1997). However, endothelial cells do not appear to be a long-term latent reservoir for the virus that can provide a significant source of progeny virions. KSHV DNA is infrequently detected in non-diseased skin of KS patients (Nuovo and Nuovo, 2001; Boshoff *et al.*, 1995; Chang *et al.*, 1994; Moore and Chang, 1995) and the virus is usually not detected in skin following regression of lesions (Aluigi *et al.*, 1996; Ambroziak *et al.*, 1995). Furthermore, the number of viral copies per cell appears to be at least one order of magnitude lower in endothelial cells than in other latently infected cells (Boshoff *et al.*, 1995; Chang *et al.*, 1994). Although the dermal endothelium is probably not a long-term latent reservoir, infected spindle cells may release progeny virus that can subsequently infect local keratinocytes and eccrine epithelium in the tumor (Reed *et al.*, 1998).

A significant question for KSHV reactivation and pathogenesis concerns the mechanism by which the virus disseminates from the peripheral blood reservoir to sites of KS development. A strong argument for direct seeding of putative tumor sites by infected B-cells comes from tissue culture studies that show: (i) promotion of specific arrest and *trans*endothelial migration of KSHV-infected B-cells in response to the chemoattractant stromal derived factor (SDF)-1 (Yao *et al.*, 2003), and (ii) transmission of virus from stimulated B (PEL) cells to primary endothelial cells (Sakurada *et al.*, 2001). However, KSHV-infected mononuclear cells have only been detected in some (Blasig *et al.*, 1997; Aluigi *et al.*, 1996; Reed *et al.*, 1998; Sirianni *et al.*, 1998) but not all (Pyakurel *et al.*, 2004; Staskus *et al.*, 1997), histopathologic samples of KS tissue. Furthermore, among the studies that have detected KSHV-infected mononuclear cells in tumors, the immunophenotype of the cells has been described variably as either lymphocytic (Reed *et al.*, 1998), or monocytic/macrophagic (Blasig *et al.*, 1997; Pyakurel *et al.*, 2004; Sirianni *et al.*, 1998). Therefore, although early KS lesions contain readily detectible lymphocytic and plasma cell infiltrates (Niedt *et al.*, 1990), the peripheral blood reservoir of the virus may not directly, or continually, seed the tumor. An alternative mechanism may be that KSHV-infected, CD34+ spindle cells circulating in

peripheral blood (Henry *et al.*, 1999; Browning *et al.*, 1994; Sirianni *et al.*, 1997, 1998) may be endothelial precursor cells (Asahara *et al.*, 1997) that subsequently populate the tumors.

While the peripheral blood probably maintains the long-term cellular reservoir of KSHV that can serve as a source of progeny virus for dissemination within an individual, a second, oral/salivary reservoir appears to be critical for producing high titer virus that can be transmitted between individuals. In fact, the titer in saliva is higher than in PBMCs (LaDuca *et al.*, 1998; Koelle *et al.*, 1997; Pauk *et al.*, 2000), and viral DNA can be detected in saliva in individuals with undetectable PBMC virus (Blackbourn *et al.*, 1998). The virus appears to maintain latency in oral epithelium (Triantos *et al.*, 2004; Pauk *et al.*, 2000), but significant amounts of encapsidated KSHV can be found free of cells in salivary fluid (Vieira *et al.*, 1997; Blackbourn *et al.*, 1998), and are transmissible to cultured cells (Duus *et al.*, 2004; Vieira *et al.*, 1997). Thus, reactivation of virus from latently infected cells in the oral cavity may provide the natural source of KSHV for inter-personal transmission. However, direct transmission of cells infected by KSHV cannot be excluded, as this mechanism has been reported in some cases of post-transplant KS (Barozzi *et al.*, 2003; Luppi *et al.*, 2003).

Primary effusion lymphoma (PEL) cells: a tissue culture model for KSHV latency and reactivation

Within the family *Herpesviridae*, the most robust systems for understanding molecular events in latency and reactivation are tissue culture models of infection by the gamma-2-herpesviruses like KSHV (Cesarman *et al.*, 1995, 1996; Nador *et al.*, 1996; Renne *et al.*, 1996a,b). The first model systems for understanding KSHV latency and reactivation have been cells cultured from clinical specimens of primary effusion lymphoma (PEL). PEL is the only B-cell lymphoma conclusively associated with KSHV infection (Drexler *et al.*, 1998; Cesarman *et al.*, 1995; Uphoff *et al.*, 1998), and is pathologically and phenotypically unique among all non-Hodgkin's lymphomas (Nador *et al.*, 1996). Comparison of all HIV-associated lymphomas shows that PELs are BCL-6-/MUM1+/syn-1+, an immunophenotype that is unique to PEL among all serous effusions (Carbone *et al.*, 2000, 2001) but is shared with EBV-transformed cells that express LMP-1 (Carbone *et al.*, 2001).

Cytogenetic and gene expression analyses classify PEL cells as preterminally differentiated, postgerminal center B-cells, with overall similarities to plasma cells. Although PELs are immunophenotypically non-B/non-T-cells, their B-cell origin is revealed by clonal rearrangements of heavy and light chain immunoglobulin (Ig) genes that contain mutations suggestive of antigen selection (Fais *et al.*, 1999). Genome-wide expression profiling using microarrays has confirmed that PELs cluster phenotypically with transformed plasma cells, EBV lymphoblastoid cell lines, and multiple myeloma cells, but nonetheless remain a distinct NHL subset (Jenner *et al.*, 2003; Klein *et al.*, 2003). PEL cell lines are transformed (Picchio *et al.*, 1997; Strauchen *et al.*, 1996; Gaidano *et al.*, 1996; Boshoff *et al.*, 1998), and most PELs are coinfected with KSHV and EBV (Drexler *et al.*, 1998); however, the existence of EBV-negative PEL lines suggests that KSHV infection is sufficient for transformation of B cells. In fact, the cellular gene expression profiles of PELs singly infected with KSHV, or doubly infected with KSHV and EBV, are indistinguishable (Jenner *et al.*, 2003; Klein *et al.*, 2003).

During normal maintenance and passage, the PEL cells are infected uniformly with 40–150 episomal copies of clonal virus per cell genome (a characteristic of each line (for review see Drexler *et al.*, 1998), with the virus remaining circularized and nuclear (Renne *et al.*, 1996a). Latency is distinguished by highly restricted viral gene expression and lack of mature virus production (although a characteristic 1–5% of each cell line's population undergoes spontaneous reactivation). Upon treatment with various stimuli, including phorbol ester (i.e., TPA) or histone deacetylase inhibitors (i.e., sodium butyrate or trichostatin A), viral lytic genes are induced in a cascade fashion, leading to viral replication and progeny virus production (Renne *et al.*, 1996a,b; Zhong *et al.*, 1996; Miller *et al.*, 1997). As in the other gamma-herpesviruses, viral DNA is packaged into enveloped virions as a 160–170 kilo-basepair (kbp) linear molecule (Renne *et al.*, 1996a).

Kinetic classification of KHSV lytic gene expression

In tissue culture and clinical samples, KSHV exhibits both latent (non-productive) and lytic (productive) replication, which are characterized by virtually distinct gene expression programs (Renne *et al.*, 1996b; Zhong *et al.*, 1996; Miller *et al.*, 1997; Staskus *et al.*, 1997). The formal classification of the kinetics of expression of the lytic genes following treatment of latent virus with inducing agents has been defined for immediate–early (IE) and late genes.

Transcription of IE genes requires no previous protein expression, as evidenced by resistance to protein synthesis inhibitors like cycloheximide (CHX). In herpesviral reactivation systems, the IE genes are the prime candidates to

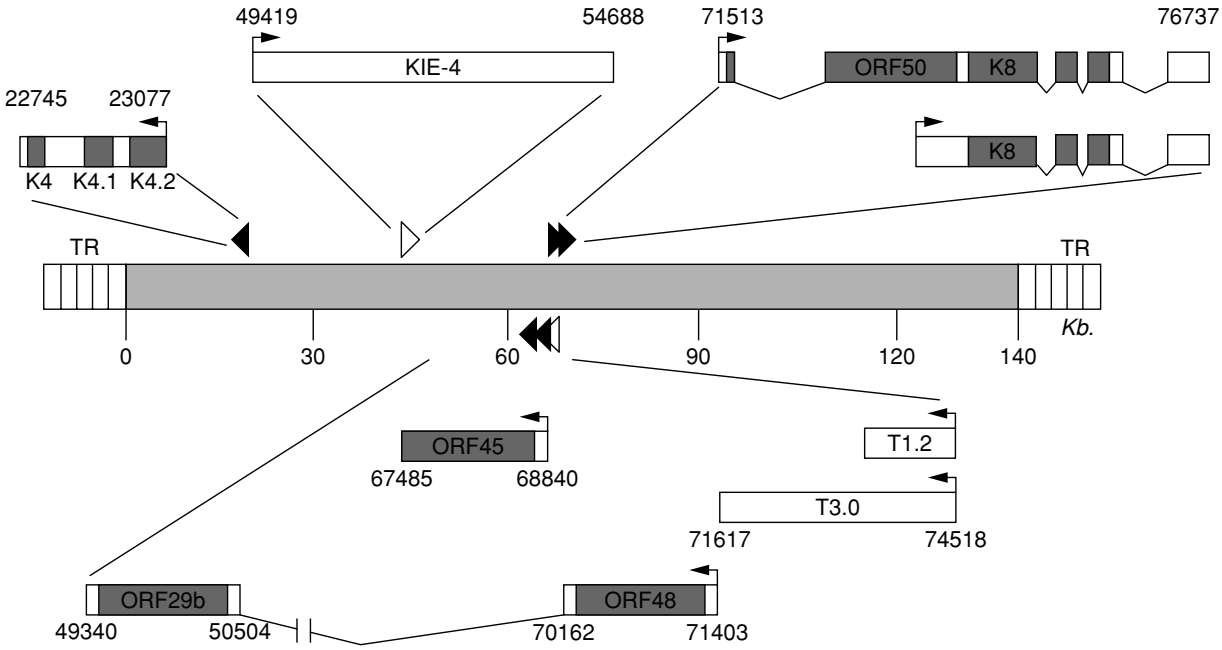

Fig. 26.1. The immediate–early (IE) loci of KSHV. This schematic represents the genome of KSHV. Arrowheads depict the relative locations and directions of IE gene expression. Each is expanded to show the details of transcript architecture. Each box represents a transcript, shading indicates open reading frames, non-shaded indicates untranslated regions, lines indicate introns. Names of each transcript and corresponding ORF are indicated. K8 is expressed in alternatively spliced, mono- and bi-cistronic transcripts; only one of K8's alternatively spliced products is shown here, for simplicity. "TR" = terminal repeat of virus. Numbering refers to nucleotide position on genome (as in Russo *et al.*, 1996). References can be found in the text.

function as master controllers of the latent-to-lytic switch, a characteristic conserved in KSHV (discussed below). Eight distinct transcripts that are expressed in an IE fashion during KSHV reactivation encode ORF50/K8α/K8.2, K8α, ORF45, K4.2/K4.1/K4, ORF48 and ORF29b, K3 and ORF70, and two with no apparent coding potential (Fig. 26.1) (Wang *et al.*, 2004b; Zhu *et al.*, 1999a; Saveliev *et al.*, 2002; Rimessi *et al.*, 2001). Transcription of the L genes requires prior viral DNA replication, and the L transcriptome has been defined using the replication inhibitor cidofovir (CDV), a nucleoside analog (Lu *et al.*, 2004). The study showed that expression of all of the known virion structural genes was inhibited by prior treatment of PEL cells with CDV. However, only about 25% of the viral membrane glycoproteins were inhibited by CDV. Most of the lytic cycle homologs of cellular genes were insensitive to CDV, except for the viral interferon regulatory factors vIRF-2 and vIRF-3/LANA2, viral macrophage inflammatory protein (vMIP)-III, and the viral FLICE inhibitory protein (vFLIP). Also insensitive to CDV were the IE transactivators and all of the known viral replication proteins. By default, lytic genes that have not been classified as IE or L fall into the delayed early (DE) class.

Genome-wide approaches have been used to classify KSHV transcription based on (i) quantity of expression in the presence or absence of TPA (Sarid *et al.*, 1998), or (ii) time of first appearance and peak level of expression (Fakhari and Dittmer, 2002; Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001). These studies have generally agreed that (i) the latent genes are typically expressed regardless of TPA addition, (ii) putative regulatory genes are expressed weakly prior to TPA addition, but strongly within 10 hours postinduction (pi), (iii) genes for putative DNA repair and nucleotide metabolism proteins are only expressed 10–24 hours pi, and (iv) genes for virion formation and structural proteins are expressed 48–72 hours pi. The mechanisms regulating coordinate induction of expression of most of the lytic genes during reactivation have not been evaluated in a systematic fashion.

ORF50/Rta is the viral lytic switch protein

Among a number of candidate KSHV genes, only transfection of Rta (the product of the ORF50 gene) can induce lytic reactivation of the virus in PEL cells, as detected by

Northern and Western blotting, and immunofluorescence (Lukac *et al.*, 1998; Sun *et al.*, 1998). Induction of the ORF59 (DE) and K8.1 (L) proteins by Rta transfection is quantitatively equivalent to TPA treatment, and K8.1 induction is blocked by PFA treatment, suggesting that Rta induces authentic viral DNA replication (Lukac *et al.*, 1998; Polson *et al.*, 2001). Productive release of encapsidated KSHV virions in response to forced expression of Rta confirms that Rta induces the entire lytic gene cascade (Gradoville *et al.*, 2000; Nakamura *et al.*, 2003).

ORF50 encodes a 691 amino acid protein that is a direct and selective transcriptional transactivator of DE promoters in uninfected cells (Lukac *et al.*, 1998). Rta shares with its homologues in the gamma-herpesviruses two regions of relatively high primary amino acid homology, in the far N- and C-termini (Lukac *et al.*, 1998). The N-terminal 272 amino acids can bind independently to KSHV promoter DNA (Lukac *et al.*, 2001; Song *et al.*, 2002), and the C-terminus is a potent transactivator when targeted to promoters by fusion to heterologous DNA binding domains (Lukac *et al.*, 1999; Seaman *et al.*, 1999; Wang *et al.*, 2001). Deletion of the activation domain generates a mutant of Rta that forms mixed multimers with wild-type Rta and functions as an ORF50-specific dominant negative inhibitor of transactivation (Lukac *et al.*, 1999). Expression of this dominant negative Rta mutant in PEL cells suppresses viral reactivation induced by TPA, sodium butyrate, and ionomycin (Lukac *et al.*, 1999). Therefore, transcriptional transactivation by Rta is both sufficient and necessary for viral reactivation, and multiple reactivation signals that function using different biochemical mechanisms all converge at ORF50/Rta to successfully reactivate the virus (Lukac *et al.*, 1999).

ORF50/Rta binds directly to the DNA of several KSHV promoters (Fig. 26.2) with varying affinity and sequence-specificity. The relative binding strengths for Rta to these promoter elements have been estimated as PAN>kaposin>ORF57>vIL-6 (Song *et al.*, 2003), with a dissociation constant (K_d) for binding to the PAN element in the nanomolar range (Song *et al.*, 2002). The PAN and kaposin promoters share a 16-bp core sequence that is also found in *ori-Lyt* (L) (Wang *et al.*, 2004b; Kirshner *et al.*, 2000; Song *et al.*, 2002; Chang *et al.*, 2002), but differs significantly from a second DNA element shared by the ORF57/Mta and K8 promoters (Lukac *et al.*, 2001), and a third element in the viral IL-6 promoter (Deng *et al.*, 2002).

However, direct DNA binding by Rta to all of these promoters is insufficient to specify them as targets for transactivation; instead, Rta requires combinatorial interactions with cellular proteins. Scanning mutagenesis of the Rta-responsive elements of both the PAN and Mta promoters demonstrated incomplete concordance between DNA binding by Rta and transactivation, i.e., some mutants that failed to bind Rta remained strongly transactivated by Rta, and vice versa (Song *et al.*, 2002; Lukac *et al.*, 2001). Furthermore, fusion of Rta's minimal DNA binding domain (Song *et al.*, 2002; Lukac *et al.*, 2001) to a heterologous activation domain is insufficient to transactivate the PAN promoter in vivo, but requires additional Rta amino acids that likely interact with heterologous proteins (Chang *et al.*, 2002).

To this end, Rta transactivation requires cooperative interactions with various cellular transcription factors (Fig. 26.2). Genetic and biochemical experiments demonstrate that *trans*-activation of the ORF57/Mta promoter by Rta requires a direct interaction with the sequence-specific DNA binding protein RBP-Jk (aka CBF-1 and CSL). RBP-Jk-binding sites also mediate Rta-driven activation of the promoters of KSHV ORF6/single-stranded DNA binding (SSB) protein, the viral GPCR, and of Rta itself (auto-activation) (Liang and Ganem, 2003, 2004; Liang *et al.*, 2002). A central regulatory role of the RBP-Jk/Rta interaction was demonstrated by the inhibition of KSHV reactivation in murine embryo fibroblasts null for RBP-Jk (Liang and Ganem, 2003). Rta promotes DNA binding of RBP-Jk, a mechanism that is fundamentally different from that established for the RBP-Jk-activating proteins, Notch intracellular domain (NICD) and EBV EBNA-2 (Carroll *et al.*, 2006). Cooperation between RBP-Jk and Rta requires intact DNA binding sites for both proteins, and trimeric complex formation between the three molecules in vitro. In infected cells, chromatin immunoprecipitations reveal that RBP-Jk is virtually undetectable on the viral ORF57, K-bZIP, vGPCR, and cellular IL-6 and hairy/enhancer of split (HES)-1 promoters (Carroll *et al.*, 2006). These data provide one explanation for the ability of KSHV to establish latency in RBP-Jk null cells (Liang and Ganem, 2003). However, during viral reactivation. RBP-Jk is significantly enriched on all of those promoters in an Rta-dependent fashion. Accordingly, Rta, but not EBNA2 and NICD, reactivates the complete viral lytic cycle. KSHV might have evolved this mechanism to ensure that only Rta efficiently reactivates the virus in environments of consititutive Notch activity.

Rta also participates in complex, combinatorial interactions with the cellular protein C/EBPα for transient transactivation of various KSHV promoters (Fig. 26.2). Rta and C/EBPα cooperate to activate transcription of the K8, ORF57/Mta, ORF50/Rta, and nut-1/PAN promoters, each of which contains at least one binding site for C/EBPα (Wang *et al.*, 2003a,b). A direct interaction between C/EBPα and Rta is required for transcriptional cooperation (Wang

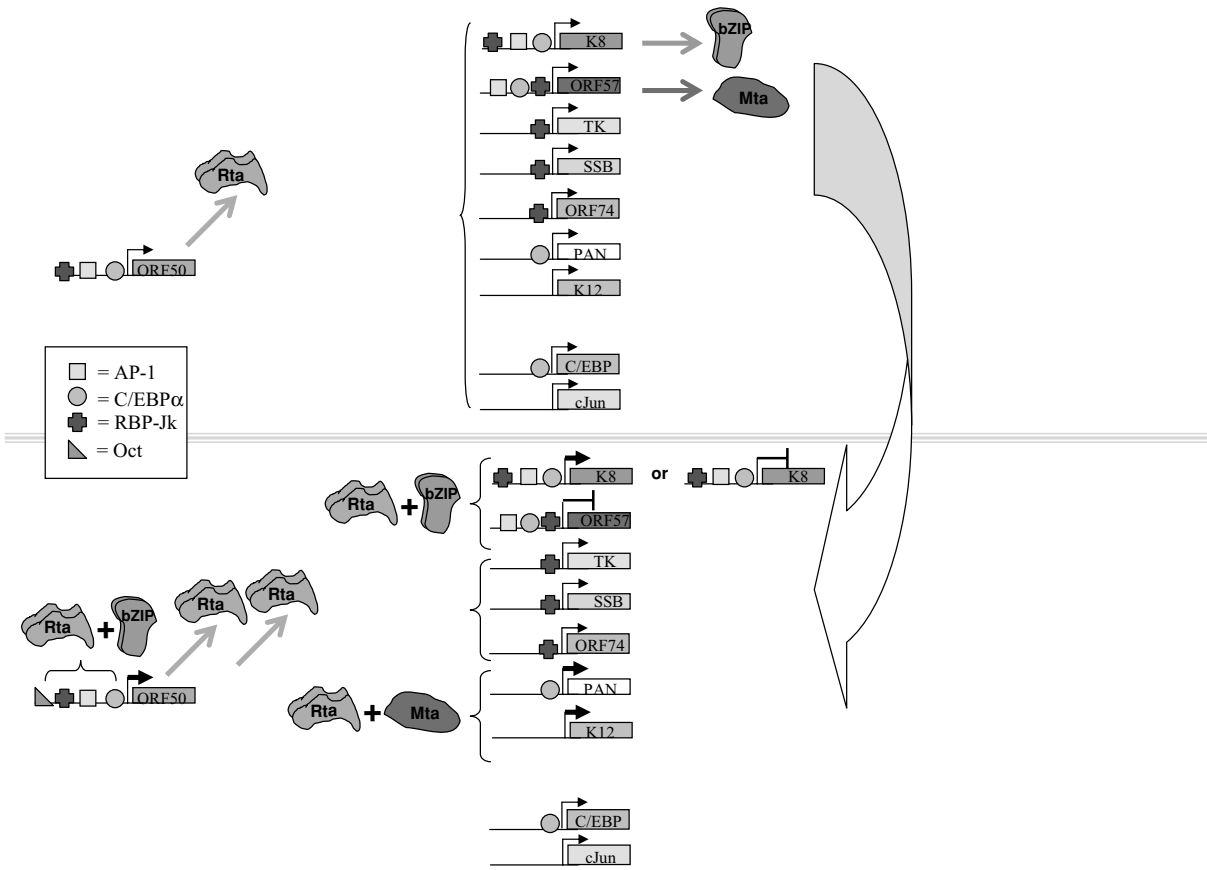

Fig. 26.2. Rta is the KSHV lytic switch protein. The viral and cellular promoters transactivated by Rta. *Cis* elements are indicated by symbols placed on each promoter, and *trans*-acting factors are indicated by the colored arrows. The size of the arrow at the transcriptional start site reflects relative amounts of transcription. See text for details.

et al., 2003a,b), and the C/EBPα binding sites overlap the Rta binding sites in the Mta and K8 promoters (Lukac *et al.*, 2001). In infected PEL cells, C/EBPα and Rta are found associated with the Rta, PAN, or Mta promoters only following viral reactivation (Wang *et al.*, 2003b); immunodepletion of C/EBPα prior to chromatin immunoprecipitation (ChIP) eliminates Rta's association with the Rta promoter, and reduces its association with the K8 promoter. Data also suggest that Rta cooperates with C/EBPα in auto-activation of the C/EBPα promoter, such that Rta and C/EBPα mutually participate in a positive autoregulatory loop during reactivation of KSHV from latency (Wang *et al.*, 2003a,b).

Rta and the cellular protein interferon regulatory factor (IRF)-7 participate in another regulatory loop. An IRF-7 binding site overlaps the Rta-responsive element in the ORF57 promoter, and IRF-7 inhibits Rta transactivation by competitive DNA binding to the element (Wang *et al.*, 2005). Rta contains intrinsic E3 ubiquitin ligase activity that targets IRF-7 for degradation by the host proteasome (Yu *et al.*, 2005). Interestingly, Rta also autoregulates its own degradation by self-ubiquitination (Yu *et al.*, 2005).

Rta also cooperates with other cellular proteins in promoter association and transactivation. cJun and cFos interact directly with each other and Rta, and all three cooperate to transiently transactivate the K8, Mta, and Rta promoters in uninfected cells (Wang *et al.*, 2004). Exogenous expression of Rta induces expression of cJun in BCBL-1 cells, and cJun coprecipitates with the K8, Mta, and Rta promoters in TPA-treated, but not untreated, BCBL-1 cells (Wang *et al.*, 2004). Rta and cJun may also cooperate through a mutual interaction with the coactivator CBP (Gwack *et al.*, 2001a). Rta can also be directed to autoactivate its own promoter through interactions with the cellular protein Octamer-1, but not Octamer-2, and an Octamer DNA element near the ORF50 transcription start site (Sakakibara *et al.*, 2001). Activation of the K9/vIRF promoter by Rta appears to depend exclusively upon unknown cellular DNA binding factors and not by direct Rta binding (Ueda *et al.*, 2002).

Nonetheless, DNA binding by Rta is obligatory for transactivation of the Rta-responsive elements of the PAN and Kaposin promoters (Chang *et al.*, 2005b).

The promoter association of Rta is also regulated by post-translational modifications and homotypic interactions. Poly-ADP-ribosylation and phosphorylation of Rta's serine–threonine (ST)-rich region (AAs 505–520) decreases Rta's interactions with the Rta and Mta promoters in reactivating BCBL-1 cells (Gwack *et al.*, 2003b). The cellular proteins poly(ADP-ribose) polymerase-(PARP)-1, and the human homologue of kinase from chicken (KFC), interact directly with the ST-rich region of Rta to add these modifications, elimination of which enhances Rta-mediated transactivation and viral reactivation (Gwack *et al.*, 2003b). Other data show that Rta oligomerizes to bind the K8 promoter in vitro (Liao *et al.*, 2003). All of the above data suggest that Rta expression alone may not be sufficient to reactivate KSHV, but additional levels of control following Rta expression are also essential. Indeed, in single cell reactivation assays, less than 10% of Rta-transfected PEL cells express viral lytic proteins (Lukac *et al.*, 1998, 1999). Progression down the lytic gene cascade may therefore be inefficient, an observation reported, as well, in infection of cultured endothelial cells (Ciufo *et al.*, 2001).

After Rta associates with lytic KSHV promoters, its ability to reactivate the virus from latency depends upon successful recruitment of the cellular SWI/SNF chromatin remodeling complex, and the TRAP/mediator coactivator (Gwack *et al.*, 2003a). Direct contacts of Rta to individual proteins in both complexes is required for Rta-mediated transactivation, and Rta presumably recruits the remaining members in stoichiometric complexes to mediate these effects (Gwack *et al.*, 2003a). In the case of promoters that require interactions of Rta with RBP-Jk (Liang *et al.*, 2002; Liang and Ganem, 2004; Lukac *et al.*, 2001), this suggests that Rta can replace the role of the activated cellular Notch protein in recruiting histone acetyl-transferase (HAT) complexes to RBP-Jk dependent promoters.

Rta's activity is also modulated by complex interactions with a second KSHV IE protein, K8/KbZIP (also known as RAP). Unlike its homologue in EBV, the Zta protein, KSHV KbZIP is unable to reactivate the KSHV lytic cycle (Polson *et al.*, 2001). Instead, stable expression of the K8/KbZIP protein in BCBL-1 cells inhibits replication of KSHV in response to TPA induction (Izumiya *et al.*, 2003a). This function may be due to the ability of K8/KbZIP to inhibit Rta-mediated transactivation of the ORF57/Mta and K8 promoters (Liao *et al.*, 2003; Izumiya *et al.*, 2003a). The K8/KbZIP protein directly targets the transcriptional coactivator CREB-binding protein (CBP) to transcriptionally repress signaling induced by either TPA or TGFβ, as well as the cFos promoter (Hwang *et al.*, 2001; Tomita *et al.*, 2004). However, the ability of K8/KbZIP to repress Rta-mediated activation requires a direct interaction between itself and Rta, and is not relieved by overexpressing transcriptional coactivators (Liao *et al.*, 2003).

There are also conditions in which K8/KbZIP activates transcription. K8/KbZIP can cooperate with Rta to transactivate the K8 and Rta promoters (Wang *et al.*, 2003a), but does not affect Rta-mediated activation of the nut-1/PAN promoter (Izumiya *et al.*, 2003a). Collectively, these data suggest that K8/KbZIP may cooperate with Rta to ensure strong induction of Rta expression, but then tempers lytic cycle progression by inhibiting Rta's ability to activate downstream promoters, like that of ORF57 and K8. As described below, K8/ KbZIP also inhibits cell cycling, so the mechanisms by which K8/ KbZIP influences Rta function are likely to be complex.

Other viral proteins exert both positive and negative effects on Rta. A DE target of ORF50/Rta transactivation, ORF57/Mta, is essential for infectious virion production from latently infected cells (Han and Swaminathan, 2006). The Mta ORF encodes protein domains with putative transcriptional and post-transcriptional functions, and stimulates the accumulation of viral lytic mRNAs (Han and Swaminathan, 2006). Mta uses an un-characterized mechanism to synergize with Rta in a promoter-specific fashion (Kirshner *et al.*, 2000). The ORF73 protein, Latency-Associated Nuclear Antigen (LANA)-1, represses both Rta-mediated transactivation and reactivation, as well as Rta expression, through interactions with the cellular protein RBP-Jk (Lan *et al.*, 2005).

Signals that control lytic reactivation of KSHV

Various laboratory chemicals are the strongest inducers of the KSHV lytic cascade in PEL cells, and have provided important clues regarding the intracellular pathways that control viral reactivation. Since these chemicals function by divergent mechanisms, it suggests that more than one pathway is sufficient to reactivate KSHV. However, the candidate physiologic ligands that stimulate these pathways are virtually unknown (Fig. 26.3).

TPA has been the standard reagent that induces the entire lytic gene cascade and release of mature progeny virus from PEL cells (Renne *et al.*, 1996b; Miller *et al.*, 1997). TPA added to PEL cells rapidly induces the DNA binding of the cellular proteins C/EBPα and cJun to the Rta promoter; in the absence of TPA, transfection of expression vectors for C/EBPα or the AP-1 constituents cFos and cJun induce Rta expression (Wang *et al.*, 2003a,b, 2004). Newly

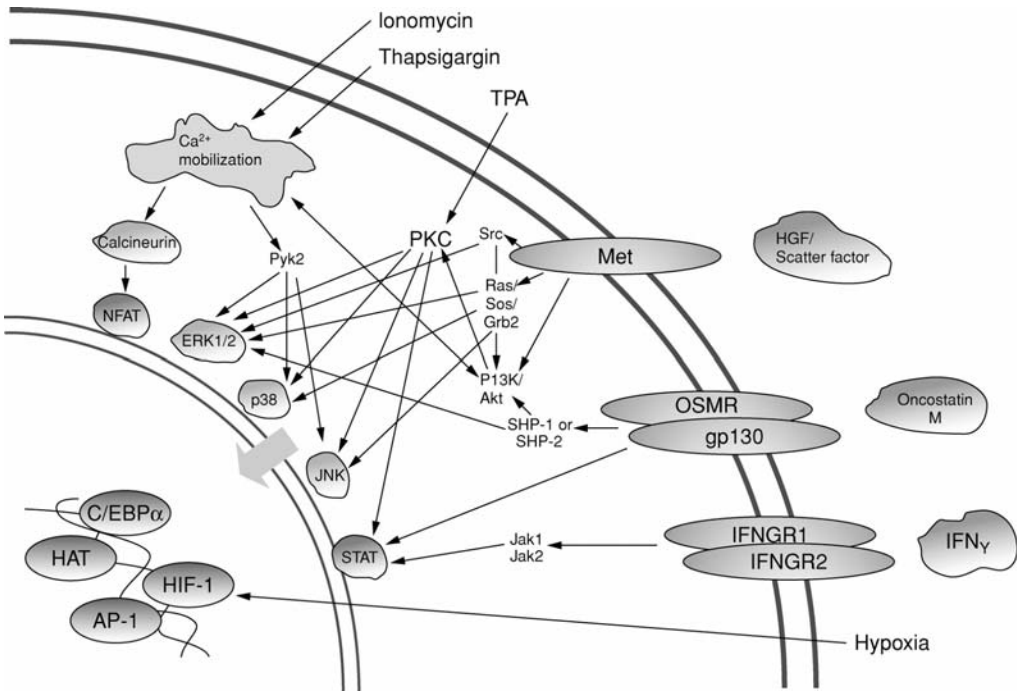

Fig. 26.3. Signals that reactivate KSHV in PEL models of latency. Published or hypothetical pathways that induce KSHV reactivation in PEL cells; see text for details and citations (for review see Maulik *et al.*, 2002; Taga and Kishimoto, 1997; Ernst and Jenkins, 2004; Leonard and O'Shea, 1998; Feske *et al.*, 2003; Yang and Kazanietz, 2003). Abbreviations: "NFAT" = nuclear factor of activated T cells, "TPA" = 12-O-tetradecanoyl-phorbol-13- acetate, "PKC" = protein kinase C, "HGF" = hepatocyte growth factor, "PI3K" = phospho-inositol-3-kinase, "JNK" = jun N-terminal kinase, "OSMR" = oncostatin M receptor, "SHP" = src homology domain-2 domain-containing protein tyrosine phosphatase, "IFN" = interferon, "IFNGR" = interferon gamma receptor, "Jak" = janus kinase, "STAT" = signal transducer and activator of transcription, "C/EBP" = CCAAT/enhancer binding protein, "HAT" = histone acetyl-transferase, "HIF" = hypoxia induced factor.

expressed Rta subsequently induces additional C/EBPα and cJun expression, and both proteins are detected in increasing amounts on DE promoters (Wang *et al.*, 2003a,b, 2004). Chemical inhibitors of protein kinase C (PKC) reduce TPA-induced lytic reaction of KSHV in PELs by 70–75% (Zoeteweij *et al.*, 2001). Collectively, these data suggest that TPA reactivates KSHV primarily by activating AP-1 and C/EBPα in the nucleus through induction of protein kinase C activity. As shown in Fig 26.3, PKC sits at the crossroads of many candidate physiologic ligands and downstream effectors (for review see Yang and Kazanietz, 2003), suggesting that it probably plays a prominent role in controlling KSHV reactivation in vivo.

Although stimulation of PKC can also lead to activation of the NF-kB family of transcription factors (Yang and Kazanietz, 2003), NF-kB is constitutively active in PELs in the absence of TPA. Rta and other lytic proteins are induced if NF-kB is inhibited, resulting in reactivation of KSHV (Brown *et al.*, 2003). Transfection of an expression vector for p65, a transcriptionally active subunit of NF-kB, inhibits the ability of Rta to transactivate its own promoter, and that of nut-1/PAN. This effect is overcome by overexpression of a dominant negative inhibitor of NF-kB (Brown *et al.*, 2003). The latently expressed KSHV protein, vFLIP (viral fas-ligand IL-1 β-converting enzyme inhitibory protein), maintains constitutive activity of NF-kB in PELs, inhibition of which induces apoptosis (Ghosh *et al.*, 2003; Keller *et al.*, 2000). Evolutionary pressure might thus have selected this function of vFLIP to enhance the stable maintenance of KSHV latency.

Calcium ionophores also reactivate KSHV from latency in PEL cells (Renne *et al.*, 1996b; Chang *et al.*, 2000), but are blocked by chemical inhibitors of calcineurin, suggesting a PKC-independent pathway downstream of Ca^{2+} (Yang and Kazanietz, 2003; Zoeteweij *et al.*, 2001). Typically, calcineurin stimulation activates the nuclear factor of activated T cells (NFAT) growth control pathway (for review see Feske *et al.*, 2003). However, NFAT signaling alone is

apparently insufficient to reactivate KSHV: the viral K1 protein, a constitutive activator of NFAT (Lagunoff *et al.*, 1999; Lee *et al.*, 1998), is incapable of inducing reactivation when ectopically overexpressed in PEL cells (Lukac *et al.*, 1998). A mutant of K1 unable to stimulate NFAT blocks reactivation of KSHV induced by Rta, suggesting that NFAT stimulation is essential for events downstream of Rta (Lagunoff *et al.*, 2001). Overexpression of wild-type K1 can also inhibit reactivation without altering Rta expression (Lee *et al.*, 2002), suggesting that NFAT activation must be "fine-tuned" during lytic cycle progression.

Many of the inflammatory cytokines and other soluble factors found in KS lesions (for review see Ensoli *et al.*, 2001) can reactivate the virus if added to the growth media of PEL cells. These include oncostatin M, hepatocyte growth factor, interferon γ, HIV-1 Tat, and an unidentified soluble factor released from HIV-1 infected cells (Blackbourn *et al.*, 2000; Chang *et al.*, 2000; Huang *et al.*, 2001; Mercader *et al.*, 2000; Monini *et al.*, 1999b; Varthakavi *et al.*, 1999). Furthermore, many of these factors are required for growth of uninfected, explanted KS spindle cells (Cai *et al.*, 1994; Ensoli *et al.*, 1989; Miles *et al.*, 1992; Naidu *et al.*, 1994), suggesting that reactivation of KSHV may be co-regulated with stimulation of putative target cells. Supporting this hypothesis, the persistence of KSHV in explanted PBLs from infected humans requires the addition of inflammatory cytokines to the culture (Ensoli *et al.*, 2000; Monini *et al.*, 1999b; Sirianni *et al.*, 1998). Similarly, MHV-68 infection induces the pro-inflammatory cyclooxygenase (COX)-2 protein, and COX-2 inhibitors globally suppress MHV-68 gene expression and virion production (Symensma *et al.*, 2003). However, not all inflammatory cytokines augment KSHV replication: interferon α inhibits reactivation of KSHV in PELs, and reduces the viral load in cultured PBLs (Monini *et al.*, 1999a).

Growth of PELs in hypoxia (limited O_2) results in the accumulation of the cellular transcription factor HIF-1 and also reactivates KSHV (Davis *et al.*, 2001). The messages for Rta and ORF34 are induced in hypoxia, and both contain putative hypoxia response elements (HREs) in their promoters (Haque *et al.*, 2003). Using reporter plasmids for the two viral promoters, the effect of hypoxia is also seen in uninfected cells, and can be reproduced by transfection of expression vectors for HIF-1 and HIF-2 (Haque *et al.*, 2003). These data are provocative considering that (i) classic KS has a predilection to affect the lower extremities of elderly men (Hengge *et al.*, 2002), which often have relatively low tissue oxygen concentrations (Ubbink *et al.*, 1997), and (ii) endemic KS is highly prevalent in areas of the world with concurrent malaria or common hereditary anemias (Sarid *et al.*, 1999), which also lead to tissue hypoxia. Thus, hypoxia may favor reactivation of latent virus, increased viral titer, and consequently, increased KS or increased transmission of KSHV.

Many studies suggest that KSHV reactivation signals ultimately lead to relief of transcriptionally repressive chromatin architecture by increasing acetylation and chromatin remodeling of viral promoters, especially that of Rta. Histone deacetylase (HDAC) inhibitors, like sodium butyrate, trichostatin A, and valproic acid (Lu *et al.*, 2003; Miller *et al.*, 1997; Renne *et al.*, 1996b; Shaw *et al.*, 2000; Vieira and O'Hearn, 2004), all reactivate KSHV from latency, and can directly activate Rta's promoter (Lu *et al.*, 2003). ChIP experiments show that HDACs 1, 5, and 7 are associated with the Rta promoter in latently infected cells, and nuclease mapping shows that a nucleosome is stably positioned over the Rta start site under these conditions (Lu *et al.*, 2003). Treatment with an HDAC inhibitor releases the positioned nucleosome, recruits the Ini1/Sn5 subunit of the BRG1 chromatin remodeling complex, and induces Rta expression (Lu *et al.*, 2003). These data suggest that chromatin remodeling of the Rta promoter, specifically at its start site, may be the molecular mechanism that is critical for a reactivation signal to be effective. The relief of repressive chromatin by recruitment of histone acetyltransferases (HATs) to critical DNA elements of the EBV genome also appears to be a crucial regulatory event (Jenkins *et al.*, 2000).

How are HDACs recruited to the Rta promoter to repress its expression and maintain KSHV latency? Bisulfite genomic sequencing demonstrates that the Rta promoter is highly methylated at CpG dinucleotides during latency; premethylation of the Rta promoter prior to transfection severely represses its activity in transient reporter assays (Chen *et al.*, 2001). These data suggest that the methyl CpG binding protein MeCP2 might bind to methylated bases, and recruit HDAC complexes that promote latency. Indeed, treatment of BCBL-1 cells with 5-azacytidine, a DNA methyltransferase inhibitor, reactivates the virus from latency (Chen *et al.*, 2001). Remarkably, even TPA treatment of BCBL-1 cells seems to relieve the repressive effects of methylation of the Rta promoter (Chen *et al.*, 2001), suggesting that regulation of the methylation status of the promoter might be a general mechanism to regulate the latent-to-lytic transition of KSHV. Concordant with the orchestration of the KSHV lytic cycle by Rta and pathogenic progression, the ORF50/Rta promoter in a latent KSHV carrier was highly methylated, while it was virtually unmethylated in most patients with MCD, PEL, and KS (Chen *et al.*, 2001).

However, there are also examples in which lytic cycle genes can be induced independently of Rta expression.

IFNα treatment of BCP-1 cells directly induces vIL-6 from latent KSHV in an IE fashion in the absence of any other viral gene expression (Chatterjee *et al.*, 2002). Twenty-four KSHV genes are induced by forced over-expression of constitutively active Notch in PEL cells, in the absence of induction of Rta (Chang *et al.*, 2005) or productive reactivation of the virus (Carroll *et al.*, 2006). These data suggest that pathways of lytic gene induction that are independent of Rta expression can develop in latently infected cells.

Lytic replication and interactions with the host cell

G1 arrest

It is postulated that many herpesviruses actively promote G1 arrest to favor efficient lytic replication (for review see Flemington, 2001), a function that appears to have been conserved by KSHV. Induction of the lytic cycle by TPA in JSC-1 or BCP-1 (PEL) cells arrests them in G1, as measured by an increase in the 2N DNA content and lack of BrdU incorporation (Wu *et al.*, 2002; Izumiya *et al.*, 2003b). Stable expression of K8/KbZIP in BCBL-1 cells can further delay G1 progression after TPA induction (Izumiya *et al.*, 2003b). The G1 arrest is reproduced by expression of the K8/KbZIP protein in KSHV-negative cells (Wu *et al.*, 2002), in which K8/KbZIP cooperates with C/EBPα to transcriptionally activate the p21 cyclin-dependent kinase inhibitor WAF1/CIP in a p53-independent manner (Wu *et al.*, 2002). These effects require a direct interaction of both proteins through their respective leucine zippers, and do not occur if K8/KbZIP is expressed in C/EBPα null cells (Wu *et al.*, 2002). K8/KbZIP also regulates both C/EBPα and p21 post-translationally; in in vitro proteosomal degradation assays using BCBL-1 extracts, K8/KbZIP stabilizes both the C/EBPα and p21 proteins in a leucine-zipper dependent manner (Wu *et al.*, 2002). K8/KbZIP can also inhibit the kinase activities of the cdk2/cyclinA and cdk2/cyclin E complexes by directly binding to them through the KbZIP basic domain (Izumiya *et al.*, 2003b). Nonetheless, the K8/KbZIP protein itself is phosphorylated by cdk/cyclinA in complexes immunoprecipitated from induced BCBL-1 cells (Polson *et al.*, 2001).

Expression of a second lytic cycle protein, the vGPCR, also promotes a G1 arrest in reactivating PEL cells (Cannon *et al.*, 2006). vGPCR mediates this effect by inducing expression of the cdk inhibitor protein p21 to block cdk 2 activity. Interestingly, this results in counteracting the TPA-induced expression of viral lytic cycle proteins including the lytic switch Rta, and ORF26.

Apoptosis

Expression of Rta in uninfected BJAB cells results in apoptosis, but stable, tetracycline-regulated induction of Rta in BCBL-1 (PEL) cells does not lead to cell death, even up to 13 days following initial expression. These data suggest that, in the absence of viral infection, Rta is proapoptotic, but that a protein(s) expressed in infected cells counteracts cell death induction (Nishimura *et al.*, 2003). KSHV encodes various lytic cycle proteins that are candidates for inhibiting Rta-induced programmed cell death, and use remarkably different mechanisms. Rta itself can inhibit p53-mediated cell death (Gwack *et al.*, 2001b), and can also function as a ligand-independent inducer of the antiapoptotic STAT3 protein (Gwack *et al.*, 2002). K8/KbZIP binds to p53 to repress its transcriptional activity (Park *et al.*, 2000). KSHV ORF16 encodes vBcl-2, which partially reverses cell death induced by Bax (Cheng *et al.*, 1997; Sarid *et al.*, 1997), and counteracts the ability of the pro-apoptotic protein Diva to inhibit Bcl-XL. The K7/viral inhibitor of apoptosis protein (IAP) is a mitochondrial membrane protein that employs at least three different strategies: (i) it helps target cellular Bcl-2 to activated caspase-3 to inhibit its function (Wang *et al.*, 2002); (ii) it binds a cellular cyclophilin ligand to enhance Ca^{2+} flow and protect cells from mitochrondrial damage (Feng *et al.*, 2002); and (iii) it promotes degradation of IkB and p53 by preventing the cellular PLIC1 protein from protectively binding to them (Feng *et al.*, 2004). K9 encodes vIRF-1, a homologue of cellular IRFs, that inhibits apoptosis induced by various means and is required for reactivation of KSHV and expression of lytic genes (Burysek *et al.*, 1999; Flowers *et al.*, 1998; Gao *et al.*, 1997; Jayachandra *et al.*, 1999; Kirchhoff *et al.*, 2002; Li *et al.*, 1998; Lin *et al.*, 2001; Nakamura *et al.*, 2001; Seo *et al.*, 2001). K9 can inhibit p53-dependent transcription (Seo *et al.*, 2001; Nakamura *et al.*, 2001), and blocks transcriptional activation by the cellular proteins IRF-1 and IRF-3 (Burysek *et al.*, 1999; Flowers *et al.*, 1998; Kirchhoff *et al.*, 2002; Li *et al.*, 1998; Lin *et al.*, 2001).

Shut-off of host gene expression

At early times during reactivation of KSHV (10–12 hours post-induction), global mRNA turnover is accelerated in KSHV infected endothelial cells (Glaunsinger and Ganem, 2004). Overexpression of the KSHV ORF37 gene reproduces this effect, so has been termed the SOX protein (for shut-off and exonuclease). Viral transcripts seem to be largely unaffected by the SOX protein, while only a limited number of host transcripts can escape the shut-off. These host transcripts include those encoding HIF-1α and IL-6, both of which play prominent roles in KSHV pathogenesis.

Regulation of lytic DNA replication

A subset of KSHV delayed–early RNAs encode enzymes required for lytic replication of the viral genome, and regulatory factors that initiate and control the DNA replication process. Viral DNA synthesis begins shortly after the appearance of the delayed–early proteins. As in other herpesviruses, KSHV lytic phase replication proceeds via a mechanism that is distinct from latent viral DNA replication (discussed in detail in the Chapter 24). First, latent DNA replication initiates at *ori-P* and proceeds bidirectionally, while viral lytic replication initiates from a distinct origin (*ori-Lyt*) and proceeds via a rolling-circle mechanism. Second, latent DNA replication depends on host cellular DNA polymerase and accessory factors, while viral lytic replication utilizes a DNA polymerase and other factors encoded by KSHV. Third, latent viral replication occurs in synchrony with the host cell to maintain a stable number of viral episomes per host genome, while viral lytic replication amplifies the viral DNA by one-hundred- or even one-thousand-fold.

Origins of lytic DNA replication

Lytic cycle DNA replication of KSHV initiates from two lytic origins (*ori-Lyt-L and ori-Lyt-R*), located in the genome between K4.2 and K5, and between K12 and ORF71, respectively (AuCoin *et al.*, 2002; Lin *et al.*, 2003). Both *ori-Lyt*s share an almost identical 1.1 kb core sequence, juxtaposed to 600 bp GC-rich repeats (Fig. 26.4).

Each 1.7 kb *ori-Lyt* sequence is necessary and sufficient as a *cis*-acting signal for KSHV lytic replication in transient replication assays (Lin *et al.*, 2003). However, in the context of the viral genome, *ori-Lyt-L* appears to be sufficient to propagate the viral genome whereas *ori-Lyt-R* alone seems inert to direct amplification of viral DNA, as suggested by an investigation using recombinant KSHVs that removed one or both of the *ori-Lyts* in the genome (Xu *et al.*, 2006). Three essential sequence motifs are conserved in the 1.1 kb. region: (i) an 18-bp AT-palindromic sequence, (ii) eight C/EBP binding motifs, arranged as four spaced palindromes, and (iii) an ORF50/Rta responsive element (RRE) linked to a TATA box (Wang *et al.*, 2004b). Substitution or deletion of any of these three core elements abolishes *ori-Lyt* function (Wu *et al.*, 2003; Wang *et al.*, 2004b), while the 600-bp GC-rich tandem repeats are also required for efficient DNA replication (Lin *et al.*, 2003; Wang *et al.*, 2006).

The AT-palindromic sequence (Fig. 26.5) is also present in the core loop structures of HSV-1 *ori-L* and *ori-S,* as well as in the HHV6 and HHV-7 lytic origins. In fact, an AT-rich palindrome is a common feature of both cellular and viral DNA replication origins (Challberg and Kelly, 1989; DePamphilis, 1993). It is believed that an AT-rich palindrome facilitates DNA unwinding and enhances helicase activity during DNA replication.

The eight C/EBP binding motifs are organized as four spaced C/EBP palindromic pairs within a 240-bp sequence (Wu *et al.*, 2003; Wang *et al.*, 2004b). Each palindrome contains two head-to-head CCAAT consensus motifs that are separated by a 13- or 12-bp spacer sequence. One of the KSHV origin binding proteins (OBPs), the K8/KbZIP protein, associates with *ori-Lyt* at the CCAAT motifs (discussed below) (Wang *et al.*, 2004b, 2006).

The RRE/TATA box motif functions as a cis-acting transcriptional promoter whose activity is required for replication from *ori-Lyt*. The KSHV ORF50/Rta protein binds directly to the RRE to activate transcription at *ori-Lyt*. The promoter in *ori-Lyt-L* normally directs transcription of a 1.4 kb RNA containing the GC-rich repeats and a putative open reading frame of 75 amino acids, and the promoter in *ori-Lyt-R* controls the synthesis of the 2.3-kb mRNA encoding K12 (Wang *et al.*, 2004b). Transcription events controlled by these promoters are essential for DNA replication from the *ori-Lyt*, as prematurely termination of the transcription by inserting an SV40 polyadenylation sequence upstream of the GC-rich repeats completely abolished the transcription activity as well as DNA replication (Wang *et al.*, 2006). The EBV *ori-Lyt* also contains a promoter whose transcriptional activity is required for replication (Hammerschmidt and Sugden, 1988), but the role of these promoters and transcripts in gamma-herpesviral lytic replication are unknown.

The 600-bp GC-rich tandem repeat sequences adjacent to the *ori-Lyt* core sequences are represented as both 20-bp and 30-bp tandem arrays in the *ori-lyt-L,* and two types of 23-bp tandem repeats in the *ori-Lyt-R.* Such GC-rich tandem repeats are also found in the *ori-Lyts* of EBV and RRV (Hammerschmidt and Sugden, 1988; Pari *et al.*, 2001).

K8/KbZIP and ORF50/Rta are origin-binding proteins that are responsible for recruiting pre-replication complexes to *ori-Lyt* DNA

Initiation of herpesviral lytic replication requires binding of OBPs to *ori-Lyt* elements. Subsequently, the OBPs recruit DNA replication enzymes and accessory factors to the origins. The recruitment of replication proteins by OBPs is dictated by specific protein–protein interactions, and facilitated by linking and distortion of the origin DNA by the OBPs.

All four of the C/EBP palindromes in *ori-Lyt* are indispensable for replication, and mutagenesis studies have

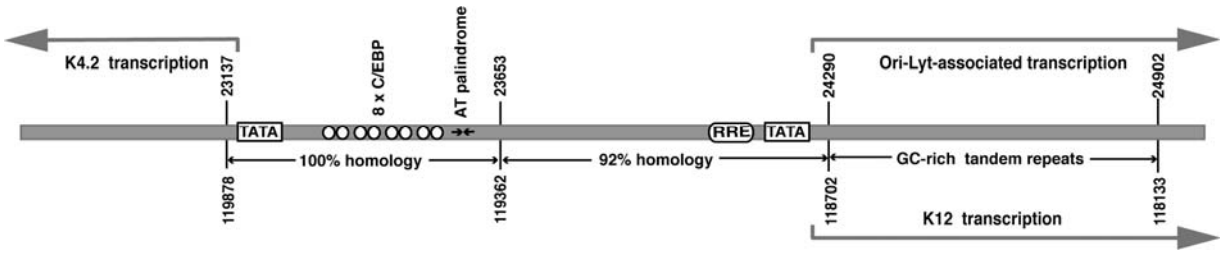

Fig. 26.4. Structure of the KSHV origin of DNA replication (*ori-Lyt*). The positions of various characteristic motifs (TATA boxes, C/EBP binding motifs, AT palindrome, RRE and GC tandem repeats) are as indicated. The homologies of subregions between two *ori-Lyts* are compared and shown on the bottom.

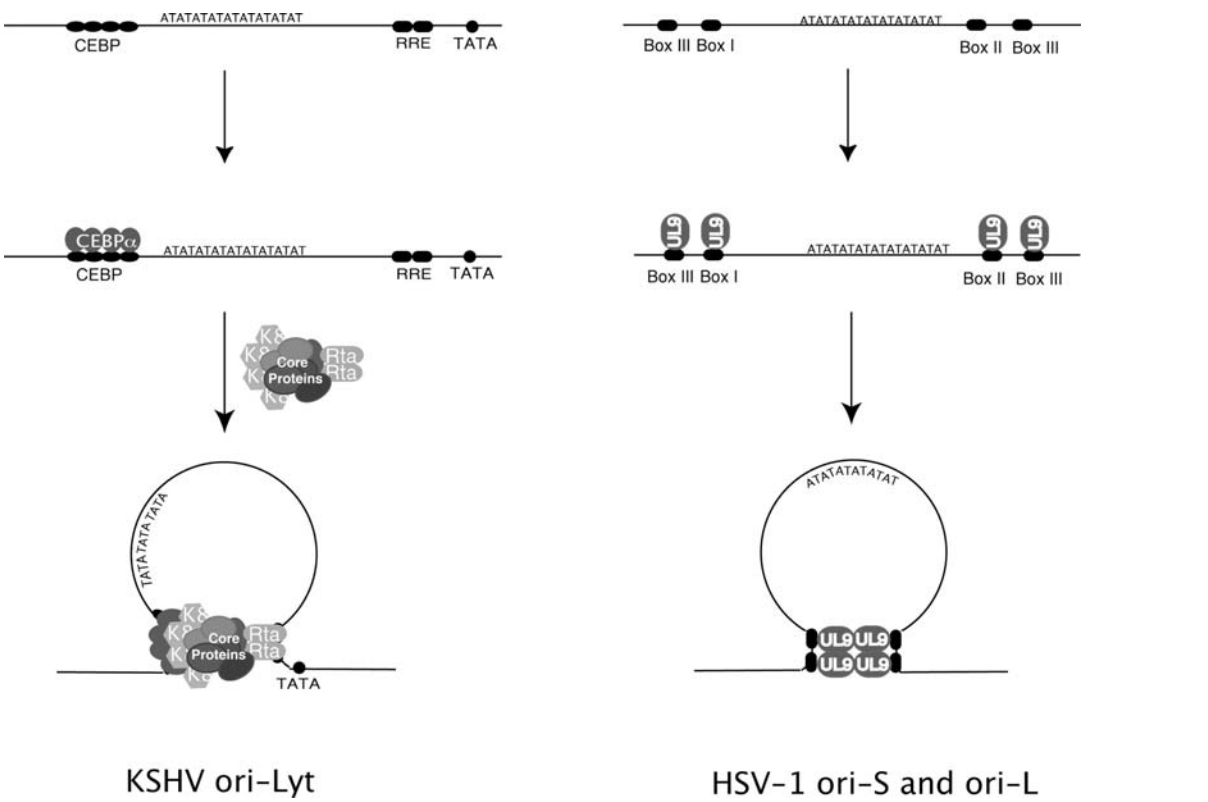

Fig. 26.5. Model for recruitment of core replication proteins to KSHV *ori-Lyt* DNA through ORF50/Rta and K8/KbZIP. Six core replication machinery proteins (referred to as core proteins for simplicity), ORF50/Rta and K8/KbZIP (referred to as Rta and K8, respectively, for simplicity) form a pre-replication complex regardless of the presence of *ori-Lyt* DNA. The pre-replication complex is loaded at a KSHV *ori-Lyt* by a two-point-contact through RTA and K8, each of which interacts with their binding motifs in the *ori-Lyt*. The interaction may lead to looping and distortion of the *ori-Lyt* DNA (left panel), which resembles the binding and looping of HSV-1 *ori-S* and *ori-L* by UL9 proteins (right panel)

shown that three of the individual C/EBP sites C/EBP 1, 2, and 6 are essential for *ori-Lyt* function. Although deletion or mutation of these C/EBP motifs also impairs the association of K8/KbZIP with the *ori-Lyt*, subsequent EMSA experiments have failed to demonstrate direct protein-DNA interactions between the two (Wang *et al.*, 2004b). However, the observation that (i) C/EBP α binds directly to four of the C/EBP sites, and (ii) C/EBP α binds specifically to the K8/KbZIP protein (Wu *et al.*, 2003), implies that K8/KbZIP binds to KSHV *ori-Lyt* through interacting with DNA-bound C/EBP α (Fig. 26.5) (Wang *et al.*, 2004b).

Binding of the ORF50/Rta protein to the RRE in *ori-Lyt* is absolutely essential for *ori-Lyt*-dependent DNA replication, suggesting that Rta is a second critical OBP. The RRE closely resembles the RRE sequence in the nut-1/PAN promoter (Wang *et al.*, 2004b; AuCoin *et al.*, 2004), and deletion of the RRE or the downstream TATA box abolishes transcription and replication at *ori-Lyt*. If the RRE is replaced by a binding site for the heterologous Gal4 protein, a Gal4-ORF50 fusion protein can rescue replication, suggesting that Rta-mediated transactivation is required for replication. In addition to the transcriptional activation Rta also participates in replication complex formation on *ori-Lyt* by interacting with the K8/KbZIP protein and other core replication machinery proteins (Wang *et al.*, 2006). This notion is derived from several lines of evidence as follows: (i) Rta was found to be a component of viral replication compartments in the nuclei of infected cells, and shown to interact with core replication machinery complexes (or pre-replication complexes) composed of at least six core replication proteins and K8/KbZIP, (ii) The loading of the core replication machinery complexes on the *ori-Lyt* DNA appears to be mediated by Rta and to be dependent upon the RRE in the *ori-Lyt*, as the deletion of the RRE abolished the association of replication proteins with *ori-Lyt* DNA. This suggests that Rta plays a role in recruiting the core replication machinery complexes to the *ori-Lyt* DNA, (iii) The association of Rta with pre-replication complexes is not DNA-mediated. Instead, the complexes are assembled independent of the presence of *ori-Lyt* DNA and become less stable once they are recruited and loaded on *ori-Lyt* DNA, perhaps in order to convert to replication fork complexes (Wang *et al.*, 2006).

K8/KbZIP also interacts with core replication machinery proteins and has a similar function as Rta in recruiting and loading pre-replication complexes to the *ori-Lyt* DNA. Thus, formation of a functional DNA replication initiation complex on an *ori-Lyt* requires the efforts of both RTA and K8/KbZIP in loading pre-replication complexes on *ori-Lyt* (Wang *et al.*, 2006). Based on these data, a model of K8/KbZIP and ORF50/Rta recruiting pre-replication complexes to *ori-Lyt* is proposed in Fig. 26.5. In this model, a pre-replication complex apparently binds to an *ori-Lyt* DNA through two contact points, one at the K8 binding region (the C/EBP cluster) near one end of the *ori-Lyt* and the other at the RRE near the opposite end. The two-contact-point binding may bring the two ends of the *ori-Lyt* element together, looping the DNA between the K8 and Rta binding sites. An 18-bp AT palindrome sequence is located in the looped region (Fig 26.5). A similar loop structure has been seen in the HSV-1 DNA replication system, in which two UL9 protein dimers (OBP) bind to two binding sites (Boxes I and II) in *ori-S* and *ori-L* and the protein-protein interactions between the UL9 molecules loops the *ori-Lyt* DNA centered by an AT-palindrome sequence (reviewed in Boehmer and Lehman, 1997). The looping leads to bending and distortion of *ori-Lyt* DNA, facilitating unwinding of the DNA sequence.

Viral enzymes and accessory factors essential for KSHV ori-Lyt-specific DNA replication and DNA replication machinery

Following binding of the OBPs to an origin, DNA replication enzymes and accessory factors are recruited to the origin, and DNA replication begins. Herpesvirus-encoded enzymes and trans-acting factors essential for lytic DNA replication are referred to as the core replication machinery. Homologues of the core proteins have been found in all herpesviruses studied to date, and are structurally and functionally conserved. In fact, both the HSV-1 and KSHV-encoded replication proteins can replicate the EBV *ori-Lyt* in the presence of the EBV OBP *Zta* (Fixman *et al.*, 1995; Wu *et al.*, 2001).

The candidate KSHV replication core machinery proteins were originally identified by sequence similarity to HSV-1 and EBV homologues (see Table 26.1) (Wu *et al.*, 2001; AuCoin *et al.*, 2004), and include (i) a DNA polymerase (POL encoded by ORF9), (ii) a polymerase processivity factor (PPF by ORF59), (iii) a single-stranded DNA binding protein (SSB by ORF6), (iv) a helicase (HEL by ORF44), (v) a primase (PRI by ORF56), and (vi) a primase-associated factor (PAF by ORF40/41). Co-transfection of expression vectors for these proteins and the OBPs (K8/KbZIP and ORF50/Rta) is necessary and sufficient to support DNA replication of a plasmid containing a KSHV *ori-Lyt* in mammalian cells. If any of the core replication proteins are omitted in the system, no replicated KSHV *ori-Lyt* plasmid DNA is detected (AuCoin *et al.*, 2004). In these crucial transient co-transfection-replication assays, replicated *ori-Lyt*-containing DNA becomes resistant to methylation-sensitive restriction enzymes that can only digest the input

Table 26.1. KSHV DNA replication proteins and their analogues in other herpesviruses

			KSHV vs. HSV-1			KSHV vs. EBV			
Protein and enzyme	Gene	Size (aa)	Name	Sim(%)	Iden(%)	Name	Sim(%)	Iden(%)	Activities
K8/KbZIP	K8	237				BZLF1		–	*Ori-Lyt binding protein*
ORF50/Rta	ORF50	691				BRLF1	32.2	20.6	Transcription activator, *ori-Lyt* binding protein
SSB	ORF6	1133	UL29	36.1	27.1	BALF2	65.5	42.1	Single-stranded DNA binding
HEL	ORF44	788	UL5	49.6	37.7	BBLF4	67.8	51.1	Helicase subunit
PRI	ORF56	843	UL52	39.5	29.0	BSLF1	56.6	35.4	Primase subunit
PAF	ORF40/41	670	UL8	—		BBLF2/3	47.1	23.3	Primase-associated factor
POL	ORF9	1012	UL30	60.0	41.7	BALF5	70.9	55.6	DNA polymerase subunit
PPF	ORF59	396	UL42	—		BMRF1	50.7	28.3	Double-stranded DNA binding protein, DNA polymerase processivity factor subunit

aa: amino acid; Sim%: percent similarity; Iden%: percent identity.

plasmid; the replication products are then detected by Southern blotting. The six core replication proteins can form a large globular shaped replication compartment even in the absence of an *ori-Lyt* DNA (Wu *et al.*, 2001), suggesting that they spontaneously assemble a pseudo-replication compartment (without DNA) in solution, then land on with the *ori-Lyt* DNA aid of OBPs. The biochemical properties of the individual KSHV DNA replication proteins are reviewed as follows:

Single-stranded DNA binding protein (SSB)

Among the core replication proteins, SSB is one of two intrinsic nuclear proteins (the other is PPF) that contributes to the nuclear translocation of the other core proteins, especially the primase-helicase tripartite subcomplex proteins PAF, HEL and PRI (Wu *et al.*, 2001; AuCoin *et al.*, 2004). The mechanism of KSHV SSB has not been studied in detail, but is probably similar to that of its HSV-1 counterpart (for review see Boehmer and Lehman, 1997). SSB rapidly and cooperatively binds to single-stranded *ori-Lyt* DNA formed as a result of binding of OBP proteins, and unwinds short regions of duplex DNA to further destabilize the DNA helix. These functions of SSB promote viral DNA replication by enhancing subsequent DNA polymerase and DNA helicase-primase activities.

DNA helicase–primase complex

The KSHV proteins HEL, PRI, and PAF form a tripartite primase/helicase complex, similar to their homologues in HSV-1 and EBV. Unlike its counterparts, efficient translocation of the KSHV complex to the nucleus requires co-expression of the three other core replication proteins (Wu *et al.*, 2001). High homologies between the KSHV and the HSV-1 proteins (or subunits if the tripartite complex is considered a holo-enzyme) suggest similar modes of action. The HSV-1 holoenzyme consists of a 1:1:1 association of UL5 (HEL), UL52 (PRI) and UL8 (PAF) proteins, and has a native molecular mass of 270 kDa. However, the UL5/UL52 sub-assembly displays DNA-dependent ATPase, 5′–3′ helicase, and primase activities, as well as a primer synthesis function that is stimulataed by the UL8 protein (reviewed in Boehmer and Lehman, 1997).

DNA polymerase and processivity factor

As in other herpesviruses, the KSHV DNA polymerase consists of two subunits, POL (polymerase) and PPF (polymerase processivity factor). KSHV POL not only shares a high homology with its HSV-1 counterpart, but also with DNA polymerases from mammals, yeast, *E. coli,* and bacteriophage. In the absence of the PPF subunit, the KSHV POL incorporates only several nucleotides from a primer template. However, association with the PPF enables POL to incorporate thousands of nucleotides continuously without dissociation from the template (Lin *et al.*, 1998).

Association with a processivity factor is an evolutionarily-conserved mechanism by which DNA polymerases achieve catalytic efficiency. The most conserved processivity factors are the ring-shaped sliding clamps, which encircle DNA templates and enable the associated DNA polymerases to slide along the template without dissociating. However, the HSV-1 processivity factor

is of insufficient size to form an encircling sliding clamp; instead, it tethers the DNA polymerase to the DNA template by double stranded DNA binding. The KSHV and HSV-1 PPF subunits display only limited sequence similarity, ~40 amino acids near their carboxy termini, so the mechanism of KSHV PPF remains elusive (Chen *et al.*, 2004). Since processivity factors adopt divergent states during DNA replication, they may serve as good targets for the design of novel and specific anti-herpesviral therapies.

In addition to these essential DNA replication proteins, KSHV also encodes several other enzymes for its DNA replication, including thymidine kinase, ribonucleotide reductase, alkaline exonuclease, uracil N-glycosylase and deoxyuridine triphosphatase. However, the functions of these enzymes are not essential for viral DNA replication.

Late genes and KSHV virion structure

The KSHV virion conserves the major structural elements of herpesviruses, including the genomic DNA, the capsid, the tegument, and the envelope. Proteins required for assembly and structure of DNA viruses have traditionally been regarded as viral late genes that require prior viral DNA replication for expression. This is likely true for the KSHV proteins that comprise the capsid and are inserted into the envelope, although there are exceptions (as discussed above and in Chapter 23). Proteins that comprise the tegument, however, are likely to be expressed from all kinetic classes of lytic replication; as discussed below, the ORF45 protein is an IE protein that is packaged into the KSHV tegument (Zhu and Yuan, 2003).

Virions released from induced PEL cells have provided the first detailed understanding of virion structures for the γ-herpesviruses. When PELs are treated with TPA and sodium butyrate, purified virions contain three types of capsid, named A, B, and C, respectively (Nealon *et al.*, 2001). Fully mature C capsids have a total mass of 300 Mda, and in declining order of abundance, contain the proteins ORF25/MCP (Major capsid protein), ORF65/SCIP (small capsomer-interacting protein), ORF26/TRI-2 (triplex-2), ORF62/TRI-1, and the 160–170 kb (unique region plus repeats) viral genome (Nealon *et al.*, 2001). A capsids contain the four proteins listed above, but lack viral genomic DNA. B capsids, the most abundant category released from lytic PEL cells, have the identical constituents as A capsids but also contain the scaffolding protein encoded by ORF17.5 (Nealon *et al.*, 2001). The capsid components are organized into a discrete series of capsomers containing hexons, pentons, and triplexes of one or two proteins each. The hexons and pentons contain six and five copies of the MCP, respectively, and the triplexes contain a dimer of TRI-2 protein and a monomer of TRI-1 (Trus *et al.*, 2001; Wu *et al.*, 2000). SCIP associates with MCP on hexamers, but not pentamers, and its location at the outermost portions of the capsid suggests that it might directly contact the tegument (Lo *et al.*, 2003). This localization of SCIP to the outer capsid region is conserved in virions of Rhesus monkey rhadinovirus, but not with α-herpesviruses, suggesting a potential unique function for γ-herpesvirus teguments (Yu *et al.*, 2003).

Cryoelectron microscopy at 24-Ångström resolution and digital reconstruction demonstrate that the mature capsid is icosahedral with a diameter of approximately 1140–1300 -Ångström (Wu *et al.*, 2000; Trus *et al.*, 2001). The *T*=16 icosahedral structure of the KSHV capsid is similar to that of the γ-herpesvirus herpes simplex virus-1, and the β-herpesvirus, Human cytomegalovirus, but the overall sizes of each capsid are proportional to the sizes of each virus's genome (Wu *et al.*, 2000; Trus *et al.*, 2001). Phylogenetic comparisons of the MCP protein reveal that the β- and γ-herpesviruses are more closely related to each other than to the α-herpesviruses (Trus *et al.*, 2001).

When protein lysates of purified virions are displayed on SDS-PAGE gradient gels, approximately 30 proteins can be differentiated (Zhu and Yuan, 2003); 24 of these have been identified by proteomic analyses (Zhu *et al.*, 2005). Those that are not capsid proteins are predicted to be parts of the tegument or envelope layers characteristic of mature herpesviral virions, which are presumably added to KSHV capsids during cellular egress. Various glycoproteins of KSHV, including K8.1, glycoprotein (g) B, gH, gL, gM, and gN, have been identified by sequence analysis and/or have been demonstrated to be membrane components of KSHV virions (Akula *et al.*, 2001; Baghian *et al.*, 2000; Pertel, 2002; Birkmann *et al.*, 2001; Wang *et al.*, 2001; Zhu *et al.*, 1999). Detergent treatment of virions releases membrane glycoproteins, but not tegument proteins, which are sandwiched between the capsid and membrane (Zhu *et al.*, 2005). Although the tegument of HSV-1 contains the well-characterized virion protein (VP)16, a transcriptional transactivator essential for expression of HSV-1 IE genes during *de novo* infection (reviewed in (Roizman and Sears, 1996)), the functions of KSHV tegument proteins are virtually unknown. The first tegument protein of KSHV to be identified is the product of ORF45 (Zhu and Yuan, 2003), a protein that counteracts the cellular α-interferon response by blocking the phosphorylation and nuclear accumulation of interferon regulatory factor (IRF)-7 (Zhu *et al.*, 2002). This suggests that ORF45 is packaged into the tegument so that it can function at the earliest stages of *de novo* KSHV infection. Eleven KSHV RNAs are

also found packaged in the virion, and may get translated after infection (Bechtel *et al.*, 2005).

Perspectives

KSHV has conserved the hallmark of herpesvirus pathogenesis: latent infection that persists for the lifetime of the host, requiring successful establishment and maintenance of latency in long-lived or self-perpetuating cellular reservoirs. Selective pressure exerted for millions of years on herpesviruses would not be expected to favor an increase in virulence unless it allowed greater replication and transmission of the virus. The obvious contribution of lytic genes to KS pathogenesis, therefore, is to facilitate dissemination of the virus from its long-term reservoir to sites of disease or of shedding. However, as highlighted in other chapters of this book, twelve viral open reading frames (ORFs) that have independent transforming, pro-angiogenic, pro-growth, anti-apoptotic, or immunomodulatory functions, are expressed following lytic reactivation of the virus. Therefore, it is likely that the pathogenic requirement for KSHV lytic reactivation and replication, as observed in epidemiologic studies, reflects both a necessity for increased viral titers to facilitate viral dissemination, as well as a contribution of viral lytic cycle proteins as direct effectors of the disease phenotypes. Lytically infected cells may thus serve not only as reservoirs of infectious virus but also as reservoirs of pathogenic viral proteins. Translated to the clinical setting, this may represent a pathogenic mechanism by which KSHV initiates or maintains the aggressive inflammatory infiltrate that characterizes KS lesions.

EBV gene expression and regulation

Lawrence S. Young, John R. Arrand, and Paul G. Murray

Cancer Research UK Institute for Cancer Studies, University of Birmingham Edgbaston, UK

Introduction

Epstein–Barr virus (EBV) is an extremely efficient virus infecting the majority of the world's adult population (Rickinson and Kieff, 2001). Following primary infection, EBV persists in the infected host as a lifelong asymptomatic infection. Early in the course of primary infection, EBV infects B-lymphocytes, although it is not known where B-lymphocytes are infected and whether this involves epithelial cells of the upper respiratory tract. To achieve long-term persistence in vivo, EBV colonizes the memory B-cell pool where it establishes latent infection, which is characterized by the expression of a limited subset of virus genes, known as the "latent" genes (Thorley-Lawson, 2001). There are several well-described forms of EBV latency, each of which is utilized by the virus at different stages of the virus life cycle and which are also reflected in the patterns of latency observed in the various EBV-associated malignancies (Rickinson and Kieff, 2001; Young and Murray, 2003). Furthermore, during its life cycle EBV must periodically enter the replicative cycle in order to generate infectious virus for transmission to other susceptible hosts, although it is also not clear whether this occurs in B-lymphocytes or in other cell types of the oropharynx (Rickinson and Kieff, 2001).

This chapter describes the EBV latency and replicative programs utilized by the virus as a means to understand how the virus infects and then establishes persistence in the host. The function of each of the key latent and lytic genes will be described in detail and will provide the foundation for later chapters which describe the contribution of some of these EBV genes to the pathogenesis of the EBV-associated malignancies.

Virus and genome structure

EBV is a gammaherpesvirus of the *Lymphocryptovirus* (LCV) genus and is closely related to other LCVs present in Old World non-human primates, including EBV-like viruses of chimpanzees and rhesus monkeys. In fact, the rhesus monkey LCV and EBV share similar sequences and genetic organization, and are both capable of maintaining infection in the oropharynx and in B cells (Moghaddam *et al.*, 1997). Recently, a transforming, EBV-related virus has also been isolated from spontaneous B cell lymphomas of common marmosets and is thus the first EBV-like virus to be identified in a New World monkey species (Cho *et al.*, 2001; Rivailler *et al.*, 2002). Sequencing of the genome of the marmoset LCV revealed considerable divergence from the genomes of EBV and Old World primate EBV-related viruses.

The EBV genome is composed of linear double-stranded DNA, approximately 172 kilobase pairs (kb) in length. EBV has a series of 0.5 kb terminal direct repeats (TRs) and internal repeat sequences (IRs) that divide the genome into short and long, largely unique sequence domains (Fig. 27.1(a)). The infectious mononucleosis-derived, B95–8 strain of EBV was the first herpesvirus to have its genome completely cloned and sequenced (Baer *et al.*, 1984; Accession number V01555). This prototype B95-8 strain of EBV is atypical of the majority of isolates, in particular it is missing an 11.8 kb segment of the genome (Fig. 27.1). In order to present a sequence more representative of the majority of isolates, a "hybrid" sequence has been assembled (accession number NC_007605) in which the 11.8 kb sequence determined from the Raji strain of EBV (Parker *et al.*, 1990) has been

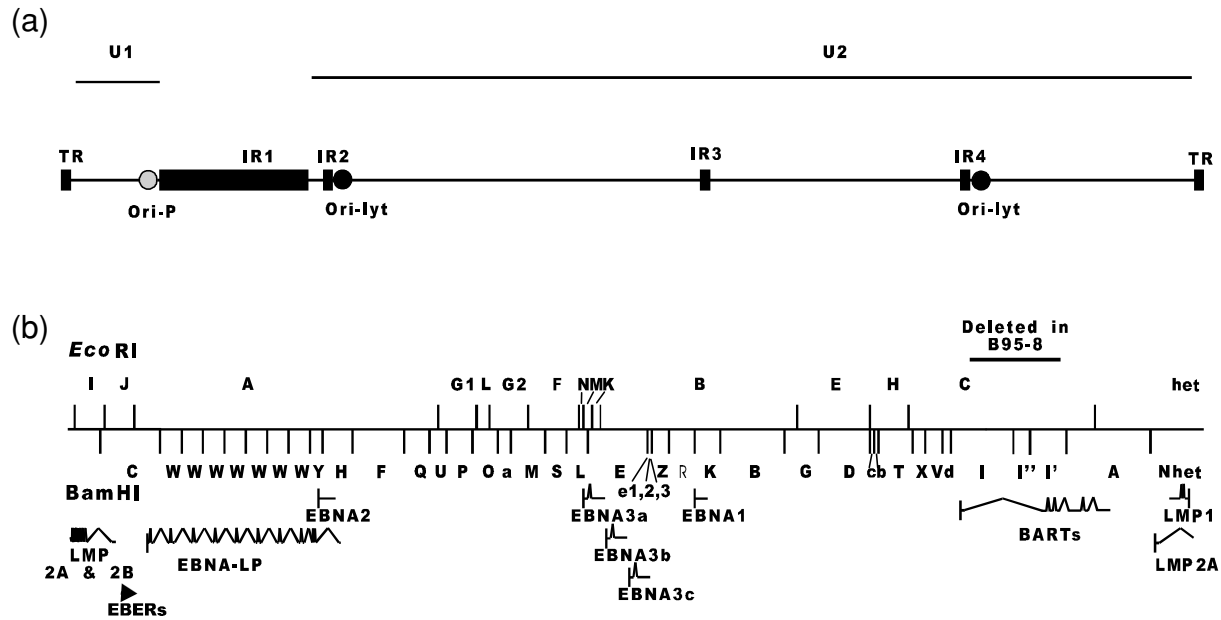

Fig. 27.1. The Epstein–Barr virus (EBV) genome. (a) General organization of linear, EBV virion DNA. U1 and U2 are the short and long unique regions of the genome, respectively. These are interspersed with the four internal repeat regions IR1–4. TR represent the terminal repeats. The origin of replication (Ori-P) of the intracellular, circular, episomal form of the genome is indicated by the grey circle whilst the lytic origins of replication (Ori-lyt) are shown as black circles. (b) *Eco*RI and *Bam*HI restriction endonuclease maps of EBV DNA and the positions of the genes expressed in latency. The *Bam*HI fragments are named according to the well-established B95–8 designations with the exception of I (which is larger than its B95–8 counterpart), I′ and I″ (which are absent in the B95–8 strain). The splicing patterns of the latent RNAs through the coding regions are indicated. EBNA-LP is transcribed from variable numbers of repetitive exons. The full transcriptional patterns of the remaining EBNA genes are more complex than shown here (see text) and the BARTs consist of a number of differently spliced RNA species emanating from the same promoter (Smith *et al.*, 2000; de Jesus *et al.*, 2003). Note that the LMP2 proteins are produced from mRNAs that splice across the terminal repeats in the intracellular, circularised EBV genome. This region has often been referred to as Nhet to denote the heterogeneity in this region according to the number of terminal repeats within different virus isolates.

inserted into the B95–8 sequence to make good the deletion. Recently the complete sequences of two more strains of EBV have been determined: GD1, derived from a Chinese nasopharyngeal carcinoma patient (Zeng *et al.*, 2005; accession number AY961628) and AG876 (Dolan *et al.*, 2006; accession number DQ279927), derived from a Ghanaian Burkitt lymphoma (Pizzo *et al.*, 1978). Since the prototype B95–8 genome was sequenced from an EBV DNA *Bam*HI fragment cloned library, open reading frames (ORFs), genes and sites for transcription or RNA processing are frequently referenced to specific *Bam*HI fragments, from A to Z, in descending order of fragment size (Fig. 27.1(b)). The virus has the coding potential for around 80 proteins, not all of which have been identified or characterized. Characterized gene products are listed in Table 27.1. Analysis of the sequences of GD1 and AG876 together with correction of the B95–8 sequence has led to the identification of four previously unrecognized open reading frames: BVLF1 and BDLF3.5 whose functions are unknown, BFRF1A which by homology with other Herpesviruses probably has a role in DNA packaging, and BGLF3.5 which is likely to be a tegument protein (Dolan *et al.*, 2006).

EBV latency in vitro and in vivo

The lymphoblastoid cell line LCL

When peripheral blood lymphocytes from healthy EBV sero-positives are placed in culture, the few EBV-infected B-lymphocytes that are present regularly give rise to spontaneous outgrowth of EBV-transformed, immortalized cell lines, known as lymphoblastoid cell lines (LCLs), provided that immune T-lymphocytes are either removed or inhibited by the addition of cyclosporin A to the culture (Rickinson *et al.*, 1984). LCLs can also be generated by direct infection of resting B-lymphocytes with EBV derived from producer B-cell lines.

Table 27.1. List of characterised genes. References pertain to genes that are not considered further in the text. Open reading frames within the EBV genome are named sequentially after the *Bam*HI fragment within which they begin and the direction in which they are read. Thus, for example, BZLF1 refers to ***B****am*HI-**Z** **l**eftward reading **f**rame number **1**.

BDLF3	glycoprotein gp150	
BMRF2	53/55Kd membrane protein	
BALF3	glycoprotein transport?	Pellett *et al.*, 1986
BCRF1	viral IL-10	

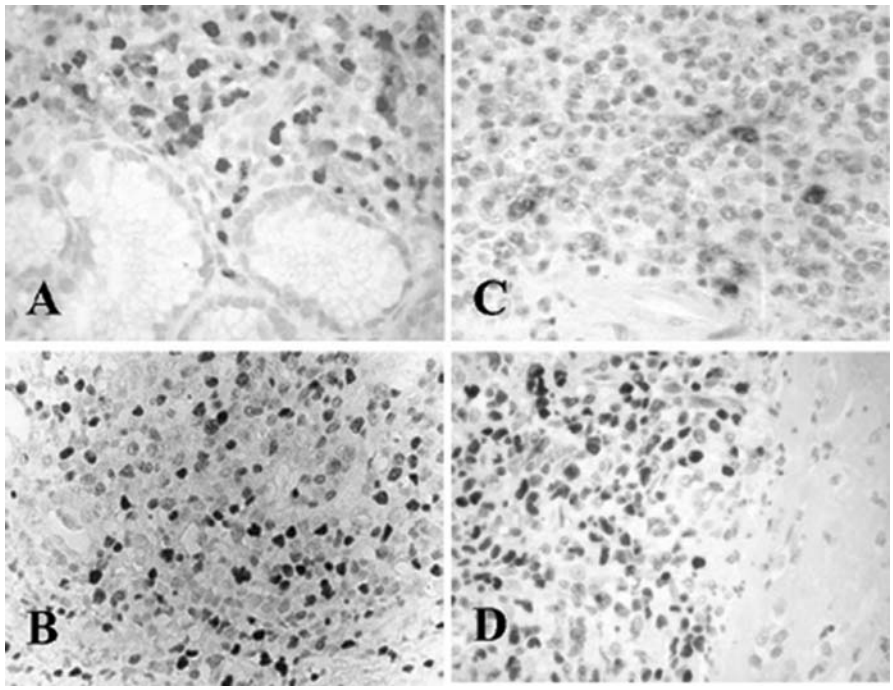

Fig. 27.2. Latency III pattern characteristic of the majority of cases of post-transplant lymphoproliferative disease. All known EBV latent genes are expressed in this form of latency: (a) EBERs, (b) EBNA1, (c) LMP1, (d) EBNA2. (See color plate section.)

Every cell in an LCL carries multiple copies of circular extra-chromosomal viral DNA (episomes) and produces a number of latent proteins, including six nuclear antigens (EBNAs 1, 2, 3A, 3B, 3C and -LP) and three latent membrane proteins (LMPs 1, 2A and 2B) (Fig. 27.1(b)). Transcripts, referred to as BARTs (BamHI A rightward transcripts), from the *Bam*HI A region (Bam A) of the viral genome are also detected, although whether these encode proteins remains controversial (Kieff and Rickinson, 2001). In addition to the latent proteins, LCLs also show abundant expression of the small non-polyadenylated RNAs, EBERs 1 and 2; the function of these transcripts is not clear but they are believed to be expressed in all forms of latent EBV infection and have served as excellent targets to detect EBV in tumors (see later chapters). The relative positions and orientations of these viral genes are illustrated in (Fig. 27.1(b)) under a linearized restriction map of the viral genome. The different EBNAs are encoded by individual mRNAs generated by differential splicing of the same long (over 100 kb) "rightward" primary transcript expressed from one of two promotors (Cp or Wp) located close together in the *Bam*HI C and W region of the genome (Speck and Strominger, 1989). A switch from Wp to Cp occurs early in B cell infection as a consequence of the transactivating effects of both EBNA1 and EBNA2 on Cp. The LMP transcripts are expressed from separate promoters in the *Bam*HI N region of the EBV genome, with the leftward LMP1 and rightward LMP2B mRNAs apparently controlled by the same bidirectional promoter sequence (ED-L1) which also responds to transactivation by EBNA2 (Hofelmayr *et al.*, 1999; Kieff and Rickinson, 2001; Speck and Strominger, 1989). The LMP2A promoter is also regulated by EBNA2. Both LMP2A and LMP2B transcripts cross the TRs into the U1 region thus requiring the circularization of the genome for transcription. Circularization occurs by homologous recombination of the TRs resulting in fused termini of unique length and this has been used as a measure of EBV clonality on the assumption that fused TRs with an identical number of repeats denote expansions of a single infected progenitor cell (Raab-Traub and Flynn, 1986). This contention has recently been challenged by the observation that EBV clonality post-infection may be a consequence of the selective growth advantage achieved by optimal LMP2A expression over a minimal number of TRs (Moody *et al.*, 2003). The pattern of latent EBV gene expression observed in LCLs is referred to as the "latency III" (Lat III) form of EBV infection and is characteristic of the majority of post-transplant lymphomas (Fig. 27.2).

The Lat III pattern of EBV gene expression seen in LCLs is matched by an equally consistent and characteristic cellular phenotype with high-level expression of the B-cell

activation markers CD23, CD30, CD39 and CD70 and of the cellular adhesion molecules, leukocyte function associated molecule-1 (LFA-1; CD11a/18), LFA-3 (CD58) and intercellular adhesion molecule-1 (ICAM-1; CD54) (Rowe *et al.*, 1987). These markers are usually absent or expressed at low levels on resting B cells, but are transiently induced to high levels when these cells are activated into short-term growth by antigenic or mitogenic stimulation, suggesting that EBV-induced immortalization can be elicited through the constitutive activation of the same cellular pathways that drive physiological B cell proliferation. The ability of EBNA2, EBNA3C and LMP1 to induce LCL-like phenotypic changes when expressed individually in human B cell lines implicates these viral proteins as key effectors of the immortalisation process (Kieff and Rickinson, 2001; Rickinson and Kieff, 2001; Wang *et al.*, 1990).

Other forms of EBV latency

The examination of EBV latent gene expression in virus-associated tumors and in cell lines derived from Burkitt lymphoma (BL) biopsies identified at least two additional forms of EBV latency. EBNA1 is the only EBV protein consistently observed in EBV-positive BL tumors along with the EBER and *Bam*HIA transcripts; this form of latency is referred to latency I or Lat I (Fig. 27.3) (Gregory *et al.*, 1990; Rickinson and Kieff, 2001; Rowe *et al.*, 1987). Some reports have documented expression of LMP1 and EBNA2 in small numbers of cells in a few cases of endemic BL (Niedobitek *et al.*, 1995), and LMP1 in several cases of sporadic BL (Carbone *et al.*, 1995). In BL biopsies and representative BL cell lines EBNA1 is transcribed from the Qp promoter rather than Wp or Cp (Nonkwelo *et al.*, 1996). Qp, a TATA-less promoter, has many features of the promoters driving expression of housekeeping genes and a downstream element, the Q locus, binds EBNA1 resulting in the repression of Qp transcription (Sample *et al.*, 1992). Recent studies indicate that Qp is also positively regulated by the JAK/STAT pathway (Chen *et al.*, 1999).

BL cells exhibit high level expression of CD10 and CD77, a phenotype most closely resembling that of centroblasts in germinal centers. When cells from some EBV-positive BL tumors are passaged in culture, the other EBNAs and LMPs are expressed, and the EBNA2and LMP1-induced cell surface antigens, such as CD23, CD30, CD39, LFA1, LFA3, and ICAM1, also are up-regulated (Gregory *et al.*, 1990). EBNA2 and LMP1 are the major mediators of EBV-induced B lymphocyte growth in vitro and the lack of expression of these proteins in tumor cells suggests that they are not required for BL growth (Rickinson and Kieff, 2001).

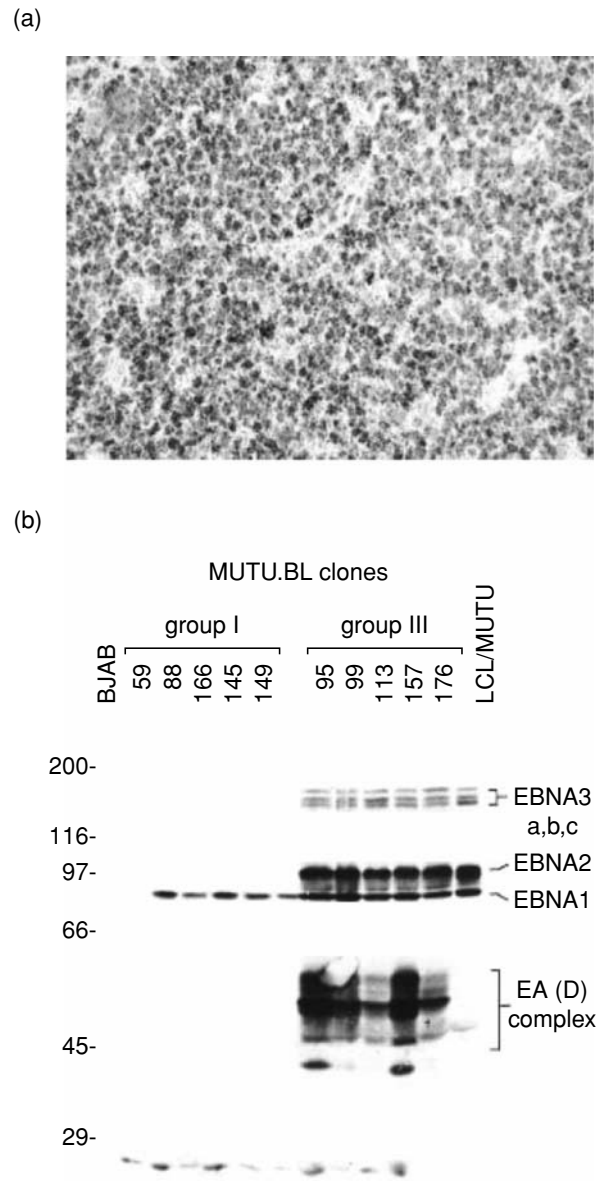

Fig. 27.3. Latency pattern characteristic of Burkitt's lymphoma (BL). (a) Expression of EBERs in the tumor cells of BL tissue shown by isotopic *in* situ hybridization and (b) Immunoblotting demonstrating protein expression limited to EBNA1 in so-called 'group I' BL cell lines which recapitulate the in vivo expression profile. 'Group III' BL lines have an expression pattern similar to that of LCLs (Latency III) and represent cell lines that have 'drifted' from a latency I pattern in vitro. (See color plate section.)

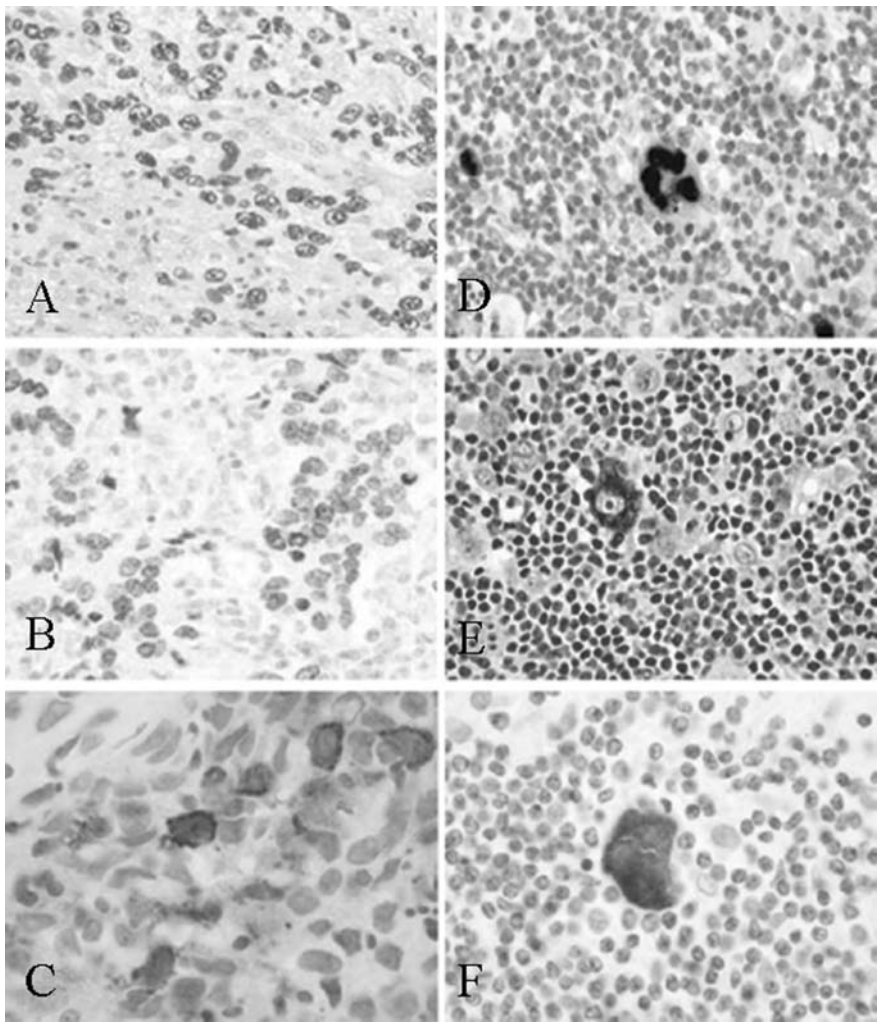

Fig. 27.4. EBV latency type II. Left panel shows (a) Expression of EBERs, (b) EBNA1 and (c) LMP1, in the tumor cells of nasopharyngeal carcinoma (NPC). LMP1 expression is not a regular feature of these tumors. LMP2 protein has not yet been reported in NPC tumors, despite the detection of LMP2 RNA. Right panel shows EBV gene expression in the rare tumor cells of (HRS cells) Hodgkin's lymphoma. (d) EBERs, (e) LMP1 and (f) LMP2. EBNA1 protein is also detectable in the majority of cases (not shown). In contrast to NPC, both LMP1 and LMP2 protein are almost always detectable in EBV-infected HRS cells. (See color plate section.)

Another form of EBV latency, Lat II, was originally identified in biopsies of nasopharyngeal carcinoma (NPC) and subsequently found in cases of EBV-associated Hodgkin's lymphoma (HL) (Brooks *et al.*, 1992; Deacon *et al.*, 1993; Pallesen *et al.*, 1991; Young *et al.*, 1988). Here, expression of the EBERs, Qp-driven EBNA1 and *Bam*HI A transcripts is accompanied by expression of LMP1 and LMP2A/B (Fig. 27.4). Transcription of LMP1 is controlled by an EBNA2-independent promoter located within the viral terminal repeats (L1-TR) and is regulated by the JAK/STAT signaling pathway (Chen *et al.*, 2001, 2003). The factors responsible for LMP2A and LMP2B expression in the absence of EBNA2 in NPC and HL have yet to be defined. Whilst this Lat II pattern of EBV latent gene expression is a consistent feature of virus-associated HL, LMP1 expression in NPC is variable with only around 20% of biopsies being unequivocally positive for LMP1 at the protein level (Niedobitek *et al.*, 1992). The mechanisms underlying differential LMP1 expression in NPC and the consequent effects on the NPC phenotype remain unknown.

The observation that the majority of NPC tumors do not express the Lat II form of EBV latent infection and that EBNA2 can occasionally be detected in BL tumour cells emphasizes the limitations of the operational

categorization of virus latency into three distinct forms. It is clear that in vivo there is often a spectrum of EBV latent and lytic gene expression within the same infected tissue. The need for caution in the rigid application of these forms of EBV latency is highlighted by a recent study in which expression of the EBNA3 family through Wp-driven transcription has been identified in a subset of BL biopsies (Kelly *et al.*, 2002). It appears that in these tumors the selective pressure to down-regulate EBNA2 expression has occurred via deletion of the EBNA2 gene rather than through the switch to Qp usage observed in the conventional BL scenario. Other forms of EBV latency in which the EBERs are not expressed have been reported in breast carcinoma and hepatocellular carcinoma but here the association of EBV with these tumors remains controversial (Bonnet *et al.*, 1999; Murray *et al.*, 2003; Sugawara *et al.*, 1999).

EBV replication/the lytic cascade

The cascade of events in the lytic phase of the EBV life cycle is divided into three phases of regulated gene expression: immediate–early, early and late. The immediate–early gene products are transactivator proteins that trigger the expression of the early genes, the products of which include enzymes that are required for viral DNA replication. In turn, amplification of EBV DNA defines the boundary between early and late gene expression. During the late phase of the cycle viral structural proteins are expressed and assembled into virus particles into which the DNA is packaged prior to release of infectious virions.

The principal switch from latency to productive infection involves activation of the immediate–early genes BZLF1 and BRLF1 (Biggin *et al.*, 1987; Countryman and Miller, 1985; Hardwick *et al.*, 1988; Rooney *et al.*, 1989). On induction of the lytic cycle these two genes are expressed simultaneously (Sinclair *et al.*, 1991) and respectively encode the transactivator proteins known as ZEBRA (Countryman *et al.*, 1987), EB1 (Chevallier-Greco *et al.*, 1986) or Zta (Lieberman *et al.*, 1990) (BZLF1) and Rta (BRLF1). The two proteins can be expressed from a major 2.9 kb and a minor 3.8 kb bicistronic R-Z RNA transcribed from the R-promoter (Rp) whilst ZEBRA is also expressed from a smaller 0.9 kb mRNA initiated at the downstream Z-promoter (Zp). In addition, another 0.9kb message encoding a putative fusion protein known as RAZ and consisting of parts of both Rta and ZEBRA is transcribed at low level (Fig. 27.5) (Manet *et al.*, 1989). The in vivo significance, if any, of the putative RAZ protein is unclear although it appears to be able to act as an inhibitor of ZEBRA (Furnari *et al.*, 1994; Segouffin *et al.*, 1996). Both Zp and Rp are activated by ZEBRA whilst Rta can up-regulate Zp and autoactivate its own synthesis. However, maximum activation of the upstream Rp promoter for the bicistronic messenger is obtained by the synergistic effects of ZEBRA and Rta (Liu and Speck, 2003). This synergism suggests that low levels of the two proteins are sufficient to trigger the lytic cascade. Transcription of the immediate–early genes does not require *de novo* protein synthesis (Biggin *et al.*, 1987) implying that physiological signals from the host cell are involved in triggering activation of the lytic cycle. Lytic inducers activate intracellular signaling pathways that culminate in the dephosphorylation of the Zp-binding myocyte enhancer factor 2D (MEF-2D, see Fig. 27.5) which recruits histone acetylase leading to hyperacetylation of histones within the chromatin structure of Zp and promoter activation (Bryant and Farrell, 2002; Deng *et al.*, 2003; Gruffat *et al.*, 2002b; Jenkins *et al.*, 2000; Speck *et al.*, 1997). It has recently been shown that the BRRF1 gene product is a transcription factor that activates Zp and also cooperate with Rta to induce lytic infection (Hong *et al.*, 2004).

ZEBRA is a member of the basic-zipper family of transcription factors and binds as a homodimer to ZEBRA response elements (ZREs) within early gene promoters. Whilst ZEBRA alone activates some early genes, others are maximally stimulated by the synergistic effects of ZEBRA and Rta, whereas a third class is maximally induced by Rta alone (Feederle *et al.*, 2000; Ragoczy and Miller, 1999).

In common with other herpesviruses, EBV encodes several early genes that are involved in nucleotide metabolism e.g. thymidine kinase (BXLF1) and in DNA replication, e.g., DNA polymerase. Studies of herpes simplex virus (HSV) suggest that many genes of the former class are non-essential for replication of the virus, at least in cell culture, since their functions are duplicated by host cell enzymes (Roizman and Knipe, 2001). Conversely six of the latter, BMRF1 (polymerase-associated factor), BALF2 (single-stranded DNA binding protein), BALF5 (DNA polymerase), BSLF1 (primase), BBLF4 (helicase) and BBLF2/3 (primase accessory protein) have been referred to as core replication genes (Fixman *et al.*, 1992) and are obligatory for viral DNA replication and the progression from the early to late phase of the life cycle.

The lytic origin of replication that is employed in the synthesis of virion DNA, ori-lyt (Hammerschmidt and Sugden, 1988), is distinct from the plasmid DNA replication origin, ori-P, that is used to maintain the episomal virus DNA in synchrony with host cell division during latency. Ori-lyt lies within the *Bam*HI H region of EBV DNA and contains two essential cis-acting regions: the BHLF1 promoter and a second region about 0.5 kb distant that is required for

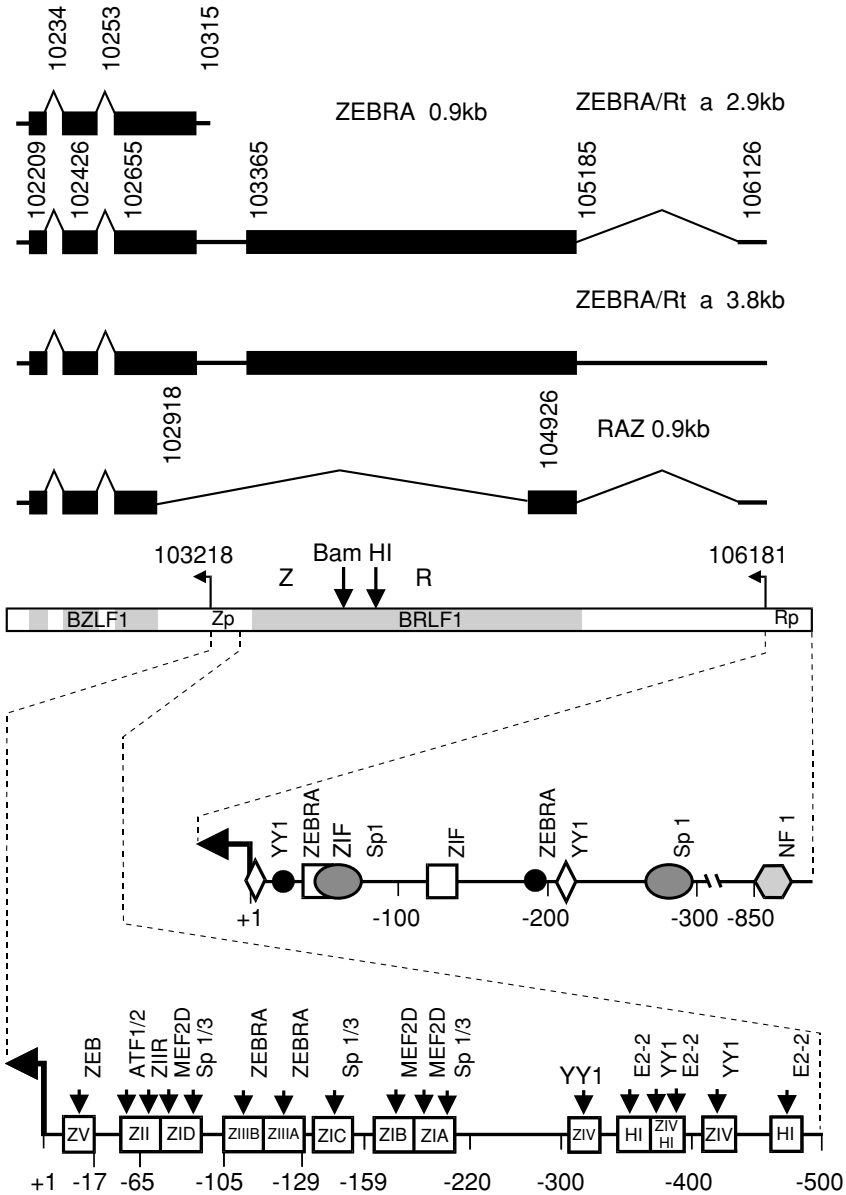

Fig. 27.5. Schematic organization of the immediate–early transactivator genes. The open box in the center represents the BamHI Z-R region of EBV DNA. The BZLF1 and BRLF1 open reading frames and their respective promoters Zp and Rp are indicated with their transcriptional initiation points represented by raised arrows. The four immediate–early transcripts are shown at the top. Horizontal lines represent exons with the coding regions indicated by thicker portions. Genome coordinates are numbered with reference to the B95–8 sequence (Genbank accession number V01555). The organization of the Rp and Zp promoters is illustrated below: +1 refers to the site of transcription initiation. Although Rp contains two ZREs the proximal site is dominant in mediating transcriptional activation by ZEBRA (Liu and Speck, 2003). The NF1 site appears to be a positive regulator in epithelial but not lymphoid cells (Glaser *et al.*, 1998) whilst the Sp1 sites may be involved in the autoactivation of Rp by Rta (Ragoczy and Miller, 2001). The Zif site is a positive trancriptional regulator (Zalani *et al.*, 1995) whereas the YY1 sites are negative regulatory elements that may be involved in the maintenance of latency (Zalani *et al.*, 1997). The Zp promoter (bottom) has been shown to contain multiple regulatory domains (for review see Speck *et al.*, 1997) indicated by the open boxes. Transcription factors that bind to the various domains are marked by the down arrows. The four ZI domains (ZIA – D) are A+T-rich sequences that bind MEF2 transcription factors, principally MEF2D, and seem to play a critical role in the latent to lytic switch (see text). With the exception of ZIB, the ZI domains also bind Sp1 and Sp3 factors. The ZII domain is also potentially responsive to extracellular stimuli by virtue of its affinity for cAMP response element binding (CREB) factors, e.g., ATF1 and 2. In addition, the ZII domain contains a *cis*-acting negative regulatory element (ZIIR) whose putative cellular binding-factor remains unknown (Liu *et al.*, 1998). The ZIII domains bind ZEBRA and are likely involved in autoactivation. The ZIV, ZV and HI domains are negative regulatory elements that bind YY1, zinc finger E-box binding factor (ZEB) and E2–2, respectively (Montalvo *et al.*, 1995; Kraus *et al.*, 2003; Thomas *et al.*, 2003).

replication but not needed for BHLF1 transcription. The BHLF1 promoter contains ZREs that, if mutated, eliminate ori-lyt-directed replication (Schepers *et al.*, 1993). These and other data have demonstrated that ZEBRA is an essential component of lytic DNA replication and it has recently been shown that physical interaction with the EBV helicase targets ZEBRA to viral DNA replication compartments within the nucleus (Liao *et al.*, 2001).

Several herpesviruses replicate their DNA only in G1-arrested host cells (Flemington, 2001); a situation that has been suggested as being advantageous to the virus due to lack of competition with cellular DNA replication. Again ZEBRA has been implicated as a key regulatory element in the EBV lytic cycle. In this instance ZEBRA interacts with C/EBPa leading to accumulation of $p21^{CIP-1}$ and G1 cell cycle arrest (Wu *et al.*, 2003). Further studies suggest that whilst inhibiting cellular DNA synthesis, EBV induces an S-phase-like cellular environment during lytic replication (Kudoh *et al.*, 2003, 2004).

The checkpoint between early and late gene expression involves productive viral DNA replication. How is this linked to the induction of late gene expression? Methylation of promoter sequences can lead to gene repression (Jansson *et al.*, 1992) and thus newly replicated, unmethylated promoter sequences may be activated. However, this mechanism does not appear to be involved since inhibitors of DNA methyltransferase do not activate EBV late genes (Fronko *et al.*, 1989; Szyf *et al.*, 1985). A transient transfection-based reporter assay using EBV early and late promoters within non-replicating plasmids faithfully reproduced the early/late promoter expression profile during different phases of the virus life cycle (Serio *et al.*, 1997). This result demonstrates that a *trans*-relationship exists between viral DNA replication and late gene expression. The steps in the chain of events leading to the activation of late promoters remain to be elucidated. However, Serio *et al.* (1998) provide evidence that a variant TATA element within the core promoter region of the late genes is located within a transcriptionally inert environment and is a critical effector in their regulation. In addition, *cis*-regulatory elements appear to operate in the immediate vicinity of this core to activate late gene expression.

Functions and associated properties of lytic cycle gene products

Lytic cycle gene products were originally identified immunologically as distinct fluorescent antigen complexes referred to as virus capsid antigen (VCA), early antigen (EA) and membrane antigen (MA) (Ernberg and Klein, 1979). These descriptions survive to this day but we now know that these antigens consist of a number of viral structural proteins, replicative enzymes and membrane proteins, respectively. Examination of the sequence of the EBV genome reveals a coding potential for around 80 proteins. Our knowledge of the properties of these gene products encompasses a spectrum of characterization ranging from genes that have been analyzed in minute detail to those that still remain hypothetical. Some aspects of the properties of lytic gene products are summarized below.

Early gene products, early antigens, and diagnostic tests

The early proteins constitute the serologically defined EA complex. More than 20 years ago Henle and colleagues showed that IgA antibodies to EA in the sera of NPC patients were indicative of the disease (Henle *et al.*, 1970). This work was extended as a potential diagnostic and prognostic test for NPC (Zeng *et al.*, 1983) and individual early gene products have now been identified as antigenic determinants and proposed as being potentially useful as more objective diagnostics (Baylis *et al.*, 1989; Connolly *et al.*, 2001; Dardari *et al.*, 2000; Feng *et al.*, 2001; Fones-Tan *et al.*, 1994; Liu *et al.*, 1994; Stolzenberg *et al.*, 1996). More recently, combination assays using more than one target antigen have been evaluated (Chan *et al.*, 2003; Cheng *et al.*, 2002). Whilst several assays appear promising, none has yet been routinely adopted.

DNA replicative enzymes

The six "core replication proteins" together with ZEBRA are absolutely required for the amplification and replication of the viral genome from ori-lyt. The intermediate replication product is a concatemeric structure consisting of several genome units linked head to tail (Hammerschmidt and Sugden, 1988). The enzymatic mechanism involved in cleavage of the concatemers is uncertain (Zimmermann and Hammerschmidt, 1995). The replication proteins have been shown to function as (a) complex(es). The helicase, primase and primase accessory protein physically associate as a nuclear complex (Yokoyama *et al.*, 1999). This heterotrimeric complex interacts (a) with ZEBRA via a helicase association (Gao *et al.*, 1998; Liao *et al.*, 2001) and (b) with the DNA polymerase (Fujii *et al.*, 2000) which itself binds the polymerase accessory protein (Zeng *et al.*, 1997). The DNA binding protein can interact with this tetrameric complex (Gao *et al.*, 1998) and also significantly stimulates DNA synthesis by the core polymerase suggesting an association between these molecules (Tsurumi *et al.*, 1996). These and

other data suggest the following partial scenario for EBV lytic cycle DNA replication: ZEBRA interacts with the helicase/primase/accessory protein complex and recruits this to the ZEBRA binding sites on ori-lyt to form a pre-priming complex to which the DNA binding protein attaches. This complex opens the DNA helix at the origin and synthesizes RNA primers. The DNA polymerase and its accessory protein subsequently attach to the complex allowing DNA replication to proceed (Fujii *et al.*, 2000).

In addition, the ori-lyt-binding host cell encoded transcription factors ZBP-89 and Sp1 interact with the polymerase/accessory protein complex and stimulate viral DNA replication (Baumann *et al.*, 2000). These data suggest an additional, complementary mechanism whereby cellular transcription factors tether the viral replication proteins to ori-lyt.

The mRNA export factor, BMLF1

The early gene product from the BMLF1 ORF is referred to as EB2 (Chevallier-Greco *et al.*, 1986), Mta (Fixman *et al.*, 1992) or SM (Cook *et al.*, 1994). It was originally thought to be a transcriptional transactivator that in conjunction with ZEBRA and Rta regulates lytic cycle activation. It is a heterogeneous, nuclear phosphoprotein with a major species of about 60 kDa.

The export of mRNA from the nucleus to the cytoplasm is significantly enhanced by splicing and requires the action of a multiprotein exon junction complex. However, since the majority of EBV lytic cycle mRNAs are unspliced, an alternative export mechanism such as an mRNA-bound adaptor protein needs to be invoked. The properties of the BMLF1 product are consistent with such a role since it shuttles between nucleus and cytoplasm, contains two nuclear export signals, is an RNA-binding protein in vivo and promotes the cytoplasmic accumulation of unspliced EBV mRNA, notably including some of the core replication genes (Gruffat *et al.*, 2002a; Semmes *et al.*, 1998).

Using a mutant EBV deleted for BMLF1 Gruffat *et al.*, 2002a) showed that EB2/Mta is essential for virion production. The HSV protein homologue of EB2/Mta, ICP27, has been shown to be a viral adaptor molecule that is involved in the nuclear export of intronless viral mRNA (Koffa *et al.*, 2001). ICP27 can partially complement the defect in the BMLF1negative EBV (Gruffat *et al.*, 2002a).

Bcl-2-related proteins

Different members of the bcl-2 family of proteins either induce or repress apoptosis. EBV encodes two bcl-2 homologues; BHRF1 and BALF1. The BHLF1 gene product is a 17 kDa putative membrane protein that is highly conserved in all EBV isolates (Khanim *et al.*, 1997) and is non-essential for virus replication or virus-mediated cellular transformation in vitro (Lee and Yates, 1992; Marchini *et al.*, 1991).

Expression of BHRF1 in a number of cell types in vitro enhances their apoptosis resistance to a variety of appropriate stimuli (Henderson *et al.*, 1993; Kawanishi, 1997; Tarodi *et al.*, 1994). In addition to its anti-apoptotic function BHRF1 promotes rapid transit through the cell cycle (Dawson *et al.*, 1998). These and other data suggest that *in vivo* the primary role of BHRF1 may be to delay host cell apoptosis during the EBV lytic cycle thereby facilitating complete virus replication and assembly (Dawson *et al.*, 1995, 1998).

The second bcl-2 homologue, BALF1, is a 182 amino-acid polypeptide that has counterparts in the EBV-related viruses of other primates (Bellows *et al.*, 2002). This protein appears to act as an antagonist of the anti-apoptotic effects of BHRF1; a situation reminiscent of cellular bcl-2 family members that can counteract each other's functions. How these two proteins interact in the virus's life cycle remains to be determined.

BNLF2a

The $CD8^+$ T-cell response to EBV lytic cycle antigens is markedly skewed towards immediate-early and early proteins whilst late proteins are recognised only rarely (Pudney *et al.*, 2005). Nevertheless, in vivo EBV replicates successfully in spite of this robust immune reponse to lytic antigens. Ressing *et al.* (2005) demonstrated that cells undergoing lytic infection have reduced TAP-mediated transport of peptides to the endoplasmic reticulum and impaired presentation at the cell surface. It has recently been shown that the BNLF2a gene product is the mediator of this immune evasion mechanism by blocking the interaction of peptides with the TAP transporter and likely explains the bias of immune response towards early proteins, i.e. prior to BNLF2a function (A. D. Hislop, personal communication).

BARF1

The BARF1 ORF encodes a product of about 33 kDa that is secreted into the medium of cultured cells (Strockbine *et al.*, 1998). It may be post-translationally modified by N-linked glycosylation, myristylation and phosphorylation (Sheng *et al.*, 2001). It binds to and inhibits the proliferative effects of human colony-stimulating factor 1 (CSF-1). It was proposed that by blocking CSF-1 activity the BARF1 protein might impair cytokine release from mononuclear cells thereby modulating host immune responses to EBV infection (Cohen and Lekstrom, 1999; Strockbine *et al.*,

1998). In addition, a BARF1-negative EBV has revealed a second effect of the BARF1 protein on innate immunity; the deletant was impaired in its ability to inhibit α-interferon production by mononuclear cells (Cohen and Lekstrom, 1999).

Although BARF1 appears temporally as an early gene in the viral life cycle it can act as an oncogene when stably expressed in cultured murine, human or simian cells (Wei *et al.*, 1994, 1997; Wei and Ooka, 1989). In addition, Akata BL cells that had lost their tumorigenic phenotype through loss of the EBV genome regained the ability to form tumors in SCID mice following transfection with BARF1 (Sheng *et al.*, 2003). The N-terminal 49 a.a. appear to be essential for the transforming ability (Sheng *et al.*, 2001). However, a BARF1deleted virus was not defective in its capacity to immortalize B cells in vitro indicating that in the context of the whole virus BARF1 is not essential for this function (Cohen and Lekstrom, 1999).

Nevertheless, observations of the EBV-positive epithelial tumors NPC and gastric carcinoma are provocative. Analysis of BARF1 transcription using RT-PCR or of protein expression by Western blot and immunohistochemistry detected the presence of this antigen in around 85% of NPCs and 100% of gastric carcinomas (Decaussin *et al.*, 2000; zur Hausen *et al.*, 2000). EBV-positive gastric carcinomas and the majority of NPCs do not express LMP1. It has been suggested that in these cases BARF1 may be acting as the viral oncogene in the absence of LMP1. These data also suggest that in epithelial tumors BARF1 is a latent, rather than early, gene.

Late gene products

Glycoproteins

EBV encodes a number of glycoproteins of which eleven have been described. The glycoproteins present in the classical MA complex are gp350/220 (BLLF1) and gH (gp85, BXLF2) (Edson and Thorley-Lawson, 1981). The BLLF1 ORF is transcribed as two mRNA species, the smaller of which is generated by an in-frame splice such that gp220 is effectively an internally deleted version of gp340 (Biggin *et al.*, 1984). These products are highly glycosylated; around 50% of their mass is carbohydrate. The region that is spliced out of gp350 to generate gp220 contains a repetitive region consisting of a basic 21-amino-acid unit composed of three 7-amino-acid subunits. In some units, the third subunit is missing. In common with other repetitive regions of the EBV genome, the length varies between strains and has been observed to range from 56 to 126 a.a. (Lees *et al.*, 1993).

The N-terminal region of gp350/220 mediates binding of EBV to its B-cell receptor, CD21 (also known as CR2) (Fingeroth *et al.*, 1984; Nemerow *et al.*, 1989). This interaction induces capping of the receptor, endocytosis of the virus into the cell (Tanner *et al.*, 1987) and triggers tyrosine/PI kinase and NF-κB-dependent intracellular signaling pathways that activate the Wp promoter (Sinclair and Farrell, 1995; Sugano *et al.*, 1997). However, a BLLF1 deletant was able to infect B-cells and epithelial cells indicating that the gp350/220-CD21 interaction is not exclusively required for infection and that other viral proteins can mediate cellular attachment (Janz *et al.*, 2000). This function could be performed by the gH/gL/gp42 complex (see below).

gp350/220 is the major EBV neutralizing-antibody determinant (Thorley-Lawson and Poodry, 1982) and for this reason has been the focus of efforts to develop an anti-EBV vaccine (Arrand, 1992). Following encouraging human trials using a recombinant vaccinia-based delivery system (Gu *et al.*, 1991) a subunit gp340 vaccine (Jackman *et al.*, 1999) has progressed through phase 1 clinical trials and is now in phase 2 (http://www.medimmune.com/pipeline/EpsteinBarrVirusvaccine.asp).

The third component of MA, gH (BXLF2), forms a heterotrimeric complex with two more glycoproteins, gL (BKRF2) and gp42 (BZLF2). This complex is involved in the penetration of B-cells by EBV and uses cell-surface HLA class II molecules as coreceptor. It is proposed that primary binding of EBV to the B cell is mediated by the gp350/220–CD21 interaction. This is subsequently augmented by gp42 binding to HLA class II followed by virus–cell fusion mediated by the gH/gL complex (Hutt-Fletcher and Lake, 2001).

Infection of epithelial cells is somewhat different since they do not express surface HLA class II. In this case EBV uses a dimeric complex of gH-gL (without gp42) to bind to an unidentified receptor. EBV carries both dimeric and trimeric complexes in order to infect both types of host. The presence or absence of HLA class II in the virus-producing cell alters the ratio of these complexes such that epithelial cell-derived virus efficiently infects B cells and vice versa (Borza and Hutt-Fletcher, 2002).

A second EBV glycoprotein complex consists of gN (BLRF1) and gM (BBRF3). Co-expression of gM with gN is required for processing of the latter to its mature form (Lake *et al.*, 1998). Recombinant EBV in which the gN gene is inactivated fails to accumulate gM. In cells infected with this virus many of the capsids remain trapped in the nucleus and the majority of the virions are non-enveloped (Lake and Hutt-Fletcher, 2000).

The BALF4 ORF encodes gp110, a highly conserved homologue of the abundant envelope protein gB of other herpesviruses which is involved in virus–cell fusion. In contrast, EBV gB appeared to be virtually absent from the virion and to be localized to the nuclear membrane and endoplasmic reticulum (Gong and Kieff, 1990; Gong

et al., 1987; Papworth *et al.*, 1997). A recombinant EBV lacking gp110 was not released from the cell (Herrold *et al.*, 1996). These data led to the notion that the EBV gB is involved in the egress of virions from the lytically infected cell.

Recent data (Neuhierl *et al.*, 2002) indicate that B95–8 cells and virions are unusual and that in other virus strains gB is present both in the virion and on the plasma membrane of the host cell. Virions that contain gB have an enhanced infectivity and a wider cell tropism, consistent with a role in virus–cell fusion and viral entry similar to other herpesviral gBs. In keeping with this, a virus-free assay has shown that gB can mediate membrane fusion (Haan *et al.*, 2001).

EBV also encodes four poorly characterized membrane proteins; gp78 (BILF2), a highly glycosylated virion envelope glycoprotein of unknown function (Mackett *et al.*, 1990), gp150 (BDLF3), gp60 (BILF1) and BMRF2.

gp150 is an envelope glycoprotein that is ~75% carbohydrate and is non-essential for growth in B cells in vitro. A gp150-negative virus was fully competent for binding, infectivity, assembly and egress of both B cells and epithelial cells. Mysteriously, it had an enhanced infectivity for epithelial cells (Borza and Hutt-Fletcher, 1998).

gp60 and BMRF2 are both predicted to have multiple membrane-spanning domains and gp60 appears to be glycosylated (Hutt-Fletcher and Lake, 2001). BMRF2 is a 55 kD membrane protein (Modrow *et al.*, 1992) that can interact with integrins to facilitate the infection of basolateral surfaces of epithelial cells by EBV (Tugizov *et al.*, 2003).

Structural proteins

In addition to the virion glycoproteins described above, some members of the immunologically defined VCA complex have been characterized as products of specific ORFs. The major capsid protein is p160 (BcLF1) and three small capsid proteins, p18, p23 and p40 (BFRF3, BLRF2 and BdRF1) have been identified (Reischl *et al.*, 1996; van Grunsven *et al.*, 1993). The BVRF2 ORF overlaps BdRF1 and appears to encode a protease that is involved in the maturation of p40 (Donaghy and Jupp, 1995).

Studies on the protein composition of purified virions (Johannsen *et al.*, 2004) reveal that the tegument contains several late proteins including BNRF1, the major 143kD tegument component (Cameron *et al.*, 1987) and the large, 3149 a.a. tegument protein BPLF1 (Schmaus *et al.*, 2004). Interestingly a number of host cell proteins including β-actin, cofilin, tubulin, Hsp70 and Hsp90 were also present in the tegument. It is suggested that inclusion of these host cell proteins within the virion may indicate that they have a role as "mediators of morphogenesis" (Johannsen et al., 2004).

Immunofluorescent assays for VCA are still used in EBV diagnosis and, as with EA, the immunological utility of individual, purified VCA components as more objective targets has been examined. Immunogenic determinants have been associated with p160, p143, p38, p40, p18 and gB (Chen *et al.*, 1991; Hinderer *et al.*, 1999). As with novel ELISA assays using EA components, late proteins showed excellent performance in initial tests but the classical immunofluorescence assays remain in clinical use.

Viral interleukin-10

The BCRF1 ORF of EBV is highly conserved between strains (Stuart *et al.*, 1995) and exhibits extensive sequence and functional homology with the human cytokine interleukin-10 (hIL-10) (Moore *et al.*, 1990). It is therefore termed viral IL-10 (vIL-10). The mature protein sequences share 83% identity and most of their divergence is found in the N-terminal 20 amino acids. Functional activities, involving cells of the immune system, include deactivation of macrophages and dendritic cells, inhibition of cytokine synthesis by $CD4^+$T cells and proliferation and differentiation of activated B-cells (Moore *et al.*, 2001). However, some differences between hIL-10 and vIL-10 have been noted (Salek-Ardakani *et al.*, 2001).

In terms of the effects of vIL-10 on the life cycle of EBV, it has been shown that whilst vIL-10 is not absolutely required for B-cell transformation addition of exogenous vIL-10 significantly enhanced the efficiency of viral transformation of B-cells, increased cell viability and inhibited the production of antiviral interferon-γ (Stuart *et al.*, 1995; Swaminathan *et al.*, 1993). In addition, vIL-10 has been shown to counteract the inhibitory effect of T-cells on EBV-induced B cell transformation (Bejarano and Masucci, 1998). Since vIL-10 is a late gene product these observations suggest a model whereby lytically infected cells produce both virions and vIL-10. The latter acts on the surrounding cellular environment to facilitate propagation of EBV both by enhancing the susceptibility of B-cells to be transformed by the virus and by inhibiting the host's immunological defences against such action.

EBV persistence in vivo

Several lines of evidence support a role for the B lymphocyte as the site of EBV persistence in vivo. Indeed, therapy aimed at eliminating virus replication using long-term acyclovir treatment (which following conversion to

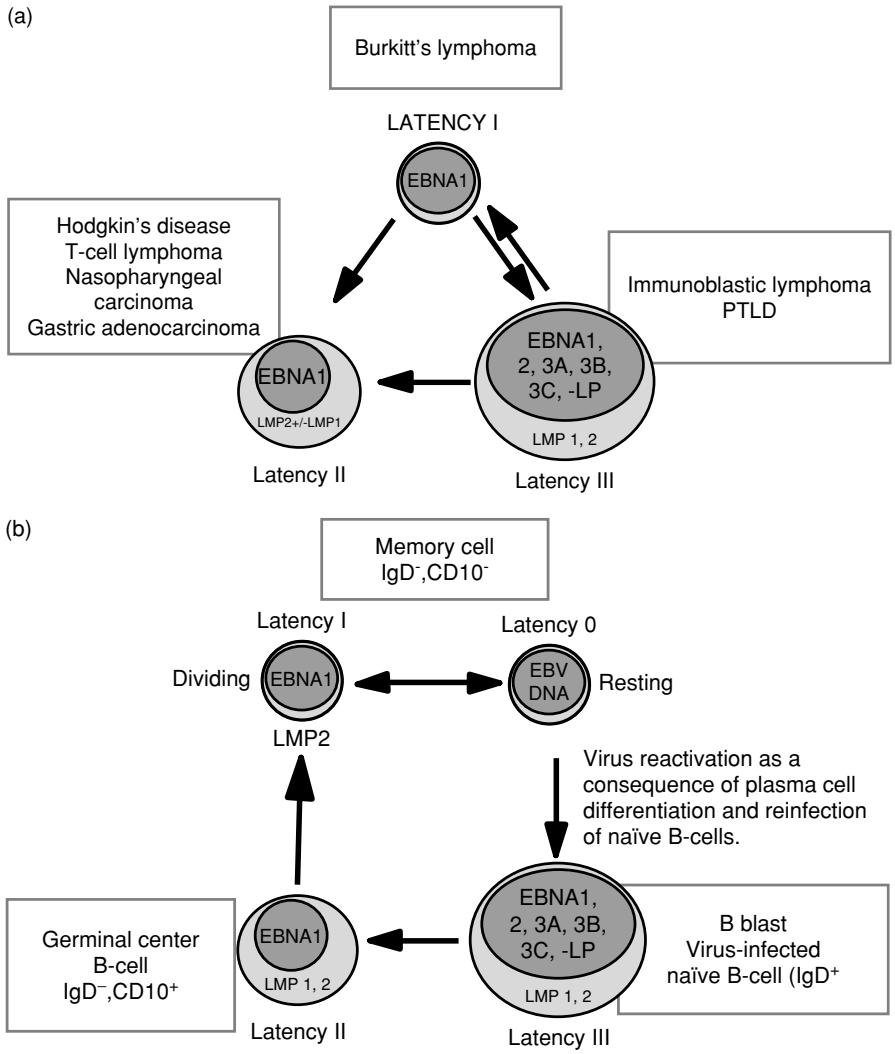

Fig. 27.6. The different forms of EBV latency manifest in virus-associated tumors (a) and during infection of normal differentiating B-cells (b). Arrows depict the interchangeable forms of latency observed by various manipulations in vitro (a) which are believed to recapitulate those occurring during B-cell differentiation in vivo (b).

acyclovir triphosphate interferes with viral replication by competing with deoxyguanosine triphosphate for viral DNA polymerase) eliminates virus excretion from the oropharnyx but does not affect the level of latent infection in B-cells (Ernberg and Andersson, 1986). As soon as treatment is halted, virus can be detected in the oropharyngeal secretions at pre-treatment levels (Yao *et al.*, 1989). In addition, studies of EBV strains in donor–recipient pairs before and after bone marrow transplantation (BMT) have shown that the recipient's strain disappeared from the oropharynx and was replaced by the donor's strain, indicating that the bone marrow B-cells harbor EBV (Gratama *et al.*, 1990). Furthermore, patients with X-linked agammaglobulinemia (XLA), who are deficient in mature B-cells, are found to be free of EBV infection, suggesting they are not able to maintain a persistent infection (Faulkner *et al.*, 1999).

EBV exists in the peripheral blood within the IgD memory B cell pool; EBV gene expression in these cells being restricted to LMP2A and possibly EBNA1 (Fig. 27.6) (Babcock *et al.*, 1998). Recent work has shown that a subset of healthy tonsils contains EBV^+ naïve (IgD^+) B-cells and that these cells express the Lat III programme and show an activated phenotype, suggesting they have been directly infected (Joseph *et al.*, 2000). These cells are

presumably either eliminated by virus-specific cytotoxic T-lymphocytes (CTLs) or differentiate to IgD memory B-cells, which then leave the tonsil. Some of these memory B-cells will pass through mucosal lymphoid tissues and terminally differentiate into plasma cells, whereupon they might enter the lytic cycle. However, a proportion also exits the cell cycle and will replenish the peripheral pool of infected memory cells. Recent work suggests that the majority of resting EBV-infected memory B-cells in vivo do not express virus latent genes and that EBNA1 expression only occurs when these cells divide (Hochberg *et al.*, 2004). The Lat II pattern of EBV gene expression has also been detected in tonsillar memory B-cells and germinal center B-cells (Babcock and Thorley-Lawson, 2000). LMP1 can provide surrogate T cell help via mimicry of an activated CD40 receptor and LMP2A can substitute for B cell receptor engagement (see later). Thus, the virus might enter a germinal center reaction and re-express LMP1 and LMP2A, providing a mechanism for the antigen-independent expansion of EBV-infected B-cells (Babcock and Thorley-Lawson, 2000; Thorley-Lawson, 2001). However, these data are not supported by studies of CD40 null mice, which are defective for isotype switching and germinal center formation. When LMP1 is constitutively expressed from a transgene in the B-cells of these mice, they are still not able to form germinal centers or produce high-affinity antibodies (Uchida *et al.*, 1999). Furthermore, germinal centers are also not formed when LMP1 is expressed in a wild-type (CD40+) background suggesting that, rather than facilitating a germinal centre reaction, LMP1 actively inhibits this process. These conflicts remain to be resolved.

Although much of the evidence described above implicates the B cell compartment as the site of persistence, a role for infection of squamous epithelial cells is suggested by the detection of EBV in oral hairy leukoplakia (Fig. 27.7), a benign lesion of the oral epithelia observed in immunosuppressed patients characterized by intense lytic infection of these tissues (De Souza *et al.*, 1989). However, EBV is not usually detectable in normal epithelial tissues, including desquamated oropharyngeal cells and tonsilar epithelium from IM patients (Karajannis *et al.*, 1997; Niedobitek *et al.*, 1989, 2000) and normal epithelium adjacent to EBV-positive UNPCs (Sam *et al.*, 1993) and gastric carcinomas (Gulley *et al.*, 1996). Therefore, it is still not clear what role, if any, epithelial cells play in the normal life cycle of the virus. It may be that epithelial infection acts to amplify EBV via virus replication during primary infection or occasionally during asymptomatic persistence and that this effect is exaggerated in hairy leukoplakia as a consequence of immunosuppression. The establishment of EBV latent infection in epithelial cells is likely to be an unusual event dependent on underlying changes within the cell that permit the stable maintenance of the virus genome (Jones *et al.*, 2003; Knox *et al.*, 1996). This latter scenario is consistent with recent studies on the genetics of NPC that demonstrate that loss of heterozygosity of certain key loci occurs as an initiating event prior to EBV infection (Lo and Huang, 2002).

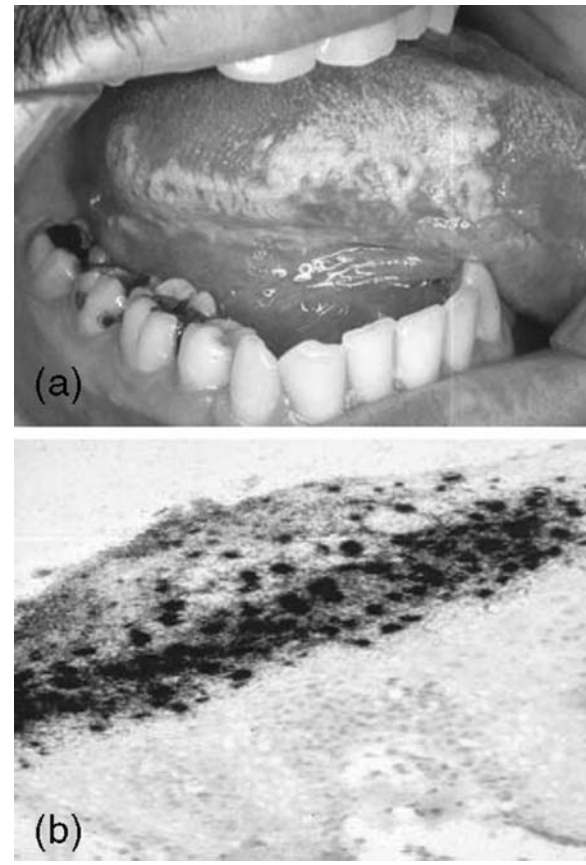

Fig. 27.7. Oral hairy leukoplakia (OHL) is a benign condition of the oral tissues that is characterized by white plaque-like lesions on the lateral tongue, as shown in (a). (b) *In situ* hybridization demonstrates the presence of abundant EBV DNA in the upper layers of the squamous epithelium of an OHL lesions consistent with virus replication.

EBV strain variation

The discovery of genetic differences between EBV carried in the Burkitt's lymphoma cell lines of West African origin, Jijoye and AG876, and the prototype B95.8 virus has led to the study of EBV strain differences. EBV isolates are characterized as type 1 (B95.8-like) or type 2 (Jijoye-and

AG876-like); these were originally referred to as A and B, respectively. EBV-1 and EBV-2 are mostly identical over the bulk of the EBV genome (Dolan *et al.*, 2006) but show allelic polymorphism (with 50–80% sequence homology depending on the locus) in a subset of latent genes, namely those encoding EBNA-LP, EBNA2, EBNA3A, EBNA3B and EBNA3C (Dambaugh *et al.*, 1984; Sample *et al.*, 1990). A combination of virus isolation and sero-epidemiological studies suggest that type 1 virus isolates are predominant (but not exclusively so) in many Western countries, whereas both types are widespread in equatorial Africa, New Guinea and perhaps certain other regions (Young *et al.*, 1987). In vitro studies show that type 1 isolates are more potent than type 2 in achieving B-cell transformation in vitro; the type 2 virus-transformed LCLs characteristically show much slower growth especially in early passage (Rickinson and Kieff, 2001). In addition to this broad distinction between EBV types 1 and 2, there is also minor heterogeneity within each virus type. Individual strains have been identified on the basis of changes, compared with B95.8, ranging from single base mutations to extensive deletions. Of particular note is the 11.8 kb deletion in the BamHIA region of the B95.8 strain (Fig. 27.1) which further emphasizes that this strain is not generally representative of the majority of naturally occurring isolates.

It was originally believed that in contrast to most immunologically compromised patients, who were shown to be infected with multiple EBV strains (Yao *et al.*, 1996b, 1998), the majority of healthy individuals are only infected with one virus type (Yao *et al.*, 1991). This led to the suggestion that the immune response to an existing EBV strain may protect the immunocompetent host from infection with additional exogenous viral strains. However, there is increasing evidence that immunocompetent carriers may also be infected with two or more separate EBV strains. For example, in one recent study that utilized the host cytotoxic T-lymphocyte response to a polymorphic EBV epitope as an indicator of the resident virus strains, 3/15 EBV-seropositive donors harbored more than one virus strain (Brooks *et al.*, 2000). A further study, which examined EBV strain variation in collections of peripheral blood mononuclear cells and multiple lymphoid and epithelial tissues of EBV-positive carriers, also demonstrated that immunocompetent individuals frequently harbor at least two strains (Srivastava *et al.*, 2000). More recent work using novel genotyping techniques confirmed that many healthy individuals harbor multiple EBV isolates and that their relative abundance and presence appears to vary over time (Sitki-Green *et al.*, 2003; Walling *et al.*, 2003).

An interpretation of the more recent data is that both immunocompromised persons and immunocompetent normal carriers are infected with multiple EBV strains, but that the rarer strains are more readily detectable in immunosuppressed individuals probably because of a higher viral load. This also implies that the immune response to an existing infection might not protect the host from subsequent infection with additional exogenous viral strains. Coinfection of the host with multiple virus strains could have evolutionary benefit to EBV enabling the generation of diversity by genetic recombination. Such intertypic recombination has been demonstrated in HIV-infected patients and appears to arise via recombination of multiple EBV strains during the intense EBV replication that occurs as a consequence of immunosuppression (Walling and Raab-Traub, 1994; Yao *et al.*, 1996a).

More contentious is the possible contribution of EBV strain variation to virus-associated tumors. Many studies have failed to establish an epidemiological association between EBV strains and disease and suggest that the specific EBV gene polymorphisms detected in virus-associated tumors occur with similar frequencies in EBV isolates from healthy virus carriers from the same geographic region (Edwards *et al.*, 1999; Khanim *et al.*, 1996). However, this does not exclude the possibility that variation in specific EBV genes is responsible for the distinct geographic distribution of virus-associated malignancies. In this regard, an LMP1 variant containing a 10 amino acid deletion (residues 343 to 352) was originally identified in Chinese NPC biopsies and has oncogenic and other functional properties distinct from those of the B95.8 LMP1 gene (Dawson *et al.*, 2000; Fielding *et al.*, 2001; Li *et al.*, 1996; Miller *et al.*, 1998). It is therefore likely that variation in LMP1 and other EBV genes can contribute to the risk of developing virus-associated tumors but more biological studies using well-defined EBV variants are required.

Function of the EBV latent genes: from persistence to pathology

An understanding of EBV latent gene function is relevant both to the factors contributing to the establishment of persistent infection in the memory B-cell pool and to the role of the virus in the oncogenic process. The advent of recombinant EBV technology has confirmed the absolute requirement for EBNA2 and LMP1 in the in vitro transformation of B-cells and highlighted a role for EBNA-LP, EBNA3A, EBNA3C and LMP2A in this process (Kieff and Rickinson, 2001). These studies confirm that EBV-induced B cell transformation requires the coordinate action of several latent genes but do not address the consequences of the more restricted patterns of EBV latent gene expression

observed in persistent infection and in certain EBV-associated tumors. More recent studies using recombinant EBV to infect either virus-negative BL cell lines or epithelial cell lines are beginning to define the contribution of more limited EBV latent gene expression to the cell phenotype and to dissect the mechanisms responsible for regulating virus gene expression in different cellular environments. A brief description of EBV latent gene function follows but other Chapters will provide a more comprehensive review of this area.

EBNA1

EBNA1 is a DNA-binding protein that is required for the replication and maintenance of the episomal EBV genome; a function that is achieved through the binding of EBNA1 to oriP, the plasmid origin of viral replication (Kieff and Rickinson, 2001). EBNA1 also interacts with two sites downstream of Qp to negatively regulate its own expression (Nonkwelo *et al.*, 1996). EBNA1 also acts as a transcriptional transactivator and up-regulates Cp and the LMP1 promoter (Kieff and Rickinson, 2001). The EBNA1 protein contains a glycine–glycine–alanine (gly–gly–ala) repeat sequence, which varies in size in different EBV isolates. This gly–gly–ala repeat domain is a *cis*-acting inhibitor of MHC class I-restricted presentation and appears to function by inhibiting antigen processing via the ubiquitin-proteosome pathway (Levitskaya *et al.*, 1995). Failure to present EBNA1-derived peptides results in ineffective CD8+ T-cell responses to EBNA1 when expressed in target cells. Directing EBNA1 expression to B-cells in transgenic mice results in B-cell lymphomas suggesting that EBNA1 might also have a direct role in oncogenesis (Wilson *et al.*, 1996). On the contrary, similar experiments using a different strain of mice failed to reveal any EBNA1-induced lymphomagenesis (Kang *et al.*, 2005). Furthermore, experiments using an EBNA1-negative EBV are also consistent with EBNA1 not being oncogenic: EBNA1 is not essential for the immortalisation of B cells by EBV and such immortalised cells have similar tumourigenic properties in SCID mice as do B-cells immortalised with wild-type, EBNA1-positive EBV (Humme *et al.*, 2003). However, a previous study demonstrates that EBNA1 is toxic in certain epithelial cell environments and that this is associated with the processing and presentation of EBNA1 to specific CTLs (Jones et al., 2003). This suggests that the establishment of EBV latency is dependent on the cell background and that CTL responses to EBNA1 may contribute to the control of latent infection. EBNA1 has recently been shown to interact with an ubiquitin-specific protease called USP7 or HAUSP that has been previously implicated in the stabilisation of p53and this may account for the ability of EBNA1 to protect B cells from apoptosis (Kennedy *et al.*, 2003; Saridakis *et al.*, 2005). Given these effects and the ability of EBNA1 to function as a transcriptional activator of several viral genes, it is likely that EBNA1 will also be able to influence cellular gene expression.

EBNA2

The inability of an EBV strain, P3HR-1, carrying a deletion of the gene encoding EBNA2 and the last two exons of EBNA-LP, to transform B cells *in vitro* was the first indication of the crucial role of the EBNA2 protein in the transformation process (Kieff and Rickinson, 2001). Restoration of the EBNA2 gene into P3HR-1 has unequivocally confirmed the importance of EBNA2 in B-cell transformation and has allowed the functionally relevant domains of the EBNA2 protein to be identified (Hammerschmidt and Sugden, 1989; Rabson *et al.*, 1982). EBNA2 is a transcriptional activator of both cellular and viral genes, and up-regulates the expression of certain B-cell antigens, including CD21 and CD23, as well as LMP1 and LMP2 (Kieff and Rickinson, 2001; Wang *et al.*, 1990). EBNA2 also transactivates the Cp promoter thereby inducing the switch from Wp to Cp observed early in B-cell infection. EBNA2 interacts with a ubiquitous DNA-binding protein, RBP-Jκ, and this is partly responsible for targeting EBNA2 to promoters that contain the RBP-Jκ sequence (Grossman *et al.*, 1994). The RBP-Jκ homologue in *Drosophila* is involved in signal transduction from the Notch receptor, a pathway that is important in cell fate determination in *Drosophila* and has also been implicated in the development of T-cell tumors in humans (Artavanis-Tsakonas *et al.*, 1995). Recent work demonstrates that EBNA2 can functionally replace the intracellular region of Notch (Hofelmayr *et al.*, 2001; Sakai *et al.*, 1998; Strobl *et al.*, 2000). The c-*myc* oncogene is also a transcriptional target of EBNA2; an effect that is likely to be important for EBV-induced B-cell proliferation (Kaiser *et al.*, 1999).

EBNA3 family

Studies with EBV recombinants have demonstrated that EBNA3A and EBNA3C are essential for B-cell transformation in vitro, whereas EBNA3B is dispensable (Robertson, 1997). EBNA3C can induce the up-regulation of both cellular (CD21) and viral (LMP1) gene expression (Allday and Farrell, 1994), repress the Cp promoter (Radkov *et al.*,

1997), and might interact with the retinoblastoma protein, pRb, to promote transformation (Parker *et al.*, 1996). While not essential for transformation, EBNA3B has been shown to induce expression of vimentin and CD40 (Silins and Sculley, 1994). The EBNA3 proteins associate with the RBP-Jκ transcription factor and disrupt its binding to the cognate Jκ sequence and to EBNA2, thus repressing EBNA2-mediated transactivation (Robertson, 1997). Thus, EBNA2 and the EBNA3 proteins work together to precisely control RBP-Jκ activity, thereby regulating the expression of cellular and viral promoters containing Jκ cognate sequence. EBNA3C has been shown to interact with human histone deacetylase 1, which, in turn, contributes to the transcriptional repression of Cp, by RBP-Jκ (Radkov *et al.*, 1999).

EBNA-LP

EBNA-LP is encoded by the leader of each of the EBNA mRNAs and encodes a protein of variable size depending on the number of *Bam*HI W repeats contained by a particular EBV isolate. The precise role of EBNA-LP in B-cell transformation *in* vitro is not clear but EBNA-LP is required for the efficient outgrowth of LCLs (Allan *et al.*, 1992). Transient transfection of EBNA-LP and EBNA2 into primary B-cells induces G0 to G1 transition as measured by the up-regulation of cyclin D2 expression (Sinclair *et al.*, 1994). EBNA-LP can also cooperate with EBNA2 in up-regulating transcriptional targets of EBNA2, including LMP1 (Harada and Kieff, 1997; Nitsche *et al.*, 1997). EBNA-LP has been shown to colocalize with pRb in LCLs and in vitro biochemical studies have demonstrated an interaction of EBNA-LP with both pRb and p53 (Jiang *et al.*, 1991; Szekely *et al.*, 1993). However, this interaction has not been verified in LCLs and, unlike the situation with the human papillomavirus (HPV)-encoded E6/E7 and adenovirus E1 proteins, EBNA-LP expression appears to have no effect on the regulation of the pRb and p53 pathways.

LMP1

LMP1 is the major transforming protein of EBV behaving as a classical oncogene in rodent fibroblast transformation assays and being essential for EBV-induced B-cell transformation in vitro (Kieff and Rickinson, 2001). LMP1 has pleiotropic effects when expressed in cells resulting in induction of cell surface adhesion molecules and activation antigens (Wang *et al.*, 1990), up-regulation of anti-apoptotic proteins (Bcl-2, A20) (Henderson *et al.*, 1991; Laherty *et al.*, 1992) and stimulation of cytokine production (IL-6, IL-8) (Eliopoulos *et al.*, 1997, 1999). Recent studies have demonstrated that LMP1 functions as a constitutively activated member of the tumor necrosis factor receptor (TNFR) superfamily activating a number of signaling pathways in a ligand-independent manner (Gires *et al.*, 1997; Kilger *et al.*, 1998). Functionally, LMP1 resembles CD40, a member of the TNFR, and can partially substitute for CD40 in vivo providing both growth and differentiation responses in B-cells (Uchida *et al.*, 1999). The LMP1 protein is an integral membrane protein of 63 kD and can be subdivided into three domains: (a) a N-terminal cytoplasmic tail (amino acids 1–23) which tethers and orientates the LMP1 protein to the plasma membrane, (b) six hydrophobic transmembrane loops which are involved in self aggregation and oligomerization (amino acids 24–186); (c) a long C-terminal cytoplasmic region (amino acids 187–386) which possesses most of the molecule's signaling activity. Two distinct functional domains referred to as C-terminal activation regions 1 and 2 (CTAR1 and CTAR2) have been identified on the basis of their ability to activate the NF-κB transcription factor pathway (Huen *et al.*, 1995). This effect contributes to the many phenotypic consequences of LMP1 expression including the induction of various anti-apoptotic and cytokine genes. More recent work demonstrates that LMP1 can also regulate the processing of p100 NF-κB2 to p52 and that this is independent of the pathways responsible for controlling the canonical NF-κB pathway (Eliopoulos *et al.*, 2003). LMP1 is also able to engage the MAP kinase cascade resulting in activation of ERK, JNK and p38 and to stimulate the JAK/STAT pathway (Eliopoulos *et al.*, 1999; Eliopoulos and Young, 1998; Gires *et al.*, 1999; Kieser *et al.*, 1997; Roberts and Cooper, 1998). Many of these effects result from the ability of TNFR-associated factors (TRAFs) to interact either directly with CTAR1 or indirectly via the death domain protein TRADD to CTAR2. The binding of TRAFs to the multimerized cytoplasmic tails of LMP1 provides a platform for the assembly and activation of upstream signaling molecules including the NIK and Tpl-2 MAPK kinase kinases (Eliopoulos *et al.*, 2002; Sylla *et al.*, 1998). The precise mechanisms responsible for signal initiation from these multiprotein complexes remain unknown. The region between CTAR1 and CTAR2 (so-called CTAR3) has been suggested to be responsible for the JAK/STAT pathway, although other data refute this finding and deletion of this region has no effect on the efficiency of B-cell transformation (Gires *et al.*, 1999; Higuchi *et al.*, 2002; Izumi *et al.*, 1999). Recent work has also demonstrated that LMP1 can also activate the phosphatidylinositol 3-kinase (PI3-K) pathway resulting in a variety of effects including cell survival mediated through the Akt (PKB) kinase,

actin polymerisation and cell motility (Dawson *et al.*, 2003).

LMP2

The gene encoding LMP2 yields two distinct proteins, LMP2A and LMP2B. The structures of LMP2A and LMP2B are similar; both have 12 transmembrane domains and a 27 amino acid cytoplasmic C-terminus (Kieff and Rickinson, 2001). In addition, LMP2A has a 119 amino acid cytoplasmic amino-terminal domain. LMP2A aggregates in patches within the plasma membrane of latently infected B-cells (Longnecker and Kieff, 1990). Neither LMP2A nor LMP2B are essential for B-cell transformation (Longnecker, 2000). The LMP2A amino-terminal domain contains eight tyrosine residues, two of which (Y74 and Y85) form an immunoreceptor tyrosine-based activation motif (ITAM) (Fruehling and Longnecker, 1997). When phosphorylated, the ITAM present in the B-cell receptor (BCR) plays a central role in mediating lymphocyte proliferation and differentiation by the recruitment and activation of the *src* family of protein tyrosine kinases (PTKs) and the *syk* PTK. LMP2A also interacts with these PTKs through its phosphorylated ITAM and this association appears to negatively regulate PTK activity (Fruehling and Longnecker, 1997). Thus, the LMP2A ITAM has been shown to be responsible for blocking BCR-stimulated calcium mobilization, tyrosine phosphorylation and activation of the EBV lytic cycle in B cells (Miller *et al.*, 1995).

Expression of LMP2A in the B cells of transgenic mice abrogates normal B cell development allowing immunoglobulin-negative cells to colonize peripheral lymphoid organs (Caldwell *et al.*, 1998). This suggests that LMP2A can drive the proliferation and survival of B-cells in the absence of signaling through the BCR. Taken together, these data support a role for LMP2 in modifying the normal programme of B-cell development to favor the maintenance of EBV latency and to prevent inappropriate activation of the EBV lytic cycle. A modulatory role for LMP2B in regulating LMP2A function has been suggested (Longnecker, 2000). The consistent expression of LMP2A in HD and NPC suggests an important function for this protein in oncogenesis but this remains to be shown. LMP2A also recruits Nedd4-like ubiquitin protein ligases; this might promote *lyn* and *syk* ubiquitination in a fashion that contributes to a block in B-cell signaling (Ikeda *et al.*, 2000). Furthermore, a recent report shows that LMP2A can transform epithelial cells and that this effect is mediated, at least in part, by activation of the PI3-kinase/Akt pathway (Scholle *et al.*, 2000). This suggests that LMP2A-induced activation of the Akt pathway may be relevant to the long-term survival of persistently infected memory B-cells.

EBERs

In addition to the latent proteins, two small non-polyadenylated (non-coding) RNAs, EBERs 1 and 2 are probably expressed in all forms of latency. However, the EBERs are not essential for EBV-induced transformation of primary B-lymphocytes (Swaminathan *et al.*, 1991).

The EBERs assemble into stable ribonucleoprotein particles with the auto-antigen La (Lerner *et al.*, 1981), with ribosomal protein L22 (Toczyski *et al.*, 1994) and bind the interferon-inducible, double-stranded RNA-activated protein kinase PKR (Clemens *et al.*, 1994). PKR has a role in mediating the antiviral effects of the interferons and it has been suggested that EBER-mediated inhibition of PKR function could be important for viral persistence perhaps by protecting cells from interferon induced apoptosis (Nanbo *et al.*, 2002). Studies in transfected NIH 3T3 cells demonstrated that EBER1 can enhance protein synthesis by a PKR-independent mechanism (Laing *et al.*, 2002).

Reintroduction of the EBERs into EBV-negative Akata BL cells restores their capacity for growth in soft agar, tumorigenicity in SCID mice and resistance to apoptotic inducers; features identical to those observed in the parental EBV-positive Akata cells (Komano *et al.*, 1999). The detection of IL-10 expression in EBV-positive, but not in EBV negative, BL tumors and the observation that the EBERs can induce IL-10 expression in BL cell lines, suggests that IL-10 may be an important component in the pathogenesis of EBV-positive BL (Kitagawa *et al.*, 2000). Recently, it has been shown that stable expression of bcl-2 or the EBERs in EBV-negative Akata cells significantly enhanced the tumourigenic potential of these cells, but neither bcl-2 nor the EBERs restored tumorigenicity to the same extent as EBV (Ruf *et al.*, 2000). Overall, these studies suggest that EBV genes previously shown to be dispensable for transformation in B-cell systems (e.g., EBERs) might make more important contributions to the pathogenesis of some EBV-associated malignancies and to EBV persistence than was previously appreciated.

BARTs

The BARTs were first identified in NPC tissue (Hitt *et al.*, 1989) and subsequently in other EBV-associated malignancies such as BL (Tao *et al.*, 1998), HD (Deacon *et al.*, 1993) and nasal T-cell lymphoma (Chiang *et al.*, 1996) as well as

in the peripheral blood of healthy individuals (Chen *et al.*, 1999). The BARTs encode a number of potential open reading frames (ORFs) including BARF0, RK-BARF0, A73 and RPMS1. The protein products of these ORFs have not be identified and remain controversial (van Beek *et al.*, 2003). However, in vitro studies have suggested potential functions including the negative regulation of EBNA2 and Notch activity (RPMS1) and the modulation of kinase signaling (A73) (Smith *et al.*, 2000).

MicroRNAs

Micro RNAs (miRs) are small, noncoding RNA molecules of only 21–24 nucleotides in length and have been shown to play a role in the posttranscriptional downregulation of target mRNAs (Bartel, 2004; Du and Zamore, 2005; Kim and Nam, 2006). Eukaryotic cells express large numbers of miRs, often in a cell- or tissue-specific manner; indeed the July 2006 release of the microRNA database, miRBase, (Griffiths-Jones *et al.*, 2006; http://microrna.sanger.ac.uk) lists 462 human miRs. Cellular miRs are transcribed by RNA polymerase II into a long precursor molecule (primary miRNA) containing one or a cluster of several miRs. This primary transcript is then processed and transported to the cytoplasm by a series of enzymatic mechanisms (Bartel, 2004; Du and Zamore, 2005). The resulting active complex containing the mature miR is called an RNA-induced silencing complex (RISC) (Bartel, 2004; Du and Zamore, 2005; Kim and Nam, 2006). If the RISC encounters an mRNA containing extensive homology to the miR within the complex then the mRNA is degraded. Alternatively, and probably more commonly, the RISC will bind to an mRNA with only partial complementarity in which case translational repression ensues (Bartel, 2004; Du and Zamore, 2005).

Herpesviruses also enode miRs: HSV1, MHV68, hCMV, KSHV, rLCV and EBV each encode at least 2, 9, 11, 12, 16 and 23 species respectively (Cullen, 2006; Gupta *et al.*, 2006; Cui *et al.*, 2006). The EBV miRs are arranged in two clusters within the viral genome: three adjacent to the BHRF1 gene (the BHRF1 cluster) and the BART cluster which comprises the remaining 20 miRs located in the introns of the BART transcripts. (Pfeffer *et al.*, 2004; Cai *et al.*, 2006; Grundhoff *et al.*, 2006).

Intriguingly, the two clusters of EBV-encoded miRs are differentially expressed in cells exhibiting different forms of EBV latency. The BART cluster is expressed predominantly in latency I or II whereas the BHRF1 miRs are associated with latency III and Cp/Wp promoter usage. This suggests that the BHRF1 miRs may be processed from an intron in the large EBNA primary transcripts (Cai *et al.*, 2006; Cullen, 2006). The expression levels of several miRs from both clusters are enhanced following induction of lytic infection (Cai *et al.*, 2006). The significance of all these differential expression profiles is currently unclear.

The function of EBV-encoded miRs is also unclear. miR-BART2 is antisense to the BALF5 open reading frame and has been proposed to have a role in the regulation of viral DNA polymerase expression via the degradative mechanism (Pfeffer *et al.*, 2004). The rest of the miRs do not exhibit such extensive homology with EBV genes leading to the hypothesis that they are more likely to target cellular genes by translational inhibition.

Conclusions

Compelling evidence implicates EBV in the pathogenesis of tumors arising in both lymphoid and epithelial tissues. The virus adopts different forms of latent infection in different tumor types recapitulating the forms of EBV latency used to establish long-term persistence in the memory B-cell pool. These forms of latency reflect the complex interplay between EBV and the host cell environment involving differential regulation by both viral and cellular factors of the promoters driving latent gene transcription. Superimposed on this intrinsic regulation of EBV latency are extrinsic factors such as the immune response and the local milieu that may influence the growth and survival of EBV-infected cells as well as govern their entry into the virus lytic cycle. Studies of the function of individual EBV latent and lytic genes have highlighted the ability of these proteins to target specific cellular pathways and more detailed analysis using recombinant forms of EBV offers the possibility of precisely defining the role of these viral genes in the EBV life cycle. Thus, as clearly evidenced by work with proteins encoded by other viruses, an understanding of the functions of EBV proteins will not only be relevant to the role of the virus in health and disease but will also help to elucidate the fundamental mechanisms regulating cell growth, survival and differentiation. It is hoped that this work will also provide novel approaches to the therapy of EBV-associated diseases. Adoptive transfer of EBV-specific CTLs has already proved useful in the treatment of immunoblastic B-cell lymphomas and this approach as well as other vaccine strategies are currently being evaluated in patients with HD or NPC. The possibility of more direct therapeutic intervention targeting the function of essential EBV latent genes such as EBNA1 and LMP1 is also a possibility. Thus, drugs that prevent the ability of EBNA1 to bind to oriP or of the TRAFs to interact with LMP1 are likely to be developed. Finally,

gene therapy strategies which exploit either the transcriptional regulation of the EBV genome or target the functional effects of EBV latent genes offer exciting possibilities for the development of both therapeutic and preventative strategies.

KSHV gene expression and regulation

Thomas F. Schulz[1] and Yuan Chang[2]

[1]Department of Virology, Hannover Medical School, Germany
[2]Molecular Virology Program, University of Pittsburgh, PA, USA

Introduction

In this chapter, both in vivo and in vitro KSHV viral gene expression patterns are described. Observations in both systems have been critical for the identification of viral proteins contributing to the pathogenic properties of this virus and for our appreciation of how this virus persists and replicates in the course of naturally occurring infections, the vast majority of which are asymptomatic (see *Epidemiology*). In contrast to other human herpesviruses, cell-free infection with KSHV in vitro is still inefficient and only a few studies have investigated viral gene expression following *de novo* infection. However, informative studies using *in situ* hybridization (ISH), immunohistochemistry (IHC), and various methods of transcript analysis have been carried out with stably infected, primary effusion lymphoma (PEL)-derived cell lines and, to a lesser extent, biopsy samples. Gradually, a picture on viral gene expression patterns and their regulation in different cell types is beginning to emerge.

Viral gene expression patterns in culture

PEL derived cell lines

PEL cell lines remain the most tractable system for examining KSHV viral gene expression. The vast majority of cells are infected latently and express a restricted repertoire of genes, while a small percentage (this varies from cell line to cell line, usually in the order of 1%–5%) of cells spontaneously switch into the lytic replication cycle. Lytic reactivation can be enhanced (up to 20% in some cell lines) in this system by chemical treatment with butyrate or phorbol esters. Despite the convenience of working with PEL cell lines, limitations exist: (1) if a bulk analysis of all cells in such a culture is carried out using Northern blots or RT-PCR, both the group of genuinely latent genes and that of strongly expressed, albeit only in a few cells, lytic genes may be detected, (2) chemical manipulation may have extraneous and secondary effects on viral gene expression, and (3) expression patterns in PEL B cell lines may not extend to expression patterns in KSHV infected tissues, in particular, spindle cells. With these caveats in mind, Fig. 28.1 shows an overview of the KSHV viral genome and the position of individual viral genes. The color coding reflects their expression during the different stages of lytic replication or latency. The coding is the result of a comparison of three publications that used gene arrays covering the entire viral genome (Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003), and two earlier publications using Northern blots to investigate the basal expression and induction of KSHV genes in PEL cell lines following treatment with butyrate or phorbol esters (Sarid *et al.*, 1998; Sun *et al.*, 1999).

The first report to systematically analyze the expression pattern, by Northern blot, of the vast majority of KSHV genes in PEL cells before and after induction of the lytic cycle (Sarid *et al.*, 1998) distinguished three categories of viral genes: class I genes, expressed during latency and not upregulated by chemical induction; class II genes, characterized by a baseline expression of variable abundance (high, moderate, and low) before, and increased expression after, chemical induction; class III genes that are only expressed after chemical induction. Class I genes comprised those marked in red in Fig. 28.1, i.e. ORF73 (encoding LANA1), ORF72 (vCYC), and ORF71/K13 (vFLIP). Transcripts most likely related to ORFs K2 (vIL6), ORF70, K4 (vMIP-II), K5 (MIR1), K6 (vMIP-I), K7 (PAN/nut-1/T1.1 RNA), K8 (bZIP), ORF57, the vIRFs locus, and T0.7/Kaposin were classified as class II genes, as were at least another five transcripts that could not be unambiguously assigned to

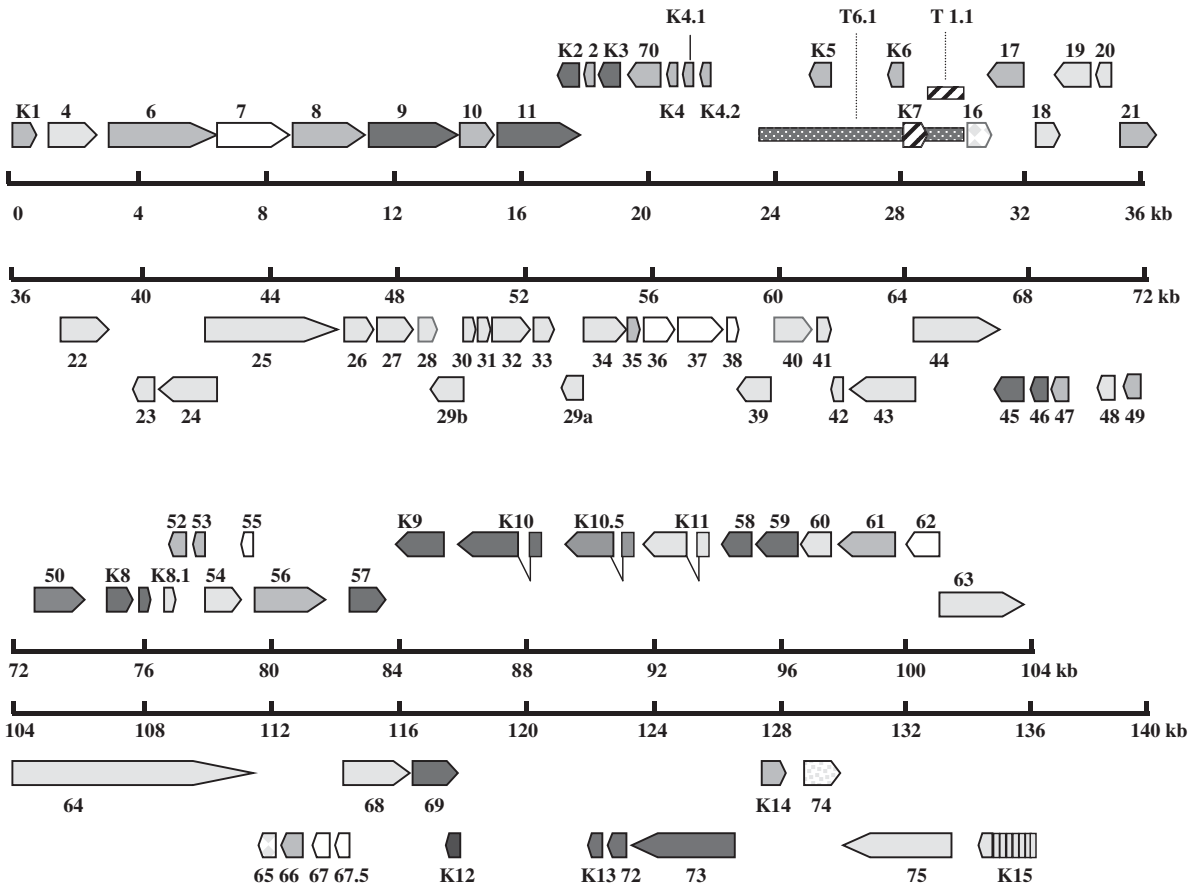

Fig. 28.1. KSHV gene expression in PEL cell lines and biopsy samples. This Figure summarizes the expression of individual KSHV genes in PEL cells during latency and following reactivation of the lytic cycle by treatment with TPA, Na-butyrate or heterologous expression of RTA by transfection or transduction. Also included are results from in situ hybridization or immunohistochemistry studies on biopsy samples of KS, MCD or PEL tumors. As discussed in the text, the color-coding is based on a comparison of several reports that studied KSHV genes by Northern blot, real time PCR or DNA array. (See color plate section.)

- Latent gene
- Latent gene in B cells only
- Latent gene in KS spindle cells in vivo; early (in some studies delayed) expression kinetics in PEL cells in vitro
- Immediate–early gene as judged by cycloheximide resistance
- Very rapid onset of gene expression in at least 2 studies
- Early lytic transcript: TPA inducible, unaffected by PFA
- Delayed onset of gene expression
- Late gene expression profile
- Late gene expression profile confirmed by PAA sensitivity
- Discrepant results in different gene array studies

individual ORFs. The remainder were considered class III genes. The existence of Class II transcripts outside of the classical dichotomous lytic-latent classification may, in part, be explain by a recent publication from H. Chang and colleagues which showed that a subset of immunoregulatory and growth promoting KSHV genes can be activated by RTA-independent notch signaling. Further, detection of these transcripts was shown to be dissociated from the full repertoire of lytic viral gene expression (Chang *et al.* 2005).

A subsequent study (Sun *et al.*, 1999) attempted to relate the pattern of viral gene expression seen following the induction of the lytic cycle by treatment with Na-butyrate or phorbol-12-myristate-13-acetate (TPA) to the conventional cascade of herpesviral gene expression

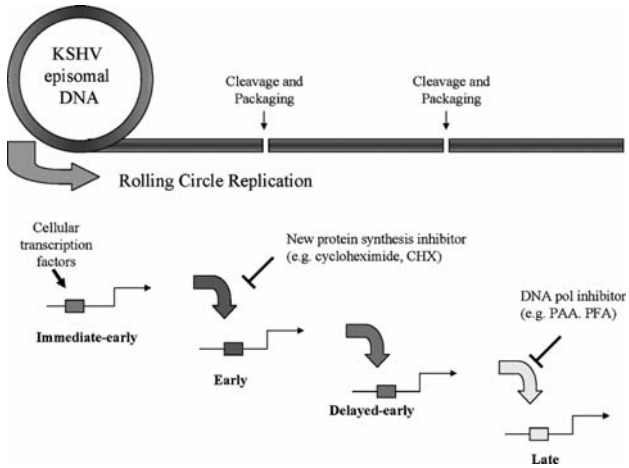

Fig. 28.2. KSHV lytic replication. Herpesvirus lytic replication is characterized by wide-spread gene activation, classically in an ordered cascade of sequential induction. The full expression of this cascade can be chemically manipulated to temporally distinguish immediate early, early and late lytic genes. Lytic activation is believed to result in a rapid increase in virion DNA as well as host cell death.

during lytic replication (Fig. 28.2). This conventional classification distinguishes immediate–early, early, and late genes: Immediate–early genes are expressed immediately following viral entry, do not require the *de novo* expression of viral proteins and are therefore resistant to treatment of the infected cell with cycloheximide. Early genes are sensitive to cycloheximide (i.e., require *de novo* protein synthesis in the infected cell) but are expressed prior to the replication of the viral genome and therefore are resistant to PAA or PFA.

Sun *et al.* (1999) classified ORF50 (RTA) as an immediate–early gene on the basis of its early onset of transcription (8 hours) following treatment with Na-butyrate and (only partial) resistance to cycloheximide. In spite of a similar rapid onset of expression seen with several other genes (e.g., h vIL6, vMIP-II, PAN/nut-1, vTS), none of these other genes examined by Sun *et al.* were resistant to cycloheximide and these therefore represent early genes. Since none of the gene array studies (see below) examined cycloheximide resistance, ORF50/RTA is therefore the only gene for which at least a partial resistance to cycloheximide has been demonstrated. It could be argued that the criterion of cycloheximide resistance should not be overinterpreted since reactivation rather than de novo infection (as in the classical experiments with alpha herpesviruses) was examined in all these studies, and that the designation of "immediate–early" for a KSHV gene on the basis of cycloheximide resistance is therefore problematic. However, ORF50/RTA stands out as the only KSHV gene with rapid expression kinetics for which this property has been demonstrated and is also the first viral gene to be expressed following *de novo* infection. Functional studies (see below and elsewhere in this book), as well as a systematic survey of viral genes whose expression is induced, directly or indirectly, by RTA (Nakamura *et al.*, 2003), have shown that RTA is the central regulator of the lytic replication cycle. It has therefore been labeled pink in Fig. 28.1.

In addition to ORF50/RTA, a few other viral genes have been shown to be resistant to cycloheximide in chemically induced PEL cell lines and thus to have immediate–early characteristics (Zhu *et al.*, 1999; Haque *et al.*, 2000; Rimessi *et al.*, 2001). In their study, Zhu *et al.* (1999) found the transcripts for ORFK8, ORF45 and ORFK4.2, in addition to that for ORF50/RTA, to have immediate-early characteristics. Haque *et al.* (2000) reported this for the ORFK5 transcript and Rimessi *et al.* (2001) for the ORFK3 mRNA.

Four groups (Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003; Fakhari & Dittmer, 2002; Dittmer, 2003) have recently examined KSHV gene expression patterns in PEL cells by DNA array or real time PCR methods. All studies attempted to group individual viral genes into categories reflecting their onset or rate of expression. The results correlate on the whole, except for a few genes classified differently by several studies. These are indicated by open boxes in Fig. 28.1. All studies group ORFs 73 (LANA1), 72 (vCYC), 71/K13 (vFLIP) together as expressed in PEL cell lines prior to, and increasing only moderately following, induction of the lytic cycle ("latent" or "constitutive" genes). Based on *in situ* hybridization or immunohistochemistry, these genes, or their proteins, are expressed in the majority of infected cells in vivo (see below). These are therefore, marked in red in Fig. 28.1. As outlined below, these three viral genes are expressed from two alternatively spliced mRNAs (Fig. 28.4), with vCYC and vFLIP expressed from the same bicistronic mRNA. In spite of the general consensus that these are latent transcripts, the study by Nakamura *et al.* observed an increased expression of these mRNAs early (ORF71/ORF72) or late (ORF73) after triggering the lytic cycle by RTA expression. Since this has not been seen when Na-butyrate or phorbol esters were used to induce the lytic cycle, it may reflect the more "physiological" induction of the lytic cycle by RTA in this experiment and indicate that this group of mRNAs, although expressed during latent persistence, may increase during lytic replication.

The non-coding nuclear RNA variously referred to as PAN, nut-1 or T1.1, and T0.7 or Kaposin, one of several transcripts derived from ORFK12, were the first abundant transcripts to be identified in KS biopsies (Zhong

et al., 1996). On Northern blots from uninduced vs. induced PEL cell lines both mRNAs show basal expression that is increased upon induction of the lytic cycle (Sarid *et al.*, 1998; Sun *et al.*, 1999) and were designated as class II transcripts by Sarid *et al.* In a gene array study, Jenner *et al.* found that the expression kinetics of T0.7/Kaposin resembled that of ORFK10 (these were designated latent/lytic transcripts), while that of T1.1/PAN clustered with those of ORFK7, ORFK14 and other early genes, grouped together as "primary lytic" genes. However, in a similarly designed study by Paulose-Murphy *et al.* (2001) and in that by Nakamura *et al.* (2003) T0.7/Kaposin and K10 did not group together, with T0.7/Kaposin having later expression kinetics. Similarly, T1.1/PAN, ORFK7, ORFK14 did not group together in these two studies. We therefore chose a separate color coding in Fig. 28.1 for T0.7/ Kaposin to reflect its probable latent nature in KS spindle cells in vivo. In spite of the controversial expression kinetics for T 1.1/PAN and K7, reflected in a hatched box in Fig. 28.1, it is clear that both are lytic genes.

Recently, in the region encompassing both T1.1/PAN and K7, Taylor *et al.* (2005) found a large transcript of approximately 6.1 kb by northern blot hybridization designated T6.1. This transcript is inducible with TPA, but is resistant to PFA. RACE identified the 5′ end of the transcript at nucleotide 23,586, and 5 excised clones from a screening of a PEL cDNA lambda phage library identified the 3′ end of the transcript at nucleotide 29,741 making the transcript co-terminal with T1.1/PAN (Fig. 28.1). This transcript encompasses K7 in the same orientation and ORFs K5 and K6 in the reverse orientation. Thus far, this 6.1 kb transcript is the largest found in the KSHV genome, but the presence of large lytic transcripts is not unique to KSHV and have been reported for other herpesviruses. Smuda *et al.* (1997) found high molecular mass overlapping early lytic transcripts of 6 kb, 8 kb, 10 kb, and 14 kb within the human cytomegalovirus genome. Wirth *et al.* (1989) identified a 6 kb immediate–early transcript and six late lytic transcripts ranging from 4.5 kb to >8 kb in bovine herpesvirus 1. It is unclear why these herpesviruses produce such large transcripts, although it has been postulated that their size may lead to RNA stability by the formation of pseudoknots. Regardless of function, the presence of this large transcript has implications in the examination of expression patterns for overlapping ORFs if DNA array and real time PCR methods are used.

The KSHV genome contains a region encoding a series of proteins with homologies to cellular interferon regulatory factors (IRFs). In this region one spliced gene, K10.5, shows latent gene expression in PEL cell lines in vitro (Rivas *et al.*, 2001; Cunningham *et al.*, 2003) and the corresponding protein, LANA2 or vIRF3, has been demonstrated by immunohistochemistry in all infected B cells in MCD and PEL in vivo, suggesting a B-lineage specific latent expression pattern (Rivas *et al.*, 2001). However, the study by Nakamura *et al.* (2003) indicates that its expression is increased at a late stage following activation of the lytic cycle by RTA in a PEL cell line. Because of its B-cell specific expression pattern, K10.5/vIRF3 has been given its own (light brown) color coding in Fig. 28.1.

Three other genes in this locus, ORFs K9, K10, K11, are induced after activation of the lytic cycle (Cunningham *et al.*, 2003; Nakamura *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Jenner *et al.*, 2001). Jenner *et al.* (2001) classified ORFK10, encoding vIRF4, as a "latent/lytic" gene, since its expression kinetics was similar to that of the T0.7/Kaposin transcript. The two other published gene array studies (Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003) concur to the extent that the ORFK10 transcript increases early after induction of the lytic cycle but group it with several other early transcripts. We have based our color coding of this gene on their results. In a similar manner, ORFK9 appears to be expressed relatively early, while in comparison ORFK11 expression appears to come on somewhat later. The upstream exon of K11, termed K11.1 in the study by Nakamura *et al.* (2003) and referred to as vIRF2 by Jenner *et al.* (2001), was classified in an earlier expression group than the second K11 exon by Nakamura *et al.* (2003), but in the same group as the second exon by Jenner *et al.* (2001).

Although the three gene array studies published so far do not always concur on the expression kinetics of individual viral genes, as illustrated by the above examples, there is broad agreement that viral proteins required for DNA replication or gene expression are produced earlier in the lytic cycle than viral structural proteins necessary for assembly of new virions. Likewise, lytic viral proteins known to be expressed in a slightly higher number of productively infected cells *in vivo* such as vIL6 or PF8 (see below) appear to be encoded by transcripts expressed in PEL cells early during the lytic cycle, whereas a structural glycoprotein encoded by ORFK8.1 and expressed only in few cells in vivo has been grouped with late transcripts. However, it needs to be emphasized that other factors than the stage of the lytic cycle may affect the expression of certain genes, e.g., vIL6, in vivo. However, in the case of vGPCR, the viral homologue of a G-coupled receptor that has been proposed to play an important role in KS pathogenesis by virtue of its ability to induce the secretion of VEGF and other paracrine factors from infected cells, the available data are controversial. While its expression kinetics in PEL cells resembled that of an early gene in the study by Jenner *et al.* and Nakamura *et al.*, Paulose-Murphy *et al.* found a delayed onset and Sun *et al.* (1999) showed that its transcript was at least partially

sensitive to PAA, suggesting late viral gene expression. However, using Northern blots Kirshner *et al.* (1999) did not see an inhibition of the vGPCR mRNA by PAA and classified it as an early lytic gene.

Viral gene expression in newly infected cultured endothelial, epithelial or fibroblast cultures

Experiments with KSHV released from PEL cell lines after chemical induction, or with recombinant KSHV preparations induced in Vero or 293 cells, have shown that KSHV can infect a wide variety of cultured cells belonging to several lineages (endothelial, epithelial, fibroblast) with the notable exception of lymphoid cell lines (Bechtel *et al.*, 2003; Lagunoff *et al.*, 2002; Moses *et al.*, 1999; Vieira *et al.*, 1997; Renne *et al.*, 1998; Gao *et al.*, 2003; Ciufo *et al.*, 2001). It is not know at this time why B lymphocytes are resistant to de novo infection, however, Chen and Lagumoff have shown that naked DNA of a KSHV BAC, engineered with a selectable element, can be introduced into BJAB cells such that virus can be maintained in latency as well as undergo lytic reactivation (Chen and Lagunoff, 2005). In the majority of these reports, KSHV quickly established a latent infection, as defined by the expression of LANA1, in most infected cells. Only a small proportion of infected cells express viral transcripts or proteins characteristic of the lytic replication cycle such as ORF59/PFA, the K8.1 envelope glycoprotein, or the minor capsid protein mCP/SCIP encoded by ORF65 (Renne *et al.*, 1998; Lagunoff *et al.*, 2002; Ciufo *et al.*, 2001; Vieira *et al.*, 1997; Moses *et al.*, 1999; Bechtel *et al.*, 2003). In these latently KSHV-infected cells the lytic replication cycle can be reactivated using phorbol esters (as in PEL cell lines), or by superinfection with CMV (Vieira *et al.*, 1997), and expression of RTA by transfection or transduction can do so in all cell types examined (Bechtel *et al.*, 2003). A possible interpretation of these findings is that events upstream and controlling the expression of RTA are responsible for the blocked lytic replication and default latency in these cells. As discussed above, methylation of CpG residues in the ORF50/RTA promoter may represent such an event (Chen *et al.*, 2001).

In one experimental system, which used a recombinant KSHV carrying a bacterial artificial chromosome and GFP cassette between ORFs 18 and 19, spontaneous transient lytic activation of KSHV in newly infected endothelial cells was observed during the first week of culture which subsided subsequently, giving way to long-term latent infection (Gao *et al.*, 2003). Lytic reactivation in this experimental system was measured by the expression of the minor capsid protein SCIP, encoded by ORF65, and latent infection by expression of LANA1 (Gao *et al.*, 2003).

Investigating early events following virus entry Dezube *et al.* (2002) found that rapid circularization of the viral genome occurred within 8 hours of infecting cultured endothelial cells with PEL-line derived KSHV. This was followed by the appearance of linear genomes, indicating lytic replication, approximately 72 hours after infection. Expression of the lytic transcripts T1.1/PAN and K8.1 could be detected by Northern blot at 3–6 days, and increased up to days 8–10, after infection. Latent transcripts for ORF72 (vCYC) and ORF73 (LANA1) were first detected on day 8. Interestingly, ORF74 (vGPCR) mRNA expression oscillated between days 1–8 (Dezube *et al.*, 2002).

Viral gene expression early after *de novo* infection of endothelial cell and fibroblast cultures has also been investigated using a KSHV microarray (Krishnan *et al.*, 2004). Following *de novo* infection, a limited number of KSHV genes are initially expressed (Fig. 28.3, Krishnan *et al.*, 2004). However, with the exception of the latent transcripts for LANA1, vCYC and vFLIP, all mRNAs are down-regulated over the following 24 hours and KSHV therefore quickly adopts a transcriptional latency pattern. The first viral transcript to be expressed following *de novo* infection encodes ORF 50/RTA, the central regulator of the viral lytic replication cycle (Krishnan *et al.*, 2004). However, only a limited number of RTA-activated viral genes (see below) show a transient expression. These include the genes for vIL6 (ORFK2), vMIP-II (ORFK4), MIR2 (ORFK5), vMIP-I (ORFK6), vIRF2 (ORF11) and the survivin homologue (ORFK7), which are all thought to play a role in modulating the response to interferon, cytotoxic T-lymphocytes, NK cells or apoptosis. In contrast, many KSHV genes involved in DNA synthesis or encoding structural proteins were not expressed. This pattern of viral gene expression suggests that, unlike α- or β-herpesviruses, KSHV quickly adopts a latent program of gene expression and only transiently expresses a set of genes that counteract the effects of the interferon system – which is induced in endothelial and fibroblast cells very early following KSHV infection (Naranatt *et al.*, 2004) – or other components of the innate or adaptive immune system. Which viral or cellular factors determine this switch into latency and interfere with the completion of the full lytic transcription program is not understood at present and remains one of the most interesting aspects of the control of KSHV gene expression.

Viral gene expression in vivo

Despite the relative ease of working with KSHV infected PEL-derived cell lines, a major problem of studying viral gene expression in such a system is that expression patterns may not reflect that found in infected tissues.

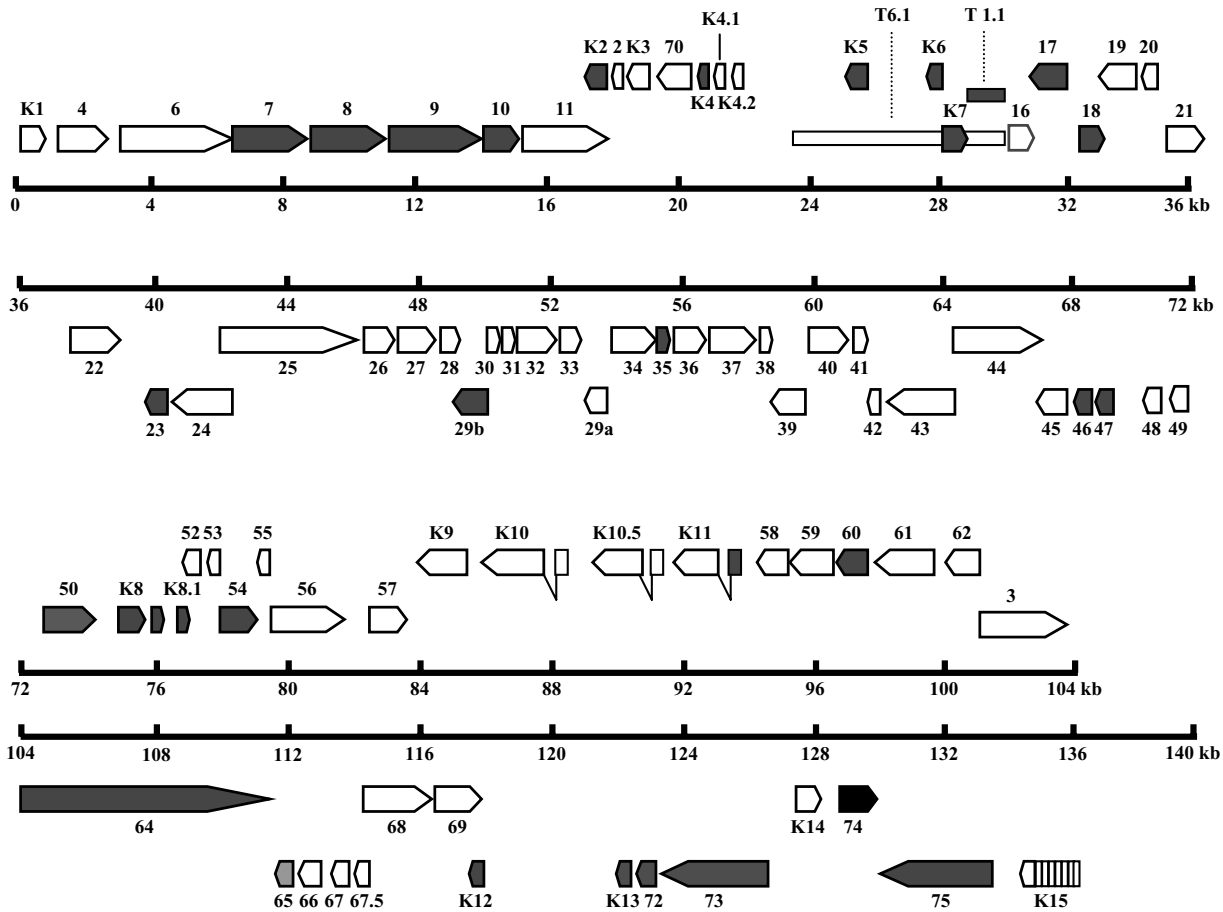

Fig. 28.3. KSHV gene expression pattern in endothelial and fibroblast cells following *de novo* infection. This figure summarizes the expression of individual KSHV genes following *de novo* infection of endothelial and fibroblast cultures reported in Ciufo *et al.*, 2001; Dezube *et al.*, 2002; Bechtel *et al.*, 2003; Gao *et al.*, 2003; Krishnan *et al.*, 2004.

- Latent gene
- Immediate-early gene in Krishnan *et al.* (2004)
- Transient expression during the first days after de novo infection (Dezube *et al.*, 2002; Ciufo *et al.*, 2001; Bechtel *et al.*, 2003; Krishnan *et al.*, 2004)
- Transient expression during first week of culture (Gao *et al.*, 2003)
- Cyclic expression pattern in the study by Dezube *et al.* (2002)

Initial results from immunohistochemistry suggest that some KSHV genes can become dysregulated in tissue culture and that tissue-specific patterns of expression exist. The lack of a KSHV-infected spindle cell line raises additional concerns regarding generalizing findings from infected B cell lines to endothelial-derived KS lesions.

KS lesions

The first studies on viral expression in KS lesions examined the abundance of the T1.1/PAN and T0.7/Kaposin transcripts by *in situ* hybridization. The vast majority of spindle cells comprising KS lesions expressed T0.7/Kaposin in a cytoplasmic distribution with a predicted membrane proclivity (Zhong *et al.*, 1996). By colocalization, a subpopulation (1%–10%) of T0.7/Kaposin positive cells also expressed T1.1/PAN transcripts and is thought to represent cells supporting lytic viral replication. The T1.1/PAN transcripts, although expressed in few cells, were present in high abundance ranging from an estimated 10 000 to 25 000 transcript copies per cell and were targeted to the nuclear compartment (Zhong *et al.*, 1996). Consistent with a transcript expressed in lytic replication, T1.1/PAN also co-localized to the same cell population with probes to

the major capsid protein (ORF25) (Staskus *et al.*, 1997) and to the viral GPCR (ORF74) (Kirschner *et al.*, 1999). The transcripts of two other genes, K3, K8 were shown to have a similar distribution to T1.1/Kaposin in KS lesions (Rimessi *et al.*, 2001).

By immunohistochemistry, LANA1 protein is expressed in almost all tumor spindle and endothelial cells (Rainbow *et al.*, 1997; Dupin *et al.*, 1999; Katano *et al.*, 2000). This is consistent with in vivo hybridization studies using the T0.7/Kaposin riboprobe as a surrogate marker for viral latent replication. Although vCYC and vFLIP proteins have not been formally shown to be expressed in a similar manner as LANA1, *in situ* hybridization studies of their transcripts in KS lesions demonstrate their presence in the majority of spindle cells (Reed *et al.*, 1998; Dittmer *et al.*, 1998; Sturzl *et al.*,1999). Reed and colleagues additionally found vCYC transcripts in epithelial cells of eccrine ducts and scattered epidermal cells (Reed *et al.*, 1998). In contrast to the expression of latent genes, only a few cells within KS tumors express proteins associated with lytic replication indicating a relatively tight regulation of lytic viral reactivation. The low number of cells hosting viral lytic reactivation in KS lesions is reflected in the numerous reports where lytic viral proteins are detected not at all or in only a few cells (<1%) when a series of KS lesions are examined. Viral proteins found to be expressing in rare cells of KS lesions include PF-8 (ORF59), (Katano *et al.*, 1999a,b; Parravicini *et al.*, 2000) and ORF50 (Katano *et al.*, 2001). The expression of vIL6 protein was found to be highly variable. Parravicini and colleagues were unable to detect the protein in 15 KS lesions they examined, while Cannon and colleagues found its expression in one out of 13 KS cases in one series but 7 out of 7 KS cases in another series deliberately selected for the presence of lytic foci (Parravicini *et al.*, 2000; Cannon *et al.*, 1999). The vIRF1 protein has not been detected in KS lesions by immunohistocheminstry thus far (Parravicini *et al.*, 2000). This is most likely due to antibody sensitivity, since cells hosting lytic replication would be expected to express the full spectrum of encoded proteins.

Primary effusion lymphomas

Due to the scarcity of these lymphomas, extensive sampling of *in vivo* viral gene expression has not been done in this disorder. In a pattern similar to that found in KS lesions, tumor cells in PEL all express LANA1 protein (Dupin *et al.*, 1999; Katano *et al.*, 1999a,b) and only rarely express ORF50 (Katano *et al.*, 2001). The major difference detected between PEL and KS lesions at this point is the expression of LANA2 which appears to be lymphoid specific. In contrast to ORF50 protein which is rarely detected, vIL6 is present in up to 5% of the PEL tumor cells. This partial uncoupling of vIL6 gene expression from RTA activation has been confirmed by in vitro studies on PEL cell lines showing that the vIL6 gene has a promoter containing two interferon stimulated response elements (ISRE) with the ability to induce vIL6 expression in cells treated with IFN-α. Additional evidence that transcriptional regulation of vIL6 is unique comes from microarray studies showing that only vIL6 transcripts in PEL cell lines were upregulated in response to IFN-α in the presence of cycloheximide (Chatterjee *et al.*, 2002). These results show that additional pathways, beyond the dichotomous latency-lytic pathways traditionally described for herpesviruses, regulate vIL6 transcription.

The LANA2/vIRF3 gene (K10.5) is one of the few KSHV proteins which has been found to be latently expressed in PEL and MCD cells in vivo; however, LANA2/vIRF3 is not expressed in the vast majority of KS spindle cells. This finding reinforces the concept that KSHV is capable of multiple latency expression programs, and genes that are expressed in some tissues or cell lines may be silenced or absent in others. LANA2/vIRF3 differs from vIL6 in that vIL6 is expressed in a minority population of PEL tumor cells. Since vIL6 is a secreted cytokine, limited expression of vIL6 may nonetheless contribute to the pathogenesis of PEL tumors. In contrast, LANA2/vIRF3 expression is uniformly present in PEL tumor cells, indicating that it may have a critical role in maintaining the PEL tumor cell phenotype. These patterns of expression could be expected if the vIL6 promoter is activated by cytokine signaling pathways that are dependent on the local cellular milieu, whereas the LANA2/vIRF3 promoter is activated by B-cell transcription factors. It bears repeating at this point that although PEL-derived cell lines also express LANA2/vIRF3 and vIL6 there is a greater percentage of cells positive for class II and class III proteins (see above) in vitro suggesting that regulation of KSHV protein expression may be different in culture (Parravicini *et al.*, 2000).

Multicentric Castleman's disease

In MCD, the majority of cells in affected lymphoid tissues are not infected with KSHV: the LANA1 positive cells are largely confined to the mantle zone of lymphoid follicles. These KSHV-infected cells are negative for T-cell or monocytic markers and are felt to be B-cells, although only a minority express CD20 or CD79 B-cell markers. A subset of these LANA1 positive mantle zone cells also express vIL6, K8, K10, PF-8, and ORF65 proteins. However, in contrast to both PEL and KS lesions there are a higher percentage

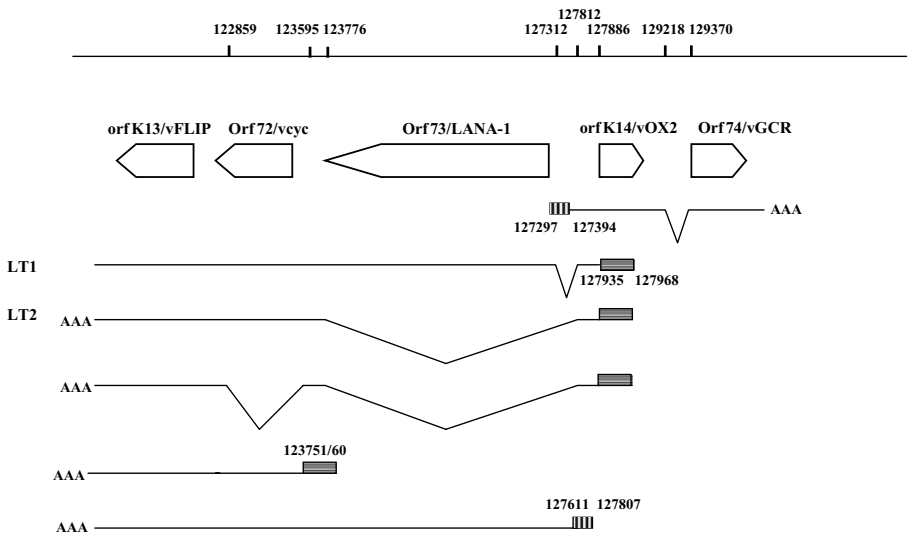

Fig. 28.4. Splicing pattern of latency-associated and neighboring transcripts. Two main transcripts, LT1 and LT2, and an additional minor transcript are directed by a latent promoter (horizontally striped box) and are translated to yield LANA1, vCYC and vFLIP. An additional latent promoter located in the 3′ end of the orf73/LANA1 gene (horizontally striped box) directs the expression of a bicistronic mRNA for vcyc and vFLIP. Both latent promoters also direct the expression of the kaposins and the viral miRNAs (see Fig. 29.8). In addition, expression of orf73/LANA1 can also be directed by a lytic promoter (vertically striped box). Overlapping with an intron spliced out of these transcripts is the promoter directing a bicistronic mRNA for ORFK14 and vGPCR. Numbering at the top refers to the position of splice donors and acceptors.

of LANA1 positive cells in MCD that express protein associated with lytic activation. Of these lytic cycle-associated genes, vIL6 appears to be expressed in a larger percentage of KSHV-infected cells. KSHV infected mantle zone cells therefore reproduce the pattern of viral gene expression observed in TPA-stimulated PEL-derived cell lines, in which a small, but significant subset of cells expresses class II and III genes (Parravicini *et al.*, 2000; Katano *et al.*, 2000).

Immunohistochemical techniques address critical aspects of virus behavior in infected tissue culture cells and pathological lesions that cannot be explored by mRNA studies. Although extensive mRNA mapping of viral gene expression has been performed in KSHV infected cell lines, tissue localization studies show that KS, PEL, and MCD are characterized by differing and unique patterns of KSHV protein expression.

Regulation of gene expression

Splicing

Genomic region containing KSHV latent genes and the viral chemokine receptor homologue

Gene expression in the locus encoding the major latent genes of KSHV, ORF73 (LANA1), ORF72 (vCYC), ORF71/K13 (vFLIP) is controlled by a constitutively active promoter located between nucleotides 127 935 and 129 370, with a minimal promoter region mapped to 127 935–127 968 of the prototypic KSHV sequence (Russo *et al.*, 1996), as shown in Fig. 28.4. (Jeong *et al.*, 2001). This promoter has the characteristics of a latent promoter, i.e. is not upregulated by treatment with phorbol esters or butyrate (Jeong *et al.*, 2004) however, it may be regulated in a cell cycle specific manner (Sarid *et al.*, 1999). It directs the expression of two more abundant and one rare mRNAs. The first transcript, latent transcript 1 (LT1; Fig. 28.4) encodes LANA1, while the second, LT2 represents a bicistronic mRNA from which both vCYC and vFLIP are translated. To enable efficient translation of the downstream reading frame for vFLIP, this mRNA contains an internal ribosomal entry site (IRES) located within ORF72 between nucleotides 122 973 and 123 206 (Bieleski & Talbot, 2001; Grundhoff & Ganem, 2001; Low *et al.*, 2001). In addition, Grundhoff & Ganem (2001) reported the existence of a further spliced mRNA from which most of the ORF72 coding sequence was removed and only vFLIP could be translated (see Fig. 28.4). However, this doubly spliced mRNA was of low abundance and only detected by RT-PCR after induction of the lytic cycle suggesting a mechanism for increasing the expression of this normally latent (Low *et al.*, 2001) anti-apoptotic

protein during lytic replication. Low *et al.* (2001) have also suggested that the IRES dependent translation of vFLIP may allow its expression during apoptosis when normal cap-dependent translation is less efficient due to cleavage of eIF4G by caspase 3 (Low *et al.*, 2001). A further bicistonic mRNA fo vcyc and vFLIP is directed by an additional latent promoter located in the 3′ end of the ORF73/LANA1 gene (Pearce *et al.*, 2005; Cai *et al.*, 2006). This promoter also directs the expression of a spliced mRNA, from which the Kaposin proteins are translated (see below and Fig. 28.8). In addition, un unspliced mRNA transcribed from his promoter serves as the precursor RNA for the viral miRNAs (see below and Fig 28.8).

Upregulation of LANA1 by the activator of the lytic cycle RTA shortly after infection of a cell by KSHV is directed by a lytic promoter (127,807–127,620) located downstream of the major constitutive (latent) LANA1 promoter. This lytic mRNA starts at position 127,611, i.e. within the intron in the LT1 latent mRNA (Matsumara et al., 2005).

A recent report (Canham and Talbot, 2004) suggests the existence of a further mRNA which is prematurely polyadenylated within ORF73 and would be predicted to encode a truncated variant of LANA1 lacking the 76 c-terminal amino acids. Based on a deletion analysis of the c-terminal end of LANA1 (Viejo-Borbolla *et al.*, 2003) such a truncated version of LANA1 would be expected to be deficient in its interaction with the nuclear matrix and in its ability to activate heterologous promoters and to replicate viral episomal DNA (Canham and Talbot, 2004; Viejo-Borbolla *et al.*, 2003).

The region upstream of ORF73 contains a second promoter that directs the expression of another bicistronic mRNA, expressed during the lytic replication cycle and oriented in the opposite direction (Fig. 28.4). This mRNA contains the reading frames K14 (vOX2) and 74 (vGPCR) (Talbot *et al.*, 1999; Kirshner *et al.*, 1999; Jeong *et al.*, 2001; Nador *et al.*, 2001; Chiou *et al.*, 2002; see Fig. 28.4). This promoter is activated by RTA, the central regulator of the lytic cycle and the minimal region response to RTA has been mapped to nucleotides 127 297–127 394 (Jeong *et al.*, 2004; Chiou *et al.*, 2002). At this promoter, activation by RTA is mediated through its interaction with the cellular transcriptional repressor RBP-Jκ, rather than by direct DNA binding (Liang and Ganem 2004). The bicistronic ORFK14/ORF74 mRNA results from splicing out an intron located between these two viral genes (Kirshner *et al.*, 1999; Talbot *et al.*, 1999; Nador *et al.*, 2001; Chiou *et al.*, 2002; Fig. 28.4). Although there is clear evidence from immunohistochemical staining of KS, PEL and MCD samples, as well as of TPA-induced PEL cell lines in vitro, that the vGPCR protein is expressed in cells undergoing lytic replication (Chiou *et al.*, 2002), it is not yet clear how this protein is translated from its downstream position in a bicistronic mRNA. Internal ribosomal entry, translational reinitiation, modified ribosomal scanning have been suggested as possible mechanisms (Kirshner *et al.*, 1999). In addition, Nador *et al.* (2001) found an additional monocistronic mRNA encoding only ORF74/vGPCR which was however much less abundant than the bicistronic mRNA for ORFs K14 and 74. The significance of this monocistronic mRNA and its contribution to vGPCR translation is not clear at present.

Genomic region containing immediate–early genes

The immediate–early gene ORF50, encoding the activator of the lytic cycle RTA, is located next to the multiply spliced early gene ORFK8, which encodes another player in lytic cycle regulation, KbZIP or RAP (Fig. 28.5). RTA is translated from an mRNA which incorporates a small exon located upstream of ORF49 in addition to the originally predicted reading frame 50 (Russo *et al.*, 1996; Lukac *et al.*, 1999; Zhu *et al.*, 1999; Saveliev *et al.*, 2002). The immediate–early expression kinetics of ORF50 mRNA, which has been reported to be upregulated by some groups as early as 1 hour following TPA treatment of PEL cell lines, has been discussed above. Expression of this mRNA is directed from a promoter that is autonomous and dependent on cellular factors (Seaman *et al.*, 1999; Deng *et al.*, 2000). In transient transfection assays using constructs in which the RTA promoter was placed upstream of a reporter gene, its activity can be further upregulated by RTA itself, but also by Na-butyrate or phorbol ester treatment and by co-transfection of some other viral proteins, e.g., vGPCR (Deng *et al.*, 2000; Chiou *et al.*, 2002). The autoactivation of the RTA promoter by RTA itself was also seen in persistently infected PEL cell lines (Deng *et al.*, 2000).

In latently infected cells the RTA promoter is partially silenced by methylation and it has been suggested that this provides a mechanism by which KSHV latency could be controlled (Chen *et al.*, 2001). Methylation of CpG islands in the RTA promoter region is seen in persistently infected PEL cell lines in vitro, as well as in samples from KSHV-associated diseases (KS, PEL, MCD) or KSHV-infected cells in vivo (Chen *et al.*, 2001). Treatment of PEL cell lines in vitro with 5-azacytidine, an inhibitor of methyltransferase, activates the lytic cycle (Chen *et al.*, 2001). Activation of the lytic cycle in PEL cell lines by TPA involves demethylation of the ORF50 promoter (Chen *et al.*, 2001). It has therefore been suggested that methylation of the ORF50 promoter is one of the mechanisms by which KSHV establishes latency in vivo (Chen *et al.*, 2001).

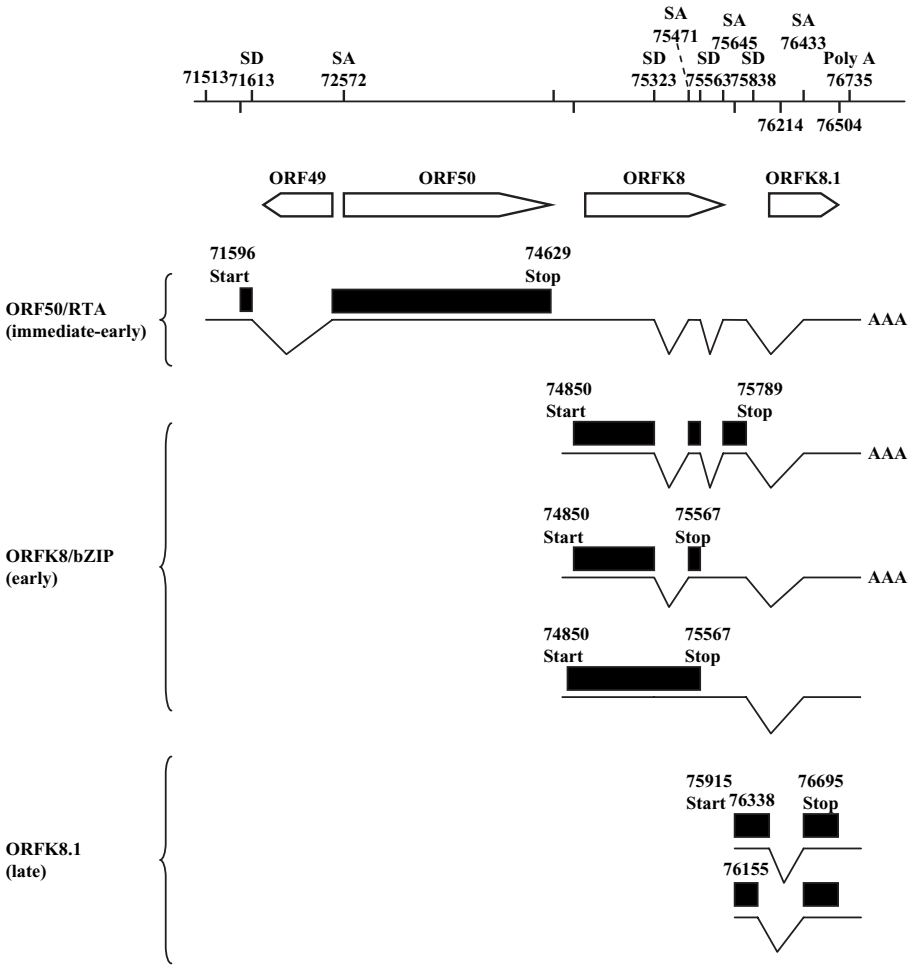

Fig. 28.5. Splicing pattern of transcripts originating in the immediate-early region of the KSHV genome. The region between ORFs 48 and 52 (see Fig. 28.1) encodes the immediate-early ORF50 transcript, as well as an early transcript for the ORFK8-derived proteins. The KbZIP protein involved in lytic replication consists of sequences included in 2 exons within the originally annotated ORFK8 in addition to a third, downstream exon encoding the leucine zipper region defining KbZIP. The mRNA for the ORFK8.1 glycoprotein also exists in two splice variants and has late expression kinetics (see Fig. 28.1).

The mRNA encoding ORF50 extends through two neighboring downstream genes, K8 and K8.1 (Fig. 28.5) but it is not clear whether there is any translation of these genes from this mRNA. However, a promoter located between ORF50 and K8 directs the expression of three alternatively spliced mRNAs, expressed at the ratio of 16:4:1 (Lin *et al.*, 1999; Fig. 28.5). One of these contains three splice events and consequently joins two exons from the originally predicted K8 reading frame to a downstream third exon which contains a leucine zipper region (Lin *et al.*, 1999; Gruffat *et al.*, 1999). Together with a basic region found in the second exon (Fig. 28.5) the resulting protein resembles members of the basic leucine-zipper transcription factors (bZIP) which includes jun, fos and the activator of the EBV lytic cycle, Zta or BZLF-1 (Sun *et al.*, 1998; Lin *et al.*, 1999; Gruffat *et al.*, 1999; Zhu *et al.*, 1999; Seaman *et al.*, 1999; further references in Sinclair, 2003). This protein, KbZIP or RAP is the predominant protein expressed in PEL cell lines after induction of the lytic cycle (Polson *et al.*, 2001). In contrast to Zta, KbZIP cannot on its own activate the lytic cycle (Lukac *et al.*, 1999; Polson *et al.*, 2001). On the contrary, it has been suggested that KbZIP, by binding to RTA, could repress the ability of RTA to activate some (e.g., ORF57), but not all (e.g., PAN/nut-1), lytic cycle genes (Izumiya *et al.*,

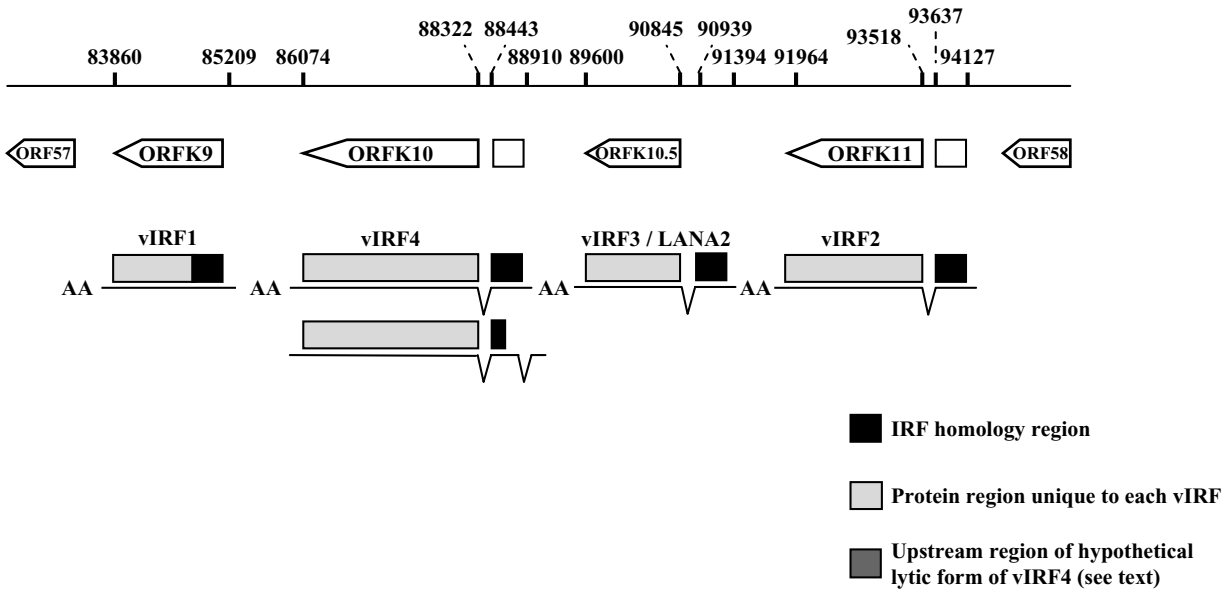

Fig. 28.6. Splicing patterns in the vIRF region of the viral genome. There are 4 KSHV proteins with sequence homology to cellular interferon regulatory factors (IRFs). The region of IRF homology is located at the amino terminal end of the viral proteins and encoded by a different exon in 3 out of 4 vIRFs.

2003a). The basic region of KbZIP is required for the interaction with RTA (Izumiya *et al.*, 2003a), as well as for the more recently described binding to cyclin A/E-cdk2 and its consequent phosphorylation by cdks (Polson *et al.*, 2001) and the resulting slowing of the cell cycle (Izuimya *et al.*, 2003b). The expression kinetics of KbZIP indicates that it is an early gene, since the corresponding mRNAs are sensitive to treatment with cycloheximide, but not phosphonoacetic acid (Lin *et al.*, 1999).

The fourth exon of the three K8/KbZIP mRNAs (Fig. 28.5) overlaps with another reading frame, ORFK8.1, encoding a structural glycoprotein incorporated into the KSHV virion and of importance for the binding of virions to glycosaminoglycans (Birkmann *et al.*, 2001; Wang *et al.*, 2001a, b). However, as shown in Fig. 28.5, this protein is translated from two alternatively spliced mRNAs, whose expression is controlled by a different promoter and which use the same splice acceptor at nt 76,433 as the K8/KbZIP mRNAs, but two different splice donors at nt 76,155 and nt 76,338 (Gruffat *et al.*, 1999; Raab *et al.*, 1998; Chandran *et al.*, 1998). This results in two isoforms of the K8.1 glycoprotein which run at molecular weights of 35 and 38 kDa on SDS gels (Raab *et al.*, 1998; Chandran *et al.*, 1998; Birkmann *et al.*, 2001; Wang *et al.*, 2001). As befits a structural virion glycoprotein, the K8.1 mRNAs have late expression kinetics, with doubling of expression between 16 and 24 hrs after treatment of PEL cell lines with TPA or overexpression of RTA (Nakamura *et al.*, 2003; Jenner *et al.*, 2001; Gradoville *et al.*, 2000) and sensitivity of the 0.9 kb K8.1 transcript to PAA (Gradoville *et al.*, 2000).

vIRF Locus

A gene locus located between nt 83,500 and 94,200 of the KSHV genome contains several homologues of cellular interferon regulatory factors, termed vIRFs (Russo *et al.*, 1996; Neipel *et al.*, 1997). Although initially controversial, the gene expression and splicing patterns, as well as the proteins encoded by the different ORFs in this locus, have recently become clearer. A current consensus view is summarized in Fig. 28.6 (Cunningham *et al.*, 2003). The first vIRF to be studied in detail, vIRF1 is encoded by an unspliced gene, ORFK9 (Gao *et al.*, 1997; Chen *et al.*, 2000; Wang *et al.*, 2001a, b; Cunningham *et al.*, 2003). ORFK9 shows expression kinetics compatible with its classification as an early gene: on Northern blots its expression is detected 8–12 hours after induction of PEL cell lines by TPA and is sensitive to treatment with cycloheximide but resistant to PAA (Wang *et al.*, 2001a, b). In DNA array studies ORFK9 expression peaked at 24 hours (Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003) and was classified as a secondary lytic gene by Jenner *et al.* (2001). Immunofluorescence studies with an antibody to vIRF1 have also indicated a marked increase in vIRF1 expression following TPA stimulation of PEL cell lines (Parravicini *et al.*, 2000).

In cells undergoing lytic viral replication a major transcriptional start site has been mapped to two adjacent

nucleotides 74 and 77 bp upstream of the translational start codon by one group (Chen *et al.*, 2001; Inagi *et al.*, 1999) and to a neighboring nucleotide (–76 bp) by two other groups (Wang *et al.*, 2001a, b; Cunningham *et al.*, 2003). This start site is located 20–25 bp downstream of a TATA box. In addition, Chen *et al.* (2001) reported another transcriptional start site, found only in latently infected cells, approx. 84 bp upstream of the lytic start site. In contrast, in spite of finding 5′ RACE products with varying start sites upstream of position – 77, Cunningham *et al.* (Cunningham *et al.*, 2003) could not confirm the existence of a defined latent start site and the evidence for the existence of an additional latent promoter for vIRF1 must therefore be seen as inconclusive. In vivo, vIRF1 expression could only be seen by immunohistochemistry in MCD tissue, but not in KS or PEL tissues, in keeping with the notion, derived from the in vitro studies, that vIRF-1 is expressed early during the lytic cycle (Parravicini *et al.*, 2000).

The neighboring viral gene, ORFK10, is also inducible in PEL cell lines (Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003; Cunningham *et al.*, 2003). Jenner *et al.* and Nakamura *et al.* noted the very rapid onset of expression following chemical induction of PEL cell lines and Jenner *et al.* classified ORFK10 as a "latent/lytic" gene because of the basal expression seen in uninduced PEL cell lines. The ORF K10 transcript is spliced (Fig. 28.6). The open reading frame originally designated as K10 (Russo *et al.*, 1996) started at an ATG at position 88,164, i.e., within the larger downstream exon depicted in Fig. 28.6. For this reason, some authors refer to the smaller upstream exon as K10.1 (Jenner *et al.*, 2001; Neipel *et al.*, 1997). This upstream exon contains the protein regions with homology to the DNA binding domains of cellular IRFs (Jenner *et al.*, 2001; Cunningham *et al.*, 2003). However, analysis of the splicing patterns in the K10 region has shown that the original "K10" is expressed as part of a spliced mRNA that includes "K10.1" and consequently the inclusion of the IRF homology domains justifies the designation vIRF4 for the corresponding protein (Cunningham *et al.*, 2003; Jenner *et al.*, 2001; see Fig. 28.6). Cunningham *et al.* (2003) concluded that this spliced mRNA is inducible in PEL cells, while Jenner *et al.* (2001) considered this mRNA as "latent/lytic" but reported the existence of an additional alternatively spliced mRNA, found only in induced PEL cells, which eliminates the first 111 bp of the coding region in the upstream region. This would theoretically lead to a protein of 767 amino acids and a predicted molecular weight of 82 kDa, initiated at an internal ATG, which lacks the IRF homology region. However, Cunningham *et al.* (2003) found the alternative splice acceptor to be used by several mRNAs spliced to upstream viral regions as well as cellular sequences and queried whether this alternative transcript would be relevant physiologically. Using an antibody to K10, Katano *et al.* (2000) detected a dominant band of 100 kDa on Western Blots of induced but not uninduced PEL cell lines, in reasonable agreement with the predicted protein size of 98 kDa for the 905 aa translated from the singly spliced mRNA (Fig. 28.6). Although the existence of an additional minor protein cannot be completely ruled out, vIRF4, derived from the singly spliced mRNA, appears to be the dominant protein and expressed during the lytic cycle. By immunohistochemistry of pathology sections, vIRF4 was found to be expressed in 5% of KSHV-infected cells in MCD, but in less than 1% of cells in KS and PEL samples (Katano *et al.*, 2000). This staining pattern is compatible with the expression of K10/vIRF4 during lytic viral replication.

ORFK10.5 is contained in a spliced mRNA (Lubyova and Pitha, 2000; Rivas *et al.*, 2001; Jenner *et al.*, 2001; Cunningham *et al.*, 2003). In contrast to the original assignation of this ORF, the resulting protein (vIRF3, LANA2) contains sequences from both exons (Rivas *et al.*, 2001; Cunningham *et al.*, 2003; see Fig. 28.6). As in the case of the other vIRFs, a region with homology to cellular IRFs is located at the N-terminal end of vIRF3/LANA2 (Rivas *et al.*, 2001; Cunningham *et al.*, 2003; see Fig. 28.6) and derived from this first exon. While Lubyova and Pitha characterized this gene as inducible and Jenner *et al.* classified it as "secondary lytic" on their KSHV microarray using a probe for the upstream exon, Rivas *et al.* and Fakhari and Dittmer found it to be constitutively expressed in B-cells by northern blots or real time PCR. Using an antibody to vIRF3/LANA2, Rivas *et al.* could show its constitutive expression in latently infected PEL cell lines, as well as in PEL cell tumors and MCD specimens, but not in the endothelial and spindle cells of KS lesions. Cunningham *et al.* found several transcriptional start sites for the vIRF3/LANA2 transcript, none of which is in close proximity to a TATA box (Cunningham *et al.*, 2003). The TATA box noted by Lubyova and Pitha is located approximately 500 bp further upstream and thus unlikely to direct the transcriptional start of the vIRF3/LANA2 mRNA. However, Cunningham et al. noted the sequence element AAGGTAATGAGGT approx. 250 bp upstream of most 5′ RACE products in their study. This element is closely related to a motif AAGGTAATGAAAT in the latent LANA1 promoter (Talbot *et al.*, 1999) and the Oct-1/TAATGARAT element of immediate–early promoters in other herpesviruses (O'Hare, 1993).

ORFK11, as originally assigned by Russo *et al.* (1996), is also part of a larger coding region generated by a splice event that joins it to an upstream exon. As in the case of vIRF3/LANA2 and vIRF4, this upstream exon contains the region showing homology with cellular IRFs (Cunningham *et al.*, 2003). ORFK11/vIRF2 is an inducible gene in PEL cells (Sarid *et al.*, 1998; Cunningham *et al.*, 2003) which doubles

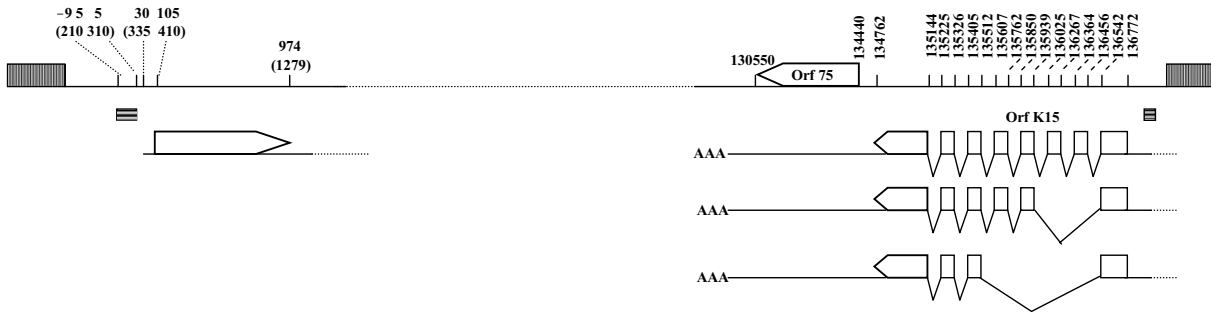

Fig. 28.7. Splicing pattern of transcripts and location of promoters at either end of the viral genome. The K1 gene at the "left" end of the viral genome is controlled by a promoter located next to the terminal repeat region. At the opposite end, the K15 gene is multiply and alternatively spliced to produce a group of proteins. A K15 promoter element is located adjacent to the terminal repeat region.

its basic expression level at about 20–24 hours after TPA treatment when measured on gene arrays (Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001). In induced PEL cell lines, the vIRF2 mRNA has a single transcriptional start site located 23 nucleotides downstream from a TATA box (Cunningham *et al.*, 2003). Using an antibody raised against ORFK11, Katano *et al.* (2000) could show that expression of the 110 kDa vIRF2 protein was only seen in TPA-induced PEL cells and that it is only rarely seen in KSHV-infected cells in KS, PEL or MCD, in keeping with its classification as a lytic gene product (Katano *et al.*, 2000).

Terminal membrane proteins

Two viral genes, K1 and K15, located at either end of the virus genome, encode membrane-associated proteins, VIP and TMP, respectively, that can trigger several cellular signal transduction pathways (Lee *et al.*, 1998a,b; Lee *et al.*, 2000, 2002; Lagunoff *et al.*, 1999, 2001; Glenn *et al.*, 1999; Poole *et al.*, 1999; Choi *et al.*, 2000; Brinkmann *et al.*, 2003). Both have no, or minimal, expression in uninduced PEL cells and mRNAs can be detected by northern blot, RT-PCR, RNAse protection or gene array following treatment with TPA or Na-butyrate (Lagunoff and Ganem, 1997; Sarid *et al.*, 1998; Glenn *et al.*, 1999; Choi *et al.*, 2000; Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Fakhari and Dittmer, 2002; Nakamura *et al.*, 2003). ORFK1 encodes a type I transmembrane protein, containing two hypervariable extracellular domains and an ITAM (immunoreceptor tyrosine activation motif) in its cytoplasmic domain (Lagunoff and Ganem, 1997; Lee *et al.*, 1998; Lagunoff *et al.*, 1999; Poole *et al.*, 1999; Cook *et al.*, 1999). The K1 encoded protein has therefore been termed VIP for variable ITAM containing protein.

ORFK1 gene expression was reported to increase significantly 8–10 hrs following TPA addition and to peak after 24 –72 hours. Lagunoff and Ganem (1997) found that the increase in its mRNA is not sensitive to PAA and therefore classified K1 as an early gene. The rate of increase of K1 gene expression led Jenner *et al.* (2001) to classify it as a 'tertiary lytic' gene, expressed with the same kinetics as many structural viral proteins. Similarly, Paulose-Murphy *et al.* (2001) placed it among the lytic genes with slightly delayed expression kinetics (peak expression after 36 hours). Nakamura *et al.* (2003) grouped K1 together with some structural proteins (ORF65/SCIP, a capsid protein; ORF47/gL, a virion glycoprotein; ORF62, a tegument gene), but also the ORF56 DNA replication protein and the ORF74/vGPCR chemokine receptor homologue.

The promoter for ORFK1 has been mapped to a region in the long unique region (LUR) of the viral genome immediately adjacent to the terminal repeats (Fig. 28.7). A 100 bp fragment corresponding to nucleotides 210–310 of the partial BCBL-1 sequence reported by Lagunoff and Ganem (1997), but located largely outside the prototypic KSHV genome sequence reported by Russo *et al.* (1996), can confer promoter activity to a heterologous indicator gene and has moderate but significant constitutive activity in B cells, epithelial cells and endothelial cells (Bowser *et al.*, 2002). The ORFK1 promoter is activated directly by RTA and TPA in B cells and epithelial cells; however, in SLK endothelial cells this effect is only weak (Bowser *et al.*, 2002). These results are in keeping with the reported lytic cycle expression kinetics of ORFK1. Lee *et al.* (2003) used monoclonal antibodies to the extracellular domain of K1 to demonstrate its expression early after induction of the lytic cycle in PEL cells and in a small proportion of KSHV-infected cells in MCD biopsies.

ORFK15, at the other end of the genome, consists of 8 exons, which are multiply and alternatively spliced (see Fig. 28.7) to give rise to a family of proteins that share a common c-terminal cytoplasmic domain encoded by exon 8 but vary in the number of membrane anchor domains

encoded by exons 1–7 (Glenn *et al.*, 1999; Poole *et al.*, 1999; Choi *et al.*, 2000). The reading frame originally designated as ORFK15 by Russo *et al.* (1996) represents only a small part of this gene and overlaps with exon 2 (see Fig. 28.7). The designation of TMP (for terminal membrane protein) has recently been adopted for the K15 proteins. The largest of the K15/TMP proteins has an apparent molecular weight of 45 kDa on SDS-PAGE, is predicted to contain 12 such transmembrane segments in addition to the c-terminal cytoplasmic domain, and has recently been shown to be a potent activator of the Ras/ERK, JNK and NF-κB pathways (Brinkmann *et al.*, 2003).

Like K1, K15 is inducible in PEL cells and has been classified as a class III gene on the basis of its inducibility but lack of basal expression in PEL cells (Sarid *et al.*, 1998). One of the three published gene array studies classified K15 as "tertiary lytic" (Jenner *et al.*, 2001), another (Nakamura *et al.*, 2003) reported a relatively early (8 hours) onset of K15 transcription which continued to increase up to 48 hours, whereas a third (Paulose-Murphy *et al.*, 2001) observed peak expression at 24 hours with a subsequent decrease. In all three gene array studies (Nakamura *et al.* 2003; Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001) K15 and K1 were grouped close to each other on cluster analysis. A promoter element directing the expression of the K15 gene has recently been identified in the long unique region between the first K15 exon and the terminal repeat region (Wong and Damania, 2006). A region derived from a terminal repeat subunit has promoter activity in vitro but is not responsive to RTA (Henke-Gendo, Rainbow & Schulz, unpublished data). In contrast to the similar expression kinetics of K1 and K15, regulation of K15 gene expression may therefore differ from that of K1.

At the protein level, different TMP isoforms have been demonstrated in transient transfection assays using expression constructs with differentially spliced mRNAs (Glenn *et al.*, 1999; Choi *et al.*, 2000; Sharp *et al.*, 2002; Brinkmann *et al.*, 2003). Recent findings suggest that the 45 kDa K15 protein is expressed in epithelial cell lines harboring a recombinant KSHV genome (M. M. Brinkmann *et al.*, unpublished data). A 21 kDa isoform, much smaller than the expected molecular weight of most TMPs, has been seen in some PEL cell lines and could represent a proteolytic cleavage fragment (Sharp *et al.*, 2002). Immunoreactive K15 protein has been detected in a small number of B cells in MCD biopsies using a monoclonal antibody to K15, in keeping with the predicted lytic expression pattern of K15 (Sharp *et al.*, 2002).

"Kaposin" locus

The region between nt 117,432 and nt 118,758 of the prototype KSHV sequence was originally predicted to contain an open reading frame, ORFK12, defined by a start ATG at position 117 919 and a stop codon at position 118 101 and expected to encode a small hydrophobic protein of 60 aa (Russo *et al.*, 1996; see Fig. 28.8). Independently, an 0.7 kb mRNA (T0.7) was cloned from a pulmonary KS sample and found to be latently expressed in KS biopsies and PEL cell lines by *in situ* hybridization (Zhong *et al.*, 1996; Staskus *et al.*, 1997; Stürzl *et al.*, 1997). By Northern blot, an mRNA originating in this region was also strongly expressed in uncultured PEL cells (Li *et al.*, 2002). K12/T0.7 has since been regarded as a marker of latently infected cells. However, in PEL cell lines, K12/T0.7 mRNA expression is induced by treatment with TPA or butyrate, with one group classifying it as a class II gene in view of its detectable basic expression in the BC-1 cell line in the absence of chemical treatment (Sarid *et al.*, 1998), while another classified it as an early gene because of the cycloheximide-sensitive induction of T0.7 mRNA 13 hours following Na-butyrate treatment of the same PEL cell line (Sun *et al.*, 1999). In more recent gene array experiments K12/T0.7 was classified as a latent/lytic gene (Jenner *et al.*, 2001) or as a lytic gene with relatively late doubling of expression (Paulose-Murphy *et al.*, 2001; Nakamura *et al.*, 2003). The contrast between the in vivo gene expression pattern (constitutive) and that in cultured PEL cell lines (inducible) suggests that the regulation of gene expression in PEL cells may have been affected by in vitro culture.

Although the term T0.7/Kaposin is now often used as a synonym for K12-derived transcripts, recent work has shown that in most PEL cell lines, in a primary PEL sample and in KS biopsies a larger transcript of varying size (approx. 1.4–2.4 kb, depending on the sample studied) predominates (Sadler *et al.*, 1999; Li *et al.*, 2002). The varying size of these transcripts is explained by the variable number of repeat units in two groups of repeats, DR1 and DR2 (Sadler *et al.*, 1999; Li *et al.*, 2002). This genomic arrangement has been seen in tumor samples or PEL lines of subtype A (see Fig. 28.8; Poole *et al.*, 1999). In addition to the variable length of the DR1 and DR2 repeats, additional repeat elements, I and IIa-c, have been described in a primary PEL sample of subtype B (Li *et al.*, 2002). However, the assignation of genomic subtypes in the K12 region is based on the sequence of the original K12 open reading frame (Fig. 28.8) and no extensive analysis of the genomic arrangement in the upstream repeat region in different KSHV subtypes has been carried out.

The larger mRNA encoded in this region originates at position 118,758 according to one report (Sadler *et al.*, 1999), or at position 123,842 between ORFs 72 (vCYC) and 73 (LANA1) and involving a splice event between nt 118,779 and 123,595 (Li *et al.*, 2002; see Fig. 28.8). The latter report found evidence for conservation of this splice

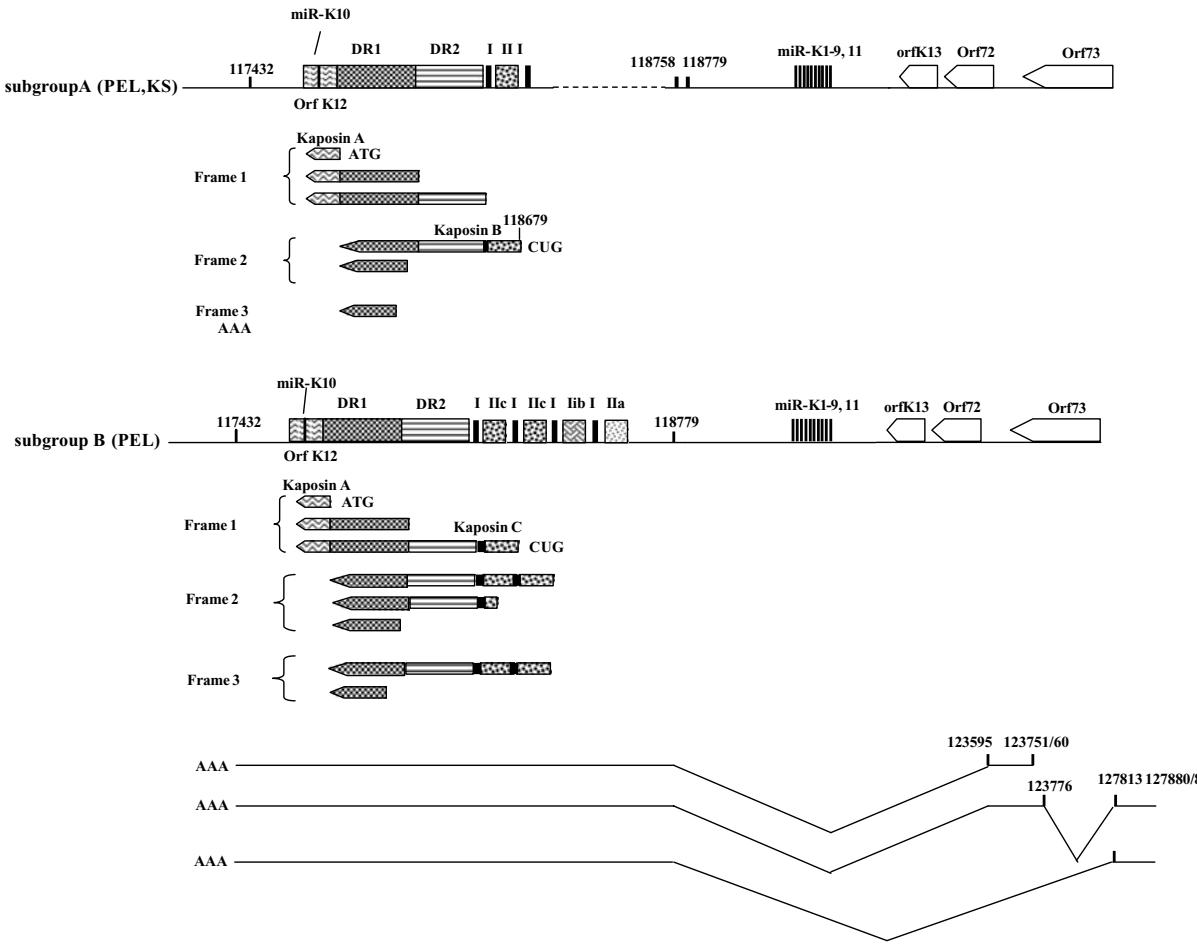

Fig. 28.8. Splicing patterns and translation products in the K12 region of the KSHV genome. Transcripts in the K12 region appear to originate upstream of K12. In the case of a primary PEL tumor, a promoter has been identified in the latent region of the genome, within ORF73. Translation appears to occur in different reading frames and from conventional (ATG) as well as unconventional (CTG) start codons.

event in all examined PEL cell lines and showed that the region between ORFs 72 and 73 contains a constitutive promoter element between nt 123,842 and 124,242, i.e., overlapping with ORF73 (LANA1) (Li *et al.*, 2002). The existence of this promoter has recently been confirmed by two other groups, although several start sites for the latent transcript originating at this promoter have been identified around 123751/60 (Pearce *et al.*, 2005; Cai *et al.*, 2006; see Fig. 28.8).

This latent mRNA uses alternative start codons (CUG, GUG) to translate several proteins in different frames whose sequence is derived from the repeats upstream of the original K12 (Sadler *et al.*, 1999; see Fig. 28.8). In frame 1 the original ORFK12 is also translated from a conventional ATG start codon, giving rise to the small (60 aa) hydrophobic membrane associated protein "kaposin A." Being thus located at the 3′ end of a bicistronic mRNA it is not clear at present whether its translation involves an internal ribosomal entry site, the inefficient use of the upstream alternative CUG start codon, ribosomal scanning, or a separate smaller mRNA. However, evidence for its expression in PEL cell lines has been presented (Kliche *et al.*, 2001).

A CUG start codon (nt 118 679) in frame 2 directs the expression of "kaposin B", a 48 kDa protein; evidence for its expression comes from transfection studies with an expression vector that contained an epitope tag in frame with, and downstream of, the predicted "kaposin B" sequence (Sadler *et al.*, 1999). "kaposin B" was the predominant protein expressed from the repeat region upstream of K12

(Sadler *et al.*, 1999) and also detected in a PEL cell line (Kliche *et al.*, 2001). However, the CUG start codon used by "kaposin B" was absent from the subtype B PEL sample investigated by Li *et al.* (2002). Not all KSHV subtypes may therefore express "kaposin B." A further alternative start codon (CUG) in frame 1 could be used to translate a third protein, "kaposin C"; however, expression of this protein appeared inefficient in the studies by Sadler *et al.* (1999) and Kliche *et al.* (2001). It is conceivable that it predominates in other KSHV subtypes (Li *et al.*, 2002), but no direct evidence for this currently exists.

As a consequence of the 23 bp repeat elements that constitute the DR1 and DR2 region the reading frame with regard to each individual element shifts in each consecutive element. The resulting proteins translated from the three different frames therefore share a repetitive 23 aa sequence motif (PGTWCPPPREPGALLPGNLVPSS for DR1; HPRNPARRTPGTRRGAPQEPGAA for DR2) and a monoclonal antibody to the DR1 motif will react with proteins translated in all three reading frames (Sadler *et al.*, 1999). This antibody detects DR1 containing proteins in a subpopulation of latently infected KS spindle cells, underscoring the expression of at least some DR1-derived proteins in vivo (Sadler *et al.*, 1999).

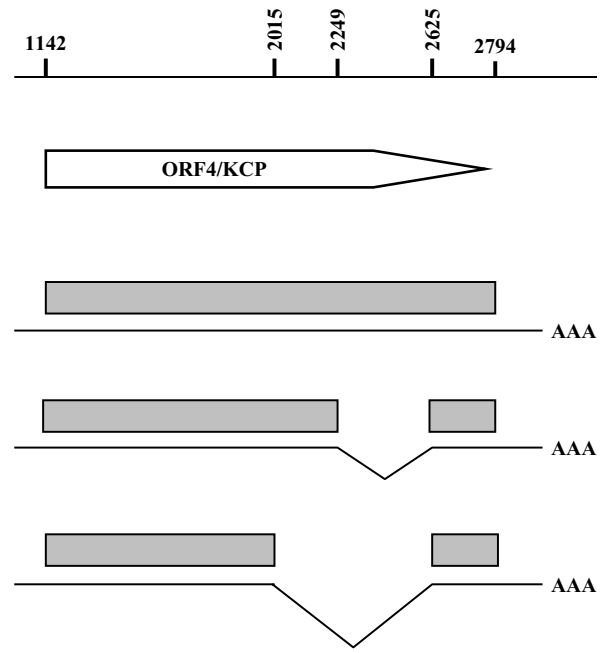

Fig. 28.9. Splicing patterns of ORF4 transcripts. Two of several alternatively spliced transcripts co-terminal with an unspliced full length transcript of ORF4, all inducible with TPA.

Viral microRNAs

In 2005, several groups independently identified a cluster of microRNAs (miRNAs) in the KSHV genome. Of 11 currently known miRNAs, 10 are encoded between the "Kaposin" locus and ORF71/K13 (miR K1-9,11), while a single miRNA has been identified in ORFK12 (Fig. 28.8). All KSHV miRNAs are derived from latent mRNAs directed by either the latency promoter in the 3′ end of ORF73/LANA1 or the major latency promoter upstream of ORF73/LANA1 (position 127,935–127,968; see Figs. 28.4 and 28.8). While miR K10 is located in an exon present in all spliced forms of these latent mRNAs the miR K1-9, 11 cluster is located in an intron present in the corresponding pre-mRNAs (Fig. 28.8; Cai *et al.*, 2005; Pfeffer *et al.*, 2005; Samols *et al.*, 2005; Grundhoff *et al.*, 2006). This ensures the expression of these miRNAs during latency, suggesting a role in the regulation of latent persistence. Potential viral and cellular mRNAs that could be targeted by these viral miRNAs are currently being explored.

Other spliced genes in the KSHV genome

ORF4 (KSHV complement control protein-KCP)

ORF4 encompasses nucleotides 1,142 through 1,794 and shares homology with cellular genes encoding proteins referred to as regulators of complement activation. Northern blot analysis and RT-PCR studies in PEL-derived cell lines demonstrate at least two alternatively spliced co-terminal transcripts in addition to an unspliced, full length mRNA of 1,679 bp (Fig. 28.9) which are induced by TPA treatment (Spiller *et al.*, 2003). These three transcripts encode proteins which retain C-terminal transmembrane domains and four N-terminal complement control protein (CCP) domains required for membrane attachment and complement regulation respectively. Analysis of complement regulation by soluble and membrane associated KCP demonstrated its ability to inhibit C3b deposition on cell surface and to act as a cofactor for factor I-mediated inactivation of complement proteins C3b and C4b, subunits of classical C3 convertase (Mullick *et al.*, 2003; Spiller *et al.*, 2003).

ORF40/41 (PAF)

ORF40 and ORF41 are both located on a spliced 2.2 kb mRNA that removes the region between these two ORFs and generates a long joint reading frame, ORF40/41, and has been shown to encode a protein of 75 kDa. Based on sequence homology, the 75 kDa protein is likely to be a primase-associated factor (PAF) (AuCoin and Pari, 2002; Wu *et al.*, 2001). The joint ORF40/41 transcript starts at position 60, 226, eliminates the genomic region between nt 61,658 and 61,784 and uses a polyadenylation site at position 62,546 (AuCoin and Pari, 2002; Wu *et al.*, 2001). A region

5′ to the start of this transcript has been found to contain a strong promoter activity when inserted into a luciferase vector (AuCoin and Pari, 2002). In addition, a second transcript of 0.7 kb initiates at nt 61,871 and thus only contains a part of ORF41; the corresponding protein is predicted to be translated from an ATG at position 61,908, within ORF41 (AuCoin and Pari, 2002). A 439 bp fragment upstream of the start site for this mRNA (nt 61,372–61,811) also has strong promoter activity (AuCoin and Pari, 2002). However, the existence of a protein translated from this mRNA has not yet been demonstrated. *ORF57*: The originally assigned ORF57 is located between nt 82,717 and 83,541 and was predicted to encode a homologue of an early herpesviral gene widely conserved among different herpesviruses, e.g., *herpesvirus saimiri* (HVS) ORF57, herpes simplex virus (HSV) ICP27 and Epstein–Barr Virus (EBV) BMLF1 (Russo *et al.*, 1996). For many of these homologues a role in RNA processing and nuclear export of unspliced mRNAs has been shown (detailed literature in Bello *et al.*, 1999). Subsequent RT-PCR studies, prompted by the smaller than expected size of KSHV ORF57, showed that the ORF57 mRNA is spliced and thus encodes a larger reading frame, of which the originally assigned ORF57 represents the c-terminal end. This splice removes an intron (nt 82,118–82,225) and with it an in frame stop codon upstream of the original ORF57. The spliced ORF57 mRNA initiates at nt 82,003, contains several in frame translational start codons in its first exon, uses the stop codon of the original ORF57 at 83,544 and a polyadenylation site at nt 83,608 (Bello *et al.*, 1999; Kirshner *et al.*, 2000). ORF57 is an early lytic gene whose expression becomes detectable on northern blots 2–4 hours after TPA induction of BCBL-1 cells, i.e., slightly later than ORF50/RTA and at about the same time as ORFK8/KbZIP, but before other early lytic genes (Lukac *et al.*, 1999). One of the more recent gene array studies classified it as a primary lytic gene (Jenner *et al.*, 2001), while another found a doubling of expression at 8h and a peak of expression at 72 h (Paulose-Murphy *et al.*, 2001). The ORF57 promoter is activated by RTA (Lukac *et al.*, 1999; Wang *et al.*, 2003a, b, c), placing ORF57 expression immediately downstream of the expression of RTA.

The ORF57 protein (SSM or MTA) enhances the expression of the bicistronic ORF59/ORF58 mRNA (as well as that of the ORF59/PFA protein), of the untranslated nuclear T1.1/PAN, RNA, and, in the presence of ORF50, RTA, of luciferase reporters driven by the nut-1 and kaposin promoters (Kirshner *et al.*, 1999). ORF57/MTA does not activate these promoters on its own, but enhances their ORF50/RTA-mediated activation. These findings suggest that ORF57 acts at a post-transcriptional level, but does so in a promoter-specific manner (Kirshner *et al.*, 2000).

ORFK3

The proteins encoded by ORFs K3 and K5 downmodulate major histocompatibility class I (MHC-I) proteins, NK receptors and coactivation molecules, thereby allowing KSHV-infected cells to escape both cytotoxic T-cell (CTL) and natural killer (NK) cell responses (Coscoy and Ganem, 2000; Haque *et al.*, 2000; Ishido *et al.*, 2000). Viral transcripts containing ORFK3 include three early (cycloheximide-sensitive) transcripts that also cover the neighboring ORF70 (TS). As shown in Fig. 28.10, one of these, an unspliced bicistronic mRNA, includes the entire ORF70 gene with the ORF70 translational start codon and presumably serves to translate the viral thymidylate synthase (Rimessi *et al.*, 2001). Another unspliced mRNA initiates downstream of the ORF70 start codon and could therefore translate a shortened ORF70 protein, or represent a monocistronic mRNA from which only the ORFK3 protein (MIR1, ZMP-B) could be translated. The third early mRNA splices out most of ORF70 and, although it does retain the ORF70 start codon and therefore represents a bicistronic transcript, could again serve to translate the ORFK3 protein. In addition to these early transcripts, an immediate-early, doubly spliced transcript that lacks most of the ORF70 coding region (but does retain the ORF70 ATG and is therefore bicistronic) could serve to translate the ORFK3 protein (Rimessi *et al.*, 2001).

Finally, a low abundance 2.5 kb latent transcript was recently identified by Taylor *et al.* (2005) which is coterminal with and encodes K3 in its entirety. When mapped, this transcript shows a complicated splicing pattern and encodes the entire K3 open reading frame (nt 18 585–19 671) along with 208 base pairs of the amino terminus of ORF70 (nt 20,096–20,304) and 70 base pairs of a region more than 3kb upstream (nt 23,770–23,840 (Fig. 28.10). Although low levels of ORFK3 protein expression has been documented in KS biopsies in vivo (Rimessi *et al.*, 2001), it is not yet clear which of these mRNAs is most efficiently translated to yield the ORFK3 protein and whether the novel 2.5kb latent transcript also plays a role in down-regulation of MHC class I during latent infection.

Events leading to the activation of immediate–early and early KSHV genes

In the experimental model commonly used to study the early stages of the lytic cycle, i.e., the induction of PEL cells by TPA or Na-butyrate, the immediate–early ORF50 gene, encoding RTA, is the earliest viral gene to be expressed. The ORF50/RTA promoter contains several transcription factorbinding sites, including AP-1, Sp1, Oct 1, CEBP/alpha (Deng *et al.*, 2000; Sakakibara *et al.*, 2001; Wang *et al.*,

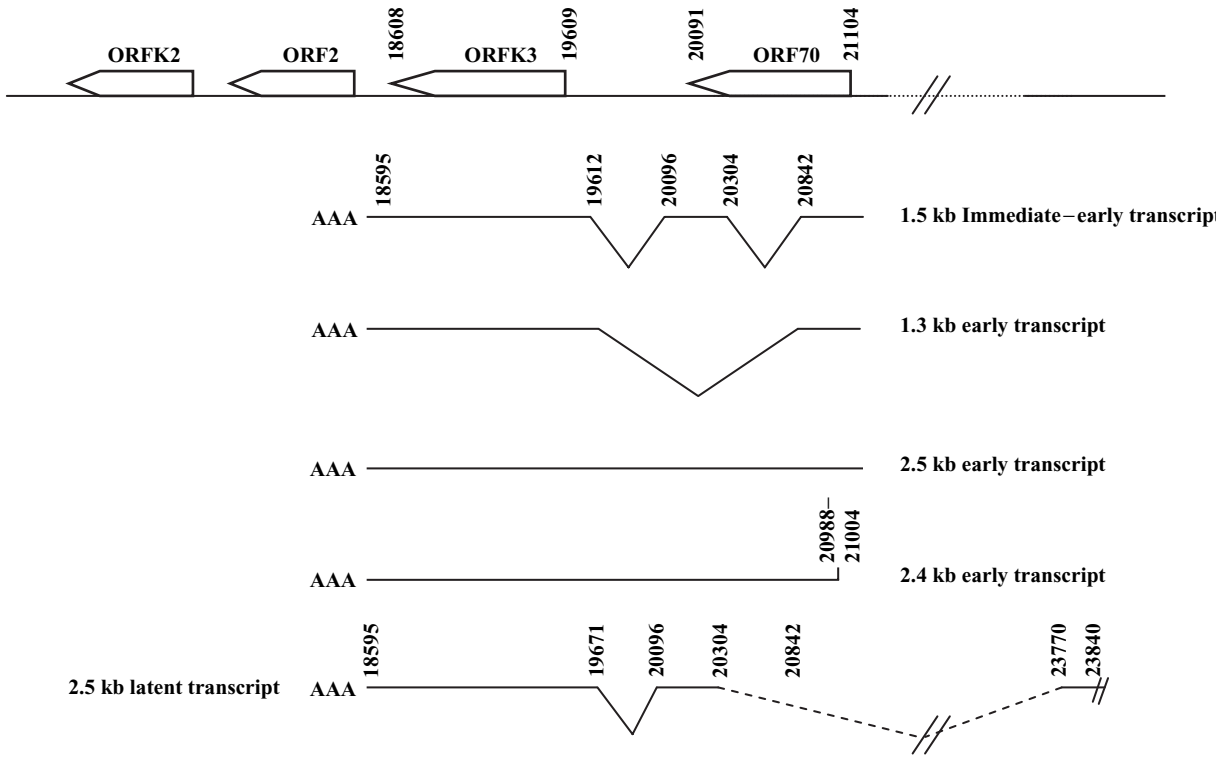

Fig. 28.10. Splicing patterns in the ORFK3-ORF70 region of the genome. Four transcripts are expressed during lytic induction of virus while a fifth transcript is detected at low levels during latent infection in PEL cell lines.

2003a,b,c). RTA activates its own promoter through two of three CEBP/alpha binding sites, most – likely by physically associating with CEBP/alpha (Wang *et al.*, 2003a,b). RTA also increases the expression of CEBP/alpha, thereby generating an amplification loop that leads to the expression of not only the immediate–early ORF50/RTA gene, but also of other early genes (see below).

In persistently infected PEL cell lines the ORF50/RTA promoter appears to be methylated in a region (–315 to –255 of the transcriptional start site) located between the two CEBP/alpha sites that are important for RTA-mediated activation (Chen *et al.*, 2001; Wang *et al.*, 2003a,b). In KSHV-infected B-cells in vivo this regions also appears to be heavily methylated, whereas in PEL biopsies, MCD lesions and in KS tumors in vivo, the methylation pattern is lighter, with an inverse correlation between the expression of lytic viral proteins and the methylation status of the ORF50 promoter in individual samples (Chen *et al.*, 2001). Treatment of persistently infected PEL cell lines with TPA or 5-azacytidine reduces the number of methylated CpG residues in the ORF50 promoter and activates the lytic cycle (Chen *et al.*, 2001). It is therefore, conceivable that methylation of the ORF50 promoter during viral persistence regulates, at least in part, the spontaneous activation of the lytic cycle in persistently infected cells. However, given the presence of transcription factor sites that are targeted by components of signaling pathways known to be induced by TPA or Na-butyrate (e.g., AP-1) these could also contribute to the activation of the lytic cycle.

RTA also activates a number of viral early promoters, including those of ORF, K8 (KbZIP/RAP), nut-1 (T1.1/PAN), ORF57 (MTA), ORFK2 (vIL6), vMIP, ORFK12 (kaposin), ORF74 (vOX2/GPCR). In at least some target promoters, i.e., T1.1/PAN, ORFK12, vIL6, RTA binds to specific DNA sequence elements (type II RTA responsive elements; RRE) (Chang *et al.*, 2002; Deng *et al.*, 2002; Song *et al.*, 2002; Wang *et al.*, 2003a,b). In contrast, the promoters for ORF50 (RTA), ORFK8 (KbZIP/RAP), nut-1 (PAN), and ORF57 (MTA) contain CEBP/alpha binding sites and their activation by RTA involves an interaction of RTA with DNA-bound CEBP/alpha (Wang *et al.*, 2003a,b).

In addition to the ability to directly bind DNA of target viral promoters, RTA can also target promoters lacking direct recognition elements by interaction with host DNA-binding factors such a RBP-Jκ. RBP-Jκ belongs to a family of sequence-specific transcriptional repressors which

recruits other corepressors to silence gene activation. By binding to RBP-Jκ, it appears that RTA not only displaces associated corepressors, but also allows for ligand independent activation of target genes. Although specific genes including PAN, ORF57, and SSB have been individually shown to be regulated in this manner, the broader implication is that RTA-mediated redirection of RBP-Jκ activity from repression to activation is critical for lytic reactivation (Liang *et al.*, 2002; Liang and Ganem, 2003).

The ORFK8 encoded protein, KbZIP or RAP, related to the EBV lytic-cycle Z transactivator (ZTA), as discussed above, contains a leucine zipper oligomerization domain and may interact with cellular transcription factors like CBP and CEBP/alpha (Wang *et al.*, 2003b). Although it plays a role in the KSHV lytic replication cycle, as shown by its association with PML domains and recruitment into lytic replication compartments (Wu *et al.*, 2001), it is, unlike EBV ZTA, not sufficient to trigger the activation of the lytic cycle and does not directly bind to viral DNA (Polson *et al.*, 2001; Chiou *et al.*, 2002). There is, however, evidence for its indirect association with the promoters for RTA, ORF57/MTA, as well as its own promoter, most likely as a consequence of its ability to associate with CEBP/alpha (Wang *et al.*, 2003b).

Regulation of the lytic cycle by other viral proteins

In addition to the regulatory role of RTA, KbZIP/RAP and ORF57/MTA during the immediate–early and early phase of the lytic cycle several other KSHV proteins may have the role of modulating lytic replication. Thus the membrane-associated glycoprotein encoded by ORFK1 has been found to inhibit the TPA-induced activation of the lytic cycle in the BCBL-1 PEL cell line (Lee *et al.*, 2002). A detailed analysis of the viral gene expression pattern in this cell line following the overexpression of K1 and treatment with TPA showed that the majority of viral genes appears to be downregulated as the result of K1 overexpression; however, a small number, including ORF72/vCYC, K15/TMP, ORF48 and K1 itself appeared to be upregulated. In contrast, K1 does not appear to affect the ORF50/RTA mediated activation of the lytic cycle, suggesting that TPA-induced events upstream of the ORF50/RTA promoter are modulated by K1. Among these the TPA-mediated activation of AP-1, NF-κB and Oct-1 in this PEL cell line appears to be inhibited by overexpression of K1 (Lee *et al.*, 2002). Lagunoff *et al.* (2001) also reported that K1 may moderately augment the activation of the lytic replication cycle in a PEL cell line but did observe a dominant negative effect of K1 signaling defective mutants on the ORF50/RTA-mediated activation of the lytic replication cycle in the same PEL cell line (BCBL-1).

Other factors that increase lytic viral replication

Several clinical observations suggest that reactivation of KSHV could be mediated by environmental factors or injury. Thus the frequent localization of classic KS lesions on the feet has been linked to an exposure to volcanic soil (Ziegler, 1993) or to reduced blood flow and poor oxygenation of the lower extremities in elderly individuals. Experimentally, hypoxia has been shown to activate KSHV lytic replication in PEL cell lines (Davis *et al.*, 2001). Haque *et al.* (2003) reported the presence of functional hypoxia response elements in the ORF50/RTA and ORF34 promoter. These elements are activated by either HIF-2 alpha (ORF50/RTA promoter) or by both HIF-1alpha and HIF-2alpha (ORF34 promoter) and hypoxia induces the transcription of ORF34 and ORF50/RTA mRNAs (Haque *et al.*, 2001). Chang *et al.* (2000) and Zoeteweij et al. (2001) reported that calcium ionophores, such as ionomycin and thapsigargin, could activate KSHV lytic replication cycle in PEL cells and further synergized with the effects of phorbol esters (Chang *et al.*, 2000). That KS lesions can arise in scar tissue or regions of traumatized skin (Köbner phenomenon) is another well-established clinical observation (Sachsenberg-Struder *et al.*, 1999).

In addition, an extensive body of experimental work has suggested some inflammatory cytokines may accelerate the development of KS lesions in AIDS patients (for a review see Ensoli *et al.*, 2001). Thus Monini *et al.* (1999) showed that inflammatory cytokines, and in particular interferon gamma, can increase the viral load in cultured PBMC of KSHV infected individuals. In a similar experiment Mercader *et al.* (2000) identified oncostatin M, hepatocyte growth factor/scatter factor and interferon gamma as cytokines that are released from HIV-1 infected T cells and can induce the expression of ORFK12 and ORF26 mRNA, as well as ORF59 and K8.1 proteins, in the BCBL-1 cell line. In vitro examination of KSHV infected cell lines demonstrates that inflammatory cytokines had diverse effects on KSHV induction. While interferon gamma consistently induced lytic activation, Chang *et al.* (2000) found other cytokines including tumor necrosis factor, IL-1, IL-2, IL-6, granulocyte-macrophage colony stimulating factor, and basic fibroblast growth factor did not. Further, interferon alpha inhibited KSHV induction (Monini *et al.*, 1999; Chang *et al.*, 2000).

Recently, it was shown that KSHV-infected keratinocytes could activate the lytic replication cycle upon epithelial differentiation in raft cultures (Johnson *et al.*, 2005), suggesting that, similar to human papillomavirus, KSHV infected epithelial cells could be programmed to allow the production of new virions at the epithelial surface.

Effects on apoptosis, cell cycle and transformation, and comparative aspects of EBV with other known DNA tumor viruses

George Klein and Ingemar Ernberg

Microbiology and Tumor Biology Center, Karolinska Institutet, Stockholm, Sweden

The list of human viruses presently known to cause or to contribute to tumor development comprise four DNA viruses, Epstein–Barr virus, certain human papilloma virus subtypes, hepatitis B virus, and Kaposi sarcoma herpesvirus (HHV-8); and two RNA viruses, adult T-cell leukemia virus (HTLV-1) and hepatitis virus C. In addition, while HIV infection is not directly tumorigenic, it increases the incidence of certain tumors.

The purpose of this chapter is to consider EBV and HHV-8 in relation to the known DNA tumor viruses, with particular focus on tumorigenicity.

Viral strategy at the molecular level as a tumor risk factor

Altered genes or environmental factors are usually considered as major risk factors for tumor development. However, the strategy of certain viruses may constitute a risk factor in itself. Tumor-associated viruses in humans have a survival strategy, like other viruses, aiming to maintain, replicate and propagate their genomes, but some features of this strategy entail a risk to initiate or favor tumor development under certain circumstances. This implies that only a small minority of the infected cells enter the pathway towards a malignant tumor and even fewer succeed.

Three types of virus–host cell interactions may carry a risk

1. Blocking of late viral functions or blocking the replicative cycle, by mutation or deletion of genetic material, e.g., due to the integration of the viral genome, as exemplified by HPV or adenovirus transformation in vitro.
2. Infection of cells that are not fully permissive for viral replication, for species or tissue specific reasons. Permissiveness for the early but not the late functions of the viral cycle is particularly dangerous. The early viral proteins may exert continuous proliferation stimulating and/or apoptosis preventing effects. Infection of hamster or guinea pig cells with some of the human adenoviruses and SV40 infection of rodent cells may serve as examples.
3. Latent viral persistence may subvert normal controls. This can be illustrated by EBV infection of B-lymphocyes in immunodefective hosts.

Early history: up and down

Views on the role of viruses in the etiology of cancer have been polarized between two extreme positions during the major part of the last century. The belief that viruses have nothing to do with cancer was as widespread at certain times, as the suspicion that most and perhaps all tumors are caused by virus at other times. The field started with the discovery of Peyton Rous in 1911 that chicken sarcomas could be transmitted with cell-free filtrates (Rous, 1911). The tumors arose at the site of inoculation and were of the same histological type as the original sarcoma. This created great excitement : the cancer problem was solved! The enthusiasm subsided rapidly, however, when mouse and rat tumor filtrates failed to induce tumors. In retrospect we may see this as the consequence of exaggerated expectations, hasty experiments and increasing lack of confidence. It became the prevalent view that viruses may play a role for tumors in birds, but not in mammals.

Two decades later, Richard Shope (1933) found that benign warts could be transmitted from the wild cottontail

to the domestic rabbit by cell-free filtrates. This did not change the climate of opinion. The rabbit was a mammalian but warts were benign tumors, not cancers. Several important points were overlooked by outside commentators, however. The initially benign rabbit papillomas turned occasionally into carcinomas. This could be accelerated by the topical application of chemical carcinogens. The term tumor progression was originally coined by Rous to designate this transition, or, in its generalized form, the process whereby "tumors go from bad to worse." Later, Leslie Foulds (1958) defined and extended the term. It refers to the development of tumors by multiple, stepwise changes in several "unit characteristics." Today we see them as distinct phenotypic traits. They are individually variable and reassort independently of each other. Tumor progression can therefore proceed along several alternative pathways and each tumor becomes individually unique from the biological point of view.

The early work on Shope papilloma was also interesting from the immunologist's point of view. The virally induced warts that did not progress to carcinoma were rejected simultaneously by a systemically acting host response, mediated by lymphocytes, rather than by antibodies. This was the first example of a tumor rejection response that targeted virally encoded proteins in DNA virus transformed cells.

In the 1930s, John Bittner (1936) discovered the milk factor, later called the mouse mammary tumor virus (MMTV). This discovery did not create any major change of opinion either. This may have been due, at least in part, to the way the findings were presented and discussed. The genetically oriented mouse mammary tumor biologists proceed by careful, gradual analysis that fitted the long duration of each experiment (2 years or more). It showed that MMTV could increase the frequency of mammary cancer, but it was neither necessary nor sufficient for tumor induction. Hormonal and genetic factors modified the risk considerably. The role of MMTV as a tumor-susceptibility factor in selectively inbred high cancer strains was readily accepted, but its role as a "tumor virus" remained questionable. It was appreciated, however, that the probability of tumor development could be influenced by multiple factors, including viruses.

Up again, and how!

A major paradigmatic shift occurred in the 1950s. It was triggered by the discovery of the murine leukemia virus by Ludwik Gross (1951) and the polyoma virus by Sarah Stewart and Bernice Eddy(Stewart *et al.*, 1958). Gross found that cell free filtrates prepared from the "spontaneous" leukemias of the high leukemic AKR strain could transmit the disease to a low leukemia strain, C3H. In contrast to many others who failed before him, Gross succeeded for three reasons: his serendipitous use of newborn, less than 24 hours old mice as recipients; his fortuitous choice of C3H, the only low leukemia strain available at the time that happened to be susceptible to the virus carried by the AKR strain, later called the Gross virus; and the dogged persistence of Ludvik Gross in an area where nobody expected positive results.

The scientific community received Gross's first report with surprise and disbelief. This attitude prevailed for 5 years, until the originator of the AKR strain, Jacob Furth, took pains to repeat Gross's experiments under the original conditions and with the same recipient C3H subline (Furth *et al.*, 1956). He succeeded, in contrast to others who were less meticulous in their choice of experimental conditions. Furth's confirmation has led to the immediate acceptance of Gross's findings. The discovery of the polyoma virus also stemmed from Gross's work, but in a more indirect fashion. Gross has observed occasional parotid tumors in C3H mice inoculated with AKR leukemia filtrates. He realized that they may have been induced by another virus, provisionally referred to as the parotid tumor agent.

Stewart and Eddy started out on the assumption that Gross's leukemia virus experiments were correct. Since the virus was apparently quite weak, however, they wished to amplify it by adding the leukemia filtrates to embryonic mouse fibroblast cultures. After a few days culturing, they inoculated the filtered supernatants into newborn mice. The mice developed a wide variety of sarcomas and carcinomas, but no leukemia. Due to its ability to induce many types of tumors, the virus was named polyoma.

Classes of experimental tumor viruses

The viruses so far mentioned fall into three major categories. Rous sarcoma virus belongs to the acute or class I RNA tumor viruses. The murine leukemia and the mammary tumor virus fall into the category of chronic or class II RNA tumor viruses. The Shope papilloma and the polyoma virus are DNA tumor viruses.

Some interesting generalizations can be made on the basis of this and later experimental work that has identified many additional viruses in all three categories.

All experimentally derived RNA tumor viruses belong to the retrovirus family. They carry their genetic information in RNA. Following their entry into a susceptible target cell, the virally encoded reverse transcriptase rewrites their RNA into proviral DNA that can insert into cellular

DNA at random. When virus production is activated again, the proviral DNA is transcribed into RNA. This is followed by viral RNA replication, the production of new viral proteins, the assembly of new viral particles, and their release by budding, but it is not accompanied by any cytopathic effect. Virus production is therefore compatible with cell proliferation.

Activation and transcription of the integrated provirus is an error-prone process. Adjacent cellular DNA may contribute to the RNA sequences carried by the viral particle. In the vast majority of the cases, this has no notable consequences, but occasionally the incorporated cellular sequence may originate from a gene whose activated product can stimulate the entry of the cell into the S-phase. Virus particles that carry such sequences may cause cell proliferation when they infect new recipient cells. The probability that this happens is very low, because every step in the process, from the integration of the virus into the "right place," through the production of the appropriately (in frame) fused viral–cellular messages, the release and the replication of competent virus and the subsequent new infection of a susceptible cell, are all low probability events. A tumorigenic virus variant is usually generated by the purposeful and often prolonged selection for tumorigenicity This requires great persistence on the part of the investigator. Following the early discovery of the Rous sarcoma virus, it took four decades before new acute or class I RNA tumor viruses were isolated that could induce tumors at the site of inoculation and to transform normal into tumor cells in vitro. Following the revival of viral oncology in the 1950s, some 40 such viral strains, carrying about 20 different cell derived oncogenes, as they were to be called, were isolated in rapid succession from fowl, rodent, feline and simian tumors.

Class I RNA tumor viruses are not known to play any tumorigenic role in nature. This is understandable, because most of them are defective, due to the replacement of essential viral genetic information, by the inserted cellular gene. With only some notable exceptions, they produce crippled virus particles that can only multiply in the presence of complete, but non-transforming "helper virus."

Chronic or class II RNA tumor viruses have no transforming activity in culture. They do not induce tumors at the site of inoculation and carry no cellular oncogenes. Insertion of the proviral DNA in the immediate neighborhood of a cellular oncogene is the most frequent mechanism whereby they contribute to the tumorigenic process. Since the proviral DNA integrates at random, the likelihood of such an insertion is low. Very high level of virus production, accompanied by viremia, is usually mandatory for tumorigenicity. This is the reason why only some mouse strains that can support virus replication and/or are deficient in their immunological responsiveness to the virus, are susceptible to the tumorigenic effect of murine leukemia virus or mammary tumor virus.

Insertion in the neighborhood of a cellular protooncogene is not the only mechanism whereby an RNA tumor virus can initiate tumor development, but other alternatives are less well documented. HTLV-1, or adult T cell leukemia (ATLV) virus, is an example of this. It is believed to stimulate the expansion of preneoplastic cell populations, paving the way to cellular changes that may be more directly involved in the tumorigenic process (Gallo *et al.*, 1983).

In conclusion, the RNA tumor viruses have provided a wealth of information about virus-cell interactions in relation to the tumorigenic process and have led, indirectly, to the discovery of numerous cell division regulating cellular genes. They can be regarded as a model of what can happen, but they give us very little information about what does actually happen in the genesis of human tumors.

The DNA tumor viruses provide a very different picture. They belong to several unrelated virus families. In contrast to the RNA tumor viruses that can replicate in growing cells without killing them, the DNA tumor viruses kill the cells in which they replicate. Their tumorigenic activity depends therefore on the blocking of the lytic viral cycle. This may occur in cells that are non-permissive for the lytic cycle due to their species and/or tissue derivation.

The transforming genes of all DNA tumor viruses are genuine constituents of the viral genome. The number of virally encoded transforming genes varies between one (SV40), two (adeno- and papillomaviruses) and six (EBV). The virally encoded transforming proteins are immunogenic, as a rule. The challenge of viral transformation is met by the immune surveillance of the host. Cells transformed by these viruses grow usually only in immunosuppressed hosts. They represent the major part of the "opportunistic tumors" that arise exclusively or predominantly in congenitally, iatrogenically (as after organ transplantation) or virally (e.g., by HIV) immunosuppressed persons.

Inactivation of Rb and p53 is an important prelude to viral replication, as discussed below. Early after primary infection, DNA tumor viruses induce a round of DNA replication in the recipient cells. This carries the risk of malignant proliferation. The host inhibits the progressive growth of the transformed cells by its immune response, however. While the immunocompetent host rejects virus driven, proliferating cells, the virus goes into hiding. It persists in non-proliferating cells where it is not "seen" by the immune response. The example of EBV provides a particularly interesting "success story" that favors the survival of both the

virus and the host. A comparison with the smaller DNA tumor viruses, in the next section highlights both parallels and contrasts.

What does the type of virus-cell interaction tell us about tumorigenic risk?

There is a fundamental difference between the small DNA tumor viruses and the herpesviruses, with regard to potentially tumorigenic interactions with their host cell. Permissiveness for the early but not for the late (lytic) steps of the viral cycle constitute the main risk for the former group. Convergent evolution has provided SV40, the transforming adenoviruses and the tumor associated papillomaviruses with the ability to inactivate two of the main tumor suppressor pathways that involve p53 and Rb, respectively. Inactivation of the same two pathways appears to be mandatory for non-virally related tumor development. As discussed elsewhere in this chapter, this impairs two of the main controlling functions that prevent the replication of cells driven by illegitimately activated oncogenes.

Inactivation of both pathways by the small DNA tumor viruses is part of the viral strategy. Both the integrating and the episomal viruses need to induce an S-phase, as already mentioned, in order to integrate or to establish the appropriate chromosomal–episomal balance, respectively. They also need to protect the activated cell from apoptosis, in order to secure their persistence.

In the natural host cell, the growth stimulating and anti-apoptotic effects of these viruses have no lasting consequence, because virus production and cell lysis sets a natural endpoint.

In the case of the tumor associated herpesviruses and particularly of EBV, the possible tumorigenic contributions of the virus need to be considered in relation to the different forms of non-productive virus–cell interactions. EBV has evolved mechanisms to activate and expand its primary host cell population, the human B-lymphocyte. It is also capable of switching off its B-cell activating program and remain latent in long-lived resting memory B cells. The virus can thus use several non-lytic interaction programs, tailored to different B cell subclasses. They lead to different programs of viral expression that also differ in their ability to induce a CD8+ T-cell mediated immune response in the host that prevents the excessive proliferation of the virally transformed immunoblasts.

Unlike the small DNA tumor viruses, where tumorigenicity is favored by the structural or regulatory impairment of the lytic genes, the latent EBV-B cell interaction that occurs without any genetic defect in the virus, is a potential tumor risk in the immunodeficient host. This is due to the fact that, apart from the occasional activation of the viral cycle in EBV-carrying B cells, the interaction is largely non-lytic. In EBV-carrying immunoblastomas that arise in transplant recipients, or in certain congenitally T-cell defective patients (XLP in particular) as well as in part of the AIDS associated lymphomas (with immunoblastic morphology), the interaction of the virus with proliferating immunoblasts is comparable to or identical with the usual interaction of the virus with normal B-cells. The tumorigenic "accident" occurs at the level of the host and not at the level of the virus or the cell.

None of the other EBV-associated B-cell derived malignant lymphomas, such as BL, HL, or PEL or the unusual, EBV carrying T-cell lymphomas express the proliferation driving, blastogenic program of the virus. The virus expresses only minimalistic programs designated as latency I or II, in contrast to the full immunoblastic program (III). The tumor promoting contribution of the virus must therefore be sought in other, less direct effects.

In BL, one needs to depart from the fact that the lymphoma originates in the post-GC, centroblastic or centrocytic cell, that is either resting or is on its way to a long-lived resting memory cell, but cannot leave the cycling compartment because it is driven by an Ig/myc translocation. The translocation results from a faulty recombination that occurs in the course of physiological Ig gene rearrangement. Conceivably, EBV may contribute to the emergence of the virus carrying BL clone by expanding the original population or, alternatively, or in addition, by protecting the myc-driven, apoptosis prone cell from apoptosis. (See further in the section on EBV and BL below).

Human tumor viruses

Four of the six viruses known to be involved in the causation of human cancer in a direct or a contributory capacity are DNA viruses (EBV, HPV, HBV, HHV-8) while the remaining two are RNA viruses (HTLV-1 and HCV).

As discussed below, EBV is most directly involved in the causation of immunoblastomas that arise in immunodefective persons, such as transplant recipients, certain congenital immunodefectives, and HIV-infected persons. EBV may also play a role in Burkitt lymphoma (BL) and nasopharyngeal carcinoma (NPC), as indicated by the regularity of its association with these tumors, but the nature of the viral contribution is not fully understood.

Special subtypes of the human papilloma viruses are known to contribute to the genesis of cervical carcinomas and of skin tumors. Human herpesvirus no.8 (HHV8, also called KSHV) is associated with Kaposi sarcoma,

Castelman's disease and body cavity lymphoma. Hepatitis virus type B and C contribute to the genesis of primary liver cancer. The evidence for these virus-tumor associations is epidemiological and molecular, but the relative role of the virus and of cellular changes has not been properly established.

The following two sections deal with the two human tumor associated gamma herpesviruses, Epstein–Barr virus (EBV) and, to a minor extent, Kaposi sarcoma herpesvirus (KSHV or HHV-8).

Epstein-barr virus (EBV)

EBV is the causative agent of a self-limiting lymphoproliferative disease, infectious mononucleosis. In immunodefectives, the proliferation may proceed to progressively growing immunoblastomas. Multiple viral genomes, derived from a single infectious event, are regularly found in high endemic Burkitt lymphomas (BLs) and in low differentiated or anaplastic nasopharyngeal carcinomas (NPCs). EBV is also found, although less regularly, in Hodgkin's lymphomas, nasal T-cell lymphomas, gastric carcinomas, salivary gland tumors and leiomyosarcomas (Table 29.1).

Table 29.1. EBV-associated tumors in man (the percentage figures indicate the frequency of EBV carrying tumors)

Lymphoid tissues		Epithelial tissues	
Burkitt's lymphoma, endemic	98%		
Burkitt's lymphoma, sporadic	25%	Gastric adenocarcinoma	5–10%
AIDS-immunoblastic lymphoma – in CNS	60% 100%	Nasopharyngeal carcinoma undifferentiated	100%
Post-transplant lymphoma	100%	Salivary gland carcinomas	<100%
Hodgkin's lymphoma	50%	Leiomyosarcoma in immunosuppressed	100%
T-cell lymphomas -lethal midline granuloma	10–30% >90%		

EBV exploits B-cell specific regulatory mechanisms and signals

Normal B cell physiology is tightly regulated. The generation of B-cell receptor diversity by immunoglobulin gene rearrangements, activation of resting B cells by cognate antigen and associated molecules, expansion of the activated population, migration through germinal centers and concomitant hypermutation, generation of long-lived memory cells and differentiation into secretory subtypes, plasma cells in particular, is regulated both by internal programs and external signals, including antigens, ligands and cytokines that influence homing, proliferation, differentiation and death of the cells. EBV has a whole gamut of highly refined mechanisms that exploit normal B cell physiology. Unlike many other viruses, its strategy is not limited to the turning of its host cell into a viral protein factory with the single purpose of virus production and release to the environment, although it can switch on that mechanism when it enters the lytic cycle. Rather, the virus follows a "live and let live" principle. Its vast success in infecting all human populations and persisting in latent form over the lifetime of the host without causing disease, except by accident, testifies to the validity of this strategy, both for the virus and for the cells.

The exploitation of normal B-cell physiology by the virus manifests itself at many different points. Already the very first step, viral attachment and penetration, is based on the use of a B-cell specific surface moiety, CD21 (also called the C3d receptor). This receptor is normally involved in B-cell activation by antigen, antibody and complement complexes. Activated B-blasts secrete cytokines and lymphokines that can stimulate B cell proliferation and express the corresponding receptors (e.g., CD 23), creating an autocrine loop. Moreover, the virus encodes three membrane proteins, LMP1, 2a and 2b, of which at least two control and modulate incoming signals, that participate in Ig-receptor activation, TNF-response and programmed cell death. As discussed in more detail below, the LMPs are constitutively active multifunctional membrane proteins. LMP1 interferes with TNF-α signaling. It can replace many CD40 induced functions and activates major signaling systems in B-lymphocytes and epithelial cells, such as NFkB, JNK-kinase and one JAK/STAT-pathway. Protection from apoptosis is one of its major downstream effects. LMP2a modulates kinase signaling from membrane receptors. Most notable are the eight N-terminal phosphotyrosine motifs that interact with the Ig-receptor induced kinases lyn and syk. LMP2a has an Immunoglobulin Transactivation Motif (ITAM) – with complete homology to the corresponding Ig-receptor ITAM-motif of its gamma-chain, that binds the syk kinase in its activated, phosphorylated state. Interspersed with these motifs are a PPPPY-motif that interacts with WW-domains of the Nedd-family of E3-ubiquitine ligases (Winberg *et al.*, 2000). It is conceivable that LMP2a may attract the kinases and is involved in their fast destruction by guiding the complex to the ubiquitine –proteasome system. Characteristically, the expression of

Table 29.2. Overview of the EBNA proteins

Name	Sub-type	Viral functions	Interactive cellular proteins	Expression	Required for in vitro transformation
EBNA-1		Maintains viral episomes Regulates viral promoters	Karyopherins 2 α and β; TAP/p32; USP7 (HAUSP); RPA	All EBV-carrying cells	Yes
EBNA-2	A& B	Activates viral and cellular promoters	PU.1; hSNF5; Spi-B; RBP-J kappa; p300/CBP; DP103; p100; TFIIE;TFIIH; TFIIB; TAF40; myb; TBP	Latency III in B-cells	Yes
EBNA-3 (EBNA-3A)	A& B	Represses the RBP-J kappa dependent transcription	RBP-J kappa; RBP-2N; CtBP; epsilon-subunit of TCP-1; XAP-2; F538 (UK/UPRT); AhR	Latency III in B-cells	Yes
EBNA-4 (EBNA-3B)	A& B		RBP-J kappa; RBP-2N	Latency III in B-cells	No
EBNA-5 (EBNA-LP)		Enhances EBNA-2 dependent transcription	Hsp27; Hsp70 (Hsp72); Hsc70 (Hsp73); HAX-1; HA95; alpha & beta tubulins; prolyl-4-hydroxylase alpha-1 subunit; p14ARF; Fte-1/S3a	Latency III in B-cells	Yes
EBNA-6 (EBNA-3C)	A& B	Represses the RBP-J kappa dependent transcription	RBP-J kappa; RBP-2N; DP103; ProT-alpha; SMN; NM23-H1	Latency III in B-cells	Yes

these proteins still permits the corresponding physiological signaling pathways to operate.

For example, LMP1 can replace CD40 ligand-CD 40 signalling, but does not interfere with physiological CD40-reception. LMP2 does not completely abolish Ig-receptor signaling, although it is likely to increase the signal threshold. It may be noted that the HHV8 membrane proteins K 1 and K 15, in combination, carry many of the motifs that function in the LMPs, such as the NFkB activation site and ITAM-motifs. Their role in latency, lytic cycle and tumorigenesis remains to be elucidated.

The following section will deal with the EBV-encoded growth transformation associated proteins in some more detail.

Growth transformation associated EBV encoded proteins

Table 29.2 summarizes the information of the six nuclear proteins (EBNAs).

EBNA1 is encoded by the ORF/KBRF1. It is a DNA binding protein of highly variable size (60–100 kD) due to the presence of a glycine alanine repetitive sequence, inserted in the first molecule that is flanked by a highly basic domain. The C-terminal part of the protein contains a stretch of acidic amino acids. It is expressed in most EBV-carrying cells, with the possible exception of latently infected resting B-cells (Reedman & Klein, 1974; Lindahl *et al.*, 1974; Andersson-Anvret *et al.*, 1978; Hennessy & Kieff, 1983; Dillner *et al.*, 1986a,b; Chen *et al.*, 1995a,b). In all other cell types that have been studied, EBNA 1 is expressed irrespectively of the cell phenotype, level of differentiation or, in the case of lymphocytes, activation status (Niedobitek *et al.*, 1989; Hamilton-Dutoit *et al.*, 1991; Prevot *et al.*, 1992; Zhou *et al.*, 1994). It is the only latency associated EBV-encoded protein whose expression is not influenced by the cell phenotype. In somatic cell hybrids between EBV carrying immunoblasts that express the full type III program of six nuclear and three membrane proteins and EBV negative non-B cells where all B-cell specific markers are eclipsed, EBNA1 but not EBNA 2–6 remains expressed (Contreras-Salazar *et al.*, 1989). EBNA1 is also the only member of the EBNA-family that remains associated with the chromosomes in metaphase (Ohno *et al.*, 1977; Jiang *et al.*, 1991). It is randomly distributed among the chromosomes, but binds specifically to the origin of latent viral DNA replication (*OriP*). This binding is necessary for the maintenance of the EBV episomes, by equal distribution to the daughter cells in mitosis (Jones *et al.*, 1989). EBNA 1 has three specific binding regions in the viral DNA, each multiple. 20 binding sites are in the family of repeats (FR), four in the dyad symmetry, and two downstream of the Q promoter (Reisman & Sugden, 1986; Sugden & Warren, 1989; Ambinder *et al.*, 1990; Rawlins *et al.*, 1985).

The latent replication of the viral DNA starts from ori P. EBNA1 binds to ori P as a dimer. It is composed of a flanking domain and a core domain. The flanking domain

includes a helix that projects into the major DNA grove and an extended chain that travels along the minor grove. This motif is responsible for all sequence determined contacts with DNA. The core domain makes no direct contact with DNA (Polvino-Bodnar *et al.*, 1988). The binding to chromatin is mediated via chromatin protein (ref). EBNA1 binding to the chromosomes is essential for the precise division of the replicated DNA into the two daughter cells.

Through the multiple interactions with viral DNA, EBNA 1 causes DNA looping by multimerization. This increases the complexity of its promoter regulation. Dyad symmetry controls S-phase associated viral DNA replication. EBNA 1 regulates viral promoters via its multiple binding sites. FR acts as an enhancer for the C-promoter, directing all six EBNA transcripts and the Qp elements that are negative regulators of Qp-driven EBNA1 transcription through a negative feedback loop (Bodescot *et al.*, 1987; Sample & Kieff, 1990).

EBNA1 contains a glycine–alanine repeat of variable length that inhibits its processing through the proetasomes and the subsequent MHC class 1 association of the derived peptides, a prerequisite for recognition by CD8 positive cytotoxic T-cells (Levitskaya *et al.*, 1995). This results in a dramatically extended half life of EBNA 1 to more than 2 weeks, and may contribute to its presence in resting B-cells without *de novo* synthesis.

EBNA2

EBNA2 (ORF:BYRF1) is an 82 kD phosphoprotein. It contains a 14 AA long domain that is responsible for transactivation. In contrast to EBNA1, the expression of EBNA2 is restricted to immunoblasts (Dillner *et al.*, 1985; Hennessy & Kieff, 1985; Ernberg *et al.*, 1986). On primary infection of B-cells it acts as a transcriptional transactivator (Rickinson *et al.*, 1987). It is essential for the transformation of B-cells into immunoblasts and the derivation of LCLs (Cohen *et al.*, 1989). EBNA2 defective viral substrains cannot activate B-cells. EBNA2 is the EBV encoded oncoprotein that differs most extensively between EBV types 1 and 2 (Zimber *et al.*, 1986). Type I EBV is a more efficient transformer of primary B lymphocytes than type 2 (Rowe *et al.*, 1989). EBNA2 is associated with nucleoplasmic, chromatin and nuclear matrix fractions.

EBNA2 induces a variety of activation markers and other cellular proteins in B-cells, including CD23, CD21, c- fgr and c-myc. It is required for the expression of EBV encoded LMP1 and LMP2a in immunoblastic cells (Wang *et al.*, 1987a,b, 1990; Aman *et al.*, 1990).

The interaction of EBNA 2 with the cellular proteins p300 and CBP is critical for EBNA2 mediated transactivation, due to the intrinsic histone acetylase activities of the former and their interaction with transcription factors (Bornkamm & Hammerschmidt, 2001). CBP has been implicated in EBNA2 activation of c-myc promoter.

Even though EBNA2 is a potent activator of many cellular and viral genes, it does not bind directly to DNA. It influences the responding promoters through its interaction with RBP-Jk, PU1 and other cellular proteins. The complexes formed modify the affinity of histones for DNA. Further chromatin remodeling activity is achieved through an interaction between EBNA2 and hSFN5. Recruitment of EBNA2 to DNA is essential for the transforming activity of EBV and RBP-Jk is the most extensively studied partner. RBP-Jk functions as a downstream target of the cell surface receptor known as Notch. Notch genes encode cell surface receptors that regulate developmental processes in a wide variety of organisms. The cleaved product of Notch is targeted to the nucleus where it binds to RBP-Jk and can activate transcription, but with a lower efficiency than the intracellular part of Notch. The binding of ligand to the extracellular domain of Notch results in the cleavage of an intracellular domain. This intracellular fragment of Notch (Notch-IC) migrates to the nucleus, binds to DNA-bound RBP-Jk and converts thereby a repressor of transcription into an activator (Hsieh *et al.*, 1996).

On the basis of these findings, EBNA2 is regarded as a constitutively active homologue of Notch. However, Notch can only partially substitute for EBNA2 in B-cell transformation experiments, probably because it does not upregulate the transcription of LMP1 or c-myc. The EBNA2 induced activation of the LMP1 promoter requires additional B lymphocyte specific factors, such as PU.1 (Johannsen *et al.*, 1995) and RBPJK (Johannsen *et al.*, 1996). Elements responsible for EBNA2 responsiveness have been characterized in EBV-Cp, LMP1 and LMP2 promoters and the cellular promoter for CD23. All have at least one RBP-Jk binding site.

As already mentioned, the interaction of EBNA2 with the cellular sequence specific DNA binding protein, RBP-Jk, is critical for transformation and LCL outgrowth. A sequence in EBNA2 closely mimics a corresponding sequence in the notch-receptor. Notch and EBNA2 may activate transcription from the RBP-Jk and PU.1 promoters by interacting with SKIP, a component of the HDAC2 corepressor complex. The EBNA2 domain that interacts with PU.1 includes the site that interacts with RBP-Jk. The targeting of PU.1 by the EBNA2 transactivator is an important aspect of EBV adaptation to lymphoid cells (Tamura *et al.*, 1995).

The essential role of EBNA2 in the immortalization of B-cells is thus due to its transactivation of viral promoters

(Cp, LMP1 and 2) and a variety of cellular genes associated with B-cell activation and growth, among them c-myc. Myc activation in lymphocytes induces protein synthesis and increase in cell size, D-type cyclins, cyclin E. It downregulates the inhibitors p21 and p27. The induction of c-myc is regarded as a major link between EBNA2 and the cell cycle machinery (Kaiser *et al.*, 1999).

EBNA2 is also required to maintain the EBV driven proliferation of B-cells, as shown in the conditional LCL designated as EREB2–5, that contains an EBNA2-estrogen receptor fusion protein. The removal of estrogen from the growth medium results in cell cycle arrest and apoptosis. Early reintroduction of estrogen stimulates renewed cell cycle entry and proliferation (Kempkes *et al.*, 1995). EBNA2 can be replaced by the constitutive expression of exogenous c-myc. The switch from the EBNA2 driven to the myc-driven state is accompanied by a phenotypic change of the LCL-like cell to a more BL-like cell, resembling dividing germinal center B-cells (Polack *et al.*, 1996).

Paradoxically, EBNA2 can also inhibit proliferation in established BL lines. EBNA2 is a transcriptional repressor of the immunoglobulin mu-gene. In BL lines where myc is controlled by the immunoglobulin mu enhancer, EBNA2 expression results in suppression of the myc transcription from the translocated myc gene, leading to growth arrest (Jochner *et al.*, 1996).

EBNA5 (alternative name: **EBNA-LP)**. **EBNA5** is a nuclear phosphoprotein that localizes to distinct subnuclear bodies. It is spliced from a variable number of W1-W2 exon pairs, 66 and 132 nucleotides long, respectively, forming 66 aminoacid long repeats and, from the Y1 and Y2 exons, a C-terminal 45 AA unique region. Its progenitor, the giant primary transcript originates from the W or C promoter in immunoblastic cells (and only there) (Dillner *et al.*, 1986a,b; Wang *et al.*, 1987a,b; Bodescot & Perricaudet, 1986). Together with EBNA2, EBNA5 is the earliest viral protein expressed in freshly infected B-cells. The two proteins can induce the entry of resting B-cells into the G1 phase. Coexpression of EBNA5 with EBNA2 enhances EBNA2 mediated transcriptional activation. EBNA5 is tightly associated with the nuclear matrix, and often accumulates in PML bodies (Pokrovskaja *et al.*, 2001). It migrates together with various components of the proteasome dependent degradation machinery in heat shocked cells, and in cells treated with proteasome inhibitors, raising the possibility that EBNA5 participates in the regulation of specific protein degradation in the nucleus. Kashuba *et al.*'s experiments on EBNA5 also showed that it does not bind to Rb and p53 in the yeast two hybrid assay, but can exert an inhibitory effect on the p53-Rb axis by targeting the p53 regulator p14 ARF(Kashuba *et al.*, 2003). The latter can bind MDM2, suppress its ability to mediate in the degradation of p53 and thereby increase the expression level of p53. It was suggested that EBNA5 participates in the elimination of the p14 ARF-HDM2- p53 complexes and thereby contributes to the downregulation of p14 ARF and p53 protein levels in EBV infected B-cells (see also Kanamori *et al.*, 2004).

EBNA3 family

EBNA3 (ORF: BLRF3 + BERF1), EBNA4 (ORF: BERF2a + BERF2b) and EBNA6 (ORF: BERF3 + BERF4) are three large nuclear phosphoproteins in a size range of 140–180 kD. EBNA3 and EBNA6, but not EBNA4 is necessary for in vitro transformation. Individual sequences of these three EBNAs show little similarity, but they are all composed of a highly charged N-terminal half and a C-terminal half that contains numerous repeat elements. EBNA4 also contains an LxCxE motif. **EBNA6** is transactivator that induces CD21, 23 and LMP1 (alternative nomenclature: EBNA3a,b,c). All three proteins are encoded by tandemly arranged genes, localized in the middle of the viral genome (Hennessy *et al.*, 1985; Dillner *et al.*, 1986a,b; Shimizu *et al.*, 1988). They are all highly hydrophilic. They are stable proteins that accumulate in intranuclear clumps, sparing the nucleolus. They are believed to act as transcriptional regulators and can interact with RBP-Jk (Radkov *et al.*, 1997; Zhao *et al.*, 2003; Hickabottom *et al.*, 2002). The three proteins use unrelated peptide sequences for their interaction. EBNA3 and 6, but not EBNA4, are required for B-cell transformation (Parker *et al.*, 1996). By and large, the EBNA 3 family member, have similar but more limited effects on cellular gene expression compared to EBNA 2. EBNA4, as also EBNA3 and 6, generate highly immunogenic peptides that can associate with MHC class I molecules. Some peptide-HLA class I combinations can induce CD8+ CTL mediated rejection in immunocompetent hosts.

The following further information on the two members of the EBNA 3 family involved in growth transformation, EBNA 3 and 6, are of interest.

EBNA 3 (alt: EBNA 3a)

Kashuba *et al.* (2000, 2002) have identified two EBNA3 interacting proteins, using a two-hybrid technique. TCP-1 is part of a chaperonine complex (Kashuba *et al.*, 1999). EBNA3 binds to the epsilon subunit of TCP-1. Kashuba *et al.* proposed that nascent EBNA3 is folded by the TCP-1 containing chaperon complex through its binding to the apical region of the epsilon subunit. EBNA3 may thereby receive help for its proper folding.

Table 29.3. Overview of the EBV latent membrane proteins

Name	Variants	Functions	Major protein interactions	Expression	Necessary for in vitro transformation
LMP1	Latent form	Mimics CD 40 Activation of NFkB, JNK-kinase, JAK/ STAT, MAP kinase, Akt cell survival induction of adhesion and immune regulatory membrane proteins	TRAF 1, 2, 3 TRADD BRAM 1 LMP2A	B-cell latency II-III, BL, HL, DLBCL, T-cell lymphoma, NPC	Yes
	Lytic	Not known	Not known	Lytic cycle	No
LMP 2	LMP2A	Interacts with phosphotyrosine kinases incl Src-family and PI3-kinase Blocks lytic cycle Block BCR activation	Src, Lyn, Lck ZAP-70, Syk, AIP4/Nedd 4	B-cell latency I-III, HL, DLBCL, T-cell lymphoma, NPC	No
	LMP2B	Blockc LMP 2A?	Not known	B-cells latency III, DLBCL, NPC	No

Kashuba *et al.* (2000) also found that EBNA3 interacts with p38/XAP-2. In the presence of EBNA3, the cytoplasmic p38/XAP-2 translocates to the nucleus. XAP-2 also binds to the hepatitis B virus X antigen, believed to be involved in the oncogenic effect of hepatitis B virus. XAP-2 is known to be involved in the regulation of the aryl hydrocarbon receptor (AhR) pathway. AhR is a ligand activated transcription factor, a member of the HLH transcription family.

EBNA3 was also shown to interact with a new member of the UK/UPRT (uridine kinase/uridine phosphoribasyl transferase) family (Kashuba *et al.*, 1999). The predominantly cytoplasmic enzyme translocates to the nucleus in the presence of EBNA3. It was suggested that EBNA3 may influence the uridine salvage pathway by contributing to the increase of the nuclear UTP pool, required for active cell proliferation.

EBNA6 (alternative EBNA3c) is the only member of the EBNA3 family that has a leucine zipper (West *et al.*, 2004). EBNA6 associates with histone deacetylase and can repress transcription through the Notch signaling pathway. EBNA6 is unique among the EBNAs in its ability to coactivate the LMP1 promoter with EBNA2 (Lin *et al.*, 2002). EBNA6 has also a number of specific repressive effects (Touitou *et al.*, 2001; Radkov *et al.*, 1999). Moreover, EBNA6 associates with histone deacetylase and can repress transcription through the Notch signaling pathway (Radkov *et al.*, 1999).

EBNA6 can also cooperate with oncogenic mutant H-ras in the immortalization and transformation of REFs (Parker *et al.*, 2000). It can also override the suppression of this transformation by p16, by targeting the checkpoint at the G1/S transition, regulated by Rb. EBNA6 can induce aberrant nuclear division that results in multinucleated cells, polyploidy and eventually cell death (Allday review, sid.36). All this suggests that EBNA6 may disrupt multiple cell cycle checkpoints and produce a similar phenotype as the K cyclin of KSHV (Krauer *et al.*, 2004).

Table 29.3 summarizes some of the known interactions of the EBNAs with cellular proteins:

The latent membrane proteins (LMP) of EBV

In the course of infection, replication or persistence, viral gene products frequently interact with proteins that regulate signaling pathways in the host cell. This capacity to modify host cell signal transduction is particularly apparent in the control of EBV.

EBV can express three membrane proteins during latent infection, latent membrane protein (LMP) 1 and 2 A and B (LMP 2A and B) (Hennessy *et al.*, 1984; Laux *et al.*, 1988; Longnecker & Kieff, 1990). These proteins interfere with multiple cellular signal transduction pathways so as to modulate apoptosis and cell surface receptor signalling. They are both transmembrane proteins with six (LMP 1) or twelve (LMP 2) anchoring transmembrane domains, according to computer based structure predictions. No full crystal structures have been established. Neither one acts as a ligand-receptor, but through constitutive activation at cellular membranes (Gires *et al.*, 1997). If there are no ligands, why are they located as membrane proteins?

The main function of both membrane proteins appears to be directed towards interaction with signalling and adaptor molecules normally regulated by cell membrane receptors. They are highly multifunctional and interact with several cellular signalling pathways. Importantly both proteins are expressed at the cell surface membrane as well as in intracellular membranes of the Golgi and endoplasmic reticulum (Lynch *et al.*, 2002; Eliopoulos &

Young, 2001). The significance of this compartmentalization is not known, since the function of the intracellularly localized LMPs has not been the subject of focused studies. Both proteins can be expressed in two forms, one full length and one shorter variant where the first (LMP 1) or the last exon (LMP2B) is excluded by alternative promoter usage or alternative splicing. The shorter variants appear structurally competent to disrupt or block the constitutive activation of the full length protein, by interfering with activation mechanism. LMP 1 is activated by aggregation to trimeres or multimeres, mediated by the transmembrane domains. The truncated protein variant lacks the C-terminus and four of the transmembrane domains. LMP 2 depends on the N-terminal tail and its phosphorylation for activation, which cannot take place with LMP 2B. Both LMP1 and 2 are expressed in latency forms II and III immunoblasts and derived tumors and cell lines (Rea *et al.*, 1994). LMP2A transcripts are also expressed in resting virus carrying B-lymphocytes in healthy individuals, the reservoir of persistently latent EBV (Chen *et al.*, 1995a,b; Qu & Rowe, 1992; Tierney *et al.*, 1994). Both proteins are also detected in epithelial tumors of the nasopharynx (NPC) and during the early stages of oral hairy leukoplakia (Pathmanathan *et al.*, 1995; Webster-Cyriaque & Raab-Traub, 1998). In NPC between 35 and 65% of the tumors are LMP-positive. LMP1 and 2 are expressed in a coordinate fashion Their transcription is co-regulated via a 600 bp bi-directional promoter-enhancer control element designated as the LMP-regulatory sequence (LRS). LMP 2 can only be expressed from viral episomes, since the precursor transcript passes through the terminal repeats (Table 29.3).

The short variant of LMP1 has only been demonstrated during productive, lytic virus infection where it may block the constitutive action of full length LMP 1.

Latent membrane proteins 1 (LMP1)

LMP 1 is a 356 amino acid protein with a short intracellular N-terminus and 150 aa C-terminus.

LMP1 is essential for the transformation of B lymphocytes into lymphoblastoid cell lines (Dirmeier *et al.*, 2003). It confers a survival advantage on EBV-infected B cells by protecting them from apoptosis. This is largely due to the LMP1-induced upregulation of the anti-apoptotic protein Bcl-2 and the block of p53 mediated apoptosis by the latter (Henderson *et al.*, 1991).

EBV-encoded LMP1 can also transform established rodent fibroblasts in vitro (Baichwal *et al.*, 1989; Fahraeus *et al.*, 1990). Furthermore, expression of LMP1 is correlated with a more favorable influence of treatment (chemotherapy/irradiation) on patients with NPC (Kawanishi, 2000) or Hodgkin's lymphoma (Montalban *et al.*, 2000). Clinical and follow-up data from 74 cases of NPC showed that LMP1 positive NPC grew faster and more expansively than LMP1 negative tumors.

LMP 1 almost completely mimicks the function of CD 40 mediated signalling and is thus functionally homologous to the TNF receptor (TNFR) family of proteins (Eliopoulos *et al.*, 1996, 1997; Kilger *et al.*, 1998; Zimber-Strobl *et al.*, 1996; Lam & Sugden, 2003). LMP1 has been shown to interact with several proteins of the TNFR signaling pathway through its C-terminal activation region (CTAR) 1 and 2. Hence, LMP1 can bind TRAF (TNFR-associated factor) 1, 2 and 3, as well as TRADD (TNFR-associated death domain protein), an adaptor protein that serves to recruit caspases to the death-inducing signaling complex (DISC) of the TNFR (Mosialos *et al.*, 1995; Devergne *et al.*, 1996). These interactions result in the NFκB-dependent upregulation of a number of genes, including those encoding anti-apoptotic proteins such as A20 and Bcl-2 (Hatzivassiliou, 2002). Bone morphogenetic protein receptor IA-binding protein (BRAM1), a novel LMP1-interacting protein, interferes with LMP1-mediated NFκB activation and reverses the resistance of cells to TNFR-mediated apoptosis (Chung *et al.*, 2002). Kawanishi (2000) has provided evidence that LMP1 domains CTAR1 and 2 are involved in the enhancement of TNF-induced apoptosis in epithelial cells.

It has been shown that EBV also modulates host apoptotic sensitivity by modifying the relative level of caspase-8, an initiator caspase and its competitor, FLIP (FLICE inhibitor protein (Tepper & Seldin, 1999). LMP1 may alter the ratio of caspase-8 and FLIP.

The findings of Zhang *et al.* (2002) suggest that the apoptotic modulation by LMP1 is stimulus dependent: tumor necrosis factor (TNF) induced apoptosis was inhibited while Fas ligation- and etoposide- induced apoptosis was potentiated. The attenuation of TNF induced apoptosis partallelled the induction of the anti-apoptotic zinc finger protein A20.

LMP 1 also induces IL 6 and IL 6-receptor expression via the JAK/STAT pathway and JNK-kinase and MAP-kinase (Eliopoulos *et al.*, 1997; Gires *et al.*, 1999; Kieser *et al.*, 1997). Through its interference with a number of major signaling pathways in B-cells and epithelial cells, LMP 1 mediates deregulation of several hundred cellular proteins. LMP 1 also induces the expression of adhesion molecules such as ICAM-1 and LFA, and MHC Class I and II (Mehl *et al.*, 2001; Rowe *et al.*, 1995).

LMP2 modulation of signaling in B-cells and epithelial cells

LMP2A has an intracellular N-terminal cytoplasmic region of 119 residues, which is predicted to be followed by 12 membrane-spanning regions and a short C-terminal cytoplasmic tail, also intracellular. It has been reported to aggregate into "cap-like" structures at the plasma membrane and specifically associate with lipid rafts (Dykstra *et al.*, 2001; Higuchi *et al.*, 2001). The C-terminal tail of LMP2A has been reported to possess a clustering signal as well (Matskova *et al.*, 2001).

LMP2, along with EBNA1 and LMP1, is consistently detected in some latently infected B cells and EBV-associated diseases in vivo, and plays presumably important roles in vivo, related to viral replication, persistence and EBV associated diseases (Qu & Rowe, 1992; Miyashita *et al.*, 1997). A major role of LMP2A in relation to latent EBV infection may stem from its ability to inhibit the activation of lytic EBV replication by cell-surface-mediated signal transduction (Miller *et al.*, 1994). This may prevent lytic replication in latently infected B-cells as they circulate in the blood, bone marrow or lymphatic tissues, where they might encounter antigens, superantigens or other ligands capable of engaging B-cell receptors and activating the viral cycle. In this context it may be relevant that LMP 2A also downregulates telomerase birth in B-cells and epithelial cells (Chen *et al.*, 2004; Scholle *et al.*, 2000).

LMP2A's ability to interfere with BCR signaling and to maintain viral latency may stem from protein–protein interaction motifs located within the amino-terminal tail (see Fig. 29.2). These include a YEEA (amino acid; single letter code) site that, when phosphorylated on the tyrosine residue (Y112), can serve as a binding site for the Src Homology 2 (SH2) domain of the Src family tyrosine kinase Lyn (Burkhardt *et al.*, 1992; Miller *et al.*, 1994; Frueling *et al.*, 1998). In addition, LMP2A possesses an immunoreceptor tyrosine-based activation motif (ITAM) with the consensus sequence YXXI/V-$X_{(6–8)}$-YXXI/V which is found in a number of immunoreceptors including the BCR, the T-cell receptor (TCR), as well as the Fcε receptor that binds IgE. This motif in LMP2A, when phosphorylated on tyrosines 74 and 85, provides a binding site for the dual SH2 domains of the tyrosine kinase Syk (Fruehling & Longnecker, 1997). LMP2A also possesses 2 PPPPY (PY) motifs that can bind to the WW domains of the NEDD4 family of E3 ubiquitin ligases including AIP4, NEDD4-2, and WWP2 (Winberg *et al.*, 2000; Ikeda *et al.*, 2000). Binding to NEDD4 proteins is abrogated by mutation of both tyrosines in the PY motifs (Y60; Y101). NEDD4 family proteins contain HECT (homologous to E6-associated protein carboxy-terminus) domains that catalyze the ubiquitination of proteins such as those associated with the WW domains and target them for degradation via either the 26S proteasome or a lysosomal pathway. LMP2A and the LMP2A-associated kinases are substrates for the NEDD4 family of proteins, suggesting that LMP2A may not only sequester tyrosine kinases away from the BCR, but may also direct them to ubiquitin-mediated pathways including degradation.

Somewhat paradoxically, LMP2A has also been shown to mimic BCR signaling. When expressed as a B-lineage specific transgene in mice, it can both drive B-cell development and promote the survival of mature B cells in the absence of surface immunoglobulin (Ig) expression (Caldwell *et al.*, 2000). Furthermore, this signal appears to be attenuated by the NEDD4 family protein, Itch, indicated by the finding that Itch −/− introduced into the LMP2A transgenic background enhanced LMP2A-mediated signaling (Ikeda *et al.*, 2003). This suggests that LMP2A may act as a survival factor for EBV-positive B-cell tumors that have lost the expression of surface Ig, while also preventing virus reactivation, such as in HL.

LMP2A has also been shown to activate PI3 kinase and the downstream phosphorylation of Akt in epithelial cells and B cells. This may result influence cell growth and apoptosis (Swart *et al.*, 2000).

EBV LMP2A and HHV8 K1 and K15 membrane proteins both target the BCR, but in different ways. While the LMP2A effects on cellular signal transduction have been widely studied, the functions of the HHV8 membrane proteins have been given equal attention (Choi *et al.*, 2000; Lee *et al.*, 2000).

The transforming HHV8 K1 transmembrane transforming protein associates spontaneously to form a trimer in the membrane, which, like LMP2A, carries ITAM motifs. K1 prevents cell surface expression of the BCR by the association of its N-terminal domain with the μ-chains of the BCR, thus preventing the CD79α and β chains from binding. The K1-BCR complex is retained in the ER. The ITAM-motif of K1 is thus available for interaction with cytoplasmic signaling proteins. It has been speculated that the ITAM motif is speculated to function by delivering growth and survival signals to the target cell (Lee *et al.*, 2000). The K15 has a similar topology as LMP2A, with 12 transmembrane helices, but lacks the N-terminal signal transduction domain of LMP2A. It reportedly blocks BCR signaling but the mechanism is not known.

Thus, similar functional elements of function appear to have been conserved in the latent membrane protein of these two distantly related herpesviruses, although the protein structure differs.

In view of the puzzling fact that K1 appears to bind to the μ-chain of BCR in the ER, with intracellular retention of the complex as a result, it is important to determine whether its ITAM motifs bind the Syk tyrosine kinase or a different SH2-domain protein. This could answer the question how K15 can stimulate B-cell survival and proliferation.

The elucidation of the function of the gamma herpesvirus signal transduction mediators may thus allow a refined understanding of BCR signaling functions, by way of a perturbation analysis.

Immunoblastic lymphomas arise in bone marrow or organ transplant recipients (PTLD), congenital immunodeficiencies, particularly the X-linked lymphoproliferative syndrome (XLP) and in AIDS patients. In PTLD and XLP, EBV carrying immunoblasts proliferate, as in mononucleosis, but without being arrested by the immune response. Initially, the proliferation may be polyclonal but becomes eventually monoclonal. During the polyclonal phase, the progression of the disease can often be halted by viral DNA inhibitors such as acyclovir, indicating that virus release and recruitment of new virally transformed cells play a role in the initial development of the disease, but not after it has turned into a monoclonal lymphoma.

EBV carrying immunoblastomas express the full (type III) set of the virally encoded growth transformation associated antigens. They provide the virus carrying B-cells with proliferation drive and antiapoptotic protection. They include the highly immunogenic members of the EBNA3 triad (EBNA 3,4 and 6, also called EBNA 3a,b,c), explaining why passive immunotherapy with sensitized CD8+CTLs or with unsensitized but immunocompetent, histocompatible T-cells can bring about dramatic regression even of widely disseminated tumors.

The immunoblastomas and lymphomas that arise in AIDS patients show a broader picture. Only part of them resemble the post-transplant immunoblastomas. Others are more akin to EBV carrying Burkitt lymphomas, mainly because they carry BL-type Ig/myc translocations, as discussed in more detail below, but they have a more variable cellular and viral expression phenotype. In the strict (type I) phenotype, associated with high endemic BL (only EBNA1 and the EBERs are expressed), Ig/myc translocation carrying tumors with a more immunoblastic cellular and viral (typeIII) expression phenotype are also found. This may be related to the well established fact that EBV-carrying type I BL cells tend to drift towards a more immunoblastic phenotype and full (type III) antigen expression during in vitro culturing. The selective filter that normally removes the highly immunogenic immunoblasts is, not surprisingly, impaired in immunodefectives.

EBV and Burkitt lymphoma (BL)

EBV is associated with 98% of the high endemic BLs, but only with about 20% of sporadic BLs. Both types contain essentially similar Ig/myc translocations, with only minor differences (Magrath, 1990). Only EBNA1 and the EBERs but none of the growth transformation associated EBV proteins (EBNA 2–6, LMP1–2) are expressed in BLs. The virus can therefore not be held directly responsible for the proliferation of the tumor. The latter function is attributed to the constitutive activation of the c-myc protooncogene, resulting from its juxtaposition to one of the three Ig-loci by chromosomal translocation.

Phenotypically, BL cells differ from EBV transformed or mitogen activated immunoblasts. Their markers and their V-gene mutations identify them as post–germinal center memory cells. Even in the most highly BL prone areas of Africa where malaria is rampant and where the regularly high EBV antibody levels in most young children indicate early infection and a high viral load – proven risk factors for the development of BL (Geser *et al.*, 1982) – only a very small fraction of normal B cells (<0.1%) carry the virus. The 98% EBV positivity of the BLs must therefore mean that the presence of the virus increases the probability of lymphoma development. This is the same as to say that the virus contributes to the development of the tumor.

Falling short of the activation of cell proliferation, EBV is likely to contribute to the genesis of BL in some other way. According to one theory, apoptosis protection by the EBERs may be responsible (Takada, 2001). Another indication of a possible apoptosis protecting role has been derived from experiments with EBV negative sublines of originally EBV positive BLs that have lost the virus accidentally, or after hydroxyurea treatment. Viral loss is accompanied by decreased clonability and tumorigenicity (Komano *et al.*, 1998). Comparison of three independently established EBV carrying BLs and their EBV–loss variants showed a marked downregulation of the tcl-1 oncogene (Kiss *et al.*, 2003). Tcl-1 is highly expressed on both T and B cell derived leukemias. EBV reinfection has upregulated tcl-1 again in the EBV-loss variants. Since originally EBV negative BLs express tcl-1 at a high level, we have suggested that the EBV negative BLs switch on tcl-1 constitutively during their neoplastic development. In the virus carriers, EBV is responsible for the upregulation. Tcl-1 activates the apoptosis protective AKT pathway and may thus further increase the apoptotic threshold in these myc-driven and thereby apoptosis prone cells. Conceivably, EBV may also act at the pretranslocation level, by contributing a strong B-cell proliferation, driving stimulus. This would be further enhanced by malaria associated immune dysregulation

and opportunistic coinfections. This could expand the target population available for the critical myc-translocation.

The absence of the virus from the EBV negative BLs is consistent with the interpretation that the virus is a contributory, but not a mandatory factor for BL development. The Ig/myc translocation is, on the other hand, regularly found in all BLs and must therefore play a more central role in the origin of the tumor.

The Ig/myc translocation carrying murine tumor prototype, plasmacytoma (MPC) develops earlier and in a higher frequency when the precursors are infected with the pre-B-cell-immortalizing Abelson virus, that carries the v-abl oncogene that has a known antiapoptotic effect.

Since myc-driven cells are highly apoptosis prone, as already mentioned, it is hardly surprising that BL cells are protected against apoptosis at several different levels. Both the Rb and p53 pathways are crippled in BLs, as a rule. In most cases, the Rb pathway is impaired by p16 promoter hypermethylation. The p53 pathway can be inactivated in at least three alternative ways: p53 mutation, ARF mutation or deletion, and MDM2 amplification (Lindström & Wiman, 2002). In spite of this. the BL cell is still quite apoptosis prone, as indicated by its "starry sky" histology, where the "stars" are macrophages that have engulfed apoptotically generated nuclear fragments from the lymphoma cells, and also by the high chemotherapeutic sensitivity of the tumor.

The primary localization of African Burkitt lymphomas may be relevant in this context as well. It suggests that the cytokine environment associated with local tissue proliferation may favor the outgrowth of Ig/myc translocation carrying cells. Jaw tumors are frequent around the age of dentition, ovary and testis are frequent primary sites of BL in prepubertal and pubertal children. Lymphomas may arise in the long bones of teenagers, and BLs with a primary mammary localization have been seen in young lactating women. Some of them regressed when nursing was interrupted. Chronic inflammation may act in a similar way. EBV carrying body cavity lymphomas can be associated with pyothorax of 20 or more years' duration. They carry HHV-8 as well. They present as diffuse large cell lymphomas, sometimes with an immunoblastic appearance. This is in line with numerous examples in the experimental literature, showing that chronic inflammation may act as a tumor promotor.

Hodgkin's lymphoma (HL)

Almost half of the HL-cases in Western countries carry EBV-positive Hodgkin Reed-Sternberg (HRS) cells, that express EBERs, EBNA 1, LMP1 and presumably LMP2a, although this has been less extensively studied (Glaser *et al.*, 1997; Levine *et al.*, 1994; Ohshima *et al.*, 1996; Lennette *et al.*, 1995). The frequency of these presumably malignant cells is surprisingly low in the tumors (1–3%). Conceivably, the HRS cell orchestrates tissue derangement, by recruiting immune bystander cells such as non-neoplastic helper T lymphocytes, plasma cells, macrophages and eosinophilic granulocytes (Molin *et al.*, 2001; Enblad *et al.*, 1993; Weng *et al.*, 2003). It is frequently surrounded by a rosette of CD4+ T-lymphocytes of both the Th1 and the Th2 type. EBV positive HLs show a shift towards Th1. The tumor is described as a "malignant inflammatory process." It produces a large variety of cytokines (Dukers *et al.*, 2000). The HRS cells carry non-functionally rearranged immunoglobulin heavy chain genes and contain somatic mutations in a high frequency, indicating post-germinal center derivation (Kuppers *et al.*, 2002; Muschen *et al.*, 2000; Spieker *et al.*, 2000). They may have been frozen in a non-physiological state that prevents further differentiation or apoptosis.

Several findings suggest that EBV positive HRS originate from latently EBV infected B cells. Like BL and NPC cells, HL cells carry complete viral genomes in the form of multiple covalently closed episomal DNA. TR analysis revealed that viral genomes were clonal, suggesting that they have originated in a common proliferating precursor (Langerak *et al.*, 2002). This argues against any role of virus replication in the establishment of the tumor cell.

Enhanced permissiveness and virus replication may still have a role as a risk factor, HD patients frequently have elevated antibody titres to EBV early antigen (EA) already at the presentation of disease and often years before. Significantly increased EBV genome load has been detected in the blood several years before the disease (Drouet *et al.*, 1999). This suggests that the disease may be preceded by increased EBV reactivation and deregulation of the virus-host balance. Moreover,it has been shown that patients with acute infectious mononucleosis run an increased risk of developing HD (Amini *et al.*, 2000; Axdorph *et al.*, 1999).

In contrast to BL-cells and LCLs, it is difficult to grow HRS-cells in vitro. Only a dozen HL-/HRS-dervied cell lines have been established in vitro. They are EBV-negative, with only one exception. EBV-positive and negative HLs show no convincing differences in phenotype or clinical behavior. But while HD is less common in developing countries, it is much more frequently EBV-positive, (up to 90%). This is reminiscent of the difference between African and sporadic BLs (98% vs. 20% EBV positives).

Two studies have shown no difference in the prognosis of EBV positive and negative cases of HD. Morente *et al.* (1997) found however, that EBV-positivity was associated

with improved overall survival and resulted in a higher complete therapeutic response, together with a significantly longer disease free interval. According to a fourth study (Murray *et al.*, 1999) EBV positive tumors are easier to treat and treatment leads to longer disease free intervals.

EBV and nasopharyngeal carcinoma

Low differentiated or anaplastic NPC is the most regularly EBV associated tumor. It is the commonest malignant tumor among men in Southern China, the Guangzhou region in particular. The carcinoma cells carry multiple viral episomes, like BL cells. Terminal repeat (TR) analysis revealed that they have been derived from a single infectious event like the EBV positive BLs.

Some apparent paradoxes need to be reconciled. Given that the virus replicates lytically in epithelial cells, as particularly well shown in oral hairy leukoplakia (OHL, see below), why does it remain latent in NPC where it expresses only EBNA1, the EBERs and the LMPs (latency II)? Is this due to the fact that NPC cells do not proceed to squamous differentiation? In OHL, the productive viral cycle is only switched on when the cells move upwards within the epithelium, to the level where they start engaging in squamous differentiation.

Early reports claiming that latent EBV could be detected in the basal layer of normal epithelia by in situ techniques have not been confirmed. Foci of lytic viral replication are only found in OHL, which is an EBV-induced lesion. It is found in immunodefectives and can be cursed by acylovir.

The robustly latent interaction between EBV and NPC is puzzling. It raises the question whether EBV inhibits the differentiation of NPC cells and, if so, whether this gives a clue to its role in the genesis of NPC.

It is not clear how and when the NPC-precursor cell becomes infected. In contrast to the EBV-infectability (and transformability) of B cells with EBV and the persistence of the virus in this compartment, epithelial cells are difficult to infect, unless a genetically engineered virus is used that carries a selectable marker like neomycin resistance.

Two experimental findings may offer possible clues. Comparing three different lines of EBV negative carcinoma cells with their EBV infected sublines, Nishikawa *et al.* (2003) found that the virus switched on the expression of a truncated basic hair keratin gene in all three lines. Conceivably, the truncated keratin may interfere with the production of full sized keratin and, thereby, differentiation.

But why would the keratin be truncated in the first place? This could stem from some of the multiple genetic changes found by PCR in NPC precursor lesions. Dolly Huang's group has shown that some of the changes, particularly the frequent deletions affecting chr.3p and 9p, occur prior to EBV infection (Lo & Huang, 2002). A possible scenario proceeds from an early genetic change that endows the precursor cell with the ability to produce a variant keratin, potentially capable of interfering with differentiation. This variant would be switched on by some viral product, expressed within the latency II program. From the viewpoint of viral strategy, such a scenario would protect the virus from self-elimination by lytic infection and secure its persistence in latently infected, dividing, and undifferentiated cells.

Viral expression in carcinoma cells, cell behavior and host relationships in NPC

About two thirds of NPC tumors express LMP1 in vivo. In the non-expressors, the promoter region of the gene is hypermethylated (Hu *et al.*, 1991). A comparison between non expressed LMP1 genes taken from NPC biopsies and the corresponding genes from LMP1 expressing tumors, showed that the former but not the latter could confer immunogenicity (rejection inducing capacity) on a non-immunogenic mouse mammary carcinoma, transplanted to syngeneic hosts (Hu *et al.*, 2000). This suggested that the LMP1 expressors may have been sculpted by immunoselection in vivo that favored cells with genetic or epigenetic LMP1 inactivation.

LMP1 has been shown to convey increased agarose clonability and tumorigenicity on immortalized epithelial cells in vitro (Hu *et al.*, 1993). Moreover, LMP1 expressing NPCs grew more expansively in immunodefective mice than non-expressors (Hu *et al.*, 1995). Nevertheless, patients with LMP1 positive tumors showed better survival in a retrospective study than patients with LMP1 negative tumors, suggesting that the immunoselective sculpting of the LMP1 positives may still have left the tumors with a certain residual immunogenicity.

In addition to NPC, EBV genomes were also found in other solid tumors, notably gastric carcinomas, salivary gland tumors and a case of thymic carcinoma. Since these associations are not equally regular, they will not be included in this comparative discussion.

Immune surveillance and the oncogenic herpesviruses – the role of immunological "anticipation"

Viewed as a group, four of the potentially oncogenic herpesviruses, Marek's disease herpesvirus (MDHV), *H.*

saimiri (HVS), *H. ateles* (HVA) and EBV provide us with some important lessons about surveillance mechanisms that can protect against viral tumorigenesis, without reducing the spread of the virus. This results in a largely non-pathogenic "live and let live" situation.

MDHV is the only known DNA tumor virus that can cause tumors by epizootic infection. Unlike the three other viruses, MDHV is not ubiquitous in its natural host, the chicken. Infection of immunologically naive birds can therefore cause horizontally spreading epizootics. The frequency of the lymphoproliferative tumors and the level of their malignancy is influenced both by genetic and evironmental (e.g., stress) factors. One of the genetic resistance factors is linked to MHC. This is in line with the known role of the locus as an immune response regulator. It is reasonable to assume that a more general spread of the agent in chickens would have selected the natural host species for a similarly solid resistance that has been achieved by the other three viruses.

HVS infection is ubiquitous in the natural New World primate host, the squirrel monkey, and the same applies for HVA and its natural host, the spider monkey. Neither of the two viruses are known to be associated with any disease. But the number of examined animals and the observation periods are not comparable to what is known about EBV and the human host. The effect of immune defects is not known for the two simian viruses either.

In distantly related but HVS and HVA naive New World primates, such as marmosets, both HVS and HVA cause rapidly proliferating T-cell malignancy. The tumorigenic potential of both viruses is also consistent with their ability to immortalize human T-lymphocytes.

What makes the natural host solidly resistant to the tumorigenic effect of transforming viruses that can cause rapidly growing malignancies in related but immunologically naive species? Some years ago we performed an experiment with Friedrich Deinhardt's group (Klein *et al.*, 1973) that may throw a certain light on this question. We compared the primary antibody response of squirrel monkeys and marmosets to HVS inoculation soon after birth. Since all previously tested squirrel monkeys were found to carry HVS, fully mature fetuses were removed by Cesarian section from their mothers and were kept virus free by isolation, surrogate mothers and bottle feeding. After a few weeks they were inoculated with live HVS, in parallel with young marmosets. Both species responded with antiviral antibody production but while the squirrel monkeys reached peak antibody titers already 10–12 days after inoculation, the marmosets started responding only after 3 weeks. By that time the lymphoproliferative disease was already in progress, however.

Even though this study was restricted to humoral antibodies and gave no information about the more important cell mediated arm of the immune response, the time difference in the onset of the reaction indicated that the natural host of the virus has been selected for some kind of "immunological anticipation" of the impact of HSV that succeeds in infecting most and perhaps all members of the species under natural conditions.

EBV is also ubiquitous in its natural human host and causes only a self-limiting proliferative disease, mononucleosis, and only in about half of the primarily infected adolescents and adults. The other half and most children under the age of ten respond with "silent," symptom-free seroconversion. Mononucleosis is characterized by the temporary proliferation of EBV transformed immunoblasts, followed by a rejection reaction, mediated by multiple immune effectors. In immunodefectives, whether of congenital (e.g., XLP) or iatrogenic (e.g., transplant recipient) or infectious (e.g., HIV) origin, immunoblastic proliferation may be fatal, as already discussed in the section on immunoblastomas. Moreover, and in further similarity to HVS and HVA, EBV can induce progressive lymphoproliferative malignancy in marmosets and owl monkeys, New World primates that do not have EBV-like viruses of their own. Old World primates that have their own EBV-like viruses carry cross reactive antibodies and are solidly resistant against EBV infection.

Neither BL nor NPC, nor any of the other malignancies where EBV is only found in a proportion of cases, are directly caused by EBV. Therefore, the relatively non-tumorigenic association of this ubiquitous virus with its natural human host is not very different from what HVS and HVA have achieved in their natural simian hosts. Our "immunological anticipation" of EBV is reflected by the surprisingly high frequencies of CD8+T-cells specific for latent and lytic EBV antigens in healthy virus carriers. As many as 5.5% circulating CD8+T cells in a virus carrier can be specific for a single EBV lytic protein epitope, as shown by tetramer staining (Tan *et al.*, 1999). Lymphocytes carrying TCRs specific for latent proteins were found at somewhat lower, but still considerable (0.4–3.8%) frequencies. The preparedness of the immune system for the encounter with EBV transformed B-cells is also reflected by the fact that autologous T cells, admixed to EBV infected B-cells, undergo blast transformation and generate cytotoxicity at equally high levels as allogeneic, MHC-incompatible mixed lymphocyte cultures.

Surveillance of the human host against the development of EBV carrying neoplasia is thus virtually watertight. Occasional tumor development is due to an immunological or cytogenetic accident. Directly EBV-driven immunoblastomas can only arise in immunodefective hosts. Burkitt

lymphoma is driven by the unrelated accident of the Ig/myc translocation, probably assisted by an anti-apoptotic effect of the minimal, non proliferation driving type I viral expression program. In NPC, the role of EBV is even less clear. Our findings prompt the speculation that it may act by inhibiting squamous differentiation.

HHV-8 (KSHV)

This is the most puzzling virus of the DNA tumor virus family. It has hijacked more than a dozen cellular genes, many of which have potential tumor related functions. They include genes that influence the cell cycle, apoptosis, various other types of signaling and can create chromosomal imbalance. If a tumor biologist had been given the task of designing a tumor virus, he could not have done better. Surprisingly, however, the virus does not transform in vitro any target cell so far tested. The lack of an in vitro transformation system has hampered the functional analysis of tumorigenicity. Still, there are very good grounds to believe that the virus is responsible for three tumors, Kaposi sarcoma, multicentric Castleman's disease (CD, a polyclonal B cell hyperplasia) and PEL, monoclonal body cavity lymphoma of the B cell series. Each of the three major proliferative syndromes associated with HHV-8 has a partially different virus expression program.

Only the viral ORF73-coded nuclear antigen, LANA1, is regularly expressed in all three HHV-8 related neoplasms. LANA1 binds to the histone H-1 which tethers the viral DNA to the chromosomes during mitosis, securing the maintainance of HHV-8 episomal DNA in infected cells and the delivery of the viral progeny to the daughter cells. LANA1 is a highly immunogenic protein, expressed predominantly by latent virus in KS cells and in PEL lines. LANA1 represses p53 transcription in a highly specific fashion (Friborg *et al.*, 1999).

The viral cyclin D homologue, K cyclin is expressed from the same polycistronic transcript as LANA1. It can promote apoptosis and growth arrest (Verschueren *et al.*, 2002). DNA synthesis, but not mitosis, continues, leading to multinucleation and polyploidy. Centrosome amplification leads to aneuploidy. In the absence of functional p53, aneuploid cells survive and expand. K cyclin expression in p53−/− and also in wild-type mouse embryonic fibroblasts induces massive centrosome amplification with multiple spindles and fusion bridges. In p53 knockout mice, viral K cyclin induces lymphomas.

Similarly to the small DNA tumor viruses, HHV-8 impairs both the p53 and the Rb pathway. But, unlike the small DNA tumor viruses, HHV-8 has developed multiple tactics to corrupt Rb functions. The viral cyclin K which is, like LANA1, constitutively transcribed in HHV-8 carrying cell lines, inactivates Rb and activates EF2 related transcription (Radkov *et al.*, 2000). LANA 1 and Rb coexist as a complex in vivo. Similarly to adenovirus E1A, papillomavirus E7 and SV-40LT, LANA 1 targets the hypophosphorylated, active form of Rb. Moreover, LANA 1 can overcome the flat cell phenotype, induced by the Rb protein in SAOS2 cells. In cooperation with ras, LANA 1 transforms primary REF cells and renders them tumorigenic. While LANA 1 thus resembles SV40LT in being able to interfere with both Rb and p53 function, its ability to inactivate the two main tumor suppressor pathways is not as complete as the action of LT, because LANA 1 cannot transform by itself.

Double HHV8/EBV carrying PEL cells

The majority of the body cavity (PEL) derived lymphoma lines carry both viruses while some carry only HHV-8. EBV expresses its minimal (type I) program, characteristic for BL. The growth transformation associated, proliferation driving genes, characteristic for the type III program of the LCLs, are not expressed, indicating that the double virus carrier lines are not driven by EBV. EBV may have a similar accessory function as it has in BL.

But are the PEL lines, whether single or double virus carriers, driven by HHV-8? This is a reasonable possibility, but it cannot be taken for granted. Body cavity lymphoma lines have numerous chromosomal changes. Some of them may be responsible for the proliferative activity. There is no single, common cytogenetic change like the Ig/myc translocations in BL. Multiple rearrangements may cover more specific changes, however, as in the cryptic Ig/myc translocations that often hide within the massively rearranged karyotypes of cell lines derived from human multiple myeloma, only detectable by the SKY technique (Gratama *et al.*, 1988).

If HHV-8 occupies the driver's seat in the body cavity lymhomas, RNAi or antisense techniques directed against either LANA1 or viral cyclin K should cause growth arrest or apoptosis. This experiment could go a long way in clarifying the role of the virus in PEL. In the absence of direct transformation systems, such evidence may be quite crucial.

Other HHV-8 genes that may be directly relevant for tumorigenesis include the pirated MIR1 and 2 genes, encoded by K3 and K5. They inhibit MHC class I surface expression, through a unique mechanism not found in other viruses. They remove the MHC I proteins from the plasma membrane by enhanced endocytosis. V-FLIP,

another pirated gene, is a powerful inhibitor of receptor mediated apoptosis. It is expressed constitutively on latent transcripts and it enhances the tumorigenicity of mouse lymphomas. In addition to the crippling of Rb and p53, and the virally encoded bcl-2, v-FLIP may provide additional protection against apoptosis.

Conclusions

EBV and HHV-8 associated malignancies show interesting parallels and contrasts. The main parallel is the universally occurring expression of the viral product required to maintain the viral episomes, EBNA1 in EBV, LANA1 in HHV-8. Both are nuclear proteins, but they act quite differently.

The most prominent and best known feature of EBV is its finely poised adaptation to the B cell compartment and its sophisticated exploitation of B cell biology – in different ways – for viral expansion, the control of that expansion, and for the latency of the persisting virus. It uses a B-cell surface receptor, CD21, as its receptor. It stimulates the infected B-cells to blast transformation, using or mimicking the normal immunoblastic transformation pathways, and it "immortalizes" its targets, driving them to continuous expansion in vivo and in vitro. The immune response of the host, directed against one of the immunogenic, growth transformation associated proteins (the choice depending on the MHC constitution of the host), rejects the expanded blasts, but not before they have substantially raised the viral load. Meanwhile, the virus secures its lifelong latency by downregulating its proliferation driving and its immunogenic proteins (the two categories overlap partly but not completely) and establishes permanent residence in long-lived, post-germinal center memory cells. Since successful bone marrow transplantation eradicates the resident virus population (Damania *et al.*, 2000), all the persisting virus must reside in the hemopoetic compartment, and probably in B-cells.

We have no knowledge as yet of host cell gene expression pattern in latently HHV8 infected cells. It is therefore still an open issue whether the HHV8 tumorigenic process develops from a latent infection, from infection of "non-physiological" host cells or the abortion of a lytic infection. Several of the HHV8 proteins that have not yet been detected in tumors are interesting candidates in relation to tumor risks. Conceivably, the patterns of viral gene expression may differ in precursor cells of different phenotypes.

Interestingly, motifs of the two membrane proteins K1 and K15 mimic several features of LMP 2 a and LMP 1, which are frequently expressed in EBV-associated tumors. They contain potential NFkB- and ITAM-interacting motifs (Damania *et al.*, 2000; Nicholas, 2003). In contrast to the smaller DNA tumor viruses, they may be less in need to control their long term persistence in the host cell and the fate of the host cell through long periods of time. On the other hand, that may be more dependent on modulators of the acute immune response and intracellular controls of proliferation and apoptosis, as part of their lytic virus replication.

Neither the proliferative, nor the resident phase of the viral life cycle requires crippling of the two main tumor suppressor pathways, Rb and p53. The situation is different in EBV carrying malignancies that are not driven to proliferate by EBV (like BL and NPC), but where the virus is present in an adjuvant capacity, probably as an accessory antiapoptotic device.

Most and perhaps all malignant tumors need to inactivate both the Rb and the p53 pathways. This can happen by a number of alternative mechanisms. In BL, the p53 pathway can be crippled by p53 mutation/deletion, ARF mutation or MDM2 amplification. The Rb pathway can be inactivated by Rb mutation/deletion, p16 inactivation or CDK4 amplification. There is no reason why the minimal (type I) EBV program expressed in BL cells should interfere with the Rb or the p53 pathway and there is no evidence that it does.

In HHV-8 associated tumors, the situation is quite different. In the absence of an in vitro transforming system, we cannot tell whether any of the viral genes (including the genes pirated from the host cell) can drive cell proliferation. We know, however, that two of the genes, LANA1, and viral cyclin K cripple the Rb and p53 pathways. This brings HHV-8 into the previously established DNA tumor virus fold.

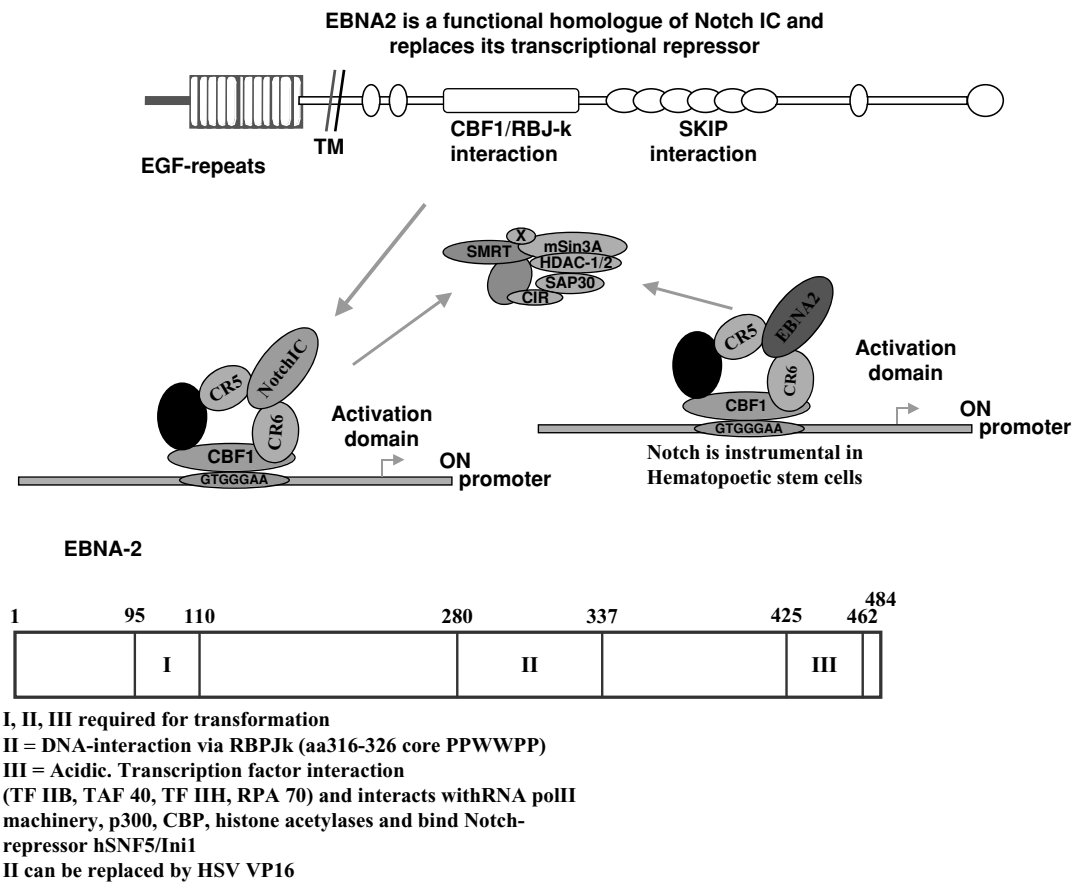

Fig. 29.2. Schematic representation of EBNA 2 and its major functions.

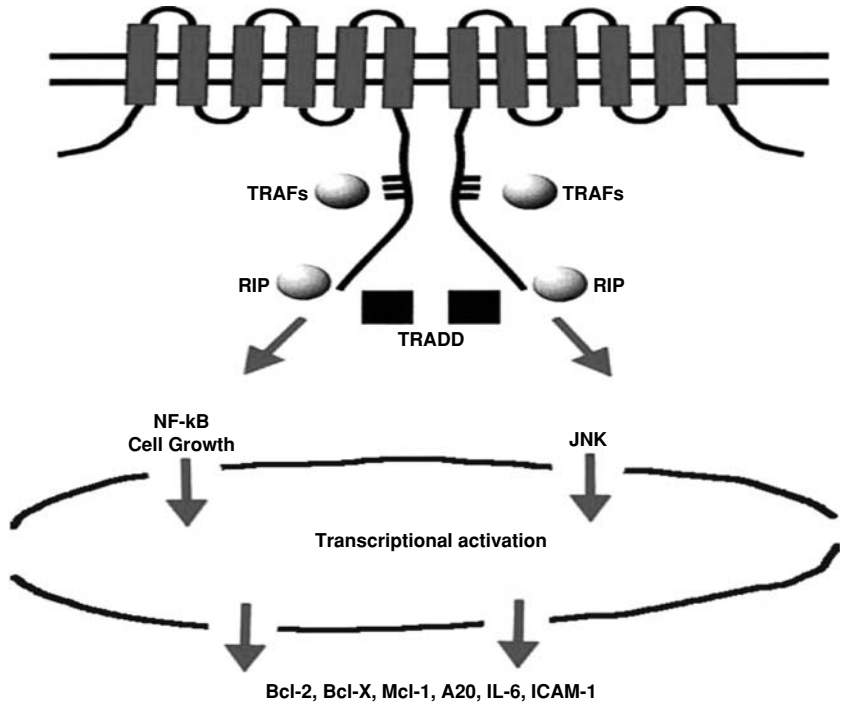

Fig. 29.3. Established major signaling pathways of LMP 1. Studies have revealed several functional domains of the cytoplasmic tail of LMP1 that are important for activation of transcription factor NF-kB, AP-1 and P38 through its interaction with TRAF and TRADD. These findings suggest that LMP1 mimics TNFR aggregation, which is essential for subsequent signal transduction.

KSHV manipulation of the cell cycle and apoptosis

Patrick S. Moore

Molecular Virology Program, University of Pittsburgh Cancer Institute, Pittsburgh, PA USA

Disruptions of cell cycle and apoptotic regulatory control are primary hallmarks tumor cells. It is therefore not surprising that Kaposi's sarcoma-associated herpesvirus (KSHV/HHV8), a tumor virus, encodes viral proteins targeting these cell growth regulation mechanisms. The extent and range of KSHV genes devoted to manipulating these processes is, however, remarkable.

As described in previous chapters, herpesviral structural and replication-related genes are highly conserved among the herpesviruses, including KSHV. In contrast, regulatory genes generating proteins that modify the cellular environment – particularly during latency – are generally unique to each virus. As will become evident in this chapter, even though KSHV and EBV are closely related to each other, there are few sequence homologies among the oncogenes and non-structural regulatory genes found in the two viruses. Despite this, there is a striking functional similarity between the two viruses (Table 30.1). EBV encodes multiple highly evolved transcription factors and signaling proteins that induce many of the same cellular genes that KSHV has pirated into its genome. Further, once herpesvirus targeting of a cellular pathway has been found for one herpesvirus (e.g., HSV-1 downregulation of MHC I surface expression, Hill *et al.*, 1994), searching for functional similarities among other herpesviruses has been particularly rewarding (e.g., Coscoy *et al.*, 2000). It is therefore not surprising that KSHV and EBV share pathways for cell transformation although they achieve this through very different mechanisms.

Several general principles for KSHV regulatory gene functions that affect cell transformation and tumorigenesis can be made with the important caveat that exceptions exist to each rule.

1. Although there is little or no sequence homology among oncogenes encoded by different tumor viruses, the cellular targets for viral oncogenes are frequently conserved (Table 30.1). For example, direct inhibitors of p53 from KSHV, adenoviruses, polyomaviruses, and papillomaviruses have no apparent similarity to each other but all of these viral proteins target and inhibit p53 functions.
2. KSHV proteins encoded by viral genes pirated from the cellular genome have similar functions to their cellular counterparts. They generally differ in their regulation rather than their function. For example, the KSHV vCYC protein acts as D-type cyclin in cells but unlike cellular cyclins it is resistant to inhibition by cyclin-dependent kinase inhibitors but are modified to escape normal cellular regulation. The evolution of entirely new KSHV gene functions is uncommon and differences between cellular and KSHV homologues lie primarily in their expression and regulation (for an exception, however, see description of ORF36 mRNA shut-off functions in Chapter 56).
3. KSHV targeting of cellular tumor suppressor pathways also inhibits host defenses against viral infection which indeed may be the principle benefit to the virus for these proteins (Moore & Chang, 1996, see also Chapter 31). Signaling pathways controlling of tumor cell growth, such as Fas-FasL death receptor signaling, also critical for both innate and adaptive immune responses, and are targeted by putative KSHV oncoproteins.

This chapter describes the effects of individual KSHV proteins on cell cycle control, apoptosis, and cellular transformation. It is, by necessity, an artificial division of these functions, since cell growth control mechanisms are intimately tied into other aspects of the viral lifecycle such as maintenance of latency (Chapter 24) and immunoevasion (Chapter 31). Caution is warranted given the limitations to our ability to study how KSHV contributes to cancer. Our understanding of viral effects on cell growth are generally based on in vitro cell culture systems, e.g., PEL cell

cultures, and on the study of individual genes in isolation. Much can be learned from this reductionist approach, but it is important to keep in mind that results from the bench-top do not always translate to the bedside, which is more fully addressed in Chapters 50 and 56).

Cell cycle and programmed cell death regulation

The normal cell cycle is actively regulated through specific protein-kinase regulatory subunits, cyclins (Murry, 2004), that are cyclicly expressed during the different phases of the cell cycle and degrade as the cell exits each phase (Fig. 30.1). Cyclins regulate the periodic oscillations of the cell cycle by coupling to cyclin-dependent kinases (which tend to be constitutively expressed) to phosphorylate specific cell cycle regulatory targets, for example, the retinoblastoma protein (pRB1) controlling expression of genes necessary for transit from G1 into S phase. The cyclin component of the dimeric complex generally serves as the targeting moiety directing CDK phosphorylation to specific substrates.

Some cyclins such as cyclin A and the D-type cyclins do not appear to be essential for intrinsic cell cycle periodicity but serve to regulate it (Kozar *et al.*, 2004). pRB1 (a member of a family of related proteins that also includes p130) is a transcriptional repressor that binds and inactivates E2F family transcription factors involved in transcription of genes required for DNA synthesis prior to S phase. These enzymes include dihydrofolate reductase, thymidine kinase, and several other nucleotide synthesis enzymes expressed during the G1/S phase transition and have been pirated by KSHV (Russo *et al.*, 1996). When pRB1 is hyperphosphorylated by cyclin D-CDK4 or CDK6, it is inactivated and releases E2F allowing expression of DNA synthesis enzymes. Thus pRB1 is a critical regulator for the transition between G1 and S phase and controls the cellular environment to prevent unscheduled DNA synthesis. Another substrate phosphorylated by cyclin-CDK complexes is the anaphase-promoting complex (APC), which controls chromosome separation during mitosis and acts as a checkpoint protein at the G2/M cell cycle transition.

Viral manipulation of cell cycle checkpoint proteins could be an obvious advantage to a virus, particularly during lytic viral replication when large amounts of viral DNA must be generated. But, interference with normal cell cycle regulatory circuits often activates cell cycle arrest or programmed cell death (apoptosis) signaling. Cell cycle and apoptotic pathways are characterized by extensive feedback interactions that not only serve to prevent tumor cell generation but also to inhibit viral replication within cells (Takaoka *et al.*, 2003). Viral inhibition of pRB1, for example, results in p53 activation through p14ARF and MDM2 (Fig. 30.1). Thus, overexpression of individual cellular or viral oncoproteins may paradoxically result in cell cycle arrest or cell death rather than proliferation, as is the case for cellular cMYC, or adenoviral E1A (de Stanchina *et al.*, 1998, Debbas and White, 1993; Zindy *et al.*, 1998). Because of this feedback regulation, viral proteins that initiate dysregulated cell cycle entry can be mistaken to have the exact opposite effect, e.g., cell cycle arrest or apoptosis. Caution must be used to interpret the consequences of viral protein expression in the context of the actual viral lifecycle in which multiple KSHV proteins may be acting in concert.

Table 30.1. Functional similarities between KSHV, EBV and other tumor viruses

	KSHV	EBV	Other viruses
pRB1 inactivation	vCYC	EBNA2/EBNA-LP	Ad, HPV, SV40
β-catenin stabilization	LANA1	LMP1	
p53 inhibition	LANA1, vIRF1, LANA2	LMP1	Ad, HPV, SV40
Anti-apoptotic, NF-κB activation	vBCL2, vIAP, vFLIP, LMP1	BHRF1, LMP1	Many viral proteins
BCR signaling	ORFK1, LAMP	LMP2	?
Death receptor inhibiton	vFLIP	LMP1	HVS, MCV
CBP/p300 inactivation,	vIRF1	EBNA2	Ad, CMV, HTLV I,
Interferon transcription factor inhibition	ORF45 protein		HPV, SV40
MHC down-regulation	MIR1/2	–	Ad, HSV, CMV
IL-6 signaling	vIL-6	LMP1	?
Telomerase activation	LANA1	?	HPV
Th2 Chemokines	vMIP 1-3	?	CMV

Cell cycle dysregulation during viral latency

LANA-1

Although lytic KSHV replication may contribute to tumor formation in humans though paracrine mechanisms (see Chapter 56), most interest is focused on the latent viral genes constitutively expressed in tumor cells as oncogenes. Whereas latent virus replication is compatible with cell expansion, virion production generally leads to cell death. As described in Chapter 28, the division between "latent" genes and "lytic" genes, however, has become increasingly blurred. Intracellular notch (Chang *et al.*, 2005) or interferon signalling (Chatterjee *et al.*, 2002) can activate expression of genes such as K1 (KIS) and K2 (vIL-6) that are traditionally referred to as lytic genes without full lytic cascade

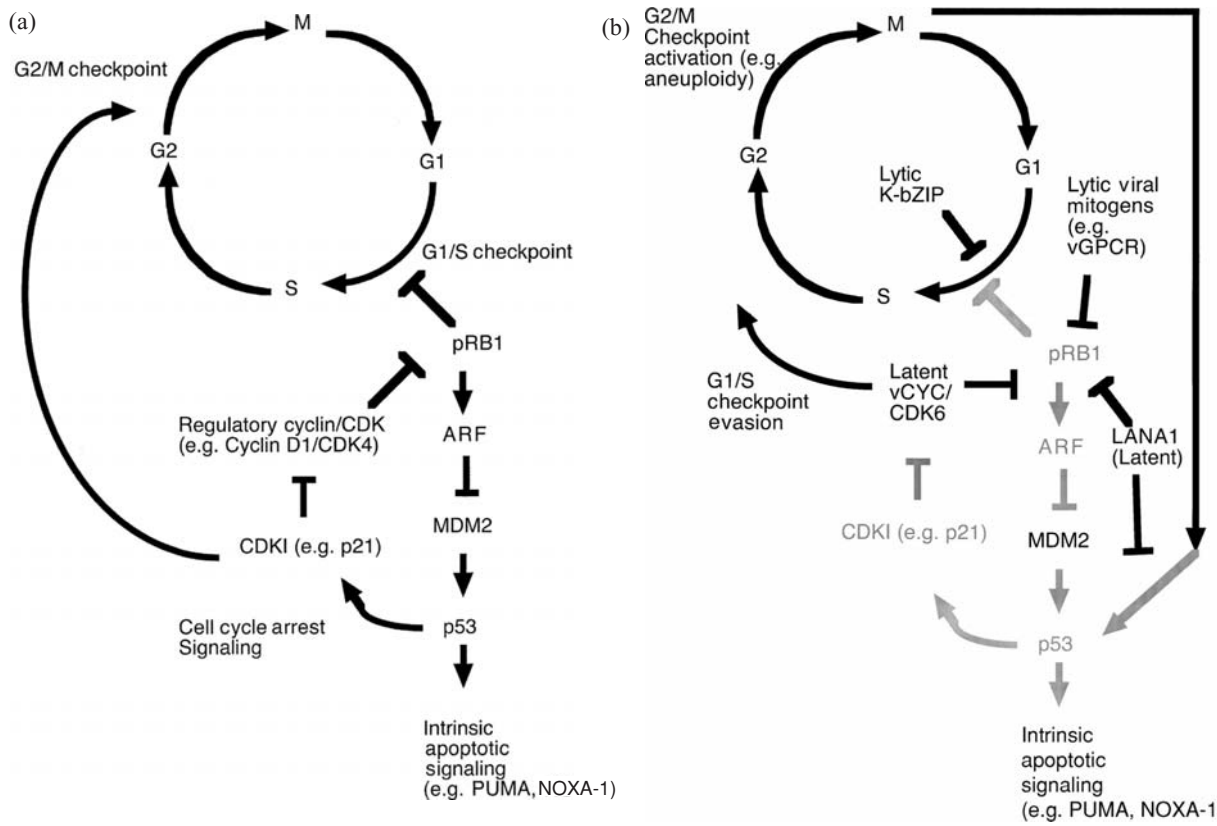

Fig. 30.1. A schematic diagram of cell cycle control interactions between the G1/S checkpoint retinoblastoma protein (pRB1) and p53. (a) Normal feedback control allows pRB1 to negatively regulate entry into the S phase by inhibition of E2F-regulated DNA synthesis genes and positively regulate p53 activity through ARF-dependent inhibition of the p53 E3-ligase, MDM2. Mitogenic cyclins such as cyclin D bind to cyclin-dependent kinases that than phosphorylate and inactivate pRB1, allowing S phase entry. Uncontrolled activation of this circuit will induce p53 activity to initiate cell cycle arrest or apoptosis. KSHV vCYC and LANA1 proteins act together during latent viral replication to inhibit both the pRB1 control functions and p53-dependent apoptosis. Inhibition of p53 may be particularly important since dysregulated entry into the cell cycle by vCYC can initiate aneuploidy and dysregulated cytokineses. During lytic replication a more complicated pattern arises since KSHV proteins can both block (K-bZIP) and enhance (vGPCR, vIL-6) G1/S cell cycle transit, to enhance virion production.

activation and cell death. Notch signaling in particular appears to be responsible for the Type II pattern of KSHV gene activation (Sarid *et al.*, 1998), markedly increasing the number and range of KSHV genes having potential to play a role in KSHV-induced tumorigenesis. Intriguingly, the latent antigen LANA1 has been reported to activate notch signaling and intracellular notch activity is high in resting PEL cells (Lan *et al.*, 2006).

LANA

The major latency locus on the right-hand end of the genome (Fig. 30.2) encodes three open reading frames (ORFs K13, 72 and 73) for the vFLIP, vCYC and LANA1 proteins. An additional long transcript expressed by polyadenylation site read-through from this promoter is processed into at a number of miRNAs that are also constitutively expressed (Pfeffer *et al.*, 2005; Cai *et al.*, 2005). While the viral or cellular targets for these miRNAs are unknown, they are of particular interest since cellular miRNAs have been closely associated with cancer cell regulation (Esquela-Kerscher and Slack, 2006). Recent studies also reveal the complexity of gene expression at this locus with some transcripts extending to the K12 region. Some overlapping transcripts for ORFs K12, K13, 72 and 73 have been shown to be induced during lytic replication demonstrating that the widely-held view that these genes are expressed in a static fashion is incomplete (Cai and Cullin, 2005; Pearce *et al.*, 2005).

ORF73 encodes LANA1 (Latency-associated nuclear antigen)1, first discovered as a serologic antigen useful for

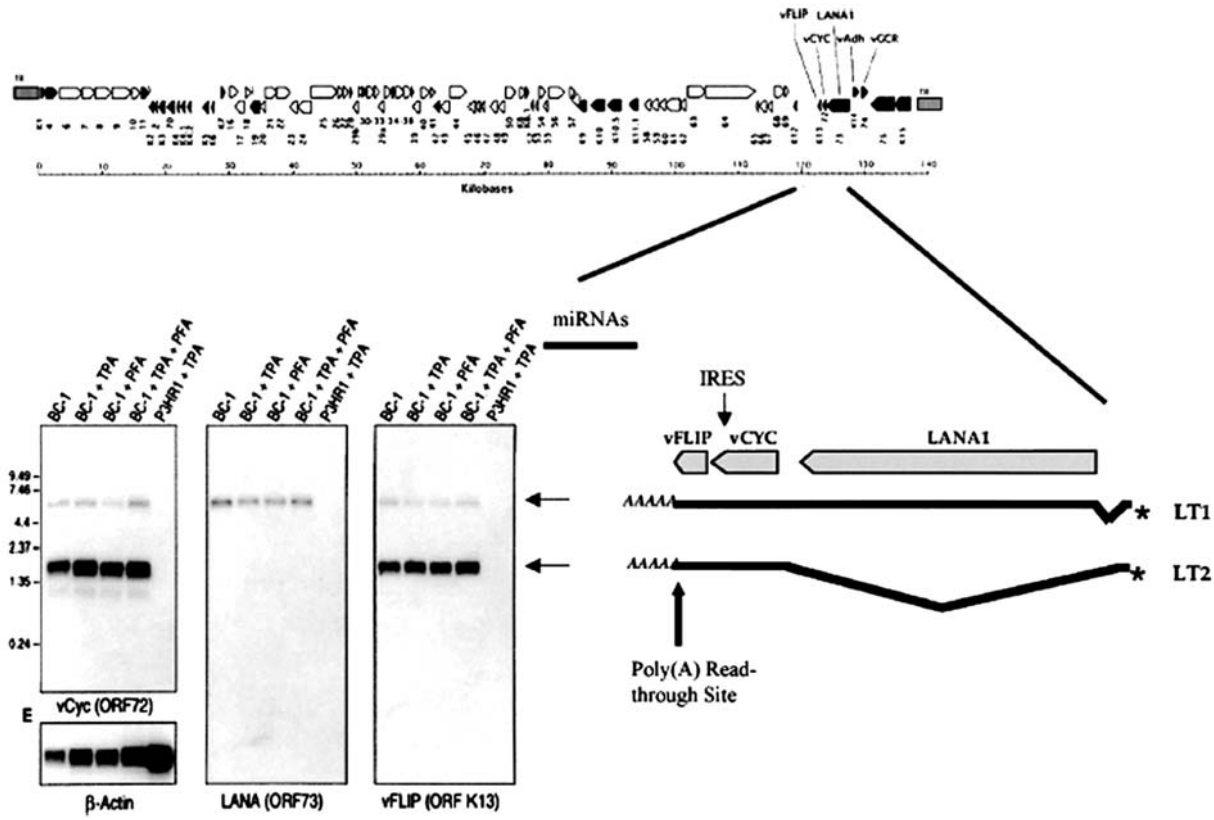

Fig. 30.2. Diagram of the KSHV major latency locus. Northern blots are shown for the major genes in this region under conditions of lytic induction (TPA) or viral DNA synthesis inhibition using the DNA polymerase inhibitor, phosphonoformic acid (PFA). The genes encoding LANA1, vCYC and vFLIP are expressed in the BC-1 cell line under all conditions, but they are also under cell cycle regulation. Less abundant transcripts, including transcripts expression KSHV miRNAs after read-through of the LT1/LT2 polyadenylation site, are not seen at this exposure. (From Sarid *et al.*, 1999.)

Table 30.2. Major KSHV proteins affecting cell cycle control machinery

	Protein	Gene	Target(s)
Latency	LANA1	ORF73	pRB1
	vCYC	ORF72	pRB1, p27, ORC1, H1, Cdc25a
Lytic or Induced	vGPCR	ORF74	Akt, SAPK pathways
	KIS	ORF K1	ITAM signaling
	vIL-6	ORF K2	Interferon, IL-6 signaling
	vMIP 1–3	ORFs K4, 4.1 and 6	Angiogenesis
Lytic	K-bZIP (RAP1)	ORF K8	C/EBP-α, p21

detecting KSHV infection (Moore *et al.*, 1996), that functions to maintain the viral episome by tethering it to cellular chromosomes during mitosis (Ballestas *et al.*, 1999, see Chapter 24). LANA is mainly expressed from a polycistronic transcript (LT1) that includes vCYC and vFLIP (Figure 30.2). These two latter proteins are also expressed from a second transcript (LT2) that originates from the same promoter but splices out ORF73. The latency promoter is cell cycle-regulated with highest expression during late G1 (Sarid *et al.*, 1998) and LANA1 positively autoregulates its own expression as well (Jeong, *et al.*, 2004). Although LANA1 and vCYC proteins are translated from LT1 and LT2 respectively, vFLIP translation requires an internal ribosomal entry site (IRES) located at the 3' end of the vCYC message (Grundhoff and Ganem, 2001; Bieleski and Talbot, 2001; Low *et al.*, 2001). Outside of the major latency locus, the ORF K10.5 gene product, vIRF3 or LANA2, is also constitutively expressed in KSHV-infected hematopoeitic cells but not KS

tumor cells (Cunningham *et al.*, 2003). Other KSHV genes, including K12 (kaposin) are expressed during latency but are also induced during lytic replication and by other transcriptional activation, such as notch-signaling (Chang *et al.*, 2005).

LANA1 is a large protein (*ca.* 150 kDa) composed of basic, glutamine-rich amino- and carboxyl-terminal domains separated by a highly acidic, aspartic- and glutamic acid-rich repeat region that includes a leucine zipper domain (see Chapter 24). Because of its highly charged, amphipathic structure it runs as a 220–224 kDa doublet on denaturing gel electrophoresis. This multifunctional protein is reminiscent of the SV40 virus large T-antigen (LT ag), since it tethers the episome to cellular DNA during mitosis and also disrupts both cell cycle and p53-mediated apoptosis.

LANA1 abrogates cell cycle arrest through its binding to at least two of the many cellular interaction partners for LANA1 that have been described. Radkov and colleagues (Radkov *et al.*, 2000) found that LANA1 directly binds the hypophosphorylated (active) form of RB1, inhibiting RB1's ability to serve as a transcriptional repressor of the E2F family. LANA1 binds the pocket region of RB1, but not the related RB1-like protein p130, through interactions with a central region that includes the leucine zipper domain. This effectively sequesters RB1, allowing E2F transactivation (Figure 30.1). Dysregulation of the G1/S checkpoint by LANA1 can be functionally demonstrated rodent cell transformation assays. While LANA1 expression alone does not enhance cellular transformation, oncogenic cooperativity occurs when LANA1 is coexpressed with the activated H-Ras oncogene.

Aside from direct inhibition of RB1, LANA1 as a second pro-mitogenic activity through its ability to activate the Wnt signaling pathway. Hayward and colleagues identified glycogen synthase kinase – 3β (GSK-3β) as a protein interactor with LANA1 through yeast two-hybrid screening (Fujimuro and Hayward, 2003; Fujimuro *et al.*, 2003). GSK3-β normally phosphorylates β-catenin causing the cytoplasmic sequestration of this proto-oncoprotein. LANA1, however, inhibits GSK-3β regulation of β-catenin allowing it to accumulate in the nucleus and transactivate responsive promoters, including the cMYC promoter. cMYC has diverse mitogenic activity and activates the hTERT promoter, which may contribute to the ability LANA1 to activate telomerase activity in KSHV infected cell lines (Verma *et al.*, 2004; Wu *et al.*, 1999). GSK3-β inhibition could potentially also indirectly modulate cell cycle entry through its ability to phosphorylate D-type cyclins resulting in their cytoplasmic accumulation (Verschuren *et al.*, 2004b). These secondary consequences of LANA targeting of Wnt pathway signaling are speculative and remain to be examined but suggest novel and unexplored ways that LANA can contribute to cell transformation. As is the case for many KSHV signaling pathways, EBV has also been shown to stabilize β-catenin showing conservation of cell signaling pathway targeting by the two vriuses (Hayward *et al.*, 2006).

Viral Cyclin (vCYC)

While LANA1 has no homologue in the human genome, KSHV also uses its pirated cyclin to hijack cell cycle regulatory control mechanisms. The vCYC protein (ORF72) (Cesarman *et al.*, 1996; Chang *et al.*, 1996) is expressed together with LANA1 from the major latency locus. As previously described, cellular cyclins positively regulate various stages of the cell cycle by partnering with CDKs to phosphorylate specific cell cycle components. KSHV vCYC retains sequence similarity to the D-type cyclins (there are three cellular D cyclins-D1, D2, and D3 which have overlapping and apparently redundant activities), which target CDK4 and CDK6 to hyperphosphorylate RB1, thereby inhibiting this inhibitor of E2F-induced transcription. KSHV vCYC partners almost exclusively with CDK6 to achieve this effect (Chang *et al.*, 1996; Godden-Kent *et al.*, 1997; Li *et al.*, 1997), initiating illicit S phase entry and DNA replication (Laman *et al.*, 2001).

Although vCYC is structurally similar to D-type cyclins, several features of the protein are unique. Unlike D-type cyclins, vCYC (also referred to as K-cyclin) targets cell cycle control proteins that are more typical targets of other cyclins such as cyclins A and E which couple to the CDK2 kinase. These targets include histone H1, the CDKI p27, and Cdc25a, as well as ORC1 and Cdc6 (Ellis *et al.*, 1999; Laman *et al.*, 2001; Mann *et al.*, 1999) (for review see Verschuren *et al.*, 2004b). Unlike cellular cyclin D/CDK6 complex, which normally requires CDK6 phosphorylation through the action of a CDK-acitvating kinase (CAK), the vCYC/CDK6 is fully active in an unphosphorylated form (Child and Mann, 2001; Kaldis *et al.*, 2001).

The vCYC gene, ORF72, like the other genes encoded in the major latency locus, is expressed during late G1 in a cell cycle-dependent fashion (Sarid *et al.*, 1999). Although direct measurement of vCYC protein levels are difficult, vCYC lacks the cyclin destruction box motif that targets cyclins for rapid protein turnover (Klotzbucher *et al.*, 1996) suggesting that the viral protein may be long-lived and active at other portions of the cell cycle including the G2/M checkpoint (Van Dross *et al.*, 2005). Also absent from the viral protein are motifs required for docking to nuclear export proteins, which may indicate that vCYC abnormally accumulates in the nucleas and may escape regulations imposed on cellular cyclin proteins (Verschuren *et al.*,

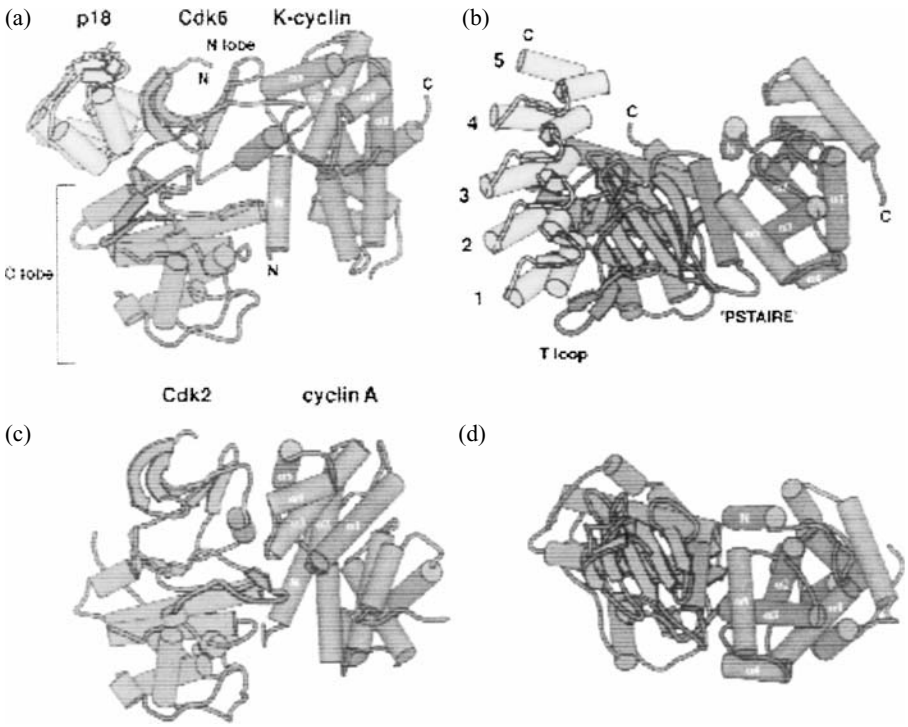

Fig. 30.3. The structure of the vCYC (purple), CDK6 (cyan), p18Inkb (yellow) complex from side (a) and top (b) views, compared to cellular cyclin A (purple), CDK2 (cyan) side (c) and top (d) views. Unlike cellular cyclins, the regulatory T-loop of CDK6 is excluded from interaction with vCYC but the PSTAIRE regulatory helix of CDK6 still forms an interface with vCYC. The PSTAIRE helix forms part of the ATP binding domain required for kinase activity while the T loop acts as a negative regulator of kinase activity and must be phosphorylated by cyclin-activating kinases (CAK) in cellular cyclin–CDK complexes. While CAK phosphorylation may enhance vCYC-CDK6 stability, displacement of the T loop by vCYC allows this complex to be active in the absence of CAK activity. The structure of vCYC-CDK6 also reveals loss of the binding pocket used by cyclin-dependent kinase inhibitors (CDKI) of the CIP1/KIP1 family. These and other features support experimental data showing the vCYC-CDK6 not only have a broader target range than cellular D-type cyclins but also escape many normal negative regulatory controls imposed on the cellular cyclin machinery. Reprinted with permission (Jeffrey *et al.*, 2000). (See color plate section.)

2004b). This is supported by transgenic mouse experiments (see below) in which constitutive vCYC expression leads to defects in chromosome segregation, abnormal cytokinesis and polyploidy (Verschuren *et al.*, 2002). Surprisingly, vCYC also phosphorylates and inactivates the antiapoptotic cellular protein BCL-2, but not the corresponding KSHV BCL-2 homologue, contributing to the pro-apoptotic properties of this protein when overexpressed in cells (Ojala *et al.*, 2000).

Another critical difference between cellular cyclins and vCYC is that vCYC escapes from normal CDK inhibitor (CDKI) control. CDKIs, including p21 and p27 and members of the p16Ink4a family, act to inhibit cyclin-dependent phosphorylation and are a critical link for transmitting cell arrest signaling from p53 to the cell cycle machinery. vCYC/CDK6 is resistant to p21 and p27 CDKI inhibition (Swanton *et al.*, 1997, 1999), but is still inhibited by Ink4 unless CDK6 is phosphorylated through the action of CAK (Jeffrey *et al.*, 2000). This has allowed crystallographic analysis of the trimolecular vCYC/CDK6/p18Inkb structure (Fig. 30.3), which has been tremendously informative for understanding the structural basis for vCYC regulation as well as regulation of the cellular cyclins. vCYC phosphorylation of p27 also diminishes cellular levels of this inhibitor protein, contributing to positive cell cycle regulation. In summary, although vCYC has similar functionality to cellular cyclins, modifications to this protein allow the virus to escape normal cell cycle regulatory constraints and to couple CDK6 phosphorylation to RB1 and other cell cycle components (for review, see Mittnacht and Boshoff, 2000; Verschuren *et al.*, 2004b).

A potential role for vCYC in cell tranformation and carcinogenesis has been uncovered using transgenic mice in which vCYC is expressed under an Eμ promoter (Verschuren *et al.*, 2002, 2004a). Overexpression of vCYC both

induces dysregulated DNA synthesis and leads to p53-dependent apoptosis. One mechanism by which this could occur is a circuit in which RB1 inactivation leads to E2F activation of p14ARF – a potent activator of p53 acting through MDM2. This, however, does not seem to be the case since p53-induced apoptosis is not reduced by mating the transgenic vCYC mice onto a p19ARF-null background. Instead, vCYC appears to dysregulate the G2/M checkpoint resulting in dysregulated cytokinesis and aneuploidy that in turn activates p53 through DNA-damage response pathways. When mice expressing vCYC are mated with p53-null mice, progeny develop lymphomas at an accelerated rate.

Other KSHV mitogenic signaling proteins

KSHV also possesses a number of proteins which act through mitogenic signaling pathways to achieve similar effects. Mitogenic signaling can occur through diverse signaling pathways which act on common regulatory points to induce cell cycle entry, such as activation of cyclin-dependent phosphorylation of RB1 (Sherr, 2004). While most of these molecules are thought to be expressed only during active lytic replication, evidence suggests that they have more complicated patterns of expression (see Chapter 28) in that at least several of them, such as the vIL-6 and the KSHV-encoded chemokines (Moore *et al.*, 1996; Parravicini *et al.*, 2000), are expressed at low levels during true viral latency (at least in tissue culture where the process can be readily examined) and are further activated during lytic viral replication or in response to specific signaling pathways. This is a similar pattern of expression to the EBV LMP1 protein. It is unclear what, if any, effects these mitogenic factors have during latency but these pathways have also received renewed interest related to the possibility that lytic virus replication contributes to the tumorigenesis, particularly in KS tumors (described more fully elsewhere in this volume).

Viral G-protein coupled receptor (vGPCR)

The best-studied example of a KSHV mitogenic signaling molecule is the vGPCR (ORF74), a seven-spanning G-protein coupled receptor that is expressed at early phases during lytic replication (Cesarman *et al.*, 1996). vGPCR is a constitutively active CXC receptor (Chiou *et al.*, 2002; Kirshner *et al.*, 1999), which activates MAPK, p38, Akt and NF-κB pathways resulting in expression of angiogenic factors, such as VEGF, and in cell transformation (Bais *et al.*, 1998; Cannon *et al.*, 2003; Masood *et al.*, 2002; Montaner *et al.*, 2001; Polson *et al.*, 2002). Although constitutively active, evidence suggests that its growth promoting activity is enhanced by host ligand binding (Holst *et al.*, 2001). The principal interest in this protein comes from the unique phenotype that it generates in transgenic mice which was first demonstrated by Lira and colleagues (Yang *et al.*, 2000) but has been confirmed using a variety of experimental systems by others (Guo *et al.*, 2003; Montaner *et al.*, 2003).

In these first experiments, vGPCR was expressed under control of the CD2 promoter, resulting in diffuse hematopoietic expression of the viral protein. Surprisingly, this resulted in endothelial tumors pathologically resembling Kaposi sarcoma tumors. These and similar results by Montaner and colleagues (Montaner *et al.*, 2003) suggest that KS tumors, unlike primary effusion lymphomas, may actually be dependent on active lytic viral replication and that KS tumor cell proliferation occurs in *trans* due to paracrine factors released by infected cells undergoing lytic replication. This is a unique pathogenic model in which paracrine factors, rather than endogenous genetic changes, are responsible for the neoplastic phenotype (Cesarman *et al.*, 2000).

Several findings, however, complicate this view. It is evident that virtually all tumor cells in KS tumors are infected with KSHV and so paracrine-effects of lytic replication appear to act in concert with endogenous viral gene expression to result in tumor cell outgrowth (Parravicini *et al.*, 2000, Katano *et al.*, 2000). KS development can be effectively prevented by antilytic DNA pol inhibitors, such as ganciclovir (Martin *et al.*, 1999), but there is no current evidence that these drugs have any effect on established KS tumors (Little *et al.*, 2003). Further, clinical studies suggest that some KS tumors arising during transplantation are donor derived (Barozzi *et al.*, 2003). Since these donors were ostensibly healthy, the prototumor was primarily latent, or at least subclinical, in the donor prior to the transplantation. Studies of cell and virus monoclonality do not clarify the origin of KS pathogenesis since both cellular monoclonality and multiclonality have been reported. KS tumors have KSHV terminal repeat patterns that are oligoclonal or monoclonal, with the possibility that tumors evolve into a monoclonal pattern over time (Judde *et al.*, 2000; Russo *et al.*, 1996). The role for paracrine-induced proliferation from vGCPR or other viral proteins may become clearer as KSHV gene regulation outside of the latent-lytic expression pattern is explored.

K1 Protein

On the opposite end of the KSHV genome (see Chapter 28), a second membrane signaling protein encoded by ORFK1, also called KIS (KSHV ITAM signaling protein), has strong mitogenic activity when expressed in cells. K1 protein is a type 1 transmembrane protein that aggregates through ectodomain disulfide bonds into a signaling complex (Lee *et al.*, 1998b). The cytoplasmic tail of the protein contains two immunoreceptor tyrosine signaling motifs (ITAMs) which recruit SH2-containing signaling kinases; NFAT, syk, vav and other downstream signaling effectors have been

shown to be activated by K1, resulting in Akt signaling activation (Lagunoff *et al.*, 1999, 2001; Lee *et al.*, 1998a, 2003; Tomlinson and Damania, 2004, Wang *et al.*, 2005). As a consequence of its mitogenic signaling activities, K1 transforms rodent fibroblasts and primary endothelial cells in vitro and when substituted into a herpesvirus saimiri backbone, induces lymphomas in rhesus macques (Lee *et al.*, 1998b, Wang *et al.*, 2005).

Clues to the functional advantage of this signaling protein for the virus, come from overlap between K1 signaling and signaling through the B cell receptor (BCR). The BCR is active as a non-specific innate immune signaling pathway. Intriguingly, K1 causes ER retention and degradation of the BCR, suggesting that K1 may serve as a decoy molecule after downregulation of this pathway (Lee *et al.*, 2000). A consequence of K1 expression is induction of paracrine angiogenic factors including vascular endothelial growth factor (VEGF) and matrix metalloproteinase-9 (MMP-9), analogous to the paracrine mitogenic induction that can occur with vGPCR (Wang *et al.*, 2004). The immunoevasion/mitogenic properties of K1 have analogy, together with the KSHV LAMP1 protein, to properties of EBV membrane proteins, LMP1 and LMP2 (Damania *et al.*, 2000).

Virus-encoded chemokines and cytokines

In addition to both vGPCR and K1 protein, which induce secretion of proliferative cytokines, KSHV itself encodes three secreted chemokines, vCCL1 (*ORF K6*), vCCL2 (*ORF K4*) and vCCL3 (*ORF K4.1*), formerly known as vMIP-I/MIP-1a, vMIP-II/MIP-1b and vMIP-III/BCK, respectively and a functional, secreted vIL-6 (ORF K2) cytokine. The chemokines are believed to act to polarize local immune responses towards a Th2 phenotype. vCCL2 initiates a strong chemotactic response through CCR3 activation (Boshoff *et al.*, 1997), while vCCL1 and vCCL3 activate CCR8 (Dairaghi *et al.*, 1999, Endres *et al.*, 1999) and CCR4 receptors (Stine *et al.*, 2000). All three chemokines have angiogenic activity and stimulate endothelial and B-lymphocytic proliferation (Moore *et al.*, 1996; Stine *et al.*, 2000). While they are generally not expressed in PEL cells during latency, they may play a role in mitogenesis in KS tumors.

Like K1 protein, KSHV encoded vIL-6 has both immune evasion and cell cycle regulatory properties (Moore *et al.*, 1996; Nicholas *et al.*, 1997) (described in more detail in Chapter 31). vIL-6 is a secreted cytokine similar to the human cytokine (25% identity, 62% similarity) that activates IL-6 signaling pathways by binding directly to the gp130 signal transducer molecule without requiring interaction with the IL-6 specific recepor, gp80 (Burger *et al.*, 1998; Chow *et al.*, 2001; Molden *et al.*, 1997; Mullberg *et al.*, 2000; Osborne *et al.*, 1999). Although this has not been directly examined, it is likely that the viral protein activates the same signaling pathways as hIL-6, resulting in RB1 hyperphosphorylation and mitogenesis (Urashima *et al.*, 1996, 1997; Zhu *et al.*, 1994). Studies of a non-adapted tissue culture PEL cell line, BCP-1, demonstrate that the cells are autocrine dependent on hIL-10 and vIL-6 (Jones *et al.*, 1999), and can reinitiate DNA synthesis for serum-starved PEL cells (Chatterjee *et al.*, 2002).

The role of vIL-6 in the lifecycle of KSHV reveals the intimate connection between cell cycle regulation and early innate immune responses (Chatterjee *et al.*, 2002). Type I interferon signaling in PEL cells causes upregulation of p21 CDKI and initiates arrest. The vIL-6 promoter, however, has transcription elements responsive to interferon signaling and is simultaneously up-regulated. Evidence suggests that vIL-6 can block interferon signaling at the receptor resulting in a negative feedback loop that protects infected cells from cell-cycle arrest effects of interferon. Interferons are activated by viral infection and the autocrine loop formed by vIL-6 appears to block antiviral effects induced by KSHV infection itself. A consequence of vIL-6 hypersecretion may include neighboring cell proliferation as is seen in multicentric Castleman's disease (Parravicini *et al.*, 1997). As an interesting aside, this demonstrates that a virus can sense and modify its environment, a property referred to as irritability, that is part of the fundamental definitions for living organisms.

Inhibition of cell cycle progression: K-BZIP/RAP

The proteins thus far described for KSHV act on cell cycle checkpoints to prevent cell cycle arrest. KSHV k-BZIP (also known as replication associated protein, RAP) encoded by ORF K8, paradoxically has opposing effects on cell cycle regulation. K-BZIP is an early spliced gene (corresponding by weak sequence homology to the EBV transactivator Zta or ZEBRA) possessing a basic-leucine zipper (bZIP) (Gruffat *et al.*, 1999; Lin *et al.*, 1999; Seaman *et al.*, 1999). This protein interacts with p53 and may sequester p53 (together with the other major lytic transactivator RTA (Gwack *et al.*, 2001b)) to promyelocytic leukemia (PML) bodies, presumably as a means of delaying p53-dependent apoptosis during the early phases of lytic reactivation (Park *et al.*, 2000). Despite this, K-bZIP causes cell cycle arrest through induction of the CDKI p21, a downstream target of p53, and CCAAT/enhancer binding protein-α (C/EBP-α) resulting in G1 arrest during lytic replication (Wang *et al.*, 2003a,b; Wu *et al.*, 2003). K-bZIP is phosphorylated by CDKs (Polson *et al.*, 2001) and also directly interacts with cyclin A/CDK2 complexes contributing to G1 arrest during early lytic replication (Izumiya *et al.*, 2003).

The reasons for this effect remain speculative. Virus-induced cell cycle arrest may seem counterintuitive – particularly in view of the limited resource hypothesis for oncogene teleology developed from analyses of small DNA

Table 30.3. Major KSHV proteins targeting apoptotic control machinery

	Protein	Gene	Target(s)
Latency	LANA1	ORF73	p53
	LANA2 (vIRF-3)	ORF K10.5	p53
	vFLIP	ORF K13	Fas, NF-κB
Lytic or induced	RTA	ORF50	p53
	K-bZIP	ORF K8	p53/p300/CBP
	vIRF-1	ORF K9	p53/p300/CBP/ATM
	vBCL-2	ORF 16	BAX?
	VIAP	ORF K7	BAX, BH-3 proteins?

tumor viruses (Braithwaite and Russell, 2001; Russell *et al.*, 2004), since S phase entry is thought to be required for viral DNA replication. Entry into a "senescent" phenotype, however, might have protective effects in preventing premature apoptosis during lytic replication. It is also unclear if expression of the lytic phase KSHV DNA synthesis enzymes whose cellular counterparts are under E2F-control (e.g., ribonucleotide reductase, thymidylate synthase, dihydrofolate reductase and thymidine kinase) can generate a quasi-S phase state in the face of K-BZIP induced cell cycle arrest. Conceivably, this may allow viral DNA replication during stasis in cellular DNA replication. K-BZIP acts during lytic replication whereas LANA1 and vCYC act during latency (possibly during lytic replication as well) indicating that the different phases of the viral life cycle require different cell cycle manipulations.

KSHV inhibition of apoptosis

Interference with cell cycle checkpoints activates cellular apoptotic pathways through p14ARF and other less well-defined mechanisms, presumably as a means to prevent tumor cell formation (Sherr, 1998, 2004). It is therefore not surprising that KSHV encodes antiapoptotic factors that mitigate this response. What is surprising, however, is the number, range and kind of anti-apoptotic factors encoded by KSHV (Table 30.3, for review see Lagunoff and Carroll, 2003). KSHV also activates survival factors, such as NF-κB, a trait shared with EBV and other B-lymphotrophic viruses.

Apoptotic signaling is divided into intrinsic and extrinsic pathways integrated with each other through the activity of the transcription factor p53 (Fig. 30.4). Extrinsic pathways are activated through apoptotic signaling receptors, such as Fas/CD95 and the tumor necrosis factor receptor (TNFR), whereas intrinsic pathways are activated in response to cellular stress and DNA damage (Danial and Korsmeyer, 2004).

Extrinsic apoptotic signaling is principally an immune response activated through death-inducing receptors by natural killer (NK) cells and cytotoxic lymphocytes (CTL). Receptors of the TNF-Fas receptor family can have either opposing proapoptotic or antiapoptotic signaling responses depending on the mechanism of activation and the cellular context of receptor activation. Extrinsic apoptotic signaling activates caspase cascade signaling which in turn results in mitochondrial release of apoptosis mediators including cytochrome C. p53 has been implicated in increasing apoptotic receptor transcription and priming other components of these pathways (Sheard *et al.*, 2003).

Intrinsic apoptotic signaling directly activates p53 through a series of kinase cascades, ultimately resulting in mitochondrial apoptosis. Although this characterization of this response is rapidly evolving, current evidence suggest that sensors of DNA damage activate signaling cascades that ultimately result in cell cycle arrest and repair or, failing this, apoptosis. Responses may differ between types of DNA damage (e.g., mismatch damage vs. single and double-strand breaks) that activate different repair responses including nucleotide-excision repair, base-excision repair, or homologous and non-homologous recombination (for review see Wood *et al.*, 2001).

One of the initial responses to DNA damage recognition is binding and activation of the MRE11- Rad51-NBS (MRN) complex, which sequentially activates Chk2 and ATM phosphorylation and subsequent phosphorylation of p53 (Banin *et al.*, 1998; Lee and Paull, 2004). The importance of this pathway to viral replication is hinted at by viruses encoding proteins that target these early responses (Weitzman *et al.*, 2004). KSHV vIRF1, for example, binds to and inactivates ATM downstream signaling to p53 (Shin *et al.*, 2006). p53 phosphorylation causes conformational changes that promote p53 binding to specific DNA regulatory elements to initiate transcription of pro-apoptotic protein genes, such as PUMA and NOXA-1, BH3-only members (see below) of the BCL-2 factor family, which act at the mitochondria to initiate mitochondrial apoptotic responses (Oda *et al.*, 2000; Yu *et al.*, 2001). These BH3-only containing BCL-2 factors bind and sequester other anti-apoptotic BCL-2 members, including BCL-2 itself and BCL-x_L (Cheng *et al.*, 2001; Schuler and Green, 2001).

Disarming the guardian: p53 inhibition

p53 has been called the "guardian of the genome" for its critical role in integrating apoptotic and cell cycle arrest signaling, most notably in response to DNA-damaging

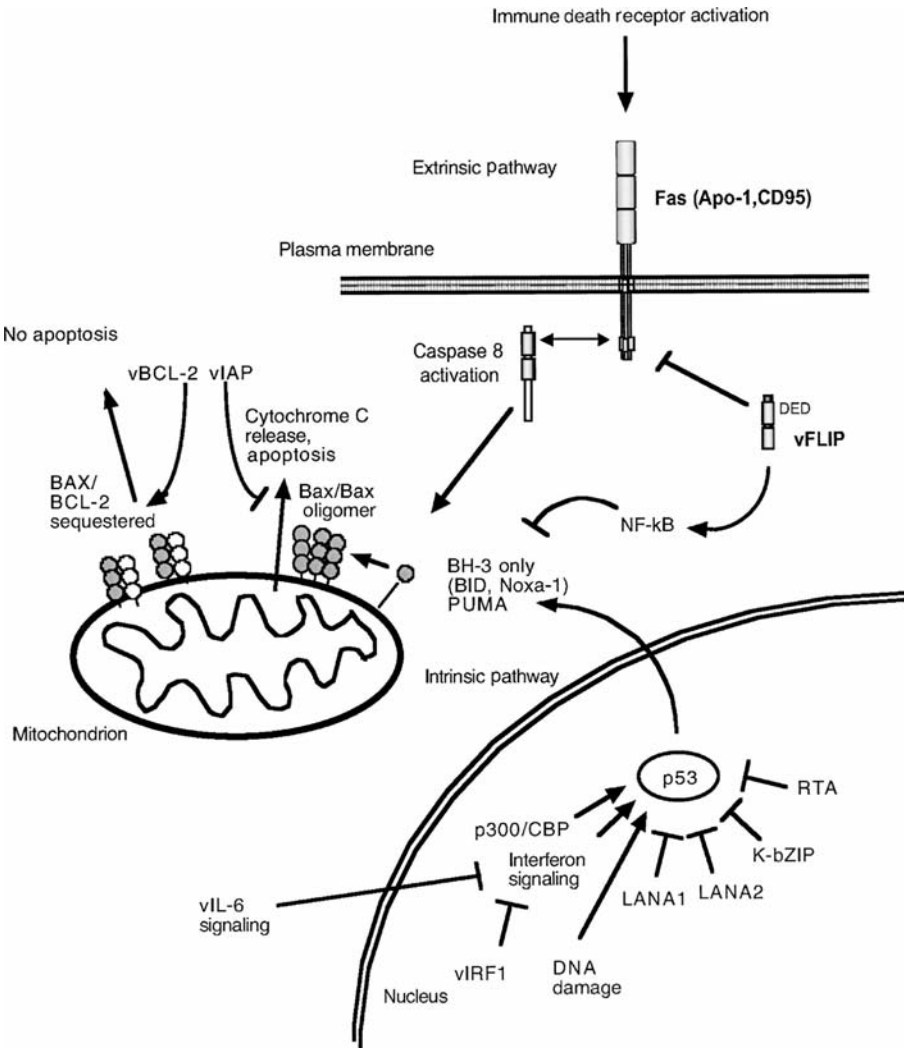

Fig. 30.4. KSHV inhibits both intrinsic and extrinsic apoptotic pathways at multiple points. Extrinsic signaling shown here is activated by cellular immune signaling (NK cell, cytotoxic lymphocyte responses) though activation of the Fas receptor. vFLIP directly inhibits this response through a dominant-negative binding to death effector domains (DED) in the death-inducing signaling complex (DISC) and also activate NF-kB through an alternative pathway which may inhibit B-cell apoptosis at the mitochondria and endoplasmic reticulum. Both vIAP and vBCL-2 act at the mitochondria to stabilize the mitochondrial membrane and inhibit the activating effects of BH3-only pro-apoptotic molecules. The central transcriptional integrator of apoptotic signaling, p53, plays a key role in mediating intrinsic apoptotic effects in response to DNA damage or interferon signaling. KSHV proteins including LANA1, LANA2, K-bZIP and RTA inhibit p53-induced apoptotic signaling either through direct binding or through inhibition of the p300/CBP coactivator used in p53 transcriptional signaling. Delaying apoptosis during lytic viral replication allows efficient production of infectious virions. Apoptotic signaling is also inhibited during latency. The reasons for viral targeting of the cell cycle and apoptotic pathways during latency remain poorly understood.

agents (Lane, 1992). p53 prevents germline transmission of mutations, since DNA damage will either cause p53-dependent arrest allowing repair prior to transmission to daughter cells or, if the damage is irreparable, commits the cell to p53-dependent apoptosis. The molecular decision-making process between apoptosis or cell cycle arrest remains unclear, although p21 has a key role in determining whether p53-activation results in arrest or cell death (Gorospe *et al.*, 1997).

For somatic cells, the roles for p53 are less clear. As a tumor suppressor, p53 may prevent cell transformation resulting from DNA damage. More recently, evidence has accumulated that p53 also acts to prevent viral nucleic acid replication (Moore & Chang, 1998; Takaoka *et al.*, 2003).

Replicating extrachromosomal DNA may activate ATM-p53 signaling, thus serving as an intracellular innate immune response. It is now widely accepted that cellular responses limiting viral replication include apoptosis (Benedict et al., 2002; Meinl *et al.*, 1998), although programmed cell death is not universal for all viral infections and some viruses may actually capitalize on cell dissolution during apoptosis to enhance replication (Teodoro and Branton, 1997).

As a critical integrator of cell cycle regulation and apoptotic signaling, p53 is a common target for tumor viruses that have convergently evolved very different mechanisms to inhibit this major regulatory protein (for review, see Lagunoff and Carroll, 2003). KSHV is no exception to this, and it directly targets p53 during both latency and during lytic replication. Unlike many malignancies, apoptosis in not prominent in KSHV-related disorders, p53 is expressed in tumor cells and p53 mutations do not appear to be common in KSHV-induced tumors (Katano *et al.*, 2001b).

LANA-1

To balance the cell cycle dysregulation effect of vCYC and LANA1 during latency, KSHV must also inhibit p53-mediated apoptotic signaling for infected cell survival. This is most clearly seen in unopposed vCYC transfection assays which induce apoptosis, and vCYC transgenic mice which have a dramatically increased rate of lymphomagenesis in a p53-null background. LANA1 encoded by ORF73 was the first p53 inhibitor discovered in KSHV (Friborg *et al.*, 1999), in which the carboxyl terminus of the protein was shown to interact with p53 and inhibit its transcriptional activator function. This work has since been extended to other rhadinoviruses such as herpesvirus saimiri whose ORF73 protein – while structurally different from the KSHV LANA1 protein – also inhibits p53 activity (Borah *et al.*, 2004).

LANA2/vIRF3

While LANA1 is expressed in all KSHV-infected cells, LANA2 (also known as vIRF3) encoded by the spliced gene ORF 10.5, is expressed exclusively in KSHV-infected hematopoeitic cells. LANA2 shares with LANA1 p53-inhibitory functions although evidence for direct interaction with p53 is less certain due to the inherent "stickiness" of the protein (Rivas *et al.*, 2001). Transient expression of LANA2 abrogates apoptosis caused by activation of p53 signaling or by direct overexpression of p53 protein. Paradoxically, LANA2 simultaneously activates interferon transcription pathways (Lubyova *et al.*, 2004)and inhibits NF-kB signaling pathways (Seo *et al.*, 2004) – two signaling events that would be expected to induce lymphocyte apoptosis. The role, if any, of this molecule in PEL survival and transformation remains largely unknown.

RTA, K-bZIP and vIRF1

KSHV p53-inhibitory proteins active during lytic replication include the lytic transactivator proteins RTA (encoded ORF50) and K-bZIP (encoded by K8 and describe above), and the interferon regulatory factor homologue vIRF1 encoded by ORF K9. These three proteins appear to inhibit p53 transcriptional activity (Gwack *et al.*, 2001b; Park *et al.*, 2000; Nakamura *et al.*, 2001) principally by binding to the p300/CBP family of histone acetyltransferases (HAT) that serve as transcriptional coadaptors for p53 (Gwack *et al.*, 2001a; Hwang *et al.*, 2001; Li *et al.*, 2000; Lin *et al.*, 2001). Direct binding by vIRF1 and K-bZIP to p53 may also occur. HAT activity is required to not only acetylate p53 itself, but also histones to prepare the operon for p53-directed transcription.

By sequestering HATs from the transcriptional complex, these KSHV proteins inhibit transcription not only at p53-regulated promoters but also (in the case of vIRF-1) interferon-regulated promoters (Gao *et al.*, 1997; Lin *et al.*, 2001; Zimring *et al.*, 1998). K-bZIP may also directly sequester p53 to promyelocytic leukemia protein (PML) bodies rendering it inactive for participation in apoptotic signaling (Katano *et al.*, 2001a). The use of CBP/p300 coadaptors is widespread in growth control transcriptional responses, and K-bZIP's ability to sequester CBP/p300 has also been shown to inhibit SMAD3 transcriptional response in the TGF-beta signaling cascade (Tomita *et al.*, 2004).

Beyond p300/CBP sequestration, vIRF1 also activates p53 degradation, possibly by enhancing the E4 ubiquitin-ligase activity of p300/CBP (Shin *et al.*, 2006). vIRF1 has the unusual property of binding to and inhibiting ATM, as well. Thus, vIRF1 has a multiple roles in inhibiting ATM-p53 activation during viral infection.

Induction of p53-mediated apoptosis during lytic viral replication is thus postponed by the activity of several proteins expressed during the earliest phases of viral replication. This presumably forestalls early cell death to optimize virion production. Since cells undergoing full viral replication eventually undergo apoptosis, it is clear that, in the struggle between the virus and the cell, the cell eventually wins–but presumably not before the virus is able to generate infectious progeny. The actual apoptotic triggers initiated by viral replication remain unknown. One possibility is that viral DNA breaks, as a consequence of massive but inefficient viral DNA replication, initiate ATM-p53 signaling. Other possibilities include endoplasmic reticulum stress due to hijacking of cellular protein synthesis machinery or the degradation of cellular mRNA with concomitant

transcriptional inhibition by the KSHV ORF 37 protein (Glaunsinger and Ganem, 2004).

Inhibition of extrinsic apoptotic signaling

vFLIP

KSHV down-regulation of MHC I during both lytic (Coscoy and Ganem, 2000) and latent (Tomescu *et al.*, 2003) viral replication leaves the infected cell open to NK cell attack (see Chapter 31). Intercellular killing is mediated by released membrane toxins (granzyme) and activation of Fas signaling. KSHV vFLIP encoded by ORF K13 potentially abrogates Fas-mediated apoptosis through two dominent-negative death-effector domains (DED) that block the formation of the death-induced signaling complex (DISC) (reviewed in Krueger *et al.*, 2001).

vFLIP encoded by ORF K13 has generated considerable interest as an antiapoptic protein since it is expressed during latency through an IRES in the ORF 72 (vCYC) gene on LT1 and LT2 transcripts (Bieleski *et al.*, 2004; Bieleski and Talbot, 2001; Grundhoff and Ganem, 2001; Low *et al.*, 2001). While its caspase-inhibition functions have a clear benefit in preventing NK immune killing of an infected cell, the ability of this protein to activate NF-kB may have even greater importance in maintaining the infected tumor cell (Chaudhary *et al.*, 1999). NF-kB is constitutively activated in PEL cells through IkB inhibitor phosphorylation due to vFLIP signaling (Field *et al.*, 2003; Matta and Chaudhary, 2004) and this activity may inhibit BH3-only molecule-induced apoptosis (Fig. 30.4). Cesarman and colleagues have demonstrated the importance of this to PEL cell survival using specific NF-kB inhibitors which rapidly induce PEL cell apoptosis (Guasparri *et al.*, 2004; Keller *et al.*, 2000). Differentiating the effects of vFLIP on caspase inhibition from NF-kB activation suggests that the latter is critical for PEL cell survival in tissue culture. vFLIP activates NF-kB through direct interactions with the Ikappa B kinase (IKK) complex which targets inhibition of the NF-kB inhibitor, Ik-B (Liu *et al.*, 2002). Evidence suggests this specifically activates an alternative NF-kB pathway that favors processing of the p52 subunit of NF-kB (Matta and Chaudhary, 2004). Latent expression of vFLIP makes this protein an attractive candidate for contributing to human tumors. Expression of vFLIP enhances tumorigenicity of mouse B lymphoma cells in immunocompetant mice strains (Djerbi *et al.*, 1999), suggesting a role in human KSHV-induced tumors.

The mitochondrial anti-apoptotic proteins: vBCL-2, vIAP

Both intrinsic and extrinsic apoptotic signaling ultimately merge at mitochondria to initiate membrane depolarization, release of cytochrome c and formation of the apoptosomal proteins required for chromatin condensation and endonucleolytic cleavage, volume contraction and the breakdown and blebbing of membrane structures that result in apoptotic cell death (Danial and Korsmeyer, 2004).

As previously indicated, critical components of this process are the BCL-2 family of proteins (BCL-2 referring to the second B-cell lymphoma related rearrangement protein found (Bakhshi *et al.*, 1985) with the cyclin D1 being "BCL-1"). BCL-2 members have up to four conserved BCL-2 homology (BH) domains and dimerize with each other in the mitochondrial membrane. BH1, BH2 and BH3 domains on antiapoptotic members form a hydrophobic pocket which sequesters proapoptotic BH3-only containing members, such as BID, of the BCL-2 family. Some proapoptotic BCL-2 family members, including BAX and BAK, possess all three BH domains but may have specific activation at the BH3 domain which initiates their proapoptotic activity (Danial and Korsmeyer, 2004).

KSHV and other DNA viruses (Cuconati and White, 2002) encode homologues to the cellular BCL-2 antiapoptic protein (Sarid *et al.*, 1997). vBCL2 encoded by ORF16 was the first KSHV protein to be investigated for its apoptosis-inhibitory properties (Cheng *et al.*, 1997; Sarid *et al.*, 1997) and possesses BH1 and BH2 domains. Solution structure studies suggest structural similarities to BH3 and BH4 domains being present (Huang *et al.*, 2002) allowing the KSHV protein to tightly bind pro-apoptotic Bak and Bax peptides, consistent with two-hybrid heterodimerization studies (Sarid *et al.*, 1997). Whereas cellular BCL-2 can be cleaved by caspase proteolysis and converted to a pro-apoptotic version, KSHV vBCL-2 lacks this cleavage site and escapes cellular regulation (Bellows *et al.*, 2000). Also, as previously indicated, vBCL-2 may serve a specific role in KSHV infected cells since it escapes inactivation by the KSHV vCYC protein which can occur for the cellular BCL-2 (Ojala *et al.*, 2000).

Recent studies also suggest an novel role for viral BCL-2 members in preventing cell death. In addition to apoptosis, autophagy – programmed lysosomal degradation of cytosolic components – plays a critical role in inhibiting intracellular pathogens and initiating CD4+ antigen presentation (Schmid *et al.*, 2006). Liang and colleagues demonstrated that the murine γHV-68 vBCL-2 binds to the autophagy signaling complex composed of UVRAG and Beclin-1 (Liang *et al.*, 2006). vBCL-2 inhibition of autophagy is an attractive mechanism for gammaherpesviruses to escape this innate immune signaling pathway. Thus, vBCL-2 may help KSHV and related viruses escape both apoptotic and autophagic surveillance systems.

vBCL-2 is expressed as an early gene during lytic replication (Sarid *et al.*, 1997; Sun *et al.*, 1999), and presumably delays apoptosis to allow optimal virion production (Cuconati and White, 2002). Immunostaining of KS tissues shows vBCL-2 production in a minority of infected spindle cells of advanced nodular lesions also consistent with a role primarily in delaying lytic apoptosis in vivo (Widmer *et al.*, 2002).

Another KSHV molecule acting as an antiapoptotic factor at the mitochondrial member is the recently investigated viral inhibitor of apoptosis protein (vIAP) encoded by ORF K7 (Feng *et al.*, 2002; Wang *et al.*, 2002). KSHV vIAP possesses a BH2 domain and localizes to mitochondrial membranes where it stabilizes mitochondrial membranes from apoptotic Ca+2 depolarization induced by a variety of agents (Feng *et al.*, 2002). While a BCL-2-like interaction may account for some of the antiapoptotic properties of this protein, vIAP interacts with ubiquillin (also known as PLIC1) which regulates the proteosomal machinery. K7 binding to ubiquillin may enhance polyubiquitin-mediated proteolysis of key apoptotic signaling molecules including IK-B and p53 (Feng *et al.*, 2004). vIAP is expressed during lytic replication, but also can be seen immediately after infection with KSHV suggesting a critical role for this protein in preparing the cell for successful viral invasion (Krishnan *et al.*, 2004).

Conclusions

Further, recent studies suggest that many of these "lytic cycle" proteins are actually activated during latency by transcriptional signaling such as notch. Thus, there is a large array of KSHV nonstructural proteins that may contribute cell transformation, and by extension, to KSHV-related tumorigenesis.

In contrast to the small DNA tumor viruses that have only one, or a few, likely viral oncoproteins, KSHV possesses startlingly large number of nonstructural proteins targeting cellular control pathways that regulate cellular proliferation. Multiple KSHV proteins inhibit cellular controls of the cell cycle. Both LANA1 and vCYC directly target negative cell cycle regulators and bypass normal cellular feedback controls that limit cell proliferation. Similarly, KSHV inhibits intrinsic and extrinsic apoptotic signaling at multiple levels using many different proteins, that include direct targeting of p53 as well as targeting both upstream and downstream signaling pathways to p53.

While it is likely that only a few KSHV proteins principally contribute to oncogenesis, it remains to be determined which proteins this are. Latency-expressed proteins are the leading candidates but recent studies reveal that KSHV genes traditionally thought of as being lytic cycle genes can be induced during viral latency. In addition, paracrine contributions to neoplasia have long been thought to be important for KS tumors adding an additional layer of complexity to KSHV-induced cell transformation. One likely reason for the large number of KSHV proteins targeting cellular control machinery is that they act in different tissues that are infected with the virus. This is most obvious example for this is LANA2 which is not appreciably expressed in KS endothelial cells. Similarly, vIRF1 and K1 may have widespread expression in KS tumors that is not found in cultured PEL cells in the laboratory. Although KSHV appears to encode many more 'oncoproteins' than other viruses, this may be more apparent than real. KSHV molecular piracy makes identification of regulatory proteins relatively easy; it is possible that additional, functionally-similar proteins will be found in the other herpesviruses as well.

A more salient question is "Why does KSHV dysregulate the cell cycle and control apoptotic signaling?" One explanation is that during lytic replication, KSHV needs to generate a cell environment that can replicate thousands of copies of viral DNA. This view assumes a passive role for the cell during virus replication. It is becoming increasingly clear, however, that lytic virus replication activates host cell defenses that attempt to shutdown the cell cycle or to initiate apoptotic cell death. While the tumor suppressor feedback control machinery is traditionally thought to be a means of preventing spontaneous tumor cell generation, it works extremely well to also limit virus replication (Moore & Chang, 2003). Evidence for the interplay between innate immune signaling and tumor suppressor signaling (Takaoka *et al.*, 2002) makes it increasingly likely that tumor suppressor pathways have evolved for the equally important role of controlling viral replication (Moore & Chang 1998). Seen from this light, KSHV 'oncoproteins' may actually be innate immunity evasion proteins that allow the virus to escape from hostile cellular responses to virus infection.

Introduction

The human γ-HVs are able to establish a lifelong, persistent infection that is largely clinically inapparent within the immunocompetent host. However, when these viruses are not kept in check, a variety of lymphoproliferative and neoplastic disorders result that will be detailed elsewhere within this volume. In brief, for HHV-8, also known as Kaposi's sarcoma-associated herpesvirus (KSHV), these neoplasias include Kaposi's sarcoma (KS), multicentric Castleman's disease (MCD) and primary effusion lymphoma (PEL). HHV-4, or Epstein–Barr virus (EBV), has been etiologically associated with infectious mononucleosis, Burkitt's lymphoma, nasopharyngeal carcinoma (NPC), Hodgkin's disease, hemophagocytic lymphohistiocytosis syndrome and some gastric cancers. Through coevolution with their hosts, these viruses have acquired a number of genes that act to set a fine balance between the uncontrolled, virally driven cellular proliferation seen in the immunocompromised host and complete elimination of infected cells by the immune responses. Several of these gene products cause selective suppression of normal immune system functioning and allow for an apathogenic, persistent infection.

Immune system overview

The immune system provides multiple mechanisms of protection from invading pathogens, whether viral, bacterial or parasitic. These immune responses include both broad spectrum, innate responses and highly specific, adaptive responses. Mechanisms of the innate response include the production of viral replication blocking interferons, opsonization and lysis by the complement cascade and natural antibodies, apoptosis, as well as clearance of infection by natural killer (NK) cells, macrophages, neutrophils and T-cells. The adaptive response mechanisms include the $CD4^+$ T-helper cell directed production of specific, high avidity neutralizing antibodies by the B-cells and elimination of infected cells by antigen-specific cytotoxic T-lymphocytes (CTL). A complex network of protein–protein interactions, providing numerous targets for viral intervention and deregulation, governs all of these processes.

Evasion of innate host immunity

By definition, the innate immune responses are the host's first line of defense against viral infection. These defenses can be roughly broken down into complement-mediated responses (both antibody-dependent and -independent), cytokine responses, apoptotic responses and cell-mediated responses. These responses are broad, able to target multiple pathogens, but by no means non-specific. The innate immune response utilizes a large number of germ line-encoded receptors capable of sensing moieties that are common to many pathogens. Other members of the innate immune system, such as the natural killer (NK) cells, have evolved mechanisms for determining the "health" of a cell by examining the cell for changes in the repertoire of surface molecules. This complexity built in to the innate immune responses excludes the possibility of non-specific targeting of host cells, but also provides a number of regulatory checkpoints which invading pathogens can usurp. Both of the known human γ-HVs have devised a number of strategies for thwarting the efforts of the innate immune system to clear them from the body and for deregulating the cross-talk between the innate and adaptive responses.

Complement deregulation

The complement response is mediated by a series of heat-labile plasma proteins, each given a number designation, whose cleavage and activation from an inactive circulating zymogen is controlled by a host of regulatory proteins. It is initiated through one of three pathways: the classical, alternative or mannan-binding-lectin-associated serine protease (MASP) pathways (for review see Medzhitov and Janeway, 2000). Triggering of the complement response results in activation and cleavage of the first zymogen to its active form, which then in turn cleaves and activates the next zymogen in the cascade. After cleavage, the resulting zymogen products are given lettered subscripts. For example, the cleavage of the C4 zymogen by active C1 results in production of C4a and C4b products (Fig. 31.1). The complement system protects against infection by both bacteria and viruses in three different ways. First, several of the complement proteins, when activated, can covalently bind to pathogens in a process called opsonization. Complement receptor-bearing phagocytes can then internalize and clear the infecting organism. This opsonization also contributes to the activation of the adaptive, humoral response. Second, multiple complement protein cleavage products act as anaphylotoxins, recruiting and activating circulating phagocytes. Third, several activated complement proteins can form a large multimeric structure called the membrane attack complex (MAC). This protein complex is capable of creating a pore in lipid membranes resulting in the lysis of cells, enveloped virus or bacteria onto which it has been deposited. While each pathway is initiated by a different triggering event, they converge at the production of the multi-component C3 convertase and ultimately, each result to different degrees in opsonization, anaphylotoxin production and MAC formation. Regulation of the complement cascade is complex, involving proteins that mediate the degradation of complement components into inactive fragments, as well as other inhibitory proteins capable of irreversible binding to and inactivation of complement proteins. The γ-HVs have taken advantage of this complexity by encoding viral genes that interfere with this regulation which are outlined in Table 31.1.

KSHV encodes a homologue of the human complement control protein CD46 (Neipel *et al.*, 1997a,b). Like its human homologue, the ORF4 gene product, termed KCP or Kaposica, contains four short consensus (SCR) or sushi domains. These domains are characteristic of the cellular regulators of complement activation (RCA) (Klickstein *et al.*, 1987; Law, 1988). The SCR are typically 60–70 amino acids in length and contain four conserved cysteine residues, which are disulfide-linked. KCP/Kaposica is encoded from a 1650 nucleotide long open reading frame and work by Spiller *et al.* (2003) has demonstrated that it is expressed as three alternatively spliced constructs, an unspliced 550 residue form and two singly spliced forms of 425 residues and 347 residues (depicted in Fig. 31.2). All three forms retain the putative membrane-spanning region. The unspliced product (ORF4-F) has 14 N-X-S/T, consensus N-linked glycosylation sites. However, the NetNGlyc neural network N-linked glycosylation prediction program (http://www.cbs.dtu.dk/services/NetNGlyc) (Gupta *et al.* 2002), indicates that only 10 of these have a significant probability of being glycosylated. The other two forms, designated ORF4-M and ORF4-S, have five and four probable sites, respectively. Additionally, ORF4-F has potential for modification by O-linked glycosylation in a serine/threonine-rich region just upstream of the predicted transmembrane domain, while the other forms lack this region. Examination of the lysates of TPA-treated PEL cells showed three anti-ORF4 antibody reactive bands at 175 kD, 82 kD and 62 kD (Spiller *et al.*, 2003). Examination of culture supernatants demonstrated the presence of only the two more slowly migrating forms. At this time, the contribution of glycosylation or additional post-translational modifications to the higher than predicted molecular weights of these products or differences in the functioning of each product has not been clarified. Since all of the proposed products maintain a trans-membrane domain, the mechanism of secretion also needs further investigation.

KCP/Kaposica strongly enhances the decay of the classical C3 convertase (C4b2a) but poorly promotes decay of the alternative pathway C3 convertase (C3bBbP) compared with the host complement control proteins (Mullick *et al.*, 2003; Spiller *et al.*, 2003). It acts as a co-factor to aid Factor I (fI), a major cellular complement control protein, in its degradation of both C4b and C3b (Fig. 31.1). Unlike cellular fI co-factors, however, KCP/Kaposica is able to drive production of the C3d complement protein as a final product of fI-mediated cleavage of iC3b (Spiller *et al.*, 2003). Production of this molecule is usually driven by a cellular protease in a non-fi-dependent manner. In addition to accelerating decay of the C3 convertase, thus preventing the action of complement, this production of C3d by KCP/Kaposica probably plays an additional role in KSHV biology. The C3d molecule is capable of binding to complement receptor 2 (CR2, CD21), which complexes with CD19 and CD81, resulting in a dramatic increase in B cell responsiveness to B cell receptor stimulation (Dempsey *et al.*, 1996). So, the actions of KCP/Kaposica likely have some effects on B cell production of antibodies in response to viral antigens. Whether this directly alters anti-viral responses or aids the

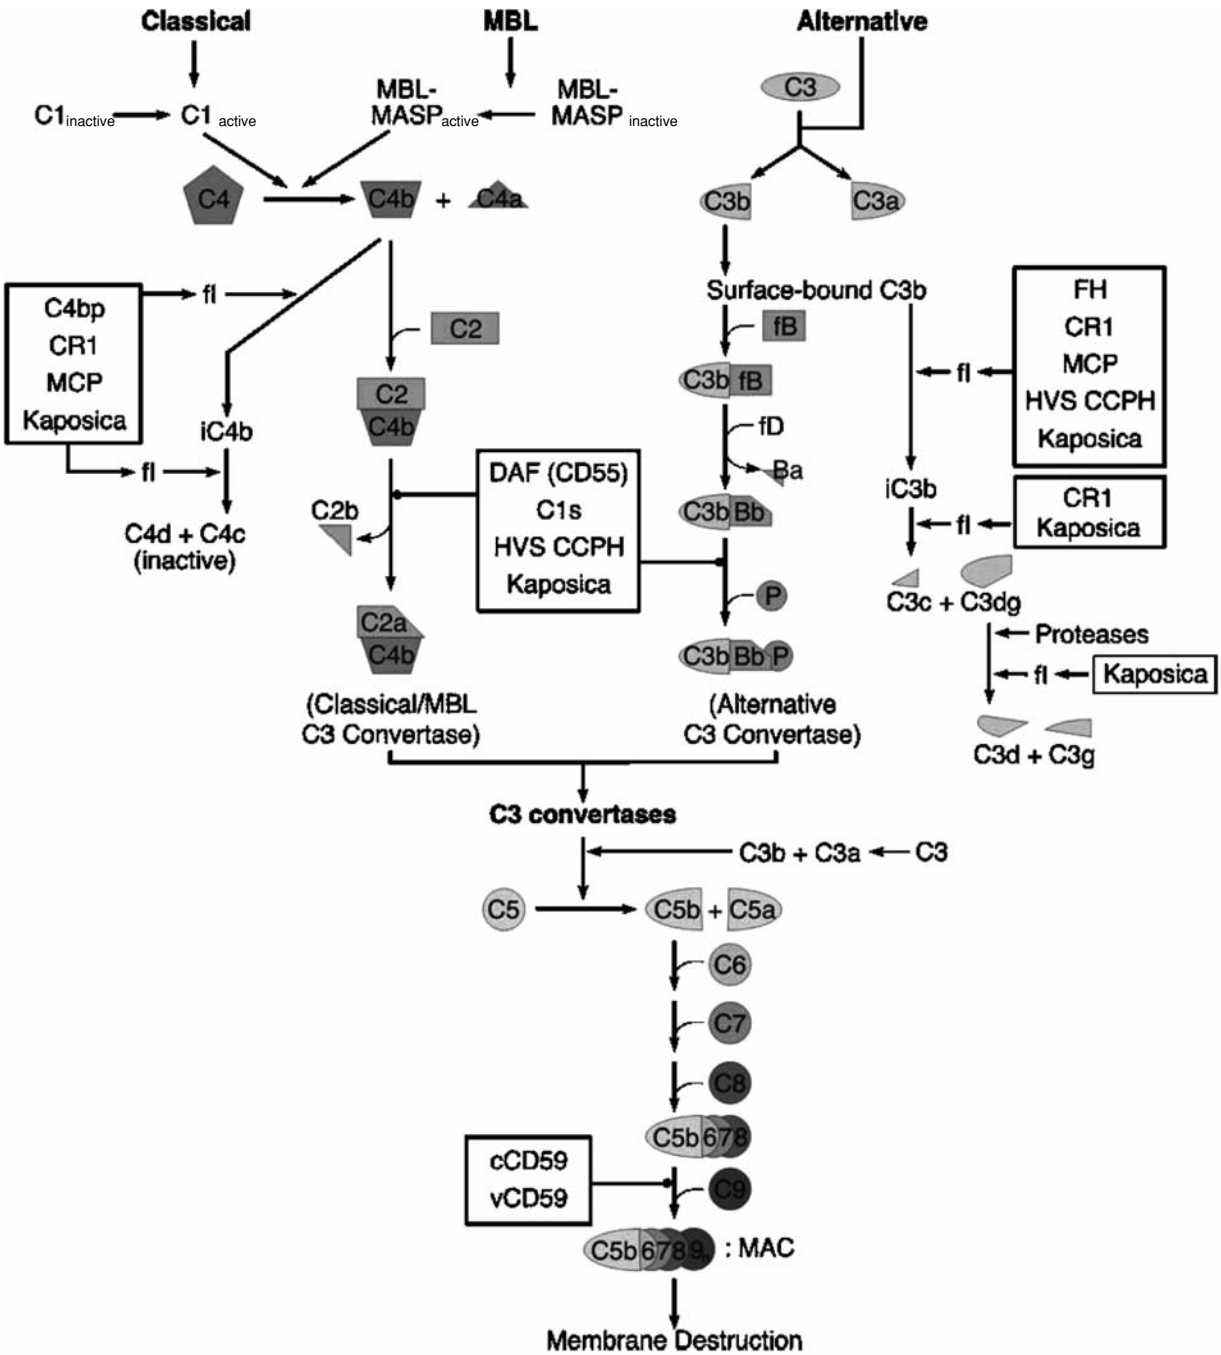

Fig. 31.1. Outline of the Complement cascade with interfering herpesvirus products noted. The complement cascade is a complex series of zymogens and regulating proteolytic enzymes. This high-level of complexity gives multiple opportunities for intervention by the herpesviruses. Additional details are given in the text.

Table 31.1. Viral complement regulators. Complement forms an important facet of the innate immune response. Not only does it play a role in direct defense, through lysis of infected cells or enveloped viruses, but it also helps to co-ordinate later adaptive responses. Both human γ-herpesviruses encode gene products with the potential to alter the complement response. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	ORF4	KCP/Kaposica	Homologue of human CD46, accelerates the decay of the C3 convertases and drives production of C3d, which binds complement receptor 2 (CR2)
EBV	BLLF1a/b	gp350/220	Binds to CR2, might interfere with complement mediated B cell stimulation or aid in viral dissemination

Fig. 31.2. Products of the Kaposica/KCP open reading frame. The Kaposica/KCP open reading frame has multiple splice forms. Regions in bold are shared by all three isoforms. The underlined region is found in both the M and F forms. Green residues indicate the location of the potential transmembrane domain. Blue residues indicate areas of potential N-linked glycosylation with the first residue colored red if the NetNGlyc neural network prediction program determined that that site was above the predicted probability threshold for glycosylation.

virus in recruiting additional target cells or possibly altering viral entry is still unclear.

While no EBV-encoded proteins to date have been shown to have a direct effect on complement regulation, EBV also targets CR2. The gp350/220 viral envelope protein is capable of binding to and mediating viral entry into $CD21^+$ cells. The binding of gp350/220 to CR2, while not identical to C3d, probably overlaps the complement binding region (Moore *et al.*, 1991; Prota *et al.*, 2002). However, it is currently unclear if binding to this receptor by EBV significantly alters complement activation or responses. Again, it is possible that the virus utilizes this ability to aid in dissemination without effects on complement. It is clear, however, that binding of EBV or the gp350/220 glycoprotein to CR2 has effects on cytokine production and survival for several cell types and will be discussed in later sections.

A number of other viruses have been shown to incorporate host complement regulatory proteins into their

envelopes including human cytomegalovirus and HIV (Saifuddin *et al.*, 1994; Spiller *et al.*, 1996). While no experimental evidence has yet been shown for a similar strategy employed by the human γ-HVs, this is a tantalizing possibility.

Cytokine responses

The cytokines are a large number of mostly soluble proteins, able to bind to a wide variety of cellular receptors expressed both on other immune effectors and non-immune related host cells. Through binding to their receptors they can induce proliferation, differentiation and activation both in the producer cell (autocrine effects) and in other targets (paracrine effects). Included in this large group of proteins are several super-families of proteins including the interleukins, interferons and chemokines. Generally, the interleukins (usually given an IL designation) are proteins that are produced by one leukocyte and act on another, however numerous examples exist that don't fall into this general definition. These proteins act to attract and activate a number of immune effector cells, activate the host acute-phase response and drive the differentiation of cells to result in a polarized immune response. The interferons (IFNs) are an evolutionarily conserved group of proteins that play a crucial role in the innate response to viruses. These proteins are able to mediate signaling through their receptors to induce the expression of a large number of cellular proteins that are able to alter cellular physiology to be less hospitable for viral replication. The chemokines interact with cellular 7-transmembrane, G-protein-coupled receptors (GPCRs) stimulating leukocyte trafficking and development, as well as regulating angiogenesis. Crucial to immune system functioning is their ability to recruit various effector cells to the site of inflammation. The spectrum of chemokines that are produced govern which cells respond to the site of inflammation and have a large influence in directing how the immune system reacts to invading pathogens. The signals that these cytokines transmit to the cells can stimulate the production of additional cytokines and chemokines, providing a complex cross-talk evolved to coordinate an effective immune response.

Two main subpopulations of $CD4^+$ T lymphocytes, termed T helper (Th)1 and Th2 cells, coordinate the type of immune response that is made to an infecting pathogen. Th1 cells predominantly secrete IFN-γ, GM-CSF and TNF-α, but also secrete TNF-β, IL-3 and IL-2. Additionally, they usually express CD40 ligand and/or CD95 ligand on their surface. These types of cells act to activate macrophages, direct B-cells to produce opsonizing antibodies and cause inflammatory cell infiltration of tissues. Thus, the Th1 cells select for cell-mediated immune responses against pathogens. Th2 cells secrete IL-4 and IL-5, but also IL-10, TGF-β, eotaxin and IL-3. They also express CD40 on their surface. These types of cells act to activate antigen-specific B-cells to produce neutralizing antibodies and thus direct the immune effectors toward a humoral response against the invading pathogen. Additionally, the cytokines released by Th2 cells tend to inhibit inflammation. These two populations of T-lymphocytes result from the differentiation of naïve $CD4^+$ T-cells in response to the cytokine milieu, cytokines which have been released from either infected cells or other immune effectors such as NK cells. Shifts in the dominance of Th1 or Th2 immune effectors can dramatically influence the type and importantly, the effectiveness of responses made against invading pathogens.

Interleukin and chemokine responses

KSHV expresses multiple chemokine homologues, homologues of the macrophage inflammatory proteins, vMIP-I, -II and –III, a homologue of the cellular IL-6 protein and a homologue of the cellular Ox2 protein, which is involved in the release of a number of different cytokines. A summary of these gene products is outlined in Table 31.2. The viral MIPs are able to bind to a variety of cellular chemokine receptors, acting as agonist and antagonists (Boshoff *et al.*, 1997; Kledal *et al.*, 1997; Sozzani *et al.*, 1998; Dairaghi *et al.*, 1999; Endres *et al.*, 1999; Stine *et al.*, 2000). The gene products of ORFs K6 and K4 of KSHV, vMIP-I (vCCL1) and v-MIP-II (vCCL2) respectively, share homology with the cellular CC chemokine macrophage inflammatory protein-1 alpha (MIP-1α) (Moore *et al.*, 1996; Neipel *et al.*, 1997a,b). The similar size of the K6 (95 residues) and K4 (94 residues) products and their high degree of sequence identity suggest that they arose through a gene duplication event. The third chemokine homologue, vMIP-III (vBCK, vCCL3) is 114 residues in length, encoded by the K4.1 ORF and has homology with MIP-1β as well as several other members of the cellular CC chemokine family (Neipel *et al.*, 1997a,b; Stine *et al.*, 2000). The target of the vMIPs seems to be the Th2 lineage $CD4^+$ T cells based on the fact that vMIP-I can act to induce chemotaxis of CCR8-bearing cells; vMIP-II, chemotaxis of CCR3-bearing cells; vMIP-III chemotaxis of CCR4 -bearing cells, and all of these receptors are found on Th2 cells (Sallusto *et al.*, 1998) (Fig. 31.3). Each of the vMIPs have been shown to induce the chemotaxis of Th2 cells (Stine *et al.*, 2000). Further, Weber *et al.* demonstrated that vMIP-II is able to block the chemotaxtic effects of RANTES on Th1 cells and monocytes, thus inhibiting their recruitment to sites of vMIP production (Weber *et al.*, 2001) (Fig. 31.3). Nakano *et al.* (2003), in contrast, demonstrated

Table 31.2. Viral chemokine regulators. Recruitment of immune effectors is critical to the generation of an effective immune response. The soluble chemokines play a large role in this recruitment. Both human γ-herpesviruses encode multiple gene products with the potential to alter the chemokine response. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	K6	vMIP-I (vCCL1)	Alters chemotaxis, causes Th2 polarization, neo-angiogenesis, VEGF-A elicitation
	K4	vMIP-II (vCCL2)	Alters chemotaxis, causes Th2 polarization, neo-angiogenesis
	K4.1	vMIP-III (vCCL3, vBCK)	Alters chemotaxis, causes Th2 polarization
	K2	vIL-6	Acts as growth factor, stimulates elicitation of VEGF-B, causes Th2 polarization and Th1 inhibition, activates multiple signaling cascades
	Orf13	vFLIP	Binds TRAF2 causing the induction of cIL-6, causes Th2 polarization, acts as a growth factor
	K14	vOX2	Stimulates macrophage/monocytes to release IL-1β, IL-6, MCP, causes Th2 polarization, may have role in viral dissemination
EBV	LMP-1/EBI-3	cIL-12 subunit	Alters IL-12 signaling, Th2 polarization, might alter IL-4 and IFN-γ production, might effect NKT cells
	BCRF-1	vIL-10	Blocks IFN-γ and IL-2 production, inhibits dendritic cell maturation, Th2 polarization

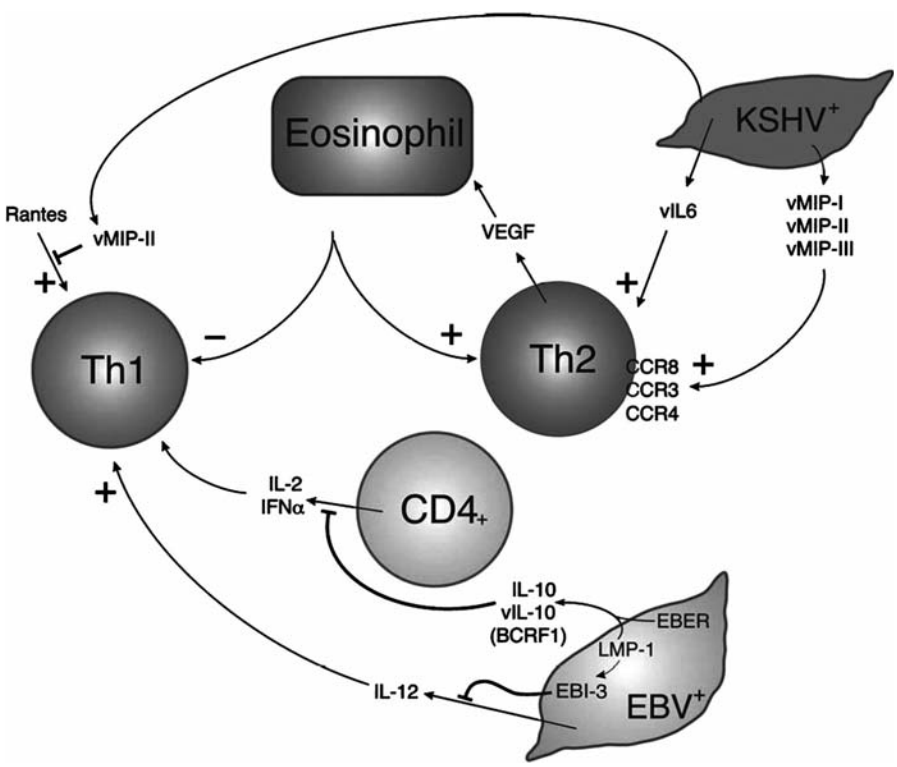

Fig. 31.3. Herpesvirus skewing of the Th1/Th2 balance by multiple gene products. Both KSHV and EBV express multiple gene products that mimic cellular cytokines. These proteins have multiple effects on a number of immune effectors including the $CD4^+$ T helper cells, further detailed in the text. The web of viral and cellular cytokines have a net effect of favoring a Th2, humoral response.

that vMIP-I and –II induced chemotaxis of a monocyte cell line. However, these two groups used different experimental designs and much different target cells, a transformed monocyte cell line versus primary monocytes. The majority of the published data suggests that it is to the advantage of the virus to polarize the immune response to a Th2 pattern, suggesting that cellular adaptive immune responses are more likely to clear the virus from the body.

The vMIP proteins are also likely to have other effects in addition to their role in immune evasion. Both the vMIP-I and –II proteins are highly angiogenic in the chorioallantoic assay (Boshoff *et al.*, 1997). Additionally, vMIP-1 can induce chemotaxis of endothelial cells through its interactions with the CCR8 receptor (Endres *et al.*, 1999). Combined, this suggests that the vMIP proteins might be playing a large part in directing the development of the structure of the vascular KS lesions. Liu *et al.* (2001) have shown that addition of the vMIP-I protein to PEL cell lines resulted in the expression of vascular endothelial growth factor type A (VEGF-A). This VEGF-A can have both paracrine and autocrine effects, influencing PEL cell growth, extravasation and recruitment of other cells such as eosinophils, which can release Th2-type cytokines (Weber *et al.*, 2001; Feistritzer *et al.*, 2003) (Fig. 31.3). Again, pointing to a dual role for the vMIP proteins in directing KS lesion formation as well as altering anti-viral immune responses.

Further, supporting the thesis that KSHV better survives a Th2-biased immune response, the virus produces yet another soluble factor which favors the development of a Th2 response. Viral IL-6, encoded by KSHV ORF K2 is 204 residues in length and has approximately 25% homology with human IL-6 (Neipel *et al.*, 1997a,b; Nicholas *et al.*, 1997). Message for vIL-6 is very rapidly transcribed after infection (within 2 hours) and then is just as quickly downregulated, disappearing by 8 hours post-infection (Krishnan *et al.*, 2004). Cellular IL-6 (cIL-6) performs multiple functions, including inducing the differentiation of B-cells into antibody-secreting plasma cells (Beagley *et al.*, 1989). It promotes Th2 differentiation and simultaneously inhibits Th1 polarization through two independent molecular mechanisms. It also acts as both an autocrine and paracrine growth factor, delivering a signal through the IL-6 receptor, a heterodimer made up of gp80 and gp130 (Kawano *et al.*, 1988; Klein *et al.*, 1989; Kishimoto *et al.*, 1995; Nakashima and Taga, 1998) (Fig. 31.3). This signal in many ways resembles the signal transmitted by INF-α/β interactions with its receptor, proceeding through members of the JAK kinase family to transmit a signal to the cellular STAT3, which can then stimulate transcription of a group of IL-6 responsive genes (Murakami *et al.*, 1993; Narazaki *et al.*, 1994; Stahl *et al.*, 1994; Guschin *et al.*, 1995). Additionally, STAT1 also becomes phosphorylated, dimerizing with STAT3 to bind and transactivate genes containing interferon-inducible GAS sequences (Feldman *et al.* 1994; Lutticken *et al.*, 1994; Wegenka *et al.*, 1994; Guschin *et al.*, 1995). The stimulation of cells with cIL-6 also causes the phosphorylation of STAT5 and the induction of the MAP kinase pathway (Diehl and Rincon, 2002).

The KSHV vIL-6 protein, like cIL-6, has been shown to perform numerous functions. It is capable of activating STAT1, 3 and 5, as well as the MAP kinase signaling cascade (Molden *et al.*, 1997; Osborne *et al.*, 1999; Hideshima *et al.*, 2000). However, unlike cIL-6, only the gp130 subunit of the IL-6 receptor is required, although the gp80 subunit can allow vIL-6 to signal more promiscuously (Molden *et al.*, 1997; Aoki *et al.*, 1999; Wan *et al.*, 1999; Li *et al.*, 2001; Klouche *et al.*, 2002; Li and Nicholas, 2002). This ability to signal through the gp130 subunit alone probably allows vIL-6 to continue to transmit anti-apoptotic and growth stimulatory signals even after down regulation of the p80 protein, a normal cellular response to cIL-6 signaling. KSHV vIL-6 likely plays a critical role in the pathology of the virus. There are greater levels of expression in MCD and PEL samples than KS lesion samples, and one group has demonstrated high level vIL-6 production in KSHV-associated germinotropic lymphoproliferative disorder, a rare, newly described disease (Boshoff *et al.*, 1996; Parravinci *et al.*, 1997; Staskus *et al.*, 1997; Du *et al.*, 2002). Both cIL-6 and vIL-6 transmit a proliferative signal to PEL cell lines, both through induction of VEGF-B and induction of pro-survival pathways (Neipel *et al.*, 1997a,b; Nicholas *et al.*, 1997; Burger *et al.*, 1998; Jones *et al.*, 1999; Hideshima *et al.*, 2000; Liu *et al.*, 2001). Although there is great overlap in the functions of vIL-6, Foussat *et al.* demonstrated a clear need for cIL-6 in PEL cell tumor progression in mice (Foussat *et al.*, 1999). Antibodies against cIL-6 slowed tumor growth even though vIL-6 was still being produced. In addition to a role of vIL-6 in delivering a positive growth signal and protecting from programmed cell death, it probably plays additional roles important to immune effector avoidance. As described above, cIL-6 is critical in driving immunoglobulin production from committed B-cells. The KSHV vIL-6 probably plays a similar role, further polarizing the immune responses, along with the other virally-encoded or –induced cytokines, toward a Th2 response. More recently, Klouche *et al.* demonstrated that unlike cIL-6, vIL-6 can induce the production of pentraxin-3 (PTX-3, TSG14) (Alles *et al.*, 1994; Klouche *et al.*, 2002). This acute-phase protein is capable of binding to apoptotic cells and preventing their recognition by dendritic cells, possibly preventing auto-immunity during the acute phase response in which there is a high amount

of cell death (Rovere *et al.*, 2000). Therefore, it is possible that the production of PTX-3 by vIL-6 helps to reduce recognition of virally-infected cells by APC. However, since PTX-3 only binds to C1q, the initiating protein of the classical complement pathway, or the surface of cells undergoing programmed cell death, the ability of vIL-6 to aid in immune avoidance through this mechanism requires additional experimental examination (Rovere *et al.*, 2000; Mantovani *et al.*, 2003; Nauta *et al.*, 2003). Further underlining a potentially high importance of IL-6 to KSHV persistence or replication is the finding that the vFLIP protein, discussed later in detail, can induce the production of cIL-6 through interactions with TRAF2, which activates the JNK/AP1 pathway and induces IL-6 synthesis (An *et al.*, 2003).

The cellular OX2 protein (CD200) plays a role in co-stimulation of activated T-cells and suppression of monocyte lineage cell responses (Borriello *et al.*, 1997; Gorczynski *et al.*, 1999). It has been shown to provide a co-stimulatory signal for activated T-cells, leading to an increase in IL-4 and TGF-β, but not IL-2 production (Borriello *et al.*, 1997). In contrast OX2 delivers a negative signal to macrophage and monocytes, inhibiting their proliferation (Gorczynski *et al.*, 1998; Gorczynski *et al.*, 1999). Work by Foster-Cuevas *et al.* (2004) has shown that the interaction of OX2 with its receptor (CD200R) on activated macrophages results in a block to TNF-α production. In mice lacking OX2, dramatic increases in the macrophage and monocyte populations in the mesenteric lymph nodes supports the hypothesis that OX2 plays a role in negatively regulating these cell populations (Gorczynski *et al.*, 1999).

KSHV encodes a gene product from ORF K14 with approximately 40% homology with human OX2. This viral protein is 271 residues in length, migrates with an apparent molecular weight of 55kDa and contains five putative N-linked glycosylation sites (Chung *et al.*, 2002). The higher than predicted molecular weight and experiments with N-glycosidases suggest that all of the putative carbohydrate modification sites are used (Chung *et al.*, 2002). The expression of vOX2 protein is increased after TPA-treatment of PEL cell lines. Although this homology is rather low it is still able to bind to CD200R with affinity and kinetics similar to OX2 (Foster-Cuevas *et al.*, 2004). The biological activity of this viral OX2 is controversial. The experimental work of Chung *et al.* (2002) demonstrated that the viral protein, provided as a soluble GST-coupled protein, delivers a stimulatory signal to macrophage/monocyte and dendritic cells causing them to elicit several pro-inflamatory cytokines including interleukin-1β (IL-1β), IL-6, monocyte chemoattractant protein 1 (MCP-1), and TNF-alpha. Further, expression of vOX2 on the surface of a B-cell line could stimulate the production of TNF-α and IL-12 from U937 cells in the presence of IFN-γ. In contrast, Barclay's group found that when vOX2 expressed on the surface of Chinese hamster ovary (CHO) cells was presented to human peripheral monocyte-derived macrophages there was no increase in TNF-α production (Foster-Cuevas *et al.*, 2004). To the contrary, there was an inhibition of TNF-α production, similar to what was seen when cOX2 was delivered in a similar manner. Reductions were also seen in the amounts of MCP-1 and G-CSF. However, the experimental methodologies of these two groups were radically different. It is a distinct possibility that the two groups were measuring the effects of vOX2 on different receptors. Further experimental verification is still required to determine the biological activity of this protein. The exact role of this protein and the advantage it conveys upon this virus also still requires further study. One possibility is that the virus is altering the cytokine response profile to control or misdirect anti-viral immune effector proliferation and recruitment. Increases in IL-6 production would be expected to bias $CD4^+$ Th2 cell generation. However, it is also possible that the virus is utilizing cellular cytokines to induce proliferation/recruitment of additional target cells as well as facilitating cytokine-mediated angiogenic proliferation to aid in viral dissemination. If vOX2 has a negative effect on monocyte stimulation it could be acting within KS lesions to block responses from the local infiltrating macrophages which could recruit other immune effectors.

EBV expresses a variety of genes that influence the cellular cytokine milieu. As mentioned previously, LMP-1 induces the expression of EBI-3 resulting in decrease in IL-12 production and increases in IL-27 secretion (Devergne *et al.*, 1996, 1997). This has effects on IFN-γ and Th1 responses from both monocytes and $CD4^+$ T cells (Nieuwenhuis *et al.*, 2002; Pflanz *et al.*, 2002) (Fig. 31.3). Further, the BCRF1 gene, a homologue of IL-10, also modulates cytokine production. Its expression limits the production of both IL-1 and IL-2 from $CD4^+$ T-cells (de Waal Malefyt *et al.*, 1991; Liu *et al.*, 1997; Zeidler *et al.*, 1997; Hayes *et al.*, 1999). vIL-10 can also alter the responsiveness of dendritic cells to MIP-1α and MIP-1β. Although vIL-10 is expressed during the lytic program, LMP1 and the EBERs have been shown to induce production of cIL-10. Examination of immune responses against epitopes in LMP1 in EBV^+ and EBV^- individuals demonstrated that the majority of responding cells were Th1 cells, which secrete IL-10, suppressing T-cell proliferation and IFN-γ production (Marshall *et al.*, 2003) (Fig. 31.3). In addition to these specific genes that have been mentioned, EBV likely possesses a number of additional mechanisms for altering the host chemokine and cytokine profile. These changes seem to play a large role in driving the pathophysiology of EBV infection.

As is seen for KSHV, EBV seems to alter the cytokine milieu to favor the development of a Th2 response. The IL-12 protein influences naïve CD4 T-cells to differentiate toward a Th1 profile. EBI-3 decreases IL-12 production, thus reducing one pro-Th1 factor. Further cellular IL-10 can inhibit Th1 cell generation. The BCRF1 viral protein likely plays a similar role and additionally, like cellular IL-10, inhibits the Th1 cytokines IL-2 and IFN-γ. Again, further in vivo investigation is required to better understand the correlates of an effective immune response against the γ-HVs.

Interferon responses

The interferons (IFN) are a family of critically important cytokines that act to modulate cell proliferation and play an important role in innate and adaptive immunity. The type I IFN-α/β and IFN-ω are produced by virally infected cells, whereas the type II IFN-γ is produced by innate immune system effectors cells, as well as adaptive response effectors such as Th1 cells and $CD8^+$ cells (Biron *et al.*, 1999). These proteins act by binding a variety of cell surface receptors and transmitting a signal through the Janus protein kinases (JAKs) and signal transducers and activators of transcription (STATs) to induce expression of a variety of interferon response factors (IRFs) (reviewed in Leonard, 2001; Sato *et al.*, 2001; Taniguchi *et al.*, 2001). In turn, these IRFs regulate the transcription of a wide variety of genes containing either IFN-stimulated response elements (ISRE) or γ-interferon activation sequences (GAS) in their promoters. Regulated proteins include multiple protein kinases, the tumor necrosis factor receptor and MHC class I and class II proteins (Pober *et al.*, 1983; Collins *et al.*, 1984; Boehm *et al.*, 1997; Stark *et al.*, 1998). The interferon responsive proteins act to induce an anti-viral state in the expressing cells, targeting multiple steps in the life cycle of the virus. For example, through the action of the IFN-responsive oligoadenylate synthase, RNase L is activated. This endoribonuclease is active against double-stranded RNA (dsRNA), thus targeting those viruses with either dsRNA genomes, such as the *Reoviridae* (Miyamoto *et al.*, 1983), or containing extensive dsRNA structure, such as the *Picornaviridae* (Robberson *et al.*, 1982). Another major IFN-inducible gene is the protein kinase PKR, capable of phosphorylating the eIF-2α initiation factor, inhibiting mRNA translation and blocking the production of viral proteins (Thomis and Samuel, 1992). Yet a third major antiviral interferon response is the induction of the MxA protein. MxA is a dynamin-like GTPase that is able to bind to the nucleocapsids of some viruses altering their intracellular transport (Haller and Kochs, 2002; Kochs *et al.*, 2002). Further, the IFNs are able to stimulate the production of a number of other chemokines and cytokines, influencing the immune response to invading pathogens.

Activation of the IFN response can occur in at least two ways. First, as described above, binding of interferon to its cognate receptor on the surface of the cell transmits a signal that modulates the IRFs. However, this mechanism requires that IFNs already have been synthesized, either by the responding cell or a surrounding cell. Activation can also occur by a much more direct method. The cellular IRF-3 is part of a complex of proteins called the double-stranded RNA-activated transcription factor complex (DRAF1), which also includes p300/CREB binding protein (CBP) (Weaver *et al.*, 1998). DRAF1 is sensitive to the presence of dsRNA and becomes serine/threonine phosphorylated upon viral infection. This results in a nuclear accumulation of DRAF1, where it binds to and activates ISRE sequences (Kumar *et al.*, 2000). This results in the up regulation of a number of "interferon-responsive" genes as well as production of IFN-α and -β, which can then act in both autocrine and paracrine activation of the interferon pathway (Weaver *et al.*, 1998). A schematic of the multiple mechanisms that the herpesviruses use to interfere with the IFN response pathway is given in Fig. 31.4 and detailed in the text below.

KSHV was the first virus identified as carrying an IRF (Moore *et al.*, 1996). The K9 protein, vIRF-1, is a 449 residue product with some limited homology to the cellular IRFs (Moore *et al.*, 1996). It is capable of inhibiting both type I and II interferon signaling and additionally has transforming activity (Gao *et al.*, 1997; Li *et al.*, 1997; Inagi *et al.*, 1999) (Table 31.3). Expression in NIH 3T3 cells allows growth in soft agar and at low serum concentration (Gao *et al.*, 1997). Further, these vIRF-1-expressing NIH 3T3 cells lose contact inhibition and are tumorigenic in nude mice. These activities of vIRF-1 are the result of interactions with multiple cellular proteins including the cellular IRF-1 and IRF-3 transcription factors, however it does not effect IRF-7-mediated transactivation (Lin *et al.*, 2001). Interactions with these cellular IRFs block production of IFN-β and the RANTES chemokine, important in directing the infiltration of a number of leukocytes including NK and effector T-cells (Lin *et al.*, 2001). These interactions also block the ability of IRF-1 and IRF-3 to direct transcription from the ISG and IFNA4 promoters. However, at least for IRF-3, binding by vIRF-1 did not effect dimerization, nuclear translocation and DNA binding activity. Rather, vIRF-1 interacted with the p300/CBP and efficiently inhibited the formation of transcriptionally competent IRF-3-CBP/p300 complexes (Lin *et al.*, 2001). The further implications of the ability of vIRF-1 to interact with p300/CBP will be discussed later. Additionally, the interaction of

Table 31.3. Viral interferon regulators. Both human γ-herpesviruses encode multiple gene products with the potential to alter the IFN response. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	K9	vIRF-1	Blocks IFN-a, -β and -γ effects and production, anti-apoptotic, transforming
	K11.1	vIRF-2	Blocks IFN-α and -β effects, anti-apoptotic
	K11	?	?
	K10.5/10.6	vIRF-3/LNA-2	Inhibits IFN-α and -β production
	K2	vIL-6	Blocks IFN-α activation of p21CIP1/WAF1, allowing cell cycle progression
	ORF45	KIE-2	Reduces IFN-a production through inhibition of IRF-7 function
	ORF10	RIF	Blocks STAT1, STAT2 and Tyk2 phosphorylation, reducing ISG production
EBV	BCRF1	vIL-10	Blocks IFN-γ and IL-2 production, inhibits dendritic cell maturation, Th2 polarization
	BZLF1	ZTA	Blocks STAT1 activation, MHC class II up regulation and IFN-γ production, anti-apoptotic, disperses PML bodies
	BARF1	vCSF-1R	Blocks IFN-α production, inhibits macrophage proliferation, transforming
	LMP-1/EBI-3	cIL-12 subunit	Alters IL-12 signaling, Th2 polarization, might alter IL-4 and IFN-γ production, might effect NKT cells

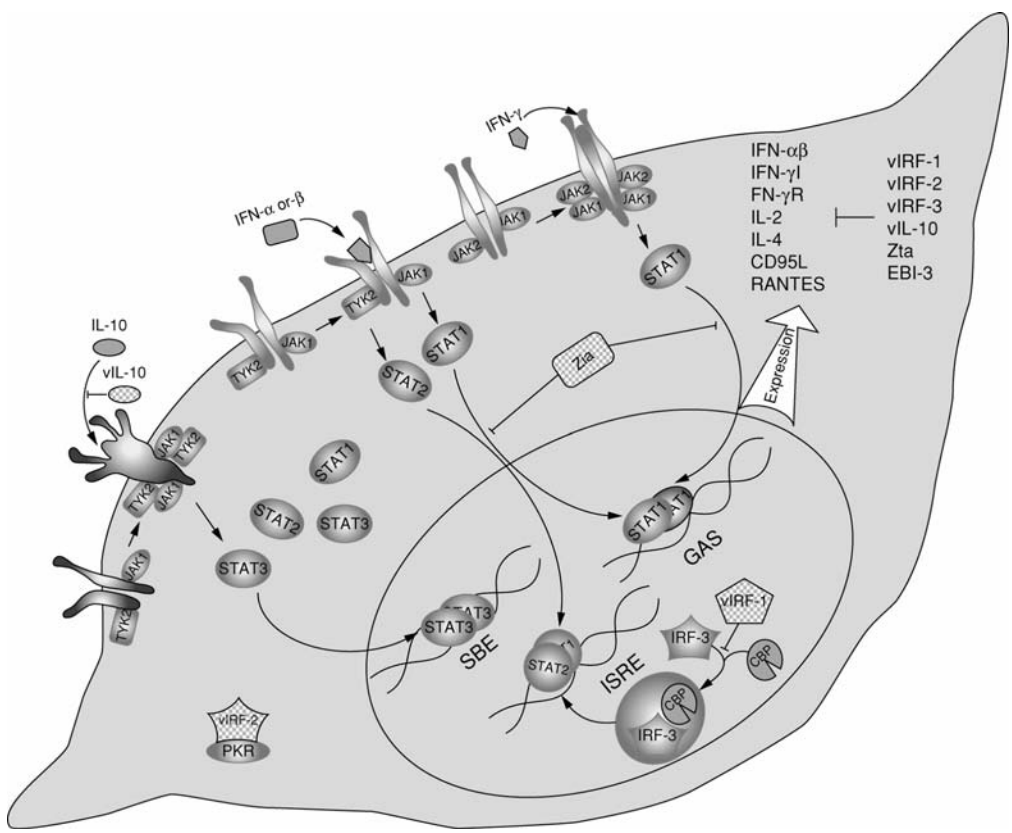

Fig. 31.4. Viral proteins involved in control of the anti-viral IFN responses. A number of γ-HV proteins, detailed in the text and shown in a checkered pattern, are capable of interfering with the IFN responses. Some prevent STAT assembly on GAS, ISRE or STAT binding element (SBE) DNA sequences in the nucleus. Others interfere with the down stream products of the IFN response, such as the binding of PKR by vIRF-2. Additional mechanisms of interference are discussed in the text.

vIRF-1 with the cellular IRF-1 is likely responsible for its ability to suppress CD95L up-regulation and FAS mediated cell death after TCR/CD3 stimulation (Kirchhoff *et al.*, 2002). However, this effect might also be a result of interactions with p300/CBP. More recently, the group of Seo *et al.* (2002) identified an additional binding partner of vIRF-1, retinoid-IFN-induced-mortality-19 (GRIM19). This gene enhances caspase-9 activity and induces apoptosis in response to signals from IFN and retinoic acid treatment of cells. vIRF-1 binding suppresses the ability of GRIM19 to induce apoptosis in HELA and MCF-7 cells. This inhibition of apoptosis through interactions with multiple transcription factors along with an ability to increase c-myc expression all contribute to the transformation ability of vIRF-1.

KSHV encodes three additional vIRFs, vIRF-2, a 489 bp ORF encoded by the ORFK11.1 gene and its close homologue encoded by the ORFK11 gene and vIRF–3, also termed LANA-2, encoded as a 1072 bp spliced product of the ORF K10.5 and 10.6 genes (Burysek *et al.*, 1999; Lubyova and Pitha, 2000). Over expression of these genes results in suppression of both IFN-α and -β signaling (Table 31.3). Unlike vIRF-1, the vIRF-2 protein does not seem to possess transforming activity (Burysek *et al.*, 1999). It is capable of binding to several cellular factors including IRF-1, IRF-2, interferon consensus sequence binding protein, RelA/p65 and CBP (Burysek *et al.*, 1999). vIRF-2 is capable of homodimerizing and binding to DNA encoding the NF-kB sequence (Burysek *et al.*, 1999). More recently it was shown that vIRF-2 is able to interact with the double-stranded RNA-activated protein kinase (PKR) and prevent its autophosphorylation (Burysek and Pitha, 2001). As detailed above, PKR targets the elongation initiation factor 2α (eIF-2α), critical to the initiation of protein synthesis, phosphorylating the GDP-bound inactive form. This phosphorylated form acts as a dominant negative, binding to the eIF-2β guanine nucleotide release factor, preventing the reloading of GTP onto other eIF-2α molecules, thus preventing the initiation of new rounds of protein synthesis (Thomis and Samuel, 1992). All of these abilities of vIRF-2 contribute to its ability to block the effects of the Type I interferons. Intriguingly, vIRF-2 transcripts are present at high levels within 2 hours of viral infection and then subside to undetectable levels by 8 hours post-infection (Krishnan *et al.*, 2004). Further, like vIRF-1, vIRF-2 is able to block FAS-mediated apoptosis through an ability to block up regulation of CD95L on the surface of expressing cells (Kirchhoff *et al.*, 2002).

The transcription pattern of vIRF-3 is more complicated than the other v-IRF genes. Its mRNA is a spliced product of two genomic regions previously thought to code for two separate proteins, ORF K10.6 and ORF K10.5 (Lubyova and Pitha, 2000). It has homology with the vIRF-2 and ORFK11 proteins as well as the cellular IRF-4 (Rivas *et al.*, 2001). It can block the activities of both IRF-3 and IRF-7 on the IFNA promoter, inhibiting the production of both α- and β-interferon (Lubyova and Pitha, 2000). More recent work from Rivas and colleagues has shown that vIRF-3 is able to block PKR-mediated apoptosis, but not oligoadenylate pathway-mediated apoptosis (Esteban *et al.*, 2003). In these studies the expression of vIRF-3 was able to prevent PKR mediated inhibition of protein synthesis, at least partially through a block to the phosphorylation of eIF-2α. Further, vIRF-3 was able to block the activation of caspase 3, a member of the FADD/caspase 8 pathway of apoptosis that is activated by PKR. However, no effects of vIRF-3 were observed on caspase 9, another PKR activated caspase. Since vIRF-2 also targets the PKR pathway, an exploration of the co-expression of these genes and their potentially additive effects on antiviral interferon responses would be interesting.

More recently, in a comprehensive screen of the KSHV lytic genes, Ganem's group identified a viral protein capable of blocking interferon signaling at a membrane proximal position, unlike the majority of KSHV gene products that block responses in the nucleus. ORF 10, now named RIF (regulator of Interferon Function), is able to block phosphorylation of STAT1, STAT2 and Tyk2 following IFN-α stimulation (A-L Page, SA Bisson and D Ganem, personal communication). Interestingly, this viral protein directly interacts with the STAT proteins, potentially blocking their multimerization. This mechanism seems distinct from that of the EBV BZLF1 gene product ZTA, which will be discussed in detail later in this section, as ZTA only blocks STAT1 phosphorylation following IFN-γ stimulation, not IFN-α (Morrison *et al.*, 2001).

The interferon responses typically take place very quickly after viral infection. Therefore, in order to persist within the host the virus must take immediate protective action. Zhu *et al.* have identified a KSHV protein encoded by ORF45 that is incorporated into the virus particle as a tegument protein (Zhu and Yuan, 2003). This protein, KIE-2, is able to bind to IRF-7, blocking its phosphorylation and accumulation in the nucleus (Zhu *et al.*, 2002). This results in a blockage of IFN-α and IFN-β transcription in response to viral infection. As its name suggests, KIE-2 is an immediate early protein of ~78kDa and is found within the cytoplasm of expressing cells. Based on the presence of the protein in preparations of purified virus and its resistance to detergent treatment combined with sensitivity to detergent plus trypsin suggests that this protein is found in the tegument of the virus. This protein, therefore, would be available to block the interferon responses immediately following viral infection.

KSHV possess yet an additional way of mitigating the effects of interferon on viral replication and persistence. The viral IL6 homologue is able to block the induction of $p21^{CIP1/WAF1}$, a cyclin-dependant kinase inhibitor, by IFN-α (Table 31.3). Normally treatment of cells results in an up regulation of this protein, arresting the cells in G_1/S (Chatterjee *et al.*, 2002). Further, treatment of cells with vIL-6 was shown to block the IFN-α stimulated binding of ISGF3 to ISRE probes. Interestingly, IFN-α downregulates the gp80 sub-unit of the IL-6 receptor blocking the ability of cIL-6 to transmit a signal. On the other hand, vIL-6 only requires the gp130 sub-unit to signal and thus, is not blocked by the down regulation of gp80. Additionally, vIL-6 expression is induced by IFN-α, providing a negative feedback loop to control this antiviral response in virally-infected cells.

One remaining question is why seven different gene products potentially involved in regulating the cellular IFN responses are encoded by the virus. Several non-exclusive answers exist. First, although each of the studied products possess similar functions, they are not identical. Given the importance of the IFN response in the control of other viruses, as well as a proven ability of interferon treatment to block KS progression in a large percentage of patients, this simplistic answer is probably also true (Von Roenn and Cianfrocca, 2001). Recent work by a number of groups using DNA array technology has pointed to another potential answer. When examining expression of each vIRF gene, it was found that the kinetics and tissue-expression of each differed (Jenner *et al.*, 2001; Paulose-Murphy *et al.*, 2001; Fakhari and Dittmer, 2002; Dittmer, 2003). Unlike vIRF-1, the vIRF-3/LANA-2 protein is detectable in primary effusion lymphoma (PEL) cell lines without TPA stimulation. The work of Fakhari and Dittmer demonstrated that the kinetics of vIRF-3/LANA-2 mRNA production mirrored that of LANA-1, v-FLIP and v-cyclin, all non-TPA induced, latency-associated genes in the BCBL-1 PEL cell line (Fakhari and Dittmer, 2002). In KS lesions, however, expression of vIRF-1 and not vIRF-3 clusters with LANA-1. So, a degree of tissue- or disease-specific expression might also contribute to the need for multiple genes to combat this facet of innate immunity. An understanding of the role of the vIRFs during infection is further complicated by the work of Pozharskaya *et al.* (2004). In experiments looking at vIRF-1 it was found that during latency in BCBL-1 PEL cells, only low levels of vIRF-1 are expressed and are not able to block the effects of IFN-α and while higher levels were initially expressed after TPA induction, these levels quickly fell off. Further, the vIL-6 gene is transcribed to high levels shortly after infection (Krishnan *et al.*, 2004). In summary, KSHV expresses multiple genes capable of blunting the production and effects of the interferon genes. These genes are expressed during both the lytic and latent programs, underlining the importance of the interferon proteins in the control of viral infection.

Like KSHV, EBV encodes multiple genes that help it avoid the antiviral effects of interferon. Among these are BCRF1, BZLF1 and BARF1 (Table 31.3). Additionally, viral infection induces the expression of a cellular protein named EBI-3, also involved in regulating the effects of interferon. The mature BCRF1 gene product (vIL-10) possesses 84% identity with cellular interleukin-10 (Hsu *et al.*, 1990). A 170 residue protein, it is expressed late in the lytic program, although one group reports expression of BCRF1 in a small number of patients with nasal type, extranodal natural killer (T(NK/T)-cell) lymphoma, which is usually associated with latent EBV infection (Swaminathan *et al.*, 1993; Xu *et al.*, 2001). This gene product indirectly effects the production of the type II IFN-γ by binding to the cellular IL-10 receptor. This results in a blockage of IL-2 and IFN-γ production (Liu *et al.*, 1997; Takayama *et al.*, 2001). Like cellular IL-10, vIL-10 can block the maturation of dendritic cells causing them to down regulate CCR7 and up regulate CCR5. This blunts their ability to stimulate T cell release of IFN-γ (Takayama *et al.*, 2001). In addition to aiding the virus in escape from IFN responses this has profound effects on CTL induction, which will be discussed in a later section of this chapter. Viruses containing a truncated BCRF1 protein or completely deleted for the gene were functionally similar to wild-type virus (Swaminathan *et al.*, 1993). Like the parental virus, BCRF1 deleted virus was able to transform B-lymphocytes into long-term lymphoblastoid cell lines (LCLs), and these LCLs were capable of inducing tumors in SCID mice to the same degree as wild-type derived LCLs (Swaminathan *et al.*, 1993). This suggests that BCRF1 is playing a larger role in immune regulation than in viral pathogenesis.

The BZLF1 gene expresses an immediate early viral protein with a wide number of functions. Not only is it important in directing the lytic replication program through its binding to the lytic origin of replication and within several of the early lytic gene promoters, but it also blocks tyrosine phosphorylation and nuclear translocation of STAT1, an important molecule in IFN response signaling (Kenney *et al.*, 1989; Rooney *et al.*, 1989; Packham *et al.*, 1990; Morrison *et al.*, 2001). Additionally, this protein blocks IRF-1 activation and decreases the amount of IFN-γ α-chain receptor expression (Morrison *et al.*, 2001). BZLF1 is able to decrease the ability of IFN-γ to activate a variety of important downstream target genes, such as IRF-1, p48, and CIITA, and prevents IFN-γ-induced class II MHC surface expression (Morrison *et al.*, 2001). Like BCRF1, not only does BZLF1 affect interferon responses, but it also

interferes with activation of helper T-cells and it possesses anti-apoptosis activity, both of which will be discussed in greater detail in later sections of this chapter. Interestingly, through competition for limiting amounts of the SUMO-1 protein, BZLF1 can also disperse nuclear PML bodies, which are induced by interferon and posited to have antiviral effects (Adamson and Kenney, 2001).

The BARF1 gene encodes a 31–33 kDa soluble receptor for colony stimulating factor 1 (CSF-1) that is expressed as an early lytic gene (Wei and Ooka, 1989; Strockbine *et al.*, 1998). Its expression inhibits macrophage proliferation and blocks IFN-α production by monocytes (Cohen and Lekstrom, 1999). Additionally, BARF1 can act as an oncogene when expressed in fibroblasts, B-lymphoma cells and monkey kidney cells (Wei and Ooka, 1989; Wei *et al.*, 1994, 1997). It increases c-myc, CD21 and CD23 expression and introduction into EBV^- Akata cells resulted in increased Bcl-2 expression and tumor induction in SCID mice (Wei *et al.*, 1994; Sheng *et al.*, 2001, 2003). However, Cohen and Lekstrom (1992) demonstrated that a $BARF1^-$ virus was competent for B cell transformation. Groups have reported that in both gastric adenocarcinomas and NPC, BARF1 is strongly expressed along with a number of the other latent proteins (Hayes *et al.*, 1999; Decaussin *et al.*, 2000; zur Hausen *et al.*, 2000). In the case of EBV positive gastric adenocarcinomas, this is in the absence of the LMP1 oncogene, giving greater weight to the ability of BARF1 to act as an oncogene, at least in certain tissues or cell-types. Fewer reports have been made concerning the potential immune evasion role of BARF1.

One final gene utilized by EBV to control the anti-viral interferon responses is encoded by the host and induced by the LMP1 protein (Devergne *et al.*, 1996, 1998). EBV-induced gene-3 (EBI-3) is a 34 kDa glycoprotein which localizes primarily to the ER of expressing cells (Devergne *et al.*, 1996). It is homologous to the IL-12 p40 subunit and can bind to IL-12 p35 (Devergne *et al.*, 1996). IL-12 normally triggers Th1 polarization of naïve $CD4^+$ T-cells, which then secrete IFN-γ. Recently, Pflanz and coworkers (Pflanz *et al.*, 2002) demonstrated that IL-27 is made up of a complex of EBI-3 and IL-12 p35. This interleukin is produced by activated antigen presenting cells and can drive expansion of naïve $CD4^+$ T cells, although the effects on EBV are not yet clear since IL-12 can synergize with IL-27 for IFN-γ production and effect both CTL and NK cell development (Pflanz *et al.*, 2002). An EBI-3-knockout mouse has normal numbers of most immune effectors except invariant natural killer T cells. This results in decreased IL-4 production and some decreases in IFN-γ production. The cellular EBI-3 protein, therefore, is playing a critical role in the generation of Th2 immune responses and its induction by EBV infection probably drives polarization of the anti-viral immune response (Nieuwenhuis *et al.*, 2002).

The LMP1 protein makes at least one potential additional contribution to viral avoidance of the interferon defenses. Quizzically, LMP1 induces the expression, activation and nuclear translocation of IRF-7, the same IRF that the KSHV ORF45 gene product inactivates (Zhang and Pagano, 2001; Zhang *et al.*, 2001). It has been shown that expression of LMP-1 in cells induces a number of ISGs and can block the replication of vesicular stomatitis virus (Zhang *et al.*, 2004). The paradoxical stimulation of what would seem to be an antiviral state within the cell most likely plays a role in controlling EBV latency and superinfection of EBV^+ cells by other viruses.

Thus, like KSHV, EBV encodes numerous proteins capable of altering the antiviral interferon responses. These proteins are expressed at multiple time points during the viral life cycle, highlighting how important the interferon responses are for the control of viral infections. Further examination of these groups of genes in an in vivo context should yield important information about how the interferon responses are modulated within the host.

Apoptosis responses

Apoptosis or programmed cell death plays a role both in innate immunity and normal cellular regulation. It is a mechanism by which intrinsic or extrinsic signals are capable of inducing cell death for the purposes of removing a diseased or unwanted cell from the body. Central to the intrinsic apoptotic responses are the members of the BCL-2 protein family. These proteins are capable of either inducing or suppressing apoptosis and possibly function through homo- or hetero-dimerizing with other family members, although this is controversial. The extrinsic responses, such as those triggered by $CD8^+$ CTL, largely depend on members of the tumor necrosis factor (TNF) receptor family. These receptors contain death response domains in their cytoplasmic tails and upon multimerization transmit a signal to the intracellular caspases that initiate the apoptosis response. It is critical that the γ-HV control apoptosis in order to insure that the infected cell is not eliminated prior to virion production.

Both EBV and KSHV encode homologues of the cellular Bcl-2 gene (Table 31.4). The KSHV Bcl-2 homologue (vBcl-2) is expressed from ORF16, but only possesses low homology with cellular Bcl-2 (Russo *et al.*, 1996; Neipel *et al.*, 1997a,b). Little is known of the mechanism of action of this protein. While it can inhibit Bax toxicity in yeast and fibroblasts, there is conflicting data concerning its ability to dimerize with the cellular Bcl-2 family members (Cheng

Table 31.4. Viral apoptosis regulators. Cellular suicide, whether self-induced or induced by other effectors, is an important immune response to control the replication and spread of viruses. Both human γ-herpesviruses encode multiple gene products with the potential to alter the cell suicide, apoptosis response. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	Orf16	vBcl-2	blocks both Bax and vCyclin induced apoptosis
	Orf13	vFLIP	up regulates Bcl-x(L) through the NF-kB pathway blocking starvation-mediated apoptosis, up regulates IL-6 in a TRAF2/JNK/AP1 dependent fashion, blocks Fas-mediated apoptosis, interferes with caspase-3, -8 and -9, tumorigenic
	K9	vIRF-1	binds IRFs, GRIM19, p53 and p300/CBP, blocks p53 and IFN + retinoic acid induced apoptosis
	K7	K7/vIAP	binds CAML, cBcl-2 and caspase-3, preserves mitochondrial membrane potential, blocks TRAIL, staurosporin and thapsigargin-induced apoptosis
EBV	BHRF1	vBcl-2	preserves mitochondrial membrane potential, blocks TRAIL and Fas-mediated apoptosis
	BCRF1	vBcl-2	binds HAX-1 and Bcl-2 through EBNA-LP effecting apoptosis
	BALF1	vBcl-2	binds Bax and Bak, can modulate BHRF1 activity
	BNLF1	LMP-1	increases Bcl-2, A20 and Traf1 expression blocking TNF-mediated apoptosis, can induce bfl-1 blocking p53-mediated apoptosis

et al., 1997; Sarid *et al.*, 1997). Additionally, vBcl-2 is capable of blocking the apoptosis induced by viral cyclin, so whether KSHV vBcl-2 is acting to protect virally infected cells against the extrinsic pro-apoptotic immune responses or intrinsic virally-mediated apoptotic responses is unclear (Ojala *et al.*, 1999, 2000).

In addition to a Bcl-2 homologue, KSHV also encodes a homologue of the cellular FLICE inhibitory protein, termed vFLIP (Chang *et al.*, 1994). It is expressed from ORF13 as a multi-cistronic transcript with ORF72 (vCyclin) and ORF73 (LANA) through either differential splicing or expression from an IRES element (Sarid *et al.*, 1999; Grundhoff and Ganem, 2001; Low *et al.*, 2001). FLICE, or caspase-8, is a member of the ICE family of cellular caspases, and is important in the apoptosis response (Muzio *et al.*, 1996). Interestingly, all three of these genes are transcribed rapidly after infection, underscoring a potential need to combat the apoptotic response soon after viral entry into cells (Krishnan *et al.*, 2004). The vFLIP protein has been shown to block pro-apoptotic signaling mediated by the Fas-receptor, resulting in decreases in caspase-8, -9 and –3 activity (Thome *et al.*, 1997; Djerbi *et al.*, 1999; Belanger *et al.*, 2001). A recent study has shown that vFLIP can target the NF-kB pathway, up regulating Bcl-x(L) resulting in protection of cells from serum withdrawal (Sun *et al.*, 2003). Additionally, vFLIP physically interacts with tumor necrosis factor receptor associated factor 2 (TRAF2) activating the JNK/AP1 pathway in a TRAF-dependent fashion (An *et al.*, 2003). This modulation of the JNK/AP1 pathway results in the induction of IL-6, important in directing a Th2 polarization of the immune response and having proliferative effects as detailed earlier (An *et al.*, 2003). Further, vFLIP expression promoted tumor formation after injection of syngeneic and semiallogeneic mouse strains with A20 cells expressing this protein (Djerbi *et al.*, 1999).

The K9/vIRF-1 protein, able to block the anti-viral interferon responses as described above, also has a role in blocking programmed cell death. In addition to binding cellular IRF and GRIM19, vIRF-1 has been shown to bind both p53 and p300/CBP through tryptophan- and proline-rich sequences (Li *et al.*, 2000; Seo *et al.*, 2000; Nakamura *et al.*, 2001; Seo *et al.*, 2001). The irreversible cell cycle arrest and cell death induced by p53 are considered part of host surveillance mechanisms for detecting and preventing viral infection and tumor induction. The activity of p53 is regulated by a series of kinases, phosphatases and acetylases. Acetylation of the carboxyl-terminal region of p53 is mediated by p300 and p300/CBP-associated factor (PCAF) (Sakaguchi *et al.*, 1998). This modification leads to increased DNA binding activity. Interactions of vIRF-1 with p53 and p300/CBP lead to decreased acetylation of p53 as well as decreased phosphorylation, resulting in a dramatic decrease in p53 activity (Nakamura *et al.*, 2001). Blocking p53-dependent transcription suppresses Bax and p21 transcription, mediators of p53-mediated apoptosis, thus rescuing vIRF-1 expressing cells from programmed cell death (Nakamura *et al.*, 2001; Seo *et al.*, 2001). Additionally, interactions of vIRF-1 with CBP results in hypoacetylation of histones H3 and H4, reducing transcription from the early inflammatory gene promoter (Li *et al.*, 1998).

KSHV encodes at least one additional protein that has anti-apoptotic activity. The K7 protein, also termed vIAP, localizes to the mitochondria of expressing cells where it can interact with the cellular calcium-modulating

cyclophilin ligand (CAML) (Feng *et al.*, 2002; Wang *et al.*, 2002). This interaction helps to maintain the mitochondrial membrane potential after treatment with a variety of pro-apoptotic compounds including TRAIL, staurosporin and thapsigargin (Feng *et al.*, 2002). Additionally, K7 has been shown to interact with the Protein-linking integrin-associated protein and cytoskeleton 1 (PLIC1) (Feng *et al.*, 2004). PLIC1 is capable of dimerizing and binding to poly-ubiquitin containing proteins, as well as associating with the 19s unit of the proteasome (Feng *et al.*, 2004). KSHV K7 is able to reduce the ability of PLIC1 to homodimerize and bind to ubiquitinylated proteins, with the end result that two of the targets of PLIC1 activity, Iκb and p53, are rapidly degraded in the presence of K7 (Feng *et al.*, 2004). This reduction of p53 levels within the cell contributes to the anti-apoptotic action of K7. Finally, the K7 protein has also been shown to interact with cellular Bcl-2 and caspase-3, but not with Bax and these interactions are critical to its anti-apoptotic activity (Wang *et al.*, 2002). Like the vFlip gene, K7 is transcribed rapidly after viral infection (Krishnan *et al.*, 2004).

The EBV BHRF1 protein is an early lytic protein capable of blocking the pro-apoptotic actions of TNF-related apoptosis inducing ligand (TRAIL) and FAS (Cheng *et al.*, 1997; Foghsgaard and Jaattela, 1997; Kawanishi, 1997; Kawanishi *et al.*, 2002). TRAIL normally causes cleavage of Bid, a BCL-2 family member, via activation of caspase 8. BHRF1 doesn't block Bid cleavage, but it does block loss of mitochondrial membrane potential, an important downstream apoptotic effect (Kawanishi *et al.*, 2002). Recently, the NMR structure of BHRF1 was solved, demonstrating some clear differences with the structure of its cellular counter-part (Huang *et al.*, 2003). Unlike Bcl-2, it does not contain a hydrophobic groove important in homo- or hetero-dimerization with other apoptotic factors. Additionally, BHRF1 doesn't bind to peptides from Bak, Bax, Bik, and Bad, indicating it functions in a fundamentally different way than the cellular Bcl-x(L) or Bcl-2 (Kawanishi *et al.*, 2002; Huang *et al.*, 2003). BCRF1 protein is also able to complex with another EBV protein, EBV nuclear antigen leader protein (EBNA-LP) (Matsuda *et al.*, 2003). Previously it was shown that EBNA-LP can bind to the HS1-associated protein X-1 (HAX-1), while more recently it was shown that this protein can bind to cellular Bcl-2 (Kawaguchi *et al.*, 2000; Matsuda *et al.*, 2003). The implications of this complex web of interactions to apoptosis is made more complicated by a third EBV protein, BALF1. BALF1 is also an early lytic, Bcl-2 homologue (Hatfull *et al.*, 1988). It can interact with both the Bak and Bax BCL-2 family members and was originally demonstrated to have apoptotic effects (Marshall *et al.*, 1999). More recent experiments have shown that BALF1 can block the action of BHRF1 through an unknown mechanism, but itself has no direct pro- or anti-apoptotic activity (Bellows *et al.*, 2002).

The LMP-1 gene of EBV is expressed during latency and has been shown, in addition to its latency regulatory activity, to prevent apoptosis. It can increase the expression of cellular Bcl-2 as well as a number of other cellular proteins including A20 and TRAF1, important in the anti-apoptotic TNF receptor pathway, through its activation of NF-κB (Henderson *et al.*, 1991; Devergne *et al.*, 1998). LMP-1 is additionally able to induce the expression of bfl-1, a Bcl-2 homologue able to suppress p53 mediated apoptosis (D'Souza *et al.*, 2000). Ectopic expression of bfl-1 in an EBV-positive cell line exhibiting a latency type I infection protects against apoptosis induced by growth factor deprivation, thereby providing a functional role for bfl-1 in this cellular context and adding bfl-1 to the list of anti-apoptotic proteins whose expression is modulated by EBV.

As outlined in this section, the γ-HVs encode a large number of proteins aimed at controlling the cellular apoptosis response. These proteins likely aid the virus in escape from immune effectors such as NK cells and CTL, as well as preventing viral replication from inducing cell death. Given the central importance of programmed cell death in immune function, additional viral mechanisms to avoid apoptosis are likely to be discovered.

Natural killer (NK) cell responses

The NK cells play a critical role in clearing virally-infected cells through direct lysis and the release of various cytokines, which coordinate other immune responses. Although the task that they perform is simple, their regulation is not. A complex set of cell:cell interactions determine whether the NK cell will release its deadly cargo of perforin and granzyme to induce programmed cell death in the target cell, secrete large amounts of IFN-γ to stimulate Th1 T cell production or release the target cell unharmed. The cell surface receptors that govern NK activity can be split into four classes (for review see Anderson *et al.*, 2001; Boyington *et al.*, 2001; LaBonte *et al.*, 2001; Long *et al.*, 2001; McVicar and Burshtyn, 2001; Volz *et al.*, 2001). The killer cell immunoglobulin receptors (KIR) make up the first class. They are capable of binding to a variety of MHC class I haplotypes and generally transmit a negative signal. The second class is the C-type lectin receptor family composed of heterodimers of CD94 and one of several NKG2 proteins. Like the KIR, these receptors also bind MHC class I molecules, but only HLA-G and –E. The natural cytotoxicity receptors (NCR) compose the third class of receptors. The NCR don't interact with class I, but as of yet no cognate ligands have been identified. All identified NCR transmit

Table 31.5. Viral NK regulators. The immune system employs a number of specialized cellular effectors that perform general "house-keeping" function, including the elimination of diseased cells. The natural killer cells are a sub-set of these effectors that are capable of sensing the health of a cell through a number of cell surface receptors, including several which recognize MHC class I. Both human γ-herpesviruses encode gene products with the potential to alter the response of NK cells to infection. The open reading frame, product and potential function are listed for each, with additional details in the text

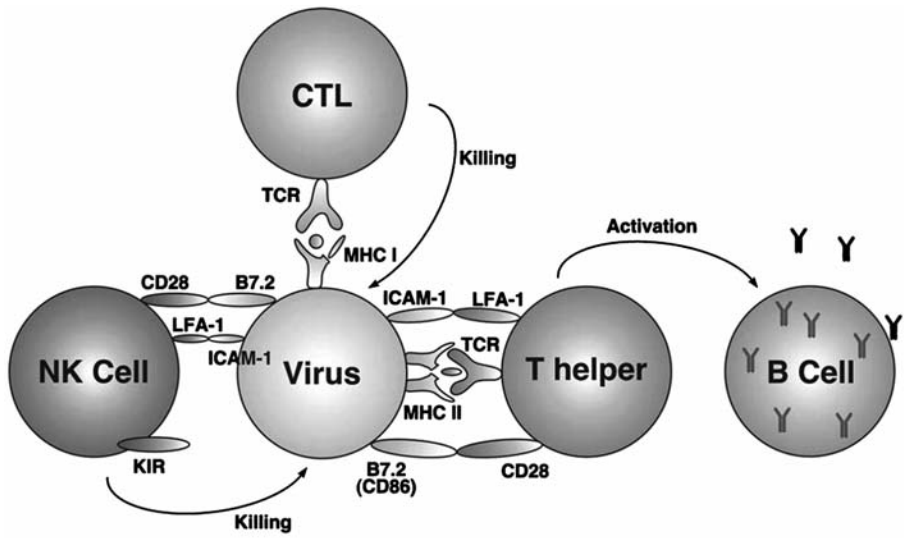
	Gene	Product	Function
HHV-8	K5	K5 (MIR-2)	Down regulates HLA-A and –B, B7.2 and ICAM-1, but leaves HLA-C on the surface of cells blocking NK cell lysis
EBV	LMP-1/EBI-3	cIL-12 subunit	Stabilizes HLA-G1 surface expression sending a negative signal to the NK cells

positive signals to their expressing NK cells, inducing killing and cytokine release in the absence of stronger negative signals. The fourth class, the leukocyte immunoglobulin-like receptor (LIR) family, similar to the class two receptors, can bind HLA-G to transmit a negative signal. The net overall strength of each positive and negative signal determine whether the NK cell will be turned on to make a response or induced to release the target cell.

Important to NK surveillance are multiple adhesion molecules on both the NK and target cell. These molecules include the integrins, intracellular adhesion molecule 1 (ICAM-1), CD2 and LFA3. Interactions between these molecules help to bring the NK cell into close conjugation with its target. This allows both for the NK cell to survey the target cell for the many positive and negative regulatory factors and to potentially deliver the perforin/granzyme payload specifically to the closely juxtaposed target. Antibodies that block the binding of the NK adhesion molecules to the target cell have been shown to block NK cell lysis (Papa *et al.*, 1994; Komatsu and Kajiwara, 1998). Experiments from Burshtyn *et al.* demonstrated that when the KIR interacts with MHC class I on the target cell and transmits a negative signal, there is a decrease in the ability of the NK cell to stay in conjugation with the target (Burshtyn *et al.*, 2000).

The KSHV K5 protein is capable of inducing the down regulation of several cell surface proteins through increasing their rate of endocytosis. This protein will be further discussed later, but as a brief introduction, K5 seems to act as an E3 ubiquitin ligase, targeting ICAM-1, B7.2 and some MHC class I haplotypes for destruction by the ubiquitin: proteasome system (Coscoy and Ganem, 2000; Ishido *et al.*, 2000a,b; Coscoy and Ganem, 2001; Coscoy *et al.*, 2001; Means *et al.*, 2002; Sanchez *et al.*, 2002). This destruction happens in a sequential manner with the targeted proteins first being endocytosed from the cell surface into the trans-Golgi network (Means *et al.*, 2002). Target proteins are then redirected into the lysosome, where they undergo destruction (Means *et al.*, 2002). While MHC I normally acts to transmit a negative signal to NK cells, the ICAM-1 and B7.2 molecules act as anchors to bring the NK cell into close conjugation with target cells. By removing these last two molecules from the surface of infected cells, K5 reduces the average time that the NK cell stays in contact with the K5-expressing target cell (Table 31.5). Thus, even without MHC class I present to transmit a negative signal through the KIR, the NK cell releases the K5-expressing cell unharmed, simply because it can't stay in contact long enough to get a strong positive signal and turn on granzyme/perforin or cytokine release (Ishido *et al.*, 2000a,b) (Fig 31.5).

Less information is available concerning the avoidance of NK cell responses by EBV. The work of Devergne *et al.* (2001) demonstrated that the EBV-induced EBI-3 protein is capable of stabilizing HLA-G presentation on the surface of cells (Table 31.5). HLA-G1 is capable of transmitting a negative signal to NK cells, preventing the activation of killing or cytokine elicitation (Adrian Cabestre *et al.*, 1999; Navarro *et al.*, 1999; Rajagopalan and Long, 1999). Further, HLA-G1 expression was shown to block the lysis of cells presenting HLA-A2-restricted influenza epitopes to specific CTL clones (Le Gal *et al.*, 1999). However, no experimental data has been presented to demonstrate that the LMP1-mediated up regulation of EBI-3 is able to convey these immune avoidance phenotypes in the context of EBV infection (Fig 31.5). One other mechanism that EBV may be using to avoid NK surveillance is through direct infection. While NK cells lack the CD21/CR2 EBV receptor, studies have shown that they become briefly $CD21^+$ after conjugation with $CD21^+$ B-cell targets (Tabiasco *et al.*, 2003). Acquisition of this molecule allows for EBV infection and likely underlies the genesis of EBV^+ NK cell lymphomas, while at the same time allowing for viral escape from NK surveillance.



NK Cell

Gene	Modulation target
K5	ICAM-1
LMP-1	HLA-G1

CTL

Gene	Modulation target
K3	MHC I
K5	MHC I
BCRF1	TAPI → MHC I

T-helper and B-cell

Gene	Modulation target
K5	B7.2
	ICAM-1
BZLF1	MHC II

Fig. 31.5. Viral alteration of immunomodulatory proteins. Through the down regulation of multiple immunomodulatory proteins both KSHV and EBV are able to alter the ability of innate and adaptive immune effectors to recognize and mount responses against virally infected cells. Diagramed are some of the cellular proteins altered by viral gene products and their binding partners. The viral proteins and their targets are listed in the tables below the diagram. Details of the interactions are given in the text.

While it is clear that both of the human γ-HV interfere with NK cell surveillance the possibility of additional viral mechanisms for avoiding these effectors remains. For example, the human cytomegalovirus (HCMV), a β-herpesvirus, encodes the UL16 protein. This protein is able to bind and down regulate the cellular UL16-binding proteins (ULBP) 1 and 2, which are ligands for the c-type lectin NKG2D activating receptor on NK cells (Rolle *et al.*, 2003). This effectively protects HCMV-infected cells from NK cell lysis. To date, no human γ-HV protein has been shown to target an NK cell activating receptor.

Evasion of other innate cellular responses

The immune system employs a number of additional innate effectors which surveil the body, including the professional phagocytes, neutrophils and macrophage that internalize and destroy extracellular pathogens such as bacteria or virus, as well as eosinophils and basophils, both able to release a number of immunomodulatory proteins. Like NK cells, these cells represent the first line of defense against infecting pathogens and are able to modulate the later adaptive responses. It is therefore critical that the γ-HV deregulate or avoid recognition by these cells in order to establish a persistent infection.

EBV is able to infect both neutrophils and monocytes, macrophage-precursors. While EBV infection of neutrophils is abortive, multiple changes in cellular physiology important to the potential escape of the virus from immune avoidance occur (Larochelle *et al.*, 1998). First, viral infection causes the up regulation of Fas ligand. Neutrophils express CD95/Fas, which plays a role in immune privilege, and the increased expression of Fas ligand results in apoptosis (Griffith *et al.*, 1995; Larochelle *et al.*, 1998). This effectively eliminates responding neutrophils. However, EBV infection also triggers these cells to release a number of cytokines, including IL-8, MIP-1α, IL-1α, IL-1β and the IL-1R antagonist (Beaulieu *et al.*, 1995; McColl *et al.*, 1997; Roberge *et al.*, 1997). These chemokines, along with the highly-induced leukotrien B4, act to recruit additional leukocytes, potentially aiding in viral dissemination (Gosselin *et al.*, 2001).

Table 31.6. Viral CTL Regulators. $CD8^+$ T-cell responses play a critical role in the elimination of virally-infected cells. Both human γ-herpesviruses encode multiple gene products with the potential to alter the ability of host CTLs to recognize and eliminate virally-infected cells. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	K3	K3 (MIR-1)	Down-regulates MHC class I, blocking induction of CTL responses
	K5	K5 (MIR-2)	Down-regulates HLA-A and -B, B7.2 and ICAM-1 blocking CTL and T helper activation
	LANA	LANA	Block *in cis* CTL epitope presentation
EBV	BKRF1	EBNA-1	GAR region interferes with the proteasome and MHC class I presentation
	BCRF1	vIL-10	Down regulates TAP1 and cLMP2 interfering with MHC class I loading and presentation

In contrast, infection of monocytes, while highly inefficient, seems to be productive, resulting in transformed monocyte cell lines displaying type II latency (Masy *et al.*, 2002). The route of infection is unclear since monocytes do not express detectable levels of CD21, however, transient CD21 expression might result from the engulfment of $CD21^+$ cells (Inghirami *et al.*, 1988). Addition of the gp350/220 glycoprotein of EBV to monocytes results in the elicitation of IL-1, IL-6 and TNF-α (D'Addario *et al.*, 1999; 2000). However, addition of the whole virus does not up regulate IL-1 expression and blocks TNF-α secretion (D'Addario, 1999; Gosselin *et al.*, 2001). Finally, EBV infection has been shown to decrease the production of prostaglandin E2 (Savard *et al.*, 2000). This would be expected to induce or favor a Th1 response, but in the face of other virally-elicited cytokines, it probably acts to elicit an inflammatory response, recruiting additional targets for viral infection.

These alterations in innate cellular responses along with the alterations in eosinophils function described earlier likely all contribute to long-term control of the anti-viral immune responses. By controlling the cells which initially determine the direction the immune response is to take, the γ-HV are able to insure that they are able to establish a persistent infection. Using these cells, the virus is able to skew responses made by the immune effectors such that the additional immunomodulatory genes are most effective.

Evasion of adaptive host immunity

The adaptive immune responses are mediated by the $CD4^+$ and $CD8^+$ T-cells and the antibody producing B-cells. Like the innate responses, there are multiple levels of regulation and therefore, multiple opportunities for viral intervention. The adaptive immune responses provide two critical "improvements" over the innate responses: the memory response, allowing the immune system to react more quickly and effectively to a previously seen pathogen, and response maturation, allowing for a more targeted, higher affinity response to a pathogen. These differences from the innate responses can also be taken advantage of by invading pathogens in the form of dominant epitopes or antigenic variation, both of which can mislead the immune system into making ineffective responses.

Evasion of CTL responses

The cytotoxic T-lymphocytes are $CD8^+$ T cells that can directly lyse and induce apoptosis in infected cells, as well as releasing cytokines such as IFN-γ, TNF-α and TNF-β. Presentation of non-self antigens in complex with MHC class I on the surface of infected cells along with co-stimulatory molecules can activate this killing and the γ-HVs have devised several ways of preventing this from occurring as outlined in Table 31.6.

KSHV encodes two genes, K3 (MIR-1) and K5 (MIR-2), whose products are able to down regulate MHC class I from the surface. Respectively, they are the eleventh and fourteenth Orfs from the left end of the genome, encoding products with approximately 40% identity (Russo *et al.*, 1996). They are early lytic proteins and showed increased expression in TPA treated PEL cells (Sun *et al.*, 1999). Work from Krishnan *et al.*, (2004) demonstrated that the K5 gene product is also expressed very rapidly after infection with KSHV. The levels of this protein then slowly decline over the next several days. The K3 and K5 proteins are both type III integral membrane proteins containing a zinc-binding Really Interesting New Gene (RING-CH) sequence at the N-termini, two hydrophobic transmembrane regions and a series of protein motifs important in cellular trafficking in the C-terminus (Coscoy and Ganem, 2000; Ishido *et al.*, 2000; Means *et al.*, 2002; Sanchez *et al.*, 2002). Both have been shown to insert into the ER membrane such that the N- and C-termini are projecting into the cytosol (Sanchez *et al.*, 2002). The PHD domains of these proteins resemble

those found in a number of E3 ubiquitin ligases and are capable of mediating self ubiquitinylation when fused to the GFP protein (Coscoy *et al.*, 2001). While the exact mechanism of MHC class I molecule down regulation is still only partially understood, this ability of K3 and K5 to act as an E3 ligase seems critical. The transmembrane regions of these two proteins probably play at least two roles. First, they define the target specificity. K3 is able to down regulate multiple HLA haplotypes, whereas K5 down-regulates a much more restricted set. However, K5 is additionally able to target the cellular B7.2 costimulatory molecule and ICAM-1 adhesion molecule for down-regulation (Coscoy and Ganem, 2000; Ishido *et al.*, 2000; Means *et al.*, 2002; Sanchez *et al.*, 2002). The selection of targets is regulated by the transmembrane domains (Sanchez *et al.*, 2002). Second, these sequences probably allow K3 and K5 multimerization, although it isn't clear what role this plays in their function (Sanchez *et al.*, 2002). Downstream of the transmembrane regions, both contain a conserved series of residues identified as being important in protein:protein interactions and cellular trafficking (Means *et al.*, 2002; Sanchez *et al.*, 2002). Several of these motifs, including a Y–X–X–ϕ endocytosis sequence, direct internalization of the target proteins from the cell surface into the trans-Golgi network (TGN) (Means *et al.*, 2002). From there other motifs, primarily two stretches of acidic amino acids, redirect the target proteins to the endosomal/lysosomal compartment where they undergo destruction by the ubiquitin:proteasome system (Lorenzo *et al.*, 2002; Means *et al.*, 2002). Without MHC class I on the cell surface, no peptides are presented to induce CL activation and K3/K5 expressing cells are able to escape killing (Ishido *et al.*, 2000) (Fig. 31.5). Down regulation of ICAM-1 likely also reduces the non-specific surveillance of cells by $CD8^+$ effectors.

EBV also regulates MHC class I presentation of viral peptides. EBV nuclear antigen (EBNA)-1 is a latent viral protein and contains a glycine, alanine repeat (GAR) region and plays a critical role in maintenance and segregation of the viral episome (Hennessy and Kieff, 1983; Yates *et al.*, 1984). The GAR region inhibits proteasome functioning, greatly decreasing presentation of EBNA-1 peptides derived from full-length protein, as well as limiting EBNA-1 mRNA translation (Levitskaya *et al.*, 1997; Yin *et al.*, 2003; Blake *et al.*, 1997). This has the effect of keeping the levels of EBNA-1 low, but stable, in latently infected cells. In addition to proteasome-independent presentation of EBNA-1 peptides, most likely by professional APCs that take up dead or dying EBV-infected cells, EBNA-1 peptides are probably also generated by degradation of aberrant translation products in a proteasome-dependant manner (Khanna *et al.*, 1996; Lee *et al.*, 1996; Lautscham *et al.*, 2003). Several papers have now shown that the anti-EBNA-1 $CD8^+$ T-cells are present in most EBV-infected healthy individuals, however, only with more sensitive IFN-γ detection are these CTL detected and not with less sensitive killing assays (Meij *et al.*, 2002; Lee *et al.*, 2004; Tellam *et al.*, 2004; Voo *et al.*, 2004). Given this new information the overall role of EBNA-1 in protection from $CD8^+$ T-cell responses needs to be evaluated. There is a possibility that EBV has evolved a mechanism for allowing limited CTL recognition of infected cells in order to maintain its latency program.

KSHV, like EBV, seems to have evolved a similar mechanism for blocking CTL recognition of its major latency-associated protein, LANA. Like EBNA-1 for EBV, LANA acts in maintenance of the KSHV episome by tethering it to the cellular chromosome (Barbera *et al.*, 2006). Also like EBNA-1, LANA contains long repetitive sequences, that can be broken up into three sections composed of repeats of aspartic acid and glutamic acid, glutamine and glutamic acid, or aspartic acid and glutamine, respectively. These repeat sequences are capable of blocking the processing of CTL epitopes *in cis*, but not *in trans* (Zaldumbide *et al.*, 2006). Further exploration of this function by the Moore group has demonstrated that the block occurs both through synthesis retardation and reduced defective ribosomal product (DRiP) formation and processing (P Moore, personal communication). The overall contribution of this viral impediment to MHC class I antigen presentation on viral immune escape still requires further investigation.

The BCRF1 protein, described earlier in this chapter as a deregulator of the interferon responses, is also able to block MHC class I-dependent CTL responses against viral antigens (Fig. 31.5). This protein, like cellular IL-10, is able to down regulate the transporter associated with antigen processing subunit 1 (TAP1) and a proteasome subunit, low molecular weight protein 2 (LMP2), but not the TAP2 protein (Zeidler *et al.*, 1997). The TAP proteins act to transport peptides from the cytosol into the ER, where they can be loaded onto MHC class I, while LMP2 is a constituent of the proteasome, which degrades antigenic proteins into peptides. After treatment of primary tonsillar B cells with human or viral IL-10 both TAP1 and LMP2 mRNA levels were seen to decrease dramatically (Zeidler *et al.*, 1997). So, EBV has hijacked an immunoregulatory cytokine, which likely plays a role in preventing autoimmune responses, to dramatically decreases the $CD8^+$ CTL antiviral responses (Fig. 31.5).

Evasion of $CD4^+$ T helper cell and B cell responses

The $CD4^+$ T helper (Th) cells are able aid in the recognition and elimination of pathogens in multiple ways. The

Table 31.7. Viral B-cell regulators. The B-cell response is controlled both by signals given directly to the antibody-producing B-cell and signals transmitted to T-helper cells, which in turn aid the B-cell response. Both human γ-herpesviruses encode multiple gene products with the potential to alter the host's humoral response through interfering with both of these aspects of B-cell stimulation. The open reading frame, product and potential function are listed for each, with additional details in the text

	Gene	Product	Function
HHV-8	ORF4	KCP/Kaposica	Accelerates the decay of the C3 convertases and drives production of C3d, which binds complement receptor 2 (CR2) found on B cells
	K5	K5 (MIR-2)	Down regulates ICAM-1 and B7.2 reducing T helper cell activation and reducing the B cell response
EBV	BLLF1a/b	gp350/220	Binds to CR2, might interfere with complement mediated B cell stimulation or aid in viral dissemination
	BZLF1	Zta	Down-regulates MHC class II through CIITA inhibition blocking T helper cell activation

Th1 cells, after recognition of foreign peptides complexed with MHC class II, are able to activate macrophages, as well as activating B cells to produce certain subclasses of antibodies. The CD Th2 cells, in an analogous way, are able to drive the activation and differentiation of B-cells such that they produce a wide variety of immunoglobulins. The B-cell responses are closely tied to this activation of the $CD4^+$ T helper cells and binding of non-self peptides by MHC class II. On the surface of B cells, the B cell antigen receptor (BCR) can bind to antigens, which are then internalized and degraded into peptides that are loaded onto MHC class II. These complexes are transported to the cell surface, where they can be recognized by antigen-specific Th2 cells causing the T-cell to produce both cell surface and secreted proteins. This T-cell help causes the B cell to proliferate and its progeny to differentiate into antibody-secreting cells. The threshold of this proliferation and antibody production can be significantly lowered if the B cell is additionally stimulated through the B-cell coreceptor made up of CD19, CD21 and CD18. Antibodies produced by the activated, differentiated B-cells can then act to neutralize and clear free virus, as well as drive antibody-dependent cell-mediated cytotoxicity (ADCC) reactions where NK cells can target infected cells through Fc receptors on their surface.

Both KSHV and EBV have mechanisms by which they can possibly block B-cell responses as outlined in Table 31.7 and in Fig. 31.5. One component of the B-cell coreceptor, CD21, is capable of binding to C3d. The KSHV KCP/Kaposica protein drives inactivation of the complement C3 convertase and production of C3d, detailed more fully earlier in this chapter (Spiller *et al.*, 2003). It is unclear whether this aberrant production of C3d is capable of altering B-cell responses. It is also possible that C3d is produced in order to attract $CD21^+$ B-cells, which KSHV can then target for infection. EBV also targets CD21 through its gp350/220 envelope protein. This protein is a constituent of the viral envelope and is capable of binding to CD21 to aid in viral entry. Again, it is unclear what implications this has for anti-viral B cell responses.

Much in the same way that the KSHV K5 (MIR-2) protein was able to block the anti-viral activities of the NK cells, it is also able to inhibit T-helper cell activation (Coscoy and Ganem, 2001). Both ICAM-1 and B7.2 play crucial roles in inducing T-help. The down regulation and destruction of these molecules, therefore, prevents the induction of a vigorous B cell response (Coscoy and Ganem, 2001). The presence of multiple cytokines that enhance the Th2 response, however, might diminish the immune evasion potential of this mechanism.

The EBV BZLF1 protein, earlier introduced as having a role in altering interferon responses, is able to block IFN-γ-induced MHC class II surface expression by inhibiting the CIITA transcription factor (Morrison *et al.*, 2001). This has the effect of shutting down T-helper cell activation, limiting the humoral response. While a similar mechanism has not been described for KSHV, the presence of multiple genes capable of interfering with the actions of IFN-γ leave open the possibility that MHC class II induction and stimulation of T-help is being blocked in a similar manner.

Finally, the GAR region of the EBNA-1 protein of EBV was originally thought to limit the $CD4^+$ T-cell responses. This doesn't, however, seem to be true. Several groups have demonstrated an ability to detect strong EBNA-1 $CD4^+$ Th1 responses in healthy individuals (Munz *et al.*, 2000; Bickham *et al.*, 2001; Leen *et al.*, 2001; Paludan *et al.*, 2002; Voo *et al.*, 2002). These cells are capable of recognizing LCLs, EBV transformed cells and Burkitt's lymphoma cell lines (Munz *et al.*, 2000; Bickham *et al.*, 2001; Paludan *et al.*, 2002; Voo *et al.*, 2002). Thus, the role of EBNA-1 in escape from Th and B-cell responses needs further evaluation.

Conclusions

An understanding of the mechanisms by which these viruses evade the antiviral immune responses is informative on several levels. First, by examining viral inhibition of specific immune responses much can be learned about regulation and functioning of the immune system. Second, virally-associated neoplasms can be viewed as aberrations where the normal balance between control of the virus by the host immune responses and avoidance of those same responses by the virus has been corrupted. By understanding what responses are capable of controlling viral proliferation in the case of the immunocompetent host then more effort can be directed at vaccinating to induce protective responses.

Pathogenesis

The transmission of herpes simplex virus (HSV) infection is dependent upon intimate, personal contact of a susceptible seronegative individual with someone excreting HSV. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. With viral replication at the site of primary infection, either an intact virion or, more simply, the capsid is transported retrograde by neurons to the dorsal root ganglia where, after another round of viral replication, latency is established (Fig. 32.1(a), left panel). The more severe the primary infection, as reflected by the size, number, and extent of lesions, the more likely it is that recurrences will ensue. Although replication sometimes leads to disease and, infrequently, results in life-threatening infection (e.g., encephalitis), the host-virus interaction leading to latency predominates. After latency is established, a proper stimulus causes reactivation; virus becomes evident at mucocutaneous sites, appearing as skin vesicles or mucosal ulcers (Fig. 32.1(b), right panel).

Infection with HSV-1 generally occurs in the oropharyngeal mucosa. The trigeminal ganglion becomes colonized and harbors latent virus. However, it has been increasingly common to detect evidence of HSV-1 in the genital tract, usually the consequence of oral-genital sex. When such occurs, recurrences of HSV-1 in the genital tract are uncommon. Acquisition of HSV-2 infection is usually the consequence of transmission by genital contact. Virus replicates in the genital, perigenital or anal skin sites with seeding of the sacral ganglia (Fig. 32.2). As is the case of HSV-1's ability to infect the genital tract, HSV-2 can infect the mouth. Recurrences at this site are uncommon.

Operative definitions of the nature of the infection are of pathogenic relevance. Susceptible individuals (namely, those without pre-existing HSV antibodies) develop primary infection after the first exposure to either HSV-1 or HSV-2. A recurrence of HSV is known as "recurrent infection." Initial infection is when an individual with pre-existing antibodies to one type of HSV (namely, HSV-1 or HSV-2) can experience a first infection with the opposite virus type (namely, HSV-2 or HSV-1, respectively). Primary infection has, more recently, been labeled first-episode disease because some individuals present with what appears to be a clinically severe primary infection but have pre-existing antibodies to the causative type. This observation indicates that individuals may have a well-established latent infection before the first episode of clinically evident disease occurs.

Reinfection with a different strain of HSV can occur, albeit extremely uncommon in the normal host and is called exogenous reinfection. Cleavage of DNA from an HSV isolate by restriction endonuclease enzymes yields a characteristic pattern of subgenomic products. Analyses of numerous HSV-1 and HSV-2 isolates from a variety of clinical situations and widely divergent geographic area demonstrates that epidemiologically unrelated strains yield distinct HSV DNA fragment patterns. In contrast, fragments of HSV DNA derived from the same individual obtained years apart, from monogamous sexual partners, or following short and long passages *in vitro*, have identical fragments after restriction endonuclease cleavage (Buchman *et al.*, 1978). Utilizing endonuclease technology, exogenous reinfection is exceedingly low in the immune competent host.

Unique biologic properties of HSV that influence pathogenesis

HSV-1 and HSV-2 exhibit two unique biologic properties that influence pathogenesis and subsequent human disease. Both viruses have the capacity to invade and replicate

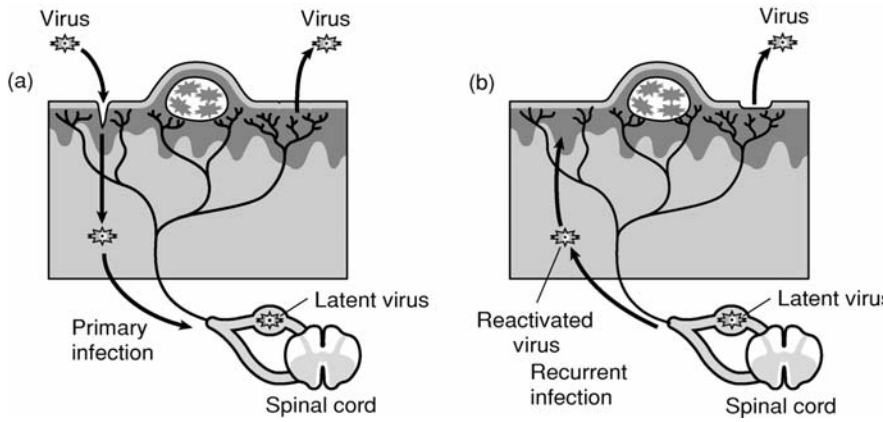

Fig. 32.1. (a) Primary infection. (b) Recurrent infection.

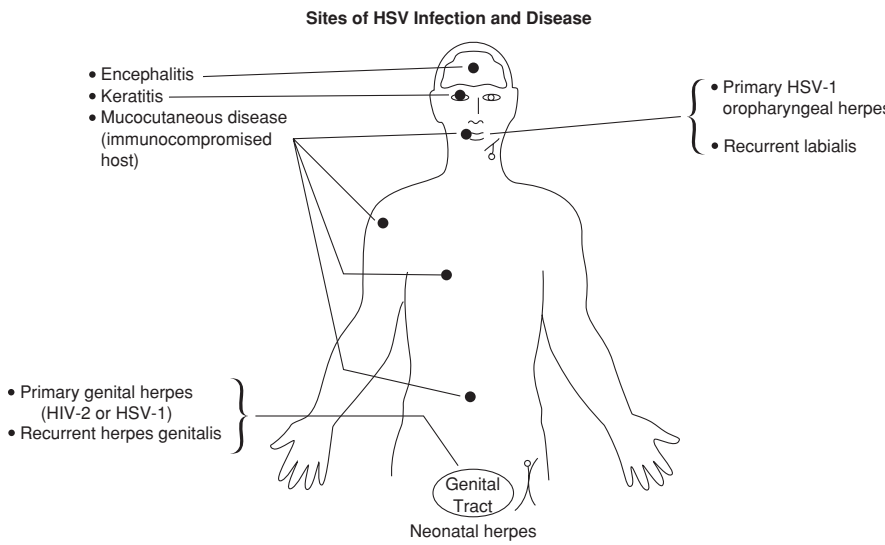

Fig. 32.2. Sites of HSV infection and disease (Whitley, 2001).

in the CNS and the capacity to establish a latent infection in dorsal root ganglia (Roizman and Pellett, 2001).

The term, neurovirulence, encompasses both neuroinvasiveness from peripheral sites and replication in neuronal cells. When paired isolates (brain and lip) from patients with HSV encephalitis are evaluated by PFU/LD_{50} ratios following direct intracerebral inoculation in mice, the encephalitis isolates have lower PFU/LD_{50} ratios than isolates from lip lesions. Neurovirulence appears to be the function of numerous genes (Roizman and Knipe, 2001). In fact, deletion of virtually any of the genes dispensable for viral replication in cell culture reduces the capacity of the virus to invade and replicate in CNS. Mutations affecting neuroinvasiveness have also been mapped in genes encoding glycoproteins. Access to neuronal cells from usual portals of entry into the body requires postsynaptic transmission of virus and, therefore, a particularly vigorous capacity to multiply and to direct the virions to appropriate membranes. In addition, since neuronal cells are terminally differentiated and do not make cellular DNA, they lack the precursors for viral DNA synthesis that are also encoded by the viral genes dispensable for growth in cell culture. Of particular interest, however, is the role of $\gamma_1$34.5 gene in neurovirulence (Chou *et al.*, 1990; Chou and Roizman, 1986; Hesselgesser and Horuk, 1999; Whitley *et al.*, 1993). Although $\gamma_1$34.5 deletion mutants multiply well in a variety of cells in culture, they are among the most avirulent mutants identified to date in vivo.

Latency has been recognized biologically since the beginning of the century (Baringer and Swoveland, 1973; Bastian *et al.*, 1972; Stevens and Cook, 1971) and has been extensively reviewed (Roizman and Knipe, 2001; Nahmias and Roizman, 1973; Roizman and Sears, 1987). The molecular basis for latency is addressed in Chapter 33. Following entry, both HSV-1 and HSV-2 infect nerve endings and translocate by retrograde transport to the nuclei of sensory ganglia. The virus multiplies in a small number of sensory neurons, which are ultimately destroyed. In the vast majority of the infected neurons, the viral genome remains for the entire life of the individual in an episomal state. In a fraction of individuals, the virus reactivates and is moved by anterograde transport to a site at or near the portal of entry. Reactivations occur following a variety of local or systemic stimuli.

Patients treated for trigeminal neuralgia by sectioning a branch of the trigeminal nerve develop herpetic lesions along the innervated areas of the sectioned branch (Carton and Kilbourne, 1952; Cushing, 1905; Goodpasture, 1929; Pazin *et al.*, 1978). Reactivation of latent virus appears dependent upon an intact anterior nerve route and peripheral nerve pathways. Latent virus can be retrieved from the trigeminal, sacral, and vagal ganglia of humans either unilaterally or bilaterally (Bastian *et al.*, 1972). The recovery of virus by in vitro cultivation of trigeminal ganglia helps explain the observation of vesicles that recur at the same site in humans, usually the vermilion border of the lip. Recurrences occur in the presence of both cell-mediated and humoral immunity. Recurrences are spontaneous, but there is an association with physical or emotional stress, fever, and exposure to ultraviolet light, tissue damage, and immune suppression. Recurrent herpes labialis is three times more frequent in febrile patients than in non-febrile controls (Baringer and Swoveland, 1973; Roizman and Sears, 1987; Selling and Kibrick, 1964).

Little is known regarding the mechanisms by which the virus establishes and maintains a latent state or is reactivated. There are in fact disagreements on the fate of neurons in which latent virus became reactivated. The relevant issues may be summarized as follows.

1. Sensory neurons harboring virus contain nuclear transcripts arising from approximately 8.5 kbp of the sequences flanking the U_L sequence. These transcripts are known as the latency associated transcripts or LATs. A shorter region is more abundantly represented in the nuclei. The RNA transcribed from this region forms two populations 2 kbp and 1.5 kbp, respectively, and represents stable introns of an unknown, and relatively unstable transcript. The abundant 2.5 and 1.5 kbp RNA play no role in the establishment or maintenance of the latent state although they may play a role in reactivation. These LATs may have an apoptotic function, which might explain the higher efficiency of reactivation of viruses expressing LATs.

   The source of genetic functions required for the establishment or maintenance of the latent state remains unknown. All of the deletion mutants tested to date establish latency but not all reactivate. Whereas establishment or maintenance of latency are functions expressed by dorsal root neurons, the activation of viral gene expression that leads to viral replication does require a full complement of viral gene.
2. Usually, replication of HSV-1 and HSV-2 destroys the infected cell, but reactivation of latent virus may not destroy neurons harboring the virus. This suggestion is based on the observation that patients do not suffer from local anesthesia at the site of frequent, multiple recurrences. An alternative explanation is that nerve endings from adjacent tissues innervated by other neurons extend into the site of the healed lesion (Roizman and Knipe, 2001; Roizman and Sears, 1987).

Pathology

The histopathologic characteristics of a primary or recurrent HSV (Fig. 32.3) reflect viral-mediated cellular death and associated inflammatory response. Viral infection induces ballooning of cells with condensed chromatic within the nuclei of cells, followed by nuclear degeneration, generally within parabasal and intermediate cells of the epithelium. Cells lose intact plasma membranes and form multinucleated giant cells. With cell lysis, a clear (referred to as vesicular) fluid containing large quantities of virus appears between the epidermis and dermal layer. The vesicular fluid contains cell debris, inflammatory cells, and often multinucleated giant cells. In dermal substructures there is an intense inflammatory response, usually in the corium of the skin, more so with primary infection than with recurrent infection. With healing, the vesicular fluid becomes pustular with the recruitment of inflammatory cells and scabs. Scarring is uncommon. When mucous membranes are involved, vesicles are replaced by shallow ulcers.

Pathology of central nervous system disease

HSE results in acute inflammation, congestion and/or hemorrhage, most prominently in the temporal lobes and usually asymmetrically in adult (Boos and Esiri, 1986) and

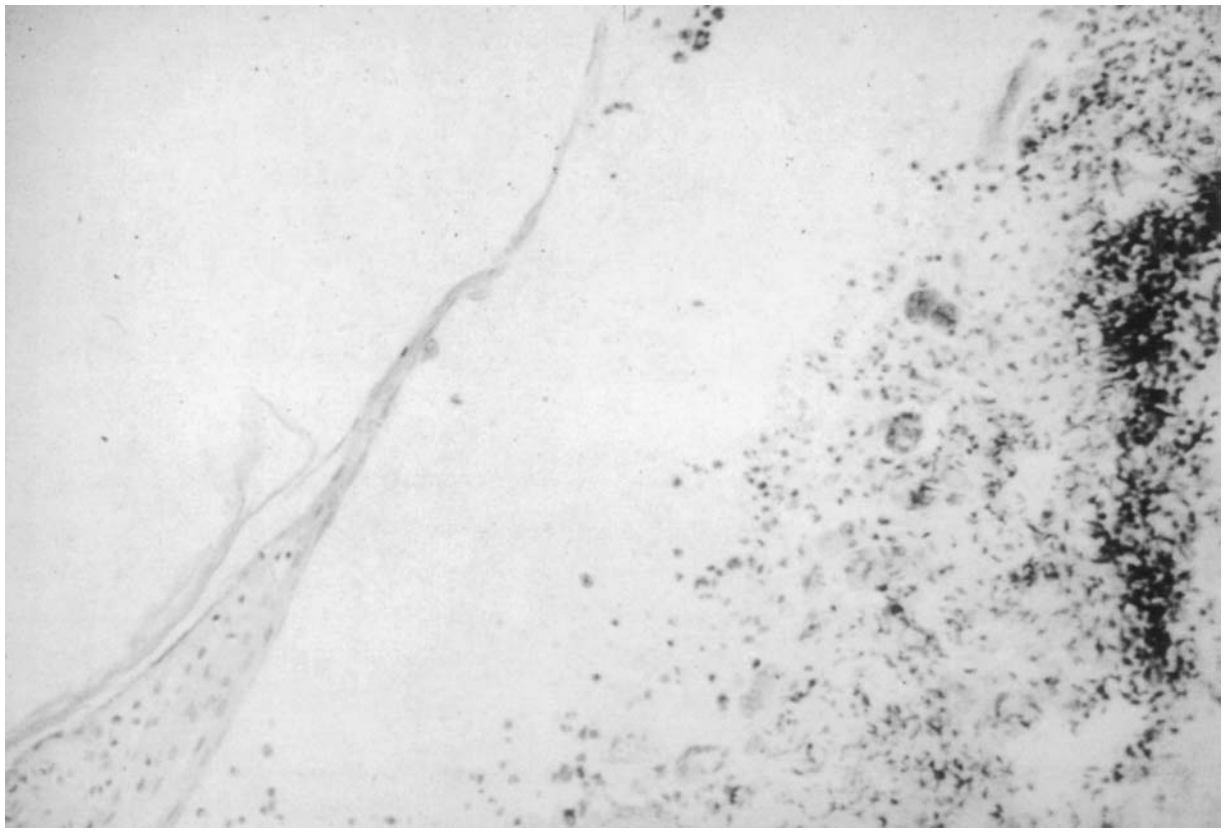

Fig. 32.3. Histopathology of herpes simplex virus infection (Whitley, 2001).

more diffusely in the newborn. Adjacent limbic areas show involvement as well. The meninges overlying the temporal lobes may appear clouded or congested. After approximately 2 weeks, these changes proceed to frank necrosis and liquefication, as shown in Fig. 30.4. Microscopically, involvement extends beyond areas that appear grossly abnormal. At the earliest stage, the histologic changes are not dramatic and may be non-specific. Congestion of capillaries and other small vessels in the cortex and subcortical white matter is evident; other changes are also evident, including petechiae. Vascular changes that have been reported in the area of infection include areas of hemorrhagic necrosis and perivascular cuffing (Fig. 32.5(a), (b)). The perivascular cuffing becomes prominent in the second and third weeks of infection. Glial nodules are common after the second week (Boos and Kim, 1984; Kapur *et al.*, 1994). The microscopic appearance becomes dominated by evidence of necrosis and, eventually, inflammation; the latter is characterized by a diffuse perivascular subarachnoid mononuclear cell infiltrate, gliosis, and satellitosis-neuronophagia (Boos and Esiri, 1986; Garcia *et al.*, 1984). In such cases, widespread aras of hemorrhagic necrosis, mirroring the area of infection, become most prominent. Oligodendrycytic involvement and bliosis (as well as astrocytosis) are common, but these changes develop very late in the disease. Although found in only approximately 50% of patients, the presence of intranuclear inclusions supports the diagnosis of viral infection, and these inclusions are most often visible in the first week of infection. Intranuclear inclusions (Cowdry type A inclusions) are characterized by an eosinophilic homogeneous appearance and are often surrounded by a clear, unstained zone beyond which lies a rim of marginated chromatin, as shown in Fig. 32.6.

Impact of host response to infection on disease

The pathogenesis of HSV infections is influenced by both specific and non-specific host defense mechanisms (Lopez *et al.*, 1993). With the appearance of non-specific inflammatory changes, paralleling a peak in viral replication, specific host responses can be quantitated but vary from one

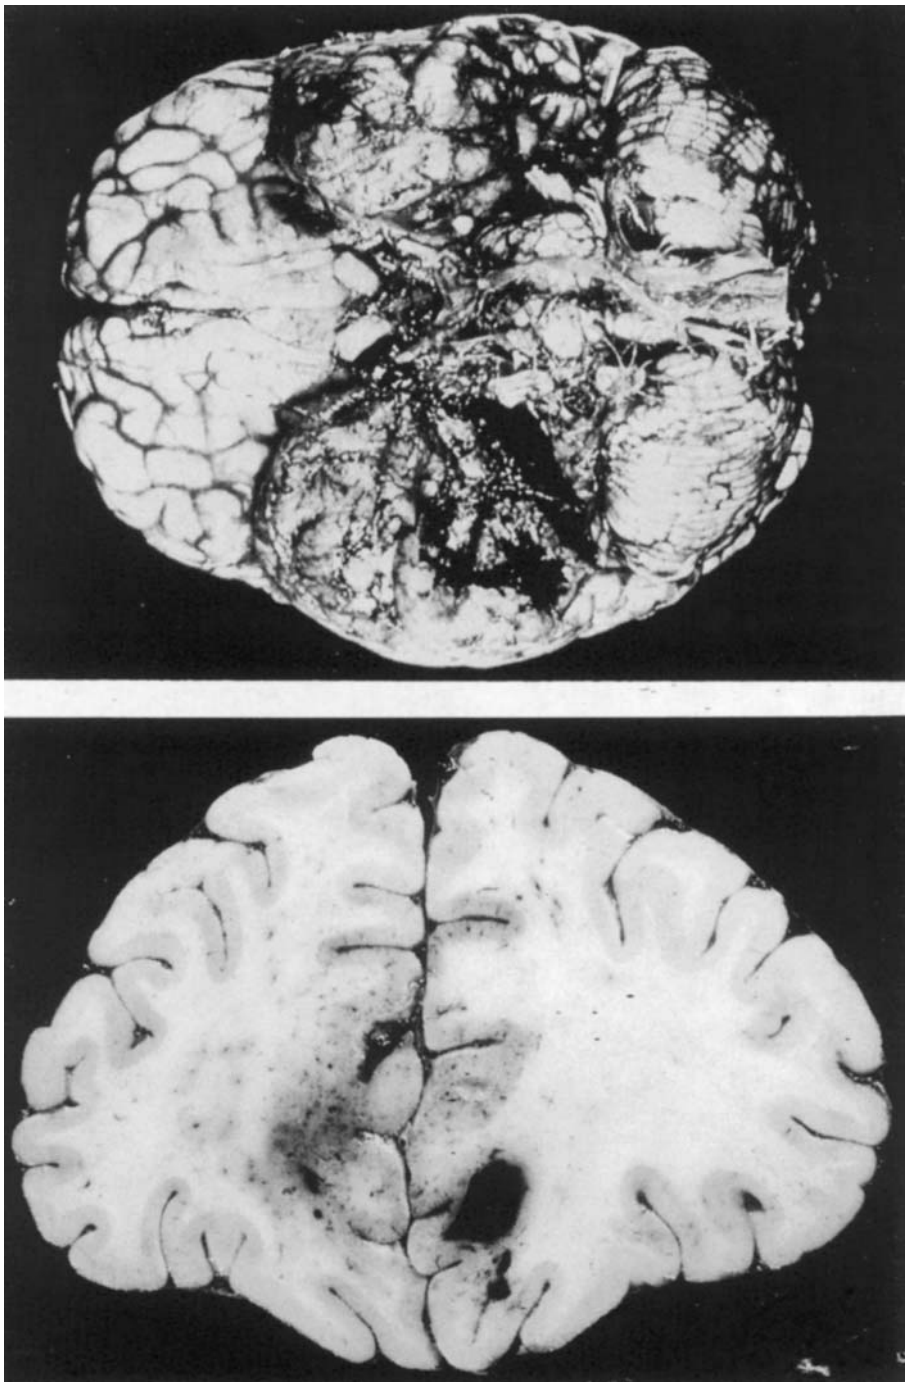

Fig. 32.4. Gross pathologic findings in HSE, illustrating hemorrhagic necrosis of the inferior medial portion of the temporal lobe (Whitley, 2001).

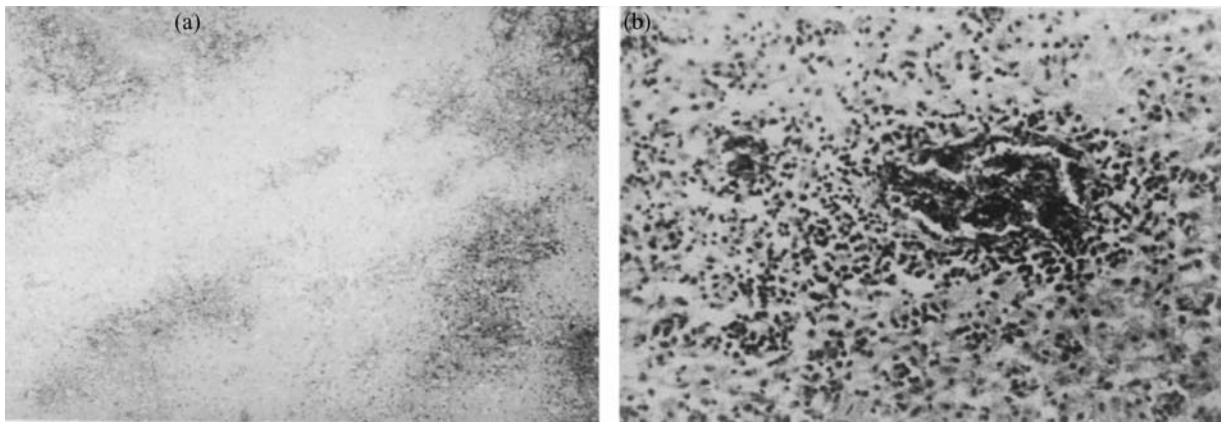

Fig. 32.5. (a) Hemorrhagic necrosis on microscopic examination (Whitley, 2001). (b) Perivascular cuffing on histopathologic examination of a patient with HSE (Whitley, 2004).

animal system to the next. In the mouse, delayed-type hypersensitivity responses are identified within 4–6 days after disease onset, followed by a cytotoxic T-cell response and by the appearance of both IgM- and IgG-specific antibodies. Host responses in humans are delayed, developing approximately 7–10 days later. Immunodepletion studies have identified the importance of cytotoxic T-cells (CTLs) in resolving cutaneous disease. Adoptive transfer of $CD8^+$ or HSV-immune $CD4^+$ T cells also reduces viral replication or protection from challenge.

T-cell lymphocyte subsets have been examined for host susceptibility to infection, including those cells responsible either for H2-restricted cytotoxicity or for in vitro or adoptive transfer of delayed-type hypersensitivity (Kohl *et al.*, 1989). These latter cells have a requirement for both the IA and H2 K/D regions (Nash *et al.*, 1981). Studies utilizing a specific infected cell polypeptide product (ICP4) have identified its requirement for mediation of T-cells (Martin *et al.*, 1988). Prior immune responses to HSV-1 infection have a protective effect on the acquisition of HSV-2 infection (Mertz *et al.*, 1992). Polyclonal antibody therapy will decrease mortality rates in the newborn mouse (Brown *et al.*, 1991). In addition, administration of these antibodies can limit progression of both neurologic and ocular disease. Protection can be achieved with monoclonal antibodies to specific viral polypeptides, especially the envelope glycoproteins. Such results have been accomplished with both neutralizing and non-neutralizing antibodies. Antibody-dependent cell-mediated cellular cytoxic host responses also correlate with improved clinical outcome, as will be noted below for neonatal HSV infections.

Numerous reports have incriminated or refuted HLA associations with human HSV infections. For recurrent fever blisters, these studies have included HLA-A1, HLA-A2, HLA-A9, HLA-BW16, and HLA-CW2. Recurrent ocular HSV infections have been associated with HLA-A1, HLA-A2, HLA-A9, and HLA-DR3. These conflicting associations can be faulted by population selection bias.

Humoral immune responses of humans parallel those following systemic infection of mice and rabbits. IgM antibodies appear transiently and are followed by IgG and IgA antibodies, which persist over time. Neutralizing and antibody-dependent cellular cytotoxic antibodies generally appear 2–6 weeks after infection and persist for the lifetime of the host. Immunoblot and immunoprecipitation antibody responses have defined host response to infected cell polypeptides and correlated these responses with the development of neutralizing antibodies (Bernstein *et al.*, 1985; Eberle *et al.*, 1981). After the onset of infection, antibodies appear which are directed against gD, gB, ICP-4, gE, gG-1 or gG-2, and gC. Both IgM and IgG antibodies can be demonstrated, depending upon the time of assessment.

Lymphocyte blastogenesis responses develop within 4–6 weeks after the onset of infection and sometimes as early as 2 weeks (Corey *et al.*, 1978; Russell, 1974; Sullender *et al.*, 1987). With recurrences, boosts in blastogenic responses can be defined promptly; however, these responses, as after primary infection, decrease with time. Non-specific blastogenic responses do not correlate with a history of recurrences.

Host response of the newborn to HSV differs from that of older individuals. Impairment of host defense mechanisms contributes to the increased severity of some infectious agents in the fetus and the newborn. Factors which must be considered in defining host response of the newborn include the mode of transmission of the agent (viremia vs mucocutaneous infection without blood-borne spread), and time of acquisition of infection.

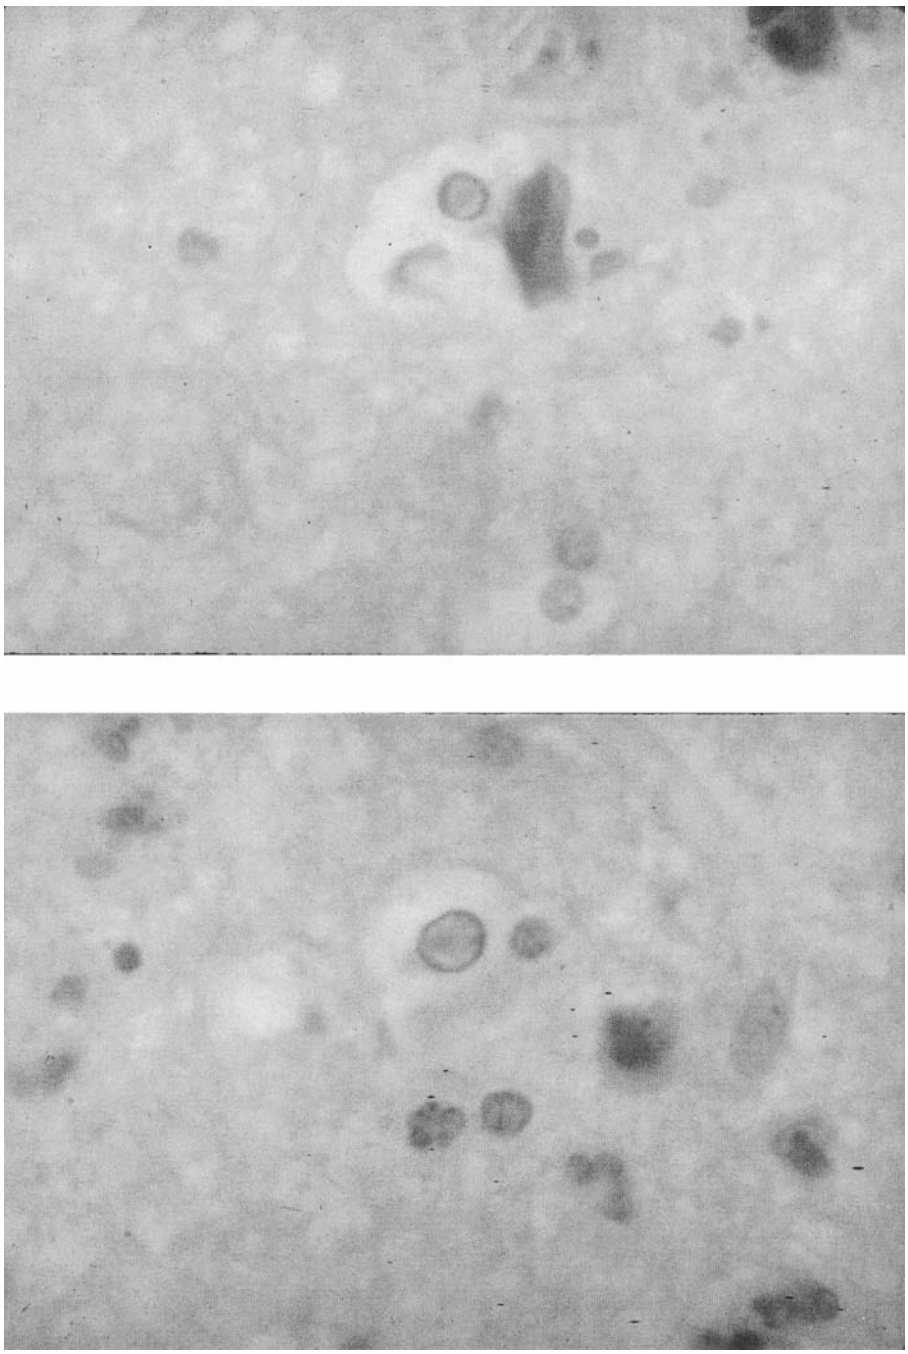

Fig. 32.6. Intranuclear inclusions (Whitley, 2004).

Humoral immunity does not prevent either recurrences or exogenous reinfection. Thus, it is not surprising that transplacentally acquired antibodies from the mother are not totally protective against newborn infection (Kohl *et al.*, 1989; Sullender *et al.*, 1987). The quantity of neutralizing antibodies is higher in those newborns who do not develop infection when exposed to HSV at delivery (Prober *et al.*, 1987). Transplacentally acquired neutralizing antibodies either prevent or ameliorate infection in exposed newborns, as do antibody-dependent cell-mediated cytotoxic antibodies (Prober *et al.*, 1987). Nevertheless, the presence of antibodies at the time of disease presentation does not

necessarily influence the subsequent outcome (Whitley *et al.*, 1988; Whitley *et al.*, 1980).

Infected newborns produce IgM antibodies (as detected by immunofluorescence) specific for HSV within the first 3 weeks of infection and increase rapidly during the first 2–3 months, being detectable for as long as 1 year after infection. The most reactive immunodeterminants are the surface viral glycoproteins, particularly gB and gD (Sullender *et al.*, 1987).

Newborns infected by HSV have a delayed T-lymphocyte proliferative response as compared to that of older individuals (Sullender *et al.*, 1987). Most infants have no detectable T-lymphocyte responses to HSV 2–4 weeks after the onset of clinical symptoms (Sullender *et al.*, 1987; Rasmussen and Merigan, 1978). These delayed responses may be associated with disease progression (Sullender *et al.*, 1987).

Infected newborns have decreased α-interferon production in response to HSV antigen as compared to adults with primary HSV infection (Sullender *et al.*, 1987). Lymphocytes from infected babies also have decreased responses to α-interferon generation (Sullender *et al.*, 1987).

Disease consequences

Most individuals who have prior serologic evidence of infection with HSV-1 and/or HSV-2 do not recognize that they have been infected (Whitley and Roizman, 2001). Therefore, most infections are asymptomatic or associated with non-specific signs and symptoms. However, when symptoms do occur, they tend to be more severe with primary compared with recurrent infections. Also, whether accompanied by symptoms or not, viral excretion during primary infection is more prolonged than shedding during recurrent infection.

The most common sites of HSV infection include the skin and mucosal surfaces. HSV-1 and HSV-2 infections tend to be transmitted by different routes and infect different areas of the body but signs and symptoms of infection with either virus are similar (Whitley and Roizman, 2001). In general, infections caused by HSV-1 occur above the waist and those caused by HSV-2 occur below the waist. However, over the last several decades considerable overlap in site of infection has evolved.

Orolabial infection

Primary infection

The oropharynx is the most common site of infection caused by HSV-1. Although most primary orolabial infections appear to be mild or asymptomatic, some young children develop extensive orolabial lesions accompanied by systemic symptoms. A typical course of severe infection includes, high fever, irritability, tender submandibular lymphadenopathy, and a widespread mucocutaneous eruption. Vesiculo-ulcerative lesions involve the palate, gingiva, tongue, lip, and perioral area (Kuzushima *et al.*, 1991). Dehydration, due to impaired eating and drinking, is the most common reason for hospital admission (Cesario *et al.*, 1969). Symptomatic primary infection may evolve over 2 to 3 weeks.

Primary HSV infection in older children and adults can present as pharyngitis. HSV has been isolated from the posterior pharynx of up to 24% of college students with symptoms of pharyngitis, including pharyngeal erythema, exudative or ulcerative lesions on the posterior pharynx and tonsils, enlarged cervical lymph nodes, and fever (McMillan *et al.*, 1993).

Reactivation

Reactivation of HSV from the trigeminal ganglia often is asymptomatic; silent excretion of virus by healthy previously infected individuals occurs on about 1% of days for children and 5% to 10% of days for adults (Scott *et al.*, 1997). In some individuals, viral reactivation, with or without associated symptoms occurs in association with fever, exposure to ultraviolet radiation or wind, non-specific stresses, manipulation of the trigeminal nerve root, or dental extraction (Openshaw and Bennett, 1982). It is estimated that 20 to 40% of adults experience recurrent herpes labialis (Bader *et al.*, 1978; Lowhagen *et al.*, 2002).

The outer edge of the vermilion border is the most common site of reactivation; on average three to five lesions are present. The lesions usually begin as vesicles, evolve into pustules or ulcers after 1 to 2 days, and heal within 8 to 10 days. Prodromal symptoms including burning, itching, or tingling may precede the outbreak by several hours and pain, when evident, is maximum at the onset of eruption, resolving after 4 to 5 days (Spruance *et al.*, 1977).

Genital infection

Primary infection

The majority of primary genital herpes infections occur in the absence of symptoms. When symptoms do occur, they tend to be more severe when infection is caused by HSV-2 than HSV-1 (Whitley, 2001). Systemic symptoms, including headache, fever, myalgia, and backache occur in about 70% of women and 40% of men seeking medical care for primary genital herpes (Corey *et al.*, 1983). These symptoms peak during the first 4 days of infection and abate

over the subsequent 7 to 10 days. Itching and local pain often precede visible lesions by 1 to 2 days. Lesions erupt over 7 to 8 days and evolve from vesicles and pustules to wet ulcers over approximately 10 days; crusting and healing follows over the ensuing 10 days. Common sites for lesions in women are the labia majora, labia minora, mons pubis, vaginal mucosa, and cervix. Lesions in men typically are found on the shaft of the penis. More than 80% of women and 40% of men have dysuria for 7 to 10 days. Tender inguinal adenopathy appears during the second to third week of illness and is generally the last sign to resolve. Complications are more common in women than men and include aseptic meningitis, paraesthesias and dysaesthesias of the legs and perineum, mucocutaneous lesions beyond the genital area, pharyngitis, and visceral dissemination. Perianal infection and proctitis are common in men who have sex with men.

Reactivation

Most recurrences of genital herpes are asymptomatic and, on any given day, symptomless shedding occurs in approximately 3 to 5% of women previously infected with HSV-2 (Wald *et al.*, 1997). Importantly, when PCR is used to detect evidence of HSV excretion in the genital tract of women known to have genital herpes, infectivity increases by at least fourfold. Thus, these women can be infectious as often as one out of four days.When symptoms do occur, they tend to be mild; constitutional complaints are present in less than 10% of patients and local prodromal symptoms are apparent in less than 50% (Corey *et al.*, 1983). Genital lesions are few in number and localized; they typically evolve from vesicle to healing in 8 to 10 days. The buttock, thighs and perianal mucosa may be unrecognized sites of recurrent infection. It has been suggested that herpes infection be considered in the differential diagnosis of unexplained recurrent itching, burning, blistering, or erythema at any site below the waist (Simmons, 2002). Approximately one-third of patients will not have recurrent infections, one-third will have two recurrences per year, and one third will have more than six recurrences per year (Whitley, 2001). Emotional stress, menses, and sexual intercourse have been some of the factors implicated in precipitating recurrences.

Keratoconjunctivitis

Herpes simplex virus is a major cause of ocular scarring and visual loss (Simmons, 2002). It is estimated that in excess of 300 000 cases of HSV eye infections are diagnosed each year in the United States (Whitley *et al.*, 1998). Beyond the neonatal period, the majority of these infections are caused by HSV-1. Infection may be unilateral or bilateral, beginning with follicular conjunctivitis associated with pain, photophobia, and tearing and followed by chemosis, periorbital edema, and preauricular lymphadenopathy (Pavan-Langston, 1990). Progressive infection may result in sight-threatening corneal ulcers, characterized by pathognomonic branching dendritic lesions. Healing may be slow, requiring more than 1 month. About one-third of individuals develop recurrences during the ensuing 5 years.

Cutaneous infections

HSV can infect virtually any part of the skin or mucosa. One of the most common cutaneous sites for HSV-1 or HSV-2 infection is the pulp or nail bed of the finger. This is referred to as herpetic whitlow and most commonly occurs in medical and dental professionals, in whom it results from digital contamination with genital or oral secretions (Feder and Long, 1983). When a young child develops herpetic whitlow, it may result from autoinoculation during primary oral herpes infection or when an infected adult trims the child's nails by biting (Feder and Long, 1983). The typical clinical course of whitlow involves the initial appearance of discrete vesicular or pustular lesions over the distal phalynx which subsequently coalesce over several days. Pain often is associated with a tingling or burning sensation. Fever, lymphangitis, and tender swelling of local lymph nodes may be present. The diagnosis of herpetic whitlow is most often confused with bacterial cellulitis.

Close contact between abraded skin and oral secretions results in cutaneous infections caused by HSV-1 among participants in certain contact sports including wrestlers (herpes gladiatorum) and rugby players (scrumpox) (Becker *et al.*, 1988; Stacey and Atkins, 2000). In descending order, the most common sites of infection among wrestlers are the head, extremities, and trunk (Belongia *et al.*, 1991). About 40% of infected athletes have associated sore throat and 25% have fever, chills, and headache (Belongia *et al.*, 1991). Herpes infections also can result in severe cutaneous infection when they occur on skin damaged by diaper dermatitis, burns, or atopic dermatitis (Jenson and Shapiro, 1987; Wheeler and Abele, 1966; McMill and Cartotto, 2000). Finally, HSV is the most common precipitating factor for recurrent erythema multiforme (Orton *et al.*, 1984).

Central nervous system infections

Herpes simplex viruses cause a variety of peripheral and CNS illnesses of infectious and post-infectious nature

(Simmons, 2002; Schmutzhard, 2001). HSV-1 is the most common cause of sporadic severe encephalitis in the United States, accounting for an estimated 10 to 20% of all cases (Lakeman *et al.*, 1995). Without treatment, more than 70% of infected patients die and virtually all survivors have severe sequelae (Whitley, 2001). Encephalitis can result from a primary or, more commonly, a reactivated HSV infection.

Patients typically present with altered state of consciousness, bizarre behavior, and focal neurologic findings, referable to the temporal lobe. Typical abnormalities in the cerebrospinal fluid (CSF) of patients with HSV encephalitis include a few hundred white blood cells/mm^3, with a predominance of lymphoid cells (75% to 100%) and an increased number of red blood cells (Koskiniemi *et al.*, 1984). Protein concentration is normal in about one-half of CSF specimens obtained during the first week of illness, but thereafter concentrations as high as 500 to 1200 mg/dl are common (Koskiniemi *et al.*, 1984). Virus rarely is isolated from CSF but the presence of HSV DNA, identified by polymerase chain reaction (PCR), is sensitive and specific for the diagnosis of HSV encephalitis (Lakeman *et al.*, 1995; Tang *et al.*, 1999).

Typical findings on electroencephalography include focal spike and slow-wave abnormalities, with characteristic paroxysmal lateralizing epileptiform discharges. Focal edema associated with hemorrhagic necrosis may be present on neurodiagnostic images; abnormalities tend to be evident earlier on magnetic resonance imaging than computed tomography.

Other neurologic syndromes associated with HSV infection include recurrent aseptic meningitis (Mollaret's meningitis), brainstem encephalitis, ascending myelitis, post infectious encephalomyelitis, a variety of movement disorders and atypical pain syndromes, and temporal lobe epilepsy (Simmons, 2002; Schmutzhard, 2001).

Neonatal infection

Over 90% of neonatal infections caused by HSV are contracted at the time of delivery (intrapartum infection) but about 5% are contracted in utero (congenital infection). Manifestations of congenital infection include skin lesions and scars, chorioretinitis, microcephaly, hydranencephaly, and microphthalmia (Hutto *et al.*, 1987).

Neonates infected perinatally present with a range of manifestations, categorized as localized to the skin eye and mouth (SEM) or the CNS, or as disseminated infection. In a recent cohort of 79 neonates with HSV infection who were enrolled into a clinical study between 1989 and 1997, 13% had SEM, 35% had CNS, and 52% had disseminated infection (Kimberlin *et al.*, 2001).

Neonates with SEM disease usually present during the first 2 weeks of life; occasionally skin lesions are evident in the delivery room. The cutaneous lesions first appear where there has been trauma, such as the site of attachment of fetal scalp electrodes, the margin of the eyes, or over the presenting body part. Initially the lesions appear as macules but they rapidly evolve to vesicles. Outcome of SEM disease is excellent if diagnosis is considered, and antiviral therapy administered, in a timely fashion (Kimberlin *et al.*, 2001).

Neonatal HSV infection involving the CNS usually results in fever and lethargy, first appearing between the second and third weeks of life. The sign most specific for HSV infection is the presence of skin lesions. However, approximately one-third infants with CNS disease due to HSV infection do not have skin lesions at the time of clinical presentation (Kimberlin *et al.*, 2001). A common but not as specific sign of neonatal HSV infection of the CNS is the sudden onset of seizures that tend to be focal and difficult to control. Usual CSF abnormalities include a mononuclear pleocytosis (<100 white blood cells/mm^3), slightly reduced glucose, and modestly to markedly elevated protein concentration. The electroencephalogram typically is diffusely abnormal and magnetic resonance imaging reveals either temporal or diffuse cerebral disease. If untreated, most neonates with CNS infection caused by HSV die and almost all survivors are left severely neurologically impaired.

Signs of disseminated infection caused by HSV may mimic severe bacterial infection with onset during the first week of life. Common clinical manifestations include vascular instability, hepatomegaly, jaundice, bleeding, and respiratory dysfunction. Approximately 60% of patients develop skin lesions during their illness, but lesions may be absent at the onset of symptoms (Kimberlin *et al.*, 2001). Progression of infection is rapid, with death resulting from shock, liver failure with bleeding, respiratory failure, or neurologic compromise.

Infection in compromised hosts

The likelihood of complicated HSV, with attendant substantial morbidity, parallels the degree of compromise of cellular immune function (Rand *et al.*, 1977). The most frequent complication of HSV infections among immunocompromised patients is slowly progressive and chronic mucocutaneous infections, accompanied by extensive tissue damage and necrosis (Whitley *et al.*, 1984; Whitley, 2004). Contiguous mucosal spread resulting in esophageal,

tracheal, pulmonary involvement or visceral dissemination also can occur but fatal infections are not common. Organ transplant recipients, particularly human stem cell transplant recipients, and individuals with HIV/AIDS are at particular risk for both severe and frequently recurrent infections.

Acknowledgment

This project has been funded in whole or in part with Federal funds from the National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health and Human Services, under Contract (NO1-AI -65306, NO1-AI-15113, NO1-AI-62554, NO1-AI-30025), the General Clinical Research Unit (RR-032), and the State of Alabama.

Molecular basis of HSV latency and reactivation

Chris M. Preston[1] and Stacey Efstathiou[2]

[1]Medical Research Council Virology Unit, Scotland, UK
[2]Division of Virology, Department of Pathology, University of Cambridge, UK

Introduction

Primary infection with HSV-1 or HSV-2 results in productive replication of the virus at the site of infection, following the pattern of gene expression described elsewhere in this volume. During this initial phase, virus enters sensory neurons via their termini and retrograde transport takes the genome to the neuronal nuclei in the sensory ganglia that innervate the infected dermatome. At early times after infection, virus replication occurs in ganglionic neurons but within a few days no virus can be detected. The genome, however, persists in neurons in a latent state from which it reactivates periodically to resume replication and produce infectious virus. This reactivation event may be "spontaneous" but is generally thought to be provoked by stress stimuli that act on the neuron, or at a peripheral site innervated by the infected ganglion, or systemically. Three phases of latency are recognized. Establishment occurs during the period following primary infection, and although virus replication can be detected in a proportion of neurons during this phase, the initiation and normal progression of productive infection and cell death is arrested in those neurons destined to become latently infected. Unravelling the way in which the seemingly inexorable progression of the gene expression program is blocked constitutes a major challenge for the molecular virologist. The maintenance phase of latency is characterized by the lifelong retention of the HSV genome in a silent state, characterized by repression of all viral lytic genes. One region, encoding the latency-associated transcripts (LATs), remains active during latency. Questions relating to the maintenance of the latent state focus on the structure of the genome, the mechanisms that silence it, and the specific properties of the LAT transcription unit that enable it to remain active. During the reactivation phase the silent genome responds to cellular signals that provoke the resumption of viral gene expression. The molecular basis for this dramatic functional reversal is poorly understood and is the subject of considerable research effort. In view of the specific association of LAT with the latent state, questions concerning the role of this transcript pervade all aspects of latency.

Model systems to study latency

Animal systems provide the most relevant means of studying HSV latency. In mice, latency can be established efficiently and relatively reproducibly after inoculation with HSV-1 in the cornea, ear, footpad, or at other peripheral sites. The virus replicates at the site of inoculation, and as a consequence the exact dose applied to nerve termini is undefined and changing over the first few days. These factors complicate quantitative aspects of latency studies. Reactivation is difficult to achieve in mice and most investigations have relied on explantation of ganglia, with subsequent culture in the laboratory, to recover virus (Stevens and Cook, 1971). An in vivo protocol has been developed in which reactivation is achieved by exposure of mice to transient hyperthermia (Sawtell and Thompson, 1992b). While this method is inefficient in terms of the number of reactivation events per animal, it represents the most relevant mouse model currently available for paralleling latency in humans. In the rabbit, inoculation of the cornea results in latency that, for certain strains of HSV-1 such as McKrea, is characterized by long-term periodic virus shedding, described as spontaneous reactivation. Production of virus can be enhanced by procedures such as iontophoresis of epinephrine into the eye. For HSV-2, inoculation into the guinea pig vagina results in latency in which virus is periodically shed to form lesions that can be scored. Therefore, the rabbit and guinea pig provide reasonable models for

HSV-1 and HSV-2, respectively, in humans but they are more difficult and expensive to use than the mouse. All animal systems entail inoculation with relatively high virus doses, often just short of fatal, and it is by no means clear how this relates to natural infection. A further problem is the considerable variation in the efficiency of establishment of latency and reactivation between strains of HSV, a factor that frequently causes confusion when comparisons are made between the results from different laboratories.

As a more tractable system, infection of cultured neurons has been investigated (Wilcox and Johnson, 1988; Arthur *et al.*, 2001). These cells are susceptible to lytic infection with HSV, but if measures are taken to prevent virus replication, long-term retention of the viral genome can be achieved. LAT can be detected in a proportion of neurons, but all other viral genes are repressed. Production of virus can be induced by removal of nerve growth factor (NGF), inhibition of histone deacetylases, or various treatments that activate signal transduction pathways (Smith *et al.*, 1992). Alternatively, cultures may be made from ganglia dissected from mice harboring latent HSV; in this case, heat shock or treatment with dexamethasone are the most effective reactivation stimuli (Halford *et al.*, 1996).

The final type of model involves the infection of standard tissue culture cells, usually human fibroblasts, with HSV-1 mutants that are impaired for immediate early (IE) gene expression and thus do not kill cells (Preston and Nicholl, 1997; Samaniego *et al.*, 1998). The viral genome is retained in a quiescent state in which all gene expression, including that of LAT, is repressed. The only known way of reactivating quiescent virus is to provide the HSV IE protein ICP0 by superinfection of cultures. Fibroblast systems may mimic some, but certainly not all, aspects of latency.

The latent genome

Latent HSV DNA does not contain detectable termini and almost certainly exists as a circular episome, in contrast to the linear state in the virus particle (Rock and Fraser, 1983; Efstathiou *et al.*, 1986). Quiescent genomes stably retained in fibroblasts are also circular (Jamieson *et al.*, 1995; Jackson and DeLuca, 2003). Various methods of quantifying viral DNA load revealed that latently infected neurons must contain, on average, many more than one HSV genome copy per infected cell. This conclusion has been verified by the use of "contextual analysis" (CXA), in which individual neurons or small groups of cells are separated and analyzed by polymerase chain reaction (PCR) (Sawtell, 1997). The latent viral genome copy number varied generally between 1 and 100, but a small proportion of neurons contained more than 1000 viral DNA molecules per cell. Likely, the retention of such high copy numbers has an influence on neuronal physiology, and recent studies have shown that latently infected ganglia contain increased levels of certain cellular gene products (Kramer *et al.*, 2003). Furthermore, analysis of latent DNA at a gross level is skewed towards the few neurons containing thousands of viral genomes. Surprisingly, for reasons that are not understood, latent viral DNA cannot be detected by *in situ* hybridization (ISH), therefore *in situ* PCR has been applied to investigate the number of neurons that harbor HSV genomes. This approach shows that many more cells contain DNA than are detected by ISH for LAT; thus, LAT is not an unambiguous marker for latent HSV. Laser capture microdissection, in which individual neurons are excised and analyzed by PCR, confirmed that viral genomes can be isolated from LAT-negative (LAT-) neurons and essentially agreed with the quantification from CXA (Chen *et al.*, 2002). The conclusion that there is a population of latently infected neurons that does not express LAT may depend on the sensitivity of ISH, since a study using *in situ* RT-PCR suggested that LAT was present in all HSV DNA-containing neurons, albeit at low concentration in many (Ramakrishnan *et al.*, 1996).

In cells, silencing of large gene blocks occurs at the level of chromatin structure, and it is therefore suspected that an organization of this type applies to the latent viral genome. One study has addressed this issue and found that all regions of HSV DNA examined, including the LAT region, exhibit a regular nucleosomal pattern in mouse brain stem (Deshmane and Fraser, 1989). Interpretation of this result is complicated by the fact that reactivation from brain stem is inefficient and, unfortunately, it was not possible to obtain sufficient material from trigeminal ganglia for similar analyses. More recently, the application of chromatin immunoprecipitation (ChiP) assays has demonstrated the importance of histone modifications in the maintenance of latency. It is well established that post-translational modification of the amino terminal tails of histones is involved in the regulation of transcription. Thus hyperacetylation of histones is generally associated with an "open chromatin" conformation and transcriptional activity, whilst histone hypoacetylation is associated with condensed chromatin and gene silencing. Recent work on HSV-1 suggests that chromatinization of the viral genome and certain accompanying histone modifications offer a means to regulate virus gene expression during lytic infection (Herrera and Triezenberg, 2004; Kent *et al.*, 2004). In the context of latency it is of particular significance that ChiP assays have shown the LAT promoter to be enriched with acetylated

histone H3 whilst representative lytic cycle promoters exhibit a decreased association with acetylated histones (Kubat *et al.*, 2004a,b). The demonstration that enrichment of acetylated histones on the ICP0 promoter following the application of a reactivation stimulus by ganglionic explantation strongly supports the view that genome derepression is linked to the acetylation status of histones positioned on lytic cycle promoters (Amelio *et al.*, 2006). Furthermore, it has been shown that a LAT- mutant exhibits enrichment of histone modifications associated with transcriptional activation during latency, suggesting that LAT-encoded functions facilitate maintenance of a repressed chromatinized genome (Wang *et al.*, 2005). Since HSV replication in ganglia precedes latency, it has long been suspected that some viral genomes are derived from residual replication intermediates rather than from virions delivered from the periphery. During infection with TK-mutants, which replicate at the site of inoculation but not in neurons, high copy number retention of TK-virus genomes is possible and therefore some neurons can receive hundreds of viruses from the periphery (Thompson and Sawtell, 2000). In general, however, TK-mutants deposit less latent DNA than wild type virus. However, depending on the site of inoculation, TK-mutants replicate less efficiently peripherally. Thus, apparently normal latency can be established without viral replication in neurons.

The latency-associated transcripts

The only transcripts detectable during latency are the LATs, which map to the viral repeats flanking U_L (Fig. 33.1). These have been detected in latently infected neuronal tissues from experimentally infected animals and following natural infection in humans (Stevens *et al.*, 1987). Similar transcripts are synthesized during latent infection by HSV-2 and other alphaherpesviruses such as bovine herpesvirus-1 (BHV-1) and pseudorabies virus.

Structure of LATs

In HSV-1, the LATs comprise a series of colinear predominantly nuclear transcripts. They consist of a highly abundant non-polyadenylated major species of 2.0 kb that is derived by splicing from a less abundant precursor RNA termed minor (m) LAT. The mLAT is transcribed antisense to the ICP0 gene and extends to a polyadenylation signal in the short repeat region. Based on the sequence analysis of HSV-1 strain 17, in LAT spans nucleotides 118 801 to 127 143 and consists of a primary transcript of 8.3 kb. Current evidence supports the view that the 2.0 kb major LAT is an unusually stable intron which is present to at least 40 000 copies per cell. The stability of this RNA is a consequence of inefficient debranching of the intron, due to the presence of a unique non-consensus guanosine branchpoint resulting in persistence of major LAT as a lariat. Further splicing of the 2.0 kb major LAT RNA occurs within neurons to produce an additional stable RNA species of 1.5 kb, which is also considered to accumulate as a stable lariat (Zabolotny *et al.*, 1997). A less complex pattern of transcription is observed during lytic infection of cells in culture. In this setting, synthesis of the 2.0 kb LAT can be detected late in infection but there is a notable absence of the 1.5 kb major LAT species. Furthermore, a fully processed transcript composed of the spliced exons of the primary transcript has not been detected during productive or latent infection, presumably reflecting the rapid degradation of this RNA species. ISH studies of latently infected sensory neurons have shown that major LATs have a diffuse nuclear localization pattern whereas mLATs are localized within discrete nuclear foci that may represent sites of accumulation or synthesis (Arthur *et al.*, 1993). In contrast, during productive infection of cells in culture the 2 kb LAT intron is also found in the cytoplasm and associates with both ribosomal and splicing complexes in infected cells (Ahmed and Fraser, 2001). More recently it has been shown that herpesviruses, including HSV-1, encode micro (mi) RNAs (Pfeffer *et al.*, 2005; Cui *et al.*, 2006). Interestingly, a single miRNA generated from the exon 1 region of LATs has been shown to exert an anti-apoptotic effect by targeting transforming growth factor (TGF) beta and SMAD3 expression (Gupta *et al.*, 2006).

The LAT promoter

Analyses of the HSV-1 DNA sequence upstream from the minor LAT transcription start site identified a TATA box (nt 118 647), a CAAT box (nt 118 647), two CREB binding sites, and SP1 binding sites, making this a candidate LAT promoter element (LAP1). To define the role played by LAP1 in LAT synthesis, a small fragment including the TATA box was deleted (Dobson *et al.*, 1989). Although such a virus could establish latency, no LATs were produced. In addition when the rabbit beta-globin gene was inserted downstream of the TATA box, beta-globin specific RNA, but no major LATs, were transcribed in latently infected neurons. These data are consistent with latent phase transcription initiating from LAP1 to produce the large mLAT species, which is subsequently processed to generate the stable major LAT species. Considerable effort has gone into studying the activity of LAP1 in transient assays. These studies have revealed that this promoter has a high basal activity in

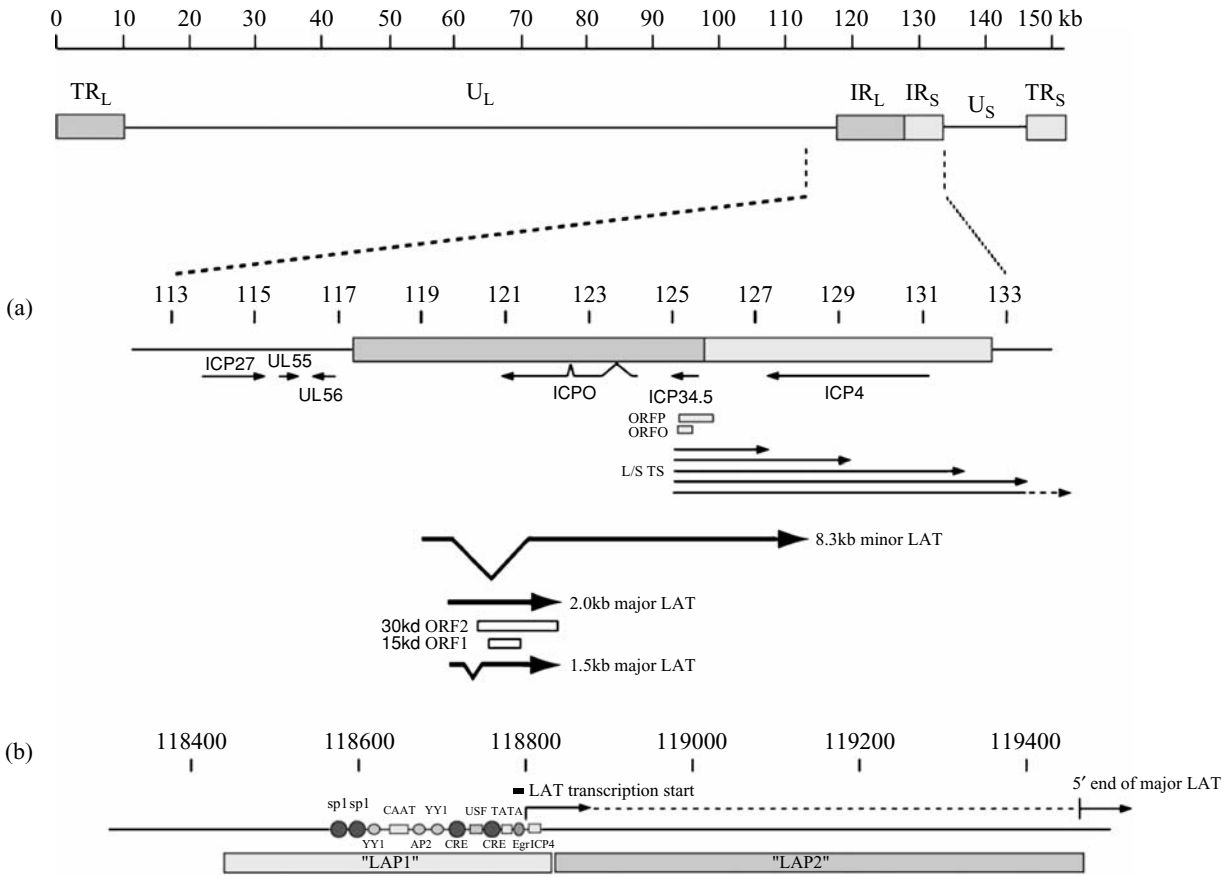

Fig. 33.1. Location and organization of HSV-1 LATs. The IR_L/IR_S region of the genome is expanded in part (a). In addition to the LATs, the positions of lytic cycle genes and a set of transcripts known as L/STs, which specify ORFs O and P, are shown. The functions of L/STs are unclear. The LAP1 and LAP2 promoters are depicted in (b).

a variety of non-neuronal cell types and shows enhanced activity in cells of neuronal origin, an observation consistent with the identification of neuron specific transcription factors which bind to upstream regions of the promoter. Since LATs are expressed to high levels in only a small proportion of latently infected neurons it is likely that their expression is tightly regulated during the various stages of latency. In support of this view, transient promoter assays in PC12 cells have identified *cis*-acting sequences which are required for activation by NGF and sodium butyrate, which mediate their affects via the Ras and Raf signalling pathways (Frazier *et al.*, 1996). The in vivo significance of these observations is unclear, although it has been suggested that the upregulation of LATs *via* expression of neurotrophins could function to block reactivation.

LAP1 contains two cAMP response elements (CREs), located at −38 bp (CRE1) and −77 bp (CRE2) relative to the LAT transcription start site, which appear to play an important role in virus reactivation. The CRE1 element has been shown to facilitate both epinephrine-induced reactivation in rabbits and reactivation in mice induced by hyperthermic stress or explantation of ganglia (Bloom *et al.*, 1996, 1997; Marquart *et al.*, 2001). Although these studies suggested that cAMP mediated up-regulation of LATs may be associated with reactivation, it is of interest to note that an *in vitro* neuronal latency model has linked expression of inducible cAMP repressors (ICERs) with downregulation of LATs and subsequent virus reactivation (Colgin *et al.*, 2001). Located adjacent to the LAP1 transcription start site is a binding site for ICP4 which functions to repress expression of LATs during lytic cycle replication. The mechanism by which the LAT promoter remains active during latency and escapes the otherwise global repression which is so efficiently imposed on the latent genome has been subject to much investigation. The observation that LAP1 deleted viruses are able to express 2 kb major LAT during lytic

infection in culture but not during latency in vivo implied the existence of a second promoter between LAP1 and the start of the major LAT intron (Nicosia *et al.*, 1993). A 600 bp fragment within this region was subsequently shown to exhibit promoter activity and was designated LAP2. This second latency associated promoter drives low level reporter gene expression when inserted at an ectopic site in the virus genome. However, despite its designation it would appear that LAP2 functions principally during lytic infection and appears to make a minimal contribution to LATs expression during latency (Chen *et al.*, 1995).

LAP1 is insufficient to mediate long-term latent phase expression, because insertion of reporter genes downstream of LAP1 results in only transient latent phase gene expression. Such studies indicate that although LAP1 contains elements necessary for neuronal expression, additional regulatory sequences are necessary for long-term promoter activity. A long-term expression element (LTE) has been shown to reside downstream of the LAP transcription start site and corresponds to a 1.5 kb fragment which contains an enhancer element and LAP2. Despite extensive efforts it has proven difficult to genetically dissect the downstream LTE sequence. This raises the possibility that the LTE cooperates with LAP1 to direct latent phase transcription (Lachmann and Efstathiou, 1997; Berthomme *et al.*, 2001).

Major LAT ORFs

Major LAT contains two prominent ORFs with the potential to encode proteins of 30 and 15 kd (Fig. 33.1). The lack of conservation of these ORFs between HSV-1 and HSV-2 and the lack of any detectable in vivo latency phenotypes of mutants in which these ORFs are disrupted has suggested that they are unlikely to be of functional significance. Nonetheless, cell lines expressing the 30 kd ORF2 can support the replication of virus mutants defective for IE gene expression and therefore that the ORF can overcome the repression characteristic of quiescent HSV (Thomas *et al.*, 2002). This raises the possibility that this ORF could play a role in reactivation. The significance of these observations remains unclear since there is currently no evidence for the expression of this ORF during infection or following the induction of reactivation from latency; further research in this area is clearly warranted.

Establishment of latency

Specific features of the neuron must be crucial for the interruption of the normal gene expression program during the establishment of latency. The point of arrest in neurons is not known at present, but a number of possibilities, not necessarily mutually exclusive, have been proposed. A description that includes all of the current data and hypotheses in a consistent manner cannot be presented, thus the concepts that are currently favored will be considered separately.

A block to HSV IE transcription

The hypothesis that viral IE transcription fails in neurons has its origins in the observation from tissue culture studies that synthesis of IE proteins is essential for virus replication. HSV mutants with mutations that prevent IE gene expression are not cytotoxic but instead are retained in a quiescent state; therefore, artificial measures to block IE protein production lead to a latency-like interaction in fibroblasts. In mouse ganglia, neurons express either viral antigens or LAT but rarely both during the first few days after infection, suggesting that early events determine the outcome of infection and that latency is incompatible with productive replication (Margolis *et al.*, 1992). Virus mutants that are unable to replicate in neurons still can establish latency. In particular, long term latent promoter activity was observed after inoculation of mice with high doses of HSV-1 mutants that lack the three major transcription activators VP16, ICP0 and ICP4 (Marshall *et al.*, 2000). These mutants enter neurons directly without replicating at a peripheral site. This approach represents the closest available to direct infection of the target cell. The results show that latency can be established in the absence of IE proteins; thus, a natural block to IE transcription in neurons is compatible with the latent state. Ideas on the mechanism by which gene expression in neurons may fail at this stage focus on the requirement for the formation of a TAATGARAT-binding multiprotein complex between VP16, Oct-1 and HCF to initiate IE transcription.

The infecting virion must travel long distances to reach the ganglion, and the structure of the subviral particle that is ultimately delivered to the neuronal nucleus is not known. One idea is that VP16, a tegument protein, fails to be transported to the ganglion with the viral genome, due either to physical loss during retrograde transport or to different uncoating mechanisms in the neuron (Kristie and Roizman, 1988). Alternatively, correct phosphorylation of VP16, especially at serine residue 375 within the Oct-1/HCF recognition domain, is required for its transcriptional activity, and this modification may be affected in neurons (O'Reilly *et al.*, 1997). Absence of functional VP16, even if Oct-1 and HCF are present, would be expected to reduce IE transcription and might, by analogy with

observations in cell cultures, predispose the genome to latency.

Oct-1 is a ubiquitous cellular protein initially defined by its ability to bind to the 'octamer' element ATGCAAAT. The protein participates in a variety of important cellular processes including transcription, and is utilized by many viruses for gene expression or replication. Oct-1 contains a 'POU' domain, which contains the DNA-binding elements and the sites for interaction with many different proteins including VP16. Sensory neurons contain Oct-1 in a form that is functional *in vitro;* thus it is unlikely that absence of this factor underlies a failure of IE transcription (Hagmann *et al.*, 1995). It is possible, however, that neuron-specific members of the POU-containing family interfere with the binding of Oct-1 to viral target sequences. Many POU-containing proteins bind to TAATGARAT elements in IE promoters but do not interact with VP16, and it would be expected that such proteins could compete with Oct-1 and thereby block gene activation (Latchman, 1999). Rodent Oct-1 varies from the human protein specifically at a few residues that are important for binding of human Oct-1 to VP16 and HCF (Cleary *et al.*, 1993). Thus, VP16 forms the multiprotein complex less efficiently with murine Oct-1, raising concerns about the relevance of the mouse models of latency. Possibly, latency is relatively favored over lytic replication in mice compared with humans. Murine Oct-1 must function to some extent in vivo, however, because HSV-1 VP16 mutants are severely attenuated for replication in mice; if Oct-1 were inactive, the absence of VP16 function would probably be inconsequential.

HCF is a large cellular protein of 2035 amino acids that undergoes internal proteolytic cleavage but nonetheless can participate in activation of transcription with only a heterodimer of the critical N- and C- terminal fragments. The N-terminal portion contains six repeats with homology to the *Drosophila* protein Kelch, that are predicted to form a propeller-like structure which binds VP16 (Wilson *et al.*, 1993). One major function of HCF appears to be stabilization of the Oct-1/VP16/HCF complex, but more recent studies suggest that HCF itself contains activating regions that may contribute to stimulation of gene expression (Lociano and Wilson, 2002). In proliferating cells HCF is associated with chromatin and is important for cell division, since a cell line harboring a temperature sensitive mutation in HCF arrests predominantly at G0/G1 upon shift to the non-permissive temperature. In sensory neurons in vivo, HCF appears to be cytoplasmic, possibly reflecting the non-dividing state of the cells (Kristie *et al.*, 1999). This localization, if maintained after infection, would prevent activation of IE transcription through the VP16-mediated pathway. Cellular proteins have been identified that, like VP16, contain the short motif $^{D}/_{E}$ HXY which interacts with the Kelch domain of HCF. One of these, named LZIP or Luman, is cytoplasmic in tissue culture cells and, when over-expressed, redistributes HCF from the nucleus to the endoplasmic reticulum (ER) (Freiman and Herr, 1997; Lu and Misra, 2000). Transfected tissue culture cells expressing Luman are impaired for productive HSV-1 replication, presumably because HCF is sequestered at the ER. Another HCF-binding protein, Zhangfei, is selectively expressed in human neurons and also blocks HSV-1 replication when ectopically expressed in tissue culture cells, possibly by counteracting VP16 (Akhova *et al.*, 2005). Clearly, if Luman, Zhangfei or other HCF-binding proteins are present in neurons, activation of IE transcription may be impaired, due to relocation of HCF to the ER, to competition for VP16-binding sites, or to interaction with VP16.

Role of LAT in the establishment of latency

Expression of LAT is not essential for any phase of latency, but there is considerable evidence that it plays a modulatory role. When LAT+ and LAT− viruses are compared virus production at the periphery and in the ganglion is generally equivalent, although early studies suggested that LAT− mutants produce greater quantities of lytic transcripts and proteins in neurons (Garber *et al.*, 1997). In general, however, LAT− mutants reactivate inefficiently and much experimentation has centered on whether this reflects a defect in reactivation *per se* or is a consequence of reduced ability to establish latency. Analysis of ganglionic viral DNA contents by direct PCR yields equivocal results, with some investigators reporting a deficit of around threefold and others detecting no significant difference. Errors in these estimations are inherently large, thus relevant differences might not score as statistically significant. The application of CXA revealed that corneal infection with LAT− mutants results in approximately threefold fewer latently infected neurons in trigeminal ganglia, although the HSV-1 genome content distribution within cells was indistinguishable from that of mice infected with a LAT+ virus (Thompson and Sawtell, 1997). These results suggest that LAT affects the number of neurons that ultimately harbor the latent genome rather than copy number within individual cells, and this conclusion is supported by investigation of the effect of LAT on neuronal survival (Perng *et al.*, 2000). Infected rabbit ganglia exhibited greater neuronal apoptosis after infection with a LAT− virus than with a LAT+ counterpart. This effect was maximal at 7 days post-infection, and, surprisingly, few apoptotic neurons were detected at 3 days post-infection, when virus

replication was at its peak. It is proposed that LAT has an anti-apoptotic activity that could result in a greater number of neurons surviving in animals infected with the LAT+ virus, thereby increasing establishment of latency. In mice, the basic observation that LAT improves neuronal survival also holds, although there is currently debate concerning whether death is through apoptosis or an alternative route (Thompson and Sawtell, 2001; Ahmed *et al.*, 2002). In tissue culture cells, expression of LAT from transfected plasmids or viruses inhibits apoptosis induced by toxic agents or by virus infection itself, supporting the idea of an anti-apoptotic role (Inman *et al.*, 2001). Furthermore, recent data showing that a miRNA encoded by the HSV-1 LAT gene regulates apoptosis induction by modulating TGF-beta signalling adds considerable support to the view that an important biological function of LATs is to prevent neuronal apoptosis during latency establishment and/or reactivation (Gupta *et al.*, 2006).

LAT has been proposed to block IE gene expression, possibly by antisense inhibition of ICP0 synthesis, an hypothesis that could explain the greater toxicity of LAT-mutants for neurons. Cultured neuroblastoma cells transformed stably to express the 2 kb LAT exhibited reduced permissiveness to HSV-1 infection and a reduction in the levels of all IE-specific mRNAs, suggesting an inhibitory effect of LAT on IE RNA production through a *trans*-acting mechanism (Mador *et al.*, 1998). However, no reduction in ICP0-specific transcript or protein levels was found in human 293T cells engineered to express 2 kb LAT (Burton *et al.*, 2003).

Alternative models for establishment of latency

In studies with cultured neurons ICP0 was not detected in the nucleus, even though ICP0-specific RNA was expressed (Chen *et al.*, 2000). The reasons for the failure to detect the protein are not clear, although post-transcriptional mechanisms are implicated. The absence of ICP0 might predispose the virus to latency.

All models for the establishment of latency are complicated by the fact that neurons are not inherently resistant to HSV infection because a proportion is able to support productive replication during the first few days after inoculation of animals. There is some evidence that specific neuronal subtypes may differ in susceptibility, but an absolute distinction between permissive and non-permissive cells has not been made to date. Most of the viral DNA produced during the acute phase is eliminated by a rapidly evolving immune response; however, there remains the possibility that some of the latent genomes are derived from replicated molecules rather than transport from peripheral sites. Studies with TK-mutants argue against this hypothesis for snout and corneal inoculation of mice, but in a flank inoculation model evidence was obtained for retention of replicated DNA in neurons that directly innervate the site of infection (Simmons *et al.*, 1992).

An all-encompassing model does not exist to describe the molecular basis for the establishment of latency. If the idea of an early decision between lytic infection and latency, with a primary block at the level of IE gene expression, is accepted, then there would be no apoptotic stimulus (in the form of *de novo* synthesized viral proteins) to the neuron. This is difficult to reconcile with the hypothesis that LAT antagonizes a response to the presence of viral proteins, which presupposes that the gene expression program proceeds past the IE stage. Possibly, there is heterogeneity in the responses of individual infected neurons, such that some escape an IE block but are arrested at a later stage by LAT. Understanding the cause of neuronal death in infected ganglia is critical to a resolution of these issues. The effect of LAT on the establishment of latency is anatomical site-specific, since LAT− mutants apparently show no difference from LAT+ HSV-1 when latency in dorsal root ganglia is examined after inoculation of the footpad (Sawtell and Thompson, 1992a).

Maintenance of latency

The stability of the latent state, together with the failure to detect viral gene expression apart from that of LAT, supports the concept that the majority of the genome is in a silent state that can be reversed only by specific triggers. Studies in the mouse using sensitive RT-PCR, however, demonstrated that transcripts from the ICP4 and TK regions of the genome could be detected in ganglia during latency (Kramer *et al.*, 1998). This observation is supported by experiments in which sections from many mouse ganglia were analyzed by ISH (Feldman *et al.*, 2002). Approximately one neuron per 10 sections was found to be positive for transcripts representing the lytic genes ICP4, TK and glycoprotein C. In addition, antigen positive neurons were detected at approximately the same frequency, and these cells were surrounded by an immune infiltrate. The most reasonable explanation for the results is that a few neurons support viral gene expression in the mouse, a view that is supported by the finding that interferon gamma and CD8+ T cells are present in murine ganglia at latent times, suggesting that active immune surveillance may operate to maintain latency (Cantin *et al.*, 1995; Khanna *et al.*, 2003). Further discussion of these results is given elsewhere in this volume. Therefore, although the majority of

latent genomes are retained in an untranscribed state, the possibility exists that some neurons express HSV-specific proteins and are prevented from producing virus by host immune responses.

Reactivation

Since viral gene products characteristic of the lytic cycle cannot, in general, be detected in latently infected neurons, cellular mechanisms must be important for reactivation. The crucial cellular events are not understood at the molecular level and are still vaguely described as applying 'stress' to the neuron. Furthermore, the models for reactivation may rely on very different cellular stimuli and hence the mechanisms involved may vary between both animals and systems. For instance, explantation is probably a more severe stress than in vivo treatments. A further serious complication arises from the fact that reactivation is an inefficient process with only a small proportion of the neurons that harbor viral genomes responding by production of virus. This means that the genomes detected at a gross level during latency may not represent those able to reactivate, with the latter possibly forming a small subset of the total. In addition, in a comparison between HSV-1 strains that differ in their abilities to respond to hyperthermia in vivo, the efficiency of reactivation correlated with the genome copy number distribution but not the number of neurons harboring latent virus (Sawtell, 1998). Therefore, the neurons containing large amounts of HSV DNA may be more susceptible to reactivation stimuli in vivo.

Models for reactivation depend critically on understanding the mechanism of establishment of latency. Thus, if the view is taken that a block in IE transcription leads to establishment, the route to reactivation can be subdivided into two basic concepts, depending on the consequences of the IE block. If, as in fibroblast models, failure of IE gene expression results in conversion of the genome into a quiescent state that is disrupted by ICP0 but is unresponsive to changes in cell physiology such as activation of signal transduction pathways, it follows that reactivation must be provoked either by the action of cellular proteins that mimic the activity of ICP0 or by induction of ICP0 synthesis. An alternative, more popular, view is that viral promoters are not repressed thoroughly, as in fibroblasts, but are inactive and potentially responsive to cellular signals provided by reactivation stimuli. The two models overlap if the genome is generally repressed but the ICP0 promoter specifically escapes repression. In this case, reactivation stimuli would initially be targeted to the ICP0 promoter, with the subsequent reversal of genome repression by the ICP0 protein. A role for LAT in reactivation is suggested by a number of experimental observations, although the interpretation of the data again depends on the events leading to establishment.

The role of ICP0 in reactivation

ICP0 was first characterized as a transcription activator that is not sequence-specific, but recent studies have shown that its primary mode of action is as an ubiquitin E3 ligase that mediates the targeted proteolysis of cellular proteins, particularly those of the nuclear structures known as ND10 (Everett, 2000; Van Sant *et al.*, 2001; Boutell *et al.*, 2002). Indeed, ICP0 rapidly and effectively mediates the disruption of all ND10 in the cell, with accompanying degradation of many of the component proteins. Since transcriptionally active input HSV genomes initially associate with ND10, it is thought that ICP0 creates an environment that is conducive to transcription, probably by directing the destruction of cellular repressors. Histone deacetylases (HDACs) promote the formation of inactive chromatin, thus it is interesting that ICP0 interacts with HDACs 4, 5 and 7 (Lomonte *et al.*, 2004). ICP0 also dissociates HDAC 1 and 2 from CoREST/REST, a protein complex that represses transcription, thereby possibly relieving repression (Gu *et al.*, 2005). These data suggest an important role for ICP0 in antagonizing histone-mediated gene silencing.The dramatic reversal of the quiescent state by ICP0 in cell culture suggests that this protein may be important for reactivation of latent HSV. Early in vivo studies showed that ICP0-deficient mutants were impaired for latency, as measured by reactivation efficiency after explantation, but it was not possible to distinguish between a true effect on reactivation and inefficient establishment due to the known reduction in replication at the periphery and in the ganglion. Immunosuppression of mice enables ICP0 null mutants to establish latency as efficiently as wild-type virus as judged by latent genome copy number, and ICP0 null mutants exhibit reduced reactivation efficiency in the explant model even when viral DNA loads in the ganglia are equivalent (Halford and Schaffer, 2001). ICP0 is therefore important for explant reactivation, but the exact stage at which it functions is unclear. Explantation might specifically induce the synthesis of ICP0, but an alternative interpretation is that ICP0 merely improves the replication, and hence detection, of HSV-1 once the reactivation stimulus has acted. The former hypothesis predicts that the promoter, or other important sequences controlling ICP0, contains elements that respond to reactivation stimuli.

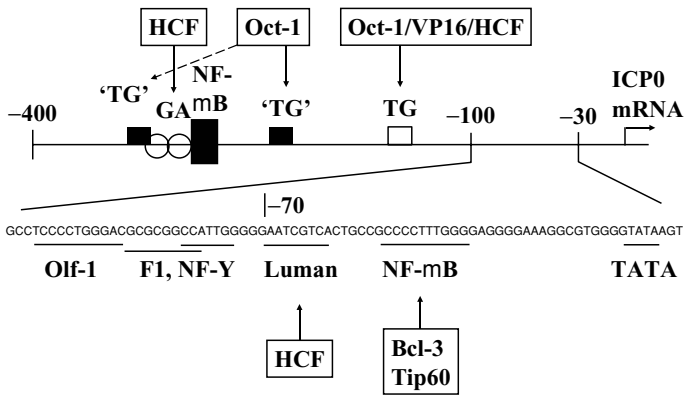

Fig. 33.2. Binding sites for transcription factors in the ICP0 promoter. The region to nucleotide −400 is shown, with the −100 to −30 sequences expanded. The major TAATGARAT element (TG), and two TAATGARAT homologies that have not been demonstrated to bind VP16 and HCF ('TG') are shown. Other sites in the −400 to −100 region predicted to bind GABP (GA; two sites) and NF-κB are also shown. There are functional data to support the binding of Olf-1, F1 plus NF-Y, and Luman to the indicated sites. The CCCCTTTGGGG motif at −57 is predicted to bind NF-κB on the basis of sequence homology.

The ICP0 promoter as a possible target for reactivation signals

The ICP0 promoter has many motifs, in addition to the TAATGARATs, that bind transcription factors, and these sites might be targets for reactivation stimuli (Fig. 33.2). Nucleotides –79 to –97 bind Olf-1, a neuron-specific factor that activates transcription (Devireddy and Jones, 2000), and sequences between –74 and –89 are recognized by two proteins, NF-Y and one of unknown identity (named F1), in the human neuroblastoma line IMR-32 (O'Rourke and O'Hare, 1993). Gene array analysis demonstrated that explantation of ganglia induces the synthesis of Bcl-3 (as well as other gene products) in neurons (Tsavachidou *et al.*, 2001). This is interesting because Bcl-3 associates with a dimer of the p50 subunit of NF-κB, and the ICP0 promoter contains NF-κB consensus binding sites at –51 and –273. Phosphorylation influences the binding of Bcl-3 to p50, thus explantation may activate kinases that promote the interaction of these proteins. Bcl-3 also interacts with Tip60, a histone acetylase, and therefore may mediate its effects by recruiting this protein and modifying chromatin structure at the ICP0 promoter. In ganglia, HCF is found in the cytoplasm of neurons but is transported to the nucleus within 20 minutes of explantation (Kristie *et al.*, 1999). If the HSV genome, or strategic regions such as the ICP0 promoter, is available for transcription then HCF, by virtue of its intrinsic activation domain, could trigger the viral gene expression program. This hypothesis requires that a mechanism exists for localizing HCF to the promoter, and binding to Oct-1 is the obvious candidate. However, HCF interacts with the ETS family member GABP, which binds to motifs of consensus CGGAAR (Vogel and Kristie, 2000). There are GABP recognition sites in the ICP0 promoter, and these might direct activation of transcription through a GABP/HCF complex. Another HCF-binding protein, Luman, is cytoplasmic in tissue culture cells but is, in essence, a basic leucine zipper transcription factor of the ATF/CREB family that can bind to CREs and activate transcription in an HCF-dependent manner (Lu and Misra, 2000). In tissue culture cells, Luman is released from the ER by the action of the site 1 protease, an enzyme that catalyzes the regulated intramembrane proteolysis (RIP) of membrane-bound transcription factors, releasing them for transport to the nucleus and activation of transcription (Raggo *et al.*, 2002). Various stress stimuli trigger RIP, thus reactivation signals may result in the release of Luman from the ER of neurons, thereby relocating a complex of this protein plus HCF to the nucleus. The proposed site of action is a CRE at position –67 in the ICP0 promoter.

Hypotheses on the significance of transcription factor binding to the ICP0 promoter must include the possibility that such binding may be relevant to replication in neurons at the early stages of infection rather than to reactivation. In addition, all of the above ideas must take account of studies on an HSV-1 mutant deleted for nucleotides –70 to –420 in the ICP0 promoter, thus lacking most of the factor-binding sequences mentioned above (Davido and Leib, 1996). This mutant established latency and displayed normal reactivation efficiency in the explantation system even though replication in cell culture was impaired, suggesting that the region between –70 and –420 in the ICP0 promoter, which includes most of the important known elements controlling expression in cell culture systems, does not contain critical target sequences for explant reactivation of latent virus. Notably, the NF-κB binding site at –51 and the CRE at –67 lie outwith the dispensable region.

Cellular reactivation signals

Among the many changes that occur in neurons following explantation of ganglia, the cyclin-dependent kinases cdk2, cdk4 and cdk7 exhibit alterations in abundance and location (Davido *et al.*, 2002). Increases in the level of cdk2 were observed, and this enzyme was found predominantly in the nucleus. In the case of cdk4, the protein was found mainly in the cytoplasm immediately after plating of explanted ganglia, but became nuclear during culture. A dramatic drop in cdk7 levels occurred within the first day of explant. HSV-1-specific antigens were found exclusively in those neurons

containing nuclear cdk2 and cdk4, suggesting that changes in the kinases might be required for reactivation. Roscovitine, an inhibitor of cdk2 that blocks HSV-1 replication in tissue culture, also prevented virus reactivation. Furthermore, no HSV-1 antigen reactivity could be detected in the presence of roscovitine, suggesting that the inhibitor blocks reactivation at an early stage rather than during spread of virus in the explanted ganglion. In tissue culture systems, roscovitine affects many aspects of HSV-1 replication, but it is noteworthy that the compound blocks the function of ICP0 due to alteration of post-translational modification. Therefore, cdk2 and cdk4 may be important for reactivation due to their roles in ensuring the activity of ICP0. In cultured primary rat neurons, withdrawal of NGF results in the rapid resumption of virus replication, to an extent mimicking one of the effects of explantation, in which the in vivo supply of NGF is disrupted (Wilcox and Johnson, 1988). Inhibition of deacetylases also reactivates latent virus in cultured neurons, suggesting a requirement for modification of chromatin structure (Arthur *et al.*, 2001). Treatment of cells with agents that activate signal transduction pathways through cAMP-mediated mechanisms is effective, and recent studies have indicated an involvement of inducible cAMP early repressors (ICER) in this process (Colgin *et al.*, 2001). ICER can heterodimerize with CREB/ATF transcription family members that mediate the transcriptional changes induced by cAMP, but since ICER lacks an activation domain the complexes act as repressors when bound to CREs. Expression of ICER itself is activated by cAMP and, intriguingly, by heat stress of neurons. Crucially, reactivation of latent HSV-1 was induced by infection of neuronal cultures with an adenovirus recombinant expressing ICER. In concert with reactivation, the levels of LAT decreased, leading to the suggestion that the known CREs in the LAT promoter mediate repression by ICER. This observation is difficult to reconcile with suggestions of a positive role for LAT in reactivation, as discussed below. However, in a model that uses cultured cells from dissociated ganglia of latently infected mice, transient heat shock or addition of dexamethasone induced reactivation but elevation of cAMP levels did not (Halford *et al.*, 1996). The nature of the reactivating stimuli therefore differs in the various cell culture systems currently available.

The role of LAT in reactivation

Early work ascertained that, in most cases, LAT− virus mutants reactivate less efficiently than their LAT+ counterparts. This observation was made in mice, for both explant and in vivo reactivation, in rabbits, and in guinea pigs infected with HSV-2. The conclusion that LAT has a role in reactivation is therefore widely accepted. This assumption is complicated by the findings, discussed above, that LAT− mutants establish latency less efficiently in some systems; clearly if fewer neurons harbor HSV genomes, a lower reactivation potential would be expected. Studies in mice, analyzing neuronal DNA contents by CXA, concluded that the impaired reactivation of LAT− mutants in trigeminal ganglia can be entirely accounted for by reduced establishment of latency (Thompson and Sawtell, 1997). Tellingly, it was possible to increase the efficiency of establishment by LAT− mutants to that of wild-type HSV-1 if hyperthermic treatment was applied during the first three days after infection. An equivalent rise in in vivo reactivation frequency to wild-type levels accompanied the increased establishment, strongly suggesting that the primary role of LAT in the mouse trigeminal ganglion is at the level of establishment of latency. In the rabbit eye model, LAT− mutants exhibit reduced efficiency of both spontaneous and induced reactivation. Analysis of latent DNA levels is difficult in this model, however, and although most studies conclude that LAT− and LAT+ mutants establish latency with equivalent efficiencies, variation in the data could obscure a three-fold difference. The question of whether LAT affects establishment or reactivation, or both, in the rabbit remains open. Intriguingly, replacement of the LAT region of HSV-2 with the equivalent region from HSV-1 revealed a role of LAT in anatomical-site specificity of reactivation (Yoshikawa *et al.*, 1996). The recombinant acquired HSV-1-like characteristics, displaying an increased response to iontophoresis of epinephrine in the rabbit but a reduced reactivation frequency in the guinea pig. Only the first 1.5 kb of the mLAT transcript, representing the LAP2 region and part of the stable LAT, is required for efficient spontaneous reactivation in the rabbit (Perng *et al.*, 1996). Re-introduction of sequences encoding this region, plus 1.8 kbp of the LAT promoter, between the UL37 and UL38 coding sequences of a LAT− mutant restored the defect and resulted in a virus exhibiting normal reactivation phenotype. Comparison between strains suggested that none of the ORFs that can be detected in the 1.5 kbp fragment is functionally important for reactivation (Drolet *et al.*, 1998). In addition, inhibition of apoptosis by HSV-1 LAT in tissue culture cells also maps to the 1.5 kbp region (Inman *et al.*, 2001). Thus, in the rabbit, the 1.5 kbp region is thought to mediate increased spontaneous reactivation by virtue of its anti-apoptotic activity. This view is strengthened by the finding that the reduced reactivation efficiency of LAT-viruses can be reversed by insertion of sequences that encode a baculovirus anti-apoptotic protein (Jin *et al.*, 2005). Therefore, the anti-apoptotic function of the LAT region may be important for prolonging survival of the reactivating cells and increasing the production of infectious virus. Deletion of a subfragment of the 1.5 kbp region, consisting of a part of LAP2, dramatically

reduced the efficiency of epinephrine-induced reactivation in the rabbit (Bloom *et al.*, 1996). This deleted region lies within the mLAT region and does not affect the accumulation of major LAT; thus, presumably either the expression of a transcript or a *cis* effect accounts for the activity of the LAP2-derived element and probably the entire 1.5 kbp region.

All of the ideas described above on the mechanism of reactivation assume that latency is essentially "static," with a switch required to reverse the silencing of the genome. The alternative "dynamic" model, in which continual low level production of virus occurs with lesions only occurring sporadically, does not readily fit with known ideas of viral gene expression but may be consistent with the detection of CD8+ T cells in ganglia (Khanna *et al.*, 2003). The use of PCR has demonstrated that aymptomatic shedding of HSV-1 and HSV-2 occurs with surprisingly high frequency in humans (Wald *et al.*, 1997), suggesting that the dynamic model, an interaction which could be envisaged as a slow persistent infection, deserves consideration.

Concluding remarks

Latency is clearly very complex at the molecular level, and the difficulties inherent in the model systems ensure that it will not be unraveled easily. The non-uniformity of latency, in terms of viral genome copy number, LAT expression and nature of reactivation stimulus, may be of fundamental benefit to the virus. If latency was uniform, a single stimulus might induce reactivation in the entire latent reservoir and result in clearance of the virus from the host. Perhaps the different virus/cell interactions respond to different host signals, explaining why it has been so difficult to arrive at a simple model for the molecular basis of latency.

Acknowledgments

We thank Valerie Preston for constructive comments on the manuscript, and Robin Lachmann for help with Figure 33.1.

Immunobiology and host response

David M. Koelle

Department of Medicine, University of Washington School of Medicine, Seattle, WA, USA

Introduction

Herpesviruses began to evolve prior to the development of acquired immunity (Arzul *et al.*, 2002). It is therefore likely that evasion of innate immunity is an ancient function of alphaherpesviruses. Additional immune evasion functions have developed to adapt to the diverse repertoires of B- and T-cell immune receptors that characterize acquired immunity (Roizman and Pellet, 2001; Littman *et al.*, 1999). Immune evasion is covered in detail elsewhere in this volume. The innate and acquired immune responses to HSV are relevant to preventative and therapeutic vaccines for HSV, HSV-induced immunopathology, and the use of modified HSV for gene or cancer therapy. While human studies are, of necessity, observational or ex vivo in nature and seldom access sites of neuronal latency, we review them in detail because of their medical relevance. The excellent tools available for murine studies, including exquisite control of the DNA sequence of HSV challenge strains, and of the phenotype and genotype of recipient animals, are yielding dramatic new insights as well. Reactivation of HSV from neuronal latency is less frequent in mice than in humans, limiting immunologic studies of this challenging phenomenon. Readers are referred to excellent reviews (Schmid and Rouse, 1992; Nash, 2000; Lopez *et al.*, 1993, Simmons *et al.*, 1992; Kohl,1992) for models and materials that cannot be covered in detail.

HSV interactions with dendritic cells

Dendritic cells (DC) are a major link between innate and acquired immunity. DC are mobile cells that can potently initiate acquired immunity. Priming of the HSV-specific CD8 response occurs promptly and vigorously, suggesting the involvement of DC. After HSV-1 footpad inoculation, draining lymph nodes (DLN) of C57BL/6 mice are infiltrated by large, activated (CD44+), CD8+, CD62L− cells that express Vβ10. In these mice, the CD8 T-cell response to HSV-1 is dominated by Vβ10+, K^b-restricted, HSV-1 $gB_{498–505}$-specific cells (Cose *et al.*, 1995; Wallace *et al.*, 1999). HSV-specific cells are detectable in DLN by tetramer staining by day 2 (Coles *et al.*, 2002), and peak at day 5 at about 5% of the total DLN CD8+ cells (Cose *et al.*, 1997; Jones *et al.*, 2000; Coles *et al.*, 2002). The low direct ex vivo HSV-specific cytotoxic T-lymphocyte CTL activity of DLN cells increases about 40-fold during simple "holding" of the cells in vitro for a few days. This functional maturation correlates with a 35-fold increase in the number of HSV-specific CD8+ cells during culture. These results imply profound in vivo stimulation of naive HSV-specific cells in vivo, which continues in vitro.

Infectious virus was not detected in the DLN (Jones *et al.*, 2000), suggesting that mobile antigen presenting cells (APC) acquire HSV antigen in the periphery and cross-present antigen to naïve CD8 T-cells in DLN. While cross-priming of HSV to naïve CD8 T-cells has not been reconstituted in vitro, fibroblastoid cells, as expected, were not competent for this function (Mueller *et al.*, 2003). The quickness of CD8 T-cell priming after HSV infection is impressive. Naïve wild-type mice were adoptively treated with syngeneic, naïve HSV-specific CD8 cells (from transgenic mice) and then infected. The HSV antigen is presented in the DLN by 6 hours after footpad infection, as detected by CD69 expression or a reporter gene, with the first cell division occurring within 24 hours. The HSV-specific cells gained effector CTL function simultaneously with replication. De novo HSV protein synthesis, rather than delivery of protein in the inoculum, was required for naïve T-cell stimulation, as demonstrated

with mutant viruses incapable of encoding the dominant epitope. Detection of viral DNA in the DLN again did not correlate with the priming of HSV-TCR (T-cell receptor) cells (Coles *et al.*, 2002).

DC subsets can be defined by tissue distribution, morphology, surface markers (which can differ between species), and responses to pathogens or other stimuli. To study which were DC involved in priming for HSV, DLN cells from two days after footpad infection were fractionated and admixed with naïve HSV-TCR cells (Smith *et al.*, 2003). B-cells, T-cells, CD11b+ macrophages, and Langerhans cells were not active APC. Depletion of cells expressing CD11c, CD8α, or DEC205 abrogated antigen presentation. The biologically active cells were CD8α+ CD45− cells, distinct from CD45+ plasmacytoid DC (O'Keeffe *et al.*, 2002). These "conventional" DC (CD8α+ in mice) are efficient cross-presenters (Iyoda *et al.*, 2002; den Haan *et al.*, 2000). While the DLN cells contained HSV DNA (Jones *et al.*, 2000; Smith *et al.*, 2003), other studies in this system (Jones *et al.*, 2000) showed no infectious virus. Similar studies were performed after flank skin inoculation with HSV, which results in a strictly epidermal infection. DC again accumulated in DLN that can prime naïve HSV-specific cells. No HSV DNA signal was detected in the active DLN cells (Mueller *et al.*, 2002). Fractionation studies (Allan *et al.*, 2003) revealed that the active APC were "conventional" CD11c+, CD8αhigh, CD205+, CD45RA− DC. Langerhans cells and plasmacytoid DC were detected in DLN, but did not have direct APC activity. Recently, the Carbone and Heath group determined that migratory DC do not directly present HSV antigen to naïve T-cells. Rather, DLN-resident CD8α+ DC appear to acquire antigen from migratory DC (Allan *et al.*, 2006). Local plasmacytoid DC-like cells and interferon-alpha may also play an important role in assisting priming of HSV-specific CD8 CTL responses (Yoneyama *et al.*, 2005). Taken together, multiple DC subsets appear to work together to prime cellular immunity after cutaneous HSV infection (Randolph, 2006).

The DC implicated in the priming of murine CD4 responses after HSV-2 vaginal inoculation may have a slightly different phenotype. Infection of steroid-treated mice with a *tk*- HSV-2 strain is confined to the epithelium. Zhao *et al.* found that CD11b+, CD11c+ cells migrated to the submucosa in areas subjacent to HSV-2 infection. DLN CD11c+ cells displayed up-regulation of costimulatory molecules for several days after inoculation. By day 2, DLN CD11c+ cells specifically stimulated HSV-specific CD4 T-cells, presumably due to presentation of HSV-2 antigen acquired in vivo. Fractionation showed that CD11c+, CD11b+ cells, but not B cells, were active APC. In contrast to the CD8 T-cell priming studies, the APC were CD8α−. Again, the active cells did not have features of Langerhans or plasmacytoid DC. No HSV DNA was detected in the DLN cells (Zhao *et al.*, 2003). Combined, these recent studies of priming after HSV infection demonstrate that specific DC subsets prime HSV-specific CD4 and CD8 T-cells in the apparent absence of their direct infection by HSV.

The APC involved in T-cell priming during primary HSV infections of humans are unknown. Langerhans cell numbers are decreased in HSV-infected skin, possibly consistent with their emigration and a role in antigen presentation (Memar *et al.*, 1995). Skin-derived Langerhans cells have APC function for HSV-specific memory HLA class II-restricted (CD4) responses in vitro (Vestey *et al.*, 1990). The ability of other cell types to present HSV antigen in the recall context is reviewed below.

In some viral infections, specific interactions with dendritic cells, such as direct infection, have roles in pathogenesis (Servet-Delprat *et al.*, 2003). Several groups have examined HSV infection of DC and the activity of immune evasion functions in these cells (Becker, 2003.) Human in vitro-generated myeloid DC express HSV entry receptors (Salio *et al.*, 1999) and can be productively infected by a clinical HSV-1 strain (Mikloska *et al.*, 2001). Efficient entry, but restricted immediate early gene expression, and little or no production of daughter virus was observed with various lab strains of HSV-1 (Rong *et al.*, 2003; Kruse *et al.*, 2000; Pollara *et al.*, 2003; Samady *et al.*, 2003). HSV is pathogenic in both murine and human DC even in the absence of productive infection (Jones *et al.*, 2003; Samady *et al.*, 2003; Pollara *et al.*, 2003). There is more agreement that HSV infection generally inhibits DC maturation and function. Addition of infectious HSV generally blocks LPS-mediated maturation of myeloid DC, as measured by up-regulation of T-cell co-stimulatory molecules, with some evidence that "bystander" uninfected DC may be activated to mature by factors released from infected DC (Salio *et al.*, 1999; Samady *et al.*, 2003; Pollara *et al.*, 2003). Bystander DC were not adversely affected in terms of cytokine secretion and T-cell stimulatory capacity for third-party responses, while infected cells were markedly functionally impaired (Salio *et al.*, 1999; Pollara *et al.*, 2003). Infection of mature myeloid DC can specifically down-regulate CD83 (Kruse *et al.*, 2000). Some genes responsible for this inhibition have been identified. In HSV-1, *vhs* (unique long gene 41, *UL41*) may be involved (Samady *et al.*, 2003). For HSV-1, deletion of vhs and US12 (encoding unique short gene 12, infected cell protein 47, ICP47) has been reported to improve DC antigen presentation (Sun *et al.*, 2003). The complex, mainly inhibitory effects of HSV on DC function were examined in the context of stimulating recall T-cell responses to HSV itself. Lower MOIs permitted detection of memory

responses, which were abrogated by high-dose infection of human myeloid DC (Pollara *et al.*, 2003).

CD8 T-cell responses to HSV

The long-term consequences of primary infection include immunologic priming and latent infection of ganglia. Events of immunologic interest in the ganglia are reviewed first, followed by a discussion of memory CD8 responses in the blood and peripheral tissues. While mice do not have spontaneous HSV recurrences, virologic and immunologic data are consistent with chronic, low level HSV gene expression and immune recognition in dorsal root ganglia (DRG). High subclinical HSV shedding rates in humans are consistent with chronic or very frequent, intermittent reactivation (4). HSV may be fundamentally less tightly controlled in human than in murine ganglia.

After recovery from HSV-1 infection, latently infected murine ganglia show persistent evidence of inflammation. Feldman *et al.* 2002) studied trigeminal ganglia (TG) of mice 5 to 7 weeks after recovery from ocular inoculation with HSV-1. mRNA for lytic HSV genes were localized to rare neuron-like cells surrounded by mononuclear leukocytes, while LAT (+) neurons lacked this infiltrate. The ratio of LAT RNA (+) to lytic RNA (+) cells was about 5000. Late protein (gC) was detected by immunohistochemistry in rare neuron-like cells. These data extend RT-PCR analyses of latently infected ganglia that detect lytic HSV-1 mRNA (Kramer and Coen, 1995). Latently infected ganglia are also enriched for mRNA encoding pro-inflammatory and lymphocyte-specific proteins such as IFN-γ. The cellular source of this IFN-γ mRNA is somewhat obscure (Tscharke and Simmons, 1999) despite the detection of HSV-specific, IFN-γ-producing cells in infected ganglia (below). Levels of these host response transcripts do not strictly correlate with the ability to reactivate: mutant *tk*- strains, which cannot reactivate to make infectious virus, still lead to persistent inflammation (Chen *et al.*, 2000). Possibly, specific viral proteins, or HSV DNA, which is rich in potentially immunostimulatory CpG sequences (McGeoch *et al.*, 1988), stimulate inflammation in the absence of complete reactivation. Therapy that interrupts HSV DNA replication reduces (but does not eliminate) inflammation in murine TG latently infected with a different HSV-1 strain (Halford *et al.*, 1997).

The CD8 response in murine ganglia can be separated into acute and latent phases. In A/J mice, the earliest cells infiltrating the TG after corneal HSV-1 strain RE infection are NK-like cells and macrophages (Liu *et al.*, 1996). Virus is cleared by day 7; TCR γδ cells start to appear at this time. The CD8 infiltrate peaks on day 12, most after viral antigen becomes undetectable. In this model, a significant number of CD4, CD8, TCR γδ, macrophage-like, and NK-like cells, and cells positive for TNF, persist in the ganglia for up to 90 days. After flank scarification of mice, CD8+ cells are involved in control of HSV-1 replication in the draining ganglia (Simmons and Tscharke, 1992). Temporally, there is a good correlation between CD8 cell infiltration and viral control (Speck and Simmons, 1998). MHC class I molecules are observed to be up-regulated on ganglionic cells during this phase, and neuronal cell death is not observed (Pereira and Simmons, 1999; Speck and Simmons, 1998; Pereira *et al.*, 1994).

CD8+ cells may "monitor" the HSV-1-infected murine ganglia and contribute to the maintenance of clinical latency. Explanted, HSV-1 latently-infected TG contain endogenous CD8+ cells that suppress reactivation. Exogenous, immune CD8+ T-cells can serve the same function in an MHC-restricted fashion (Liu *et al.*, 2000; Khanna *et al.*, 2003). A non-lytic mechanism is suggested by the continuing presence of HSV genomes (presumably in latently infected neurons) in "suppressed" cultures. IFN-γ may exert an antiviral effect. The release of IFN-γ from TG in culture is inhibited by acyclovir, implying that lymphocyte recognition of viral protein is a step in lymphokine secretion. In addition, exogenous IFN-γ protects against reactivation from latency in ganglionic explants in a model which includes initial acyclovir blockade (Liu *et al.*, 2001). Direct effects of IFN-γ on neurons, and indirect effects mediated by CD8+ cells, were both detected. Another possible effector molecule is granzyme A, a constituent of CD8 T-cell and NK cell granules (Lieberman and Fan, 2003). Animals deficient in granzyme A show decreased viral clearance from draining DRG after peripheral HSV-1 inoculation (Pereira *et al.*, 2000).

Direct evidence for involvement of HSV-1-specific "classic" CD8 T-cells in viral control in TG has been obtained in C57BL/6 mice. Cells recognizing the dominant K^b-restricted, HSV-1 $gB_{498–505}$ epitope infiltrate TG 2 to 5 weeks after ocular HSV-1 infection, as shown by tetramer staining (in situ and after dissociation of TG) and IFN-γ responses (Khanna *et al.*, 2003). Interestingly, these cells appear to become increasing activated from day 14 to day 34. The functional antiviral activity of the ganglionic CD8 cells appeared to wane somewhat by day 34 (Liu *et al.*, 2000). The duration of ganglionic localization is of interest, given the chronicity of HSV infections in humans. It is not known whether the HSV-specific CD8 cells are reacting to low levels of lytic protein expression, and/or somehow sense, or assist with the maintenance of, latent gene transcription. The factors involved in T-cell trafficking to

ganglia are unknown. Taken together, these data are consistent with a model in which HSV-specific CD8+ T-cells are persistently localized to HSV-infected ganglia. Recently, the group of Verjans and Osterhaus (Osterhaus *et al.*, 2006) has demonstrated that human trigeminal ganglia latently infected by HSV-1, contain HSV-specific CD8 T-cells capable of producing IFN-γ. It will be of great interest to determine the effector functions, phenotype, and fine specificity of these T-cells. In contrast to ganglia, DLN HSV-specific murine CD4 (Zhao *et al.*, 2003) and CD8 (Andersen *et al.*, 2000) T-cells decline dramatically in after recovery from peripheral HSV inoculation, as expected for classic cellular immune responses.

The functional importance of CD8 T-cells in mice is somewhat dependent on the details of the experimental model. Mice deficient in β2-microglobulin, and therefore in CD8 T-cells, have decreased containment of HSV infection in some models (Holterman *et al.*, 1999; Manickan and Rouse, 1995). However, these mice also lack CD1d-restricted NKT cells. Deletion of ICP47 from HSV-1 can decrease neurovirulence, consistent with an effect due to increased recognition of infected cells by CD8 T-cells (Goldsmith *et al.*, 1998). CD8 T-cells alone can provide protection against HSV-1. This was established by immunizing MHC-suitable mice with the $gB1_{498–505}$ epitope, albeit in a specialized vaccinia format (Blaney *et al.*, 1998). The immunodominance of $gB1_{498–505}$ in H-2^b mice was recently exploited to study the relationship between T-cell avidity and diversity and functional protection (Messaoudi *et al.*, 2002). Mice with an allelic variant of H-2^b were found to be relatively resistant to acute HSV-1 lethal infection compared to wild-type H-2^b congenics. The resistant mice had a higher diversity of $gB1_{498-505}$-specific CD8 T-cells in their repertoire, which included cells with very high avidity for peptide-MHC, compared to the wild-type H-2^b mice. The cause of this diversity was hypothesized to be differences in thymic T-cell positive selection, prior to viral infection. Diversity in HLA class I alleles, and hence of the T-cell repertoire, gives a selective advantage in human HIV-1 infection (Trachtenberg *et al.*, 2003) but has not yet been studied for HSV. Contributions to TCR repertoire variability from previous viral infections (Brehm *et al.*, 2002), allelic variations at non-restricting self MHC (Burrows *et al.*, 1995), and minor histocompatibility (Roopenian *et al.*, 2002) loci are well documented and are likely applicable to HSV immunology.

Human CD8 and other immune responses may be expected to differ from murine responses. Lytic replication occurs intermittently in essentially all infected people (Wald *et al.*, 2000), perhaps maintaining or "maturing" responses. Some immune evasion mechanisms, such as transporter of antigen processing (TAP) inhibition by ICP47, are much stronger in humans (Tomazin *et al.*, 1998), potentially influencing CD8 responses. On the balance, HSV stimulates readily detectable CD8 responses in humans. Based on limited tetramer analyses of chronically infected persons, responses are lower than those seen for CMV and EBV (Koelle *et al.*, 2002b; Barouch and Letvin, 2001). HSV infects mainly non-professional APC in a relatively small tissue volume. Some other chronic viral infections such as HPV, HCV, and HBV stimulate even lower-abundance CD8 responses as assessed in the blood. The reasons for this variability remain unknown.

Data concerning the importance of CD8 responses in humans is indirect. The frequency ("pCTL") of circulating CD8+ cells which, in response to HSV-2 antigen, give rise to progeny which kill autologous infected cells in classical limiting dilution assays, is on the order of 1 in 6000 peripheral blood mononuclear cells (PBMC) (perhaps 1 in 1500 or so CD8 T-cells) (Posavad *et al.*, 1996). Among HIV and HSV-2 co-infected persons, the pCTL was inversely correlated with HSV-2 disease severity (Posavad *et al.*, 1997). HLA correlation studies support a functional role for CD8 T-cells as some have shown associations between HLA class I alleles and HSV-2 infection or severity (Lekstrom-Himes *et al.*, 1999). CD8 T-cells with HSV-specific CTL and IFN-γ secretion localize to recurrent genital HSV-2 lesions, and the infiltration of CTL is temporally correlated with clearance of culturable virus (Koelle *et al.*, 1998b). It is not clear if this is simply a reactive "mop-up brigade," or if similar cells are capable of holding HSV replication below clinical threshold or even below the threshold of subclinical shedding (Wald *et al.*, 2000).

HSV-specific CD8 T-cells likely interact with many APC in vivo, including DC, ganglionic cells, and infected cells in the periphery, with different outcomes. The type and condition of APC used in vitro to characterize CD8 responses is also critically important. Fibroblasts are more susceptible than B cells to HSV-mediated down-regulation of HLA class I (Koelle *et al.*, 1993) and poorly re-stimulate memory CD8 responses (Yasukawa *et al.*, 1989; Tigges *et al.*, 1992). Recognition of fibroblasts can be obtained, but knock-out of one or both the immune evasion-related genes, *US12* and *vhs*, or pre-treatment with IFN-γ, is required (Koelle *et al.*, 2001; Tigges *et al.*, 1996). Similarly, recognition of keratinocytes, representative of the likely in vivo target cell in the periphery, requires IFN-γ and specific infection conditions (Mikloska *et al.*, 1996, 2001; Koelle *et al.*, 2001). In vivo, HSV lesions are rich in IFN-γ and display signs of local IFN-γ effects (up-regulation of keratinocyte HLA class II) quite early on (Cunningham *et al.*, 1985; Koelle and Corey, 1995), so these systems may be somewhat physiological. EBV-transformed B cells are more frequently used as APC

in the readout phase of cytotoxicity assays, but their in vivo relevance is questionable. Human HSV-specific CD8 CTL can recognize and kill bystander CD8 T-cells (Raftery *et al.*, 1999), but it is not clear if T-cells are a physiologically important target in vivo.

The number and functional characteristics of human HSV-specific CD8 cells are of interest given their potential varied roles in the nervous system and periphery. Assays of IFN-γ secretion by circulating CD8+ cells in response to HSV-2-infected DC reveals responses (median 0.64%) higher than pCTL estimates (Posavad *et al.*, 2003). While tetramer staining can reveal populations of up to 0.6% of circulating CD8+ cells to be HSV-2-specific (Koelle *et al.*, 2002b), it is not known how many of these cells have CTL, IFN-γ, or both activities. CD8 clones with CTL activity have each displayed specific IFN-γ secretion (Koelle *et al.*, 2001, 2002b). The cytolytic pathways used by HSV-specific CD8 cells are unknown, and are relevant given HSV inhibition of CTL-induced apoptosis (Cartier *et al.*, 2003). Reductions in viral output after interaction with infected target cells, noted for HSV-specific CD4 and NK cells (Yasukawa and Kobayashi, 1985), and for virus-specific CD8 cells in other systems (Yang *et al.*, 2003), are little studied for HSV and CD8 cells. Circulating HSV-2-specific CD8 cells specific for one epitope in virion protein 22 (VP22) are largely CD28+, consistent with a capacity for self-renewal through co-stimulation (Hamann *et al.*, 1997). In other human viral infections, CD28 can vary from epitope to epitope (Koelle *et al.*, 2001). Comparisons by epitope are not yet available for HSV, but we were able to recover HSV-2-specific CD8 CTL of diverse fine specificity using expression of CD28 as a selection criteria (Koelle and Corey, 2003). HSV-specific CD8 cells detected during chronic infection also express CD62L and CCR7 (+), molecules thought to assist in homing to lymph nodes (Sallusto *et al.*, 1999).

The first human CD8 epitopes in HSV were found several years ago, in gB2 and gD2, using a small panel of recombinant vaccinia viruses (Tigges *et al.*, 1992, 1996). Additional HSV antigens recognized by human CD8 T-cells have recently been described with methods such as ORF-spanning peptide pools (Hosken *et al.*, 2006) and expression cloning using whole HSV genome libraries (Koelle *et al.*, 2001, 2002a, 2003). HSV-2 proteins from diverse structural and kinetic classes are now known to be CD8 targets. Known human HSV-1 epitopes are limited to two cross-reactive epitopes in gB and VP13/14 (Tigges *et al.*, 1996; Koelle, 2003). CD8 antigens include, for HSV-2, glycoproteins gB, gD, and gE, the capsid or scaffold protein products of the *UL26* (or in-frame overlapping *UL26.5*) and *UL25* genes, and the tegument proteins VP16 (*UL48*), VP22 (*UL49*), VP13/14 (*UL47*), and the *UL7* gene product. The immediate early non-structural proteins ICP0, ICP4, and ICP27 are also recognized (Mikloska *et al.*, 2001; Koelle, 2003; Koelle *et al.*, 2001, 2002b, 1992; Tigges *et al.*, 1996). IFN-γ ELISPOT surveys have revealed stimulatory peptides in many other ORFS (Hosken *et al.*, 2006) and await complementary studies such as CTL assays and effector cell enrichment from PBMC.

Functional data from longitudinal biopsy studies of genital HSV-2 lesions in humans, in which serial specimens are used for culture of skin-infiltrating lymphocytes, have also been used to probe the CD8 response. HSV-2-specific CD8 T-cells were shown to be dramatically locally enriched, compared to the blood (Koelle *et al.*, 1998b). The mechanism of homing to skin was investigated with HSV-specific tetramers and antibodies to a skin homing-associated molecule, CLA (cutaneous lymphocyte-associated antigen) (Fig. 34.1). Pronounced expression of CLA was detected on HSV-specific cells; expression by control CD8 cells specific for the non skin-associated pathogens EBV and CMV was low (Koelle *et al.*, 2002b). CLA expression enables one-step enrichment of HSV-2-reactive CD8 CTL from blood (Koelle, 2003). Both CLA-positive cells and E-selectin up-regulation are present in human genital HSV-2 lesions (Koelle *et al.*, 2002b). The pathway by which naïve HSV-specific CD8 cells become "programmed" to express CLA is unknown. The cytokines IL-12, TGF-β, and class I IFN are present in HSV lesions (Van Voorhis *et al.*, 1996; Kokuba *et al.*, 1999; Overall *et al.*, 1981), and can synergize with T-cell stimulation through TCR to enhance CLA expression. Plasmacytoid DC can prime CLA on human CD8 T-cells (Salio *et al.*, 2003) and react with HSV as discussed below, but have yet to be documented in HSV lesions.

A CLA-associated determinant binds to E-selectin, a lumenal venular endothelial adhesion molecule up-regulated in the inflamed skin and genital tract (Johansson *et al.*, 1999). Known up-regulators of E-selectin, IL-1, IFN-γ and TNF-α, are enriched in HSV lesions (Doukas and Pober, 1990; Xia *et al.*, 1998; Cunningham *et al.*, 1985; Keadle *et al.*, 2000). In immune mice, treatment with anti-IFN-γ decreases recruitment of lymphocytes adherence to endothelium after vaginal HSV challenge (Parr and Parr, 2003), possibly via decreases in adhesion molecule expression. Parr and Parr documented up-regulation of ICAM-1 and VCAM-1, but not E-selectin or MadCAM-1 (A_EB_7 integrin ligand) in the HSV-2 infected mouse vagina (Parr and Parr, 2000).

Note was made above of the immunodominance of CD8 responses to a specific peptide in H-2^b haplotype mice. There is little information concerning diversity and dominance within the CD8 response in individual HSV-infected

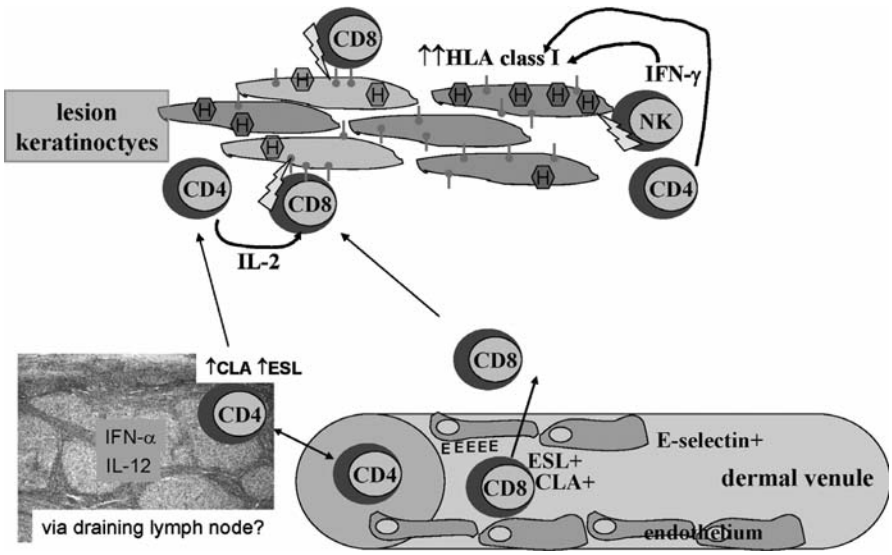

Fig. 34.1. Model of human recurrent genital HSV-2 lesion.

persons. Recently, CLA expression was used to derive panels of HSV-2-specific CD8 CTL clones from blood samples, without secondary in vitro re-stimulation with antigen. The fine specificity of each resultant clone was determined. For most subjects, clonal enumeration detected responses that were focused on one to three HSV-2 peptides per person (Koelle, 2003). Likely, subdominant responses were missed. Similar to other viral systems in humans (Betts *et al.*, 2000), the presence of a specific HLA class I allele did not exert a dominant effect over the selection of viral epitopes for recognition. In some individuals with prevalent alleles such as HLA A*0201 or B*0702, clones restricted by these alleles predominated, while the major response "ignored" these alleles in other persons. Tegument-derived peptides were recognized the most frequently when clonal specificities were categorized by viral structural and kinetic class. Virion input tegument proteins to be recognized in infected APC without a requirement for de novo protein synthesis (Koelle *et al.*, 2001), but it is not known if this contributes to the relatively frequent recovery of clones specific for tegument proteins.

Higher estimates of the diversity of the human CD8 response to HSV-2 have recently been obtained using overlapping peptide sets covering about half of the proteome and IFN-γ secretion as the readout. The median number of ORFs recognized per person was 11. Tegument and immediate early targets of the CD8 response were particularly well represented. The cumulative frequency of IFN-γ producing cells was generally well under 1% of CD8 cells (Hosken *et al.*, 2006). As with the tetramer readouts mentioned above, peptide interrogation of IFN-γ secreting cells show that the integrated CD8 response to HSV-2 in the PBMC compartment is likely much smaller than the response to CMV (Sylwester *et al.*, 2005).

CD4 T-cell responses to HSV

CD4 T-cells have several potential antiviral functions including B-cell help (Yasukawa *et al.*, 1988), CD8 help (Lu *et al.*, 2000), secretion of antiviral (Wong and Goeddel, 1986) and immune-enhancing cytokines such as IFN-γ and TNF-α, and direct cytotoxicity (Yasukawa and Zarling, 1984). These cells localize by day two to recurrent human genital HSV-2 lesions (Koelle *et al.*, 1998b), and also to the uterine cervix (Koelle *et al.*, 2000b) and to the cornea and retina in human ocular HSV infections (Verjans *et al.*, 1996, 1998; Koelle *et al.*, 2000a). Brisk lymphoproliferative responses by PBMC to killed whole HSV reflect a fairly high frequency of HSV-specific CD4 cells in seropositive persons. Quantitative estimates range from about 0.1% of PBMC by limiting dilution proliferation assays (Posavad *et al.*, 1997) to 0.2%–0.4% of circulating CD4+ lymphocytes by IFN-γ intracellular cytokine cytometry (ICC) (Asanuma *et al.*, 2000), and TNFβ ELISPOT (Schmid *et al.*, 1997). CD40L up-regulation, a vital step in B-cell and CD8 T-cell help via DC conditioning, is also detectable on about 0.5% of peripheral blood CD4 cells in response to HSV-2 antigen (Gonzalez *et al.*, 2005). The responder estimates for a specific peptide epitope are quite low (0.002% of CD4

cells) (Kwok *et al.*, 2000). Data are limited, but the response appears to be diverse within infected persons: a median of four HSV-2 ORFs were recognized among seven ORFs tested (Koelle *et al.*, 2000c). The CD4 response coexists with CD4-directed immune evasion strategies (Lewandowski *et al.*, 1993; Barcy and Corey, 2001; Neumann *et al.*, 2003; Trgovcich *et al.*, 2002), covered in detail elsewhere in this volume.

CD4+ cells contribute to protection against HSV in mice. In a zosteriform model, passive transfer of immune CD4+ cells was sufficient to confer protection, and ablation of CD4 cells increased susceptibility in naïve animals (Manickan and Rouse, 1995; Manickan *et al.*, 1995a, b). The CD4 effect was mouse strain-dependent. In the murine vaginal HSV-2 model, recently reviewed (Parr and Parr, 2003), progestin treatment thins the epithelium, increases the susceptibility of naïve animals, and alters local immune responses to HSV-2 (Kaushic *et al.*, 2003). Attenuated (*tk* mutant) intravaginal inoculation is non-fatal, and results in high-level, sterilizing, protective immunity against challenge with wild-type virus. In this model, depletion of CD4 T-cells delayed viral clearance after challenge (Milligan *et al.*, 1998). Qualitative parameters in the murine CD4 response generally support the importance of Th1-like IFN-γ responses. A survey of "long" gD1 peptides predicted to be antigenic by a computer algorithm revealed distinct elicitation of Th1 (IFN-γ-high IL-4 low) and Th2 (IFN-γ-low IL-4 high) responses by individual peptides given with an oil-in-water adjuvant. The Th1 peptides were more protective against an ocular HSV-1 challenge than were the Th2 peptides, and protection was mediated by CD4+ cells (BenMohamed *et al.*, 2003).

Recently, a subset of CD4+ T-cells with constituitive expression of CD25 (T_{reg}) have been described that have suppressor or regulatory activity (Chatenoud *et al.*, 2001). Depletion of T_{reg} in mice led to increased CD8 CTL responses against the HSV $gB1_{498–505}$ epitope, which persisted into the memory phase after T_{reg} recovery (Suvas *et al.*, 2003). CD25 depletion lead to a short window period of faster viral clearance from the inoculation site, while adoptive transfer of CD4+CD25+ cells (from naïve mice) led to delayed clearance. HSV-1 infection of mice increased the in vitro, per-cell suppressor activity of their CD4+CD25+ splenocytes. Interestingly, CD25+ cell depletion worsened CD4 T-cell mediated corneal immunopathology in a mouse model of HSV keratitis, even though it sped viral clearance (Suvas *et al.*, 2004). Recently, blood CD4+ $CD25^{high}$ cells have been shown to suppress recall lymphoproliferative responses to HSV-2 antigen in humans (Diaz and Koelle, 2006). While T_{reg} have functional TCR, they often act in an antigen non-specific manner and it is not known if HSV-specific T_{reg} occur in mice or humans.

It is not yet clear if CD4 responder cell numbers or function correlate with disease severity in humans. A general relationship is present between lower overall CD4 cell numbers and HSV shedding among HIV-infected men (Schacker *et al.*, 1998). However, in a cross-sectional study of HSV-2/HIV-1 co-infected men, HSV-2 severity did not correlate with HSV-2-specific CD4 cell numbers (Posavad *et al.*, 1997). Data from small numbers of subjects indicate that proliferative responses to specific viral proteins may be higher in symptomatic than asymptomatic persons (Spatz *et al.*, 2000). Responses to whole virus may be lower in symptomatic than in asymptomatic persons (reaching significance on one study (Frenkel *et al.*, 1989) and trending to significance in a small study (Singh, 2003a). Studies of HSV-1 disease severity and IFN-γ responses (likely, but not proven, to be CD4 mediated) were close to (Spruance *et al.*, 1995) or achieved (McKenna *et al.*, 2001) statistical significance for association between higher responses and milder disease. In a small study of HSV-2 infected persons with proliferative responses to HSV antigen were measured, asymptomatic seropositives had higher IFN-γ and lower IL-10 responses to HSV than did persons with symptomatic disease (Singh, 2003a). Longitudinal studies revealed a trend to decreased PBMC IFN-γ responses to HSV antigen over time after episodic acyclovir therapy of a genital herpes outbreak (Singh, 2003a). Two recent vaccine trials (Corey *et al.*, 1999; Stanberry *et al.*, 2002), used similar purified recombinant HSV-2 protein antigens, but different adjuvants. Partial clinical efficacy was reported only for the vaccine that included an adjuvant (alum and 3d-MPL) that elicits Th1-like CD4 responses, although head-to-head comparisons are not possible. In the recent human vaccine experience, elicitation of CD4 (and antibody) responses has not provided high-level protection from genital HSV-2 infection or disease (Koelle and Corey, 2003).

HSV-specific CD4 clones have diverse functional activities in vitro. They are heterogeneous with regards to cytotoxicity towards HSV-2-infected B-cells. All blood and genital lesion-derived CD4 clones have cytolytic potential, as all display cytotoxicity when maximally stimulated by peptide-pulsed B cells (Koelle *et al.*, 1998a; 2000a). We can speculate that CD4 immune evasion mechanisms differentially modulate the killing of infected cells by HSV-specific CD4 clones; differential resistance to CD4 CTL-induced apoptosis has been demonstrated (Jerome *et al.*, 1998). Cornea-derived HSV-1-reactive CD4 clones, in contrast, have not had CTL activity even when maximally stimulated (Koelle *et al.*, 2000a). Killing of infected keratinocytes is detectable if they are pre-treated with IFN-γ (Mikloska *et al.*, 1996). For blood-derived CD4 clones, the cytolytic mechanism for B cell targets appears to involve granules and not the Fas/FasL pathway (Yasukawa *et al.*, 1999).

The CD4 response to HSV is broadly directed. Published targets are non-structural proteins ICP8 and the *UL50* product dUTPase, glycoproteins gB, gC, gD, gE, and gH, tegument proteins VP11/12, VP13/14, VP16, VP22, and the *UL21* gene product, and the capsid protein VP5 (Koelle and Corey, 2003). Responses to the *UL29* gene product, a DNA binding protein, were detected in the blood of an HSV-2-exposed, but HSV-1/HSV-2 seronegative person and possibly represent sensitization without seroconversion (Posavad *et al.*, 2003). The HLA DR, DP and DQ loci are each well represented among alleles restricting peptide-specific responses. The population prevalence of responses to the candidate vaccine compounds gB2 and gD2 is quite high, over 80%, among HSV-2 seropositives. Responses to some of the tegument proteins can match these levels (Koelle *et al.*, 2000c).

T-cells are required in the immunopathogensis of experimental herpes simplex interstitial keratitis (HSK) in mice (Metcalf *et al.*, 1979). Controversy surrounds the requirement for HSV-specific CD4 T-cells in the pathogenesis of this disease. In humans, tissue from end-stage lesions, namely, corneas removed for blinding HSK have been examined for the presence of HSV-specific T-cells. Two research groups are in agreement (Verjans *et al.*, 1998; Koelle *et al.*, 2000a) that HSV-specific, HLA class II-restricted, CD4+ T-cell clones are readily established from these specimens. These cells recognize HSV-1/HSV-2 cross-reactive tegument protein epitopes in some instances, and generally have a Th1-like cytokine profile. A minority of patients with more superficial corneal HSV infections progress to HSK. The effects of potent immunotherapy directed at genital herpes on the natural history of ocular HSV infections deserve close medical attention.

T-cell costimulation and HSV

Both CD4 and CD8 T-cells require costimulation during primary, and to a lesser extent, recall, responses. The two-signal model of T-cell activation holds that in addition to an agonistic ligand of the T-cell receptor, usually MHC plus peptide, one or more additional signals instruct a T-cell to become activated. Major co-stimulatory pathways include CD80 and CD86 on APC interacting with CD28 on T-cells, and CD40 on APC interacting with CD154 on T-cells. In vivo, a complex mixture of activatory and inhibitory stimuli are integrated by signal transduction pathways.

The CD40-CD40L system is required for immunoglobulin class switching and the development of Th1 CD4 responses. One human with a mutation in CD40 has been found to be hypersusceptible to HSV disease (Fuleihan, 2001; Garcia-Perez, 2003). Increased monocyte CD80 and CD86 expression after incubation of immune human PBMC with HSV is not inhibited by anti-IFN-γ, and may be due to CD40L conditioning of monocytes (Singh, 2003b). Deletion of CD40L or administration of anti-CD40L antibody decreased survival after HSV-1 footpad or vaginal inoculation, and delayed DLN CD4 responses to HSV antigen (Edelmann and Wilson, 2001; Inagaki-Ohara *et al.*, 2002). Enhancement of CD40L expression via an exogenous plasmid co-administered with a gD2 plasmid vaccine increased splenocyte memory Th1 responses to gD2 protein, and also increased survival in a murine HSV-2 challenge model (Sin *et al.*, 2001). As CD40L induces B cell maturation, the increased survival after HSV-1 challenge of mice with GVHD associated with CD40L protein administration was ascribed to enhanced anti-HSV antibodies (Beland *et al.*, 1998).

CD40 and CD40L are each members of the large TNF receptor and TNF families, respectively (Croft, 2003). Other members of these families have also been implicated in HSV pathogenesis. Lopez observed in 1975 that Balb/c mice were more susceptible than C57BL/6 mice to mortality after intraperitoneal infection with HSV-1 (Lopez, 1975). The exact genetic basis of this difference remains unknown, but at least one prominent locus has been mapped to a region of murine chromosome 6 which contains TNF receptor genes (Lundberg *et al.*, 2003). CD137 (4–1BB) is a TNF family member expressed by T-cells. CD137 provides a positive co-stimulatory signal which can augment anti-viral immunity (Halstead *et al.*, 2002). Mice deficient in CD137 or treated with anti-CD137L mAb show less corneal pathology in a HSV keratitis model (Seo *et al.*, 2003). HVEM, a member of the TNFR family, is best known as a receptor for HSV entry. Less is known concerning the potential for immune modulation by gD ligation of HVEM, which is expressed by many APC and lymphocytes (La *et al.*, 2002).

An expanding family of membrane proteins in the B7 family (Prasad *et al.*, 2003) expressed by APC and stromal cells have complex positive and negative effects on members of the CD28 family (Rudd and Schneider, 2003) expressed on T-cells. CD80 or CD86, when separately coadministered with gD2 as plasmids in mice, had adjuvant and suppressive effects, respectively, using immunologic and clinical end-points (Flo *et al.*, 2000, 2001). In a vaginal model of HSV-2 infection, mice deficient in both CD80 and CD86 failed to control the infection (Thebeau and Morrison, 2002). Immune correlates included decreases in CTL responses, local IFN-γ secreting T-cells, and CD40L up-regulation by CD4 T-cells in response to antigen, and alterations in HSV-specific immunoglobulin isotypes (Thebeau and Morrison, 2003). Systemic interruption of

B7 family/CD28 family interactions with CTLA4-Ig fusion ameliorates the course of HSK in mice, correlating with decreased memory CD4 responses to HSV (Gangappa *et al.*, 1998). Local blockade of B7–1 and B7–2 (CD80 and CD86), which are present on corneal LC, also prevents HSK in mice (Chen and Hendricks, 1998). Thus far, few data link the B7 pathway and HSV in humans. A small study found that monocytes from HSV-infected persons displayed impaired CD80 and CD86 up-regulation in response to exogenous IFN-γ (Singh, 2003a).

Antibody responses to HSV

Antibody responses to HSV are known to be functionally important in the context of neonatal infection. The risk of clinically significant infection after delivery through a HSV culture-positive cervicovaginal tract is much higher during primary than during recurrent maternal infection (Brown *et al.*, 2003). In the latter instance, maternal IgG antibodies are transferred to the neonate across the placenta. Antibodies cooperate with neutrophils, monocytes, and NK-like cells in mediating antibody-dependent cell-mediated cytotoxicity (ADCC) (Kohl, 1991). Of interest, recent candidate vaccines with limited efficacy stimulated low ADCC titers, despite eliciting high levels of binding and neutralizing antibody (Kohl *et al.*, 2000).

Local antibody responses are of interest in the female genital tract. In the murine vaginal HSV-2 model, mice are protected by non-lethal vaginal infection with a *tk*- HSV-2 strain (Parr and Parr, 2003). Antibody plays a significant role in early virus containment after vaginal challenge, as shown with B-cell knock-out mice (Parr and Parr, 2003). Little evidence for local secretory IgA as an effector molecule was found, similar to findings in human genital secretions (Boggess *et al.*, 1997). In contrast, local IgG with neutralizing activity was readily detected. Attempts to induce vaginal immunity in mice through a "common mucosal immune system" pathway, via intranasal or oral immunization, have been successful in some models, but protection has not been mechanistically linked with local IgA. Human IgG immunoblot kinetic patterns differ between serum and cervical samples, suggesting that genital tract IgG may reflect local synthesis in addition to diffusion of plasma protein (Ashley *et al.*, 1994). Similar data has been presented for local antibody synthesis in HSV infections of the eye (Peek *et al.*, 2002) and CNS, especially late into HSV encephalitis (Sauerbrei *et al.*, 2000). Vaginal tissues from vaginally immunized mice contain many fairly persistent IgG-producing plasma cells, while similar vaccinations at other sites do not lead to this cell localization (Parr and Parr, 2003). Recently, specific expression of the mucosal homing molecule A_4B_7 integrin (MLA, CD103) has been demonstrated for B-cells specific for a gastrointestinal pathogen (Gonzalez *et al.*, 2003). Similar B-cell homing to the genital tract is rational but has not yet been demonstrated.

The development of a specific immune evasion function for antibodies is additional evidence of the functional importance of the antibody response (Nagashunmugam *et al.*, 1998). The HSV-encoded gE-gI high-affinity FcγR receptor is expressed on infected cells. gE-gI binds human, but not mouse, Fcγ, so a murine zosteriform spread model combines injection of human immune serum and challenge with wild-type or gE knockout HSV-1. The gE knockout has decreased virulence in the context of immune but not pre-immune human serum treatment (Lubinski *et al.*, 2002), consistent with an effect on pathogenesis mediated through immune escape. Recently, a region of gE1 capable of eliciting blocking antibodies that reduce Fcγ binding was identified (Lin *et al.*, 2003), and it has been proposed that inclusion of such an immunogen could assist vaccination against HSV (Lin *et al.*, 2004).

Neutralization of clinical HSV isolates by rabbit antisera to HSV-1 vs. HSV-2 formed the basis for early HSV typing methods. Antibodies that inhibit the absorption, or neutralize, HSV *in vitro* are specific for gB, gC, gD, or gH/gL (Fuller *et al.*, 1989; Fuller and Spear, 1987, 1985; Sanchez-Pescador *et al.*, 1992). Antibodies to gB or gD inhibit neuron to keratinocyte spread in a two-cell model (Mikloska *et al.*, 1999). Passive transfer of antibodies specific for several of these glycoproteins is protective in animals (Su *et al.*, 1996; Balachandran *et al.*, 1982); in some cases, ADCC may be involved rather than classic neutralization (Kohl *et al.*, 1986). Recent advances in the study of HSV receptors, particularly for gD, have provided a structural basis for the differential neutralization of various gD-specific mAb (Whitbeck *et al.*, 1999). Local application of neutralizing mAb can prevent disease after vaginal inoculation (Whaley *et al.*, 1994). As reviewed elsewhere (Koelle and Corey, 2003), vaccines eliciting neutralizing titers above those seen in natural infection have not been clinically effective.

Innate immunity

The importance of innate immunity is readily demonstrable in primary infection and in acute lethality models. HSV immune escape mechanisms that target innate complement and class I interferon responses are reviewed elsewhere in this volume. Mobile leukocytes and tissue stromal cells collaborate in innate immunity. As reviewed

at the outset of this chapter, dendritic cells form a crucial bridge between innate and adaptive immunity. Distinctions between innate and acquired are becoming increasingly arbitrary, as specialized pattern recognition receptors such as toll-like receptors (TLR) and NK-cell activatory receptors that recognize viral proteins in highly specific fashions (Arase *et al.*, 2002) are being described.

Complement is another major bridge between innate and acquired immunity (Mullick *et al.*, 2003). As discussed elsewhere in this volume, HSV gC specifically binds to and inactivates certain complement components (Lubinski *et al.*, 2002). Elegant studies in complement-deficient mice have shown through genetic "complementation" that gC is a virulence factor in intact animals (Lubinski *et al.*, 1999). Clinically, persons with complement deficiencies are not generally felt to have more serious HSV infections than the general population (Walport, 2001). This can be interpreted in two ways: either complement is already maximally disabled, or complement-dependent mechanisms, while active, are redundant in the otherwise normal host.

Neutrophils are not typically considered major antiviral effector cells. Neutropenic patients can have severe HSV infections, but usually in settings in which lymphocyte number or function are also impaired. Isolated neutropenia, or disorders of phagocyte effector functions such as chronic granulomatous disease (CGD), are not generally clinically associated with severe HSV infections (Andrews and Sullivan, 2003). Neutrophils do strongly infiltrate genital HSV lesions in humans at the pustule stage. Giemsa stains of cytospin preps of pustule cells from day 2–3 HSV-2 buttock or thigh lesions show >95% neutrophils (D. M. Koelle *et al.*, unpublished data). HSV vesicle fluid is rich in chemokines that can attract neutrophils (Mikloska *et al.*, 1998), and mice with genetic knock-out of chemokines which attract neutrophils have alterations in HSV pathogenesis (Tumpey *et al.*, 1998). IL-17 can assist in chemokine synthesis, is up-regulated in infected human corneas, and made by keratocytes in response to HSV infection (Maertzdorf *et al.*, 2002). Neutrophils localize to the HSV-2-infected vagina in mice. Depletion of neutrophils has measurable effects on viral clearance in both primary and vaccination/challenge models, especially at early time points and locally in the vagina (Milligan, 1999; Milligan *et al.*, 2001). Neutrophil antiviral effector functions are not well characterized. CGD neutrophils, which have defects in the formation of reactive oxygen species, digest HSV normally (Van Strijp *et al.*, 1990). Neutrophils have ADCC activity against infected cells (Siebens *et al.*, 1979). Some defensins that are expressed by neutrophils have potent anti-HSV activity (Sinha *et al.*, 2003). Neutrophils matrix metalloproteinases have been implicated in tissue damage related to HSV infection (Lee *et al.*, 2002b).

Many cells respond to viral infection by the production of class I interferons. Protein products of this multigene family (interferon alphas and beta) have autocrine and paracrine activity and trigger the expression of a characteristic pattern of genes (interferon-stimulated genes, ISG). Class I interferons have pronounced anti-HSV activity in vitro and in animals (Connell *et al.*, 1985) and appear to also be active in humans (Lebwohl *et al.*, 1992). Limitin is a class I interferon-related protein with anti-HSV activity in an acute murine HSV-1 lethality model (Kawamoto *et al.*, 2003) and potentially less toxicity.

The ISG pattern has been detected with expression arrays after infection of several cell types with HSV. Deletion of immediate early genes has been helpful to unmask this response (Nicholl *et al.*, 2000). The canonical class I interferon signaling pathway through TyK2, JAK1, and STAT1 is not required for ISG up-regulation. Therefore, an autocrine class I interferon effect is unlikely be responsible for ISG activation. HSV virions, or VP16-mutated HSV which cannot replicate in fibroblasts, also elicits ISG expression without eliciting an interferon biological activity. Cells may have an alternative sensor mechanism to trigger the ISG pathway (Mossman *et al.*, 2001). If VP16 is restored, ISG up-regulation is not detected, while cycloheximide restores ISG mRNA up-regulation during infection with wild-type HSV. HSV may therefore direct the synthesis of protein(s) that block ISG transcription, with some data suggesting ICP0 can mediate this function (Eidson *et al.*, 2002; Harle *et al.*, 2002). HSV evasion of class I interferon through γ34.5 is discussed elsewhere in this volume and was recently reviewed (Leib, 2002). In brief, γ34.5 antagonizes the protein kinase R (PKR) effector pathway for class I interferons. While PKR phosphorylates, and inactivates, EIF2α, thus reducing viral protein synthesis, γ34.5 has or induces a phosphatase activity which removes this block. Deletion of γ34.5 reduces the virulence of HSV by several orders of magnitude (Chou *et al.*, 1990), an effect that disappears in IFN-α receptor or PKR knock-out, but not RNAse-L knock-out, mice (Leib *et al.*, 1999; 2000).

Interferon-alpha is confusingly known as leukocyte interferon, in contrast to interferon-gamma, which is made more or less exclusively by lymphocytes (which are leukocytes). It was recognized very early that PBMC exposed to HSV make large amounts of interferon-alpha, regardless of donor HSV serostatus (Haahr *et al.*, 1976). Rare leukocytes in PBMC that respond to HSV by producing IFN-α have been termed natural interferon producing cells (NIPC). A prominent NIPC was recently identified as dendritic cell subtype termed plasmacytoid dendritic cells or

pDC (Siegal *et al.*, 1999; Colonna *et al.*, 2002; Fitzgerald-Bocarsly, 2002). These rare (<1% of PBMC) cells produce enormous amounts of IFN-α on a per-cell basis by up-regulating IFN mRNA after stimulation. The phenotype of pDC varies slightly from humans (CD4+ CD11c−) to mice (CD11c+CD11b-Gr-1+B220+). pDC recognize many DNA and RNA viruses, produce several different IFN-α gene products and IFN-β, and are decreased in advanced HIV infection (Chehimi *et al.*, 2002), a condition characterized by susceptibility to viral infections. Their selective expression of TLR7 (Hornung *et al.*, 2002) makes them a logical target for imidazoquinolines, TLR7 agonists (Hemmi *et al.*, 2002) with anti-HSV activity (Spruance *et al.*, 2001). It is not yet known if pDC localize to HSV-2 lesions, but pDC-like cells express CLA, a skin-homing molecule (Schmitt *et al.*, 2000), and localize to melanoma lesions (Salio *et al.*, 2003) and some inflammatory skin conditions (Wollenberg *et al.*, 2002).

Clearly, several cell types in PBMC are capable of innate responses to viral stimuli. For example, monocytes, while secreting less IFN-α than pDC on a per-cell basis (Fitzgerald-Bocarsly, 2002), are more abundant in the blood and are the main NIPC for Sendai virus (Feldman *et al.*, 1994). Dendritic cell plasticity allows non-pDC to make large amounts of IFN-α in response to some viruses (Diebold *et al.*, 2003). Monocyte-lineage dendritic cells (derived in vitro with GM-CSF and maturation stimuli) also produce IFN-α in response to HSV (Rong *et al.*, 2003). Other monocyte pro-inflammatory responses to HSV are discussed below.

The viral factor(s) involved in the detection of HSV by the innate immune system have been incompletely defined and may vary between different host responses and responder cell types. UV-inactivated virus or aldehyde-fixed, HSV-infected cells can stimulate PBMC IFN-α responses, indicating that viral replication may not be required (Rong *et al.*, 2003; Lebon, 1985). Ankel *et al.* (1998) have presented data that glycoprotein D of HSV-1 or HSV-2 is a potent trigger of IFN-α production by human PBMC. Insect cells expressing plasma membrane gD (Sf9-gD1), but not other HSV-1 glycoproteins, or soluble truncated gD1, but not soluble gH/gL complexes, stimulate PBMC IFN-α secretion. Responses to HSV-1 or Sf9-gD1 were inhibited by HSV immune human sera and also monoclonal anti-gD (Fitzgerald-Bocarsly *et al.*, 1991; Ankel *et al.*, 1998). Inter-strain differences in the ability of HSV-1 strains to stimulate various NIPC have been detected (Rong *et al.*, 2003), but their structural or genetic basis is unknown.

The host factors by which cells detect HSV and other viruses are under intense study (Vaidya and Cheng, 2003). TLR2, but not TLR4, has been implicated in sensing HSV-1 in a mouse intraperitoneal challenge model (Wakimoto *et al.*, 2003; Finberg *et al.*, 2003). A study of pDC isolated from bone marrow of gene knock-out mice, using IFN-α production as the readout, suggests a role for TLR9, but not TLR4, for responses to HSV-2 (Lund *et al.*, 2003). Both human and mouse pDC express TLR9 (Kadowaki *et al.*, 2001; Boonstra *et al.*, 2003).

MyD88 knock-out also reduced IFN-α production, but this adaptor molecule is downstream of many receptors (Takeuchi and Akira, 2002). Confirmatory evidence of the TLR9 and MyD88-dependence of pDC IFN-α responses to HSV-1 was obtained using pDC sorted from splenocytes (Krug *et al.*, 2003). HSV replication was not required, as UV-inactivated HSV-1 was able to stimulate IFN-α. In vivo, neither TLR9 knock out (in the Balb/c background) nor MyD88 knock out (in the C57BL/6 background) had any deleterious effect on the local control of HSV-1 infection. Because mice with deficiency of either the class I IFN receptor or PKR fail to contain HSV-1 infection (Luker *et al.*, 2003; Leib *et al.*, 2000), these data suggest that MyD88- and TLR-independent activation of the class I IFN pathway is possible.

Certain unmethylated CpG oligodeoxynucleotide sequences are the primary known ligands for TLR9. The IFN-α response of PBMC is inhibited by the lysosomotropic agent chloroquine, consistent with a requirement for the acidification of endosomes containing the triggering signal (Feldman *et al.*, 1994). Of note, TLR9 has been reported to be primarily expressed intracellularly (Ahmad-Nejad *et al.*, 2002). A possible link between endocytosis and TLR9 comes from the demonstration that mannose receptors (MR) on DC are involved in NIPC responses (Milone and Fitzgerald-Bocarsly, 1998). Anti-MR sera block NIPC responses, and NIPC with characteristics of human pDC (CD4+) express MR. MR is involved in internalizing ligands via endocytosis. If gD is a primary trigger for IFN-α, HSV receptors (Spear *et al.*, 2000), including an MR (Brunetti *et al.*, 1995), that recognize gD are logical candidates. Monoclonal antibodies to galactosyl cerebroside/sulfatide can block IFN-α production by PBMC in response to HSV-1 or gD (Ankel *et al.*, 1998); related structures are present on some HSV receptors (Shukla and Spear, 2001).

The consequences of NIPC interactions with HSV have only begun to be described. In addition to secreting IFN-α, pDC can secrete other cytokines that influence priming such as IL-10 or IL-12 (Krug *et al.*, 2003), prime T-cells (Fonteneau *et al.*, 2003), increase T_{reg} activity ((Gilliet and Liu, 2002), or be tolerogenic (Kuwana *et al.*, 2001). PDC priming of pseudo-naïve CD8 cells specific for a melanoma antigen reportedly up-regulated CLA expression (Salio *et al.*, 2003); as noted above, HSV-2-specific CD8 cells express CLA, but thus far animal models have not indicated that pDC are functional APC for HSV-1 (Allan *et al.*,

2003). HSV-2 interaction with pDC leads to secretion of IFN-α and IL-12, which promote the expression of CLA on human memory HSV-2-specific CD4 T-cells in an ex vivo reconstitution system (Koelle *et al.*, 2006). IFN-α biases Th responses to the Th1 phenotype in humans (Rogge *et al.*, 1998). Murine NIPC (Asselin-Paturel *et al.*, 2001) secrete IFN-α in response to HSV, but IFN-α biasing towards Th1 responses is altered in mice (Rogge *et al.*, 1998), limiting the application of murine studies to humans. Other host cytokines can have modulatory effects on NIPC responses to HSV in vitro (Gary-Gouy *et al.*, 2002; Payvandi *et al.*, 1998) and may also influence pDC in vivo.

In addition to IFN-α, monocytes and macrophages secrete other immunomodulatory cytokines after exposure to HSV. TNF-α has anti-HSV activity by synergizing with IFN-γ (Wong and Goeddel, 1986) and up-regulating nitric oxide (Kodukula *et al.*, 1999) and has both protective and immunopathologic roles in various HSV models (Kodukula *et al.*, 1999; Keadle *et al.*, 2000; Croen, 1993; Adler *et al.*, 1997). Murine IFN-γ-primed macrophage-like cells produce TNF-α in response to HSV. UV- or formaldehyde-killed virus, a gL-deficient mutant (unable to enter cells), and a VP16 mutant unable to initiate transcription elicit TNF-α elicit partial TNF-α responses, while purified gD1 is a potent stimulator in this system. Responses to HSV-2 involved transcriptional (NF-κB, ATF/Jun) and translational control (Paludan *et al.*, 2001). The use of gD vaccines (Stanberry *et al.*, 2002) and anti-TNF therapies (Bresnihan and Cunnane, 2003) in humans raises interest in studying HSV-TNF-α biology in the natural host.

IL-12 is a cytokine with prominent effects on T-helper polarization. IL-12 p40 mRNA is increased in human genital HSV-2 lesions (Van Voorhis *et al.*, 1996) and after infection of mice with HSV-1 (Kanangat *et al.*, 1996). In contrast to TNF-α, murine macrophage-like cells had poor IL-12 p40 production in response to UV- or heat-killed HSV-1. Corneal epithelial cells are poor sources of IL-12 in response to HSV when compared to macrophage-lineage cells, but produce an uncharacterized activity that induces IL-12 in macrophages. Infected macrophages are also low producers of IL-12, based on two-color confocal microscopy, indicating that paracrine induction may also take place when macrophages are infected with HSV-1. In contrast to some monokines, viral protein synthesis appears to be required for macrophage IL-12 responses to HSV (Kumaraguru and Rouse, 2002). Detectable IL-12 is present in human HSV-1 vesicle fluid, and fetal and adult keratinocytes synthesize IL-12 in response to live HSV-1 infection (Mikloska *et al.*, 1998).

IL-12 is one of several cytokines with adjuvant activity for HSV vaccines (Lee *et al.*, 2003). In a murine intravaginal HSV-2 model, IL-12 knock-out mice had faster mortality than wild-type controls (Harandi *et al.*, 2001a). IL-12 has anti-angiogenic activity in the cornea, mediated through IFN-γ and IFN-γ up-regulated chemokines, which may be relevant in herpes keratitis (reviewed by Dr. Rouse elsewhere in this volume) (Lee *et al.*, 2002a). IL-18 is an IL-1 family cytokine which synergizes with IL-12 in inducing IFN-γ secretion by T cells. When leukocytes from HSV-naïve mice are stimulated with live HSV-2, roles for IL-12, IL-18, and also IFN-αβ can be demonstrated for IFN-γ secretion (Malmgaard and Paludan, 2003). Exogenous IL-18 improves survival in an acute HSV-1 lethality model, an effect that depended on IFN-γ but not NK cells (Fujioka *et al.*, 1999). Knock-out of IL-18 alone accelerated death in a murine HSV-2 intravaginal acute lethality model. Depletion of IL-18 on an IL-12 deficient background further compromised survival. In the setting of sublethal attenuated HSV-2 vaccination, followed by a vaginal HSV-2 challenge, knock-out of either IL-12, IL-18, or both had no effect on survival, despite alterations in lymphoproliferation and immunoglobulin isotype switching (Harandi *et al.*, 2001a).

IL-15 is an IL-2-related cytokine with profound effects on NK cells. HSV increases IL-15 in vivo in mice (Tsunobuchi *et al.*, 2000) and in human PBMC; HSV-mediated increases in NK activity in these cultures are dependent on IL-15, and IL-15 neutralization increases productive HSV infection (Ahmad *et al.*, 2000). Exogenous IL-15 can be protective in a murine HSV challenge model (Tsunobuchi *et al.*, 2000). IL-15-deficient mice are about 100-fold more susceptible to acute lethality after vaginal HSV-2 inoculation (in the setting of progesterone treatment) than are wild-type congenics (Ashkar and Rosenthal, 2003). IL-15 can also increase acquired responses to HSV in the context of HSV DNA/cytokine cDNA co-vaccination (Sin *et al.*, 1999).

Experimental HSV studies in mice typically use gene disruptions, antibody blockade, or cell depletion to study innate immunity. Fewer studies have addressed the human host and natural infection. CD40 assists priming at an intersection between innate and acquired responses, and as mentioned above, a person with a CD40 mutation and severe HSV has been described. Mutations affecting IFN-γ receptors or IL-12/IL-12R are not uncommon, but no instances of severe viral infection have been reported (Fieschi *et al.*, 2003; Fieschi and Casanova, 2003). Homozygous mutations in the C-terminal phosphorylation domain of STAT1 reduce both IFN-α/β and IFN-γ signal transduction (Dupuis *et al.*, 2003). As in *IFNGR1* (IFN-γ receptor ligand-binding chain), *IFNGR2 (*IFN-γ receptor signaling chain), *IL12B* (IL-12 p40 protein), and *IL12RB1* (IL-12 receptor β1 chain*)* mutations, disseminated bacillus Calmette-Guerin (BCG) infections occur. Disseminated,

fatal childhood infection with HSV-1 is also observed. Cell lines from these subjects are resistant to the anti-HSV effects of IFN-α in vitro (Dupuis *et al.*, 2003). NK cell deficiencies are discussed below. Mutations in UNC-93B, an endoplasmic reticulum protein of unknown function, have recently been associated with lethal HSV infections and impairment of the PBMC IFN-α response to HSV virions (Casrouge *et al.*, 2006).

IL-10 is another monocyte product with pleotropic anti-inflammatory and immune modulatory activities. In models of HSV keratitis, IL-10 administered in a variety of formats decreases interstitial keratitis without increasing viral replication (Daheshia *et al.*, 1997). IL-10 mRNA is locally enriched in genital HSV-2 in humans (Van Voorhis *et al.*, 1996) and protein is detected in areas of murine (Stumpf *et al.*, 2002) and human (Mikloska *et al.*, 1998; Ongkosuwito *et al.*, 1998) HSV-1 infection. The sources of IL-10 in herpes infection in vivo are not known, and could include parenchymal cells (Zak-Prelich *et al.*, 2001) and responding lymphocytes (Koelle *et al.*, 2000a). An association between a homozygous polymorphism in the IL-10 promoter and HSV serostatus (Hurme *et al.*, 2003) awaits confirmation.

Immunomodulators and HSV

Several groups have attempted to modulate HSV infection by altering innate or HSV-specific immune responses. CpG ODN co-administration potentiates the immunogenicity and efficacy (against subsequent vaginal HSV-1 challenge) of vaccination with an immunodominant HSV CD8 peptide (Gierynska *et al.*, 2002). CpG also had an adjuvant effect when given prior to vaccination with an intravaginal sublethal dose of live HSV-2 (Harandi *et al.*, 2003). CpG ODN given intravaginally without an HSV constituent protects against subsequent intravaginal HSV-2 challenge and can also be therapeutic (Harandi *et al.*, 2003; Ashkar *et al.*, 2003; Pyles *et al.*, 2002). IFN-γ and the IFN-γ inducers IL-12 and IL-18 were induced locally by CpG ODN. Knock-out of IL-12 and IL-18 reduced protection in one model, while the effect of IFN-γ knock-out on CpG ODN protection may depend on CpG and virus dosing. Infiltration of NK1.1 (+) NK or NKT cells and CD11b+ cells (likely DC) and proliferative changes in the genital mucosa were associated with CpG ODN but not control ODN administration. The imidazoquinoline resiquimod is a TLR7 agonist that increases local IFN-α levels after topical application (Hemmi *et al.*, 2002; Arany *et al.*, 1999). Unfortunately, a phase III clinical trial of topical resiquimod for recurrent genital HSV-2 in humans was stopped without evidence of clinical activity (February 2003).

Chemokines

Chemokines are a large family of small, basic proteins with diverse cellular sources and biological activities (Bacon *et al.*, 2002). HSV-1 is not known to encode chemokine or chemokine receptor homologues. HSV-1 vesicle fluid from humans contains high levels of CCL5 (RANTES), CCL3 (MIP-1α), and CCL4 (MIP-1β) (Mikloska *et al.*, 1998). Cultured human keratinocytes synthesize these chemokines in response to live HSV-1 infection, despite cytopathic effect. The chemokines CCL2 (MCP-1), CCL3, CCL5, and CXCL8 (IL-8) are significantly increased the cerebrospinal fluid in HSV encephalitis in humans (Rosler *et al.*, 1998).

Chemokines have been hypothesized to assist with recruitment of lymphocytes and monocytes to areas of infection (Mikloska *et al.*, 1998). Studies of HSV infection and vaccination in wild-type and knock-out animals, and in vitro studies, have implicated chemokines and their receptors in adaptive, and pathogenic, host responses. Local CCL5 (RANTES) and CCL2 (MCP-1) levels are increased in the vagina after HSV-2 infection. Innate and acquired immunity both contribution to CCL5 accumulation as accelerated, heightened responses are observed in previously vaccinated animals. For CCL2, in contrast, vaginal levels were decreased after challenge of vaccinated vs. non-vaccinated animals, and local CCL2 was correlated with tissue inflammation and damage. Vaginal CCL5 protein levels were partially dependent on IFN-γ after challenge of vaccinated wild-type vs. IFNγ -/- mice (Harandi *et al.*, 2001b). CCL5 is persistently expressed in latently infected murine ganglia (Halford *et al.*, 1996). Knockout of CCL3 (MIP-1α) (Menten *et al.*, 2002) lessens histologic HSK in mice, correlating with decreased ingress of CD4+ cells and decreased IFN-γ and IL-2 mRNA levels, without effecting HSV-1 clearance (Tumpey *et al.*, 1998). Neutralization of CXCL10 (IP-10) also lessened leukocyte infiltration and pathology while transiently increasing corneal HSV-1 replication after scarification (Carr *et al.*, 2003). As with T_{reg} cells, chemokines can have complex influences on HSV pathogenesis. CXCR3-deficient mice have decreased clearance of HSV-1 in a CNS infection model, but also show increased survival (Wickham *et al.*, 2005).

NK cells

Human NK cells with activity against non HLA-restricted cytotoxicity against HSV-infected fibroblasts have long been described (Lopez *et al.*, 1982). NK activity against HSV-infected fibroblasts was always observed to take many

hours, in contrast to the killing of tumor cells such as K562, and some distinctions were found between the two effector functions. The recognition that IL-12, IL-15, and IFN-α are induced upon exposure of mixed PBMC to HSV, and are profound inducers of NK cell activity (reviewed above), may explain the time course of NK action against HSV-infected target cells.

NK recognition of HSV-infected cells is not unexpected, as HSV down-regulates HLA class I (Hill *et al.*, 1995), and this precise absence is detected by NK cells through loss of inhibitory ligand recognition (Moser *et al.*, 2002). Introduction of HSV-1 ICP47 into target cells can increase their susceptibility to NK cell lysis, as expected from decreased surface HLA class I (Huard and Fruh, 2000). However, it is increasingly recognized that NK cell activation can include ligation of specific activatory receptors in addition to loss of inhibition, and several examples of interactions between virally-encoded proteins and NK receptors have been discovered (Arase *et al.*, 2002; Mandelboim *et al.*, 2001). We believe it is likely that NK cells are involved in controlling virus in recurrent genital HSV-2 lesions that reach clinical threshold, as both NK cell numbers and NK activity were dramatically increased in cells expanded from lesional biopsies compared to normal skin (Koelle *et al.*, 1998b). No activatory interactions between HSV proteins and NK cells are known, but little work was been done in this area. Some early work suggested specific recognition of HSV-1 glycoproteins (Bishop *et al.*, 1984, 1986). In contrast, other work with replication inhibitors and mutant viruses suggest that immediate early gene expression may be sufficient to sensitize HSV-infected targets to NK lysis (Fitzgerald-Bocarsly *et al.*, 1991). With hindsight, it is possible to hypothesize that these HSV glycoproteins were triggering innate immune responses which facilitate NK cell cytotoxicity, or alternatively that direct interactions between NK surface activatory molecules and HSV glycoproteins are occurring . . . we have little real data. NK clones with cytolytic and anti-viral activities against HSV-infected cells from human blood (Yasukawa and Zarling, 1983; Yasukawa and Kobayashi, 1985), expressing clonally distributed NK receptors (Pietra *et al.*, 2000), may assist in determining the molecular basis of NK cell recognition of HSV.

Clinically, low NK cell activity has been linked with severe, usually primary, HSV infections (Biron *et al.*, 1989; Lopez *et al.*, 1983). A homozygous mutation was detected in the Fcγ RIIIa gene of a child with severe HSV infection, and low NK cell number and function, although ADCC function was not abnormal (Jawahar *et al.*, 1996). Tantalizing older literature has linked high HSV disease severity with low PBMC NK activity (Sirianni *et al.*, 1986). As with many immune assays, re-evaluation may be in order using objective measures of HSV severity such as viral shedding rates (Wald *et al.*, 2000), which can differ greatly between immunocompetent persons. Some functional data indicate that NK cells are active in acute HSV lethality models in mice (Rager-Zisman *et al.*, 1987; Bukowski and Welsh, 1986). The difference in lethal dose for 50% of animals (LD_{50}) for acute HSV-1 infection between C57BL/6 and Balb/c mice (Lopez, 1975), discussed above in the context of a TNF-receptor locus, has also been genetically mapped by a second research group to a region containing many NK-cell receptors (Pereira *et al.*, 2001). However, it is not yet known precisely what gene (or genes) is involved.

NKT cells

Several populations of NKT cells, broadly defined as expressing both TCR αβ heterodimers and NK markers such as NK1.1 or CD161, are now recognized (Kronenberg and Gapin, 2002). NKT cells can make large amounts of cytokines such as IL-4 or IFN- γ after activation (Benlagha *et al.*, 2002). In mice, many NKT cells expressing the semi-variant Vα14-Jα281 TCR. Deletion of either CD1d or Jα281 from the germline increases the early pathogenicity of HSV for zosteriform spread in the normally resistant C57BL6 background (Grubor-Bauk *et al.*, 2003). While a subset of NKT cells recognize antigens presented by CD1, the viral or host molecules involved in possible activation of NKT cells by HSV have not been defined. An NKT-like infiltrate in a region of HSV infection has been reported in a human (Taddesse-Heath *et al.*, 2003), but in vitro studies have not documented interactions between murine or human NKT cells and HSV.

TCR$\gamma\delta$ cells

T-cell expressing the gamma and delta T-cell receptor molecules (TCRγδ cells) can recognize HSV-infected cells. Non-MHC-restricted recognition of a peptide from HSV-1 gI has been documented (Sciammas and Bluestone, 1998). TCRγδ cells contribute to HSV-1 clearance in an acute cerebral infection model in mice (Sciammas *et al.*, 1997) and localize to some sites of infection (Liu *et al.*, 1996), but other models have not shown an effect when TCRγδ cells are missing (Nass *et al.*, 2001). Human TCRγδ clones can recognize HSV-1-infected cells in a non HLA-restricted manner (Maccario *et al.*, 1995). These cells can be expanded from the blood by incubation with HSV (Maccario *et al.*, 1993). The jury is still out on the importance of rare

T-cell subsets such as NKT and TCR$\gamma\delta$ cells in human HSV infection.

Additional interactions between HSV and the immune system

Chronic stress has been linked to recurrences of symptomatic HSV disease (Cohen *et al.*, 1999) although not, as yet, to quantitatively measured HSV shedding. Broadly, stressors could affect neuronal events and/or immunologic responsiveness. For example, ciliary neurotrophic growth factor and IL-6 share a receptor subunit, and have been reported to worsen clinical HSV infections in humans or promote reactivation from ganglia in culture (Kriesel *et al.*, 1994, 1997a,b). Manipulations of sympathetic enervation can reduce primary and memory HSV-specific CTL responses in mice and worsen HSV pathogenesis (Leo and Bonneau, 2000). Some data link stress and immune suppression in humans, including relevant effector functions such as NK cell number and activity and lymphocyte proliferation (Zorrilla *et al.*, 2001). Bonneau *et al.* have been studying the relationship between the nervous system, stressors and HSV-specific CD8 CTL activity in C57BL/6 mice. Stress increases the pathogenesis of HSV infection in several models (Bonneau *et al.*, 1991, 1997). Using mice previously immunized with the immunodominant gB1 epitope in a recombinant vaccinia format, the effects of restraint stress and mAb-mediated CD8 depletion were compared for intravaginal or intranasal HSV challenges (Wonnacott and Bonneau, 2002). Both stress and CD8 depletion caused similar, significant increases in acute mortality and increases in vaginal HSV replication.

Very recently, a possible mechanistic link has been suggested by the finding that structured stress decreased the number of HSV-specific CD8 T-cells in the ganglia of HSV-infected mice (Hendricks, 2006). Ongoing work will hopefully elucidate mechanisms that connect stress and the nervous and immune systems.

Summary

The broad host range of HSV and the prevalence of HSV infections in humans have enabled several decades of excellent studies, well beyond the capacity of this review or this reviewer. Despite this, it is fair to say that our understanding of the immune response to HSV is still primitive, and inadequate to address clinical and basic science issues. For example, we do not know if "immunology" can explain the variation in disease severity, how to make an effective vaccine or immunotherapy, or what goes wrong in HSK. HSV research has benefited tremendously from advances in basic immunology, such as the definition of leukocyte subsets, leukocyte-specific proteins, cytokines, and chemokines. The huge effort that has gone into human retrovirus and cancer immunology has led to the development of technique and reagents that have been very useful in the study of acquired responses to HSV in humans. Research accompanying the resurgence of interest in innate immunity over the last decade has revealed that HSV is a strong initiator of innate responses, and that HSV infection can be powerfully modified by innate immunity. Laboratory studies with materials from "outlier" patients with severe HSV, and well-characterized subjects with more routine HSV infections, together with the continuing application of animal models as new key host and viral molecules and pathways are defined, will continue to be rational lines of inquiry. Insights into basic immunology, such as the NIPC and APC identification studies discussed above, are likely to continue to result from HSV research. The challenging synthesis of HSV-specific and broader studies may hopefully lead to clinical advances in the not-too-distant future.

Immunopathological aspects of HSV infection

Kaustuv Banerjee and Barry T. Rouse

Department of Microbiology, College of Veterinary Medicine, University of Tennessee, Knoxville, TN, USA

Introduction

"What is food to one man is bitter poison to others" Lucretius *De Rerum Natura* (50BCE)

Foreign material entering multicellular organisms triggers a range of defense reactions which, when successful, subjugates and removes the invaders. Invertebrates and plants have natural defense systems, which recognize commonly shared patterns and usually react in a stereotypical manner. Long-lived animals such as vertebrates add to these natural defenses with adaptive systems that show discriminating recognition machinery, complex and varying effector mechanisms and development of persistent or "memory" responses. Under ideal circumstances, immune defense proceeds with minimal or inapparent damage to the host. In other situations, the defense system is less successful and the host tissues become damaged by the reaction. We usually consider the former situation as immunity and the latter as immunopathology. However, in both instances, mechanisms at play may be similar and deciding if the process is one or the other may require Lucretian logic.

With microorganisms, the commonest circumstance that results in immunopathology is where the microbe persists and continues to cause an innate and adaptive response. These, however, prove ineffective to remove or neutralize the agent. Thus the reaction becomes chronic and host tissues become damaged as a consequence. This situation occurs in tuberculosis as well as hepatitis B and C virus infections. Over time, many microbes with a long association with a host species find ways of persisting by evading responses that would either eliminate them or cause too much tissue damage. Human CMV infection in immunocompetent adults provides an example of this scenario (Reddehase, 2002). Other circumstances that result in immunopathology involve settings where one or more components of normal immune defense are compromised for genetic or other reasons. Prolonged severe genital herpes simplex virus (HSV) lesions in AIDS patients with very low CD4+ T-cells represent such an example (Koelle and Corey, 2003). Atopics too often have problems clearing HSV and hence often develop skin and eye lesions (Pepose, 1991a). In addition, some microbes are considered as able to trigger immune reactions that target host components themselves (autoimmune disease) or cause infected cells to undergo neoplastic transformation. The herpesvirus EBV provides an example of the latter in genetically susceptible individuals (Kieff and Rickinson, 2001). There are no undisputed examples wherein herpesviruses cause autoimmune diseases. However, HHV-6 has been proposed to cause multiple sclerosis (Swanborg *et al.*, 2003) and HSV infection may cause an autoimmune corneal inflammatory lesion (Streilein *et al.*, 1997).

Herpes simplex virus is a pathogen that only rarely appears to be involved in immune mediated tissue damage. Characteristically, primary or recurrent infections at superficial mucosal or dermal sites result in viral replication and destruction of most cells that support infection. This process induces an innate inflammatory reaction that contributes to infection control. Some cells, likely Langerhans dendritic cells, leave the site and carry viral antigens to draining lymph nodes where an adaptive response is induced or recalled. After a few days, effectors of adaptive immunity are recruited to the site, initially CD4+ T-cells followed by CD8+ cells, and these T-cells, probably assisted by antibody, complete the task of recovery (Koelle and Corey, 2003). Virus is removed and the inflammatory reaction subsides usually without trace. These events can be judged to represent immunity. When T cell function is impaired, as can happen in AIDS patients, HSV removal is impaired and the inflammatory reaction becomes unusually severe

and prolonged. This situation can be taken to represent immunopathology.

Certain tissue sites are particularly vulnerable to damage by an inflammatory response. These are sites where virus is difficult to dislodge, so the inflammatory reaction becomes prolonged and destructive, or where tissue repair leaves a functionally damaged organ. The eye is the site which best exemplifies such circumstances. In this organ, where inflammation or scar tissue along the visual axis impairs function, HSV infection may permanently impair vision. The most frequent example is herpetic stromal keratitis (SK). This chronic inflammatory reaction damages the stroma and can become sufficiently severe to merit corneal transplantation. About 20% of ocular HSV infections in humans result in stromal keratitis (Pepose *et al.*, 1996). In most instances, these are caused by HSV-1 and result from reactivation from latent infection in the trigeminal ganglion (Pepose *et al.*, 1996). Most of our understanding of the immunopathogenesis of SK comes from studies in animal models, in former times mostly the rabbit and now most usually the mouse.

Human HSV infections may also cause anterior as well as posterior uveitis (retinitis). These are rarer manifestations of HSV infection and much of the damage may result from direct viral damage more than from immunopathology. However, uveitis lesions in the rabbit and mouse models have a definite immunopathological component. Finally, HSV is the cause of a vision destroying reaction in the retina termed acute retinal necrosis (ARN). This lesion occurs both in children infected neonatally or later with HSV-2 as well as in adults where HSV-1 is usually involved (Margolis and Atherton, 1996). Acute retinal necrosis has also been studied in animal models, where lesions were shown to be immunopathological in part (Atherton, 2001).

Inflammatory reactions associated with HSV infection in the peripheral and central nervous systems may also be judged as immune mediated. The best studied example is ganglionitis, an HSV induced lesion that occurs in heterologous hosts but may not be a feature of the natural human disease. Lesions caused by HSV in the CNS are the most dramatic and devastating manifestations of HSV infection of humans. This rare disease is usually caused by HSV-1 infection in adults and is mostly a direct virologic lesion. However, immunopathological events such as demyelination may also occur in a few cases. In infants and children, encephalitis is more commonly associated with neonatal infection with HSV-2 and this lesion appears to be the direct result of a lytic virus infection.

Finally, there are some chronic inflammatory reactions that have been associated with HSV infection especially with the widespread use of modern technology to detect viral DNA. Some reports suggest that the virus or an immune response against it accounts for such HSV associated diseases as erythema multiforme, arteritis, Alzheimer's disease, Bell's palsy and Behcet's disease.

Herpes infections and ocular disease

At least four human herpesviruses have been implicated as causes of ocular disease. Two alphaherpesviruses, HSV and varicella zoster virus (VZV), the betaherpes virus CMV and the gammaherpesvirus EBV. CMV is a cause of retinitis, a lesion found only in immunosuppressed individuals, the majority of which were formerly AIDS patients, but now transplant recipients, especially recipients of bone marrow (Holland *et al.*, 1996). With the widespread use of protease inhibitors to control HIV, CMV retinitis is now mainly a disease of transplant recipients. The lesion itself is likely a direct consequence of viral replication in retinal cells. EBV is an occasional cause of SK lesions. These are characterized by an abundance of lymphoma like cells, in the stroma that are presumed to be mainly B cells (Matoba, 1990).

More commonly both HSV and VZV cause lesions in the anterior segment, principally the cornea. Both HSV and VZV can also cause uveitis and acute retinal necrosis (ARN).

Keratitis in humans

Both HSV and VZV can infect multiple structures in the eye. Lesions caused by HSV are much more common. The incidence of HSV ocular disease ranges from 4.1–20.7 cases/100 000 patient years representing the commonest single infectious cause of vision impairment in the western world (Pepose *et al.*, 1996). Of the three general types of HSV corneal disease, Infectious Epithelial Keratitis (IEK) is the most common lesion and appears to be a result of the direct effect of viral infection. Both disciform keratitis (HSV endotheliitis) and SK are thought to be mainly the consequence of immune mediated mechanisms rather than direct viral damage. IEK lesions are a result of viral replication and spread in the superficial epithelial layer of the cornea. This condition is usually self-limiting and no permanent corneal damage results. The quick remission seen with timely antiviral therapy suggests a simple viral cytolytic mechanism. However, virus invariably infects nervous ramifications in the cornea that have free ends within the epithelial layer, thus allowing retrograde transport and establishment of latency (Shimeld *et al.*, 2001). In addition, as a consequence of epithelial damage, virus can spread to the underlying stromal keratocytes and cause what is usually termed a necrotizing

form of stromal keratitis (Liesegang, 1999). This terminology is not used by many ophthalmologists since necrosis also occurs in immune mediated SK (T. P. Margolis, personal communication, 2003).

Disciform keratitis (DK) is a lesion in which the corneal endothelium is the primary site of damage. This form of ocular disease appears immunopathological based upon the fact that early intervention with corticosteroids leads to complete resolution (Liesegang, 1999). In DK, the inflammatory reaction of the endothelium sometimes results in secondary stromal and epithelial edema but there is usually no stromal infiltrate or neovascularization. One of the characteristic findings is the demonstration of keratic precipitates or KP (Liesegang, 1999). The exact nature of the KP is unknown but they could be aggregates of macrophages or NK cells attracted by the immunoglobulins on the surfaces of infected cells (Liesegang, 1999). An alternative idea is that KP represent cytotoxic T-cells recognizing viral epitopes on the endothelial cells (Liesegang, 1999). The role of live virus in disease development is supported by finding antigens, live virus and DNA in the anterior chamber and perhaps also corneal endothelial cells (Kaufman *et al.*, 1971; Sundmacher and Neumann-Haefelin, 1979a). It has been postulated that productive infection of the endothelial cell elicits a cellular and humoral immune response (Sundmacher and Neumann-Haefelin, 1979b), but this evidence is only circumstantial. Alternative suggestions include a possible delayed type hypersensitivity reaction to persisting HSV antigens within the stroma or the endothelium (Pepose, 1991b). It is difficult to resolve the nature of DK pathogenesis since animal models to study it are less than ideal. Disciform disease is seen in rabbits with an intracorneal injection of soluble viral antigen (Williams *et al.*, 1965). Using the rabbit model for DK, some have suggested that the lesions involve immune complex formation and antibody dependent cell mediated cytotoxicity (Meyers and Chitjian, 1976).

Inflammation of the corneal stroma (SK) as a result of HSV-1 (rarely HSV-2) infection can lead to a blinding immuno-inflammatory lesion of the stroma. This only accounts for approximately 2% of initial episodes of ocular disease but approximately 50% of recurrent ocular HSV disease (Norn, 1970). A similar, but even more devastating lesion can be caused by VZV infection. Fortunately, this is quite rare and also usually occurs as a consequence of reactivation (zoster). The infections usually heal quickly unless the patient is immuno-suppressed (Pepose *et al.*, 2003). Recurrent lesions can be very severe and most difficult to treat and control. Frequently, corneal lesions are accompanied by conjunctivitis, anterior uveitis and lipid keratopathy (Pepose *et al.*, 2003). If the virus is not controlled, it spreads to involve the iris and the corneal stroma. Stromal lesions can become sclerotic and very persistent and is believed to be immune mediated, however, the mechanism is not known and is difficult to study. Patients often lose sensitivity of the cornea and involuntary physical damage can result in secondary bacterial infection.

Table 35.1. Immunopathological basis for SK in humans

Lesions in the absence of virus or viral antigens
Indefinite corticosteroid therapy
Uncommon in immunosuppressed individuals
T-lymphocytes with reactivity to viral epitopes detectable in corneas with chronic lesions

Several observations suggest the operation of an immune etiology behind HSV induced SK (see Table 35.1). These include the fact that the lesions are persistent and are manifest well beyond the time that virus or viral antigens can be demonstrated. Lesions often need to be managed with indefinite corticosteroid treatment and reactivation lesions, except initially, do not benefit from acyclovir antiviral treatment. Also making a case for the pathogenesis of SK involving immunopathology is the fact that the lesion is very uncommon in immunosuppressed patients. Finally, clones of T-lymphocytes reactive to viral epitopes and possessing cytotoxic activity can be cultured from corneas showing chronic SK lesions (Verjans *et al.*, 1998; Koelle *et al.*, 2000).

Approximately 90% of patients maintain good visual acuity despite prolonged disease. However, in many cases resolution of inflammation is associated with a permanent loss of vision resulting from corneal scarring and ulceration. This necessitates treatment by corneal transplantation, which in itself can sometimes be a high risk factor for recrudescent herpetic keratitis (also called newly acquired herpetic keratitis) (Remeijer *et al.*, 1997) and super-infection with a different strain (Remeijer *et al.*, 2002)

The corneal stroma may be affected by several mechanisms; this may be secondary to disease of the epithelium (IEK) or endothelium (DK) or as a stromal edema resulting from a damaged endothelium. In humans, SK manifests itself in two primary forms that are perhaps mis-termed necrotizing SK and immune SK (Liesegang, 1999). While the former is thought to result from direct viral invasion of the stroma, chronic immune mechanisms, possibly of an autoimmune nature (yet unproven), are suspected in pathogenesis of the latter (Pepose *et al.*, 1996). These divisions are not mutually exclusive and necrosis can definitely occur in the immune form of disease. Intact virions and antigens can be detected in corneal keratocytes, endothelial cells and foci of epithelial cells

in specimens from patients with acute (necrotizing) stromal keratitis (Kobayashi *et al.*, 1972; Metcalf and Kaufman, 1976). This suggests that replicating virus and the resulting host inflammatory response leads to stromal cell destruction. This acute necrotizing form of SK eventually may become chronic, then considered to be the immune form of SK, when viral antigens are no longer present. The signs of SK are generally quite variable but they include the influx of a large number of different kinds of cells including polymorphonuclear leukocytes (PMN), macrophages, Langerhans' cells, natural killer (NK) cells, plasma cells and T-lymphocytes (Pepose *et al.*, 1985a; Youinou *et al.*, 1985, 1986; Miller *et al.*, 1993). In chronic herpetic SK in humans, the predominant population are macrophages and T-lymphocytes (Youinou *et al.*, 1985). Excess neovascularization also occurs in some patients.

The original mechanism proposed for the pathogenesis of the immune form of SK focused on the role of anti-HSV antibodies. This was based on the finding that rings (Wessely rings) seen in the mid-stroma of the cornea in immune stromal keratitis were positive for IgM, IgG and IgA (Meyers-Elliot *et al.*, 1980). Herpes virus particles have been demonstrated in these rings, many of them defective or incomplete (Meyers-Elliot *et al.*, 1980). In addition, viral antigens have been found localized in the keratocytes of the corneal stroma in transplanted corneas (Youinou *et al.*, 1986; Easty *et al.*, 1987). Hence it has been speculated that viral antigens trapped in the stroma acted as a nidus for deposition of anti-HSV antibodies that fix complement and leads to cellular damage (Pepose *et al.*, 1996). Viral antigens can also be presented to the infiltrating T-lymphocytes. In clinical specimens, increased levels of class I and II HLA antigens have been noted in areas of the greatest infiltrate, suggesting active presentation of antigens (Pepose *et al.*, 1985b). Both CD4+ and CD8+ T-cells occur in chronic herpetic SK with the former dominating the total T-cell numbers (Youinou *et al.*, 1986). Most of these cells are reactive against HSV antigens with the CD4+ subset reactive to peptide epitopes from UL21 and UL49 tegument proteins of HSV (Verjans *et al.*, 1998; Koelle *et al.*, 2000). They do not apparently recognize antigens derived from corneal tissues which would provide evidence for an auto-immune mechanism (Verjans *et al.*, 1998). Corneal derived CD4+ cells have been shown to possess cytotoxic activity suggesting the possible operation of this mechanism in stromal cell injury (Verjans *et al.*, 1998; Koelle *et al.*, 2000).

Animal models for SK

Understanding the pathogenesis of human SK from clinical observations, transplant material and the occasional samples obtained at biopsy is difficult. Fortunately, convenient animal models exist wherein HSV infection of the eye reproducibly generates a stromal inflammatory response. Moreover, this appears to reflect human immune SK at least before it is treated. The usual animal models are the mouse and rabbit with the latter now rarely used except for studies on therapy. Events in SK pathogenesis are mainly studied in primary infection of various mouse strains. Since human SK is most commonly a sequel to reactivated HSV, a better animal model should be one where lesions follow reactivation. Such models have in fact, been described for both mice and rabbit (Myers-Elliot and Chitjian, 1983; Shimeld *et al.*, 1989) but these are expensive and inconvenient and have contributed minimally to the understanding of pathogenesis. Rabbit reactivation can be achieved by ocular iontophoresis but this seldom gives rise to SK lesions (Myers-Elliot and Chitjian, 1983). The mouse reactivation model can be achieved by infecting mice under a cover of neutralizing antibody, then after some weeks asymptomatic animals are exposed to UV light. In usually a minority of animals, virus reactivates and generates an inflammatory reaction in the stroma (Shimeld *et al.*, 1989). Few papers have employed the model, and the results of these usually support the basic findings of the primary infection model; namely that SK is an immuno-inflammatory lesion mainly orchestrated by CD4+ T cells (Shimeld *et al.*, 1996).

The primary infection model usually uses strain HSV–1 RE and involves virus application to a lightly scratched cornea. Replication begins in epithelial cells of the cornea and usually the conjunctiva, but in immuno-competent mice rarely spreads to involve stromal cells or cells in uveal tissue. Characteristically, the viral replication events are over by 5–6 days and viral gene expression, as judged by protein detection or viral mRNA, are undetectable beyond a further 2–3 days (Babu *et al.*, 1996). Viral DNA, however, can be detected for prolonged periods although copy numbers, detectable by real-time PCR, do not exceed 2000–5000 copies per cornea by 14 days p.i. (our unpublished results). When looked at with an ophthalmoscope, the initial viral replication events are accompanied by a barely detectable inflammatory reaction with new blood vessel growth from the limbus (the location of blood vessels at the edge of the vessel free normal cornea) the most obvious feature. This is often referred to as the preclinical phase, although in fact with appropriate tests is readily observable.

Innate reactions to infection in the mouse model

HSV infection of the corneal epithelium sets off a range of humoral and cellular events that taken together help contain infection. Unfortunately, some of these also set the stage for subsequent immunopathology. A prominent early cellular event is the influx of polymorphonuclear neutrophils (PMN). This occurs mainly into stromal tissues subjacent to the infected epithelium. Such PMN escape

from blood vessels at the limbus presumably in response to signaling molecules generated from virus infected cells. The nature of such signaling molecules is unclear but several chemokines, including those known to be chemotactic to PMN, can be demonstrated within 12 hr p.i. (Su *et al.*, 1996; Thomas *et al.*, 1998)

The PMN response is at its peak around 48 hrs and it seems that this response helps control viral replication. Thus depleting PMN with specific monoclonal antibodies results in more intense and prolonged virus infection in the cornea (Tumpey *et al.*, 1996; Thomas *et al.*, 1997). Moreover, PMN suppressed animals may succumb to encephalitis since virus now spreads to the brain. Such observations indicate that PMN are part of the antiviral defense system although it is unclear how this function is performed. Accordingly, virus infected cells and PMN are usually not in direct contact implying that the protective function is indirect. Ideas for the mediation of such defenses include IFNγ and TNFα production as well as nitric oxide production by PMN (Daheshia *et al.*, 1998a). This topic has not been fully explored using, for example, knockout mice and other means of implicating potential antiviral mechanisms.

The PMN response to virus is not only a defense reaction. Indeed products released from PMN have been proposed to contribute to corneal damage possibly unmasking autoantigens subsequently involved in the immunopathology (Thomas *et al.*, 1997). In addition, PMN contribute to the process of neovascularization, a prominent feature of SK and a necessary step in its pathogenesis (Zheng *et al.*, 2001a; Lee *et al.*, 2002a). It appears that PMN may be a source of angiogenesis factors such as VEGF as well as tissue degrading enzymes which breakdown the stromal matrix and facilitates the growth of new blood vessels. One such enzyme released by the granules of activated PMN is MMP9 (Lee *et al.*, 2002a). Since infected mice given the MMP-9 inhibitor TIMP-1 as well as MMP9-/- mice have reduced angiogenic and SK responses, MMP9 appears to be intricately involved in SK pathogenesis (Lee *et al.*, 2002a).

Although PMN dominate the early inflammatory reaction to ocular HSV infection, other cell types can also be demonstrated. These include macrophages, dendritic cells (DC), NK cells but not B or αβ TCR T cells. The roles for these other cell types have received minimal investigation. It is likely, however that the macrophage is a source of angiogenic factors such as VEGF and FGF as well as the angiogenic CXC chemokines. For example MIP-2 (CXCL8) appears important since infected mice lacking the receptor for MIP-2 have an impaired PMN response (Banerjee *et al.*, 2004a). In addition, in vivo neutralization of MIP-2 in HSV infected mice reduces PMN migration (Yan *et al.*, 1998). Macrophages, along with DC, also act as a source of cytokines demonstrable early after infection. Most prominent of these are IL-1 and IL-6, both of which can also be produced by virus infected epithelial cells themselves (Tran *et al.*, 1998; Kanangat *et al.*, 1996). Indeed, it could be that these two cytokines are critical signaling molecules responsible for the many paracrine events set off by virus infected epithelial cells. The other early events described include the production of IL-12, VEGF and TNFα, but none of these are thought to be products of virus-infected cells themselves (Zheng *et al.*, 2001b; Kumaraguru and Rouse, 2002). We have demonstrated that IL-6, for example, can cause macrophages *in vitro* to generate VEGF (Banerjee *et al.*, 2004a), and IL-1 is well known to cause mononuclear cells to produce TNFα and other cytokines (Neta *et al.*, 1992). Our recent findings also indicate that within HSV infected corneas, IL-1 maybe responsible for IL-6 expression, which in turn upregulates VEGF production (Biswas *et al.*, 2004).

The cytokine IL-12 appears as a pivotal molecule in SK pathogenesis. Knockout mice, for example, unable to produce IL-12 have only mild SK lesions (Osorio *et al.*, 2002). The source of IL-12 following HSV infection remains to be clarified, since as mentioned it does not appear to be HSV-infected cells themselves (Kumaraguru and Rouse, 2002) However conceivably viral DNA that has pathogen associated molecular pattern (PAMP) activity could represent such a stimulus (Zheng *et al.*, 2002). The most likely producer cell types are DC and macrophages. The DC initially involved would seem to be the resident cells only recently demonstrated as present in normal non-inflamed corneas (Hamrah *et al.*, 2003). A prominent feature of the injured cornea, including that caused by HSV, is the invasion of Langerhans DC, likely from the conjunctiva, into the cornea (Jager *et al.*, 1991). However, this event takes several days to occur. Likely such cells also act as a source of cytokines and chemokines but their major function in SK pathogenesis is transport of viral antigens to lymphoid tissue where the adaptive immune response is initiated (discussed later).

The cytokine IL-12 has several downstream effects that impact on SK pathogenesis. The primary effect is induction of IFNγ production by cells with IL-12 receptors. Although not proven in the eye, the most likely cells that respond and produce IFNγ are natural killer (NK) cells. Such cells in non-ocular systems have been shown to be important for resistance to HSV. In fact, removing them results in heightened susceptibility (Rager-Zisman *et al.*, 1987). An early study of SK indicated that NK removal ameliorated SK (Tamesis *et al.*, 1994; Bouley *et al.*, 1996), although this issue warrants further investigation. Whatever the source of IFNγ, this molecule appears to be intricately involved in antigen processing as well as other events critical for

SK pathogenesis. These include up-regulation of the cell adhesion molecule PECAM-1 on vascular endothelial cells, at the limbus (Tang and Hendricks, 1996). This is a necessary step for normal PMN invasion as evidenced by the fact that neutralization of IFNγ or PECAM-1 results in diminished PMN ingress (Tang and Hendricks, 1996).

The importance of IFNγ in facilitating cell migration is further underscored by studies with human corneas. Stimulation of human corneal cells in vitro with IFNγ, and also IL-1 and TNFα, rapidly up-regulates ICAM-1 expression (another cell adhesion molecule that participates in the adhesion and extravasation of cells) (Pavilack *et al.*, 1992). IFNγ also upregulates MHC Class II expression on the antigen presenting cells involved in the induction of the initial antigen specific CD4+ T-cell response in local draining lymph nodes (Dreizen *et al.*, 1988; Foets *et al.*, 1991). On the other hand, IFNγ could help modulate lesion development since it also induces angiostatic chemokines such as IP-10 and MIG (Lee *et al.*, 2002b). Accordingly the IL-12 response to HSV infection indirectly impacts on both inflammatory and regulatory effects on SK.

In Fig. 35.1 several critical events are shown that are set into play by HSV during the first 6–7 days postinfection. By the end of this often-called preclinical phase, the corneal tissues show little or no damage. The epithelium is fully intact, the stroma has few if any inflammatory cells and cytokine/chemokine levels have fallen significantly. The most obvious sign of change is a neovascular bed that continues to expand slowly beyond the limbal region. Nevertheless, in spite of the quiet appearance, notable changes begin to occur which constitute the true immunopathological events of SK. Accordingly, the T-cell orchestrators begin to invade via the new blood vessels and an intense inflammatory response ensues. This becomes obvious upon ophthalmoscopic examination and is frequently referred to as the clinical phase.

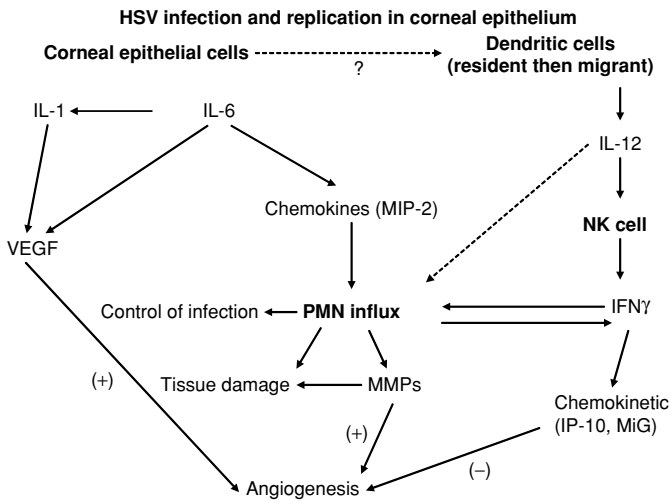

Fig. 35.1. Some early critical events occurring after HSV-1ocular infection.

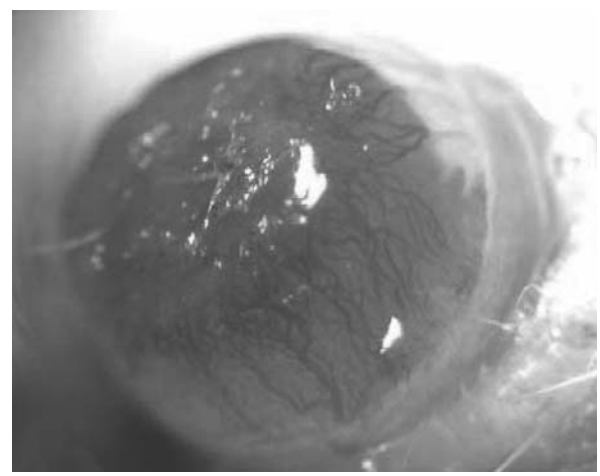

Fig. 35.2. Corneal blood vessels at the peak of HSK lesions in the mouse (day 15) with evidence of corneal opacity, necrosis and epithelial ulcers.

Adaptive immunity in SK

Migration of T-cells that express appropriate homing molecules escaping from the newly established blood vessels represents a crucial step in SK pathogenesis. Mice without T-cells never develop typical SK lesions (Metcalf *et al.*, 1979; Mercadal *et al.*, 1993), but do if given T-cell transfers (Russell *et al.*, 1984; Mercadal *et al.*, 1993). Although debated early on, most investigators now agree that CD4+ T-cells, with the type 1 producing cytokine phenotype, are the main aggressors in HSK (Niemialtowski and Rouse, 1992; Mercadal *et al.*, 1993). Such cells trigger the invasion of non-specific inflammatory cells, surprisingly once again dominated by PMN, giving rise to a peak response around 15 days after initial infection. The inflammatory response considerably thickens the stroma and neovascularization continues almost reaching the central cornea (see Fig. 35.2). Severe lesions have areas of necrosis and epithelial ulcers and uveal tissues may also be involved. The lesional T-cells, which account for only a minority of the inflammatory cells present, are mainly CD4+ T-cells. Judging from a variety of approaches, the principal cytokine necessary for the lesion expression is IFNγ (Tang and Hendricks, 1996; Deshpande *et al.*, 2002). However, SK can still be induced in animals lacking this cytokine (Bouley *et al.*, 1995). In cases where lesions do diminish in severity, the cytokine IL-10 is upregulated (Babu *et al.*, 1995). Furthermore, the artificial expression of IL-10 or IL-4 early in the syndrome can markedly diminish lesions (Daheshia *et al.*, 1998b).

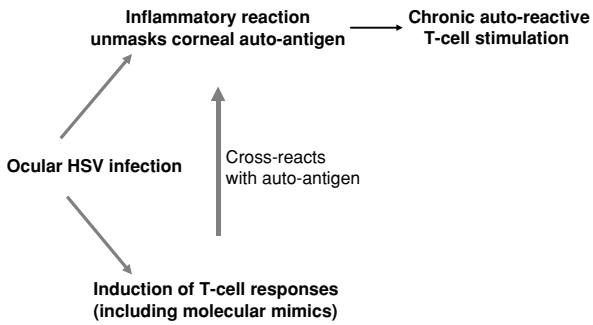

Fig. 35.3. The autoimmunity model of SK pathogenesis.

Such observations indicate that CD4+ Th1 are the principal aggressors but if a type 2 response can be induced, lesions will resolve. Whether such ideas can be applied usefully to the human system warrants investigation.

Very recently the severity of SK lesions was shown to be modulated by a second species of CD4+ T-cells (Suvas *et al.*, 2004). These were CD4+CD25+ T-regulatory cells (T_{reg}) found operative in autoimmune inflammatory lesions (Shevach, 2000). Accordingly, in animals unable to generate T_{reg} responses, SK lesions were more severe and animals more susceptible to a low dose of infection (Suvas *et al.*, 2004). In addition, there is evidence that the CD8 T cell response to HSV provides a protective function against SK (Mercadal *et al.*, 1993; Gangappa *et al.*, 1999; Banerjee *et al.*, 2004b, 2005). The mechanisms by which T_{reg} or CD8+ T-cells exert controlling effects on SK expression are not currently understood but are being actively explored.

A central issue in SK pathogenesis is the nature of antigens recognized by the CD4+ T-cell orchestrators and if such recognition occurs in the extra-lymphoid or lymphoid sites (or both). This issue becomes of interest since at the time when T-cells invade the cornea, replicating virus has usually disappeared (Babu *et al.*, 1996). Moreover, certainly at the time of peak lesions (15 days), the presence of viral antigens in stromal tissues cannot be demonstrated (Babu *et al.*, 1996). Conceivably, viral peptides expressed by DC could still be present in the cornea and draining lymph nodes, although usually T-cell target peptides turn over within 2–3 days after protein processing. Since new protein formation appears to have ceased by 6 days p.i., it is difficult to support the logical notion that peptides derived from viral proteins are the target antigens recognized by the $T_{aggressors}$.

An alternative concept is that viral specific T-cells are initially responsible for the immunopathology but subsequently the chronic phase is maintained by an autoreactive response (Deshpande *et al.*, 2002). Here the idea is that the virus infection results in unmasking of the some corneal autoantigen (see Fig. 35.3), tolerance is broken and the autoreactive T-cells induced are responsible for orchestrating lesions. A modification of this idea favored by the Cantor group is that the autoimmune process is set off by some viral peptide sharing reactivity to the unmasked corneal autoantigen (Zhao *et al.*, 1998). Thus the initial antiviral response subsequently becomes sustained by autoreactive $T_{aggressor}$ cells. This concept of molecular mimicry has aroused much interest and discussion (Deshpande *et al.*, 2002). Its best support comes from studies on closely related inbred mice. Here it would seem that the UL6 protein of HSV possesses molecular mimicry with an autopeptide that in fact represents a sequence also found on an immunoglobulin isotype (Zhao *et al.*, 1998). The molecular mimicry idea is not accepted by other groups for a number of reasons (See Table 35.2). Most, especially the UL6 proteins of HSV appear not to induce T cell responses in animals following infection with HSV (Deshpande *et al.*, 2001a). In humans also the UL6 protein appears not to be recognized (Verjans *et al.*, 1998; Koelle *et al.*, 2000; Ellison *et al.*, 2003).

Table 35.2. Lack of evidence for molecular mimicry between HSV UL6 peptide and corneal antigen

1. Failure to demonstrate an immune response directed to UL6 peptide after HSV ocular infection	Deshpande *et al.*, 2001a
2. Ocular infection with vaccinia virus expressing UL6 fails to induce HSK	Deshpande *et al.*, 2001a
3. CD4+ T-cells that are apparently tolerized to molecular mimics are able to induce SK lesions upon adoptive transfer to SCID mice	Thomas and Rouse, 1998
4. T-cells extracted from human corneas show no reactivity to HSV UL6	Verjans *et al.*, 1998; Koelle *et al.*, 2000
5. T-cells extracted from human corneas are not reactive to corneal antigens	Verjans *et al.*, 1998
6. Variation in clinical presentation of SK is not due to genetic variation in the UL6 epitope	Ellison *et al.*, 2003

An alternative idea to explain how CD4+ T-cells become activated is that the inflammatory process could be initiated by viral antigen recognizing T-cells, but subsequently is maintained by cells of the effector memory phenotype that escape into the cornea because of the highly permeable neovascular bed. Such cells, in turn, become activated by inflammatory molecules initially released by viral antigen reactive cells. The responding cells, release inflammatory

cytokines and so the process continues (see Fig. 35.4). This idea is supported by the observation that abundant non-antigen T-cells can be demonstrated and that it is possible to develop lesions identical to SK in animals whose T-cells are genetically incapable of recognizing viral antigens (Gangappa *et al.*, 1998; Deshpande *et al.*, 2001b; Banerjee *et al.*, 2002). Such was shown in several T-cell transgenic mice on SCID or RAG–/– backgrounds whose recognition repertoire did not include HSV antigen recognition (Gangappa *et al.*, 1998; Deshpande *et al.*, 2001b; Banerjee *et al.*, 2002). In these models, the chronic source of activating cytokines were cells dying of HSV infection since in this instance virus persisted and spread to the stromal site of inflammation (Gangappa *et al.*, 1998; Deshpande *et al.*, 2001b; Banerjee *et al.*, 2002).

Other ideas have also been advocated to explain which agonists drive SK, especially in the chronic phase, but the issue remains unresolved. The candidate agonists include PAMP expressed by virus, superantigen expression and inflammatory reactions driven by stress proteins (Deshpande *et al.*, 2002). Currently, a favored idea is that the HSV DNA could itself be pro-inflammatory because of its high content of bioactive CpG containing deoxynucleotide motifs (Zheng *et al.*, 2002). Such ideas await verification.

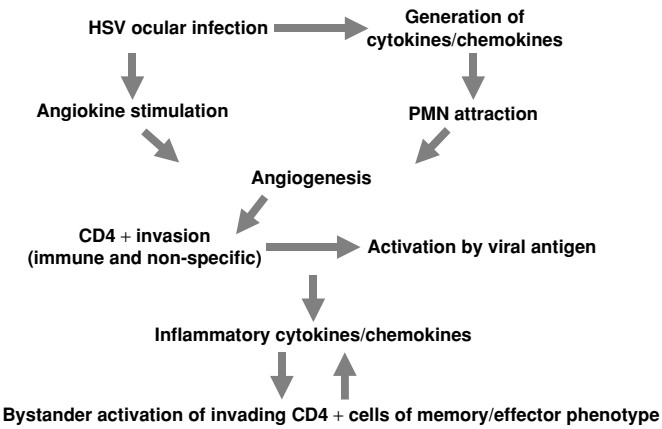

Fig. 35.4. Bystander activation model for SK pathogenesis.

Human Uveitis

Herpes simplex virus infection of the iris, ciliary body and the choroid results in an inflammatory condition known as HSV uveitis. This lesion usually accompanies SK or DK but occasionally it can stand alone. In many cases, it can occur in the absence of a previous history of HSV infection. Ophthalmoscopic examination reveals the presence of fine keratic precipitates (KP) and anterior chamber inflammation that ranges from mild to severe (Liesegang, 1999). The virus can be detected in the inflamed iris by electron microscopy. There seems to be a lack of consensus about the isolation of infectious virus from the anterior chamber of patients with HSV uveitis (Kimura, 1962; Sundmacher and Neumann-Haefelin, 1979b). This disparity may, however, result from differences among patients in the relative concentrations of anti-HSV antibodies to the virus in the anterior chamber that is needed to clear virus. Interestingly, intra-ocular antibodies recognize different viral antigens than those recognized by antibodies in the systemic immune response (Peek *et al.*, 2002). The implications of this finding are unclear but possibly persisting intraocular antibodies could be involved in the development of secondary uveitis by the formation of toxic immune complexes. Currently, the only evidence supporting an immunopathological basis for HSV uveitis in humans is the benefit of treatment achieved with administration of topical corticosteroids along with systemic acyclovir (Liesegang, 1999). Anterior chamber uveitis can precede ARN, the latter lesion initially virologic, but later on includes immune mediated events (discussed later).

The rabbit model for HSV uveitis

The possible immunopathological nature of HSV uveitis has been revealed in studies with the rabbit model (Oh, 1976). Injection of live virus directly into the vitreous humor (intravitreal injections) of the rabbit eye results in a slowly progressing inflammation of the uveal tract. Eventually an HSV neutralizing antibody response in the infected eyes, clears the virus. Only live virus is capable of producing primary uveitis. However in eyes that have recovered, secondary uveitis can be induced by injection of inactivated virus (Oh, 1976). The disease kinetics of this secondary disease is faster than that seen with the primary infection. Such results indicate that in cases of secondary uveitis the pathogenic mechanism is likely to be immune mediated.

Acute retinal necrosis (ARN) in humans

This dramatic and devastating lesion can be caused by VZV or more commonly by HSV. Lesions can result from primary or recurrent infection and in the case of VZV can stand alone or accompany chicken pox or zoster (Ganatra *et al.*, 2000). Without treatment the virus destroys the retina in 7–14 days. The initial stages of acute retinal necrosis (ARN) appear to be the direct result of viral damage but later stages involve immune mediated events.

Either HSV-1 or 2 can be involved. HSV-2 is usually the cause in infants, children and young adults (average age 27). In adults HSV-1 is usually the culprit (average age 50). With

HSV-2 induced ARN there is often a history of encephalitis and meningitis. It is thought that virus remains in the brain after such lesions, but then passes from that site to affect the retina (Margolis and Atherton, 1996). Typically, ARN starts off as a virologic lesion, but subsequently becomes immune mediated. The vitreous fills up with inflammatory cells and occlusive vasculitis can occur which deprives the retina of its blood supply (Margolis and Atherton, 1996). In addition, both CD4+ and CD8+ T-cells, possessing cytolytic and cytokine secreting functions, have been isolated from intraocular fluids of patients. These cells have been found to be reactive with HSV UL46 and UL47 encoded tegument proteins VP11/12 and VP13/14 (Verjans *et al.*, 2000).

In adults where HSV-1 is the usual cause, ARN is most commonly unilateral and usually associated with encephalitis. However there are two cases of retinitis that have occurred years after recovery from encephalitis (Margolis and Atherton, 1996).

The mouse model of ARN

Both the mouse and the rabbit model have been employed to study the pathogenesis of ARN and have yielded interesting clues for pathogenesis. If injected intra-cerebrally, virus spreads to the retina via the optic nerve (Atherton, 2001), providing evidence that a similar effect could occur in humans accounting for ARN long after an episode of encephalitis (Margolis and Atherton, 1996). ARN can also be induced by injecting HSV into the anterior chamber. Such infection usually fails to cause lesions in the injected eye, that is presumed to be protected by an IFNα response (Atherton, 2001). However, after a few days the contralateral eye develops a severe retinitis. This response is assumed to be immune mediated since it is of much milder extent in T-deficient mice. Moreover, reconstituting such mice with CD4+ immune T-cells, but not CD8+, restores lesion expression (Atherton, 2001).

Taken together, results from the mouse and human studies support the idea that a combination of viral infection of the retina and virus specific T-lymphocytes is likely involved in the pathogenesis of ARN.

Herpes simplex virus in the nervous system

In humans the most dramatic and devastating disease associated with HSV infection is herpes simplex encephalitis (HSE). Fortunately this is a rare syndrome for it is usually lethal or leaves patients with serious neurological damage. In adults, HSE is usually caused by HSV-1 and can occur following primary or more commonly recurrent infection (Whitley, 2001). Lesions are mainly considered to be the direct cytolytic effect of the virus. However, inflammatory reactions occur that include both CD4+ and CD8+ T-cells. In about 3% of adult cases demyelination has been noted likely a consequence of a T cell mediated immunopathological reaction (R. J. Whitley, 2003, personal communication). HSE in infants is occasionally associated with involvement of the retina (ARN).

Whereas HSE is a very rare disease in humans, heterologous hosts infected with this alphaherpesvirus are far more likely to suffer from HSE. Thus primary infection of susceptible mouse strains, especially with HSV-2, results in spread to the CNS and death from encephalitis (Hudson *et al.*, 1991; Whitley, 2001). Whereas in humans there is no evidence of neurotropic strains of HSV, in mice some viral strains are far more neurotropic than others (LaVail *et al.*, 1997). In some cases, the neurotropism has been associated with known amino acids in a single protein (Diefenbach *et al.*, 2002). The rodent form of HSE largely represents a direct effect of viral destruction, but immunopathology can play a role (Kastrukoff *et al.*, 1993; Hudson and Strelein, 1994). Multifocal brain demyelination (MBD) has been reported in susceptible mouse strains upon lip inoculation with HSV-1 and immunosuppression prevents the development of such lesions (Kastrukoff *et al.*, 1987; Kastrukoff *et al.*, 1993). Of the two major T-subsets, CD8+ T-cells appear to be involved in the focal lesions of the brain and depleting such cells prevents lesion development (Hudson and Streilein, 1994). Other studies indicate that CD8+ T-cells play both a protective and pathogenic role in encephalitis (Anglen *et al.*, 2003). These studies evaluated the role of such cells in stress induced HSE. If present prior to an infection, protection ensues, possibly by limiting the HSV replication and spread within the CNS; the delayed entrance of CD8+ T-cells could result in pathology, based on limited evidence (Anglen *et al.*, 2003).

Ganglionitis

A characteristic feature of all alphaherpesviruses is that they succeed in gaining access to sensory nerve fibers during primary infection and pass by retrograde axonal transport to the nerve cell bodies in the appropriate ganglion. At that site, whereas some neurons appear to support a productive infection, in others an alternative replication cycle is initiated that results in latency (Roizman and Knipe, 2001). With HSV, at least, latency is thought to be an immunologically cryptic situation, since the viral transcripts expressed have no protein product (Roizman and Knipe, 2001). Latency in a particular neuron can be maintained indefinitely, but some infected neurons restart the productive cycle and progeny virus spreads by anterograde transport to peripheral sites, such as the cornea. In their homologous hosts, alphaherpesviruses rarely spread

to the CNS after primary infection. Such events are quite common in heterologous hosts such as HSV in the mouse. Moreover, reactivation in homologous hosts often results in recrudescent lesions, but such are rare in heterologous situations. In the mouse latently infected with HSV, occasional neurons undergo reactivation (about 1 neuron in 5 days) and this induces a notable local inflammatory reaction (Feldman *et al.*, 2002). This likely prevents widespread dissemination in the ganglion.

Another event that characterizes HSV infection in heterologous hosts is a marked and prolonged ganglionitis that occurs after primary infection (Shimeld *et al.*, 1995; Liu *et al.*, 1996). This represents an immune mediated event that mainly involves CD8 + T-cells (Liu *et al.*, 1996; Liu *et al.*, 2000; Khanna *et al.*, 2003). The CD8 + T-cells seemingly function to purge productively infected neurons of virus, rather than killing them by a cytotoxic mechanism (Liu *et al.*, 2000; Khanna *et al.*, 2003). Hence there is no tissue damage and strictly speaking no pathology. Currently, the relevance of heterologous ganglionitis is not understood nor is it known if a similar phenomenon occurs in infected human ganglia. Ganglionitis, may be another example of events that occur only in heterologous hosts infected with alphaherpesviruses.

The course of events in the mouse ganglion has been carefully studied and they tell an intriguing story (Liu *et al.*, 1996; Liu *et al.*, 2000; Khanna *et al.*, 2003). The initial events involve viral replication and an inflammatory cascade that resembles that described for SK. However, after 7–10 days, CD4+ cells appear to enter and orchestrate subsequent events in SK whereas a remarkably high percentage of the inflammatory cells in the ganglia are CD8+ T-cells. Moreover, most of these are viral antigen specific and maintain this phenotype for months, which would indicate their continuous activation by antigen. However, demonstrating such antigen has proven impossible and most would agree that, after 10 days or so, virus is latent in neurons. The ganglionitis studies, however, imply that some antigen might be expressed by neurons but these are not sacrificed (Liu *et al.*, 2000; Khanna *et al.*, 2003); instead they are spared by the ability of the CD8+ T-cells to purge them of their offending virus (Liu *et al.*, 2000; Khanna *et al.*, 2003). These ideas remain to be proven and shown to be not purely a murine idiosyncrasy.

Other possible HSV induced immune mediated conditions

Herpes simplex virus affects the majority of mankind and it usually persists in some form in all it infects. Indeed, the latest sensitive molecular approaches have revealed that HSV DNA can be found in many tissues previously not recognized as an infection site. Such observations have led to the speculation that HSV could contribute to the cause of several chronic inflammatory diseases. For example, some have associated HSV with Alzheimer's disease based on the high correlation between HSV-1 in the brain and Alzheimer's disease (Pyles, 2001). On the same grounds, HSV-1 has been suggested to be a risk factor in other conditions like in Behcet's disease, Bell's palsy and Parkinson's disease (Hegab and Al-Mutawa, 2000; Simmons, 2002; Hemling *et al.*, 2003). Furthermore, HSV could also be a contributory cause of arteritis leading to atherosclerosis, an idea supported by some animal studies (Leinonen and Saikku, 2002).

In all cases where HSV is associated with chronic inflammatory lesions, experimental verification of a causative role is lacking.

Persistence in the population: epidemiology, transmission

Anna Wald[1] and Lawrence Corey[2]

Epidemiology of HSV-1 and HSV-2

Herpes simplex viruses are among the most ubiquitous of human infections. The frequency of HSV infection has been measured by testing various populations for the presence of antibody, as both virus and the immune response are thought to persist after infection for the life of the host. Worldwide, ~90% of people have one or both viruses. HSV-1 is the more prevalent virus, with 65% of persons in the United States having antibodies to HSV-1 (Xu *et al.*, 2002). The epidemiology in Europe is similar, with at least half of the population seropositive for HSV-1. In the developing world, HSV-1 is almost universal, and usually acquired from intimate contact with family in early childhood (Whitley *et al.*, 1998). After childhood, the HSV-1 prevalence rates increase minimally with age. Rates of HSV-1 infection are similar for men and women. In the United States, African-Americans and Asians have higher rates of HSV-1 infection than whites. The majority of infections are oral, although most are asymptomatic. Some data suggest that in developed countries, acquisition of HSV-1 is delayed from early childhood to adolescence or young adulthood (Hashido *et al.*, 1999; Mertz *et al.*, 2003).

HSV-2 infections are markedly less frequent than HSV-1 infections, with 15%–80% of people in various populations infected (Corey and Wald, 1999). The rates of infection vary with country as well as levels of sexual activity. In some countries, such as Spain and the Philippines, the HSV-2 prevalence hovers around 10%, increasing to 20%–30% range for most European countries and the United States (Varela *et al.*, 2001; Smith *et al.*, 2001; Enders *et al.*, 1998; Malkin *et al.*, 2002). Developing countries bear a much higher burden of HSV-2 infection, with many populations in Africa having >50% prevalence in the general population (Weiss *et al.*, 2001). Because HSV-2 infections are transmitted almost exclusively during sexual activity, the risk of HSV-2 reflects a person's level of sexual activity and the number of partners, and background prevalence of infection in the community. In communities with relatively low rates of infection, the risk of HSV-2 infection reflects more closely sexual activity of the person. However, in communities with high prevalence of infection, demographic rather than behavioral factors reflect HSV-2 risk more accurately (Sucato *et al.*, 2001; Rosenthal *et al.*, 1997; Austin *et al.*, 1999). Women have a greater risk of HSV-2 acquisition, reflecting both increased biologic susceptibility and pattern of relationships with older men, who are more likely to be HSV-2 seropositive. HSV-2 prevalence in the United States is higher among African-Americans than among whites and Asians (Fleming *et al.*, 1997). As a result, there is great disparity in infection rates according to both gender and race. For example, for white women, the risk of HSV-2 increases from about 18% among those with 2–4 lifetime partners to 35% for those with 10 to 49 lifetime partners (Fleming *et al.*, 1997). In contrast, for African-American women the risk increases steeply even with fewer partners, and exceeds 60% for women with more than 4 lifetime partners. For white men, the risk is ~10% among those who report 2 to 9 lifetime partners, and reaches 40% in those with >50 lifetime partners. Among African-American men, the risk rises from 35% in those with 2–4 lifetime partners to ~ 50% in those reporting >50 lifetime partners. The increase in the frequency of HSV-2 antibodies starts in adolescence, reflecting the initiation of sexual activity, and levels off in the 40s, probably reflecting cessation of new partner acquisition (Blower and Boe, 1993). In the United States, most people acquire HSV-2 in their 20s with a mean age at presentation of 24 years. In contrast, in South Africa, girls acquire HSV-2 infection in adolescence and >60% are infected by the age of 21 (Chen *et al.*, 2000).

The advent of the HIV epidemic initially eclipsed HSV-2 as a viral sexually transmitted disease of importance, but recent data have increasingly showed multiple interactions between the two viral infections (Corey *et al.*, 2004a). The development of molecular diagnostics has revealed that HSV-2 is the most common etiologic agent of genital ulcers in the developed and developing world (Chen *et al.*, 2000; Serwadda *et al.*, 2003). Even in regions in which syphilis and chancroid have been historically considered responsible for most genital ulcerations, the use of PCR-based techniques has clearly shown a predominance of HSV (Beyrer *et al.*, 1998; Morse *et al.*, 1997). In almost all studies, and in all populations, having HSV-2 infection increases the risk of HIV acquisition (Wald and Link 2002; Freeman *et al.*, 2006). The mechanism probably involves both HSV-2 induced skin or mucosal ulcerations, as well as influx of CD4+ cells into the herpetic lesions, cells that provide receptor for entry of HIV (Koelle *et al.*,1994). As transmission is more difficult to study than acquisition, the role of HSV-2 in the transmission of HIV is less well defined (Cameron *et al.*, 1989). However, the biology also suggests that HSV-2 infection may amplify HIV transmission, as HIV virions have been demonstrated in herpes ulcers (Schacker *et al.*, 1998c; Ballard, 2001). This topic of HSV and HIV interactions has been recently reviewed (Corey *et al.*, 2004a).

Spectrum of clinical disease

HSV can cause both mucocutaneous and systemic disease, and both HSV-1 and HSV-2 can cause the same syndromes, although the viruses are preferentially more likely to be associated with some syndromes than others. The variability in clinical expression is poorly understood, but the host immune system appears to be the main determinant of the clinical manifestations of HSV infections. The most severely affected are neonates, who usually acquire the disease during birth through exposure to infected genital secretions (Whitley *et al.*,1980). Rarely, adults can develop severe or fatal HSV infection during acquisition, and pregnant women appear to have a higher risk for this syndrome (Kobberman *et al.*, 1980; Sutton *et al.*, 1974). In most persons, HSV infections are confined to skin and mucosa. However, these can be severe, especially in persons immunocompromised either by other diseases (HIV, lupus), or iatrogenic immunosuppression or transplant, or extensive skin disease, such as eczema (Luchi *et al.*, 1995; Wheeler, Jr and Abele, 1966). Certain HSV-associated syndromes, such as HSV uveitis, have a strong immunopathogenic component and respond to immunosuppressive therapy (Balfour, 1994; Lairson *et al.*, 2003).

Immunocompetent host

Oral herpes

HSV-1 causes oral and labial, and occasionally facial, lesions. Initial infection is the most severe with ulcerative, painful stomatitis that usually occurs in children and is often associated with fever, anorexia and local edema of oral mucosa interfering with swallowing (Amir *et al.*, 1999). The lesions last a mean of 12 days and HSV-1 can be isolated in culture for the initial 7 days. The most common complication is dehydration requiring intravenous fluids, although secondary bacterial infection can also occur. In young adults, the presentation of initial oral HSV-1 infection can include pharyngitis, and tonsillectomy is occasionally (and erroneously) performed (Evans and Dick, 1964; Langenberg *et al.*, 1999).

Reactivation of HSV-1 in the mouth usually causes lesions on the lip ("fever blisters" or "cold sores"). The initial symptoms of pain, tingling, and itching occur prior to lesion appearance and are termed "prodrome" (Spruance, 1984). Initial lesion is an erythematous papule that evolves into a fluid-filled blister (Spruance *et al.*, 1997). Often there is a cluster of blisters, usually on a localized part of the lip, most often at the vermillion border. The lesions can also extend to skin on the face, and sometimes occur only on the face. The vesicles dry into a crust, and eventually re-epithelialize without scarring. The episodes last an average of 5 to 7 days. Only about 30% of persons with serologic evidence of HSV-1 have recurrent oro-labial herpes. Among those, 40% will have more than one recurrence per year. Known triggers of HSV-1 reactivation include facial trauma, surgery, fever and exposure to UV light (Spruance *et al.*, 1991). Oral labial HSV lesions were often associated with pneumococcal pneumonia and thought to be stimulated by the rapid rise in body temperature. Reactivation by UV light, such as occurs in skiers, can be abrogated by preventative use of sunscreen or antivirals (Spruance *et al.*, 1988). Recent popularity of laser skin resurfacing has been associated with severe HSV outbreaks resulting in recommendations that these procedures should be prophylaxed by antiviral therapy (Alster and Nanni, 1999; Beeson and Rachel, 2002). These triggers suggest that both systemic and skin factors can result in HSV reactivation (Hill *et al.*, 1978).

Genital herpes

HSV also causes ulcerations of genital mucosa and skin. The more common cause of genital herpes is HSV-2. However, recent studies suggest that 20%-50% of incident episodes

of genital herpes are caused by HSV-1 and the proportion of such incident cases due to HSV-1 may be increasing (Lafferty *et al.*, 2000; Lowhagen *et al.*, 2000; Vyse *et al.*,2000; Mertz *et al.*, 2003; Ross *et al.*, 1993). The reasons for this are not entirely clear but decreased HSV-1 acquisition in childhood and preferential practice of oral–genital sex during adolescence may be partly responsible. The clinical course of the initial and subsequent episodes is the same for both viruses; however, the frequency of recurrences and shedding is quite different, with HSV-1 reactivating infrequently in comparison to HSV-2 (Lafferty *et al.*, 1987; Benedetti *et al.*, 1994; Engelberg *et al.*, 2003). As such, it is important to identify the type of virus that causes the infection.

The severity of infection with HSV depends on previous immunity to HSV. Primary infection, defined as the first encounter with HSV-1 or HSV-2, is clinically most severe, and most likely to be symptomatic (Corey and Spear, 1986; Corey *et al.*, 1983). Non-primary infection is a new HSV-2 infection in a person with prior HSV-1 infection. New infections are diagnosed by detecting the virus on the mucosa in a person without concomitant antibody to the same type of virus. Recurrent infections occur as a result of reactivation of a previous, latent infection, and are identified by the presence of antibody at the time of initial presentation. It is important to note that accurate classification of an episode must include both virologic information as well as determination of antibody status because there is a wide overlap in clinical manifestations of the infection. Although primary infection is more likely to be symptomatic than an episode of reactivation, only up to 39% of people who acquire primary HSV will be diagnosed with the infection at that time (Langenberg *et al.*, 1999). A substantial proportion will become symptomatic at some point during the disease and present with a first clinical episode of genital herpes (Bernstein *et al.*, 1984; Diamond *et al.*, 1999). In a recent study of 401 persons presenting with a first episode of genital herpes, 91 (23%) had primary infection with HSV-1, 139 (35%) had primary infection with HSV-2, 36 (9%) had non-primary initial HSV-2 and 135 (37%) had a first recognized recurrence of HSV-2.

The painful genital vesicles and ulcers accompanied by inguinal adenopathy and systemic flu-like illness are part of the classic presentation of first episode of genital herpes (Corey *et al.*, 1983). The evolution of lesions is similar to those of oral herpes, usually with more rapid progression to ulcers in women, and often a prolonged vesicular phase in men. The lesions are widely distributed in the genital area, and multiple (up to 100 lesions) can be seen. During an initial episode, lesions last up to 3 weeks, and new lesion formation continues for 10–14 days. Itching, tingling and pain can be severe. Neurologic complications, such as meningitis and bladder paresis, usually transient, occur in ~10% and are more common among women. External dysuria is also common among women. Proctitis is common among MSM and can be associated with transient bowel dysfunction (Quinn *et al.*, 1981).

Recurrent episodes of genital HSV-2 occur a median of 4 (women) to 5 (men) times during the first year (Benedetti *et al.*, 1994). However, there is great variability in the frequency of recurrences, even during the first year. In a study of 457 persons with newly acquired HSV-2 infection, 38% had 6 or more recurrences and 20% had more than 10 recurrences during the first year. 14% of women and 26% of men had more than 10 recurrences and only 26% of women and 8% of men had no or 1 recurrence in the first year of infection (Benedetti *et al.*, 1994). Subsequently, the frequency of episodes slowly decreases, with an average decrease of 2 recurrences between years 1 and 5 of infection. As such, most patients will not perceive the decrease in severity until several years have elapsed. This improvement is not universal, and some people will continue to have very frequent or even more frequent recurrent episodes many years into the infection. In contrast, HSV-1 infection recurs infrequently, with a median of 195 days to first recurrence among women and 567 days among men after documented new genital HSV-1. Subsequently, the rate of recurrences falls even further with only 19% having 1 recurrence, and 15% having two or more recurrences during the second year after genital HSV-1 infection (Engelberg *et al.*, 2003).

Genital herpes is often associated with psychosocial distress, caused by having an incurable STD, stigma of having such disease, and anxiety about resuming normal sexual life after acquisition (Catotti *et al.*, 1993; Carney *et al.*, 1994; Swanson and Chenitz, 1990). The distress is usually greater among women than men and in many persons it surpasses the physical discomfort caused by the infection. Over time, most people adjust to living with herpes, although recurrences of depression and feelings of worthlessness tend to return during recurrences. Oral herpes can also be associated with feelings of being damaged, as it is cosmetically more obvious; however, it is clearly associated with less social stigma.

Other mucocutaneous infections

Despite the common involvement of oral or genital mucosa in the acquisition of HSV, cutaneous infections at other body sites are also well recognized. Eczema herpeticum occurs occasionally in persons with atopic dermatitis, regardless of whether they are receiving topical steroids (Wollenberg *et al.*, 2003; Yoshida and Amatsu,

2000). Outbreaks of herpes gladiatorum occur among young athletes involved in contact sports, often high-school wrestlers (Anderson, 2003; Becker,1992; Belongia *et al.*, 1991). Both infections are usually caused by HSV-1, and respond to therapy with antiviral medication (Niimura and Nishikawa,1988; Anderson, 1999).

Herpetic whitlow results from infection of the distal finger with HSV. Historically, this disease was caused by HSV-1 and was acquired among dental or nursing professionals (Stern *et al.*, 1959; Manzella *et al.*, 1984). More recently, with the adoption of universal precautions, the incidence of HSV-1 whitlow has decreased, and most distal finger infections arise in the setting of primary genital HSV-2 infections.

Recent studies have shown a link between erythema multiforme and recurrent HSV infections (Huff *et al.*, 1983). While the pathogenesis is not completely understood, strong association of erythema multiforme with particular HLA-DQ alleles is consistent with an immunopathologic basis (Malo *et al.*, 1998; Kampgen *et al.*, 1988). Molecular studies of the involved skin have demonstrated HSV DNA in the erythema multiforme lesions, and reports of prevention of attacks with oral acyclovir support HSV as an etiologic factor in this disease (Brice *et al.*, 1989; Miura *et al.*, 1992; Ng *et al.*, 2003; Lemak *et al.*, 1986).

HSV infection in CNS

Reactivation of HSV in the CNS is associated with 2 distinct syndromes with vastly different prognoses. Recent studies have shown that recurrent benign meningitis, or Mollaret's meningitis, results from HSV infection (Cohen *et al.*, 1994; Picard *et al.*, 1993). Most often HSV-2 is implicated, although HSV-1 has also been reported (Yamamoto *et al.*, 1991). Women are at higher risk for this complication than men, and often develop the initial episode during acquisition of genital HSV-2, with subsequent recurrent episodes. Thus, the epidemiology of Mollaret's meningitis parallels that of genital herpes. However, not infrequently the meningitis is the presenting complaint, and the association with HSV-2 is not always recognized. Spinal fluid findings are consistent with "aseptic meningitis" with a lymphocyte predominance, fairly normal protein and glucose, and sterile fluid. HSV DNA can be detected by PCR (Yamamoto *et al.*, 1991; Cohen *et al.*, 1994). While unpleasant, this condition is benign, and anecdotal data suggest that individual episodes respond well to antiviral therapy and further episodes can be abrogated in large part by suppressive antiviral therapy. In contrast, HSV encephalitis is a disease of severe morbidity (Whitley and Lakeman 1995). The usual agent is HSV-1, although HSV-2 meningoencephalitis has also been described in immunosuppressed patients (Gateley *et al.*, 1990; Linnemann *et al.*, 1976). HSV encephalitis is the most common cause of sporadic encephalitis in adults, with an estimated frequency of 1 in 200,000 to million persons. There is no gender predilection, and the age distribution appears bimodal, with a smaller peak among youth and a larger peak among the elderly. Encephalitis can develop both during primary infection (usually among younger people) and during reactivation (usually among older people) of HSV. Classically, the patient presents with fever and signs of focal encephalitis, such as seizures, headache and focal neurologic deficits. However, the initial symptoms can be insidious and include personality and cognitive disturbances. Fever is common. Spinal fluid shows increased white count, usually but not always with lymphocyte predominance, and can be bloody with abnormal chemistry. Imaging studies are not pathognomic, although temporal lobe disease is typical. The diagnosis should always be confirmed virologically. Most cases are diagnosed with the use of PCR that has surpassed the "gold standard" of brain biopsy because of similar sensitivity but virtually no risk (Lakeman and Whitley, 1995; Puchhammer-Stockl *et al.*, 1993). However, lack of positive PCR in the spinal fluid does not rule out the diagnosis of HSV, especially early in the disease, and intravenous acyclovir should be initiated if the clinical picture is compatible, no alternative diagnosis is made, and the PCR is negative (Whitley *et al.*, 1986). The lumbar puncture should be repeated in 24–48 hours and CSF submitted for PCR testing again. Untreated HSV encephalitis has >70% fatality rate. Even with therapy, HSV encephalitis results in death in a substantial proportion of patients and only a few percent return to normal function.

Eye disease

Occasionally, oral HSV-1 infection is associated with blepheritis or conjunctivitis (Souza *et al.*, 2003). While these are benign manifestations of herpetic eye infection, herpetic keratitis causes significant morbidity (Liesegang, 2001). Clinically, the disease is manifested by pain, photophobia and visual impairment. Dendritic ulcers can be visualized on examination with fluorescein staining. Recurrent episodes of reactivation are associated with stromal involvement and lead to progressive loss of vision and scarring, requiring penetrating keratoplasty or corneal transplants. Since the onset of keratitis is rarely coincidental with initial acquisition of HSV infection, the corneal infection may either result from direct inoculation of the virus into the eye, or more likely, from reactivation of HSV in the distribution that enervates the eye. The predisposition to

herpes keratitis is not well understood but the infiltrate of HSV-specific T lymphocytes supports the immunopathologic basis for this disease (Deshpande *et al.*, 2001; Koelle *et al.*, 2000; Thomas *et al.*, 1997; Thomas and Rouse, 1998; Verjans *et al.*, 2000). The complications of HSV-1 keratitis are the leading cause of infectious blindness in the United States (Lairson *et al.*, 2003). Clinical trials have demonstrated the benefit of suppressive acyclovir in the prevention of herpetic keratitis recurrences (Herpetic Eye Disease Study Group 1997, Wilhelmus *et al.*, 1998).

Acute retinal necrosis is another HSV-related syndrome that often results in blindness. The pathogenesis is poorly understood, and HSV-2 is detected more often than HSV-1 in this disease (Itoh *et al.*, 2000; Thompson *et al.*, 1994; Tran *et al.*, 2004). Immunosuppression appears to be a risk factor, as the acute retinal necrosis appears to be more common among patients with AIDS, although this syndrome has also been observed in persons with iatrogenic immunosuppression (Guex-Crosier *et al.*, 1997). The presentation is often rapid, and loss of sight is frequent. Antiviral therapy may prevent involvement of the contralateral eye, even if it does not restore vision in the affected eye (Tran *et al.*, 2004).

Other syndromes

Other, infrequent manifestations of HSV have also been reported. Of note is disseminated HSV, which occurs occasionally in persons who appear immunocompetent and has a high fatality rate (Goyette and Donowho, 1974; Flewett *et al.*, 1969; Keane *et al.*, 1976; Frederick *et al.*, 2002; Chase *et al.*, 1987). While the infection most likely begins as oral or genital herpes, these localized symptoms are often not recognized, and patients present with fulminant hepatitis with transaminases in the thousands, diffuse rash, or other systemic manifestations. Death results from sepsis with DIC, ARDS, or progressive hepatic failure. This syndrome occurs more frequently among women in the second half of pregnancy although occasional cases are reported among nonpregnant women and men. Factors predisposing to this have not been described. Early administration of acyclovir is often effective, but the disease is often not diagnosed premortem.

Neonatal herpes

The frequency of neonatal herpes varies by region and is estimated to occur from 1 in 3200 to 1 in 15 000 pregnancies (Sullivan-Bolyai *et al.*, 1983a; Tookey and Peckham, 1996; Mindel *et al.*, 2000; Brown *et al.*, 2003; Gutierrez *et al.*, 1999). Reasons for the variant frequency are poorly understood but are likely to result from interplay between sexual behavior in the population and the baseline prevalence and incidence of HSV-1 and HSV-2. Over 85% of neonatal herpes is acquired from intrapartum exposure of the newborn to infected maternal secretions. In 5% of cases, congenital infection of the fetus in the setting of new acquisition of HSV during pregnancy has been reported (Florman, 1973; Sullivan-Bolyai *et al.*, 1983a). These infants are born with clinical evidence of disseminated disease, often including skin lesions, may be premature and have a poor prognosis. Post-natal acquisition of HSV, often from non-maternal sources, has also been reported in about 10% of cases, and is associated with HSV-1 infection.

Recent prospective studies have clarified risk factors for HSV transmission during delivery (Brown *et al.*, 1997; Arvin *et al.*, 1986; Prober *et al.*, 1992). The greatest risk of neonatal herpes is conferred by viral shedding, defined as HSV isolation in maternal genital secretions at the time of parturition, with a relative risk of neonatal HSV of >300 compared with women who do not have HSV isolated during labor (Brown *et al.*, 2003). However, some infants acquire neonatal herpes despite lack of culturable virus at the time of delivery. In some of these cases, HSV DNA can be detected by PCR despite negative viral culture, suggesting that culture can be falsely negative. Of greater concern is the observation that only 5% of women who have HSV isolated from the genital tract at the time of delivery transmit HSV to the infant. As such, these women are at potential risk of unnecessary interventions.

Among women who are shedding HSV in genital secretions at labor, risk factors for neonatal herpes include newly acquired HSV infection (RR = 59), cervical vs. vulvar viral isolation (RR = 15), young mother (RR = 2.7 for women aged <21), and HSV-1 vs. HSV-2 isolation (RR = 35). Cesarean deliveries appear protective as women who are delivered abdominally had a significantly lower risk of HSV transmission compared with women who had vaginal delivery (RR = 0.14). Because even the largest series of neonatal herpes contain only a handful of cases, the exact contribution of each risk factor is difficult to measure. However, overall, most cases of neonatal herpes appear to occur among women who acquire subclinically new genital HSV-1 or HSV-2 and who deliver vaginally (Arvin *et al.*, 1982, Whitley *et al.*, 1991b). In one study, 4 of 9 women who acquired HSV so late in pregnancy that they did not seroconvert by the time of delivery transmitted the virus to their infant (Brown *et al.*, 1997). Management of recognized newly acquired genital herpes at the end of pregnancy needs to be individualized and should include consideration of administration

of acyclovir to women toward the end of pregnancy, scheduled abdominal delivery prior to rupture of membranes, and prophylactic antiviral therapy of the newborn (Prober *et al.*, 1992; Sheffield *et al.*, 2003).

Infants with neonatal herpes often present with nonspecific complaints such as fever, fussiness, sepsis, or seizures (Whitley *et al.*, 1998). Typical skin lesions are not noted universally, and depending on the disease classification, may develop only in up to 80% of patients. Clinically, neonatal herpes has been divided into 3 syndromes. In recent studies, skin, eye and mouth disease accounted for 42% of cases, and is defined by disease that is present only on skin or mucosa (Whitley *et al.*, 1998, Kimberlin *et al.*, 2001a). This form of infection has the best prognosis with negligible mortality and up to 70% of treated infants having normal development. Of interest, even those infants who did not have any evidence of CNS involvement may subsequently present with neurologic deficits, suggesting that subclinical and/or delayed involvement of the brain is not uncommon. Disseminated disease accounts for 23% of cases and has the highest mortality (60% with therapy). Among the survivors, normal development is noted in about 60%. CNS disease comprises the remaining 35% of newborns with neonatal herpes. Mortality is low, but this form of disease is associated with highest morbidity as less than 50% will have normal development. Comparison of secular trends suggests that a greater proportion of cases are diagnosed with SEM disease in recent years compared with an earlier cohort (Whitley *et al.*, 1988, 1991a, b). A potential explanation is that the diagnosis is made earlier, prior to dissemination or CNS invasion. Many cases are still diagnosed late, or post-mortem, and administration of acyclovir to infants with sepsis-like syndrome is not universally done. Prompt antiviral therapy is associated with decreased morbidity and mortality, but the prognosis remains grave for most children. HSV-2 appears more neuroinvasive in newborns than HSV-1, and as such, has a worse prognosis (Corey *et al.*, 1988).

The observations about risk factors for neonatal herpes suggest that prevention of neonatal herpes relies on prevention of HSV acquisition in late pregnancy. This strategy, in turn, relies on identification of women at risk for HSV infection with the use of type-specific serology, and, potentially, the serologic testing of their sex partners. This approach has not been widely accepted (Wilkinson *et al.*, 2000; Brown, 2000). Reasons for resistance are numerous, including lack of confidence in the performance of commercial type-specific serologies, perception that counseling about results of HSV serologies is burdensome to both providers and patients, lack of simple interventions, and the relative rarity of neonatal HSV. Of note, after institution of universal testing for Group B streptococcus (GBS) during the last trimester, the frequency of neonatal GBS sepsis now approaches that of neonatal HSV (Gibbs *et al.*, 1994; Chuang *et al.*, 2002; Schrag and Schuchat, 2004).

Immunocompromised persons

Immunosuppression, regardless of etiology, is associated with greater risk of HSV reactivation, prolonged viral shedding and more severe clinical recurrences (Meyers *et al.*, 1980; Siegal *et al.*, 1981). While even in severely immunocompromised patients most disease is mucocutaneous, extension to internal organs, such as esophagus, or dissemination, can also occur. Other syndromes include hepatitis and pneumonia (Ramsey *et al.*, 1982). Patients receiving cancer chemotherapy are at risk for HSV recurrences during periods of neutropenia; the risk in organ or marrow transplant patients is prolonged and parallels the duration of immunosuppression (Wade *et al.*, 1984a). However, the greatest risk of HSV reactivation after bone marrow transplant occurs early during the initial neutropenia associated with myeloablation. This is in contrast to other herpesvirus infections, such as VZV and CMV, which tend to occur later during the post-transplant period during maximal suppression of cell-mediated immunity. Because HSV has a significant impact on post-chemotherapy and post-transplant morbidity, acyclovir prophylaxis is administered routinely in this population (Wade *et al.*, 1984b).

In the last two decades, HIV has emerged as the most common cause of immunosuppression worldwide. Not surprisingly, early clinical reports of patients with HIV document extensive clinical HSV recurrences (Siegel *et al.*, 1988). The disease burden is especially great, as persons at risk for sexually transmitted HIV are more likely to have HSV-2 infection than the general population. Prior to the introduction of effective antiretroviral therapy, chronic HSV ulcers accounted for a small proportion of newly diagnosed persons with AIDS, and developed in many other persons as immunosuppression progressed. Despite the frequent presence of HSV-1 and HSV-2 infection (90% overall) in patients with HIV, extensive clinical disease develops only in a minority of patients (Bagdades *et al.*, 1992). The immunologic and virologic risk factors for developing severe disease are not understood. Systematic study of clinical and virologic aspects of genital HSV-2 shows that even in the absence of overt clinical disease, HIV infected persons have high rates of viral shedding. Among a group of 68 men who have sex with men with HIV infection and a

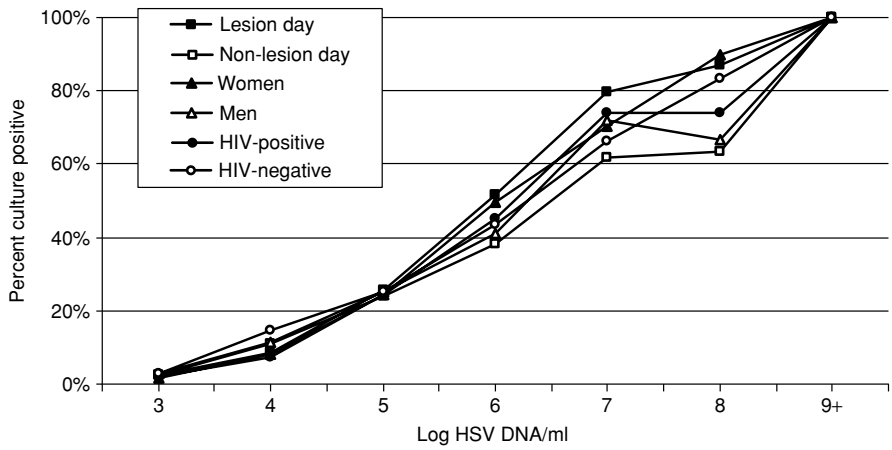

Fig. 36.1. The relationship between the probability of HSV isolation in viral culture and the number of copies of HSV DNA as detected by PCR (adapted from Wald (Wald *et al.*, 2003)).

mean CD4 count of 351, the rate of genital HSV isolation was 9.7% of days, and the perianal area accounted for 79% of isolates (Schacker *et al.*, 1998b). The relative risk of total viral shedding was elevated at 3.3 compared with men who are HIV negative, but an even greater relative risk of 6.9 was shown for subclinical shedding. These observations show that HIV has a greater effect on the virologic than clinical aspects of the natural history of HIV and may provide an explanation for a burgeoning epidemic of HSV-2 in parallel with HIV in sub-Saharan Africa.

Immune reconstitution with antiretroviral therapy (ART) has resulted in a decrease in risk of several opportunistic infections, and has allowed for stopping of prophylaxis in those patients with vigorous CD4 response. Unfortunately, the data suggest that the increase in CD4 cells associated with ART prevents lesions, with significantly lower risk of mucocutaneous lesions among patients treated with ART compared with patients who are untreated, but has a negligible effect on viral shedding (Posavad *et al.*, 2001). As such, HSV-2 & HIV seropositive patients are likely to continue to be infectious for HIV and HSV-2 and suppressive HSV therapy should be considered in that setting.

Viral shedding

HSV is present intermittently on skin or mucosa in between symptomatic recurrences. This phenomenon, defined as asymptomatic or subclinical shedding, has been described since the early clinical descriptions of genital herpes. However, the frequency, pattern, and the importance of subclinical shedding for transmission of HSV have only recently been elucidated.

The frequency of viral shedding has been measured both by culture and by PCR. Studies using amplification techniques show that HSV DNA PCR is up to 400% more sensitive for detection of HSV on mucosal surfaces than viral isolation (Wald *et al.*, 2003) (Fig. 36.1). The frequency of viral shedding varies with type of HSV, duration of infection, gender, and immune status. Most variability observed in the frequency of viral reactivation is not explained by these risk factors, suggesting that there is a strong host immunogenetic (or viral strain) factor in determining the severity of disease.

The initial study examining prospectively viral shedding among women with recent genital HSV-2 infection showed that HSV was detected by PCR on 28% of days sampled (Wald *et al.*, 1997). However, as shown in Fig. 36.2, the variability in the frequency of reactivation is great, even among this homogeneous group of women. Subsequent studies have also examined viral shedding among men. In a group of men with either recent acquisition of genital HSV-2 or a history of frequent recurrences, the overall rate of HSV detection from the genital area by PCR was 32% (median 30%; range 0 to 92%) (Wald *et al.*, 2002b). Despite the rough parallel between the frequency of viral shedding and the frequency of recurrent lesions, these two processes are somewhat independent, with some persons having frequent days with lesions, or prolonged lesions, and others having frequent viral shedding but without many recurrences. These observations suggest that the immunologic mechanisms that control viral shedding may differ from those that control lesion formation and resolution. Animal experiments, and findings in persons with immune compromise, indicate that the CD4 response predominates in control of lesions, while CD8 response is more important for control of viral reactivation (see Chapter 34).

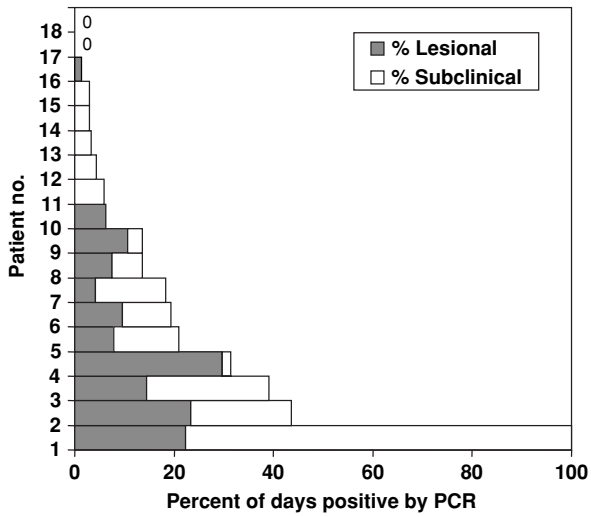

Fig. 36.2. Variability in symptomatic and subclinical shedding among 26 women with genital HSV-2 infection for less than 2 years.

Transmission dynamics

Figure 36.3 illustrates the pattern of viral shedding during inadvertent sexual transmission of HSV-2 infection. The woman participating in a daily home sampling study had symptomatic genital HSV-2 infection for 3.5 years, and had initiated a new relationship with a partner who was HSV seronegative. Despite having occasional non-specific symptoms, she did not notice a recurrence during the episode of subclinical viral shedding that resulted in transmission of HSV-2. Studies consistently indicate that transmission to sex partners, or to neonates, usually occurs during such episodes of subclinical shedding (Barton *et al.*, 1987; Mertz *et al.*, 1992).

Prospective studies of HSV-2 discordant couples have been used to estimate rate of transmission and ascertain risk factors for transmission. Unfortunately, only a few such studies have been done that included a sufficiently large number of persons to obtain reliable estimates of rates of transmission and risk factors (Mertz *et al.*, 1988, 1992; Stanberry *et al.*, 2002; Bryson *et al.*, 1993; Wald *et al.*, 2001; Corey *et al.*, 2004b). The rate of HSV-2 acquisition among persons at risk varies from a high of 8.6 per 100 person-years for women, to a low of 2.7 per 100 person-years among men. These studies have also shown that (1) women are at 2-to-6 fold higher risk for HSV-2 acquisition than men; (2) prior infection with HSV-1 does not protect against HSV-2 acquisition; (3) symptoms of first episode HSV-2 infection are less prominent among those with previous HSV-1 infection; (4) frequent sexual activity is a risk factor for HSV-2 transmission, and (5) HSV-2 is transmitted more easily than HSV-1 infection. Other characteristics that have been associated with increased risk of HSV-2 transmission, but inconsistently, or without reaching statistical significance, include short duration of relationship and short duration of genital herpes in the source partner prior to study participation, and sex during recurrences (Corey *et al.*, 2004b). Condoms appear to be protective, but the degree of protection afforded by consistent use, and effect of condom use on female-to-male vs. male-to-female transmission varies among the studies (Wald *et al.*, 2001). In addition, the use of condoms in monogamous, long-term relationships is rare, even in the settings of known HSV-2 discordance and extensive counseling in the context of a clinical trial. Available data indicate that consistent condom use offers partial protection ($\sim$ 50%) against HSV-2 acquisition at best. A recent study of daily suppressive valacyclovir has shown that transmission is decreased by 48% among those couples who were randomized to receive antiviral therapy (Corey *et al.*, 2004b). These results offer couples another option to use to decrease the risk of HSV-2 transmission, and are an added benefit to the use of daily antiviral therapy (see below).

Management and Prevention

Treatment

The advent of antiviral drugs for HSV-1 and HSV-2 infections has made clinical management of these infections a part of standard clinical practice (Table 36.1). For mucocutaneous and visceral HSV infections, acyclovir and its related compounds famciclovir and valacyclovir have been the mainstay of therapy (Whitley and Gnann Jr, 1992). Several antiviral agents are available for topical use in HSV eye infections: idoxuridine, trifluorothymidine and topical vidarabine. For HSV encephalitis and neonatal herpes, intravenous acyclovir is the treatment of choice. Acyclovir resistant virus can be encountered in immunocompromised hosts (Erlich *et al.*, 1989; Reyes *et al.*, 2003).

Acyclovir was the first antiviral clearly demonstrated to be effective against HSV infections (Elion *et al.*, 1977). It is an acyclic nucleoside analogue that is a substrate for HSV-specific thymidine kinase. Acyclovir is selectively phosphorylated by HSV-infected cells to acyclovir-monophosphate. Cellular enzymes then phosphorylate acyclovir-monophosphate to acyclovir-triphosphate, a competitive inhibitor of viral DNA polymerase. Acyclovir-triphosphate is incorporated into the growing DNA chain of the virus and causes chain termination. Acyclovir has potent in vitro activity against both HSV-1 and HSV-2.

Valacyclovir is the valyl ester of acyclovir and is metabolized in the gut, liver and epithelium to acyclovir and

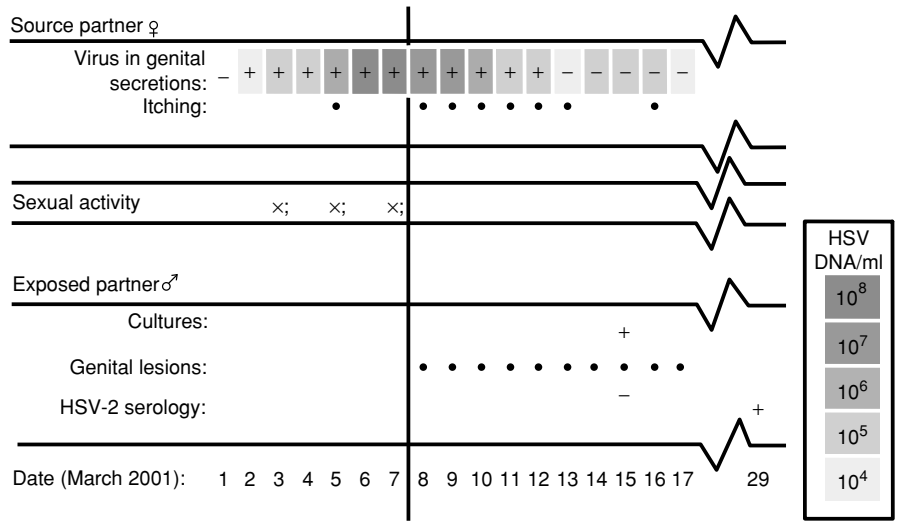

Fig. 36.3. Sexual transmission of HSV-2 during subclinical shedding.

produces much higher levels of drug leading to more convenient therapy (Soul-Lawton *et al.*, 1995). Famciclovir, the oral formulation of penciclovir, is also clinically effective in the treatment of a variety of HSV-1 and HSV-2 infections (Pue and Benet, 1993). Ganciclovir has activity against both HSV-1 and HSV-2, but because it is more toxic than acyclovir, valacyclovir, and famciclovir, it is generally not recommended for treatment of HSV infections. Numerous trials of acyclovir in mucocutaneous HSV infections of immunocompetent and immunosuppressed host have been conducted. General recommendations are outlined below (Centers for Disease Control and Prevention 2002). Increasingly, shorter courses of therapy are being utilized for treatment of recurrent mucocutaneous HSV-1 or HSV-2 in immunocompetent patients.

Treatment of recurrent mucocutaneous herpes

Among immunocompetent patients, recent studies have shown the effectiveness of short course therapy to reduce the signs and symptoms of oral and genital HSV infection. These include 2 g twice daily for one day of valacyclovir for oral-labial HSV and 2 and 3 day courses of acyclovir or valacyclovir for recurrent episode genital herpes (Spruance *et al.*, 2003; Leone *et al.*, 2002; Wald *et al.*, 2002a). One-day therapy with famciclovir for genital herpes also appears to increase the probability of an aborted recurrence and to shorten the duration of lesions and symptoms, compared with placebo (Aoki *et al.*, 2006).

Suppression of mucocutaneous herpes

Recognition of the high frequency of subclinical reactivation has provided increasing rationale for the use of daily antiviral therapy to suppress reactivations of HSV. This is especially useful for persons with frequent clinical reactivations such as those with recently acquired genital HSV infection. Immunosuppressed persons, including those with HIV infection, may also benefit from daily antiviral therapy. A variety of dosages have been utilized.

Reduction in transmission to sexual partners

Once daily valacyclovir (500mg) has been shown to reduce transmission of HSV in partnerships in which one partner has symptomatic genital HSV-2 and the other partner is susceptible (Corey *et al.*, 2004b). Serologic screening can be used to identify at risk couples, as many couples identified as discordant by history are concordant on serologic evaluation.

Severe HSV infection

Intravenous acyclovir (30 mg/kg/day, given as a 10 mg/kg infusion over 1 hour at 8-hour intervals) is effective in reducing the morbidity and mortality from HSV encephalitis (Whitley, 1988; Whitley and Lakeman, 1995). Early initiation of therapy is a critical factor in outcome. The major side effect associated with intravenous acyclovir is transient renal insufficiency, usually caused by crystallization of the compound in the renal parenchyma. This adverse reaction can be avoided if the medication is given slowly over 1 hour and the patient is well hydrated. Because CSF levels of acyclovir average only 30% to 50% of plasma levels, the dosage of acyclovir used for treatments of CNS infection (30 mg/kg per day) is double that used for the treatment of mucocutaneous or visceral disease (15 mg/kg per day). For neonatal HSV, high-dose intravenous therapy is

Table 36.1. Treatment of HSV infections

Infections in immunosuppressed patients

Acute symptomatic first or recurrent episodes: IV acyclovir (5 mg/kg q 8 h), or oral acyclovir (400 mg qid), famciclovir (500 mg po tid) or valacyclovir (500 mg po bid). Treatment duration may vary from 7 to 14 days.

Suppression of reactivation disease: IV acyclovir (5 mg/kg q 8 h), valacyclovir (500 mg po bid) or oral acyclovir (400–800 mg 3–5 times per day) prevent recurrences during the immediate 30 day post transplantation period. Longer term suppression is often used for persons with continued immunosuppression. In bone marrow and renal transplant patients, valacyclovir 2 grams 4 times daily is also effective in preventing CMV infection (Dignani *et al.*, 2002, Lowance *et al.*,1999). Valacyclovir 8 gm daily has been associated with thrombotic microangiopathy after extended use in HIV positive persons (Bell *et al.*, 1997). In HIV-infected persons, oral famciclovir (500 mg bid) is effective in reducing clinical and subclinical reactivations of HSV-1 and 2, and valacyclovir 500mg bid decreases the frequency of genital HSV-2 recurrences (Schacker *et al.*, 1998a, Romanowski *et al.*, 2000, DeJesus *et al.*, 2003).

Genital herpes

First episodes: Oral acyclovir (200 mg 5 times per day or 400 mg tid), oral valacyclovir (1000 mg bid) or famciclovir (250 mg bid) for 10–14 days are effective. IV acyclovir (5 mg/kg q 8 h for 5 days) is given for severe disease or neurologic complications such as aseptic meningitis.

Symptomatic recurrent genital herpes: Oral acyclovir (200 mg 5 times per day for 5 days, 800 mg po tid for 2 days), valacyclovir (500 mg bid for 3 or 5 days) or famciclovir (125 mg bid for 5 days). All these therapies are effective in shortening duration of lesions, viral shedding and symptoms.

Suppression of recurrent genital herpes: Oral acyclovir (200-mg capsules bid or tid, 400 mg bid, or 800 mg qd), famciclovir (250 mg bid), or valacyclovir (500 mg or 1000 mg qd or 500 mg bid) prevents symptomatic reactivation. Persons with frequent reactivation (<9 episodes) can take 500 mg daily; those with >9 should take 1000 mg/daily or 500 mg bid (Reitano *et al.*, 1998).

Oral-labial HSV infections:

First episode: Oral acyclovir (200 mg) is given 4 or 5 times per day. Famciclovir (250 mg bid) or valacyclovir (1000 mg bid) has been used clinically.

Recurrent episodes: Valacyclovir 1000 mg bid for 1 day or 500 mg bid for 3 days is effective in reducing pain and speeding healing. Self-initiated therapy with 6 times daily topical penciclovir cream is effective in speeding the healing of oral-labial HSV, topical acyclovir cream has also been shown to speed healing (Spruance *et al.*, 1997).

Suppression of reactivation of oral-labial HSV: Oral acyclovir (400 mg bid), if started before exposure and continued for the duration of exposure (usually 5–10 days), will prevent reactivation of recurrent oral-labial HSV infection associated with severe sun exposure (Spruance *et al.*, 1988).

Herpetic whitlow: Regimens used for treating genital herpes can be utilized but clinical trial data are lacking.

HSV proctitis: Oral acyclovir (400 mg 5 times per day) is useful in shortening the course of infection (Rompalo *et al.*, 1988); less frequent dosing is also likely to be effective. In immunosuppressed patients or in patients with severe infection, IV acyclovir (5 mg/kg q 8 h) may be useful.

Herpetic eye infections: In acute keratitis, topical trifluorothymidine, vidarabine, idoxuridine, acyclovir, penciclovir, and interferon are all beneficial. Debridement may be required; topical steroids may worsen disease.

CNS HSV infections

HSV encephalitis: Intravenous acyclovir (10 mg/kg q 8 h; 30 mg/kg per day) for 10 days is preferred.

HSV aseptic meningitis: No studies of systemic antiviral chemotherapy exist. If therapy is to be given, IV acyclovir (15–30 mg/kg per day) should be used in severely affected patients, followed by oral course of valacyclovir.

Autonomic radiculopathy: No studies are available.

Neonatal HSV infections: Acyclovir (60 mg/kg per day, divided into 3 doses) is given. The recommended duration of treatment is 21 days. Monitoring for relapse should be undertaken and some authorities recommend continued suppression with oral acyclovir suspension for 3 to 4 months (Kimberlin *et al.*, 1996).

Visceral HSV infections

HSV esophagitis: IV acyclovir (15 mg/kg per day). In some patients with a milder degree of immunosuppression, oral therapy with valacyclovir or famciclovir is effective.

HSV pneumonitis: No controlled studies exist. IV acyclovir (15 mg/kg per day) should be considered.

Disseminated HSV infections: No controlled studies exist. Intravenous acyclovir nevertheless should be tried, and in some cases has been reported to result in survival.

recommended (60 mg/kg per day in three divided doses) (Kimberlin *et al.*, 2001b). Intravenous therapy for neonatal herpes should be given for 21 days. Increasingly, serial testing of CSF HSV DNA has been utilized to guide the duration of therapy, and most experts advocate treating until HSV DNA is no longer detected. In immunosuppressed patients, IV acyclovir or oral valacyclovir are utilized to prevent HSV reactivations during transplantation or chemotherapy, and high doses of oral valacyclovir also prevent CMV reactivation (Dignani *et al.*, 2002; Lowance *et al.*, 1999).

Acyclovir-resistant strains of HSV have been identified, especially in HIV-infected persons. Almost all clinically significant acyclovir resistance has been seen in immunocompromised patients. Most acyclovir-resistant strains of HSV have a deficiency in thymidine kinase, the enzyme that phosphorylates acyclovir (Darby *et al.*, 1981). Thus, cross-resistance to famciclovir is usually found. Occasionally, an isolate with altered thymidine kinase specificity will arise and will be sensitive to famciclovir but not to acyclovir. In some patients infected with thymidine kinase–deficient virus, higher doses of acyclovir are associated with clearing of lesions. In others, clinical disease progresses despite high-dose therapy. Isolation of HSV from persisting lesions despite adequate dosages and blood levels of acyclovir should raise the suspicion of acyclovir resistance (Safrin *et al.*, 1992, 1994). In such cases therapy with the antiviral drug foscarnet is useful (Safrin *et al.*, 1991). Because of its toxicity and cost, this drug is usually reserved for patients with extensive mucocutaneous infections. Cidofovir is a nucleotide analogue (Snoeck *et al.*, 1994). Most thymidine kinase–deficient strains of HSV are sensitive to cidofovir. Cidofovir ointment has been shown to speed healing of acyclovir-resistant lesions (Lalezari *et al.*, 1997). Similarly, trifluorothymidine ointment has also been reported to be of utility (Birch *et al.*, 1992).

Introduction

VZV is a human alphaherpesvirus that causes varicella (chickenpox) as the primary infection and establishes latency in sensory ganglia. VZV reactivation results in herpes zoster (shingles). During the course of varicella and zoster, VZV infects differentiated human cells that exist within unique tissue microenvironments in humans. The tropism of VZV for skin is the most obvious clinical manifestation of VZV infection, producing the vesicular cutaneous lesions that are associated with varicella and zoster. The site of initial VZV infection in naïve hosts is thought to be mucosal epithelial cells of the upper respiratory tract. Entry is presumed to follow inoculation of the respiratory epithelium with infectious virus transmitted by aerosolized respiratory droplets or by contact with virus in varicella or zoster skin lesions (Arvin, 2001a; Grose, 1981). VZV in respiratory or conjunctival mucosal cells has the opportunity to interact with and infect local immune system cells and those in adjacent lymphoid tissues. Trafficking of infected peripheral blood mononuclear cells (PBMC), which appear to be predominantly T-cells, to the skin is thought to give rise to crops of cutaneous vesicles. Skin lesions contain VZV material associated with necrotic debris and, unlike virus grown in vitro, cell-free, infectious particles are detected in vesicular fluid (Williams *et al.*, 1962). The life cycle of VZV is completed upon its transmission to a susceptible host from an individual with varicella, or it can be postponed for decades by establishing latency in neurons and transmitting to future generations during episodes of zoster.

VZV shares its tropism for epithelial tissues with its relatives, HSV-1 and HSV-2, as well as with the non-human alphaherpesviruses. VZV also shares the neurotropism of these viruses, as discussed elsewhere in this volume. However, VZV seems to be more akin to the betaherpesviruses, HHV6 and HHV7, in its apparent tropism for T-cells (Ku *et al.*, 2002, 2004; Takahashi *et al.*, 1989). VZV infection of T-cells appears to represent a critical phase of its life cycle, providing a mechanism for viral transport from sites of initial infection to the skin. Sensory nerve axons terminate in the dermis and may be infected with VZV, allowing for retrograde transport to sensory ganglia, as it spreads through the skin layers (Annunziato *et al.*, 2000). VZV may also reach neurons by hematogenous spread. The outcome of VZV infection in these various cell types, which are differentiated and non-dividing, depends on interactions between virus proteins and host factors at the cellular level and is modulated by the innate and adaptive immune responses of the infected host (Chapter 39). VZV infection of dendritic cells is described in Chapter 39, and investigations of latency and reactivation in the human host and in rodent models are reviewed in Chapter 38. The goals of this chapter are to discuss VZV infection of T-cells and skin, which are essential target cells of the virus during primary infection, and the disease consequences of varicella in healthy and immunocompromised individuals.

Systems for evaluating determinants of VZV pathogenesis in human skin and T-cells

Immunodeficient (*scid/scid*) mice with thymus/liver (T-cell) or skin xenografts have provided a useful experimental model for examining VZV pathogenesis in vivo, known as the SCID-hu model of VZV infection (Moffat *et al.*, 1995). In this model, VZV-infected fibroblasts are injected into human tissue xenografts, which are then removed at intervals up to 21–28 days after infection. Initial experiments with T-cell xenografts showed that VZV proteins were expressed in CD4+, CD8+ and CD4/CD8+ T-cells and VZV was cultured from each T-cell subpopulation. T-cells released infectious VZV, which was an important

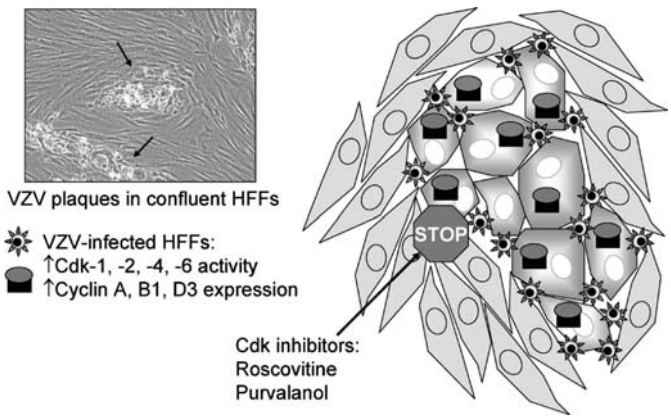

Fig. 37.1. Activation of host cyclin-dependent kinases in VZV-infected fibroblasts. VZV infects quiescent cells such as dermal fibroblasts (HFFs) to cause skin lesions. The photo of VZV plaques in HFFs (arrows) shows that the infected cells are rounded and have not fused into syncytia, though they are adherent (magnification, 10X). The uninfected cells are confluent and contact inhibited. Since they are not dividing, HFFs express basal levels of cyclin D3, and the cyclin-dependent kinases (Cdks) are inactive. Upon infection with VZV, unscheduled cyclin expression results in high levels of cyclins A, B1, and D3, which does not reflect a normal phase of the cell cycle. In association with these cyclins, several cdks are activated in VZV-infected HFFs: Cdk-1, −2, −4, and −6 (depicted as oval/rectangle heterodimers). It is not known how VZV infection dysregulates cdks or how this favors virus replication. However, when cdk activity is inhibited with roscovitine or purvalanol, VZV spread is reversibly blocked, and viral DNA synthesis is shut off. (Adapted from (Moffat *et al.*, 2004b), photo provided by Stacey Leisenfelder.)

observation because VZV replication in vitro is highly cell-associated. VZV-infected skin implants exhibited epidermal lesions that were indistinguishable from the characteristic lesions of varicella. Experiments with VZV mutants in the SCIDhu model indicate that VZV is challenged to employ more gene functions to replicate successfully in skin and T-cells in vivo, because the cellular environment in intact tissues is fundamentally different from that in cultured cells. Host cell factors such as innate immunity, cellular kinase activation, cellular transactivating proteins and protein trafficking pathways, are likely to affect virulence such that the full range of VZV gene products is needed to modify the tissue environment for effective viral pathogenesis.

Information about the molecular pathogenesis of VZV has been obtained by generating VZV recombinants with selected mutations in the viral genome using cosmid systems. Sets of four or five cosmids have been derived using genomic DNA from the parent Oka strain, pOka, a clinical isolate from Japan from which the live, attenuated varicella vaccine virus, vOka, was made (Niizuma *et al.*, 2003) and from the vOka strains used by Merck & Co., Inc. (Kemble *et al.*, 2000) and the strain deposited at the American Type Culture Collection (Cohen and Seidel, 1993). To obtain mutant viruses, alterations are made in selected VZV open reading frames (ORFs) and introduced into the cosmid that carries the gene of interest. The altered cosmid and the three or four other cosmids are transfected or transduced together into human melanoma cells. Homologous recombination between overlapping sequences generates an intact VZV genome, and if the mutation is not lethal, the virus propagates by cell-cell spread and plaques appear in the transfected cells. To discern phenotypes beyond lethality, mutant viruses are compared to isogenic parent viruses and a repaired strain, also made from cosmids. These "matched sets" of mutant, parent, and repaired viruses are evaluated in vitro using primary cell cultures and in the SCIDhu model in vivo.

Effects of VZV replication on cellular cyclin-dependent kinases and cyclins

The primary reason why VZV pathogenesis must be studied in vivo using the SCIDhu model is that the intracellular environment in human skin and thymus tissues differs greatly from the conditions in cultured cells. VZV is commonly cultivated in human melanoma cells (MeWo) or in subconfluent human fibroblasts (HFF, HELF, MRC-5, WI-38) that contain abundant metabolic precursors and enzymes involved in cell growth and division. In contrast, dermal fibroblasts, differentiated keratinocytes, and single-positive CD4+ or CD8+ T cells in xenografts in SCIDhu mice are not dividing. In these quiescent cells, regulatory proteins such as Rb and p27 suppress biosynthetic pathways for DNA replication and cell division by inhibiting transcription of cyclins and the activity of cyclin-dependent kinases (CDKs) (Olashaw and Pledger, 2002). VZV infection subverts these suppression mechanisms in an unknown manner and causes unscheduled cyclin expression and dysregulation of cyclin-dependent kinases (Fig. 37.1). In VZV-infected, confluent HFFs, high levels of CDK activity are associated with simultaneous expression of cyclins A, B1, and D3 (Leisenfelder and Moffat, 2006). This unusual protein profile is likely induced by VZV since it does not correspond with CDK and cyclin expression patterns found in cellular G0/1, S, G2, or M phases.

VZV alters the intracellular environment of resting cells by inducing kinase activity, an effect that appears to be

an essential step in virus replication because compounds that inhibit CDK activity prevent VZV spread. Roscovitine and purvalanol A are specific inhibitors of CDKs 1, 2, 5, 7, and 9 that have potent antiviral effects on VZV and other viruses (Moffat *et al.*, 2004b; Taylor *et al.*, 2004). Interestingly, as little as 5μM roscovitine or 2μM purvalanol is needed to prevent VZV replication and yet 10-fold more is needed to cause cell cycle arrest in MeWo cells. Thus VZV is acutely sensitive to levels of CDK activity, which the virus may utilize for initiation of transcription from viral promoters (CDK7 and CDK9), phosphorylation of the C-terminus of glycoprotein I (CDK1) (Ye *et al.*, 1999), and for numerous potential viral and cellular protein targets. An important role for kinase activity associated with cyclin B, presumably CDK1, is phosphorylation of IE62 since these proteins interact in the cytoplasm. Recognition sites for CDK1 are plentiful in IE62, and point mutagenesis confirmed that several are targeted by the kinase in vitro (Leisenfelder and Moffat, unpublished observations).

Investigation of events in the pathogenesis of primary VZV infection in the SCIDhu model

The clinical experience documents that primary VZV infection is initiated by inoculation of the respiratory mucosal epithelium and that the varicella rash appears after a 10–21 day incubation period (Arvin, 2001a; Cohen and Straus, 2001). Given the extreme host-range restriction of VZV, concepts about the pathogenesis of primary VZV infection have been derived from the sequence of events during primary mousepox infection (Grose, 1981). Based on this model, VZV has been thought to reach mononuclear cells in regional lymph nodes, causing a primary viremia that transports the virus to reticuloendothelial organs, such as the liver, for a phase of viral amplification. The theory has been that this amplification stage is followed by a secondary viremia in the late incubation period that carries VZV to skin sites. Recently, work using the SCIDhu model has provided experimental evidence to refine hypotheses about primary VZV pathogenesis (Ku *et al.*, 2004). According to our new model of VZV pathogenesis, VZV tropism for T-cells may facilitate viral transfer to skin (Fig. 37.2). Previous investigations in cultured cells demonstrated that T cells could be infected with VZV (Koropchak *et al.*, 1989; Soong *et al.*, 2000) and that tonsil T-cells, especially activated, memory subpopulations, are highly permissive for VZV infection (Ku *et al.*, 2002). In addition, VZV preferentially infected the activated, memory CD4+ T-cells that constitute >20% of tonsil T-cells. T-cell sub-populations that expressed the skin homing markers, cutaneous leukocyte antigen (CLA), and chemokine receptor CCR4, were also more likely to be infected and VZV did not disrupt the important chemotaxis functions of these cells. In order to investigate the hypothesis that VZV could be transferred to skin by tonsil T-cells, VZV-infected human tonsil T-cells were adoptively transferred to SCIDhu mice via intravenous injection (Ku *et al.*, 2004). The microcirculation within these skin xenografts is formed by human $CD31^+$ endothelial cells, which permits interaction with human T-cells. CD3+ T cells were detected within the epidermis, dermis and around the hair follicles in skin tissues within 24 h after injection into the mouse circulation. T-cells expressing the memory marker, CD45RO, were the predominant population. When skin xenografts were harvested at intervals after inoculation of infected T-cells, characteristic cutaneous VZV lesions were formed and progressed in size and production of infectious virus over 10–21 days. Intravenous injection of VZV-infected fibroblasts did not result in VZV transfer into skin xenografts. T-cell transfer of the virus resulted in lesions expressing the VZV proteins needed for lytic infection, such as the major immediate early ORF62 (IE62) transactivator, the ORF47 kinase and glycoprotein E (gE). VZV infection of skin resulted in extensive formation of multi-nucleated polykaryocytes, a gradual thickening of the epidermis, epidermal cell proliferation, destruction of basement membranes, and cellular degeneration. Foci of VZV-infected cells eventually extended up to surface keratinocytes but only after 14–21 days. Infectious VZV was produced throughout this period of progressive cutaneous lesion formation. Thus, the time required for VZV lesions to penetrate through the keratinocyte layer at the skin surface implies that VZV must reach cutaneous sites of replication at an early, rather than a late stage of the incubation period.

VZV alters the intracellular environment and produces lytic infection within 2 days in cultured cells in vitro. In contrast, VZV infection in skin xenografts evolved much more slowly. These observations suggested that innate immune mechanisms within the intact cutaneous tissue microenvironment in vivo might modulate VZV replication. Analyses of skin xenografts showed that interferon-α (IFN-α) and interleukin 1-α (IL-1α) were expressed constitutively in the cytoplasm of epidermal cells in uninfected skin (Ku *et al.*, 2002). After VZV infection, IL-1α was translocated to the nuclei of cells expressing VZV proteins, but remained in the cytoplasm of adjacent, uninfected cells. TNF-α expression was not present in uninfected skin and was not induced by VZV infection. Importantly, interferon-α (IFN-α) was not expressed in VZV-infected cells but was up-regulated in neighboring uninfected epidermal cells within the skin

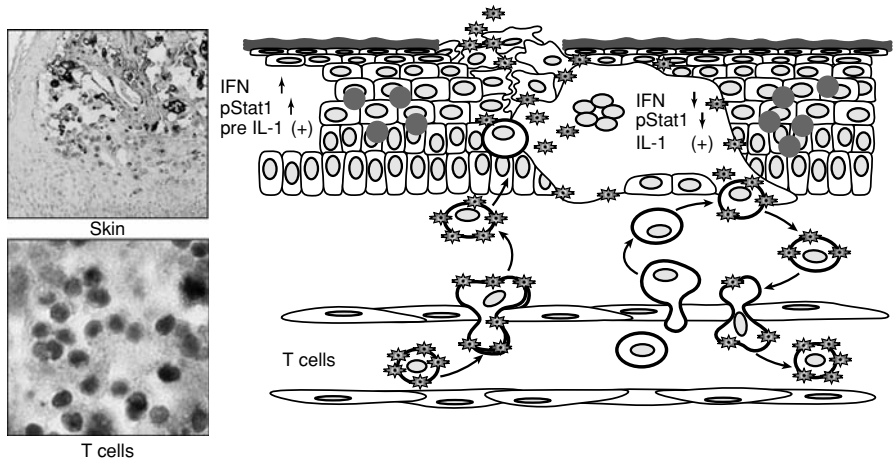

Fig. 37.2. A model of the pathogenesis of primary VZV infection. This figure illustrates new concepts about VZV pathogenesis and immunobiology that have emerged from experiments in the SCIDhu mouse model. The upper left panel shows the appearance of a mature VZV lesion in a SCIDhu skin xenograft, stained for VZV protein expression with a polyclonal human anti-VZV IgG antiserum. The lower left panel shows VZV infection of T-cells in a SCIDhu T-cell xenograft, detected by *in situ* hybridization with a VZV DNA probe. The right panel is a diagram depicting proposed events in the pathogenesis of VZV infection of skin. According to this model, T-cells within the tonsil lymphoid tissues become infected by VZV transfer into these migratory cells of the immune system following the initial inoculation of respiratory epithelial cells with the virus. Infected T-cells enter the circulation and transport the virus to the skin shortly thereafter, exiting through capillary endothelium by the usual mechanisms for trafficking of migratory T-cells. The infected T-cells then release infectious VZV at skin sites of replication. The remainder of the 10–21-day incubation period is the interval required for VZV to overcome the innate IFN-α response in enough epidermal cells to create the typical vesicular lesions containing VZV at the skin surface, as shown in the upper left panel. Signaling of enhanced IFN-α production in adjacent skin cells prevents a rapid, uncontrolled cell-cell spread of VZV. Additional crops of varicella lesions may result when T-cells traffic through early stage cutaneous lesions, become infected and produce a secondary viremia. This process continues until host immune responses trigger the up-regulation of adhesion molecules and mediates the clearance of the virus by VZV-specific antiviral T-cells. (Adapted from Ku *et al.*, 2004.)

xenograft. The phosphorylation state of Stat1 protein is a marker for activation or suppression of the IFN-α pathway because IFN-α binding to its receptors induces Stat1 phosphorylation by JAK kinases. Without phosphorylation, Stat1 is not translocated to cell nuclei and production of IFN-α does not occur. In VZV-infected skin, phosphorylated Stat1 was localized to nuclei in neighboring uninfected epidermal cells, but it was not detected in cells expressing VZV proteins. In uninfected skin, Stat1 was not phosphorylated and Stat1 and IFN-α remained cytoplasmic. Another mediator of the innate immune response, the transcription factor NF-κB, also remained in the cytoplasm of VZV-infected skin cells in SCIDhu implants (Jones and Arvin, 2006). These experiments indicated that VZV replication was associated with expression of a gene product(s) that inhibited antiviral IFN-α production in foci of infected skin cells in vivo by interference with Stat1 activation. To further document the role of the IFN-α response in regulating VZV infection and cell-cell spread between epidermal cells within intact skin tissue in vivo, skin xenografts were inoculated with VZV and SCIDhu mice were given neutralizing antibody against the human IFN-α/β receptor, in order to block type I IFN activity. In these experiments, infectious VZV titers were ten-fold higher in skin specimens when IFN signaling was inhibited by receptor blocking and the cutaneous lesions were substantially larger.

Because SCID mice lack the capacity to develop an adaptive, antigen-specific immune response, the progression of VZV infection in skin xenografts is controlled only by innate immunity. In the intact human host, biopsies of varicella skin lesions show a local inflammatory response surrounding the infected cells. The migration of immune cells into damaged tissues is signaled by the up-regulation of adhesion molecules on the vascular endothelial cells. Comparative analyses of infected skin xenografts and human VZV lesion biopsies permitted an examination of whether these changes could be induced by viral replication *per se*. Cutaneous lesions in patients biopsied at the onset of the varicella rash showed extensive expression of E-selectin, ICAM-1, and VCAM-1, whereas these proteins were not detected in capillaries of infected skin xenografts. Many infiltrating mononuclear cells were detected, most of

which expressed CD4 or CD8, and included predominantly $CD45RO^+$ memory T-cells and skin homing CLA^+ and $CCR4^+$ T-cells. In contrast, adoptive transfer of PBMC to SCIDhu mice showed no enrichment for these effector T-cell populations in VZV infected skin. These differences in adhesion molecule expression and in mononuclear cell profiles in VZV lesion biopsies and in VZV-infected skin xenografts suggested that recruitment and/or retention of inflammatory T-cells required signals provided by host cellular immunity.

Considered together, data showing VZV infection of T cells in vitro (Ku *et al.*, 2002; Soong *et al.*, 2000) and these experiments in the SCIDhu model suggest that T-cell tropism plays an essential role in VZV pathogenesis. The prolonged varicella incubation period appears to represent the time required for VZV to overcome previously unrecognized, but potent innate antiviral responses, especially IFN-α production, mediated directly by epidermal cells in vivo. The initial phase of VZV pathogenesis is also likely to be facilitated by the failure of VZV to trigger up-regulation of inflammatory adhesion molecules on capillary endothelial cells in skin and virus-mediated modulation of MHC I and MHC II expression (see elsewhere in this volume).

The role of VZV glycoproteins in T-cell and skin tropism

As is true of all herpesviruses, VZV glycoproteins have multiple functions that affect tissue tropism both within cells during virus assembly, and outside cells when they are expressed on plasma membranes and virion envelopes. VZV encodes glycoproteins designated gB, gC, gE, gH, gI, gK, gL, gM and gN. However, characterization of the functions of most of these proteins is limited. VZV is unique among the alphaherpesviruses in having no gD homologue. In transfected and VZV-infected cells, glycoproteins form gE/gI and gH/gL heterodimers and gE homodimers; noncovalent interactions between gB/gE and gH/gE have also been identified (Cole and Grose, 2003). Recycling of glycoproteins from the cell surface to the trans-Golgi network (TGN) is regulated to balance envelopment in the TGN, where infectious virions are formed, with the cell fusion that spreads VZV genomes to neighboring cells even when formation of intact virion particles is limited. The VZV glycoproteins, gB, gC, gE, gH, gI, gK, and gL have been shown to be or are likely to be structural components of the virus (Cohen and Straus, 2001; Mo *et al.*, 1999, 2002). In addition to studies of the glycoproteins using expression systems, deletions or targeted mutations of these genes that are not lethal have yielded recombinant VZV mutants for investigation of glycoprotein function in cultured cells and in SCIDhu T cell and skin xenografts in vivo. VZV gB, gE and gK have been demonstrated to be essential for VZV replication in cultured cells, based on failure to generate infectious virus from cosmids with deletions of these genes, and the rescue of infectivity when the deletion is complemented by insertion of the gene into a non-native site and in cell lines. In the SCIDhu model, interactions between VZV glycoproteins at internal sites of virion assembly and surface membranes determine the ability of VZV to replicate in differentiated human T-cells and skin. This summary focuses particularly on evaluations of the contributions of VZV glycoproteins to viral pathogenesis in T-cell and skin xenografts in vivo.

Glycoprotein C

VZV gC is the product of ORF14 (Davison and Scott, 1986). The role of gC in infectivity for human skin was assessed using gC negative mutants of vOka and VZV-Ellen (Moffat *et al.*, 1998). Whereas all of these VZV strains replicated well in tissue culture, only low passage clinical isolates were fully virulent in skin, as shown by infectious virus yields and analysis of xenografts for VZV DNA and viral protein synthesis. All strains except the gC-null Ellen strain retained some capacity to replicate in human skin, but cell-free virus was recovered only from xenografts infected with pOka or VZV-S. An HSV-1 mutant lacking gC expression was also deficient in skin infectivity. These SCID-hu mouse experiments show that gC, which is dispensable for replication in tissue culture, plays a critical role in the virulence of the human alphaherpesviruses, VZV and HSV-1, for human skin.

Glycoprotein E

Whereas the homologous protein in the other alphaherpesviruses is dispensable in cultured cells, VZV gE, encoded by ORF68, is essential for replication (Ku *et al.*, 2002). The functions of gE were analyzed further by creating point mutations or deleting the short 62 amino acid C-terminal domain (Moffat *et al.*, 2004a). These mutants were designed based on observations about functional motifs made using gE expression systems (Cole and Grose, 2003). Mutations were introduced in YAGL (aa582–585), which mediates gE endocytosis, AYRV (aa568–571), the motif that targets gE to the trans-Golgi network (TGN), and SSTT, which is an "acid cluster" comprising a phosphorylation motif (aa588–601). A substitution Y582G in YAGL prevented gE

endocytosis, and the Y569A mutation interfered with gE shuttling from the Golgi to the TGN in reports using transient expression methods. These changes were introduced into the viral genome using VZV cosmids and residues S593, S595, T596, and T598 were changed to alanines to alter phosphorylation. These experiments demonstrated a hierarchy in the contributions of gE C-terminal motifs to VZV replication in vitro and to virulence in the SCIDhu model. Deleting the gE C-terminus or mutating the YAGL motif were lethal for VZV replication in vitro. Mutations of AYRV and SSTT were compatible with recovery of VZV, but the AYRV mutation resulted in decreased plaque size and virus production in vitro. When the rOka-gE-AYRV and rOka-gE-SSTT mutants were evaluated in skin and T cell xenografts in SCIDhu mice, interference with TGN targeting was associated with substantial attenuation, especially in skin, whereas the SSTT mutation did not alter VZV infectivity in vivo. Thus, the gE C-terminus contains domains that are essential for VZV replication or are determinants of VZV virulence in differentiated dermal and epidermal cells and T-cells within intact tissue microenvironments in vivo. In addition to C-terminal functions, VZV gE has a unique N-terminal region from amino acids 1–188 (Berarducci *et al.*, 2006). Mutagenesis of this gE ectodomain region identified subdomains essential for replication, cell-cell spread and secondary envelopment and for VZV skin tropism.

Whereas VZV has been considered to be highly antigenically stable, VZV-MSP is a recently discovered wild type virus that has lost an immunodominant B-cell epitope in the gE ectodomain (Mo *et al.*, 2002). This gE "escape mutant" virus exhibited an unusual pattern of egress. When VZV-MSP was evaluated in SCIDhu skin xenografts, the spread of the VZV-MSP variant was accelerated significantly. The cytopathologic changes produced after 21 days by isolates that had the prototypical gE sequence were demonstrated at 14 days in skin xenografts infected with VZV-MSP. Thus, VZV-MSP is a naturally occurring variant with a gE mutation that is associated with a phenotype of enhanced cell–cell spread in vitro and in vivo.

Glycoprotein I

VZV mutants with deletions of gI, encoded by ORF67, can replicate in melanoma cells and fibroblasts, although not in Vero cells (Cohen and Nguyen, 1997; Mallory *et al.*, 1997). Since gI was dispensable in cell culture, gI deletion mutants were evaluated for their capacity to infect human cells in SCIDhu xenografts. Deleting gI was lethal for VZV replication in differentiated skin and T cells in vivo (Moffat *et al.*, 2002). Restoring gI into the mutated VZV genome was associated with the recovery of VZV virulence. Thus, gI is essential for VZV pathogenesis.

Analyses of the gI promoter in expression systems has demonstrated that it contains an activating upstream sequence (AUS) that binds cellular transcription factors Sp1 and USF (Specificity factor 1, Upstream Stimulatory Factor), and the viral transactivator ORF29 DNA binding protein which mediates enhancement of immediate early 62 (IE62)-induced transcription (He *et al.*, 2001). This information was used to design mutants from VZV cosmids in order to evaluate the contributions of these motifs to VZV replication in vitro and in vivo (Ito *et al.*, 2003). Recombinants rOkagI-Sp1 and rOkagI-USF, with two substitutions in Sp1 or USF sites, replicated like rOka in vitro, but infectivity of rOkagI-Sp1 was significantly impaired in skin and T cells in vivo. A double mutant, rOKAgI-Sp1/USF, did not replicate in skin, but yielded low titers of infectious virus in T-cells. The repair, rOkagI:rep-Sp1/USF, was as infectious as rOka. Thus, disrupting gI promoter sites for cellular transactivators altered VZV virulence in vivo, with variable consequences related to the cellular factor and the host cell type. Mutations in the ORF29 responsive element of the gI promoter were made by substituting each of four 10 base pair blocks in this region with a 10 base pair sequence, GATAACTACA, that was predicted to interfere with enhancer effects of the ORF29 protein. One of these mutants, designated rOKAgI-29RE-3, had diminished replication in skin and T-cells, indicating that ORF29 protein-mediated enhancement of gI expression contributes to VZV virulence. These experiments demonstrated that VZV pathogenesis is influenced by interactions of cellular transactivators with the gI promoter. Significantly, comparisons of the effects of the gI promoter mutants on growth in skin and T-cells indicated that cellular transactivators can have consequences for virulence that are cell-type specific. Mutations within promoters of viral genes that are non-essential in vitro should allow construction of recombinant herpesviruses that have altered virulence in specific host cells in vivo, and may be useful for designing herpesvirus gene therapy vectors and attenuated vaccines.

The role of regulatory proteins and viral kinases in T-cell and skin tropism

Although the difficulty of generating sufficient quantities of infectious cell-free virus has prevented experimental analysis, VZV replication is presumed to occur through a sequential expression of immediate early, early and late genes (Chapter 10). VZV regulatory proteins include viral

transactivating proteins and viral kinases, which may also be structural components of the virion tegument. While the task is far from complete, some of these genes have been analyzed for their contributions to VZV replication in cultured cells and in the SCIDhu model of VZV pathogenesis in vivo.

IE62 protein

The IE62 protein is the major VZV transactivating protein, required for expression of all viral genes tested to date (Kinchington *et al.*, 1992, 1994). It is encoded by the duplicated genes, ORF62 and ORF71. Experiments in which pOka cosmids were mutated to delete ORF62, ORF71, or the ORF62/71 gene pair demonstrated that at least one copy of ORF62 was required for VZV replication, as expected (Sato *et al.*, 2003a). Restoring a single copy of ORF62 into a non-native site in the U_S region of the VZV genome resulted in some, albeit reduced, VZV replication in vitro. VZV replication persisted despite introducing targeted mutations in IE62 binding sites that mediate interaction with the IE4 protein. Related experiments demonstrated that the ORF4 gene is essential in VZV (Sato *et al.*, 2003b). Interestingly, when a single copy of ORF62 or ORF71 was deleted, recombination events during cosmid transfection repaired the defective repeat region in some progeny viruses. Mixtures of single copy rOkaΔ62 or rOkaΔ71 and repaired rOka generated by recombination of the single copy deletion mutants was detected in some skin xenografts infected with these recombinants. The diminished replication of the pOka mutants with a single copy of ORF62 at the non-native site was associated with a complete block in VZV infection of skin xenografts in vivo. Although insertion of ORF62 into the non-native site permitted replication in cell culture, ORF62 expression from its native site was necessary for cell-cell spread in differentiated human skin tissues in vivo.

IE63 protein

The IE63 protein is encoded by ORF63 and is duplicated in the VZV genome as ORF70. IE63 protein is a nuclear phosphoprotein with some homology to HSV-1 ICP22. Sequence analysis indicates that IE63 is related to HSV-1 $U_S1.5$ protein, which is expressed colinearly with ICP22 (U_S1) (Baiker *et al.*, 2004). Removing one copy of the duplicated gene, either ORF63 or ORF70, was compatible with VZV replication in vitro (Sommer *et al.*, 2001). VZV was not recovered from transfections done with a dual deletion cosmid, but infectious virus was generated when ORF63 was cloned into the non-native site in the Us region. IE63 protein interacts directly with ORF62, the major immediate early transactivating protein of VZV. The importance of IE62 protein for VZV replication is suggested by the observation that ORF63/ORF70 could be removed and yield infectious virus in vitro if deleted cosmids were transfected along with a plasmid expressing IE62 (Cohen *et al.*, 2004).

The potential functional domains of IE63 protein were analyzed by creating 22 ORF63 mutations in expression plasmids and in the VZV genome. The effects of IE63 phosphorylation and nuclear localization, and IE63 binding to IE62, were evaluated by transient transfection and by replication of the mutant viruses. Briefly, IE63 aa55–67 constituted the IE62 binding site, with R59/L60 being critical residues; S165, S173 and S185 in the IE63 center region were phosphorylated by cellular kinases; and mutations in two putative nuclear localization signal (NLS) sequences changed intracellular IE63 distribution from a nuclear to a cytoplasmic/nuclear pattern. Infectious VZV was recovered with three of the 22 mutations in ORF63. Each of these three IE63 mutants had a single alanine substitution (T171A, S181A or S185A). The IE63 mutants, rOka/ORF63rev[T171], rOka/ORF63rev[S181] and rOka/ORF63rev[S185], replicated less efficiently, had a small plaque phenotype in vitro and had less production of gE and ORF47, indicating that IE63 was involved in expression of these early and late gene products. Virulence of the three IE63 mutants was reduced markedly in skin xenografts, but infection of T-cell xenografts was not affected. The fact that these IE63 mutants were attenuated in skin but not T-cells, suggests that the contribution of the IE63 tegument/regulatory protein to VZV pathogenesis differs depending on the human cell types and tissues that are targeted for infection.

ORF64 protein

ORF64 is duplicated as ORF69 and it has some sequence homology to the HSV-1 Us10 gene, which exists as a single copy. When ORF64 and ORF69 were deleted, either separately or together, one copy at either location in the genome was sufficient to yield infectious virus with growth kinetics and plaque morphology indistinguishable from the parent virus (Sommer *et al.*, 2001). Removing both ORF64 and ORF69 caused an abnormal plaque phenotype made up of very large multinucleated syncytia. Single and dual ORF64/ORF69 mutants were as infectious as the parent and repaired viruses when evaluated in human T-cells in vitro and in human skin xenografts in the SCIDhu mouse model of VZV pathogenesis.

ORF10 Protein

ORF10 encodes a tegument protein that enhances transactivation of VZV genes. Analysis of pOkaΔ10 and ORF10 point mutants with disruption of the acidic activation domain and the putative motif for binding human cellular factor-1 (HCF-1) showed no effects on replication, IE gene transcription or virion assembly in vitro (Che *et al.*, 2006). However, epidermal cells in SCIDhu skin xenografts infected with pOkaΔ10 had significantly fewer DNA-containing nucleocapsids and complete virions; extensive aggregates of intracytoplasmic viral particles were also observed. Altering the activation or the putative HCF-1 domains of ORF10 protein had no consequences for VZV skin infection. Deleting ORF10 did not impair VZV T-cell tropism in vivo. Thus, ORF10 protein is necessary for efficient VZ virion assembly and is a VZV virulence determinant in epidermal and dermal cells in vivo.

ORF47 protein

ORF47 encodes a serine/threonine protein kinase that is in a class of conserved herpesvirus proteins that are homologous to HSV-1 U_L13. ORF47 protein also has similarities to the casein kinase II family of cellular proteins (Cole and Grose, 2003). ORF47 appears to be a component of the virion tegument. VZV mutants that did not express ORF47 protein were made by inserting stop codons into the gene, producing ROka47S, which was shown to replicate as well as intact ROka in an infectious focus assay (Heineman *et al.*, 1996). However, these findings were not predictive of the consequences of blocking ORF47 protein synthesis in vivo, since ORF47 protein was essential for VZV infection of human T cells and skin (Moffat *et al.*, 1998). Restoring ORF47 into the genome of the ROKA47S mutant reconstituted the T cell and skin tropism of the virus. Thus, ORF47 protein functions are necessary in differentiated cells that are involved in VZV pathogenesis in vivo.

In order to further investigate the role of the ORF47 protein, VZV mutants were made that expressed a truncated ORF47 protein, by deleting the C-terminus, and that had mutations that disrupted conserved putative kinase motifs in ORF47 protein (Besser *et al.*, 2003). The mutants were tested for replication, phosphorylation and protein-protein interactions in vitro and allowed an assessment of the effects of specifically eliminating the kinase activity of ORF47 protein on VZV replication in vivo. The ORF47 C-terminal truncation mutants (rOka47ΔC) and those that disrupted the DYS kinase motif (rOka47D-N) had no ORF47 kinase activity. However, binding to IE62 protein was mapped to the N-terminal domain and was preserved. Cells infected with these ORF47 kinase defective mutants exhibited marked nuclear retention of ORF47 and IE62 proteins in vitro. Even though virus titers were not altered based on an infectious focus assay, the electron microscopy analysis of cultured cells infected with the kinase defective mutants showed severely impaired virion assembly and transport of virions to cell surfaces. Normal VZV virion assembly appears to require ORF47 kinase function. Nevertheless, rOka47ΔC or rOka47D-N-infected cells showed VZV-induced cell fusion and syncytia formation.

With regard to pathogenesis, ORF47 protein mutations that eliminated the ORF47 kinase function caused substantial reductions in the capacity to replicate and produce cutaneous lesions in skin xenografts in the SCIDhu model. However, in contrast to the complete ORF47 null mutant, rOKA47S, some replication occurred in skin in vivo if the capacity of ORF47 protein to bind IE62 protein was intact, as shown in experiments with rOka47ΔC and rOka47D-N. ORF47 kinase activity was important for VZV infection and cell-cell spread in human skin in vivo, but preserving the capacity of ORF47 protein to form complexes with IE62 protein, both of which are VZV tegument components, appeared to be the *sine qua non* for VZV infection of skin in vivo. In contrast to the skin experiments, when the kinase defective rOka47ΔC and rOka47D-N mutants were evaluated in T-cell xenografts, no infectious virus was made in vivo (Besser *et al.*, 2004). These observations were similar to the data obtained in T-cell xenografts infected with ROka47S, when no ORF47 protein was made. The comparison of the growth of kinase-defective ORF47 mutants in skin vs. T-cells suggested the hypothesis that fundamental requirements for VZV pathogenesis in skin and T-cells differ in vivo. Even though virion assembly was much diminished and intracellular trafficking of ORF47 and IE62 proteins, both components of the tegument, and of gE, was aberrant in skin in the absence of ORF47 kinase activity, VZV polykaryocytes were generated by rOka47ΔC and rOka47D-N. Thus, some cell fusion was induced by ORF47 mutants in skin and cell–cell spread occurred even though virion formation was deficient. In contrast, impaired virion assembly by ORF47 mutants was associated with a complete elimination of the capacity to infect T-cells in vivo. Since VZV-infected T-cells do not undergo cell fusion even when most cells in the T cell xenograft have been infected, transfer of incomplete virions by cell–cell fusion does not occur. Instead, virus appears to be released from T-cells for entry into uninfected T-cells in other regions of the xenograft. Considered together, these observations make it plausible to suggest that formation of complete virions

and their release is essential for VZV T-cell tropism, creating a differential requirement for virion assembly during the pathogenesis of VZV infection of T-cells and skin.

ORF66 protein

ORF66 encodes a second serine/threonine protein kinase homologous to HSV U_S 3. Like the ORF47 protein kinase, ORF66 protein was shown to be dispensable for VZV replication in cultured cells by creating ROka66S stop codon mutants. Again, ROka66 mutants replicated as well as intact ROka in cultured cells. Eliminating ORF66 expression did not impair replication in SCIDhu skin xenografts, as compared to the vaccine-derived ROka parent (Moffat *et al.*, 1998). In contrast, ORF66 defective VZV mutants had a significant decrease in their capacity to replicate in T-cell xenografts in vivo. Thus, ORF66 protein appears to be a viral kinase that is necessary to VZV T-cell tropism. When ORF66 expression was blocked in pOka, growth and VZ virion formation was reduced in T-cells in vivo, infected T-cells were more susceptible to apoptosis and pOka66S mutants had less capacity to interfere with induction of the interferon (IFN) signaling pathway (Schaap *et al.*, 2005). Thus, ORF66 kinase appears to have a unique role during T-cell infection and supports VZV T cell tropism by contributing to immune evasion and enhancing survival of infected T-cells.

Disease consequences of primary VZV infection in healthy and immunocompromised hosts

The clinical pattern of primary VZV infection is highly predictable, beginning with an incubation period of 10–21 days following a close exposure of a susceptible individual to another person with varicella or in some cases, herpes zoster (Arvin, 2001b). In contrast to other herpesviruses, primary VZV infection almost always causes symptoms although the diagnosis is missed when the child has only a few lesions and no identified exposure. Varicella often begins with a prodrome of fever, malaise, headache and abdominal pain. These initial symptoms last about 24–48 hours before skin vesicles are noted and are more common in older children and adults. The occurrence of a cell-associated VZV viremia has been well documented during the last few days of the incubation period and for a few days after the cutaneous rash appears, when specimens are tested by tissue culture or for VZV DNA (Asano *et al.*, 1990; Gershon *et al.*, 1978; Koropchak *et al.*, 1989, 1991; Ozaki *et al.*, 1986). Viral cultures of PBMC demonstrate that infectious virus can be recovered from PBMC; VZV was isolated from 11%–24% of PBMC samples taken from healthy individuals with varicella less than 24 h after the rash had appeared. DNA methods are more sensitive, with VZV being detected in 67%–74% of samples tested by in situ hybridization or PCR. Although viral cultures do not yield infectious virus, PCR methods indicate that VZV is present in oropharyngeal specimens just before and after the appearance of skin lesions. The estimated frequency of VZV infection of PBMC from healthy individuals with varicella was approximately 0.01%–0.001%, as detected by in situ hybridization (Koropchak *et al.*, 1989). According to our proposed model of the pathogenesis of primary VZV, this viremic phase may represent the infection of T cells migrating through infected skin sites and re-entering the circulation (Fig. 37.1). This early phase of the illness is usually associated with systemic symptoms, including fever and fatigue, presumably related to cytokine responses; varicella-related fever is usually mild (less than 101.5 °F). The cell-associated VZV viremia is transient, usually resolving within 24–72 hours after the onset of the rash in healthy children and adults. Primary VZV infection is often accompanied by a reduction in the numbers of circulating lymphocytes but this finding is probably secondary, rather than being due to cell destruction by the virus. Mild upper respiratory symptoms and diarrhea may occur but severe respiratory or gastrointestinal illness is rare.

The lesions caused by VZV replication in the skin appear first as small erythematous papules, each of which then evolves within about 12–24 hours to surface vesicles that are filled with clear fluid and surrounded by erythema – the so-called "dew drop on a rose petal." The first skin lesions in patients with varicella often appear on the face and scalp, or on the chest or back and are pruritic. Formation of multinucleated epithelial cells with intranuclear eosinophilic inclusions and vasculitis involving small blood vessels occurs during the early maculopapular stage. VZV virions are detected in keratinocytes and also in capillary endothelial cells by electron microscopy. VZV is delivered to mucous membrane sites as well as to skin, where it produces ulcers in the oropharynx, conjunctivae and vagina. Vesicles result from a progressive ballooning degeneration of epithelial cells and coalescence of fluid-filled vacuoles between cells. The numbers of VZV-infected cells at the base of the lesion increases during this phase and cell-free virus is released into vesicular fluid. Each lesion begins to become cloudy and crusted within about 48 hours and infectious virus is usually no longer detected after about 72–96 hours. Healing reflects the replacement of epithelial cells at the base of the lesion by cellular proliferation. New skin and mucous membrane lesions continue to develop for a period of 3–5 days in most children, with

a range of 1–7 days. Over the 1–7 day course of primary VZV infection, as few as 10 to more than 1500 lesions may appear; on average, healthy children have about 100–300 lesions. Older children and adults, those who are secondary household cases and patients with skin trauma, such as sunburn or eczema are more likely to have more cutaneous and mucous membrane lesions. The crops of lesions that appear later in the clinical course of varicella are usually on the arms and legs. Vesicle formation may be abortive, with little or no infectious virus being detected, presumably due to the induction of antigen-specific T cells by this point in the infection (Chapter 39). VZV lesions are usually superficial and do not leave scars except at the sites of the earliest skin replication; residual scars can often be seen along the hairline or eyebrows.

Secondary bacterial infection of skin lesions is the most common complication of primary VZV infection in healthy children. These infections are most often due to *Staphylococcus aureus* or *Streptococcus pyogenes* (group A beta-hemolytic streptococcus) (Dunkle *et al.*, 1991; Jackson *et al.*, 1992). Skin and mucosal damage may provide a portal of entry for these organisms such that bacteremia occurs and the organisms reach deep tissue sites. Thus, varicella may be associated with staphylococcal or streptococcal pneumonia, arthritis or osteomyelitis. Varicella lesions often involve the eyelids and ocular conjunctivae but serious eye complications are rare; unilateral anterior uveitis or corneal lesions may develop but long-term damage is unusual (Liesegang, 1991).

VZV has the capacity to infect the epithelial cells that line the pulmonary alveoli, and to induce edema and an extensive infiltration of mononuclear cells into the alveolar septae. The result of this process can be a severe viral pneumonia. Active VZV replication in the lungs is very unusual in healthy children with varicella. However, the increased morbidity and mortality caused by primary VZV infection in adults is accounted for by their much greater susceptibility to varicella pneumonia (Krugman *et al.*, 1957). Interstitial inflammation and the desquamation of alveolar lining cells into the alveoli has the potential to block the effective transfer of oxygen from the alveolar spaces into the pulmonary capillaries. The consequence is severe hypoxemia and respiratory failure. Most patients with varicella pneumonia develop cough and dyspnea several days after the onset of the cutaneous rash, which suggests that the virus reaches pulmonary epithelial sites during the later viremic phase. Physical abnormalities associated with varicella pneumonia may be difficult to detect because early signs are often limited to fever and tachypnea. The chest radiograph usually shows interstitial pneumonitis with diffuse bilateral infiltrates and perihilar nodular densities but may appear relatively benign even when patients have severe hypoxia. Severe varicella pneumonia may be fatal even with antiviral therapy (Chapter 65) and assisted ventilation.

Healthy children with varicella often have mild, sub clinical hepatitis, detected by minor abnormalities of liver function tests. These abnormalities may reflect an inflammatory response or some limited viral replication in the liver during primary VZV infection. Liver involvement is usually asymptomatic but children with the highest elevation of liver function tests may have severe vomiting. Extensive VZV infection of hepatocytes, with widespread hepatocellular destruction due to virus-induced cell lysis is a rare occurrence but is associated with fulminant hepatic failure.

In addition to its neurotropism for cells in the sensory ganglia, VZV can cause encephalitis and cerebellar ataxia. Meningoencephalitis and cerebellar ataxia are the major clinical signs of VZV-related damage to the central nervous system; some patients have signs of both cerebral and cerebellar disease (Johnson and Milbourn, 1970; Peters *et al.*, 1978). VZV was the cause of encephalitis in 13% of cases of defined etiology in CDC surveillance studies from 1972 and 1977. Although these syndromes are the most common neurologic complications of varicella, information about the pathogenesis of these disorders is limited because most children recover. How primary VZV infection might produce cerebellar ataxia is of interest because VZV is the most common cause of this syndrome in healthy children. VZV has been recovered from the brain tissue of immunocompromised children with fatal varicella encephalitis, suggesting that this syndrome might be caused by direct infection. However, it is speculated that these neurologic manifestations of primary VZV infection may be immune-mediated, for the most part. The symptoms are typically transient but neurologic complications are the second most frequent indication for hospitalization of otherwise healthy children with varicella. The onset of neurologic complications follows the appearance of the rash by several days but a few case reports describe encephalitis and ataxia beginning before skin lesions have appeared. The symptoms of encephalitis are sudden changes in the level of consciousness and generalized seizures; the signs may be meningeal, e.g., nucal rigidity, rather than encephalitic in some cases. The cerebellar syndrome is characterized by a gradual onset of irritability, ataxia, nystagmus and speech disturbances. The cerebrospinal fluid usually shows a mild mononuclear cell inflammatory pattern, with a predominance of lymphocytes, a somewhat elevated protein (<200 mg) and normal glucose, or in some cases, the cerebrospinal fluid may be normal (Gershon *et al.*, 1980).

Children under 5 and adults appear to be the most susceptible to central nervous system complications. Not surprisingly, the highest risk of fatal complications appears to be associated with encephalitis rather than cerebellar ataxia. Varicella encephalitis usually resolves within 24–72 hours, even without antiviral therapy. Information about the risk of long-term sequelae after varicella encephalitis is limited; whereas most recover fully, some patients have recurrent seizures and permanent neurologic deficits (Johnson and Milbourn, 1970). The signs of cerebellar ataxia can persist for days or weeks. Among the rare neurologic complications of varicella are transverse myelitis, optic neuritis and very rarely, Guillain-Barre syndrome.

Primary VZV infection can be associated with thrombocytopenia and coagulopathy, although these manifestations are unusual in healthy individuals. The signs of these complications include hemorrhage into the skin vesicles, petechiae, purpura, epistaxis, hematuria and gastrointestinal bleeding. The mechanisms by which thrombocytopenia may be induced include reduced production of platelets and decreased platelet survival; vasculitis, transient hypersplenism or intravascular coagulopathy may be involved. As described for varicella pneumonia, adults are at higher risk for acute hemorrhagic complications of varicella than children. Purpura fulminans, due to arterial thrombosis, is a very rare but life-threatening complication of varicella. Immune-mediated thrombocytopenia may also occur, with symptoms developing from 1 to 2 weeks or longer after varicella. Whether acute or later in their onset, bleeding complications may last for several weeks, but the thrombocytopenia usually resolves completely. Inflammatory damage to the kidneys, presenting as nephritis, is an unusual, late complication in children and adults with varicella; it is possible that this syndrome is due to secondary group A streptococcal infection. A few cases of nephritic syndrome and hemolytic uremic syndrome have been described in children with primary VZV infection. Viral arthritis, diagnosed by the isolation of VZV from joint fluid, is unusual and resolves spontaneously within 3–5 days and has not been associated with residual damage. Myocarditis, pericarditis, pancreatitis and orchitis are other very rare complications of primary VZV infection. The risks of varicella in healthy children and adults have been reduced substantially by the introduction of live attenuated varicella vaccines (Chapter 70).

Varicella in the immunocompromised host

Primary VZV infection was often a life-threatening illness in immunocompromised children before the introduction of acyclovir (Chapter 65) and can be attributed to the delayed or failed induction of VZV-specific cellular immunity (Chapter 39). Most information about the clinical course of varicella in high-risk patients is based on observations in children with leukemia and other childhood malignancies. These children often have prolonged fever and a much more extensive rash and continued formation of new lesions. Serious complications result from unchecked viral dissemination by cell-associated viremia to the lungs, liver and in some cases to the central nervous system. Immunocompromised children develop varicella pneumonia, hepatitis, coagulopathy and meningoencephalitis (Feldman and Lott, 1987; Myers, 1979). Whereas new varicella lesions are unusual after 3–5 days in most healthy children, new lesions may appear for >7 days and resolution of the lesions may take 14 days. Susceptibility to secondary bacterial infections is typically enhanced in children receiving chemotherapy or radiation because of the granulocytopenia induced by treatment of the malignancy. As is the case in healthy adults, most varicella-related deaths result from pneumonia that develops shortly after the appearance of the rash. Before antiviral drugs were available, varicella pneumonia progressed rapidly with most deaths occurring within a few days due to untreatable hypoxemia. Varicella pneumonia is often associated with hepatitis, which can progress to liver failure. Again, as is true in healthy adults, hemorrhage into varicella lesions is a clinical sign of life-threatening coagulopathy, due to thrombocytopenia and altered production of clotting factors. VZV dissemination can also cause meningoencephalitis. Severe abdominal or back pain is a clinical sign of serious primary VZV infection in high-risk patients but the etiology of the symptoms is unknown; it is possible that it is related to early infection of sensory ganglia by hematogenous spread of the virus. Other complications of disseminated varicella in children with malignancy include myocarditis, nephritis, pancreatitis, necrotizing splenitis, esophagitis, and enterocolitis.

Children who receive kidney, liver or other solid organ transplants may also develop progressive varicella as a result of the immunosuppressive drugs given to prevent rejection of the transplanted organ (Feldhoff *et al.*, 1981). Varicella pneumonia appears to be a less frequent complication than hepatitis and coagulopathy in kidney transplant patients. Steroid therapy for chronic diseases, including rheumatoid arthritis, nephrotic syndrome and ulcerative colitis, may lead to severe varicella. Asthma patients given high doses of prednisone, especially during the incubation period, are also at risk, but chronic low-dose steroid therapy does not usually result in varicella complications. The immunologic deficits caused by human immunodeficiency virus (HIV) infection are

associated with prolonged, recurrent varicella and with chronic, hyperkaratotic skin lesions but varicella pneumonia, hepatitis and other manifestations of dissemination are unusual compared to children with malignancies or organ transplants (Jura *et al.*, 1989; Kelley *et al.*, 1994). Any of the rare genetic disorders that interfere with the acquisition of antigen-specific T cell immunity results in very high risk of fatal varicella. These diseases include severe combined immunodeficiency disorder, adenosine deaminase deficiency, nucleoside phosphorylase deficiency and cartilage hair hypoplasia/short-limbed dwarfism; serious varicella also occurs in some children with Wiskott–Aldrich syndrome and ataxia telangiectasia.

Varicella in pregnancy and the newborn

Most adults are immune, but susceptible pregnant women appear to be predisposed to severe varicella at rates higher than the enhanced risk associated with primary VZV infection in all healthy adults. Varicella pneumonia is the predominant complication and appears to be more common with varicella acquired in late gestation (Pastuszak *et al.*, 1994). From the limited information available, the risk of fatal varicella, due to pneumonia, appears to be ~1%–2% (Enders *et al.*, 1994). When primary VZV infection occurs in early pregnancy, the virus can be transferred across the placenta to the developing fetus. The frequency of viral transfer is higher than the risk of fetal damage, as shown by postnatal testing of infants for VZV-specific immunity and the occurrence of zoster in early childhood among infants with no symptoms of intrauterine VZV infection (Dworsky *et al.*, 1980). The estimated incidence of varicella embryopathy is <1%, with most damage due to maternal infection acquired in the first 20 weeks of gestation. The congenital varicella syndrome is most often recognized by unusual cutaneous defects and atrophy of an extremity. Infants often have microcephaly, cortical atrophy and intracranial calcifications secondary to intrauterine VZV encephalitis, with seizures and mental retardation. Damage to the autonomic nervous system is common and produces severe gastroesophogeal reflux and neurogenic bladder, hydroureter and hydronephrosis. Eye damage, manifesting as chorioretinitis, microophthalmia, and cataracts, is typical. Although intrauterine damage is not observed, infants whose mothers develop primary VZV infection just before delivery often develop varicella during the newborn period (Preblud *et al.*, 1985). The risk of transfer of virus to the infant is highest when maternal infection begins 4 days before to 2 days after delivery, suggesting that the virus crosses the placenta during the viremia associated with lesion formation. Because of the early stage of the maternal infection, viral transfer is not associated with transplacental transport of maternal VZV IgG antibodies. Neonatal varicella can be progressive, presumably due to deficiencies in the capacity of the infant to develop VZV-specific T cell responses. Dissemination causes pneumonia and hepatitis, with a risk of meningoencephalitis. These infants require antiviral therapy to prevent such complications. Infants exposed to late gestation maternal varicella can be protected to some extent by administration of passive antibodies, given as varicella immune globulin. Some infants whose mothers have varicella more than 4–5 days before delivery are born with varicella lesions or develop lesions within a few days after birth; these infants appear to be at low risk for complications. Herpes zoster in pregnant women has not been associated with varicella embryopathy.

Summary

The principal host cell targets during the life cycle of VZV include the respiratory mucosal epithelium as a portal of entry, immune system cells, especially T-cells, for delivery of the virus to skin sites of replication, and sensory ganglia, where latency is established. VZV transmission to susceptible hosts is ensured by the release of cell-free virus into mucocutaneous lesions during varicella or herpes zoster. Like HSV-1 and HSV-2, VZV is an alphaherpesvirus that has achieved an equilibrium with the human host that has ensured its persistence in the species for millions of years.

VZV: molecular basis of persistence (latency and reactivation)

Jeffrey I. Cohen

Laboratory of Clinical Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

Primary infection with varicella-zoster virus (VZV) causes varicella manifested by fever and a vesicular rash. During primary infection the virus disseminates in lymphocytes to the skin and other organs, and replicates in and establishes a latent infection in the nervous system (Croen *et al.*, 1988). Early studies demonstrated viral DNA in human trigeminal and dorsal root ganglia by in situ hybridization and Southern blotting (Gilden *et al.*, 1983, 1987; Hyman *et al.*, 1983). More recent studies, using PCR, have demonstrated latent VZV in multiple cranial nerve, dorsal root, and autonomic ganglia (Furuta *et al.*, 1992, 1997; Gilden *et al.*, 2001; Mahalingham *et al.*, 1990). The virus can reactivate from these sites to cause herpes zoster.

The structure of the VZV genome during latency is not certain. Clarke *et al.* (1995) performed PCR on human ganglia DNA using pairs of primers specific for the unique long internal and terminal regions of the genome. Analysis of the ratio of the signals of the PCR products indicated that the termini of the genome are adjacent during latency, suggesting that the VZV genome is probably episomal.

Site of VZV latency

A number of studies have attempted to identify the cell type in which VZV is latent in human ganglia (Table 38.1). While early studies using in situ hybridization suggested that the virus was present in neurons (Hyman *et al.*, 1983; Gilden *et al.*, 1987), other studies suggested that viral RNA was latent exclusively in satellite cells that surround the neurons (Croen *et al.*, 1988). Lungu and colleagues (1995) found VZV nucleic acid in both satellite cells and neurons.

Further studies by Dueland *et al.* (1995) and Kennedy *et al.* (1998, 1999) using in situ PCR showed that VZV is latent predominantly in neurons. LaGuardia *et al.* (1999) isolated human trigeminal ganglia, fixed the tissue, minced it, treated it with collagenase, and filtered the cells through various pore sizes of nylon mesh to separate neurons from non-noneuronal cells. PCR analysis of the neurons and non-neuronal cells showed that VZV DNA was present only in neurons. Levin and colleagues (2003) purified neurons and satellite cells and found VZV in 1.5% of neurons and in none of over 20 000 satellite cells tested. Additional studies using antibodies to VZV proteins expressed during latency detected viral proteins in neurons, but not in satellite cells (Mahalingam *et al.*, 1996; Lungu *et al.*, 1998). Wang *et al.* (2005) performed laser capture microdissection isolating single neurons or non-neuronal cells from human trigeminal ganglia. VZV DNA was present in neurons, but rarely if ever in non-neuronal cells. Theil *et al.* (2003) used double fluorescence in situ hybridization to detect VZV neurons from human trigeminal ganglia; rare satellite cells were positive for VZV. A few neurons were infected with both VZV and HSV.

In summary, while a number of studies have detected VZV RNA in both neurons and satellite cells, most recent studies indicate that neurons are the principal site of latency.

Quantification of VZV DNA load during latency

Initial studies to quantify the latent viral load used competitive PCR in which an internal mutant template is added to the unknown sample in the PCR mixture to determine the copy number of VZV genomes in human ganglia (Mahalingam *et al.*, 1993). Using this method Mahalingam and colleagues estimated that there were 9 to 53 copies of VZV DNA per ug of ganglion DNA which corresponds to 6 to 31 copies of VZV DNA per 10^5 ganglionic cells (Table 38.2). This number is considerably lower than the 1 000 to 10 000

Table 38.1. Site of VZV latency in human ganglia

Site	% neurons with VZV	%non-neuronal cells with VZV	Technique	Reference
Neuron	0.1–0.3	0	ISH	Hyman *et al.*, 1983
Neuron	"most"	0	ISH	Gilden *et al.*, 1987
Satellite	0	0.01–0.15	ISH	Croen *et al.*, 1988
Neuron = Satellite	5–30%	5–30%	ISH	Lungu *et al.*, 1995

38–179			cPCR	Levin *et al.*, 2003
283	711	0.4	LCM	Wang *et al.*, 2005

cPCR = quantitative DNA PCR; rPCR = real time PCR; LCM = laser capture microdissection.

copies of HSV DNA per 10^5 ganglionic cells (Efstathiou *et al.*, 1986).

LaGuardia and colleagues (1999) performed PCR on sets of 100 neurons obtained from human trigeminal ganglia; of PCR-positive sets of neurons, there were two to five copies of VZV DNA per 100 neurons. Assuming that there are 100 cells per neuron in human ganglia (Mahalingam *et al.*, 1993), these results correspond to 20–50 copies of VZV DNA per 10^5 ganglionic cells. Levin *et al.* (2003) performed PCR on purified neurons and detected an average of 4.7 copies of VZV per latently infected neuron. Since they found that 0.8%–3.8% of neurons were latently infected, this corresponds to 3.8–17.9 copies per 100 neurons or 38–179 copies per 10^5 ganglionic cells.

Pevenstein *et al.* (1999) used real time PCR to determine the number of copies of VZV and HSV-1 DNA in human trigeminal ganglia. They estimated that the copy number of VZV DNA was 177 to 299 per 10^5 ganglion cells, while the copy number of HSV-1 DNA was 2902 per 10^5 ganglia cells. This suggests that there is about tenfold more HSV-1 DNA than VZV DNA in latently infected ganglia.

Cohrs *et al.* (2000) also used real time PCR to estimate copy numbers in human trigeminal ganglia. The mean VZV DNA copy number was 580 copies per 100 ng of ganglia DNA (corresponding to 9,046 copies per 10^5 cells) and the mean HSV-1 DNA copy number was 195 per 100 ng of DNA (corresponding to 3,042 copies per 10^5 cells). This suggests that there is about a 3-fold lower amount of HSV-1 than VZV DNA in latently infected human ganglia.

Wang *et al.* (2005), using laser capture microdissection to measure VZV DNA in trigeminal ganglia from 10 subjects, found a median of 6.9 copies of VZV per positive neuron. Since 4.1% of neurons were VZV positive, and there are about 100 cells per neuron in human ganglia, this corresponds to a median of 283 VZV DNA copies per 10^5 ganglionic cells. The same authors measured HSV DNA in ganglia from 6 subjects and found a median of 11.3 copies of HSV per positive neuron and 6.3% of neurons were positive of HSV. This corresponds to a median of 711 HSV copies per 10^5 cells.

The difference between the three studies (Cohrs *et al.*, 2000; Pevenstein *et al.*, 1999; Wang *et al.*, 2005) may be due to the difference in age of the subjects; those in the study by Cohrs *et al.* were older and may have had more episodes of asymptomatic reactivation with increased seeding of ganglia with VZV DNA. Alternatively, the differences may be due to the relatively small number of subjects tested (<20) in each study and the wide range in the amount of VZV DNA detected in ganglia from different subjects.

Animal models for VZV latency

Inoculation of several rodent species with VZV results in a latent infection of the nervous system. VZV was detected in trigeminal and thoracic ganglia from hairless guinea pigs by PCR after inoculation with a guinea pig adapted strain of virus (Lowry *et al.*, 1993). VZV DNA was present in mouse trigeminal ganglia 1 month after corneal inoculation with the virus (Wroblewska *et al.*, 1993). Inoculation of adult rats with VZV in the footpad or by paraspinal intramuscular injection results in latent virus infection in the dorsal root ganglia (Debrus *et al.*, 1995; Sadzot-Delvaux *et al.*, 1990; Annunziato *et al.*, 1998). Using this system, Sadzot-Delvaux

and colleagues (1995) found that viral DNA was present as early as 2 days after infection and up to 9 months later. In most animals, only the ganglia innervating the inoculation site were latently infected, indicating that ganglia were infected by retrograde transport of virus up the axon, rather than by viremia. Up to 80% of neurons were infected; some non-neuronal cells were also infected. The pattern of latent viral transcription and protein expression was similar in rats to that seen in humans. Kennedy and colleagues (2001) were able to detect latent transcripts in rat ganglia up to 18 months after inoculation. Sato *et al.* (2002b) inoculated cotton rats with VZV and obtained latent infection, based on DNA and RNA transcripts, in dorsal root ganglia of 50% to 70% of animals. Inoculation of animals with heat-inactivated virus-infected cells failed to result in latency. VZV was not detected in the lungs and usually not in the brain of animals (Sato *et al.*, 2003b). Brunell and colleagues (1999) inoculated neonatal rats with an early passage isolate of VZV intraperitoneally, and detected a latent viral transcript in trigeminal ganglia.

Baiker *et al.* (2004) transplanted fetal human brain stem cells into NOD-SCID mice and then inoculated the animals with VZV-infected melanoma cells. VZV infected both neural and glial cells. While latency-associated proteins (ORF62, ORF63, ORF47 proteins) were detected and a late protein not associated with latency (gE) was rarely detected in the animals, the localization of the latency-associated proteins was either in the nucleus or in the nucleus and the cytoplasm, unlike that seen in latently infected human neurons (see below). Zerboni *et al.* (2005) implanted human fetal dorsal root ganglia under the capsule of the kidney of SCID mice and then either injected the implants with VZV-infected fibroblasts or injected the animals intravenously with VZV-infected tonsil T cells. Direct injection of the ganglia resulted in a lytic infection followed by latency with expression of the ORF63 latency gene, but not the ORF62 latency gene or gB 8 weeks after infection. Intravenous injection of T cells resulted in a lytic infection in the ganglia 2 weeks after injection.

Simian varicella virus (SVV) is the simian counterpart of VZV, and the two viruses share nearly all the same open reading frames (Gray *et al.*, 2001; Gray, 2004). Intratracheal inoculation of SVV into African green monkeys results in infection of the trigeminal and dorsal root ganglia (Mahalingam *et al.*, 1991); however, other sites including peripheral blood mononuclear cells and lungs show persistent infection (White *et al.*, 2002). Naturally acquired SVV infection, transmitted from one African green monkey to another, results in a mild rash followed by latent infection of multiple ganglia, but not infection of other tissues (Mahalingam *et al.*, 2002). SVV DNA is present only in neurons of latently infected monkeys (Kennedy *et al.*, 2004) At least one VZV gene shown to be expressed during latency, ORF21, is expressed in ganglia from monkeys infected with SVV (Clarke *et al.*, 1996). The SVV model is the only animal model for VZV that recapitulates the features of varicella, latency, and reactivation.

VZV transcripts expressed during latency

A number of laboratories have detected transcripts corresponding to various VZV genes in human ganglia and from experimentally infected rodents (Table 38.3). Meier *et al.* (1993) detected transcripts for VZV ORF 29 and ORF62, but

not ORF28 by Northern blot analysis of RNA extracted from pooled human trigeminal ganglia.

Cohrs *et al.* (1996) detected VZV ORFs 21, 29, 62, and 63 from cDNA obtained by isolating RNA from pooled human trigeminal ganglia. They were unable to detect transcripts for ORFs 4, 10, 40, 51, and 61 in the library. ORF66 was also detected in latently infected human ganglia (Cohrs *et al.*, 2003).

Kennedy *et al.* (1999, 2000) used in situ hybridization and detected VZV transcripts for ORFs 21, 29, 62, and 63 during latency. ORF21 transcripts were detected in 64% of ganglia from HIV-negative subjects and in 60% from those with HIV; ORF29 transcripts were found in 38% of ganglia from HIV-negative persons and in 100% from those with HIV; ORF62 transcripts were noted in 40% of ganglia from HIV-negative subjects and in 67% from those with HIV; ORF63 transcripts were detected in 47% of transcripts from HIV-negative persons and in 80% from those with HIV. Transcripts for VZV ORFs 4 and 18 were infrequently expressed, while those for VZV ORFs 28, 40, and 61 were rarely expressed.

Cohrs *et al.* (2000) used real time PCR to detect transcripts for VZV ORF 63 from 86% of human trigeminal ganglia assayed. Transcripts for ORFs 21 and 29 were detected less frequently in 23% and 13% of ganglia, respectively. While the copy numbers for ORF63 transcripts varied over a wide range, they were consistently lower than the copy numbers for HSV-1 LAT transcripts from the same ganglia (Table 38.4).

Several studies have looked at rodents (adult rats, neonatal rats, and adult cotton rats) latently infected with VZV (Table 38.3). Transcripts for ORFs 4, 21, 29, 62 and 63 have been detected in these animals (Kennedy *et al.*, 2001; Sadzot-Delvaux *et al.*, 1990; Brunell *et al.*, 1999; Sato *et al.*, 2002b). Transcripts for ORFs 4, 28, 36, 40, and 68 were not detected. VZV gene expression during latency may be regulated by epigenetic mechanisms. Gary *et al.* (2006) showed that the VZV ORF62 and 63 promoters are associated with a histone protein (acetylated H3K9) and thereby maintained in a euchromatic state during latency and thus can be transcribed. In contrast, the ORF14 and 36 promoters whose genes are not expressed during latency are not associated with the histone protein and instead are maintained in a heterochromatic state.

In summary, a number of studies from several different laboratories have detected 6 different viral transcripts during latency in humans and in rodents. These are predicted to encode immediate-early and early proteins. In contrast, other putative early (ORFs 28, 36, 51) and late (ORFs 10, 40, 68) transcripts have not been found in latently infected human or rodent ganglia.

VZV proteins expressed during latency

Six VZV proteins have also been detected during latency (Table 38.5). Three laboratories (Mahalingham *et al.*, 1996; Kennedy *et al.*, 2000, 2004; Lungu *et al.*, 1998) have detected ORF63 protein in human ganglia using antibody to the

protein. In all four studies, ORF63 protein was found either predominantly or exclusively in the cytoplasm of neurons. This is in contrast to its usual localization in both the nucleus and cytoplasm early during lytic infection, and in the nucleus late in lytic infection in vitro (Debrus *et al.*, 1995).

Debrus *et al.* (1995) and Kennedy *et al.* (2001) inoculated rats in the footpad with VZV and detected ORF63 protein in lumbar ganglia. ORF63 protein was present in both the cytoplasm and nucleus of neurons using either a polyclonal (Debrus *et al.*, 1995) or monoclonal (Kennedy *et al.*, 2001) antibody to the protein.

In addition to ORF63 protein, ORFs 4, 21, 29, and 62 proteins were detected exclusively in the cytoplasm of neurons of latently infected human ganglia using polyclonal antibodies in one study (Lungu *et al.*, 1998) and ORFs21, 29, and 62 proteins were detected predominantly in the cytoplasm of neurons in another study (Kennedy *et al.*, 2004). During lytic infection in vitro, ORF21, 29, and 62 proteins are present predominantly in the nucleus, while ORF4 protein is present mostly in the cytoplasm. Lungu *et al.* (1998) postulated that these proteins are sequestered from the nucleus during latency and cannot function to transactivate genes or replicate viral DNA. VZV ORF 10, 14, and 67 proteins were not detected by the authors in human ganglia. Cohrs *et al.* (2003) detected ORF66 protein exclusively in the cytoplasm of neurons.

Function of VZV latency-associated proteins

Three of the VZV genes expressed during latency (ORFs 4, 62, 63) have been identified as immediate-early proteins. ORF62 protein is the major viral transactivator and up-regulates expression of all VZV genes that have been tested in transient expression assays (reviewed in Cohen and Straus, 2001). ORF4 protein transactivates expression of certain VZV genes and enhances the ability of ORF62 to transactivate VZV gene expression. VZV ORF63 down-regulates expression of ORF62 transcripts and protein (Hoover *et al.*, 2006). Cells infected with VZV ORF63 deletion mutants that are impaired for latency show an increase in ORF62 transcription relative to those infected with parental virus, while cells infected with ORF63 mutants not impaired for latency show levels of ORF62 transcription similar to parental virus. Thus, expression of ORF63 during latency may allow the cell to down-regulate ORF62 transcription and limit lytic gene expression. ORF63 protein may have a role in inhibiting apoptosis. Expression of ORF63 protein in rat neurons inhibited apoptosis induced by withdrawal of nerve growth factor (Hood *et al.*, 2006); however, ganglia from cotton rats acutely infected with an ORF63 deletion mutant did not show an increase in apoptosis (Cohen *et al.*, 2004). ORF4, ORF62, and ORF63 proteins are all present in the viral tegument.

VZV ORF29 is predicted to encode an early protein, while ORFs 21 and 66 are predicted to encode late proteins, based on their homology with HSV genes. VZV ORF21 protein is present in the viral nucleocapsid and ORF29 protein is a single-stranded DNA binding protein that regulates gene expression from the gI promoter. ORF66 encodes a serine-threonine protein kinase that phosphorylates the ORF62 protein. The actual function of these six VZV genes during latent infection is unknown.

VZV genes required for establishment of latent infection

The cotton rat model has been used to test the ability of several VZV mutants to establish a latent infection. VZV ORFs 1, 2, 13, 32, and 57 encode proteins that do not have HSV homologues. Inoculation of cotton rats with VZV mutants unable to express each of these proteins showed that each is dispensable for establishment of latency (Sato *et al.*, 2002b, 2003b). VZV ORF10, ORF14, ORF17, ORF61, and ORF67 encode the homologues of the HSV VP16 transactivator, glycoprotein C, viral host shut off protein, ICP0 immediate-early protein, and glycoprotein I, respectively. All five of these VZV proteins are dispensable for latency in the cotton rat (Kennedy *et al.*, 2004; Sato *et al.*, 2002a, 2003a, b). ORF21 and ORF66 proteins, which are expressed during VZV latency, are also dispensable for establishment of latent infection (Sato *et al.*, 2003b; Xia *et al.*, 2002). VZV ORF47 protein, which is required for infection of human T cells and skin is dispensable for latency. In contrast, deletion of ORF4 or ORF63 results in a virus that is impaired for establishment of latency (Cohen *et al.*, 2004, 2005b).

In vitro models for VZV latency

Several investigators have infected human neurons with VZV in vitro in attempts to produce models for latency. Infection of human fetal dorsal root ganglia neurons with cell associated or cell-free VZV resulted in a productive infection, but neurons were less susceptible to infection or had a slower rate of infection than non-neuronal cells (Wigdahl *et al.*, 1986; Assouline *et al.*, 1990). Somekh and colleagues (1992) prepared human fetal neuron, satellite cell, or mixed neuron and satellite cell cultures from dorsal root ganglia and infected the cells with cell-free VZV in the presence of BVaraU. After 1 week BVaraU was removed, and 1 to 3 weeks later the cells were plated onto human

fibroblasts. VZV "reactivated" from 56% of mixed cultures (neurons and satellite cells), but not from pure neuron or satellite cell cultures.

Merville-Louis *et al.* (1989) infected adult rat dorsal root ganglia neurons with cell associated or cell-free VZV and observed all three kinetic classes of VZV transcripts in the cells; CPE was not observed and virus was not produced. This suggests that the cells underwent an abortive, but not latent infection. In contrast, Kress *et al.* (2001) infected adult rat dorsal root ganglia with cell-associated virus and noted productive infection with death of the cells. Hood *et al.* (2003) infected human dorsal root ganglion neurons with cell-associated VZV and observed expression of all three kinetic classes of VZV proteins, but apoptosis did not occur, in contrast to the marked apoptosis observed in virus-infected fibroblasts.

Chen *et al.* (2003) infected guinea pig enteric neurons with cell-free or cell-associated virus. Infection with cell-associated virus resulted in a productive infection of the neurons, while infection with cell-free virus resulted in a latent pattern of infection. The latently infected neurons expressed VZV ORF4, 21, 29, 62, and 63 proteins in the cytoplasm of the cells; however, glycoproteins were not expressed. The authors postulated that cell-free VZV, unlike cell-associated virus, lacks some of the proteins that are present in virus-infected cells at the onset of infection and therefore is not able to initiate virus replication in neurons. Stallings *et al.* (2006) showed that while ORF29 and ORF62 proteins are excluded from the nucleus of cultured guinea pig enteric neurons infected with VZV, expression of VZV ORF61 protein in these cells resulted in translocation of ORF29 and ORF62 proteins to the nucleus. These studies suggest that VZV ORF61 protein may contribute to reactivation of virus from latency.

While these in vitro models recapitulate some of the features of latent VZV infection, it is not clear how well they emulate latency in vivo. The limitations of cell culture based models of HSV latency to simulate latency in vivo, and the lack of understanding of what actually constitutes latency in vivo, suggests that in vitro models for VZV may also have limitations.

Reactivation of VZV

VZV reactivation, which presents as zoster, occurs more frequently in immuncompromised persons and in the elderly. A decline in the frequency of VZV-specific T-cells is thought to allow the virus to clinically reactivate. VZV-specific cytotoxic T-lymphocytes (CTLs) have been detected that recognize the ORF4, 29, 62, and 63 latency proteins (Sadzot-Delvaux *et al.*, 1997; Arvin *et al.*, 2002). These CTLs may help to prevent reactivation of VZV from latency. The demonstration that vaccination of adults with varicella-zoster virus vaccine can reduce the incidence of zoster and postherpetic neuralgia, suggests that augmentation of the cellular immune response to VZV can reduce reactivation (Oxman *et al.*, 2005).

The molecular basis of reactivation is not known. While HSV can be cocultivated from human ganglia, infectious VZV has never been recovered from human ganglia. Vafai *et al.* (1988) cultured human ganglia in tissue culture media for 11 to17 days and detected 7 major VZV-specific proteins of 35 to 200 kDa. While these proteins were not identified, lysates from the cultivated ganglia did not react with monoclonal antibodies to VZV proteins expressed during the late phase of the replicative cycle, indicating that viral replication did not occur in vitro. Kennedy *et al.* (2000) studied human trigeminal and dorsal root ganglia that were cocultivated with monkey kidney cells for 3 to 11 days. Transcripts associated (ORFs 29 and 63) and not associated (ORFs 18, 28, and 40) with latency were detected in most of the ganglia. This pattern was very different from that observed in ganglia that were not cocultivated, suggesting that reactivation had occurred. No evidence of infectious VZV was detected after cocultivation. In one report, VZV was said to have reactivated, as detected by cytopathic effects and in situ hybridization, from VZV-infected rats after cocultivation of dissociated ganglia with human fibroblasts and repeated treatment of the cells with trypsin (Sadzot-Delvaux *et al.*, 1990). This finding has not yet been confirmed by others.

Analysis of VZV DNA in dorsal root ganglia from a person with zoster showed that viral DNA was present both in neurons and satellite cells of ganglia innervating the sites of reactivation (Lungu *et al.*, 1995). VZV DNA was present in both the nucleus and the cytoplasm of reactivating ganglia, and a late viral protein, gI, was present in the cytoplasm of these ganglia. A subsequent study showed that while latency associated proteins were present in only the cytoplasm during latency, these proteins translocated to both the cytoplasm and nucleus of neurons in ganglia undergoing reactivation (Lungu *et al.*, 1998). Latency associated proteins were not detected in the satellite cells of the ganglia.

Comparison of VZV latency with that of other alphaherpesviruses

VZV latency has a number of different features than that seen in HSV (Table 38.6). During latency of other alphaherpesvirus, such as HSV, bovine herpesvirus (BHV), or pseudorabies virus (PRV), only the latency associated

transcripts (LAT) are expressed. The BHV LAT encodes a protein, while no HSV LAT protein has been detected in latently infected humans or animals. PRV, like VZV, is a member of the varicellovirus family, however, only the PRV LAT transcript has been detected during latency. At present it is unclear why latent gene expression in VZV is different from that of the other alphaherpesviruses.

Is the large number of transcripts in VZV latency due to reactivation?

A number of observations suggest that the large number of VZV transcripts that are detected during latency in humans is not an artifact due to reactivation. First, comparison of transcripts detected from human ganglia shortly after death, with those obtained after ganglia are explanted show different patterns of gene expression (Kennedy *et al.*, 2000). Second, similar studies in which human ganglia are obtained after death detect only a single latency-associated transcript for HSV-1 (Croen *et al.*, 1988). Since HSV can undergo reactivation with productive infection in cell culture, apparently the brief period of time between death and processing the ganglia to detect latent transcripts is insufficient to induce reactivation and may also hold true for VZV. Third, the time between death and obtaining tissue at autopsy did not correlate with the number of VZV genome copies (Cohrs *et al.*, 2000). Fourth, only certain immediate-early and early VZV genes are expressed during latency. Finally, animal models of VZV, in which ganglia are processed immediately after death, show a similar pattern of VZV transcription and protein expression during latency as occurs in human ganglia (Sadzot-Delvaux *et al.*, 1995).

Models for VZV latency

The relatively large number of transcripts that are expressed during latency along with the presence of viral proteins, in latently infected neurons indicates that the mechanism of latency for VZV differs from that of herpes simplex virus. Two models may be proposed to explain the ability of the virus to remain latent, despite expression of several gene products.

VZV proteins localize to the cytoplasm, instead of the nucleus of neurons and thus are unable to carry out their activities

VZV ORF21, 29, 62, and 63 proteins, are usually present in the nucleus of cells during lytic replication. Four studies (Mahalingam *et al.*, 1996; Grinfeld and Kennedy, 2004; Kennedy *et al.*, 2000; Lungu *et al.*, 1998) have shown that ORF63 is located in the cytoplasm of latently infected neurons. Furthermore, Lungu and colleagues (1998) detected ORF21, 29, and 62 proteins exclusively in the cytoplasm of latently infected neurons. Segregated to the cytoplasm, ORF62 protein would not be able to transactivate VZV promoters, and ORF29 protein would not be able to bind to single-stranded DNA to perform its regulatory activities during DNA replication. While the functions of ORF21 and ORF63 are not known, their sequestration in the cytoplasm during latency, away from the nucleus, suggests that they might be unable to carry out their activities during latency.

How might these latency-associated proteins be sequestered in the cytoplasm during latency? Bontems *et al.* (2002) showed that the phosphorylation status of IE63 protein determines its localization in either the cytoplasm or nucleus. Transient expression of wild-type ORF63 protein resulted in a predominantly nuclear localization in Vero cells, while mutation of several serine or threonine residues that are sites of phosphorylation resulted in a predominantly cytoplasmic localization. While the phosphorylation pattern of ORF63 protein may appear to regulate its localization, the same authors showed that ORF63 protein localized to the nucleus of a neural cell line regardless of its phosphorylation status. In addition, localization of different phosphorylated forms of ORF63 is apparently dependent on whether the protein is expressed alone (Bontems *et al.*, 2002) or in the context of the rest of the genome (Cohen *et al.*, 2005a)

Table 38.6. Differences between VZV and HSV-1 infection, latency, and reactivation

Property	VZV	HSV-1
Primary infection	Disseminated	Localized
Entry into ganglia	Viremia, neural	Neural
Frequency of reactivation	Usually once	Multiple
Likelihood of reactivation	Increases with age	Decreases with age
Asymptomatic reactivation with virus shedding	No	Frequent
Distribution	Dermatome (ganglia)	Focal (sensory nerve)
Reactivation stimuli	None	UV, fever
Reactivation symptoms	Severe pain	Mild or none
Time to recurrence after immunosuppression	2–6 months	1–4 weeks
Latency associated RNAs and proteins	ORFs4, 21, 29, 62, 63, 66 RNA and protein	LAT RNA only

The phosphorylation status of ORF62 protein also regulates its localization (Kinchington *et al.*, 2000). ORF66 protein phosphorylates ORF62 protein and keeps it sequestered to the cytoplasm. Since ORF66 is expressed during latency, this might be a mechanism to keep ORF62 protein from activating transcription during latency. However, a VZV mutant that is unable to express ORF66 still maintains latent infection in an animal model (Sato *et al.*, 2003b). Thus, there are likely to be factors in addition to phosphorylation that are important for inhibiting the lytic functions of ORF63 and ORF62 protein during latency.

This model still leaves a number of questions unanswered. It is unclear from this model how ORF 21 and ORF29 are expressed if ORF62 is sequestered in the cytoplasm. Furthermore it is unclear why gene expression is limited to selected immediate-early and early genes and not other early or late genes.

VZV proteins have different activities in neurons than in permissive cells due to differences in cellular proteins

Differences in cellular proteins, such as transcription factors, may be responsible for the different activity of VZV in latently infected neurons compared to permissive cells. ORF29 protein augments the ability of ORF62 protein to transactivate the gI promoter in fibroblasts and T-cells; however, ORF29 inhibits the ability of ORF62 protein to activate the gI promoter in neuronal (PC-12) cells (Boucaud *et al.*, 1998). Similarly, ORF63 protein activates the EF-1α promoter in melanoma cells, but not in neuroblastoma cells (Zuranski *et al.*, 2005). This suggests that either neuronal cells lack an activator or that these cells express a repressor that is lacking in fibroblasts and T cells.

Neuronal cells may lack transcription factors, or may have transcription factors that are in an inactive form. VZV ORF10 forms a complex with TAATGARAT-like elements, Oct1 and host cell factor (HCF) to transactivate the ORF62 promoter (Moriuchi *et al.*, 1995). HCF is sequestered in the cytoplasm in sensory neurons, but translocates to nucleus during stimuli that induce reactivation of HSV (Kristie *et al.*, 1999). If HCF is important for reactivation of VZV, its normal sequestration in the cytoplasm may help VZV to maintain a latent infection.

Alternatively, transcription factors may act as repressors in neurons, but not in permissive cells. Transient expression Oct 2 in hamster kidney cells (in which the protein is normally not expressed) increases the basal activity of the ORF62 promoter (Patel *et al.*, 1998). In contrast, expression of Oct2 in a neuronal cell line represses the activity of the ORF62 promoter. Since Oct2 is normally expressed only in neuronal and B-cells, Oct2 may repress the ORF62 promoter in these cells and help to maintain latency.

Oct 2 can also inhibit transactivation of the ORF62 promoter by the ORF10 protein. Transient expression of Oct2 with the ORF10 transactivator and an ORF62 promoter driving CAT as a reporter construct inhibited the ability of ORF10 protein to transactivate the ORF62 promoter. Thus, expression of Oct2 in neurons may inhibit the transactivating activity of ORF10, which might otherwise stimulate reactivation of VZV in neurons.

Future directions

While the last several years have resulted in much new information about VZV latency, many issues still remain. Further studies are needed from other laboratories to confirm the pattern of VZV protein expression during latency, preferably using monoclonal antibodies.

Additional studies using animal models will be critical in studies of VZV latency. Since animals can be sacrificed and ganglia removed quickly, reactivation is less of an issue. The simian varicella virus is a particularly attractive model since one can study acute and latent disease in the natural animal model. While the simian virus is the closest homologue to VZV, there are some differences in the genomes of the two viruses, and it is uncertain if these differences would result in different mechanisms of latency.

A number of questions regarding latency remain unanswered. At present it is unclear why VZV, unlike the other alphaherpesvirus, expresses so many viral genes during latency. Why are many of the immediate-early genes, which normally initiate VZV infection, expressed during latency? What are the molecular mechanisms involved in maintaining latency and in inducing reactivation?

Immunobiology

Introduction

Varicella zoster virus (VZV) like the other herpesvirus family members is a highly successful and ubiquitous human pathogen. In order for VZV to persist in the human population, the virus has evolved strategies to avoid immune detection and potentially promote viral pathogenesis. We have demonstrated that VZV encodes two separate immune evasion strategies by specifically down-regulating cell-surface MHC class I (Abendroth *et al.*, 2001a) and inhibiting the up-regulation of interferon-γ-induced MHC class II expression (Abendroth *et al.*, 2000) during productive infection of primary human foreskin fibroblasts (HFFs). Given that VZV appears to evade host recognition by T-cells during the prolonged, 10–21 day incubation period, viral genes encoding immunomodulatory proteins are likely to delay the initial clonal amplification of VZV specific $CD4^+$ and $CD8^+$ T-lymphocytes and at least transiently enhance the ability of VZV to replicate at cutaneous sites. Recently we have studied the interaction of VZV with human dendritic cells (DCs) and T-lymphocytes. VZV has the ability to infect immature DCs and transfer virus to T-lymphocytes (Abendroth *et al.*, 2001b). VZV also readily infects tonsil T-cells (Ku *et al.*, 2002). The analysis of VZV interactions with T-cells during viral pathogenesis is described in Chapter 37. These capacities of VZV to infect DC and T-cells provide new models of viral dissemination during primary and recurrent VZV infections. Further studies assessing mature DCs have revealed a third immune evasion mechanism for VZV whereby the virus is able to productively infect a specialized immune cell (representing the most potent antigen presenting cell type), and in doing so impairs its ability to function properly.

More recently we have revealed that VZV has evolved a mechanism to limit host cell anti-viral defenses by impairing NF_{KB} activation in cultured fibroblasts and in differentiated epidermal cells in Skin xenografts in SCID by mice infected in vivo (Jones and Arvind, 2006).

VZV encoded downmodulation of cell-surface MHC class I expression

Our initial studies on VZV encoded immunomodulation began with the observation that VZV could downregulate cell-surface MHC class I expression in HFFs, which are the optimal cell-type for VZV infection and replication in vitro (Arvin, 2001). Cell-surface MHC class I and VZV antigen expression was examined by flow cytometry on HFFs infected with a low passage clinical VZV isolate (strain S) (Abendroth *et al.*, 2001a). In cells where no viral antigen was observed, approximately 70%–80% of cells had detectable MHC class I expression, whereas only about 20%–30% of the cells that had detectable VZV antigen synthesis also expressed cell-surface MHC class I. VZV selectively downregulated cell-surface MHC class I expression on HFFs as flow cytometry of these cells for transferrin receptor (CD71) expression, revealed that VZV infection did not alter cell-surface CD71 expression (Fig. 39.1). Cohen and co-workers have also found that infection of human fibroblasts with VZV results in the specific downregulation of cell-surface MHC class I expression (Cohen, 1998). We have further demonstrated that VZV isolates, whether fresh clinical isolates or tissue-culture passaged virus, specifically downregulate MHC class I expression in primary and transformed human cells.

Given this evidence for MHC class I down-regulation following VZV infection of tissue culture cells, we sought to determine the potential biological significance of this effect in facilitating VZV pathogenesis. Based on our previous

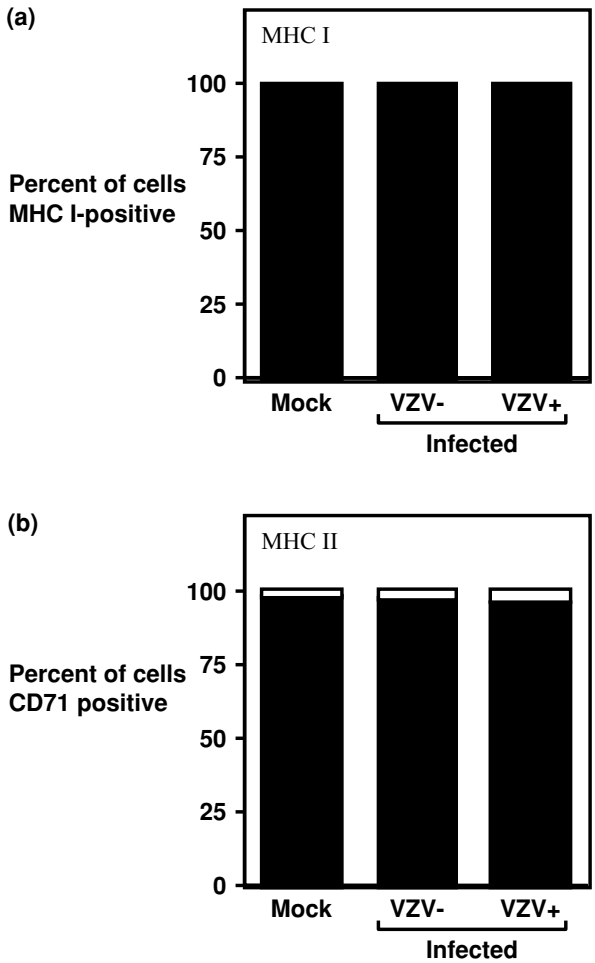

Fig. 39.1. FACS analysis of MHC class I, transferrin receptor (CD71) and VZV proteins on VZV infected cells. HFF were either infected with VZV for 24 hr or mock infected, cell preparations were stained with antibodies and fluorescent conjugates to MHC I and VZV proteins or to transferrin receptor (CD71) and VZV proteins. The percentage of VZV^{+} and VZV^{-} cell populations expressing cell surface MHC I and transferrin receptor is shown using analysis by flow cytometry.

studies showing that VZV causes cell-associated viremia during the incubation period of primary infection without inducing a detectable immune response, we evaluated whether VZV infection altered MHC class I expression on human T-cells in vivo using the SCID-hu mouse model. We have previously demonstrated that VZV infects human CD4+ and CD8+ T-cells as well as immature CD4+CD8+ in SCID-hu thymus/liver implants *in vivo* (Moffat *et al.*, 1995). To determine whether VZV infection alters MHC class I expression on human T-cells, human fetal thymus/liver implants placed under the kidney capsule of SCID-hu mice were inoculated with VZV according to our standard protocol (Moffat *et al.*, 1995). Cells from the infected and uninfected implants were immunostained with antibodies to the CD3 T-cell marker, MHC class I and VZV proteins and analysed by flow cytometry. In all mice inoculated with VZV, CD3 positive T-cells expressing viral antigens were readily detectable (range of 11%–20%). The percentage of T-cells that expressed MHC class I within the population of cells that was positive for both CD3 and VZV proteins was significantly decreased when compared to the population that was positive for CD3 but had no detectable VZV proteins. Thus, VZV replication has the capacity to cause MHC class I down-regulation on human CD3 T cells a cell-type critical for the viremic phase of VZV pathogenesis. This observation is consistent with the concept that this immunomodulatory mechanism may provide the virus with a transient advantage, allowing viral dissemination to skin sites of replication that are required to achieve transmission.

Recently, we identified the first VZV immunomodulatory gene product and described the mechanism by which VZV alters cell-surface MHC class I expression (Abendroth *et al.*, 2001a). To identify the compartment of MHC class I retention within the cell, we assessed the localization of MHC class I complexes with organelle specific markers in uninfected and VZV infected cells by confocal microscopy. Uninfected HFFs showed a uniform distribution of MHC class I throughout the cell cytoplasm and surface. In contrast, VZV infected HFs showed a strong perinuclear staining pattern for MHC class I molecules that colocalized with ceramide which labelled the membranes of the Golgi complex. The intracellular localization of MHC class I molecules to the Golgi in VZV infected cells suggests that a viral protein may interact specifically with a component of the MHC class I complex, thereby preventing efficient MHC class I transport to the cell-surface. In this respect, other herpesviruses, including HSV and human and murine CMV, have been shown to encode immunomodulatory proteins that directly associate with components of the MHC class I biosynthesis pathway (York *et al.*, 1994; Fruh *et al.*, 1995; Hill *et al.*, 1995; Ahn *et al.*, 1996; Jones *et al.*, 1996; Tomazin *et al.*, 1996; Wiertz *et al.*, 1996; Galocha *et al.*, 1997; Jones and Sun, 1997; Kleijnen *et al.*, 1997; Machold *et al.*, 1997; Reusch *et al.*, 1999). Immunoprecipitation of radiolabelled MHC class I molecules in VZV and mock infected cells did not reveal binding of a viral protein but a modified, ~40 KDa MHC class I was detected consistently in VZV infected cells, which may reflect accelerated degradation of MHC class I molecules retained in the Golgi.

Despite the sequence similarities between the VZV and HSV genomes, VZV does not encode an ICP47 homologue.

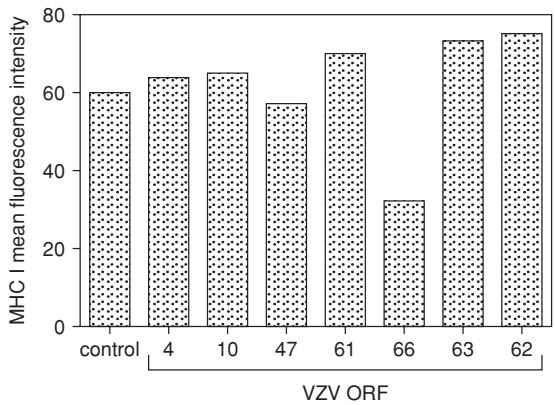

Fig. 39.2. Analysis of MHC I downregulation in cells transfected with plasmids expressing VZV proteins. HFF were transiently transfected with plasmids expressing VZV ORF4, ORF10, ORF47, ORF61, ORF62, ORF63, ORF66, or a parental control plasmid (control). 48 hr post-transfection cell preparations were stained for MHC I. Data is shown as the mean fluorescence intensity of specific cell surface MHC I staining.

In addition, VZV does not contain any identifiable homologues to the gene products of the other herpesviruses known to alter cell-surface MHC class I expression. Nonetheless, experiments using PAA to inhibit viral DNA replication suggest that an immediate-early or early VZV gene product(s) is involved in the down-modulation of cell-surface MHC class I molecules, whereas late genes were not required. VZV encodes several genes which have been reported to be expressed under immediate-early conditions (Kinchington and Cohen, 2000). To test whether these immediate-early proteins might play a role in MHC class I downregulation, HFs were transfected with the plasmids expressing ORF62, ORF63, ORF4 and ORF61. In addition, plasmids encoding the early gene products ORF10, ORF47 and ORF66 were also tested. After 48 hours, transfected cells were stained for cell-surface MHC class I expression and the mean fluorescence intensity of cell-surface MHC class I staining was determined for each transfected population of HFs by flow cytometry. Compared to the parental control plasmid, those expressing ORFs 4, 10, 47, 61, 62 and 63 did not significantly alter cell-surface MHC class I expression. In contrast, the mean fluorescence intensity of cell-surface MHC class I staining was significantly decreased on cultures transfected with the ORF66 expressing plasmid (Fig. 39.2). This is the first identification of a VZV immunomodulatory gene product that alters cell-surface MHC class I expression. Other VZV genes are also likely to encode the ability to downregulate MHC class I as another herpesvirus, HCMV, encodes no fewer than four viral genes which function to down-regulate MHC class I (Fruh *et al.*, 1999).

VZV encoded inhibition of IFN γ-mediated up-regulation of cell-surface MHC class II

Studies of adaptive immunity to VZV reveal the importance of CD4+ restricted T-cell responses during primary infection and in the maintenance of latency. Therefore, it is likely that VZV has evolved strategies for modulating the expression of MHC class II, as well as MHC class I expression. VZV specific CD4+ T-cells that are elicited during primary infection are predominantly of the Th1 type (Bergen *et al.*, 1991; Zhang *et al.*, 1994) and function to produce high levels of IFN-γ which potentiates the clonal expansion of VZV specific T-cells (Arvin *et al.*, 1986a,b; Jenkins *et al.*,1998; Wallace, *et al.*, 1994). This cytokine is also essential for the up-regulation of MHC class II on cell types that usually do not constitutively express this immune molecule. Although the classical CTL response is mediated by CD8+ T-cells that recognize viral peptides in association with MHC class I molecules, VZV specific CTLs can also exhibit MHC class II (CD4+) restricted killing of infected target cells (Cooper *et al.*, 1988; Diaz *et al.*, 1989; Hayward *et al.*, 1986, 1989; Hickling *et al.*, 1987; Sharp *et al.*, 1992). Peripheral T-cell populations contain high frequencies of CD4+ T-cells that mediate cytotoxicity against VZV-infected targets, as is also observed in HSV immunity (Arvin *et al.*, 1991; Zarling *et al.*, 1986). The potential of CD4+ T-cells to act as effective cytotoxic cells *in vivo* requires that target cells express cell-surface MHC class II molecules. These proteins are induced at sites of local inflammation, as in the case of cutaneous VZV lesions. Other herpesviruses such as human and mouse CMV have been shown to inhibit the upregulation of MHC class II expression induced by IFN-γ (Heise *et al.*, 1998; Miller *et al.*, 1998). Escape from CD4+ T-cell recognition by disrupting MHC class II expression is likely to be another VZV immune evasion strategy that has clinical significance. The block of IFNγ effects on MHC class II regulation could limit primary sensitization of T-cells to VZV peptides and delay the early amplification of VZV-specific CD4+ helper T-cells and release of cytokines at cutaneous sites of VZV replication. In vivo fibroblasts are infected by VZV and require IFNγ stimulation to up-regulate cell-surface MHC class II expression (Abendroth *et al.*, 2000). Therefore, we assessed the impact of VZV infection on IFN γ-stimulated expression of MHC class II on HFFs and the induction of genes associated with surface MHC class II expression. In these experiments, HFFs were infected with VZV and treated with 100 U/ml of IFNγ for 48 hours, beginning 12 hours post-infection.

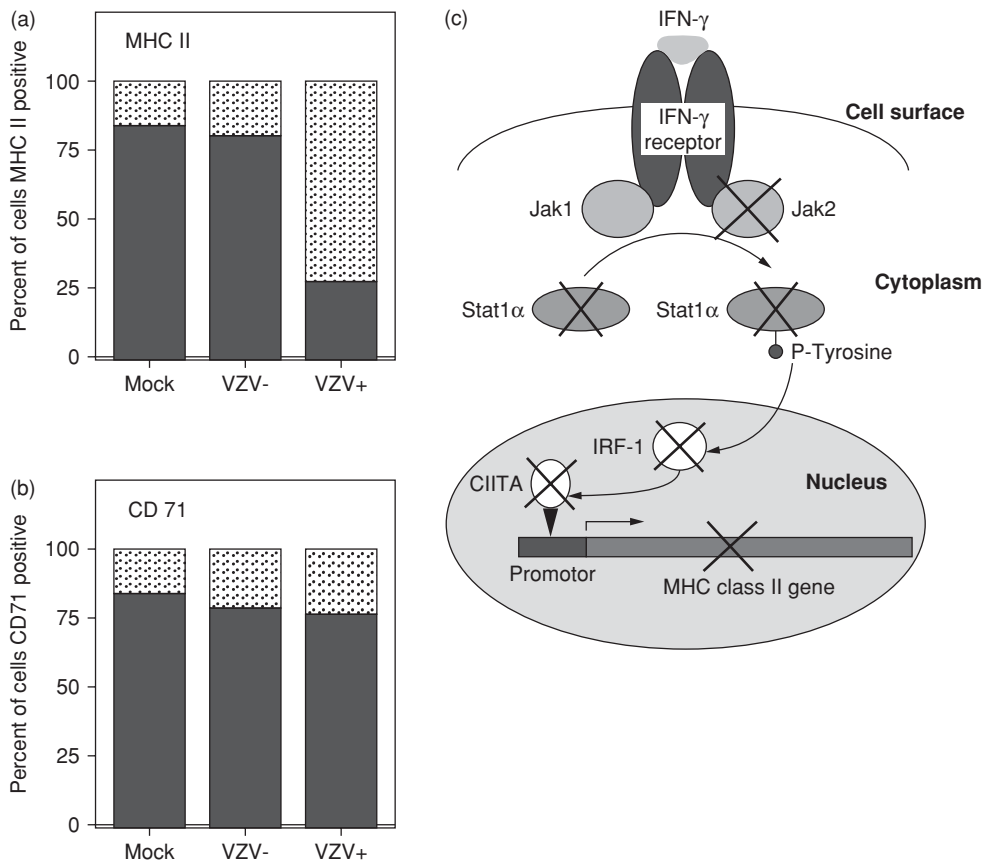

Fig. 39.3. FACS analysis of MHC class II, transferrin receptor (CD 71) and VZV proteins on VZV-infected cells treated with IFN-γ. Right panel: At 12 hours after VZV infection, HFF were treated with IFN-γ for 36 hours; cell preparations were stained with antibodies and fluorescent conjugates to MHC class II and VZV proteins or to transferrin receptor (CD71) and VZV proteins. The percentage of VZV^+ and VZV^- cell populations expressing cell surface MHC class II or CD71 is shown. Left panel: Jak/Stat signal transduction pathway, showing cellular proteins affected by VZV.

Flow cytometry analysis of VZV and cell-surface MHC class II (HLA-DR) protein expression demonstrates that IFNγ treatment induced MHC class II expression in the majority of uninfected HFs but rarely in VZV infected HFFs (Fig. 39.3). With regard to the mechanism of inhibition of IFNγ induced MHC class II gene expression, we found that MHC Class II DRα, CIITA and IRF-1 transcripts did not accumulate in VZV infected cells after treatment with IFN-γ. Stat1α and Jak2 protein synthesis was reduced compared with Jak1 and CD71, which remained unchanged (Fig. 39.3). These observations indicate that the pathway by which VZV infection alters induction of MHC class II by IFN-γ differs from the effects of HCMV and MCMV. HCMV inhibits MHC class II expression in HFFs by blocking Jak/Stat signal transduction through a specific decrease in Jak1 expression. In contrast, MCMV inhibits IFN-γ stimulated MHC class II expression in murine macrophages by a mechanism that does not involve Jak/Stat signal transduction (Heise *et al.*, 1998). Thus, among the herpesviruses, VZV, HCMV and MCMV employ different strategies to reduce MHC class II antigen presentation pathways.

The significance of the in vitro studies is substantiated by examination of skin biopsies of human varicella and herpes zoster lesions for MHC class II and VZV RNA synthesis by non-isotopic *in situ* hybridization. Cutaneous VZV lesions showed a distinct separation of VZV infected cells and cells positive for MHC class II transcripts. These experiments demonstrated that dermal and epidermal cells infected with VZV were not expressing MHC class II transcripts in vivo at early stages of lesion formation.

The persistence of VZV as a human pathogen depends upon its transmission from the cutaneous lesions that are associated with varicella, caused by primary VZV infection,

and herpes zoster, which results from reactivation of the virus from neuronal sites of latency. The ability of VZV to inhibit MHC class II expression in most infected human fibroblasts, despite exposure to high concentrations of IFNγ, provides a mechanism by which the virus can limit the consequences of immune surveillance by CD4+ T-cells. Impaired recognition of VZV-infected cells by CD4+ T-cells, which requires interaction of the T-cell receptor and viral peptides complexed with MHC class II molecules, can be predicted to allow transient viral replication in dermal and epidermal cells that is necessary for VZV transmission to susceptible individuals.

VZV interference with the NF-kB pathway

Since activation of the NF-kB pathway elicits IFN-a/b and other antiviral cytokines and proteins, herpesviruses have acquired mechanisms that inhibit this pathway. VZV interferes with NF-kB activation in cultured fibroblasts and in differentiated epidermal cells in skin xenografts in SCIDhu mice infected in vivo (Jones and Arvin, 2005). After a transient nuclear localization of the cononical NF-kB family members, p50 and p65 (Rel-A), these proteins become sequestered in the cytoplasm of VZV-infected fibroblasts. Nuclear exclusion of NF-kB proteins occurs because IkBa, which binds p50 and p65, is not degraded in VZV infected cells even though it is phosphorylated and ubiquitinated, and the 26S proteasome remains functional. VZV infection also inhibited the characteristic degradation of IkBa that is induced by exposure of fibroblasts to tumor necrosis factor alpha (TNF-α). The cytoplasmic retention of NF-kB proteins depended upon VZV replication and was in contrast to HSV-1, which induces persistent nuclear localization of p50 and p65, in a process that is required for normal HSV-1 replication. Thus, VZV has evolved a mechanism to limit host cell antiviral defenses by sequestering NF-kB proteins in the cytoplasm, a strategy that appears to be unique among the herpesviruses.

VZV infection of human dendritic cells and transmission to T-cells

The initial stage of primary VZV infection, involves the inoculation of mucosal sites with virus from respiratory droplets or cutaneous vesicle fluid from an infected individual. After inoculation, the virus remains undetected by the host immune system. (Arvin *et al., 1996*; Grose, 1981). The lymphotropism of VZV is critical for the dissemination of virus from peripheral blood mononuclear cells (PBMC) to epithelial cells, resulting in infection of the skin and the characteristic varicella rash (Arvin *et al.*, 1996). It remains unclear how VZV is transmitted from mucosal sites of inoculation to T-cells. Some T-cells may become infected in tonsillar tissues by direct transfer from infected mucosal epithelial cells (Ku *et al.*, 2004). At the same time, dendritic cells (DCs) of the respiratory mucosa may be among the first target cells to encounter VZV during primary infection and subsequently transport virus to the draining lymph nodes to enable T-cell infection as well as initiating a virus specific immune response (Jenkins *et al.*, 1999).

DCs are bone marrow-derived potent antigen presenting cells that are located in most tissues including the skin, blood, lymph and mucosal surfaces (Klagge and Schneider-Schaulies, 1999). Dendritic cells play a major role in initiating and maintaining the adaptive immune responses to pathogens such as viruses (Banchereau and Steinman, 1998; Banchereau *et al.*, 2000). Several human viruses including human immunodeficiency virus (HIV), measles virus, influenza virus, human herpes virus 6, human cytomegalovirus and herpes simplex virus have been shown to infect human DCs (Asada *et al.*, 1999; Bender *et al.*, 1998; Fugier-Vivier *et al.*, 1997; Grosjean *et al.*, 1997; Riegler *et al.*, 2000; Salio *et al.*, 1999; Schnorr *et al.*, 1997; Warren *et al.*, 1997). There is evidence that viruses exploit DCs as transport vehicles into lymphoid tissue and ultimately contribute to the transmission of the virus in the host. Viruses are also capable of modulating or interfering with the maturation, migration and function of DCs, thereby enabling potential evasion of the immune response.

Our initial interest in DCs began with determining whether VZV could infect human dendritic cells and subsequently transfer virus to T-cells. In this study, human monocyte derived dendritic cells were inoculated with VZV strain-S and assessed by flow cytometry for VZV and dendritic cell (CD1a) antigen expression (Abendroth *et al.*, 2001b). In all human DCs inoculated with VZV, CD1a positive DCs expressing viral antigens were readily detectable (range of 15%–40%). Dendritic cells were also shown to be susceptible to VZV infection by the immunoflourescence and confocal microscopy detection of immediate-early (IE62), early (ORF29) and late (gC) gene products in CD1a+ DCs. Infectious virus was recovered from infected DCs and cell-to-cell contact was required for virus transmission to permissive fibroblasts. Significantly, VZV-infected dendritic cells were capable of transferring virus to autologous human T lymphocytes, causing productive infection of these cells. This study provides the first evidence that DC are permissive to VZV infection and that infected DCs can transfer infectious virus to T-lymphocytes.

Two possible outcomes resulting from the interaction of VZV with DCs could account for transfer of infectious

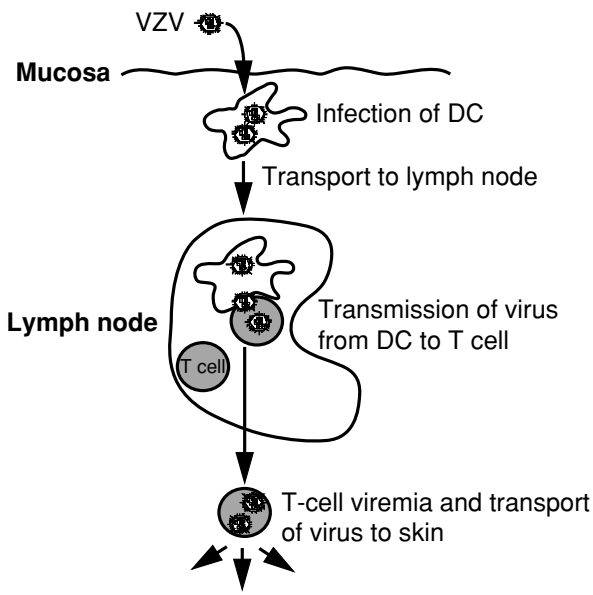

Fig. 39.4. Model of the potential role of VZV infection of dendritic cells.

virus to other cell types. Firstly, VZV may productively infect DCs and transfer new progeny virus to other cells (e.g., T-cells). Alternatively, because VZV envelope glycoproteins are known to bind mannose receptors which are found on immature DCs, the virus may be captured by DCs and internalised into trypsin resistant compartments and subsequently transmitted to other cells. Our current data clearly support the former as we were able to readily detect (by IFA and confocal microscopy) viral antigen expression from all three kinetic gene classes in sub-cellular locations consistent with those reported during productive infection of fully permissive fibroblasts (Kinchington and Cohen, 2000). This study proposed a model of VZV dissemination following primary inoculation (Fig. 39.4). In this model, upon entering the host at respiratory mucosa VZV infects DCs (Langerhans cells), which are then triggered to mobilize and migrate to the T-cell rich areas of regional lymph nodes. At this site the direct interaction of productively infected DCs with T-cells would then result in virus transmission and the productive infection of T-cells. This model, together with the potential for direct infection of T-cells by virus from VZV-infected respiratory epithelial cells are mutually compatible and consistent with a redundancy in the mechanisms by which VZV reaches T-cells. VZV pathogenesis should be facilitated by dual strategies for transfer of infectious virus into migratory T-cells. Once infection of T-cells occurs the virus should be disseminated to other sites of the body, infecting cutaneous epithelial cells with the formation of the characteristic vesicular rash of varicella. It is also possible that VZV is only captured by DCs and studies are underway to determine the mechanism of VZV entry into human DCs. Interestingly, it has been reported that HIV can either productively infect or be captured by DCs and that these two outcomes are mediated by separate pathways (Blauvelt *et al.*, 1997). Further analysis of VZV-DC interactions, including the potential to isolate infected DCs from patients undergoing primary (varicella) or recurrent (herpes zoster) infection are likely to provide additional information on these outcomes.

DCs function to present antigenic peptides on the cell surface and to stimulate T-cells. Jenkins *et al.* demonstrated that a naïve T-cell response can be induced in vitro by VZV antigenic peptides, suggesting that DCs may be involved in the initiation of the primary immune response in vivo (Jenkins *et al.*, 1999). The induction of the primary T-cell response involves not only the recognition of antigenic peptides in association with cell-surface MHC molecules, but also the interaction of co-stimulatory molecules (Marland *et al.*, 1996). Several molecules are involved in this process include CD86, CD80, CD40, CD54 and CD83 and the absence or decreased expression of these immune molecules can render a DC less capable of inducing a T-cell response (Klagge and Schneider-Schaulies, 1999). It has been postulated that interference with DC function following virus infection may enable viruses to avoid immune recognition. In this respect, measles virus and HSV have been shown to interfere with the antigen presenting capability of infected DCs by a variety of mechanisms. Measles virus can productively infect DCs and interfere with the cells ability to induce the proliferation of CD4+ naïve T-cells (Grosjean *et al.*, 1997). HSV infection of mature DCs results in a decreased T-cell stimulatory capacity and the specific degradation of the CD83 cell-surface molecule (Salio *et al.*, 1999). However, not all viruses which infect DCs interfere with DC antigen presenting function. For example, HHV-6 productively infects DCs but these cells can still function as antigen presenting cells (Asada *et al.*, 1999). As outlined above VZV has been shown to encode the ability to specifically down-modulate cell-surface MHC class I and IFNγ-induced MHC class II expression during productive infection of primary human fibroblasts (Abendroth *et al.*, 2001a, 2000). VZV-infected immature DCs showed little or no change in the level of cell-surface expression of MHC class I, MHC class II, CD40 and CD86. Current studies are in progress to determine whether VZV infection of immature DCs inhibits DC maturation given that the transition from an immature to a mature state is essential for DCs to migrate and perform their antigen presentation function. To date, several other herpesviruses

including HSV, HCMV and MCMV have been shown to inhibit the maturation of immature DCs by preventing up-regulation and expression of selective cell-surface immune molecules (Kruse *et al.*, 2000).

VZV encodes an immune evasion strategy during the productive infection of mature dendritic cells

DCs located in the periphery exist as immature cells, expressing low levels of MHC class I and MHC class II molecules and costimulatory molecules such as CD80 and CD86. Immature DCs readily take up antigen and are induced to migrate to the secondary lymphoid organs where they undergo maturation and present processed antigens to antigen specific T-lymphocytes (Steinman, 1991; Steinman *et al.*, 1997; Banchereau and Steinman, 1998). Maturation of DCs results in the down-regulation of antigen uptake and processing properties and the upregulation of MHC class I and MHC class II molecules, increased surface expression of costimulatory molecules CD80, CD86, CD40 and the maturation molecule CD83 and upregulation of adhesion molecules such as ICAM-1 (CD54) (Young and Steinman,1990; Young *et al.*, 1992; Zhou *et al.*, 1992; Zhou and Tedder, 1995; Cella *et al.*, 1997; Banchereau and Steinman, 1998; Steinman, 1999; Lechmann *et al.*, 2002). The ability of mature DCs to efficiently activate naïve T-lymphocytes which subsequently eliminate virus-infected cells has been attributed to their expression of these specific cell-surface immune molecules (Bhardwaj, 1997).

DCs should be an ideal target for viruses seeking to evade or delay the immune response by disrupting their function (Bhardwaj, 1997). In this respect, viruses including HSV-1 (Klagge and Schneider-Schaulies, 1999), HCMV (Raftery *et al.*, 2001), human herpesvirus 6 (HHV-6) (Kakimoto *et al.*, 2002), measles virus (Fugier-Vivier *et al.*, 1997; Grosjean *et al.*, 1997; Schnorr *et al.*, 1997), HIV (Blauvelt *et al.*, 1997) and lymphocytic choriomeningitis virus (LCMV) (Sevilla *et al.*, 2000) have been shown to interfere with the immune function of infected DCs by a variety of mechanisms. However, not all viruses which infect DCs interfere with DC antigen-presenting function. For example, influenza virus productively infects DCs, but these cells can still function as antigen-presenting cells (Bhardwaj *et al.*, 1994).

Given the pivotal role mature DCs play in the induction of successful anti-viral immune responses, we investigated whether VZV could infect mature DCs and interfere with their immune function. In this study, we demonstrated by flow cytometry, immunofluorescence and infectious center assays that VZV can productively infect human mature DCs and produce infectious virus (Morrow *et al.*, 2003). Following the assessment of the cell-surface expression of MHC class I, MHC class II, CD80, CD83 and CD86 by flow cytometry we found that with the exception of MHC class II, all of these molecules were down-regulated on VZV infected mature Dcs. These observations indicate that the mechanism by which VZV alters immune molecule expression on mature DCs appears novel, since the pattern of immune molecule alteration differs from that of other viruses which infect and alter mature DCs. In comparison, HSV-1 infection of mature DCs results in the down-regulation only of CD83 (Kruse *et al.*, 2000) and HSV-2 infection causes down-regulation of MHC class I, MHC class II, CD40, CD80 and CD86 on murine DCs (Jones *et al.*, 2003). It should be noted, however, that the source of cells and/or the DC maturation stimuli may have a significant bearing on the expression of immune molecules and subsequent DC function following virus infection. In this respect, HCMV has been shown to down-regulate MHC class I and MHC class II on monocyte derived DCs induced to mature with LPS or TNF-α, yet $CD34^+$ bone marrow-derived DCs induced to mature with CD40 display a down-regulation of MHC class I, MHC (Hertel *et al.*, 2003) class II, CD80, CD83, CD86 and CCR7 (E.S. Mocarski, personal communication, July 2002). Thus, among the human herpesviruses studied to date, there appear to be multiple strategies to interfere with DC immune molecule expression and the present study provides evidence that VZV has done likewise.

The most distinctive functional characteristic of mature DCs is their ability to stimulate T-cells (Banchereau and Steinman, 1998; Cella *et al.*, 1997; Steinman, 1999). Therefore, we assessed the functional consequences of the selective immune molecule alteration observed on VZV infected mature DCs. We found that VZV infection of mature DCs significantly reduced their ability to stimulate the proliferation of allogeneic T-lymphocytes. The identity of the VZV gene or genes involved in the downregulation of immune molecules and reduced T cell stimulation capacity during productive infection of mature DCs is yet to be determined. To date, ORF66 is the only identified VZV immunomodulatory gene product (Abendroth *et al.*, 2001b). Additional studies assessing ORF66 together with other viral ORFs are a focus of current experiments aimed at identifying the VZV genes responsible for the inhibition of mature DC function.

Thus, current evidence indicates that VZV is DC-tropic, and can target two distinct aspects of DC function represented by immature and mature DCs. This ability to infect both DC types confers upon the virus the potential to both increase virus dissemination in the host as well as evade the immune response.

The host immune response

Immunity during primary VZV infection

Innate immune responses are presumed to mediate the initial control of primary VZV infection. Interferon-α (IFN-α) inhibits VZV replication and is released by PBMC from naive donors exposed to VZV antigens in vitro. Early clinical trials demonstrated that the severity of varicella was reduced when immunocompromised children with varicella were given exogenous IFN-α. Our recent analysis of VZV infection of human skin xenografts in the SCIDhu mouse model of VZV pathogenesis demonstrated a dramatic increase in IFN-α production, accompanied by nuclear translocation of pStat protein within uninfected epidermal cells that surrounded skin cells actively infected with VZV (Ku *et al.*, 2004). When animals were given antibody to IFN-α/β receptor, VZV titers increased tenfold and cytopathic changes in the skin were much more extensive. Innate antiviral immunity is also mediated by natural killer (NK) cells. NK cells from naive individuals have the capacity to lyze VZV-infected targets in vitro; non-specific cytotoxicity is mediated by CD16+ T-cells and is enhanced by IL-2.

Adaptive T-cell responses, manifest as an initial burst in VZV-specific T cells, appear to be critical for resolving primary VZV infection (Fig. 39.5). Primary VZV infection is associated with an incubation period of 10–21 days before skin lesions appear. T-cell recognition of VZV is not detected in individuals tested during the incubation period, suggesting that viral mechanisms for evading immune surveillance are very effective during the initial phase of primary VZV infection (Arvin, 1999). When acquisition of VZV-specific T-cell immunity is delayed, life-threatening dissemination of the virus occurs, as described in patients with congenital T-cell immunodeficiency diseases, malignancy or immunosuppression and in newborn infants. In our early studies of antiviral immunity in immunocompromised children with varicella and malignancy, only one (7.7%) of 13 immunocompromised patients had a detectable VZV-specific T-cell proliferation response within three days after the onset of varicella compared with 19 (42%) of 45 healthy subjects ($P<0.05$) (Arvin *et al.*, 1986a). Diminished VZV-specific cellular immunity was associated with persistent VZV viremia, continued formation of new skin lesions and viral dissemination to lungs, liver and other organs. Children with HIV may develop chronic varicella, which also suggests the significance of antiviral T cell-mediated immunity in the host response to VZV. In contrast, VZV IgG and IgM antibody titers measured within the first three days, did not correlate with the severity of varicella in healthy or immunodeficient children (Arvin *et al.*, 1986a,b) and varicella appears to be uncomplicated in patients with agammaglobulinemia.

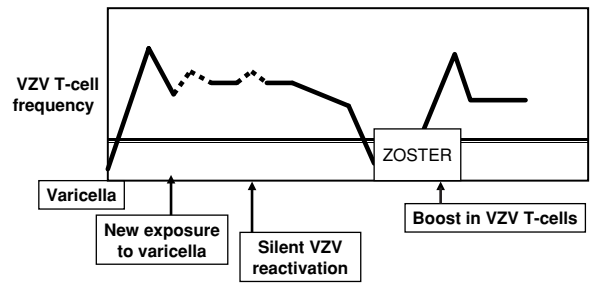

Fig. 39.5. Schema of the T-cell response to VZV.

In the healthy host with acute varicella, VZV-specific T-cell proliferation responses were detected in 12%, 31% and 47% of subjects tested at one, two and three days after the onset of rash, respectively (Arvin *et al.*, 1986a). A higher VZV-specific T-cell proliferation response, measured as the mean stimulation index (SI) at three days, was associated with fewer varicella lesions (Arvin *et al.*, 1986a). The mean VZV SI was 7.5±10.43 SD in those who had fewer than 100 lesions/m^2 when new lesion formation had stopped, compared with 1.4 ± 1.85 SD for those with >400 lesions/m^2 ($P < 0.05$). In these early experiments, activated CD4+ and CD8+ T-cells were present in peripheral blood by flow cytometry before T-cell proliferation to VZV was detected. Primary VZV infection also elicits virus-specific CD4+ T-cells that produce IL-2 and IFN-γ, which are considered Th1 cytokines. In contrast, very few VZV specific CD4+ T-cells release IL-4, a cytokine made by the Th2 subset of CD4+ T-cells (Zhang *et al.*, 1994). As expected, based on the CD4+ T cell cytokine profiles, IL-2 and IFN-γ, as well as IFN-α concentrations are increased in sera from healthy individuals with varicella (Wallace *et al.*, 1994; Arvin *et al.*, 1986a,b). Like IFN-α, IFN-γ has antiviral activity against VZV. IFN-γ, which enhances clonal expansion of antiviral T-cells, was diminished in adults with primary VZV infection compared to children. This difference may help to explain the severe cases of varicella observed in healthy adults.

Information about the VZV proteins that are recognized during the initial T cell response to primary infection is limited. Clonal expansion of T cells that recognize glycoproteins, gE and gH, and the IE62 major tegument/regulatory protein has been documented (Arvin *et al.*, 1986b). The pattern of VZV proteins that were recognized by early virus-specific CD4+ T-cells from individuals with primary VZV was variable; gE was the predominant target in 67% of healthy individuals, gH in 71% and IE62 protein in 57% of subjects. Regardless

of the predominant protein target, varicella was uncomplicated in all cases. As noted, up-regulation of class II expression permits lysis of infected cells by CD4+ cytotoxic T-cells and IFN-γ also enhances class I restricted cytotoxicity mediated by CD8+ T-cells. Although sub-populations of effector cells were not identified, high frequencies of CTL that lyze targets expressing VZV gE and IE62 protein were documented in healthy individuals with acute varicella (Diaz *et al.*, 1989).

VZV immunity during latency

VZV-specific IgG antibodies and CD4+ and CD8+ T-cells persist for decades after primary VZV infection (Arvin, 2001). VZV-specific IgG antibodies are directed against many VZV polypeptides and have functional capacities that include viral neutralization and antibody-dependent cytotoxicity (ADCC) against VZV infected targets. Most healty immune individuals also have serum antibodies to VZV.

Immune adults have VZV-specific memory T cells in peripheral blood with frequencies of approximately 1:40 000 PBMC. Glycoproteins, gE, gB, gC and gH, and the IE62 protein were recognized by T-cells in proliferation and cytokine release assays (Arvin *et al.*, 1986a). CD4+ T-cell clones specific for epitopes of gE, gB, gH or gI were derived from VZV immune donors and some clones specific for gB or gI had dual helper and cyototoxic functions. Using synthetic peptides to stimulate T-cells confirmed that regions of IE62, gB, gE and gI functioned as T-cell epitopes. In addition, VZV specific memory T-cells have been recovered from lymphoid tissue. As was reported during primary VZV infection, cytokine profiles of memory CD4+ T-cells showed that up to 85% of proliferating cells produced IFN-γ whereas only 10% released IL-4 (Hayward *et al.*, 1989). Intradermal inoculation of inactivated VZV antigens elicits delayed hypersensitivity reactions in immune children and adults (Kamiya *et al., 1977*).

MHC class I or class II restricted cytotoxic T-cells that recognize VZV proteins persist for many years after primary VZV infection (Diaz *et al.*, 1989; Hayward *et al.*, 1986; Sharp *et al.*, 1992). Memory CD4+ CTL are detected with secondary VZV stimulation and using autologous lymphoblastoid cells infected with VZV or vaccinia recombinants that express VZV proteins as targets, and CD8+ CTL can be detected withVZV-infected fibroblast targets, that express only MHC class I antigen, or with highly purified preparations of CD8+ T-cells tested against lymphoblastoid cells expressing VZV proteins. Viral protein targets that have been documented include gC, gE, gI and IE62 and IE63 proteins (Sharp *et al.*, 1992). Memory CTL specific for the IE62 protein were found at frequencies of 1:105 000 ± 85 000 SD in VZV immune subjects tested > 20 years after varicella. Mean frequencies of anti-VZV gE CTL were 1:121 000 ± 86 000 SD. Using these methods, mean frequencies of CD4+ CTLs that recognized IE62 protein were1:108 000 and 1:74 000 in the CD8+ population, which was not significantly different. VZV gE specific CD4+ CTL frequencies were 1:119 000 compared to 1:31 000 in the CD8+ population (NS).

Persistence of VZV-specific memory

The host response to VZV must protect against new exposures to varicella and against VZV reactivation from latently infected cells in the sensory ganglia (Fig. 39.5). At the same time, these exogenous and endogenous exposures to infectious VZV, constitute mechanisms by which VZV immunity may be boosted. VZV immune adults and children tested after household exposures to varicella have been found to develop increases in VZV IgG, IgM and IgA antibodies and in VZV-specific T-cell proliferation as well as enhanced delayed hypersensitivity to VZV skin test antigens (Gershon *et al.*, 1984).

Preserving VZV immunity is also important for maintaining VZV latency. VZV may undergo periodic reactivations that are asymptomatic or result in mild, undiagnosed episodes of zoster. Endogenous reactivation of VZV provides a second potential mechanism for sustaining VZV immunity over all or most of the lifetime of the host. Whereas other herpesviruses are readilty shown to reactivate at mucosal surfaces asymptomatically, VZV shedding at mucosal sites has not been documented. Evidence that subclinical VZV reactivation occurs has been suggested in studies monitoring VZV immune markers over time in healthy adults with no recent exposure to varicella. Intermittent increases in these responses may represent responses to asymptomatic VZV. The re-appearance of VZV IgM antibodies has been considered such a marker (Gershon et al. 1984). More directly, we found that 19% of bone marrow transplant patients tested during the period of highest risk for herpes zoster in these patients had subclinical cell-associated VZV viremia as detected by PCR. VZV DNA has also been detected in PBMC from some elderly individuals (Devlin *et al.* 1992). A relationship between VZV reactivation and preservation of cell-mediated immunity was suggested by the fact that many bone marrow transplant recipients had reconstitution of VZV-specific T-cell responses during the first year after transplantation, without having had any exposures to varicella or clinical signs of zoster. Recovery of VZV-specific CTL function was also observed in 50% of BMT patients who had remained asymptomatic.

Immunity during VZV reactivation

The clinical experience demonstrates a direct correlation between the increased risk of zoster and diseases or treatments that interfere with T cell function. Patients with HIV infection who have progressive depletion of CD4+ T-cells also have a high incidence of zoster. The age-related increase in the risk of zoster in healthy elderly people is also well documented and several studies have shown that VZV-specific T cell responses decline with age. In contrast, VZV IgG antibodies do not decline in high risk populations and lower titers do not predict a higher risk of VZV reactivation, causing zoster (Webster *et al.*, 1989). Elderly peole have decreases in frequencies of memory T-cells that recognize VZV in proliferation and CTL assays and delayed hypersensitivity responses to VZV skin testing are absent or diminished. In limiting dilution proliferation assays, older individuals showed reduced frequencies of CD4+ T-cells, primarily within the IFN-γ producing Th1 subset, as compared to IL-4 positive CD4+ T-cells.

In the healthy individual with zoster, the equilibrium between the virus and the host is re-established rapidly. Viral replication at skin sites is usually controlled within 1 or 2 weeks. Transfer of infectious virus into T-cells from sites of virus replication in dorsal root ganglia or skin appears to be unusual, since skin lesions are rarely found beyond the affected dermatome. In immunocompromised patients, severe, prolonged suppression of cellular immunity is associated with the highest risk of herpes zoster and of life-threatening dissemination of the virus, resulting from cell-associated VZV viremia (Arvin, 1999). Among bone marrow transplant recipients, memory CD8+ T-cells are generated after in vitro stimulation with VZV antigen in numbers comparable to those of healthy immune individuals whereas CD4+ CTL function is difficult to detect during the period after transplantation when these patients are at high risk for VZV recurrences. The observation that the risk of herpes zoster increases when patients with HIV infection have low CD4+ T-cell numbers is consistent with a role for CD4+ as well as CD8+ T-cells in the restriction of viral replication in vivo. Immunocompromised patients often have scattered cutaneous lesions indicating the occurrence of viremia during zoster. Under these circumstances, VZV may enter DC in the involved skin area and reach T-cells in regional lymph nodes, or it may be transferred into migratory T-cells, causing viremia as a result of the limitations of the host response.

Herpes zoster is followed by increased VZV IgG, IgM and IgA antibodies in healthy and immunocompromised patients. The humoral immune response is directed against a broad range of VZV proteins, including early, structural/regulatory proteins, viral enzymes and glycoproteins. Nevertheless, the contribution of humoral immunity to resolving VZV reactivation is not certain. Some individuals who have early responses with high titers of VZV IgG and IgM antibodies have severe herpes zoster whereas those with mild clinical disease may have limited increases in VZV antibody titers. Viral replication at local cutaneous sites was not inhibited when VZV immune globulin was given to immunocompromised individuals with herpes zoster before treatment with antiviral drugs was possible. However, there was some evidence that a diminished humoral immune response early in the clinical course was associated with a higher risk of viremia and viral dissemination in immunocompromised patients.

Healthy adults with herpes zoster develop a marked increase in VZV-specific T-cell responses, as shown by comparing VZV T-cell proliferation within one week after onset with responses tested from two to four weeks later. IFN-α is detected in vesicle fluid from the cutaneous zoster lesions, increasing as the lesions resolve in healthy subjects (Stevens *et al.*, 1975). Herpes zoster in immunocompromised patients is associated with delayed boosting of VZV T-cell responses. In one study of patients with malignancy and zoster, the mean SI was 1.8 ± 0.85 SD during the first week and had increased only to 5.7 ± 3.03 SD by 2 to 4 weeks. IFN-α concentrations were also low in zoster lesions in these high-risk patients and IFN-α treatment accelerated the resolution of zoster in such patients (Merigan *et al.*, 1978).

The introduction of the live attenuated varicella vaccine has introduced new considerations about the persistence of memory immunity to VZV, which are discussed in Chapter 37. Such vaccines may prove to be useful clinically as a strategy for reversing the waning VZV T cell immunity that occurs with age. In a recent study, we provided a "proof of concept" for this approach by demonstrating that inactivated varicella vaccine given to hematopoeitic cell transplant recipients resulted in early reconstitution of VZV-specific CD4 T cell proliferation and a reduced risk of symptomatic episodes of zoster (Hata *et al.*, 2002). Since the live attenuated varicella vaccine can boost VZV T cell immunity in healthy elderly adults, the successful outcome of studies to examine its effectiveness for preventing or modifying the severity of zoster suggests that VZV-specific T cells help to block the progression of VZV reactivation from latency to clinically symptomatic infection (Oxman *et al.*, 2005).

VSV: persistence in the population

Jane Seward and Aisha Jumaan

National Immunization Program Centers for Disease Control and Prevention, Atlanta, GA, USA

Like other herpes viruses, varicella zoster virus (VZV) causes disease due to the primary infection (varicella) and due to reactivation (herpes zoster). However, VZV differs from other herpes viruses in causing primary and reactivation infections that are easily recognized clinical diseases, even by the lay public. Because of this, the epidemiology of varicella and herpes zoster has been well described from clinically recognized disease (incidence, severe disease outcomes and deaths) with seroprevalence data providing additional information on the epidemiology of varicella especially in populations where varicella disease history may not be available.

Varicella occurs worldwide with ongoing endemic transmission in areas where populations are sufficiently large to support such transmission. However the epidemiology of varicella varies between temperate and tropical climates (Lee, 1998). Universal childhood vaccination programs have changed the epidemiology of varicella in countries implementing such programs with significant declines in disease. Most experience has been gained in the United States where a varicella vaccination program was initiated in 1995. Herpes zoster infections also occur throughout the world although the epidemiology of herpes zoster is less well described globally. Because the incidence of herpes zoster increases dramatically with age, countries with lower life expectancies may have lower health burdens due to this disease. A vaccine for prevention of herpes zoster and post-herpetic neuralgia was licensed in the USA in May, 2006 (Oxman *et al.*, 2005). This chapter reviews pre- and post-vaccine epidemiology of varicella and herpes zoster.

Varicella: prevaccine epidemiology

Transmission

Varicella is a highly infectious viral disease caused by the varicella zoster virus (VZV) that results from exposure to cases of varicella or herpes zoster. Herpes zoster cases represent a method for regular exposure and reintroduction of VZV into communities that otherwise may not be large enough to sustain endemic transmission of the virus. Herpes zoster is less transmissible than varicella. This may relate both to the limited number of lesions and to modes of transmission; the infection is most commonly localized and is not thought to involve the respiratory tract. Varicella can be transmitted by respiratory droplets, from skin lesions, by direct contact or possibly by aerosolization of virus from skin lesions and also, presumably from lesions in the mouth (enanthem). Studying transmission of varicella has been challenging due to the strong cell association of the virus. VZV has been consistently difficult to culture from the throat but easy to culture from skin lesions. Finally, infection of a pregnant woman in the first 2 trimesters of pregnancy may result in transplacental transmission of VZV resulting in a severe congenital infection in the fetus or newborn known as congenital (fetal) varicella syndrome (Enders *et al.*, 1994).

Varicella transmission has been described from household studies where secondary attack rates among susceptible children following household exposure has ranged from 61% to 100% (Asano *et al.*, 1977; Hope-Simpson, 1952; Ross, 1962). The highest estimates come from small groups of seronegative children involved in postexposure vaccine effectiveness studies in household settings. The lowest estimate is from observations in a general practice in England where children <15 years with a negative disease history were followed after exposure to a primary household case (Hope-Simpson, 1952). Hope-Simpson described transmissibility of varicella to be lower than measles (76%) but higher than mumps (32%). In a large study in the United States of the effect of gamma globulin on modifying varicella infections, Ross described a secondary attack rate of 87% among untreated children aged 6 months to 12 years with a negative disease history (Ross, 1962).

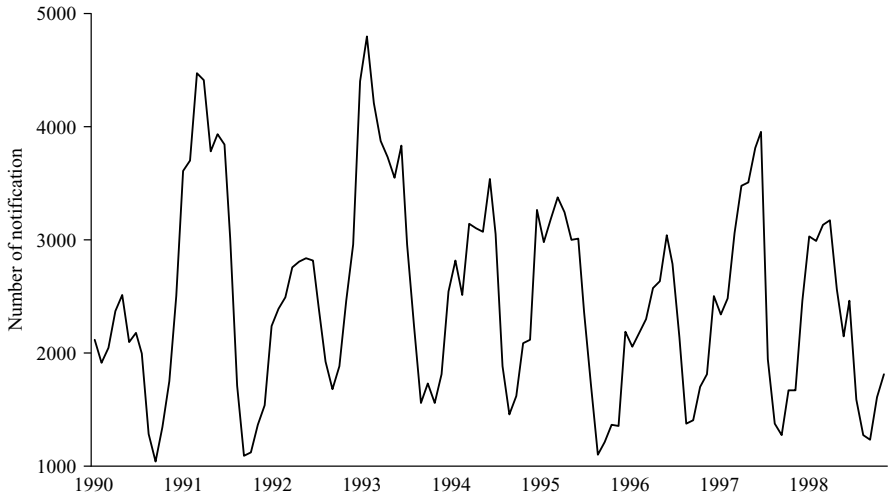

Fig. 40.1. Notification of varicella in Scotland, 4-week periods, 1990–1998.

Compared with households, transmission is lower in community settings; the relatively few published estimates available come from varicella outbreak investigations that have included vaccinated as well as unvaccinated children. In these situations, due to continuing exposure, outbreaks in child care centers may ultimately achieve a cumulative attack rate among history and vaccine negative children as high as 80%–88% (Galil *et al.*, 2002b; Izurieta *et al.*, 1997) though, depending on the size of the child care center, this may take weeks or months of transmission. In elementary schools, cumulative attack rates among susceptible children tend to be lower (30%–54%) perhaps due to different mixing patterns resulting in lower risk of exposure (Dworkin *et al.*, 2002). Yorke and London, in analyses of 30 to 35 years of monthly reported measles and varicella cases from New York City and Baltimore, suggested that varicella is only 35%–65% as infectious as measles in the community (Yorke and London, 1973).

Herpes zoster represents a method for reintroduction of VZV into the community in the absence of epidemic varicella. Patients with herpes zoster are less contagious than cases of varicella because their infection is localized and it is not thought to involve the respiratory tract. However, some studies have identified VZV antigen (by PCR) in throat samples of healthy persons with localized herpes zoster. There are few published studies on the transmissibility of herpes zoster probably because of the limited opportunities for exposure of susceptible persons to herpes zoster cases which occur predominantly, among older adults. However, Seiler reported that 11 (15.5%) of 71 susceptible children <15 years of age exposed to herpes zoster in household settings developed varicella (Seiler, 1949). This proportion increased to 17% if infants <1 year of age, who may be protected by maternally acquired antibodies, were excluded from the calculation. Young children with herpes zoster may be more contagious. In a daycare setting, a 3-year-old boy with herpes zoster transmitted in the secondary generation to ~30% of susceptible children in the day care he attended and to both his susceptible siblings (Reigle and Cooperstock, 1985). The child was reported to "lift his shirt repeatedly to scratch or to show everyone his lesions." As varicella disease declines in countries implementing universal childhood vaccination programs, transmission from herpes zoster may become more apparent.

Periodicity and seasonality

Worldwide, varicella is an endemic disease that exhibits a marked seasonal pattern in temperate climates and most temperate climates where this has been studied (Bramley and Jones 2000; Degeun *et al.*, 1998; Lee, 1998; Seward *et al.*, 2002; Tobias *et al.*, 1998) (Fig. 40.1). The exception is Singapore where seasonality has not been described from surveillance data (Ooi *et al.*, 1992). In temperate and tropical climates, the peak disease incidence is most commonly reported in the cooler, drier months during winter or spring. Periodicity with interepidemic cycles of 2–5 years is described from many countries (Bramley and Jones, 2000; Degeun *et al.*, 1998; Seward *et al.*, 2000; Tobias *et al.*, 1998) while a time period as long as 15 years between major epidemics has been described from Singapore (Ooi *et al.*, 1992).

Congenital (fetal) varicella syndrome

This condition was first described in 1947 (Laforet and Lynch, 1947). It is characterized by cicatricial skin lesions and neurologic, eye and skeletal anomalies which may include limb paresis, hypoplasia of upper or lower extremities, chorioretinitis, cataracts and cortical atrophy. Based on a large, multicenter study where 1373 women with varicella and 366 with herpes zoster during pregnancy were prospectively studied, the risk of congenital (fetal) varicella syndrome was found to be approximately 0.4% if varicella infection was acquired in the first 12 weeks of pregnancy and 2.0% from 13–20 weeks (Enders *et al.*, 1994). Maternal zoster was not associated with fetal abnormalities. Based on this study, Enders estimated that the rate of fetal varicella syndrome may be 1.6 per 100 000 births. Enders and Miller used these findings to estimate the number of cases of congenital varicella syndrome that may occur every year by applying a varicella age-specific incidence of 2/1000 population among women of child-bearing age to the number of births per year, taking into account the risk of infection occurring in the first 20 weeks of pregnancy. They calculated that, in the prevaccine era, there may have been 44 cases of congenital varicella syndrome every year in the United States, 8 in England and Wales and 9 in Germany (Enders and Miller, 2000). Incidence is likely to be higher in countries where VZV susceptibility is higher among adults though data are lacking.

Incidence and seroprevalence

Age and climate

Varicella is a highly contagious disease that occurs worldwide. The epidemiology of varicella varies between temperate and tropical climates. Though incompletely understood, these differences may relate to agent, host, environmental or a combination of these factors (Garnett *et al.*, 1993; Lolekha *et al.*, 2001; Mandal *et al.*, 1998; Seward *et al.*, 2000). Because climatic differences (as distinguished from an "island" effect reflecting reduced risk of exposure) are not observed for other highly contagious diseases such as measles, and VZV is known to be heat labile, a partial explanation may be that heat diminishes the ability of the virus to survive in the environment and thereby decreases transmission. In most temperate climates, >90% of persons are infected by 15 years of age with the highest incidence of disease occurring among children <10 years of age (Seward *et al.*, 2000; Wharton, 1996). In tropical climates, cases are acquired at older ages with a higher proportion of cases and higher susceptibility among adults (Lee, 1998).

Varicella incidence data has been described mainly from developed countries where data are collected from notifiable disease reporting, surveys or studies based on medical record encounters. Prior to the national varicella vaccination program in the United States, total annual varicella incidence measured from national household survey data, averaged over a decade, was 15.0–16.0 cases per 1000 population (Guess *et al.*, 1986; Seward *et al.*, 1998). In other temperate climates, reported incidence using different methods of data collection have been generally lower than US rates varying from <5 to ~13.0 cases per 1000 total population (Boelle and Hanslik, 2002; Bramley and Jones, 2000; Choo *et al.*, 1995; Fairley and Miller, 1996). Higher rates, especially from a single year of data collection, may reflect an epidemic disease year (Chant *et al.*, 1998) (Table 40.1).

Infectiousness of diseases is reflected in age-specific incidence. As stated by Hope-Simpson following studies of the infectiousness of measles, varicella and mumps in the household "the more infectious the disease, the younger is the age at which an attack is likely to be received" (Hope-Simpson, 1952). Studies from earlier in the twentieth century in the US showed the highest varicella age-specific incidence was among children aged 6–7 years, in the first 2 years of school (Fales, 1928). To understand age-specific disease patterns, single years of age or small age groups should be studied; grouping ages 5–14 years, for example, may mask considerable variations in incidence within this broad age span. Age-specific incidence among children 5–9 years from US national data in the 1970s and 1980s was ~90/1000 children (Guess *et al.*, 1986; Wharton, 1996). However, by the 1990s, varicella was being acquired at earlier ages. Before introduction of varicella vaccine in the United States in 1995, varicella age-specific incidence had shifted to earlier ages with preschool aged children (1–4 years) having higher age specific incidence than the 5–9-year-old age group (Seward, 1998) (Table 40.1). These data are consistent with findings in many countries including France, Italy, England and Wales, Scotland and Slovenia where the highest age-specific incidence in the 1990s has been reported among preschool-aged children <5 years (Bramley and Jones, 2000; Degeun *et al.*, 1998; Fornaro *et al.*, 1999; Ross and Fleming, 2000) with peak incidence in some studies as young as 1 or 2 years (Socan *et al.*, 2001, Yawn *et al.*, 1997). These changes in epidemiology are thought to reflect earlier exposure through attendance in child care (Wharton 1996; Yawn *et al.* 1997; Ross and Fleming, 2000)

Varicella seroprevalence data reflect age-specific disease incidence and in countries where incidence data are not available, VZV age-specific seroprevalence provide an excellent method for understanding the epidemiology of

Table 40.1. Varicella age-specific and total incidence, selected studies

Country, author, publication year	Study method	Years data collection	Age (years)						Annual total varicella incidence/1000 population
			<1	1–4	5–9	10–14	15–19	20+	
United States (Guess *et al.*, 1986)	National survey	1970–1978	33.8	82.1	90.3	17.5	2.9	0.3	16.0
United States (Seward *et al.*, 1998)	National survey	1990–1994	56.7	100.4	91.0	19.5	4.9	1.5	15.0
France (Boelle *et al.*, 2002)	Sentinel physician reporting	1990–1999	49.8	121.2	36.0		3.4		12.6
United States (Choo *et al.*, 1995)	Health maintenance organization records	July 1990– June 1991 July 1991– June 1992	52.3		41.3	14.0	6.1	1.8	7.6, 12.0
England and Wales (Fairley and Miller, 1996)	Sentinel physician reporting	1989–1990	40.0		17.3		3.1 (15–44 years)		6.3

Australia (Chant *et al.*, 1998)	Local survey	1995	110		130	60	40		33.9

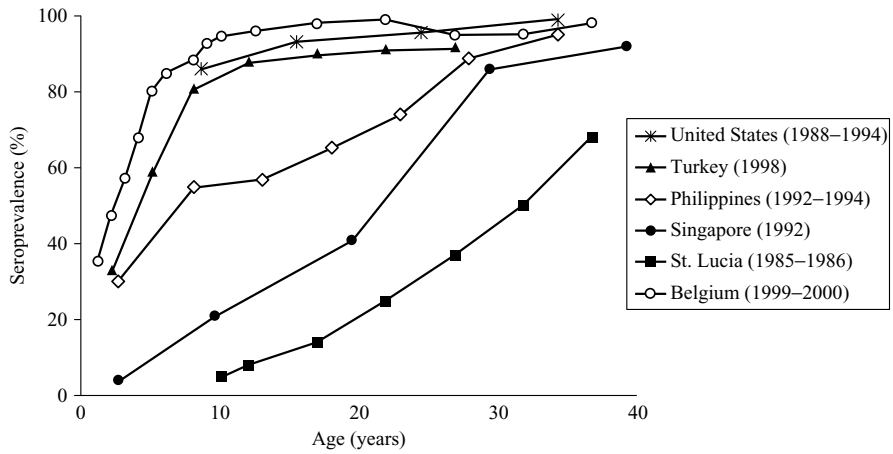

Fig. 40.2. VZV Seroprevalence by age in eight countries.

the disease. Comparing results from serosurveys should take into account improvements in sensitivity and specificity of laboratory methods over time. In addition, these studies represent a snapshot of the seroprevalence status in a community; seroprevalence will be higher if samples are obtained after a varicella epidemic. In temperate climates, >90% of adolescents or young adults are VZV seropositive (Fig. 40.2) (Kanra *et al.*, 2002; Kilgore *et al.*, 2003; Seward *et al.*, 2000; Thiry *et al.*, 2002). Slightly lower seroprevalence rates in adolescents (10–15 years) (82%) are reported from Italy whereas a study in South Africa reported a seroprevalence of 81% among adults 20–29 years (Gabutti *et al.*, 2001; Schoub *et al.*, 1985). In tropical climates, serological studies show higher susceptibility among adults reflecting a higher mean age of infection than in temperate climates (Fig. 40.2). In such countries, seroprevalence among adolescents or young adults has varied widely from less than 20% in St. Lucia (an island community in the West Indies) to >90% in tropical areas in Brazil and urban Calcutta, India (Barzaga *et al.*, 1994; Garnett *et al.*, 1993; Lee, 1998; Mandal *et al.*, 1998; Ooi *et al.*, 1992; Reis *et al.*, 2003).

Urban/rural (risk of exposure)

Urban/rural differences in varicella epidemiology are likely to be due to varying risks of exposure due to differences in population density. Analysis of surveillance data collected in the 1920s in Maryland, US, between 1913 and 1917, showed an earlier mean age of varicella infection among urban (6.7 years) compared with rural children (8.6 years) (Fales, 1928). Studies exploring reasons why the epidemiology of varicella differs between temperate and tropical climates have examined the effect of climate and population density on VZV seroprevalence. In Thailand, significantly lower age-adjusted VZV seroprevalence was found in the warmer than in the cooler regions and in the warmer regions only, the age-specific seroprevalence was significantly higher in the urban population than the rural population (Lolekha *et al.*, 2001). Urban/rural differences have also been described in Calcutta and neighboring rural areas in India. Mandel found that 96% of urban young adults aged 17–25 years were immune compared with 42% of similarly aged rural adults (Mandal *et al.*, 1998). In Eritrea, VZV seroprevalence among an isolated adult population was 44% compared with other adult groups in the same areas where immunity ranged from 91%–96% (Ghebrekidan *et al.*, 1999). Although these data suggest that the higher susceptibility in the tropics may reflect reduced exposure, this is not the only explanation for the differences described. In St. Lucia, seroprevalence for VZV was lower than for mumps, a far less infectious disease and in Singapore, which is densely populated, VZV seroprevalence among young adults has consistently been lower than in countries with temperate climates (Garnett *et al.*, 1993; Ooi *et al.*, 1992).

Other factors: sex, race, number of siblings in the household and child care

Most studies show no differences in seroprevalence by sex. In the United States, national data and studies conducted among military recruits have described differences in varicella susceptibility by race with higher susceptibility among African Americans compared with whites (Jerant *et al.*, 1998; Kilgore *et al.*, 2003). In the national data, these differences narrow with increasing age and are not apparent after approximately age 40. Some studies have shown differences in seroprevalence according to number of siblings

in the household during childhood (Jerant *et al.*, 1998; Ryan *et al.*, 2003). Because of its high incidence in young children, varicella is one of the most common communicable diseases in child care centers and attendance in child care or preschools provides the opportunity for exposure to the varicella zoster virus (VZV) at younger ages. Children attending day care have higher incidence or prevalence of varicella and an increased risk of exposure to varicella with increasing size of the center (Hurwitz *et al.*, 1991; Seward *et al.*, 2000).

Hospitalization and deaths

Though often considered a benign childhood disease, varicella may result in serious complications and death. This health burden assumes greater importance as other infectious causes of morbidity and mortality such as polio, measles and *H. influenzae* are controlled through vaccination (Rawson *et al.*, 2001). Assessing the severe health burden due to varicella in terms of economic and societal costs is important for vaccine policy decision making and to monitor the impact of vaccination programs. Data on population-based varicella mortality, case fatality and hospitalizations are rarely available from developing countries or countries with tropical climates where a higher proportion of cases occur among adults. Additionally, methodological differences in data collection as well as issues such as access to health care should be considered when comparing studies, especially across countries. Finally, calculating case fatality rates and risks of hospitalization for varicella cases is dependent on having accurate incidence data available.

In the United States, in the 5–8 years before licensure of varicella vaccine, varicella resulted in an average of 10 632 hospitalizations and 100 deaths per year (Galil *et al.*, 2002a; Meyer *et al.*, 2000); two-thirds of the hospitalizations and about half the deaths occurred in children. Although varicella is a more severe infection in immunocompromised persons, the majority of severe morbidity and mortality in developed countries occurs among healthy persons. In France (1990–1997), 70% of all varicella deaths and in the United States (1990–1994), 89% of varicella deaths among children and 75% of varicella deaths among adults occurred in persons without underlying high risk medical conditions (including HIV/AIDS, leukemia and other malignancies, other forms of blood dyscrasia and immune deficiencies) (Boelle and Hanslik, 2002; Meyer *et al.*, 2000).

In the US, between 1970 and 1994, before the use of varicella vaccine, crude varicella mortality rates (examining varicella as the underlying cause of death) declined from 0.7 per million population in 1973 to 0.2 in 1986 and then increased to average 0.4 per million population from 1990–1994 (Meyer *et al.*, 2000). Similar crude mortality rates are reported from Australia (0.3/million), France (0.35/million), England and Wales (0.5/million), Scotland (0.5/million) and Singapore (0–0.8/million) (Boelle and Hanslik, 2002; Bramley and Jones, 2000; Chant *et al.*, 1998; Fairley and Miller, 1996; Lam *et al.*, 1993; Rawson *et al.*, 2001). Reflecting the high incidence of varicella in children, varicella mortality rates are highest among children especially those <1 year of age (1.1–3.6 deaths per million population) and lowest among adults (0.2–0.3 deaths per million population).

The risk of dying from varicella is measured by the case fatality rate (CFR). In the US, data from 1970–1994 show higher case fatality rates in infants <1 year and adults ≥20 years of age compared with children 1–9 years (Meyer *et al.*, 2000). Even though CFRs among adults declined substantially from the 1970s to the 1990s, during 1990–1994, adults still had a 27 times higher risk of dying from varicella (CFR 21.3 per 100 000 cases) than children 1–4 years (0.8/100 000 cases). Similar CFRs are reported from France from 1990–97 (CFR 1.0/100 000 for children <15 years and 22.8 for persons ≥15 years) and England and Wales from 1988–1992 for persons <45 years (0.7 for 0–4 years, 1.4 for 5–14 years and 20 for persons 15–44 years of age) (Boelle and Hanslik, 2002; Fairley and Miller, 1996). Though extremely high CFRs (471 and 535) are reported for adults ≥65 years in England and Wales, and France respectively, in this age group, misclassification of varicella with herpes zoster is more likely to occur, as documented in US hospitalization and mortality data (Choo *et al.*, 1995; Galil *et al.*, 2002c).

Population-based mortality data are lacking from developing countries and from countries with tropical climates. Because of the older age of infection and case severity among adults, tropical countries may experience greater morbidity and mortality from varicella and its complications, including congenital varicella syndrome. The eradication of smallpox afforded an opportunity to study varicella in developing countries in the 1970s in more detail than has been possible since. When smallpox was still endemic, varicella was the rash illness most commonly confused with smallpox (Jezek *et al.*, 1978a). For several years after smallpox eradication, heightened surveillance for febrile rash illnesses was conducted. In India, 862 155 varicella cases and 433 varicella deaths were reported from January to December 1976 for a CFR of 5.2 per 10 000 reported cases, 50 times higher than in developed countries (Jezek *et al.*, 1978b). Reasons for the higher case fatality may include incomplete ascertainment of cases (reporting bias for more severe cases) compared with deaths, varicella epidemiology in India, and access to, and quality of, medical care. For 400 deaths where both age and sex were recorded, 80% occurred among adults >15 years and 71%

were male, reflecting varicella epidemiology in tropical climates and perhaps a reporting bias and/or medical access differences for adults and for males compared with females (Jezek *et al.*, 1978a).

Varicella hospitalizations represent severe morbidity or health burden due to varicella and its consequences, and the infection control burden due to varicella infections in hospitals. As pointed out by Wharton, "ascertaining the reason for hospitalization from hospital discharge diagnoses, in the absence of additional information from the clinical record, is difficult due to lack of standard procedures for ordering hospital discharge diagnoses" (Wharton, 1996). Some studies have validated hospital discharge codes (Choo *et al.*, 1995). Thus, when comparing studies of hospitalizations, especially across countries, it is important to consider differences in methods that may result in higher or lower estimates including how hospitalizations were identified (from discharge codes or from reviewing medical records), whether the primary discharge or all discharge codes were searched for varicella, the validity of discharge codes and how hospital admission practices, billing and coding may change over time.

Estimates of annual hospitalizations for varicella in the US during the 1970s and 1980s ranged from approximately 4000 to 9000 depending on the dates of the study, the population studied, and study methods (Guess *et al.*, 1986; Wharton, 1996). More recent estimates indicate annual hospitalizations attributable to varicella of 10 632 per year (Galil *et al.*, 2002a) and almost 15 000 per year if all varicella hospitalizations are included (Ratner, 2002). Reflecting the range of these estimates, crude varicella hospitalization rates from the US, France, Australia, Scotland, and England and Wales have varied from approximately 2–6 per 100 000 population with more recent estimates attempting to describe attributable hospitalizations in the US varying from 3.1–4.1 per 100 000 population (Boelle and Hanslik, 2002; Bramley and Jones, 2000; Chant *et al.*, 1998, Fairley and Miller, 1996; Galil *et al.*, 2002a, Ratner, 2002). The majority of varicella hospitalizations occur among children (56%–67%) reflecting the fact that 90% of varicella cases occur among this age group.

For all ages combined, overall rates of hospital admission per 1000 varicella cases have ranged from 2.2 to 4.7 in national studies in the US and France (Boelle and Hanslik, 2002; Galil *et al.*, 2002a; Ratner, 2002). The highest rate from France included principal and associated varicella hospitalizations. In the 1990s, among children <13 with varicella, a hospitalization rate of 5.5 per 1000 cases was reported from Minnesota (Yawn *et al.*, 1997). The risk of hospitalization varies by age. The pattern of age-specific risks for hospitalizations is similar to that of age-specific case fatality rates with infants and adults having higher risks of hospitalization than young children. Except in France where the risk for hospitalization is higher in infants than in adults, studies consistently report the highest risk of hospitalization in adults, an increased risk in infants and the lowest risk in children 1–4 years or 5–9 years of age (Boelle and Hanslik, 2002; Fairley and Miller, 1996; Galil *et al.*, 2002a; Guess *et al.*, 1986; Wharton, 1996).

Studies of varicella hospitalizations in developing countries are sparse and population-based hospitalization rates are commonly not available for comparison with data from developed countries. However, similar to reported varicella mortality described above (Jezek *et al.*, 1978a), studies of varicella hospitalizations in tropical climates also describe a high proportion of hospitalized cases among adults and also males, which may, in part, reflect hospital admission practices (Seward *et al.*, 2000).

The HIV epidemic may also be expected to influence the epidemiology of varicella. In countries with high HIV prevalence, varicella may cause more severe morbidity and mortality however there are few population-based data examining these issues. A retrospective review of all children admitted to the only isolation facility in Durban, South Africa from 1986–1996, showed a decline in all disease mortality of 86% over the study period mainly attributed to a decline in measles deaths. However, between 1994 and 1996, 15% of varicella admissions and 75% of varicella deaths occurred in HIV co-infected children (Jeena *et al.*, 1998).

Varicella epidemiology: post-vaccine era

A vaccination program is implemented in order to reduce, eliminate or eradicate disease. Because current strains of live attenuated varicella vaccine are neurotropic and are capable of reactivating to cause herpes zoster, albeit at lower rates than wild virus, eradication of VZV infections is not possible with currently licensed vaccines. The goal of a universal varicella vaccination program is to greatly reduce or eliminate varicella disease, especially severe disease.

The United States was the first country to implement a national varicella vaccination program in 1995 and active surveillance for varicella was established in sentinel sites to monitor impact of the vaccination program. By 2000, in these communities, vaccine coverage among children 19–35 months had reached 74%–84% and reported total varicella cases and hospitalizations had declined 71%–84% (Seward *et al.*, 2002) (Fig. 40.3, Table 40.2). Although incidence declined to the greatest extent (83%–90%) among children 1 to 4 years, incidence declined in all age groups including infants and adults indicating herd immunity effects. In the combined surveillance

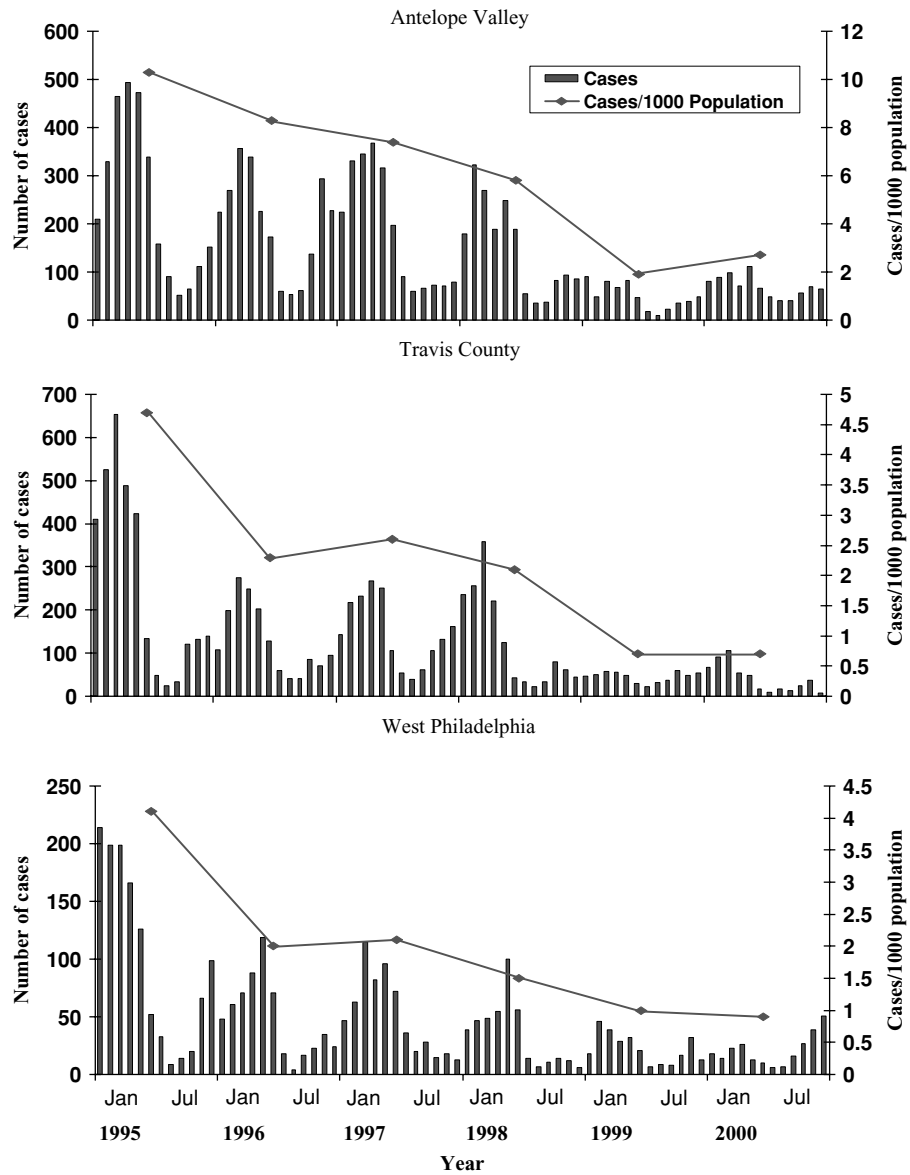

Fig. 40.3. Reported varicella cases by month and annual rates of reported cases per 1000 population in three surveillance areas, 1995–2000.

areas, varicella-related hospitalizations declined from a range of 2.7–4.2 per 100 000 population from 1995 to 1998 to 0.6 and 1.5 per 100 000 population in 1999 and 2000, respectively.

In the USA, a decline in varicella incidence has also been documented from passive surveillance systems. In four states with adequate (≥5% of expected cases) and consistent rates of reporting to the national notifiable disease surveillance system, compared with the average incidence for 1990–1994, reductions in varicella incidence in 2001 ranged from 67% to 82% with vaccine coverage among children 19–35 months ranging from 57%-84% (Centers for Disease Control & Prevention, 2003). Additionally, implementation of a varicella serological screening and vaccination program in Navy military recruits has been followed by an 80% decline in cases in this population (Ryan *et al.*, 2003). At the national level, significant declines in varicella mortality, and in varicella-related

Table 40.2. Percent reduction of reported varicella cases in 2000 compared to 1995, three surveillance areas, United States

Age	Antelope Valley, California	Travis County, Texas	West Philadelphia, Pennsylvania
	%	%	%
<1	69	81	68
1–4	83	90	83
5–9	63	77	77
10–14	65	75	80
15–19	85	83	81
≥20	66	64	68
Total	71	84	79

Note: From Seward, J. F, Watson, B. M., Peterson, C. L. *et al.* (2002).

hospitalizations and their attendant costs have been also been documented in the United States (Nguyen *et al.*, 2005; Zhou *et al.*, 2005; Davis *et al.*, 2004). Among persons less than 50 years of age, varicella deaths declined 74% or more from the immediate pre-vaccine era (1990–1994) to 1999 to 2001 and deaths in children 1 to 9 years of age declined approximately 90% (Nguyen *et al.*, 2005). For hospitalizations, from the prevaccination period to 2002, hospitalizations due to varicella declined by 88% and ambulatory visits declined 59% (Zhou, 2005).

Routine childhood vaccination programs are the most effective strategy for interrupting disease transmission and reducing varicella mortality and morbidity in both temperate and tropical climates. Achieving high vaccination coverage among children will provide the additional benefits of herd immunity with protection of susceptible adults, infants and other persons at high risk for severe varicella disease who are not eligible for vaccination. For programs that achieve high vaccination coverage, the most dramatic effect will be a marked reduction in varicella cases, severe complications and deaths in the population as is now occurring in the United States (Seward *et al.*, 2002; CDC unpublished data, 2003). Among the remaining greatly reduced number of varicella cases, a higher proportion is expected to occur among older persons, as was seen following the introduction of vaccines against measles, mumps and rubella. The shift in the proportion of cases to older persons will be minimized by catch-up vaccination of older children and adolescents. In contrast, vaccination programs targeting only adolescents and adults will have little impact on the epidemiology of varicella in temperate climates. In the US such a targeted program, assuming that all susceptible adults could be vaccinated, would be expected to result in only a 5%–10% decline in cases, a 33% decline in hospitalizations and a 50% decline in deaths. In tropical countries, providing vaccine for susceptible adolescents and adults in addition to infants and children may be more important because a higher proportion of adults are likely to be susceptible.

Although some other countries, including Uruguay, Qatar, Australia, Canada, and Germany (2005) have implemented universal childhood varicella vaccination programs, no data are yet available on the impact of these programs. Some countries are waiting for the availability of a combination MMRV vaccine (licenced in the USA in 2005) before implementing a universal vaccination program and others are considering adolescent vaccination programs. Varicella vaccines are now widely available through the private sector throughout the world. If partial and sustained vaccine uptake occurs through the private sector reaching coverage levels in the range of 30%–60%, adverse epidemiological effects may occur resulting in an increase in incidence or severe morbidity in adolescents and adults similar to those predicted for selective rubella vaccine use (Vynnycky *et al.*, 2003).

A varicella vaccination program has the potential to change the epidemiology of herpes zoster as well as varicella. Therefore, surveillance for herpes zoster as well as varicella is important for monitoring the vaccination program.

Herpes zoster epidemiology

Methodological issues

Studies of herpes zoster (HZ) incidence, morbidity and mortality have used various methodologies; the most reliable data come from prospective cohort studies. Herpes zoster incidence has been described from surveillance data where there is likely to be significant under-reporting of cases, retrospective cohort studies that use medical records thus missing cases that do not seek medical attention, and surveys that may encounter non responders. Thus, differences in the method of data collection must be taken into account when comparing HZ incidence data. In addition, because HZ incidence increases dramatically with age, comparing HZ incidence rates across studies needs to take this into account by standardizing rates to a reference population. Other methodological issues arise, especially when assessing disease burden due to HZ. Herpes zoster is more common among elderly adults, an age group that is likely to have chronic medical conditions that may cause lengthy hospitalizations or death; therefore, it is important to describe the attributable health burden or mortality from HZ. Otherwise, coincidental HZ infections that occur

during hospitalization and that may be listed in hospital discharge codes and on death certificates may inflate health burden and mortality due to HZ. MacIntyre *et al.* (2003) reported that only 40% of 4718 hospitalizations that listed HZ in discharge codes had HZ as the primary diagnosis, and that these cases had significantly shorter hospitalization stay and were less likely to die (1%) than those with a secondary HZ diagnosis (6%).

Seasonality and clustering

Because HZ results from reactivation of latent VZV, the disease does not occur in epidemics and periodicity is not described. Most studies report no seasonal variations in the incidence of HZ (Brisson *et al.*, 2001; Hope-Simpson, 1965; McGregor, 1957; Ragozzino *et al.*, 1982); however several studies report seasonality with peak incidence in the summer and some authors speculate that this may be associated with ultraviolet radiation that peaks in the summer months (Glynn *et al.*, 1990; Wilson, 1986; Zak-Prelich *et al.*, 2000).

Although small clusters of HZ cases have been reported (Hope Simpson, 1965; Palmer *et al.*, 1985; Schimpff *et al.*, 1972), most authors report no clustering, or if clustering occurred they were considered to represent coincidental episodes of disease (Brisson *et al.*, 2001; Donahue *et al.*, 1995; Glynn *et al.*, 1990; Hope-Simpson, 1965; Wilson, 1986). A few authors suggest that clusters may represent a clinical manifestation of exogenous reinfection, or stimulation of endogenous VZV reactivation, (Palmer *et al.*, 1985; Schimpff *et al.*, 1972).

Secular trends

Several studies have suggested that HZ rates are increasing. In a study in the United States spanning 15 years from 1945–1959, Ragozzino *et al.* (1982) reported an increase in the annual age standardized (1970 US white population) incidence from 1.1 to 1.5 per 1000 person years. In his study in the 1990s, Donahue *et al.* (1995) reported that once the HZ incidence rates he observed were standardized to the 1970 US white population, they increased to 2.9 per 1000 person–years, more than double that reported by Ragazzino. The increase was not associated with aging of the population or with an increase in immunosuppressed individuals. In addition, from 1979 to 1997, increases in HZ incidence of 35% and 21% have been described in Canada and England, respectively (Brisson *et al.*, 2001).

Dermatomal distribution

Most studies report no laterality to the HZ rash with both the right and left sides affected equally. The rash affects mainly one dermatome with the thoracic, cervical, lumbar, and cranial dermatomes accounting for over 90% of the dermatomes affected (di Luzio Paparatti *et al.*, 1999; Guess *et al.*, 1985; Hope-Simpson, 1965; McGregor, 1957; Petursson *et al.*, 1998; Ragozzino *et al.*, 1982). Hope-Simpson noted that the HZ rash distribution correlates with the distribution of the varicella rash that follows a centripetal distribution. The rash affects mostly the trunk (thoracic 50%), and face (cranial 13%) with similar percentages for the cervical (14%) and lumbar (13%) regions, and spares the limbs. Similar findings were reported for HZ rashes in children (Guess *et al.*, 1985; Takayama *et al.*, 2000).

Incidence

Age

It is estimated that about 10%–30% of people will get HZ during their lifetime, resulting in about 300 000–900 000 cases of HZ in the US, and 260 000 cases in the UK each year (Brisson *et al.*, 2001; Schmader, 2001). The incidence of HZ varies markedly in published studies. The total population incidence of HZ, unadjusted for age differences between populations, ranges from 1.3 to 4.8 per 1000 person–years (Table 40.3) (Chidiac *et al.*, 2001; McGregor, 1957; Ragozzino *et al.*, 1982). The differences in the rates observed across studies may be due to differences in the methods used for ascertainment of cases, case definitions, determination of population at risk, health systems capturing cases, and age distribution of population studied (that may be skewed or not reflective of the overall population) rather than to true population differences. In a prospective cohort study of all patients in his general practice in Cirencester, UK from 1947–1962, Hope-Simpson reported an annual incidence rate of 3.4 per 1000 person–years (Hope-Simpson, 1965). Much lower incidence rates were found in a community-based study in the US in which cases were identified retrospectively from medical records in a central diagnosis system that included all providers in the community (Ragozzino *et al.*, 1982). The denominator included the population of Rochester, Minnesota, obtained from census data. Other studies used well defined populations for denominators such as enrollees in a health plan in Massachusetts (Donahue *et al.*, 1995), attendants at general practices in Scotland (McGregor, 1957), England, (Hope-Simpson, 1965), and Italy (di Luzio Paparatti *et al.*, 1999). The study in France (Chidiac *et al.*, 2001) was a prospective study that did not include cases from pediatricians or from residents in institutions, and used the population from the census for the denominator. Therefore, it is important to adjust rates of studies that report age-specific incidence to a standard population for comparison purposes. The

Table 40.3. Herpes zoster age-specific and total incidence, selected studies

Country, author, publication year	Study method and population	Number of cases	Years data collection	Age (years)								Annual total zoster incidence/ 1000 population

differences in incidence rates for two studies (Donahue *et al.*, 1995; Hope-Simpson, 1965) narrowed from 2.1 and 3.4 per 1000 person–years respectively to 3.2 and 3.3 per 1000 person–years as a result of adjusting the crude rated to the 2000 US population, highlighting the need for such adjustments before comparing rates between studies.

The majority of studies report that a small proportion of persons infected with HZ may experience a second or a third episode. Hope-Simpson (1965) reported that the rate of second or more infections in persons previously infected is similar to that of first infection in the general population with 8 (4.1%) of 192 cases reporting a second episode, and one person a third episode, resulting in a rate of 3.1 per 1000 person–years. These findings were supported by other studies with recurrence ranging from 1.7%–5.2% (Donahue *et al.*, 1995; Ragozzino *et al.*, 1982; Wilson, 1982). A much higher recurrence rate of 45% was reported in one English study in persons with a first infection occurring over the age of 45 years (Edmunds *et al.*, 2001).

All published studies report that the incidence of HZ increases with increasing age (Brisson *et al.*, 2001; Chidiac *et al.*, 2001; Donahue *et al.*, 1995; McGregor, 1957; Hope-Simpson, 1965; Ragozzino *et al.*, 1982; Opstelten *et al.*, 2002) (Table 40.3). Most studies report an approximately 10 fold increase in risk with increasing age; Hope-Simpson reported incidence increasing from 0.74 among children less than 10 years of age to 10.1 per 1000 person–years among individuals aged 80–89 years. This marked increase in incidence with age results in up to 50% of people who live to 85 years acquiring HZ (Brisson *et al.*, 2001; Schmader, 2001).

Because children may not have acquired varicella and therefore may not yet be at risk for reactivation of VZV, the incidence of HZ also depends on varicella epidemiology. Therefore, comparison of HZ incidence rates in children need to take into account both the age distribution of children in the studies and the age-specific incidence of varicella which may vary across populations. Hope-Simpson, 40 years ago, speculated that the increase in HZ incidence in persons 0–20 years reflected the increase in the number of children infected with VZV, placing them at risk for HZ. He suggested that the incidence observed in the third decade, by which time almost everyone in temperate climates is latently infected with VZV, reflects the incidence in a maximally infected population. Studies of HZ in children report annual incidence rates ranging from 0.25 to 1.15 per 1000 population for children <10 years and from 0.43 to 1.60 for those <20 years (Chidiac *et al.*, 2001; Guess *et al.*, 1985; Hope-Simpson, 1965; Petursson *et al.*, 1998) (Table 40.3). Other studies used different age groups such as <5, and 5–14 years, or <14 years making comparison between studies difficult (Brisson *et al.*, 2001; Donahue *et al.*, 1995; McGregor, 1957; Ragozzino *et al.*, 1982). Guess *et al.* (1985) in Rochester, Minnesota, during the period 1960–1981, reported that the incidence of HZ increased with age from 0.20 cases per 1000 person–years in children less than 5 years of age to 0.63 cases per 1000 person–years in those 15 to 19 years of age. In contrast, Petursson *et al.* (1998) in Iceland, during 1990–1996, reported rates that ranged from 0.80 per 1000 person-years in children less than 5 years to 1.80 in those 15–19 years of age (Table 40.3). These four fold differences in rates of HZ in children in narrow (5 year) age groupings are more likely to signify differences in study methods including completeness of ascertainment than differences between populations (Guess *et al.*, 1985; Petursson *et al.*, 1998). Further studies to understand such differences are needed. Maternal varicella during pregnancy and varicella or variable exposure during the first few months of life are associated with HZ in childhood.

Sex

The majority of studies among all ages or among the elderly find no significant differences between males and females in crude or age-adjusted HZ incidence (Brisson *et al.*, 2001; Donahue *et al.*, 1995; Guess *et al.*, 1985; MacIntyre *et al.*, 2003; Wilson, 1986; Petursson *et al.*, 1998; Ragozzino *et al.*, 1982; Schmader *et al.*, 1995), while some studies report slight differences in rates between males and females (di Luzio Paparatti *et al.*, 1999; Hope-Simpson, 1965; McGregor, 1957), and others report higher rates among females (Chant *et al.*, 1998; Chidiac *et al.*, 2001; Cooper, 1987; Thomas and Hall, 2004). Wilson (1986) found that younger males 0–20 years had a higher incidence when compared to females of the same age. One study in the US found that females had a higher crude hospitalization rate of 18.5 compared to 13.4 among males; however, once age adjusted, the differences disappeared (Lin and Hadler, 2000). Although a study from Australia reported a 2.2 times higher HZ mortality rate among females (0.092 per 100 000) compared to males (0.043); these rates were not age adjusted and may be affected by the longer life expectancy in females (Chant *et al.*, 1998).

Race

The effect of race on incidence of HZ has been studied mainly by Schmader in the United States. In several studies among elderly racially diverse populations in North Carolina, blacks had a significantly lower lifetime occurrence and annual incidence of HZ than whites. In a community-based study among persons >64 years old in North Carolina, Schmader *et al.* (1995) reported that 16.1% of elderly white persons reported HZ compared with only 4.5% of elderly blacks ($P < 0.0001$). Even after controlling for age,

cancer, and demographic factors, blacks were 4 times less likely than whites to have experienced HZ (adjusted odds ratio (aOR), 0.25, 95% Confidence Interval (CI), 0.18–0.35). In a follow-up prospective study in the same community between 1989 and 1994, Schmader *et al.* (1998) reported that after controlling for age, sex, education, cancer, other chronic diseases, hospitalization, activities of daily living, self-rated health, depression, and cigarette smoking, black individuals were a little over a third as likely to develop HZ than were white individuals (aOR, 0.37; 95% CI, 0.26, 0.53; $P = 0.0001$). Hypothesized reasons for the lower risk of HZ among elderly blacks include age at onset of varicella, racial differences in VZV immunity, and lifetime exposures to varicella (Schmader, 2000). Thomas and Hall (2004), in a recent analysis of Morbidity Statistics from General Practice (MSGP) studies in the UK, have corroborated these findings with black adults having less than half the risk of HZ after adjusting for age, sex and country of birth (risk ratio (RR), 0.46, 95% CI, 0.21–0.97). However, in this analysis, the protective effect for blacks was not associated with household exposure to children.

Stress

Few studies have examined the effect of psychological stress on risk of HZ although there are case reports of HZ occurring after a stressful event. Schmader has studied psychological stress as a risk factor for HZ (Schmader *et al.* (1990). In a community-based case control study where HZ cases were matched for age, sex, and race, he reported that psychologically stressful life events were risk factors for HZ. Cases experienced negative life events significantly more often than controls 2 months before (OR, 2.60, 95% CI, 1.13, 6.27), 3 months before (OR, 2.64, 95% CI, 1.20, 6.04), or 6 months before HZ onset (OR, 2.00, 95% CI, 1.04, 3.93). Cases were more likely to perceive recent events as stressful compared to controls. In a prospective study where recall bias was not an issue, stressful life events increased the risk of HZ but the result was borderline for statistical significance (aOR, 1.38; 95% CI, 0.96–1.97) (Schmader *et al.*, 1998).

Age of varicella infection

Some researchers have speculated that the lower risk of HZ among elderly black adults may be due to later age of acquisition of varicella. Thomas and Hall (2004) attempted to address this question for adults born in tropical climates where age of varicella infections are later than in temperate climates. Persons born in countries described as having stronger evidence of late-onset varicella (the Caribbean, Central America, India, Pakistan, Sri Lanka, Bangladesh, Singapore and Malaysia), had a lower risk of HZ compared with adults born in the UK after adjusting for age and sex (RR, 0.56, 95% CI 0.28–1.12, $P = 0.072$) although these differences were not statistically significant (Thomas and Hall, 2004). Additional studies are needed to verify that this is due to age at varicella infection and not other factors related to country of birth or migration.

Exposure to varicella

Hope-Simpson first speculated that immunity to VZV may be maintained by periodic internal reactivation of VZV, external boosting of immunity through exposures to varicella or HZ or both. A number of studies have either directly or indirectly examined the role of contacts with varicella in both immunocompromised and healthy populations. Garnett and Grenfell (1992) examined weekly reported data in a time series analysis and reported no association between varicella and HZ although they reported some correlation with the annual data for some age groups. Three other studies suggest that contact with varicella cases appear to lower the risk of HZ in adults (Solomon *et al.*, 1998; Terada *et al.*, 1995; Thomas *et al.*, 2002). However, the level of exposure reported to affect herpes zoster in the above studies is unlikely to occur for most of the population. Two analyses reported that exposure to children was associated with a lower HZ risk (Brisson *et al.*, 2001; Thomas and Hall, 2004). A detailed discussion of this topic is presented in the "Impact of vaccination" section below.

Immunocompromising states

Herpes zoster is more common among individuals with depressed cell-mediated immunity from immunosuppressive disorders including cancer, especially hematological cancers (certain leukemias and lymphomas), HIV infection and transplants, and from immunosuppressive medications. A higher proportion of persons with HZ are immunosuppressed compared to the general population (Ragozzino *et al.*, 1982; Guess *et al.*, 1985; Rusthoven, 1994; Donahue *et al.*, 1995; Lin and Hadler, 2001). Guinee *et al.* (1985) conducted a retrospective cohort study of HZ from six cancer centers over a 3-year period. The cumulative incidence of HZ in the 717 patients identified with Hodgkin's disease was 9.5% after 1 year, 16.6% after 2 years and 20.6% after 3 years. To further study this issue, in a large prospective study in Canada of HZ in cancer patients >15 years of age with a minimum of 5 years of follow-up, Rusthoven *et al.* (1988) found that the cumulative incidence rate of HZ 5 years after diagnosis was highest in hematological malignancies (14% in Hodgkin's disease, 10% in leukemia and 5% in non-Hodgkin's lymphoma) compared with solid tumors (breast 2%, lung 2%, and gynecological malignancies 1%). These differences were not due to age; in fact the median age of HZ patients with hematological malignancies was younger (51 years) than patients

with solid tumors (59 years, $P < 0.005$). The finding of the highest risk of HZ in patients with Hodgkin's disease has been reported by other investigators in both pediatric and adult populations (Rusthoven, 1994; Schmader, 2000). Persons with cancers of any kind have an increased HZ risk with the administration of chemotherapy and radiation (Rusthoven, 1994). Feld *et al.* (1980) reported that 13 (8.1%) of patients with small-cell anaplastic carcinoma of the lung treated with chemotherapy and radiation developed HZ.

Persons with HIV infection also have a higher risk of incident and recurrent HZ although the risks are more comparable to solid tumors than hematological malignancies. Studies from the US, the Netherlands, Australia and Uganda that have compared rates of HZ in HIV-positive and HIV-negative persons have described 12–17 times higher risk among HIV-positive persons (Buchbinder *et al.*, 1992; McNulty *et al.*, 1997; Morgan *et al.*, 2001; Veenstra *et al.*, 1996). Incidence rates among HIV-positive persons varied in the above studies from 29.4 cases to 51.5 per 1000 person–years. Recurrence rates also varied according to the length of follow up, ranging from 10% to 25.6% (Morgan *et al.*, 2001; Veenstra *et al.*, 1996). In the Ugandan study, the incidence of HZ increased with increasing time since seroconversion to HIV + status from 7.6% at 2 years to 24.0% at 6 years. Differences in rates across studies in HIV+ populations may relate to differences in immune status and viral load because of differences in availability of effective treatment.

Persons who undergo allogeneic or autologous bone marrow transplant (BMT) experience a high risk of HZ, soon after the procedure. A variety of studies in different countries have reported this risk to range from 17%–52% (Locksley *et al.*, 1985; Nader *et al.*, 1995; Rusthoven, 1994; Schuchter *et al.*, 1989; Tzeng et al., 1995). The risk is highest in the months immediately following the procedure; the majority of HZ cases occur within a year of transplantation. Schuchter reported that 28% of 151 autologus BMT patients developed HZ after the procedure, and that 91% of the cases occurred within the first year; these findings were supported by another study in which 82% of the HZ cases occurred within the first year following BMT (Tzeng *et al.*, 1995).

Complications

Herpes zoster may lead to complications such as persistent pain (postherpetic neuralgia), bacterial infection of the lesions, pneumonia, encephalitis, and hemorrhagic complications. A number of risk factors have been found to be associated with complications, the most important of which are older age and immunosuppression. Persons >64 years have about eight times the risk of complications compared to those <25 years (Galil *et al.*, 1997). Other factors include trigeminal distribution of the HZ rash, involvement of more than one dermatome (di Luzio Paparatti *et al.*, 1999; Galil *et al.*, 1997), severe pain, rash or prodromal symptoms at HZ presentation (Choo *et al.*, 1997; Dworkin *et al.*, 2001; Nagasako *et al.*, 2002; Whitley *et al.*, 1998), persisting abnormal sensations in the affected dermatome (Decroix *et al.*, 2000) and scarring, presumed to be a consequence of rash severity (Battcock *et al.*, 1990; Bowsher, 1999). Patients who presented with severe or incapacitating pain and a large number of lesions were 18 times less likely to achieve resolution of both acute neuritis and HZ-associated pain (Whitley *et al.*, 1999).

Postherpetic neuralgia (PHN), a chronic pain syndrome, is the most common complication of HZ (Johnson, 2002; Lojeski and Stevens, 2000; Ragozzino *et al.*, 1982; Stankus *et al.*, 2000). The variability in the intensity and duration of the pain has made it complicated for researchers to agree on a standard definition making it difficult to compare results across studies. Studies have variously defined onset of PHN at rash onset or rash resolution. Study end points vary from 1, 3, 6 and 12 months after rash onset or resolution. At one month past rash onset, reported proportions of persons with PHN range from 6.5% to 45% (Haanpaa *et al.*, 2000; Opstelten *et al.*, 2002), at 3 months, the range is from 7.2% to 25% (Haanpaa *et al.*, 2000; Helgason *et al.*, 2000), and at 12 months, 3.4% to 10% (Bowsher, 1999; Helgason *et al.*, 2000). The varying proportions in PHN at the different time periods may be affected by several factors including age and percent of immunosuppressed in the population under study.

The risk of PHN increases with increasing age although the magnitude of the effect varies across studies. PHN is more common among adults older than 50 years (Bowsher, 1999; Decroix *et al.*, 2000; di Luzio Paparatti *et al.*, 1999; Dworkin *et al.*, 2001). It is estimated that about 27–68% of HZ cases over 60 years of age experience PHN (Dworkin *et al.*, 2001; Kurokawa *et al.*, 2002). In an Iceland study, older age was a significant and independent predictor of PHN; persons 55–74 years were 4.2 times more likely to develop PHN one month after rash onset compared to those younger than 55 years; while those over 75 years of age were 10.7 more likely to develop PHN (Opstelten *et al.*, 2002). An even stronger association with older age was reported in a U.S. study where age ≥50 years compared to age <50 years was associated with a 14.7-fold higher prevalence of PHN at 1 month and a 27.4-fold higher prevalence at 2 months after developing HZ (Choo *et al.*, 1997). Finally, in Singapore, Goh and Khoo (1997) reported that 20% of patients

older than 50 years suffered from PHN compared to 7% of persons less than 30 years of age. Some of the difference in magnitude of the effect of older age on PHN may be due to the fact that baseline comparison groups used in the above studies differed. Furthermore, some studies controlled for other risk factors (Choo *et al.*, 1997; Opstelten *et al.*, 2002) while others did not (Goh and Khoo, 1997).

Herpes zoster hospitalizations and complications in healthy children are rare. Guess *et al.* (1985) found low morbidity among children compared to adults. Among 173 HZ cases in person <20 years of age, there were no occurrences of post-herpetic neuralgia or other late complications and only 2 (1%) were hospitalized. Furthermore, in Iceland, none of the 112 (118 episodes) cases <20 years of age developed moderate or severe pain during the acute illness or postherpetic neuralgia (95% CI, 0 to 0.03) (Petursson *et al.*, 1998).

Hospitalizations

Fewer population-based data are available on HZ hospitalizations and no studies report hospitalization rates that are adjusted for age and high risk conditions. As with HZ incidence, the hospitalization rates increase with increasing age and high rates are seen in persons with suppressed immune systems. In the US, statewide hospital discharge data from Connecticut from 1986–1995 showed an annual crude HZ hospitalization rate of 16.1 per 100 000 person years (Lin and Hadler, 2000). A much lower crude incidence rate was observed in Northern California (2.1 per 100 000 health maintenance organization members) (Coplan *et al.*, 2001), and an intermediate rate of 4.4 per 100 000 was reported in England for 1995 to 1996 (Brisson and Edmunds, 2003). However, because the Connecticut study included all HZ diagnoses rather than HZ as the primary discharge diagnosis, hospitalization rates may have been over-estimated by including individuals with coincidental HZ (Lin and Hadler, 2000). In this study, 31.4% of all hospitalized HZ cases and the majority of HZ hospitalizations among person <50 years of age (61%) had at least one underlying condition that increased the risk or severity of HZ; the majority of these were immunocompromising conditions (82% malignancies, and 8% HIV infection). In contrast, only 8% of the HZ hospitalized cases in England had at least one underlying condition; malignancies accounted for 87% and HIV infection for 6% of the conditions listed (Brisson and Edmunds, 2003). Finally, 67% of the hospitalized cases in the Connecticut study were 64 years or older, while only 55% of those in the California study were 60 years or older emphasizing the importance of age adjustment when comparing studies.

The rates of HZ hospitalizations increase sharply among the elderly (Chant *et al.*, 1998; Coplan *et al.*, 2001; Lin and Hadler, 2000). In one US study, HZ hospitalization rates increased from 21.3 per 100 000 populations among individuals <30 years of age to 1604.5 per 100 000 among those 85 years of age or older. The steepest increase in rates occurred among those over 64 years of age (Lin and Hadler, 2000). Similar patterns are seen in other studies and other countries with hospitalization rates increasing after age 50 or 60 years though rates vary across studies (Brisson *et al.*, 2001; Brisson and Edmunds, 2003; MacIntyre *et al.*, 2003). In Australia, HZ hospitalization remained stable at about 25 per 100 000 populations among persons <60 years of age, then increased from about 50 per 100 000 for the 60–64 age groups to over 300 for the persons 85 years and older (MacIntyre *et al.*, 2003). In England and Canada, HZ hospitalization rates increased from 2 and 1 per 100 000 population in children aged <5 years to 148 and 86 in adults older than 64 years of age, respectively (Brisson *et al.*, 2001).

Some studies of HZ hospitalization did not report rates. In Singapore, between 1993 and 1994, HZ accounted for 3% of total hospitalizations with a mean age of 50 years (range 23 months to 88 years); 58% of HZ hospitalizations were older than 50 years of age (Oh *et al.* 1997). In contrast, HZ hospitalization in Australia accounted for 0.08% of all hospitalizations between 1998 and 1999 with a mean age of 69 years and 53% were older than 50 years (MacIntyre *et al.*, 2003). Chant *et al.* (1998) reported that more women in Australia than men were hospitalized for HZ (ratio of women to men was 1.4:–1.6:1), while Oh *et al.* (1997) reported no sex differences in hospitalization in Singapore.

Deaths

Studies on HZ mortality are few and study methods may not be comparable. As with incidence, hospitalizations, and complications, HZ mortality is more common among the elderly and those with suppressed immune systems. Schmader (2000) surmized based on clinical experience and the absence of HZ-related deaths in cohort studies, that HZ mortality appears to be an infrequent event at least among healthy persons. In Australia during 1971–1993, Chant *et al.* (1998) reported that 92% of HZ deaths per year occurred among persons older than 65 years. The average crude death rate for the study period was 0.068 per 100 000 population and was 10 times higher for the elderly >65 years (mortality rate 0.60). Females had more than double the rate of death compared to males however these crude mortality rates are not age adjusted (Chant *et al.*, 1998). In Lin's study in the US, 5.3% of all HZ-related hospitalizations resulted in death and about 52% of those who

died had at least one underlying high risk condition, including malignancies; leukemia, and HIV. The risk of death was higher for those with underlying high risk conditions (8.7%) than for those without any high risk conditions (3.7%). In a more recent study in Australia, 4% of 4718 hospitalized for HZ died; however, death was much less common in the group with primary HZ hospitalization (1%) compared to the group with HZ as the secondary diagnosis for hospitalization (6%) (MacIntyre *et al.*, 2003). Finally, in a study in England and Wales from 1993 to 2000, the overall HZ mortality rate was 0.094 per 100 000 person–years however, the number of HZ deaths decreased from 64 in 1993–1994 to 40 in 1999–2000 (Brisson and Edmunds, 2003). The risk of death was <0.014 per 100 000 person–years in persons aged <64 years then increased sharply to 0.566 for persons older than 64 years. Finally, similar results were observed for case fatality ranging from <2 per 100 000 HZ cases in persons <65 years of age to 61 per 100 000 HZ cases in persons older than 64 years of age (Brisson and Edmunds, 2003).

Impact of vaccination

The impact of child and adult vaccination against VZV on the incidence of HZ and PHN remains to be determined. In the US, where there are 9 years of experience with a universal varicella vaccination program, varicella incidence, hospitalizations, and mortality have declined dramatically (Seward *et al.*, 2002; Nguyen *et al.*, 2005; Zhou, 2005). In a study using data from a large Health Maintenance Organization, there was no change in the overall or age-specific incidence of HZ between 1992 and 2002 in an area with about 70% varicella vaccination coverage and a decline in varicella disease that started in 1999 (Jumaan *et al.*, 2005). Survey data from 2000 onwards from Massachusetts show an increase in herpes zoster (Yih *et al.*, 2005).

In 1965, Hope-Simpson hypothesized that the long interval observed between the infection with varicella disease, resulting in the establishment of the latent virus, and the reactivation to cause HZ may be due to internal and external boosting. The external boosting hypothesis, suggesting the need for frequent exposures to VZV to maintain immunity against reactivation of the latent virus has attracted attention, especially with the licensure of the varicella vaccine. Some researchers have speculated that a universal varicella vaccination program, with its associated decline in varicella disease, may have the unintended effect of increasing the incidence of HZ. They note that the decline in varicella disease due to the vaccination program leads to fewer opportunities for persons with a latent virus to boost their immunity through exposure to children with wild-type VZV infection.

Modeling the impact of universal varicella vaccination predicts an initial increase in the incidence of HZ that will occur within 50 years until HZ declines as vaccinated cohorts replace those with a history of varicella disease (Brisson *et al.*, 2002; Garnett and Ferguson, 1996). Although the incidence of HZ is much lower than that of varicella, some studies suggest that the health burden due to HZ is greater than that due to varicella because of the higher rates of complications, hospitalizations and deaths (Lin and Hadler, 2000; Brisson and Edmunds, 2003; Chant *et al.*, 1998; MacIntyre *et al.*, 2003). This has been raised as a serious potential concern in other developed countries considering a varicella vaccination program. However, the health burden on HZ may be overestimated. In a study in England, varicella and HZ hospitalization rates were similar at 4.5 and 4.4 per 100 000 population, respectively (Brisson and Edmunds, 2003). Furthermore, in another study in England and Canada, the reported age specific proportion of cases hospitalized and in-patient days hospitalized were only slightly higher for HZ compared to varicella (Brisson *et al.*, 2001). However, because HZ occurs mainly in the elderly compared to varicella, the overall burden on in-patient hospitalization for HZ is reported to be considerably higher (Brisson *et al.*, 2001; Brisson and Edmunds, 2003; MacIntyre, 2003). In a US study of HZ hospitalizations, the authors did not differentiate between primary vs coincidental cause of HZ hospitalization or death (Lin and Hadler, 2000). Coincidental cases of HZ may be quite common especially among elderly hospitalized adults with long hospital stays, some of whom will die from other causes (MacIntyre *et al.*, 2003). This may contribute to overestimation of the health burden due to HZ.

Several studies reported lower HZ rates among persons exposed to varicella cases (Solomon *et al.*, 1998; Terada *et al.*, 1995; Thomas *et al.*, 2002), compared to those without any exposure. Thomas showed that contacts with ≥5 varicella cases were associated with a strong protective effect against HZ after controlling for occupational and social (OR = 0.29, 95% CI 0.10–0.8) compared to those with no contacts. The two other smaller studies with methodological limitations reported that pediatricians had lower HZ incidence than the general population (Terada *et al.*, 1995), and dermatologists or psychiatrists (Solomon *et al.*, 1998). Terada based his findings on small numbers of cases; while Solomon's findings were based on low response rates (31% paediatricians) and found no differences between dermatologists and psychiatrists, groups considered to have different rates of exposure to varicella cases. Finally, in all three studies, protection was observed for groups with more exposure to varicella than is generally experienced by the general population.

Other studies have used exposure to children as a proxy for exposure to varicella. Two observational studies in England reported that household or occupational exposure to children was associated with a lower HZ incidence (Brisson *et al.*, 2002; Thomas and Hall, 2004). Brisson reported that people living with children had a significantly lower rate of developing HZ (RR, 0.75 95% CI 0.63–0.89). In a subsequent analysis of the same data, Thomas reported that individuals who reported working with young children (primary school teachers, nursery nurses, playgroup leaders and other child care providers) were significantly less likely to develop HZ after adjusting for age, sex, ethnicity and a child living in the household (RR, 0.70, 95% CI 0.58–0.85). However, it is not clear how other factors that could have contributed to such findings were adjusted for in the analysis including the fact that people with other medical health problems, who are at a higher risk for HZ, are less likely to live with children. Furthermore, Thomas and Hall (2004) in their review of risk factors for HZ report that women in general have higher incidence rates of HZ compared to males; they comment that these findings conflict with the suggested reduced HZ risk associated with exposure to varicella cases or children.

The protection against HZ due to varicella exposure is plausible and is supported by immunologic studies. One reported that 71% of adults who had household exposure to varicella experienced a boost in cellular immune responses (Arvin *et al.*, 1983), and the other found that vaccinated leukemic children with household exposure to varicella were less likely to develop HZ than vaccinated leukemic children without such an exposure (Gershon *et al.*, 1996; Hardy *et al.*, 1991). Yet, other issues still remain unknown, including factors that contribute to immune boosting, the duration of protection from such exposures, and other factors that influence VZV reactivation. Herpes zoster affects mainly the elderly, and if there is a protection from exposure to varicella, the duration of this protection is not known. However, modeling, based on the assumption that the boosting effect lasts for 20 years, suggests that an increase in HZ incidence will occur as early as five (Garnett and Ferguson, 1996) to seven (Brisson *et al.*, 2002) years following the implementation of a mass vaccination program.

Herpes zoster in vaccinated children

Current data suggest that vaccinated children experience a lower HZ incidence rate than those who have had wild varicella. Herpes zoster incidence among healthy children who received varicella vaccine is reported to be rare; the incidence of HZ among these children was reported to be approximately 13 cases per 100 000 person–years (Gershon *et al.*, 2004*)* however, longer follow-up is needed. Furthermore, studies in leukemic children have found a much lower incidence of HZ among vaccinated (2%) than among age matched children with a history of varicella (15%) (Hardy *et al.*,1991). Therefore, it is expected that HZ incidence will decline over the long term, as vaccinated cohorts replace those in the community with naturally acquired varicella.

Vaccination for prevention of herpes zoster

As populations age and the survival of people with chronic and immunocompromised conditions improves, the incidence of HZ and PHN is expected to increase. Several studies have suggested that declines in VZV-specific CMI increase the risk and severity of HZ (Arvin 1996; Miller, 1980; Oxman, 1995). Early studies on administration of a higher titer varicella vaccine to older adults 55+ have shown that vaccinated persons experience an increased VZV-specific CMI responses to levels typical of those observed in younger persons, in whom the incidence and severity of HZ are lower (Levin *et al.*, 1998; Levin, 2001). A recent study reported on the boosting in VZV-specific cell-mediated immunity from a booster dose of VZV vaccine administered ≥5 years after the first dose (Levin *et al.*, 2003). In 2005, the results of a large placebo-controlled clinical trial to test whether a shingles vaccine in persons 60 years and older would prevent or reduce the risk or severity of HZ and its complications became available. The vaccine was 51.3% efficacious in reducing herpes zoster incidence, 66.6% efficacious in reducing the incidence of postherpetix neuralgia (largely through preventing herpes zoster) and 61.1% efficacious in reducing the burden of illness due to herpes zoster (Oxman *et al.*, 2005). This vaccine, now licensed in the USA with expected licensure in other countries, has the potential to reduce the incidence of HZ or reduce/attenuate the severity of PHN, and complications of HZ. (Johnson *et al.*, 2002; Schmader, 2001; Gilden, 2005). In the U.S. Zoster vaccine was recommended for use in all adults ≥60 years without a contraindication in October 2006 (CDC, 2006).

Part III

Pathogenesis, clinical disease, host response, and epidemiology: betaherpesviruses

Edited by Ann Arvin and Richard Whitley

41

Virus entry into host, establishment of infection, spread in host, mechanisms of tissue damage

William Britt

Department of Pediatrics, University of Alabama at Birmingham, AL, USA

Introduction

Cytomegaloviruses (CMV) were initially identified by distinct histopathological findings that were observed in tissue from a variety of infected mammals, including humans. Perhaps the most well-recognized finding were inclusion bearing cells in the salivary glands of infected animals (Jesionek and Kiolemenoglou, 1904; Ribbert, 1904; Goodpasture and Talbot, 1921; Cole and Kuttner, 1926). Similar histopathologic findings of intracellular inclusions were noted in tissues from infants dying as a result of severe congenital (present at birth) cytomegalovirus infection leading to the designation of this clinical syndrome as cytomegalic inclusion disease (Farber and Wolbach, 1932). Studies by several groups of investigators provided compelling evidence from natural history studies that HCMV was a relatively frequent cause of disease in infants infected in utero and, that this viral infection could result in neurologic impairment in infected infants (Hanshaw, 1971; Stagno *et al.*, 1977; Pass *et al.*, 1980; Williamson *et al.*, 1982; Bale, 1984; Fowler *et al.*, 1992). Importantly, these early studies demonstrated that even infants with subclinical or silent infections could develop neurological sequelae (Stagno *et al.*, 1982, 1983; Williamson *et al.*, 1992). In the late 1960s, HCMV was recognized as a significant cause of disease in allograft recipients and in the case of hematopoietic allograft recipients, HCMV infection became recognized as one of the most frequent causes of death in the post-transplant period (Rifkind, 1965; Myers *et al.*, 1975; Ho, 1977; Rubin *et al.*, 1979; Winston *et al.*, 1979; Rubin *et al.*, 1981; Rubin and Colvin, 1986; Rubin, 1990). Significant morbidity and mortality rates were reported in allograft recipients infected with HCMV until efficacious antiviral chemotherapy was developed for this agent (Emanuel *et al.*, 1988; Schmidt *et al.*, 1991; Goodrich *et al.*, 1993; Winston *et al.*, 1993). Similarly, HCMV rapidly emerged as a major opportunistic pathogen in patients with HIV infection, particularly those in the late stages of the retroviral infection (Klatt and Shibata, 1988; Gallant *et al.*, 1992; Bowen *et al.*, 1995; Selik *et al.*, 1996; Spector *et al.*, 1999). The spectrum of diseases associated with infection with HCMV has been well described in immunocompromised patients with acute infectious syndromes in which virus replication can be correlated with end-organ disease. Because immunocompromised patients often present with multiorgan dysfunction secondary to chronic underlying disease and in some cases the pharmacologic agents utilized to treat allograft rejection, it has been difficult to completely define the spectrum of clinical disease associated with HCMV infection. In contrast to findings in allograft recipients, the disease manifestations of congenitally (present at birth) infected infants can be related directly to HCMV infection. Yet even in this group of patients the contribution of organogenesis particularly that of the developing central nervous system, to the pathogenesis of disease in HCMV infected infants is not completely understood. As a result, it is sometimes difficult to directly translate the clinical features of congenital HCMV infections and end-organ disease to clinical syndromes observed in other patient populations such as allograft recipients. Lastly, it should be stressed that, in nearly all cases, symptomatic disease following acute HCMV infection is limited to patients with deficits in their immune system and clinical evidence of acute HCMV infection is rarely seen in normal hosts.

In contrast to the obvious role of HCMV in acute infectious syndromes in immunocompromised hosts, the role of this agent in chronic disease syndromes remains controversial even after decades of study. Early studies suggested a role of HCMV in several chronic diseases that are more prevalent in middle-aged and older individuals such as coronary atherosclerosis (Petrie *et al.*, 1988). In addition, epidemiological studies have suggested a link

between infection with HCMV and human cancers (Rapp and Robbins, 1984; Shen *et al.*, 1993; Hsieh *et al.*, 1999). More recent studies have provided convincing evidence for a role of HCMV in the accelerated vascular disease that is observed in solid organ allograft recipients, a disease process that may represent the extreme of the spectrum of HCMV-induced vascular disease (Grattan *et al.*, 1989; Melnick *et al.*, 1993; Epstein *et al.*, 1996; Zhu *et al.*, 1999). Recent studies have also demonstrated HCMV nucleic acids and viral proteins in human cancers, providing provocative evidence for a potential role of this virus in malignant behavior of at least some human tumors (Geder *et al.*, 1977; Shen *et al.*, 1993; Cobbs *et al.*, 2002; Harkins *et al.*, 2002). The life-long persistence of the virus in the infected host, the ubiquitous nature of the infection in the population, and the recently recognized disruption of normal host cellular functions suggests that careful investigations into the role of this virus in chronic diseases should remain a major focus of research in diseases associated with HCMV infection.

Acquisition of HCMV: Sources of virus and transmission within populations

Human CMV infection, as defined by serological evidence of previous infection, is ubiquitous in most populations with HCMV seroprevalence ranging from 20%–100% in different regions of the world (Alford *et al.*, 1981; Krech and Tobin, 1981; Gold and Nankervis, 1982). In general, individuals from resource constrained countries have an increased HCMV seroprevalence and studies from sub-Saharan Africa, South America, and India have suggested that by early adulthood nearly 100% of individuals have been infected with HCMV (Alford *et al.*, 1981). In contrast, in well-developed countries in Northern Europe and North America, the seroprevalence can range from 20%–100% in adults. Seroprevalence studies in the United States, Great Britain, Italy, and Scandinavia have provided clues as to routes of virus acquisition and sources of exposure in the community (Weller, 1971). Similarly, careful epidemiological studies aided by genetic analysis of virus isolates have helped define sources of virus infection in young children attending child-care centers, hospitalized patients and hospital staff.

Sources of HCMV in the community

Infectious virus has been recovered from saliva, tears, breast milk, semen, blood products, urine, and cervical secretions. With the exception of blood products, persistent virus infection of epithelial cells in secretory glands remains a constant theme for HCMV infection. Although the phenomena of virus persistence in the salivary glands of small animal models of the HCMV infection have been intensively studied, mechanisms leading persistence of the virus in epithelial cells of apacrine glandular tissue remain incompletely described. Similarly, the question of latency with abortive virus replication vs. a chronic persistent productive infection in these tissues has not been resolved. Studies in animal models and in vitro cell culture system indicate that latent infection can occur, yet these findings have been validated in only limited types of human cells (Jordan and Mar, 1982; Jordan *et al.*, 1982; Kondo *et al.*, 1996; Sinclair and Sissons, 1996; Kurz *et al.*, 1997; Soderberg-Naucler *et al.*, 1997; Hahn *et al.*, 1998; Kurz *et al.*, 1999; Goodrum *et al.*, 2002). Regardless of whether the virus is maintained as a latent infection with periodic reactivation or as a chronic persistent infection yielding low titers of infectivity, the virus readily spreads within a population. Characteristics of HCMV infection such as prolonged virus shedding that may last for over 6 months in some individuals with acute HCMV infection favor spread within susceptible populations. In young infants, HCMV infection acquired in the perinatal period or even during infancy can result in the virus excretion lasting several years (Stagno *et al.*, 1975a,b). Thus, in contrast to periods of communicability for respiratory viruses that are often measured in weeks, acutely infected hosts can remain contagious for months to years after HCMV infection. Although the mechanisms underlying its persistence are far from understood, during its evolution with its human host the virus has developed multiple strategies for persistence in the host and in populations. Persistence in the population has been accomplished without the necessity for a secondary animal reservoir or non-human vectors for transmission.

Although infection with HCMV has been shown to be endemic in all populations studied in the world, transmissibility of the virus has been suggested to be limited based on observations that close contact is required for infection within a population. Even though the efficiency of transmission may be limited either secondary to the liability of the virus or low levels of infectious virus excretion, its persistence favors repeated exposures of susceptible hosts to infectious virus. This is perhaps best illustrated by the finding that in almost all reported studies, acquisition of HCMV serological reactivity increases with age (Alford *et al.*, 1981). In developed countries, primarily Northern Europe and North America, numerous serological studies have been carried out and together with more limited findings in populations from the developing world, have provided some understanding of the sources of HCMV in the community and modes of virus infection. In the developed

Table 41.1. Sources of community-acquired HCMV infections

Source	Infectious fluid	Mode of transmission
Pregnant women	Blood; genital secretions	Blood-borne transmission to Fetus; intrapartum ingestion of infected genital secretions
Lactating women	Breast milk	Ingestion of cell free virus by breast feeding infants
Young children	Saliva; urine	Ingestion
Adolescents/adults	Saliva; genital secretions	Ingestion; sexual contact

Table 41.2. Relationship between age and acquisition of HCMV. Estimated age for >50% seropositivity of population based on published seroprevalence and age

Location	Age at which 50% seropositive
Chile	6 mo–1 yr
Ivory Coast	< 1 yr
Birmingham, Al (low SES)	4–9 yrs
Rochester, NY (high SES)	>28–35 yrs
Tanzania	< 1 yr
India	1 yr
London	> 28–35

From Alford *et al.*, 1981.

world, the variation in the prevalence of HCMV infection has been related to age, child-care practices, sexual activity, and socioeconomic status. These epidemiological associations are consistent with the finding of infectious virus in saliva, tears, breast milk, semen, urine, and cervical secretions (Table 41.1).

Serological evidence of HCMV infection has been used as a measure of exposure to HCMV in different population. Because no specific genetic linkage has been associated with susceptibility or resistance to HCMV infection, it follows that increasing rates of serologic reactivity reflect the relative risk of HCMV exposure of individuals in that population. When HCMV sero-prevalence is compared to age in different populations, it is apparent that near universal seroreactivity in young adults from less developed regions of the world are also associated with early acquisition of HCMV (Table 41.2).

In some parts of the world such as sub-Saharan Africa and southern Asia, nearly 100% of young children are seropositive for HCMV suggesting that exposure to HCMV is universal in these populations (Alford *et al.*, 1981). In contrast, early studies in North America and Northern Europe suggested that between 10–50% of young children were seropositive for HCMV (Alford *et al.*, 1981). Increased rates of serologic evidence of HCMV infection have been noted in children from lower socioeconomic groups in the USA, although these rates do not approach those observed in similarly aged children in the developing world. In addition, increased rates of seropositivity were noted in children from populations in which breast feeding was common and in populations in which group child care was commonly utilized (Weller, 1971). There is no single explanation that accounts for the differences in the age of HCMV acquisition that has been observed in children from Northern Europe and North America and young children from the southern hemisphere. The most frequently offered explanation is that increased rates of infection in Africa and Asia are secondary to near universal breast feeding and possibly to overcrowding in homes with young children (Stagno, 1995a,b). These explanations are consistent at least with observations from child care centers in the USA which have demonstrated an increased rate of virus transmission between children attending child care centers (Pass *et al.*, 1984; CDC, 1985; Hutto *et al.*, 1985; Murph *et al.*, 1986; Adler, 1988; Dobbins *et al.*, 1993). The other component of this explanation is the observed efficient spread of HCMV through breast milk to nursing infants (Stagno *et al.*, 1980; Dworsky *et al.*, 1983a,b; Ahlfors and Ivarsson, 1985; Minamishima *et al.*, 1994; Vochem *et al.*, 1998). Breast milk has been shown to contain significant amounts of infectious virus, much of which is cell free and readily transmitted (Asanuma *et al.*, 1996; Vochem *et al.*, 1998). Studies have documented that over 60% of breast fed infants born to a HCMV infected mother will become infected with HCMV (Stagno *et al.*, 1980; Dworsky *et al.*, 1983). This rate likely underestimates the efficiency of breast milk transmission, particularly in populations in which infants are exclusively breast fed. Because young infants infected following ingestion of infected breast milk excrete significant amounts of virus for extended periods of time, infected infants readily transmit virus to household and community contacts. The rate of breast feeding in countries from the developing world far exceed those in many populations in North America and Northern Europe, particularly when compared to the decreased rates of breast feeding in women from lower socioeconomic groups in the USA. Thus, it is likely that early childhood acquisition of HCMV in populations with high rates of HCMV infection in women of childbearing age can be explained by exposure to virus containing breast milk coupled with crowded living conditions that favor spread

of HCMV among young children and other members of the household.

Young children as a source of HCMV

Young children have also been documented to be an important reservoir of infectious virus in the community. Transmission of HCMV between young children appears to be very efficient, presumably because of frequent physical contact, repeated hand-to-mouth contact, and the limited personal hygiene practices of infants and toddlers (Hutto *et al.*, 1986). The initial speculation by Weller that high rates of infection in Swedish children as compared to infants in New York was secondary to the increased use of group child-care centers in Sweden was subsequently confirmed by a number of studies (Weller, 1971). Studies carried out in child-care facilities in the United States have consistently documented increased rates of HCMV infection in young children, particularly those less than 18 months of age (Table 41.2) (Pass *et al.*, 1984; CDC, 1985; Murph *et al.*, 1986; Pass *et al.*, 1987; Adler, 1991a,b). In a study of a group care center that enrolled infants of middle and upper-middle class parents, the seroprevalence in the infants increased from about 10% in the first year of life to over 80% in the second year of life (Pass *et al.*, 1982a,b). Similar results were reported by Adler *et al.* who also noted that over 50% of initially seronegative infants acquired a day-care related strain of HCMV over a 26-month period as determined by restriction fragment length polymorphism (RFLP) of viral DNA (Adler, 1985). In addition, this study as well as other studies has documented HCMV shedding in 20%–40% young children attending day-care centers (Pass *et al.*, 1987). The ease with which HCMV can be transmitted between young children together with the prolonged duration of virus excretion in infants with congenital and perinatal infections attending child-care centers provides an ideal setting for spread of this virus to young children in group care facilities. Furthermore, infants infected following exposure in child-care centers also excrete significant amounts of virus for extended periods of time, increasing the reservoir of transmissible virus in a group-care setting. Thus, group child-care settings could mimic the exposure of young infants in developing countries in which child-care is often shared among members of the community. The routes of HCMV transmission between children has not been defined but is thought to be primarily through hand-to-mouth contact.

Young children not only readily transmit HCMV to other children but also serve as an important source of HCMV infection of adults (Taber *et al.*, 1985; Pass *et al.*, 1986; Adler, 1988, 1989, 1991; Murph *et al.*, 1991). Early studies utilizing RFLP clearly demonstrated that HCMV could be transmitted from young children to adults (Spector and Spector, 1982; Dworsky *et al.*, 1984). Similarly, several epidemiologic studies related exposure to young children with acquisition of HCMV (Yeager, 1983). These studies have documented increased annualized seroconversion rates in women exposed to young children as compared to women in homes without young children. Later studies included the parents of children attending child-care centers and at least two groups of investigators documented infections in 33%–45% for women whose children were shedding HCMV (Pass *et al.*, 1986; Adler, 1988). Interestingly, the increased rates of virus infection were not limited to the parents of children attending child-care centers but were also noted in workers in child-care centers (Adler, 1989; Pass *et al.*, 1990; Dobbins *et al.*, 1993). An approximate five fold increase in the rate of HCMV infection as measured by seroconversion was noted in one group of women employees at child care centers (Adler, 1989). Analysis by RFLP of DNA from viruses isolated from children in the childcare centers and infected workers revealed similar patterns, suggesting a common source of infection (Adler, 1989). Although it is clear that child-care workers are at risk for acquisition of HCMV secondary to their exposure to young children, an increased risk of HCMV infection has not been demonstrated in hospital workers, including nurses caring for infants with perinatal HCMV infections (Yeager, 1975; Dworsky *et al.*, 1983a,b; Adler *et al.*, 1986; Balfour and Balfour, 1986). These findings argued that with adequate attention to routine hygienic practices, the risk for acquisition of HCMV is no greater for individuals caring for children than that of the general population. Finally, in several prospective natural history studies, maternal HCMV infection and the delivery of a congenitally infected baby have been linked to exposure to young children (Pass *et al.*, 1987; Fowler *et al.*, 1997). Thus, HCMV-infected children are efficient vectors for transmission of the virus to other children and their caretakers because they serve as a reservoir of virus by shedding virus for a prolonged period and because their behavior facilitates virus spread to susceptible contacts.

Acquisition of HCMV by sexual contact

As described above, HCMV infection occurs at an early age in populations in the developing world and virus acquisition through sexual contact is likely of limited importance in primary infection of HCMV in these populations. In contrast, in some populations in North America and northern Europe, a second rapid increase in HCMV seroprevalence has been observed during adolescence, suggesting that virus is acquired through sexual contact. A large number of epidemiological studies have supported the classification

of HCMV as a sexually transmitted infection (STI). The associations between sexual activity and HCMV infection are listed in Table 41.3.

Studies of women attending sexually transmitted disease clinics have noted an increase in both HCMV seroprevalence and definitive evidence of HCMV transmission between sexual partners (Jordan *et al.*, 1973; Chandler *et al.*, 1985, 1987; Handsfield *et al.*, 1985; Collier *et al.*, 1990; Coonrod *et al.*, 1998). In addition, it appeared that previously infected individuals could be re-infected by a second strain of virus (see following section) (Handsfield *et al.*, 1985). Other associations between sexual activity and HCMV infection have included: (1) number of sexual partners, (2) number of lifetime sexual partners, and (3) co-infection with other sexually transmitted infections such as trichomonas, gonorrhea, and bacterial vaginosis (Chandler *et al.*, 1985, 1987; Handsfield *et al.*, 1985; Collier *et al.*, 1990; Fowler and Pass, 1991; Sohn *et al.*, 1991; Coonrod *et al.*, 1998). Similarly, in a sexually active male homosexual population it has been reported that over 90% of these men were infected with HCMV (Drew *et al.*, 1981; Drew and Mintz, 1984).

The association between HCMV infection and sexual activity is consistent with the shedding of this virus in the genitourinary tract. Both cervical secretions and vaginal fluid are frequent sites of virus recovery in populations of younger women (Reynolds *et al.*, 1973; Stagno *et al.*, 1975a,b; Waner *et al.*, 1977; Collier *et al.*, 1995; Coonrod *et al.*, 1998). Semen has been reported to be a rich source of virus and quantitation of viral DNA in semen has been used to monitor the in vivo response to antiviral drugs in clinical studies (Lang and Kummer, 1975; Drew and Mintz, 1984 ; Rinaldo *et al.*, 1992; Yang *et al.*, 1995; Liesnard *et al.*, 1998; Diamond *et al.*, 2000). The frequency with which HCMV can be isolated from the female genital tract varies between populations and interestingly, with the age of the woman (Collier *et al.*, 1995; Coonrod *et al.*, 1998). In some studies virus could be recovered from the genital tract of over 50% of women attending a STD clinic, whereas the rate of recovery from HCMV infected women in the post partum period were significantly lower (Pass *et al.*, 1982a,b). Thus, it is unclear if the increased rates of recovery of HCMV from women attending an STD clinic reflect increased shedding from a previous chronic infection or repeated re-infections. A second interesting observation is that age appears to influence the frequency of HCMV shedding in the genital tract of women such that young women infected with HCMV are more likely to shed virus from the genital tract as compared to older women (Fowler *et al.*, 1993; Collier *et al.*, 1995; Coonrod *et al.*, 1998). However, the relationship between risk of re-exposure to HCMV through sexual contact in these two populations and rates of genital shedding of virus remains inadequately defined. Alternatively, it has been argued that primary HCMV infection leads to more prolonged shedding of virus and the more frequent recovery of virus from the genital tract of younger women could reflect the natural history of a resolving primary infection. These two possible explanations have not been reconciled.

Table 41.3. Representative studies that have associated HCMV infection with sexually transmitted infections

Population	Evidence of sexual transmission
Sexually active male homosexuals	Increased seroprevalence (> 90% +) as compared to general population (Drew *et al.*, 1981).
Women attending STD clinic	Increased seroprevalence; increased rate of cervical shedding; increased rates of seroconversion (Chandler *et al.*, 1985; Handsfield *et al.*, 1985; Collier *et al.*, 1990; Coonrod *et al.*, 1998).
Young women	HCMV infection associated with STIs including bacterial vaginosis, trichomonas and gonorrhea (Chandler *et al.*, 1985; Fowler and Pass, 1991; Sohn *et al.*, 1991)
Young women	Increased rates of HCMV seroconversion correlated with increased number of sexual partners (Collier *et al.*, 1990; Fowler and Pass, 1991)

Sources of HCMV in hospitalized patients and health-care workers

Some of the earliest reports of the clinical syndromes associated with HCMV infection described patients infected with HCMV by nosocomial routes. Several routes of nosocomial transmission have been described but the three most frequently routes of transmission include: (1) allograft transplantation, (2) blood products, and (3) breast milk. Transfusion associated HCMV infection was recognized in cardiac surgery patients who in the past often required significant quantities of blood as a result of cardiac bypass procedures. A syndrome of fever, atypical lymphocytosis, elevated liver transaminases, and splenomegaly was associated with these procedures and the phrase post-perfusion syndrome or post-perfusion mononucleosis was coined (Holsward *et al.*, 1963; Reyman, 1966; Paloheimo *et al.*, 1968). Subsequent studies revealed that HCMV infection could be related to up 50% of these cases and it was argued that HCMV was transmitted by blood products utilized in these procedures (Prince *et al.*, 1971). From a series of studies in seronegative patients receiving blood products it was estimated that risk of acquiring HCMV infection was about 2.5% per unit of blood transfusion (Stevens *et al.*, 1970; Armstrong *et al.*, 1976; Bowden, 1995). Because the total amount of blood products also correlated with the risk of acquiring HCMV, patient populations

requiring large amounts of blood and blood products secondary to their underlying disease or complications of therapy were at increased risk for HCMV infection. In addition, the type of blood product transfused also influenced risk for transmission of HCMV. Studies in allograft recipients revealed that blood products that contain white blood cells or platelets were more likely to transmit HCMV to the recipient. As a result, several modifications were introduced to limit white blood cell contamination of blood, including the use of filters that can remove white blood cells from red blood cell transfusions and the use of frozen red blood cell preparations (Brady *et al.*, 1984; Bowden *et al.*, 1991; Ljungman *et al.*, 2002a,b). Both approaches have been shown to reduce the incidence of transfusion acquired HCMV infection. The second approach involved screening blood donors and selecting those without serological evidence of past HCMV infection. This approach has proven successful in reducing the incidence of HCMV infection in transfusion recipients, particularly in bone marrow allograft recipients (Bowden *et al.*, 1991; Bowden, 1995). However, two limitations have become apparent. The first is that in some donor populations over 50% of patients have serological evidence of HCMV infection, thus restricting the donor population and limiting the availability of blood products. The second more recent observation is that perhaps up to 15% of donors without serological evidence of HCMV infection can be shown to have evidence of previous HCMV infection when analyzed by more sensitive techniques such as PCR (Roback *et al.*, 2001; Drew *et al.*, 2003). The interpretation of this interesting finding is not straightforward as it is unclear what proportion of blood products from these serologically negative, PCR positive donors transmitted HCMV to recipients.

HCMV infections resulting from transfusions of blood products have also been shown to cause significant disease in newborn infants, particularly premature infants and infants born to women without serological immunity to HCMV (Yeager *et al.*, 1981; Adler, 1983; Adler *et al.*, 1983). Because extremely premature infants, regardless of their mothers' HCMV serologic status, are delivered prior to significant transplacental transfer of maternal antibodies, they often lack passively acquired antibody immunity to HCMV. Thus, these infants are at risk for severe HCMV infections. Perhaps one of the more interesting findings from these studies of nosocomial infections in premature infants was that passively acquired anti-HCMV antibodies provided some protective immunity. In a prospective study, infected infants with antiviral antibodies exhibited a milder disease than infected infants without passively acquired anti-HCMV antibodies and appeared to be protected from severe HCMV infections and in some cases, death (Yeager *et al.*, 1981). This observation also provided one of the most compelling arguments for a role of antiviral antibodies in host protective responses to HCMV that limit disease.

Breast milk transmission of HCMV is well described (see above) and infection of extremely premature infants as a result of ingestion of infected breast milk can be associated with severe disease (Vochem *et al.*, 1998). The finding that breast milk transmitted HCMV could result in significant disease in young infants defined an additional risk in the use of banked breast milk as nutritional support for premature infants. The lack of antiviral antibodies in premature infants was associated with symptomatic infection following breast milk acquisition of HCMV similar to infections associated with transfusions. Even though breast milk from HCMV seropositive women contains virus neutralizing antibodies of both the IgG and IgA isotypes, virus can be readily transmitted to infants. This finding suggests that antiviral antibodies cannot prevent virus transmission even if present in the inoculum.

Transmission of HCMV by transplantation of an allograft from donor previously infected with HCMV represents a major clinical problem in allograft transplantation. Human cytomegalovirus is the most common cause of infection in the post transplant period and the transplanted allograft represents the most important source of HCMV infection in allograft recipients (Peterson *et al.*, 1980; Rubin 1990; Rubin and Colvin, 1986, Griffiths *et al.*, 2000; Ljungman, 2002; Ljungman *et al.*, 2002a,b). It is estimated up to 90% of allograft recipients who have received an allograft from a HCMV infected donor will become infected with HCMV; however, it is likely that all recipients of allografts from HCMV infected donors will become infected with HCMV present in the donor allograft, regardless of their serological status prior to transplantation. Although prior experience with HCMV either as the result of natural infection or live virus vaccines has been shown to provide some protection from severe infection and end-organ disease, pre-existing immunity does not prevent infection (Plotkin *et al.*, 1991). Viral nucleic acids have been detected in the kidneys from HCMV infected donors indicating that the transplanted organ can serve as a source of virus in transplanted allografts (Gnann *et al.*, 1988). In addition, bone marrow allografts from HCMV seropositive donors readily transmit HCMV to recipients, a finding consistent with the demonstration that the cells of macrophage/monocyte lineage can harbor latent HCMV (Soderberg-Naucler *et al.*, 1997). Reactivation of latent HCMV from macrophages derived from HCMV seropositive donors has been demonstrated in-vitro, providing an explanation for the transmission of HCMV from both hematopoietic allografts as well as solid organs that almost certainly contain contaminating macrophages (Soderberg-Naucler *et al.*, 1997). Together with transfusion acquired

HCMV infection, infection in allograft recipients from the virus in allograft represent the most common mode of nosocomial transmission of HCMV.

Transmission of HCMV from patients shedding HCMV to health-care workers is exceedingly rare. Shedding of significant titers of infectious virus is usually limited to hospitalized infants and young children and studies have shown that nurses exposed to these infected infans are no more likely to become infected with HCMV than control populations in the community (Dworsky *et al.*, 1983; Adler *et al.*, 1986; Demmler *et al.*, 1987). In the case of adults, HCMV shedding in hospitalized patients is usually only observed in severely immunocompromised patients such as allograft recipients and patients with AIDS. With the implementation of universal precautions in the care of hospitalized patients, the risk of nosocomial transmission of HCMV to a healthcare worker is almost certainly lower than the risk of community acquisition of this virus.

Reinfection: acquisition of HCMV by a previously infected host

Superinfection or reinfection of previously infected immunocompromised allograft recipients has been well described (Chou, 1986, 1987; Grundy *et al.*, 1988). In addition, numerous studies in patients infected with HIV demonstrated multiple infections with HCMV and in some patients, several genetically distinct strains of HCMV could be detected simultaneously (Drew *et al.*, 1984; Spector *et al.*, 1984; Chern *et al.*, 1998). These studies provided evidence that pre-existing immunity to HCMV, both antiviral antibodies and HCMV-specific cellular immune responses, failed to prevent infection with an unrelated strain of HCMV. Anecdotal reports have suggested that normal seropositive individuals could be superinfected with new strains of HCMV; however, it was argued that reinfections were only common in immunocompromised hosts. A study of vaccine immunity following inoculation with a candidate replicating virus vaccine demonstrated that individuals infected with the vaccine strain of HCMV could be reinfected with a challenge strain of HCMV (Plotkin *et al.*, 1989). A more recent study also demonstrated that normal women infected with a vaccine strain of HCMV could be reinfected following natural exposure to young children shedding HCMV (Adler *et al.*, 1995). These studies provided definitive evidence that prior infection in a normal host could not prevent a second infection (Table 41.4). In this latter report, the authors speculated that reinfection resulted from a failure of the vaccine to induce immunity that was similar to that following natural infection with a wild type strain of HCMV (Adler *et al.*, 1995).

Table 41.4. Infection in normal hosts with preexisting immunity to HCMV. Studies demonstrating the acquisition of a second strain of HCMV in a previously infected host

Population	Evidence of reinfection
Vaccine recipients	Clinical symptoms with virus challenge; virus excretion with virus challenge (Plotkin *et al.*, 1989).
Vaccine recipients	serologic boost in previously infected host following community acquired infection; recovery of non-vaccine strain of virus in recipients of live virus vaccine (Adler *et al.*, 1995)
Infants in day care	recovery of genetically distinct viruses over time from infants in day care center (Bale *et al.*, 1996)
Women with congenitally infected infants	serological evidence of acquisition of new gentoype in women with prior HCMV infection; delivery of infected infant following reinfection (Boppana *et al.*, 2001a,b)
experimental animals	serologic and virologic evidence of reinfection in both wild and captive mouse populations; reinfection in captive non-human primates (Moro *et al.*, 1999)

More recent findings in adults as well studies in young children have demonstrated that individuals with prior HCMV immunity can be readily reinfected with a second (or possibly third, fourth, etc.) strain of HCMV as a result of natural exposure. The spread of HCMV in young children attending a child care facility clearly demonstrated that previously infected young children could be reinfected with a second strain of HCMV (Bale *et al.*, 1996). More recently, reinfection of normal women by a genetically unrelated strain of HCMV was studied utilizing an antigenic polymorphism in glycoprotein H that allowed the detection of reinfection by serologic reactivity (Boppana *et al.*, 2001a,b). In this study, reinfection of women previously infected with HCMV with a new viral strain that encoded a unique serologic determinant was shown to occur in nearly 30% of women enrolled in the study (Boppana *et al.*, 2001a,b). Interestingly, reinfection in this population was associated with intrauterine transmission of HCMV during subsequent pregnancies and damaging congenital infection was observed in three infants infected in utero as a result of maternal reinfection (Boppana *et al.*, 2001a,b). Subsequent studies in this same population have indicated that approximately 12% of women are reinfected with a second virus strain each year. It is important to note that the serologic methods utilized in this study likely underestimates the frequency of reinfection because only two antigenic variants could be detected (Boppana *et al.*, 2001a,b). Because of this limitation, it is highly likely that women in this population are frequently reinfected with genetically

different strains of HCMV. In view of the reported case of recombination between strains of HCMV, some individuals may harbor HCMV of significant genetic diversity, perhaps approaching a so-called swarm of viruses.

The importance of reinfection as a source of HCMV in a population is unclear but the ease with which HCMV can spread within populations and the apparent lack of protective immunity suggests that reinfection with new strains of HCMV are common in all populations and dependent only on the risk of exposure to infectious virus. In experimental animal model systems reinfection has been documented, including in the rhesus macaques (personal communication, J. Nelson, Oregon Health Sciences University, Portland, Or.) and mice. The spread of murine CMV in wild mice has been documented and multiple genetically unique strains of viruses have been found in a single mouse, indicating that multiple infections also occur in normal mice (Moro *et al.*, 1999). Thus, when the spread of HCMV in populations is defined it is critical to include not only seronegative individuals, a group previously viewed to be the sentinel for HCMV spread in a population, but also seropositive individuals as both populations can be readily infected with HCMV. The design and strategy for vaccine control of HCMV must keep these possibilities in mind.

Entry and spread within susceptible hosts

Infection following community exposure

Infection with HCMV following community exposure presumably occurs as a result of exposure of mucosal surfaces of the upper respiratory tract or the genital tract to infectious HCMV. Although the cellular target of HCMV infection remains incompletely defined, the widespread expression of putative cell surface receptors including, proteoglycans, integrins, and epidermal growth factor receptor, suggest that the tropism of virus is not limited to specific cell types on the mucosal surface. Presumably virus attaches and enters susceptible epithelial cells and undergoes lytic replication. Following the release of progeny virions, adjacent cells including non-epithelial cells of the underlying submucosa are infected. This earliest phase of cytomegalovirus infection has not been well studied in humans or experimental animal models and the pathway of infection and local amplification that is postulated is based on modes of virus exposure that lead to infection. The steps following local amplification leading to disseminated spread of virus to the liver and spleen and eventually to sites of persistence are essentially unknown in humans. Studies in experimental animals including mice and primates have demonstrated that infection of the oral mucosa leads to dissemination and widespread infection of organs such as the liver and spleen (Kern, 1999; Lockridge *et al.*, 1999). In a primate model of HCMV infection, Lockridge *et al.* observed that both intravenous and oral inoculation of rhesus macaques with rhesus CMV led to dissemination and widespread viral infection in a variety of organs (Lockridge *et al.*, 1999). Perhaps the most surprising observation made in this study was that oral inoculation lead to virus dissemination and infection of liver and spleen as efficiently as intravenous inoculation of equivalent amounts of infectious virus (Lockridge *et al.*, 1999). However, the kinetics of virus spread for the intravenously inoculated animals was accelerated as compared to the orally infected animals (Lockridge *et al.*, 1999). Because peak of viremia was not detected until approximately 1 week later in the animal inoculated by mucosal exposure as compared to those given virus intravenously, it could be argued that following mucosal exposure, the virus undergoes a local amplification and then spread to secondary sites of infection such as the liver and spleen and regional lymph nodes (Lockridge *et al.*, 1999). Studies in other experimental models such as mice and guinea pigs are consistent with this mode of spread in the host (Bernstein and Bourne, 1999; Kern, 1999). Thus, it appears that HCMV infection could follow a similar pathway of infection and spread as has been described for varicella-zoster virus (Grose, 1994). After mucosal infection with HCMV there is local amplification, an initial viremia that leads to infection of visceral structures such as the liver and spleen. Infection of these organs is then followed by a secondary viremia that leads to a more generalized infection. From studies in experimental animals and transfusion acquired HCMV infections, it is clear that the magnitude of the inoculum, the kinetics of virus replication at the primary site, and the host derived innate responses can influence the kinetics, duration, and magnitude of the virus replication/spread. Although the oral exposure of animals leads to widespread virus dissemination and infection of a similar spectrum of tissues, animals remained asymptomatic following oral inoculation and also did not demonstrate abnormalities in hematologic parameters that have been associated with HCMV infection (Lockridge *et al.*, 1999). In contrast, animals inoculated intravenously developed a mononucleosis syndrome that was associated with monocytosis, thrombocytopenia, and leukocytosis (Lockridge *et al.*, 1999). These observations parallel clinical observations in human subjects infected inadvertently by blood transfusion or transplantation of an infected allograft. Because intravenous (or by an allograft) inoculation allows direct access to the circulatory system, there is likely no requirement for virus amplification in local

tissue prior to spread to visceral organs and regional lymphoid tissue. Thus, the virus can replicate to higher titers earlier in the course of the infection and presumably overwhelm the host innate immune responses. Clinical disease following acute CMV infection has been correlated with increased levels of replicating virus in humans as well as in experimental animal models of HCMV disease (Cope *et al.*, 1997; Spector *et al.*, 1998; Bernstein and Bourne, 1999; Kern, 1999; Emery *et al.*, 2000; Sequar *et al.*, 2002).

Following amplification in regional lymphoid tissue and the spleen and liver, dissemination of infectious virus results in the infection of sites that have been postulated to support persistent infection *in-vivo* and include salivary gland and breast secretory epithelium, prostatic epithelium, endometrium, and renal tubule epithelium (Becroft, 1981; Borisch *et al.*, 1988; Bale *et al.*, 1989; Sinzger *et al.*, 1995). Based on studies in experimental animal models and the findings that bone marrow and lung allografts can transmit infection, other sites such as the bone marrow and lung are also infected (Myerson *et al.*, 1984; Balthesen *et al.*, 1993; Kurz *et al.*, 1997; Salzberger *et al.*, 1997). The sites of long-term persistence, be it chronic productive infection or true latency, in humans are thought to include epithelium within exocrine glands, macrophage/monocytic cells, and hematopoietic stem cells. Pivotal aspects of the earliest phases of acute HCMV infection and dissemination remain inadequately studied. As an example, local amplification of virus following mucosal exposure has been postulated based on the kinetics of virus replication in the liver and spleen, yet there is little experimental evidence supporting this proposed mechanism. Alternatively, the virus could be transported to the regional lymph nodes, liver and spleen by circulating leucocytes prior to significant amplification in local tissue. The cell types that support local amplification are unknown and interactions between these cells and the innate immune system are not well described. The local host innate immune responses to naturally acquired HCMV infection could play a key role in the ultimate outcome of the infection, *i.e.* the level of virus replication and subsequent spread to the distant sites of infection. In contrast to the well documented role of the adaptive immune responses such as cytotoxic T lymphocytes and antiviral antibodies in the control and resolution of CMV infections, the importance of early innate responses at the site of inoculation to the course of infection with this virus remain poorly understood.

Transfusion and allograft-acquired infection

Infection with HCMV that follows exposure to blood products or an allograft more often resembles the symptomatic mononucleosis like syndrome that occurs in a minority of individuals who acquire HCMV by community exposure (Foster and Jack, 1969; Bowden, 1995). Presumably, development of symptomatic infection results from either the exposure to a large inoculum, delivery of infectious virus directly into the circulatory system, or by a combination of the two. In addition, allograft recipients as well as some recipients of blood products are often immunocompromised. Thus, the increase in HCMV burden is generally accelerated and the duration of active viral replication is increased secondary to the lack of normal immune responses to this virus. Clinical characteristics of this syndrome include fever, hematological abnormalities including leukocytosis often with monocytosis, and evidence of hepatocellular damage. Some patients will develop splenic enlargement and lymphadenopathy. Similar findings have been noted in animal models of acute HCMV infection (Bernstein and Bourne, 1999; Kern, 1999; Lockridge *et al.*, 1999). During peak virus replication, HCMV disseminates to end organs and sites of persistence as described above. Resolution of active virus replication is associated with control of clinical disease but virus excretion can continue for extended periods of time.

A consistent feature of HCMV infection in allograft recipients is the temporal sequence associated with virus replication and disease. In solid organ allograft recipients such as renal transplant recipients, virus replication and clinical symptoms are commonly observed several weeks following transplantation (Rubin and Colvin, 1986; Singh *et al.*, 1988; Rubin, 2002). The seemingly prolonged interval between transplantation and expression of an acute disease syndrome remains unexplained based on an expectation that virus reactivation/replication begins shortly after transplantation. It is possible that only vanishing amounts of virus are present in the allograft and replication of sufficient amounts of virus to induce disease requires this time interval. Consistent with this speculation is the finding that the virus burden in the blood closely parallels the development of disease in these patients and has been shown to increase exponentially in the time period preceding the development of disease (Cope *et al.*, 1997; Mendez *et al.*, 1998; Emery *et al.*, 2000; Nichols *et al.*, 2001). In contrast, disease in bone marrow allograft patients characteristically developed around 60 days post-transplantation and, based on these early studies in bone marrow allograft recipients, it was subsequently shown that detection of HCMV around day 35 post transplant in patients without clinical symptoms could be successfully treated with antiviral agents (Myers *et al.*, 1975; Schmidt *et al.*, 1991; Boeckh and Bowden, 1995; Boeckh *et al.*, 1997; Boeckh and Boivin, 1998; Nichols *et al.*, 2001). This finding is in agreement

with the general time frame of HCMV replication in solid organ transplant recipients and again suggests that HCMV must first establish a productive infection and amplify its genome copy number prior to dissemination to distant sites. Studies with murine CMV and immunocompromised mice have documented the importance of virus dissemination in the development of disease following reactivation of virus (Jonjic *et al.*, 1994; Reddehase *et al.*, 1994).

Spread within the host

Cell-associated spread within the host

Although it is has been suggested that cell free virus is responsible for community acquired HCMV infection, only limited data supports this claim. Perhaps the most convincing evidence comes from studies in breast feeding women that have demonstrated that infectious virus is present in the cell-free fraction of breast milk (Hamprecht *et al.*, 1998). This finding suggests that cell free virus can infect a mucosal surface. Animal models of CMV infection have utilized either intraperitoneal or subcutaneous inoculations almost exclusively; however oral inoculation with cell free murine CMV has been accomplished (personal communication, S. Jonjic, University of Rijeka, Rijeka, Croatia). In contrast to initial infection, the spread of HCMV within an infected host is likely to be cell associated based on findings from immuncompromised patients and studies in experimental animal models. In all but the most severely immunocompromised patients, infectivity that can be demonstrated in the blood compartment is most frequently associated with peripheral blood leukocytes and endothelial cells (Percivalle *et al.*, 1993; Waldman *et al.*, 1995; Salzberger *et al.*, 1997; Gerna *et al.*, 1998; Pooley *et al.*, 1999; Maidji *et al.*, 2002). The highest titers of infectious virus have been found associated with polymorphonuclear leukocytes from the buffy coat fraction of peripheral blood (Gerna *et al.*, 1992; Schafer *et al.*, 2000; Liapis *et al.*, 2003). Polymorphonuclear leukocytes cannot support virus replication but have been shown to carry infectious virus and viral gene products (Gerna *et al.*, 2000; Kas-Deelen *et al.*, 2001). In a series of in vitro experiments, Gerna and colleagues have demonstrated that HCMV infected endothelial cells or fibroblasts can transfer infectious virus to PMNs and in turn, these cells can transmit virus to susceptible fibroblasts (Gerna *et al.*, 2000). These studies have argued that microfusion events between virus containing vesicles and PMN are responsible for transmission of virus between cells (Gerna *et al.*, 2000). Although such a mechanism has not been experimentally verified in animal models of HCMV infection, the role of PMN in transmission of infectious HCMV in vivo is well accepted and the correlation between HCMV antigen positive PMN (antigenemia assay) and disseminated infection has been repeatedly shown to be a reliable diagnostic tool for the identification of patients at risk for invasive infection with HCMV (van der Bij *et al.*, 1988; The *et al.*, 1990; Gerna *et al.*, 1991; Erice *et al.*, 1992; Landry and Ferguson, 1993; Boeckh *et al.*, 1996; Nichols and Boeckh, 2000; Singh *et al.*, 2000). Interestingly, antigen positive PMN can be detected in normal hosts infected with HCMV but with a drastically reduced frequency as compared to immunocompromised patients, suggesting that even in normal hosts that PMN may be a common mode of virus dissemination. Other cells within the leukocyte fraction of peripheral blood cells support HCMV persistence and also transmit infectious virus. These include monocyte and macrophages derived by differentiation of blood monocytes (Rice *et al.*, 1984; Taylor-Wiedeman *et al.*, 1991; Fish *et al.*, 1995; Waldman *et al.*, 1995; Sinclair and Sissons, 1996; Guetta *et al.*, 1997; Soderberg-Naucler *et al.*, 1998; Hanson *et al.*, 1999; Jahn *et al.*, 1999; Riegler *et al.*, 2000). Cells derived from granulocyte/monocyte progenitor cells have been proposed as sites of latency based on in-vitro infections and can be detected as antigen containing cells in immunocompromised patients with disseminated HCMV infection (Taylor-Wiedeman *et al.*, 1991; Fish *et al.*, 1995; Kondo *et al.*, 1996; Sinclair and Sissons, 1996; Soderberg-Naucler *et al.*, 1997; Hahn *et al.*, 1998). In contrast, macrophages derived from peripheral blood of monocytes have been shown to harbor infectious HCMV upon stimulation with specific cytokines, including TNF-α (Taylor-Wiedeman *et al.*, 1994; Hummel *et al.*, 2001; Soderberg-Naucler *et al.*, 2001). Viral replication and expression of a variety of early and late proteins can be demonstrated in macrophages following infection with HCMV, although only recently derived clinical viral isolates efficiently infect these cells. This latter observation has been made independently by numerous laboratories and will be discussed in more detail in subsequent sections of this volume. The findings that individual strains of virus exhibited different biological behaviors in tissue culture have confirmed several observations that were first noted in the earliest in vitro studies of HCMV. Current studies are directed at deciphering the viral genes that account for these in-vitro phenotypes and may yield important new findings to help define the pathogenesis of HCMV infections.

A second cell lineage that is critical to the in-vivo spread of HCMV is the endothelial cell in a variety of microvascular beds in the human host. Endothelial cells have long been known to be a target for HCMV replication in vitro and infection of these cells results in a variety of cellular responses, including the release of cytokines and chemokines (Waldman *et al.*, 1991; Sinzger *et al.*, 1995,

1997; Waldman *et al.*, 1995; Plachter *et al.*, 1996; Fish *et al.*, 1998; Gerna *et al.*, 1998; Evans *et al.*, 1999; Kas-Deelen *et al.*, 2000; Brune *et al.*, 2001a,b; Maidji *et al.*, 2002; Odeberg *et al.*, 2002). Both lytic and non-lytic productive infections have been described in endothelial cells suggesting that depending on the source of cells and the infecting virus, endothelial cells can respond very differently to infection (Sinzger *et al.*, 1997, 2000; Fish *et al.*, 1998; Kahl *et al.*, 2000). Virus infection of endothelial cells is thought to be critical for infection of various tissues during HCMV dissemination and likewise, endothelial cell infection and virus release appears to be critical for the hematogenous spread from infected tissue (Waldman *et al.*, 1995; Gerna *et al.*, 2000; Maidji *et al.*, 2002). Early studies in transplant populations described viral antigen containing cells circulating in the blood of viremic transplant patients that subsequently were shown to be infected endothelial cells (Grefte *et al.*, 1993; Percivalle *et al.*, 1993; Gerna *et al.*, 1998). These cells contain infectious virus and are thought to represent infected endothelium that sloughs into the circulation, presumably secondary to local infection and/or inflammation. These cells are usually detected only in the most immunocompromised patients but these observations serve to illustrate that HCMV infection in these patients can be associated with an endothelitis that likely seeds the blood compartment with infectious virus containing cells. A similar role for endothelial cells in spread of CMV in both the murine model and guinea pig CMV model is assumed but has not been adequately explored (Brune *et al.*, 2001a,b).

Viral genes associated with virulence: viral dissemination and in vivo tropism

The large coding capacity of the HCMV genome in comparison to other herpes viruses has raised the possibility that a sizable number of these genes may encode functions that facilitate efficient in vivo replication, spread and persistence. This indeed appears to be the case as genetic comparisons between commonly used laboratory viruses and recent clinical isolates have demonstrated that laboratory isolates have large scale deletions yet replicate in vitro to levels that often exceed those of clinical isolates (Cha *et al.*, 1996). Studies utilizing laboratory isolates and recent clinical isolates have dramatic differences in tropism when cell types other than permissive human fibroblasts are used for in vitro propagation (Waldman *et al.*, 1991; Fish *et al.*, 1998; Soderberg-Naucler *et al.*, 1998; Jarvis *et al.*, 1999; Sinzger *et al.*, 1999, 2000; Bolovan-Fritts and Wiedeman, 2001; Brune *et al.*, 2001a,b; Gerna *et al.*, 2002). It is also almost certain that the phenotype of some viral genes that contribute to growth and persistence can only be defined in vivo and therefore will be extremely difficult to dissect in vitro. Studies in experimental animals, particularly the mouse have been quite revealing and point to the importance of viral genes in the initial replication and spread of CMVs. In studies investigating the spread of murine CMV from the site of inoculation to distant sites, infection has been was shown to be primarily associated with peripheral blood mononuclear cells. In these models the importance of an initial viremic spread to the liver and spleen was demonstrated and the role of peripheral blood mononuclear cell spread of virus to sites of persistence such as salivary glands was carefully documented (Bale and O'Neil, 1989; Collins *et al.*, 1994; Stoddart *et al.*, 1994; Mitchell *et al.*, 1996; Hanson *et al.*, 1999; Kern, 1999; Reddehase *et al.*, 2002). More recently, several reports have demonstrated the importance of individual viral genes in a murine model of CMV pathogenesis. At least three viral genes encoded by m139, 140, 141 orfs of MCMV have been shown to play a critical role in viral replication in monocyte/macrophages but have little to no effects on the replication of the virus in mouse fibroblasts (Saederup *et al.*, 1999; Hanson *et al.*, 2001; Saederup *et al.*, 2001; Menard *et al.*, 2003). The finding that viruses in which these genes have been deleted exhibit limited spread in vivo following intraperitoneal inoculation illustrates a potential role for these orfs in the in vivo pathogenesis of murine CMV (Saederup *et al.*, 2001; Mocarski, 2002). To date, the mechanism that accounts for restricted replication in monocytes of MCMV with deletions in these orf is unknown. The HCMV gene(s) that permit replication in monocyte/macrophages has not been definitively identified. Although it is far from clear if the observed expanded tropism of some strains of HCMV is required for the spread of HCMV in the infected host, the conservation of this phenotype amongst low passage clinical isolates and the subsequent loss of this phenotype upon passage in tissue culture would argue that monocyte/macrophage tropism contributes to the spread of the virus in the infected host. Genetic analysis of murine CMV indicated that endothelial cell tropism can be linked to a single viral gene, M45, the viral encoded ribonucleotide reductase and may be associated with resistance of endothelial cells to murine CMV induced apoptosis (Brune *et al.*, 2001a,b). The deletion of the homologous reading frame in HCMV was not associated with the loss of endothelial tropism (Hahn *et al.*, 2002). More recently, the importance of the VL129–131 of HCMV in endothelial tropism and presumably replication in vivo has been demonstrated by several laboratories (Hahn *et al.*, 2004; Wang and Shenk, 2005a,b). Thus, the viral genes and the mechanism by which products of the viral genes contribute to the expanded tropism of some clinical viral isolates of HCMV remain poorly understood.

Human cytomegalovirus encodes three G coupled protein receptor (GPCR) like molecules in orfs UL33, UL78,

US 27 and US28 (Margulies *et al.*, 1996; Streblow *et al.*, 1999; Rosenkilde *et al.*, 2001; Beisser *et al.*, 2002). The most extensively studied is US28, a GPCR that is constitutively activated and more importantly, can also signal after interaction with chemokines including RANTES, MCP-1, and fractalkine (Bodaghi *et al.*, 1998; Streblow *et al.*, 1999; Billstrom Schroeder and Worthen, 2001). Several laboratories have reported possible roles for this molecule in the spread of HCMV in vivo including, (i) acting as a chemokine sink to limit host cell chemotaxis to HCMV infected cells, (ii) providing an anti-apoptotic function, (iii) the recruitment of infected mononuclear cells to the sites of inflammation leading to dissemination of virus and (iv) perhaps even by binding of virus or virus infected cells to chemokine expressing endothelial cells based on observations of US28 binding membrane bound fractalkine (Bodaghi *et al.*, 1998; Kledal *et al.*, 1998; Billstrom Schroeder and Worthen, 2001; Beisser *et al.*, 2002; Billstrom Schroeder *et al.*, 2002; Randolph-Habecker *et al.*, 2002). In addition, infected smooth muscle cells expression US28 have been shown to migrate down chemokine gradients, thus providing an additional mechanism for the localization of HCMV infected cells to sites containing inflammatory cellular infiltrates (Streblow *et al.*, 1999). Although the role of US28 in HCMV induced vascular disease has been well studied and supported by in vitro models of smooth muscle cell migration, the importance of US28 in virus dissemination from local site of infection remains unclear. In murine CMV, two GPCR like gene products have been identified, M33 and M78 (Davis-Poynter *et al.*, 1997; Oliveira and Shenk, 2001; Waldhoer *et al.*, 2002). Studies have suggested that M33 is required for efficient virus dissemination to the salivary glands, a finding consistent with a potential role of US28 in the spread of HCMV (Davis-Poynter *et al.*, 1997). Recently, the US28 homologue of rhesus CMV has been identified (Penfold *et al.*, 2003). The phenotype of the M78 deletion virus suggests that the gene product of this orf is important in the replication of murine CMV in both monocytes/macrophages in vitro and in vivo (Oliveira and Shenk, 2001).

Another viral gene that appears to influence the spread of HCMV in vivo is UL146 (Penfold *et al.*, 1999). The protein encoded by this orf is a secreted protein that appears to function as a CXCL chemokine (*v*-CXCL1) that can induce chemotaxis and degranulation of PMNs (Penfold *et al.*, 1999). Interestingly this orf exhibits considerable sequence variability but maintains an amino terminal motif defining it as a CXCL chemokine (Penfold *et al.*, 1999). It is thought that this viral chemokine can recruit PMNs in vivo and thus could serve to disseminate HCMV from sites of infection. In severely immunocompromised hosts such as AIDs patients with gastrointestinal and retinal disease secondary to disseminated HCMV infection, neutrophil infiltration can be observed in the lamina propria as well as in the retina (Pepose *et al.*, 1985; Jacobson *et al.*, 1988; Francis *et al.*, 1989; Wilcox *et al.*, 1998). Infection of lamina propria macrophages with HCMV in vitro results in the induction of IL-8 release from these cells, suggesting that HCMV can both induce IL-8 release and encode a viral IL-8 like molecule (Redman *et al.*, 2002). Such findings are consistent with the proposed mechanism of chemokine expression and HCMV dissemination from sites of virus replication. Although this mechanism of dissemination is consistent with the histopathologic findings noted in severely immunocompromised patients, a neutrophil infiltrate is not an invariant feature of the histopathology of naturally acquired HCMV infections suggesting that interactions between this viral chemokine and other peripheral blood leukocytes that express its cognate cell surface receptor, CXCR2, also is required for virus dissemination. Alternatively, the recent findings that HCMV engages Toll-like receptors with resultant induction of pro-inflammatory cytokines and chemokines cascades suggests that the virus infection alone can recruit cells such as monocytes and PMN to sites of infection without the requirement of a specific viral chemokine (Compton *et al.*, 2003). Regardless of the specific mechanism and the role of a viral chemokine such as that encoded by orf 146, the intimate relationship between HCMV and components of the host inflammatory response likely represents a key step in the dissemination of HCMV.

As noted previously, studies in the murine model of CMV infection have provided data consistent with cell-associated virus spread (Bale and O'Neil, 1989; Collins *et al.*, 1994; Stoddart *et al.*, 1994; Mitchell *et al.*, 1996). Murine CMV encodes a related chemokine (orf m131), MCK-1, that initially was reported to function as a chemoattractant for monocyte/macrophages (Fleming *et al.*, 1999; Saederup *et al.*, 2001; Saederup and Mocarski, 2002). MCK-1 has been shown to induce calcium signaling and adherence of macrophages suggesting that it was a functional chemokine (Saederup *et al.*, 1999). In addition, these investigators suggested that its cellular receptor was the chemokine receptor, CCR3 (Saederup *et al.*, 1999). Later studies demonstrated that the major transcript and virus-expressed product of orf 131 was actually a spliced product in which the 5′ end of the 131 0RF was fused with the entire 129 orf to generate a spliced gene termed MCK-2 (MacDonald *et al.*, 1999). The protein product of MCK-2 shares a common chemokine domain encoded by m131 and thus is assumed to have similar activity as a chemokine (Mocarski, 2002). Perhaps the most interesting findings from this series of studies was that expression of the MCK-2 protein is non-essential for growth in fibroblasts

in vitro, but virus with deletions in this viral gene have a remarkable phenotype in vivo. The deletion of MCK-2 results in virus that cannot disseminate from local sites of infection and fails to disseminate in blood monocytes (Saederup *et al.*, 2001; Noda *et al.*, 2006). Histopathological studies demonstrated that the MCK-2 deletion virus did not induce the same degree of tissue inflammation and cellular (PMN) infiltrate as the wild type virus suggesting that this virus encoded chemokine facilitated spread from local sites of infection to distant sites of virus replication, presumably by recruiting monocytes and PMN to the initial sites of virus replication (Saederup *et al.*, 2001). Infection of these cells would then allow blood-borne dissemination of virus as infected leukocytes. This mechanism together with recent findings that envelope glycoproteins of HCMV can engage cellular Toll-like receptors (see above) and induce patterned responses of the innate immune system suggest that CMVs have subverted responses of the innate immune system to enhance their spread in vivo. Undoubtedly, additional mechanisms of virus dissemination will be uncovered as future studies unravel the function of the myriad on viral genes that are non-essential for in vitro virus replication in permissive cells. In addition, the development of more representative models of HCMV infection such as the rhesus macaque will also likely lead to a greater understanding of the role of various viral genes in the spread of HCMV in the infected host.

Disease and HCMV infection: pathogenesis of end-organ disease in acute infection

Disease associated with HCMV infection can be arbitrarily divided into manifestations that follow acute infection and diseases that appear to be associated with chronic infections. Considerably more is known about disease syndromes that follow acute infection because readily definable clinical abnormalities can be related to HCMV infection. In addition, disease can be temporally related to acquisition of the virus and often to levels of virus replication. Clinical disease has been most often related to the level of virus replication which in turn is dependent on characteristics of the host response, perhaps most importantly the host immune response. In severe infections, multiorgan involvement is often present and symptomatic disease is most commonly associated with some degree of organ system dysfunction or failure. The degree of organ dysfunction and overall disease has been most closely correlated with virus replication such that higher levels of virus replication are associated with more severe disease (Bowen *et al.*, 1996; Cope *et al.*, 1997; Baldanti *et al.*, 1998; Spector *et al.*, 1999; Emery *et al.*, 2000; Boppana *et al.*, 2001a,b; Nichols *et al.*, 2001; Boeckh *et al.*, 2003). In the absence of antiviral chemotherapy or the reconstitution of HCMV specific immune responsiveness, these patients often succumb to multiorgan failure. Studies in experimental animal models of HCMV disease, particularly those utilizing immunocompromised animals are consistent with many aspects of human disease, including the relationship between virus replication and disease (Kern, 1999; Lockridge *et al.*, 1999; Brune *et al.*, 2001a,b; Sequar *et al.*, 2002). When the data from numerous studies of HCMV infection in immunocompromised populations are examined, there appears to be no absolute level of viral burden that has been associated with disease. In fact, in these patients the relative increase in virus burden appears more predictive of disease. These findings would argue that the absolute level of virus replication as measured in body compartments such as the blood or urine merely indicates virus dissemination, whereas the rate of increase in virus replication (viral burden) could more accurately reflect the loss of immunological control of virus replication in infected organs and represents a harbinger of invasive disease and end-organ dysfunction. Results from studies in an experimental murine model of HCMV infections have indicated that monitoring the viral burden in the blood compartment only indirectly correlates with viral replication in infected organs and then only in immunocompromised animals (Brune *et al.*, 2001a,b). This experimental finding provides a possible explanation for the lack of a linear correlation between viral burden and disease and suggests that increasing viral burdens are of more diagnostic value in immunocompromised hosts and should be taken as evidence of continued virus replication and dissemination.

The histopathology of tissue from patients with acute HCMV syndromes suggests that organ dysfunction and disease is secondary to both direct viral cytopathogenic effects and indirectly through bystander damage secondary effector functions of the host as evidenced by the presence of inflammatory cells in histological tissue sections. The pathognomonic finding of HCMV infection in biopsy and autopsy specimens is the finding of so called owl-eye inclusions in large cells. These cells have been shown to be HCMV infected and their presence correlates with substantial HCMV replication (Mattes *et al.*, 2000). In experimental animal models of HCMV infection, increased viral copy number in target organs such as the liver, adrenal gland, and lung are associated with the level of tissue damage and the severity of disease (Brody and Craighead, 1974; Kern, 1999; Lockridge *et al.*, 1999). Similarly in humans with disseminated HCMV infections, virus-induced damage associated with histological evidence of HCMV infection can be demonstrated in the liver, adrenal glands, lung, pancreas, colon, esophagus, eyes and CNS (Bale *et al.*, 1989; Sinzger

and Jahn, 1996). Although virus-induced cytolysis and cellular necrosis could explain the disease manifestations of acute HCMV infection, additional mechanisms of cellular damage, including apoptosis have been suggested based on in vitro studies and in limited studies in experimental animal models (Kosugi *et al.*, 1998; Goldmacher *et al.*, 1999; Brune *et al.*, 2001a,b).

Early observations in bone marrow allograft recipients raised the possibility that HCMV pneumonitis in the post-transplant period was secondary to both the host immune response to HCMV and direct viral cytopathic effects (Grundy *et al.*, 1987; Barry *et al.*, 2000). Several lines of evidence are consistent with the hypothesis that the immune response to HCMV contribute to the pathogenesis of disease including; (i) the initial development of disease in the transplanted allograft, particularly in solid organ allograft recipients, (ii) the disparity between the limited distribution of virus infection in affected organs such as the lungs and the severity of clinical disease in patients with HCMV infection, (iii) the presence of inflammatory cellular infiltration and progressive disease in AIDs patients with invasive HCMV infections, (iv) the development of accelerated disease (immune vitritis) in AIDS patients with HCMV retinitis following reconstitution of antiviral adaptive immune responses (Karavellas *et al.*, 1998; Holland, 1999; Mutimer *et al.*, 2002). Together these data have argued that the host immune response represents at least one component of the pathogenesis of diseases associated with invasive HCMV infections. In contrast to the observations in AIDs patient following reconstitution of cellular immune responses, the control of virus replication by adaptive immunotherapy with HCMV specific CTL has been shown to decrease disease in allograft recipients (Walter *et al.*, 1995). This finding suggests that HCMV specific adaptive immune responses do not directly contribute to disease in the post-transplant period if present prior to widespread viral dissemination. Thus, it could be argued that the failure to restrict virus replication by more efficient host responses such as adaptive immunity could lead to end-organ damage secondary to the non-specific activities of cells of the innate immune system. In addition, the functional activity of virus-encoded cytokines, chemokine and chemokine receptors in HCMV disease in allograft rejection could also promote HCMV associated disease in allograft recipients by the recruitment of inflammatory myeloid cells into virus infected tissue Thus, the pathogenesis of disease observed during acute HCMV infection undoubtedly requires virus replication and expression of viral gene products, but also a significant but as yet unquantifiable contribution from the host immune response.

Although it can be argued that disease in immunocompromised hosts following acute infection with HCMV can be related to the level of virus replication, the variability of disease manifestations in different patient populations indicates that additional host factors contribute to the pathogenesis of this infection. As examples, the most common disease presentations in long-lived AIDs patients are retinitis and colitis (Blaser and Cohn, 1986; Pepose *et al.*, 1987; Francis *et al.*, 1989; Dieterich and Rahmin, 1991; Drew, 1992; Gallant *et al.*, 1992; Wilcox *et al.*, 1998; Pecorella *et al.*, 2000). Although HCMV colitis occurs in severely immunocompromised transplant patients, eye involvement is rare (Aldrete *et al.*, 1975; Kaplan *et al.*, 1989; Reed *et al.*, 1990). Similarly, in congenitally infected infants colitis is not a well described component of disseminated HCMV infection. Central nervous system involvement is a hallmark of congenital HCMV infections whereas it is rarely reported in transplant recipients and when present in AIDS patients, appears to be associated with similar CNS pathology and clinical features (Becroft, 1981; Morgello *et al.*, 1987; Wiley and Nelson, 1988; Schmidbauer *et al.*, 1989; Vinters *et al.*, 1989; Gallant *et al.*, 1992; Perlman and Argyle, 1992; Achim *et al.*, 1994; Arribas *et al.*, 1996). More recent studies of allograft recipients suggest that focal HCMU encephalitis may be more frequent that previously appreciated (Ribalta *et al.*, 2002). A variety of hypotheses have been put forth to account for the variability in disease between these groups of immunocompromised patients, yet none has adequately explained the differences in the manifestations of clinical disease. However, it is evident that virus dissemination and increased virus replication alone cannot account for the pathogenesis of acute HCMV infections. The balance between host innate and adaptive immune responses and the modulation of these responses by viral gene products is almost certainly central to our understanding of the pathogenesis of acute HCMV infection; however, it is also likely that other host responses unrelated to host immunity also play a significant role in the outcome of HCMV infection.

Disease and HCMV infection: pathogenesis of end-organ disease related to chronic infections

Although clinical syndromes associated with acute HCMV infections have received the bulk of experimental and clinical study, the role of the virus in chronic human disease has only recently become the subject of more intense study. As discussed previously, several laboratories have raised the possibility that HCMV infection was associated with a variety of human diseases including coronary atherosclerotic heart disease, gastric ulcer disease, rheumatologic disorders, and some human cancers. Note that each of these chronic diseases is also associated with inflammation, a host response that is also linked to HCMV replication and gene expression (Zhu *et al.*, 2002). Definitive evidence

demonstrating a role for HCMV in any of these diseases has not been reported, yet in the last decade a significant volume of observational data has linked HCMV infection with several of these diseases, including atherosclerotic vascular disease. In addition, studies in cardiac allograft recipients have reported the relationship between the development of transplant associated vascular sclerosis and HCMV infection (Grattan *et al.*, 1989; McDonald *et al.*, 1989; Loebe *et al.*, 1990; Everett *et al.*, 1992; Koskinen *et al.*, 1993; Hosenpud, 1999; Koskinen *et al.*, 1999; Streblow *et al.*, 2001). Aspects of many of these studies remain controversial but when viewed as a group, the data appear to support a role of HCMV in vascular disease (Table 41.5).

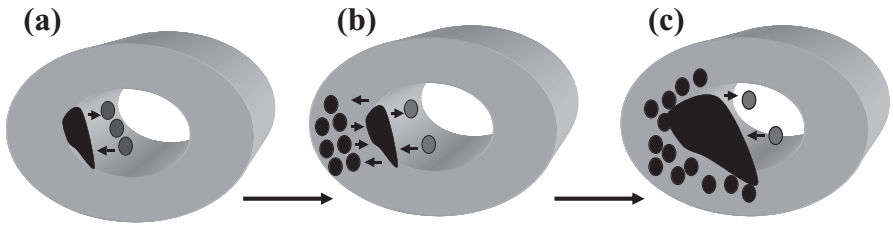
Perhaps more convincing support can be found in studies carried out in experimental animal models of allograft rejection and transplant associated vascular sclerosis. These studies have provided compelling evidence for the role of rodent CMVs in the development of post-transplant vasculopathy and coronary arteriosclerosis (Lemstrom *et al.*, 1995; Lemstrom *et al.*, 1997; De La Melena *et al.*, 2001). The relationship of HCMV infection to other chronic human diseases such as cancer is provocative yet far from conclusive (Huang and Pagano, 1978; Rapp and Robbins, 1984; Shen *et al.*, 1993; Cinatl *et al.*, 1996; Cobbs *et al.*, 2002; Harkins *et al.*, 2002). The impact of HCMV on the cell cycle during permissive infection and the less well understood relationship between viral gene expression during abortive infections and cell proliferation suggests that HCMV could at least facilitate the development of the malignant phenotype in some human cancers (Zhu *et al.*, 1995; Shen *et al.*, 1997; Fortunato *et al.*, 2000; Browne *et al.*, 2001a,b; Kalejta and Shenk, 2002; Kalejta *et al.*, 2003; Kalejta and Shenk, 2003). To unravel the possible roles of HCMV in human cancer, more comprehensive epidemiologic studies designed to determine possible relationships between infection with this ubiquitous virus and human cancer must be accomplished. In addition, it will be necessary to develop more informative in vitro model systems of cellular transformation following infection with HCMV.

In contrast to the relationship between the levels of virus replication and disease syndromes associated with acute HCMV infections, a similar relationship between HCMV virus replication and chronic diseases such as atherosclerosis in both normal and immunocompromised hosts has not been reported. To further complicate the study of HCMV infection and diseases such as coronary artery disease, it has been proposed that productive HCMV replication is not required for disease and that HCMV gene expression at a distant site could trigger disease in a target organ such as the heart (Zhou *et al.*, 1999). Finally, in vitro studies have also demonstrated that HCMV infection could be responsible for hit and run transformation event (Shen *et al.*, 1997). Thus, it is a daunting task to design a natural history study with sufficient power to identify a relationship between the development of a common disease such as coronary atherosclerotic heart disease or cancer and HCMV infection in populations in which the seroprevalence rates exceeds 60%–80%. Yet when the incredibly complex relationship between HCMV and the host cell and the life-long persistence of this virus in the host are considered together, it readily follows that HCMV could contribute to the pathogenesis of many of the diseases that have been only loosely associated with HCMV infection.

The inflammatory nature of many chronic diseases and the relationship between HCMV and inflammation has raised the possibility that HCMV is merely a passenger or bystander in these disease states and not causal. However, studies in transplant patients with accelerated vascular disease have provided strong support for a role of HCMV in chronic vascular disease observed in the normal host. The mechanisms by which HCMV promotes disease such as atherosclerosis or transplant vasculopathies are not completely understood but likely result from bi-directional interactions between HCMV and the host immune system. Studies from a number of laboratories have demonstrated that HCMV infection of host cells, including monocytes and endothelial cells, can induce expression of a variety of key mediators of the inflammatory response including adhesion molecules, chemokines, cytokines, and

Table 41.5. Evidence linking HCMV infection and vasculature disease. Studies that have demonstrated a link between HCMV infection and vascular disease

Study	Findings and interpretation
HCMV infection and coronary restenosis (Zhou *et al.*, 1996)	Increased rate of restenosis following coronary artery atherectomy in HCMV infected patients
HCMV antibody levels and carotid atherosclerosis (Nieto *et al.*, 1996)	Increased antibody titers correlated with more rapid onset of carotid vasculature disease
HCMV nucleic acids and antigen in coronary artery plaques (Wu *et al.*, 1992; Speir *et al.*, 1994)	HCMV directly associated with diseased vasculature
HCMV seropositivity and coronary artery disease (Melnick *et al.*, 1993; Epstein *et al.*, 1996; O'Connor *et al.*, 2001)	HCMV infection risk factor for development of coronary artery disease
HCMV infection and coronary vasculature disease in cardiac allograft recipients (Grattan *et al.*, 1989; Everett *et al.*, 1992; Hosenpud, 1999; Koskinen *et al.*, 1999; Valantine *et al.*, 2001)	Increased rate of vascular disease and graft loss in patients with HCMV infection



Vessel with developing plaque and/or focal area of damaged endothelium. (A) Inflammatory cellular infiltrate ( ) into area increasing local inflammation with additional damage to endothelium. (B) Release of chemokines and other attractants by mononuclear cells promotes migration of virus-infected smooth muscle cells ( ) into area. (C) Continued migration of smooth muscle cells into area leads to intimal thickening and narrowing of artery.

Fig. 41.1. Possible pathway of vasculopathy associated with HCMV infection of vessels.

pro-inflammatory host enzymes such as COX-2 (Van Dam-Mieras *et al.*, 1987; Taylor *et al.*, 1992; Koskinen, 1993; Sedmak *et al.*, 1994; Waldman and Knight, 1996; Yilmaz *et al.*, 1996; Craigen *et al.*, 1997; Grundy *et al.*, 1998; Speir *et al.*, 1998; Burns *et al.*, 1999; Redman *et al.*, 2002; Zhu *et al.*, 2002). In addition, HCMV encodes a number of immunomodulatory functions including chemokine receptors, chemokines (UL146), and cytokines (IL-10) as well as a plethora of viral evasion functions that favor viral persistence (Penfold *et al.*, 1999; Kotenko *et al.*, 2000; Spencer *et al.*, 2002). Together, interactions between virus infected cells and inflammatory cells could foster virus persistence while at the same time fueling chronic inflammation.

The proposed pathogenesis of HCMV associated vasculopathies in transplant patients is particularly revealing. Studies have reported that HCMV infection in the post-transplant period is a risk factor for graft dysfunction, including the development of vascular sclerosis in the transplant organ (Richardson *et al.*, 1981; Koskinen *et al.*, 1999; Browne *et al.*, 2001a,b; Soderberg-Naucler and Emery, 2001; Tolkoff-Rubin *et al.*, 2001). In cardiac allograft recipients, HCMV infection has been shown to be a risk factors for the development of a distinctive form of coronary arteriosclerosis in the transplanted heart (Grattan *et al.*, 1989; Koskinen *et al.*, 1994; Hosenpud, 1999; Koskinen *et al.*, 1999; Streblow *et al.*, 2003). A less than definitive clinical trial in cardiac allograft recipients with the antiviral agent ganciclovir suggested that inhibition of HCMV replication could limit the rate of development of vascular disease (Valantine *et al.*, 1999). Animal models of this disease process have been developed and data consistent with the observations in human disease have also been obtained (Lemstrom *et al.*, 1995; De La Melena *et al.*, 2001). In the rat model, rat CMV infection of animals with damaged endothelium is associated with infiltration of the intima with smooth muscle cells and narrowing of the lumen of coronary vessels of the transplanted heart (Lemstrom *et al.*, 1995; Vossen *et al.*, 1996; Li *et al.*, 1998; Zhou *et al.*, 1999; Streblow *et al.*, 2001). Early, but not late treatment of infected animals with antivirals can dramatically slow the development of these arterial lesions (Lemstrom *et al.*, 1997). From these experiments it appears that endothelial damage, inflammation and virus infection are required for the development of disease (Lemstrom *et al.*, 1995; Li *et al.*, 1998; Zhou *et al.*, 1999; Streblow *et al.*, 2003). Several models of the pathogenesis of this disease that combine these observations have been proposed. Some investigators have argued that CMV infection promotes systemic inflammation leading to an enhanced host inflammatory response that accelerates the development of vascular sclerosis in the transplanted organ. Other groups have argued that local expression of specific viral gene products in the target organ lead to disease in these animals. An example of such a viral gene product is the functional chemokine receptor HCMV US28. It has been shown that smooth muscle cells expressing the US28 viral gene product migrate down chemokine gradients (Streblow *et al.*, 1999; Streblow *et al.*, 2003). As illustrated in Fig. 41.1, damage to the endothelium either from virus infection, plaque deposition, or following allograft rejection in the case of cardiac allograft recipients, can lead to migration of infected smooth muscle cells expressing the viral chemokine receptor down a gradient of chemokines established by the infiltrating mononuclear cells or endothelial cells. The continued migration of these cells towards the gradient established by persistent local inflammation could account for the accumulation of these cell types in the intima of arteriosclerotic vessels. Because these virus infected smooth muscle cells also release inflammatory mediators, persistent HCMV infection could effectively recruit additional mononuclear cells into the focus of

infection. Infected cells, including activated mononuclear cells, can release inflammatory mediators that can further activate HCMV gene expression. Thus, infection with the virus establishes a paracrine loop that can utilize the products of host inflammation to drive viral gene expression and recruit uninfected and infected cells into an area of virus infection. Once a balance between virus replication and the elimination of virus infected cells is reached, HCMV can persist in the face of chronic host inflammation. Diseases such as coronary arteriosclerosis or transplant vasculopathy could then develop from a combination of HCMV infection and ongoing host inflammation. Although this pathway is consistent with observations made in experimental models of HCMV associated vascular disease, particularly in models of transplant vascular sclerosis, it remains to be shown if a similar pathway can be related to disease in humans. However, it is well accepted that chronic human diseases such as coronary artery disease have inflammation as a major component in their pathogenesis (Zhu *et al.*, 1999; Libby, 2002, 2003). Whether CMV plays a key role in chronic diseases such as coronary atherosclerosis remains unclear, yet this virus can be easily linked to chronic host inflammation and therefore remains a leading candidate as an infectious etiology of several chronic human diseases.

Introduction

Human cytomegalovirus (HCMV) is an ubiquitous β-herpesvirus that establishes a lifelong infection within the host. Although HCMV is generally asymptomatic within the normal individual, the virus causes severe and incapacitating disease in immune compromised patients (Pass, 2001). A critical component for HCMV persistence in the non-immune compromised host is the ability of the virus to establish cellular sites of latency as well as persistent infection. During latency, the HCMV genome is maintained within the cell with limited viral gene expression reactivating virus upon cellular stimulation. In HCMV persistent infection, infectious virus is continually produced in the cell with minimal cytopathic effect thereby enabling long-term infection. Endothelial cells (ECs) and specific subpopulations of the myeloid lineage are believed to represent important sites of persistent HCMV replication and latency, respectively. Recent studies of HCMV and the closely related murine cytomegalovirus (MCMV) are beginning to identify the virally encoded genetic determinants required for replication in these cell types. The establishment of latent infection in myeloid cells that are critical cellular components of the host immune system, also closely interconnects HCMV and the host immune response. This chapter will focus on the role of ECs and myeloid cells as sites of CMV persistent replication and latency, and the viral mechanisms that modulate cellular functions to ensure survival and reactivation within the host.

Sites of HCMV persistence and latency

HCMV infects many different cell types within the host, including: ECs, monocyte-derived macrophages (MDM), smooth muscle cells (SMCs), epithelial cells, fibroblasts, T-lymphocytes, granulocytes, stromal cells, neuronal cells and hepatocytes (Dankner *et al.*, 1990; Einhorn & Ost, 1984; Gnann *et al.*, 1985; Howell *et al.*, 1979; Myerson *et al.*, 1984; Schreier *et al.*, 1985; Sinzger *et al.*, 1995; Soderberg *et al.*, 1993; Wiley and Nelson, 1988). Recent studies have implicated ECs and specific cell types of the myeloid lineage [CD34+ hematopoietic progenitors, CD33+ granulocyte-macrophage progenitors (GM-Ps) and MDM] as critical sites of HCMV persistence and latency. The utilization of these sites as viral reservoirs appears to play an important role in enabling the virus to establish lifelong infection within the host. However, identification of these cell types as viral reservoirs does not preclude the existence of other sites of virus persistence within the host. For example, HCMV DNA has been identified in SMCs from the large arteries of healthy seropositive individuals (Gyorkey *et al.*, 1984; Hendrix *et al.*, 1989, 1990; Petrie *et al.*, 1987; Yamashiroya *et al.*, 1988). The absence of detectable viral gene expression in these HCMV DNA positive cells suggests that SMCs may represent a site of HCMV latency. The high incidence of HCMV transmission following bone marrow transplantation (BMT) (Ho, 1990) indicates that bone marrow stromal cells may also be a site of latency or persistent HCMV replication (Mayerson *et al.*, 1984). This observation is further supported by the ability to isolate infectious virus from the stroma of patients with HCMV disease, as well as the capacity to productively infect stromal cells with HCMV in vitro (Simmons *et al.*, 1990; Torok-Storb *et al.*, 1992). However, bone marrow stroma is composed of many different cell types, and ECs and myeloid progenitor cells within this heterogeneous population may actually represent the sites of virus persistence.

ECs are a site of persistent HCMV replication

ECs form the inner lining of blood vessels and are involved in a variety of processes regulating tissue homeostasis and

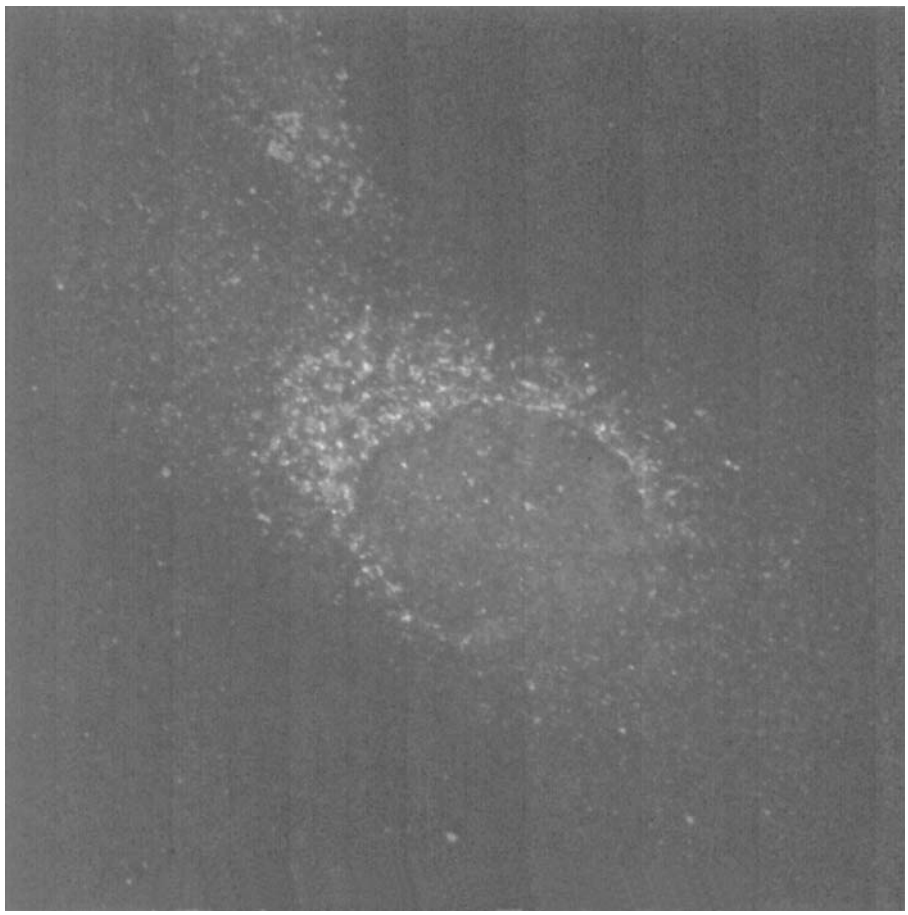

Fig. 42.1. Immunofluorescent micrograph of HCMV-infected AEC. Telomerase life-extended human AEC were infected with HCMV. Cells were fixed and stained for the presence of HCMV protein, glycoprotein B (a late product; green) and a cellular marker of the *trans*-Golgi network (TGN46; red). (See color plate section.)

inflammation. Results from a number of studies investigating the growth of HCMV in ECs have suggested a role for this cell type as an important reservoir of HCMV in the host (Fig. 42.1). The ability to infect cells with induction of minimal cytopathology is a critical requirement for a site of viral persistence. This virus-host cell interaction enables a persistent productive infection to be established for extended periods without cell death. Consistent with this requirement, early histological studies of BMT patients with acute HCMV disease showed that, in many cases, HCMV infection produced only minimal cytopathology in ECs (Friedman *et al.*, 1981). Subsequent studies identifying HCMV in the vessel walls of healthy individuals indicated that ECs also represented a site of persistent infection in individuals with normal immune function (Hendrix *et al.*, 1989; Pampou *et al.*, 2000; Smiley *et al.*, 1988; Speir *et al.*, 1994).

Recent studies have added considerably to our understanding of HCMV growth in ECs. ECs exhibit phenotypic differences that are dependent on the source (adult vs. fetal), vessel size (micro- vs. macrovascular) and anatomical location of the ECs (Page *et al.*, 1992; Turner *et al.*, 1987). Recent phage display-based assays using phage libraries expressing random peptides further emphasize the remarkable level of EC diversity, with ECs from different vascular beds expressing unique tissue-specific molecules (Rajotte *et al.*, 1998). EC origin also has a major influence on characteristics of HCMV replication. Studies comparing HCMV infection in human brain microvascular ECs (BMVEC) and macrovascular aortic ECs (AEC) have shown that HCMV replication differs significantly in these two cell types (Fish *et al.*, 1998). BMVEC, which together with astrocytes compose the blood brain barrier, possess specific transporter systems to allow the transfer of specific

metabolites from the blood to the brain parenchyma. Due to these specialized functional requirements, BMVEC are functionally and biochemically distinct from AEC (Joo, 1992; Moses & Nelson, 1994; Page *et al.*, 1992; Turner *et al.*, 1987). Although both BMVEC and AEC express viral proteins and support HCMV replication, virus fails to accumulate intracellularly in AEC resulting in a reduced level of cell-associated compared to supernatant virus (Fish *et al.*, 1998). In contrast, virus accumulates intracellularly in BMVEC resulting in comparable levels of cell-associated and supernatant virus. This difference in the distribution of virus corresponds to HCMV infection resulting in a lytic infection in BMVEC, but not AEC, suggesting that efficient removal of mature intracellular virions (by either export or degradation) may enable prolonged cell survival. Importantly, this ability of HCMV to produce a persistent long-term productive infection in AEC suggests that AEC may represent a site of persistence within the host.

Differences between individual HCMV strains also have a profound influence on HCMV growth in ECs. Results from a number of laboratories suggest that EC and non-EC tropic HCMV strains are comparable in their ability to enter ECs. However, non-EC strains appear to be deficient in the ability to translocate the viral genome to the nucleus (Bolovan-Fritts and Wiedeman, 2001; Sinzger *et al.*, 2000; Slobbe-van Drunen *et al.*, 1998). Interpretation of results from these studies has been complicated by observed differences in the capacity of even identical strains of HCMV to replicate in ECs (Bolovan-Fritts and Wiedeman, 2001; Kahl *et al.*, 2000). These discrepancies may result from differences in virus preparation and EC culture or HCMV strain derivation. For example, when compared to the United Kingdom (UK) strain, the same HCMV laboratory strain from the American Tissue Culture Collection (ATCC) was shown to differ by the presence of a 929-bp genomic region (Dargan *et al.*, 1997; Mocarski *et al.*, 1997). The cloning of an increasing number of HCMV strains as genetically stable bacterial artificial chromosomes (BACs) is overcoming many of these technical problems and is beginning to facilitate the identification of genetic determinants of HCMV EC tropism (Borst *et al.*, 1999; Hahn *et al.*, 2002, 2003; Marchini *et al.*, 2001; Yu *et al.*, 2002).

The endothelium represents the cellular interface between the blood and underlying tissues. A number of studies indicate that HCMV may facilitate hematogenous spread of virus by modulating interactions between ECs and monocytes (an important site of latent HCMV infection; see below) (Cebulla *et al.*, 2000; Knight *et al.*, 1999; Waldman *et al.*, 1995). HCMV infection of ECs increases expression of cell adhesion molecules such as ICAM-1, which corresponds to an increased interaction between ECs and monocytes resulting in monocyte infection (Knight *et al.*, 1999). Monocytes infected in this manner were capable of transmitting virus to uninfected ECs suggesting a possible mechanism for HCMV dissemination in vivo (Waldman *et al.*, 1995). ICAM-1 was shown to be upregulated at the transcriptional level by the interaction of two HCMV transcriptional activators (IE1 and IE2) with the ICAM-1 promoter (Burns *et al.*, 1999). HCMV infection also upregulates adhesion molecules indirectly by the induction of proinflammatory cytokines. HCMV-infected ECs have been shown to induce vigorous lymphocyte proliferative responses in allogeneic HCMV seropositive-derived T cells resulting in the release of IFN-γ and TNF-α (Waldman and Knight, 1996). The ability of HCMV to induce TNF-α expression in monocytes may play a critical role in disease progression due to the role of this cytokine in HCMV reactivation from this cell type (see below). These proinflammatory cytokines were also shown to induce expression of immune response molecules (ICAM-1, VCAM-1, MHC-I and MHC-II) in neighboring uninfected EC (Waldman and Knight, 1996). Clinically, CMV-mediated upregulation of adhesion and immune response molecules within transplants of solid organ transplant (SOT) and BMT patients may also increase the immunogenicity of the graft resulting in increased incidence of graft rejection (a serious complication of transplantation closely associated with HCMV infection) (Girgis *et al.*, 1996; Grattan *et al.*, 1989; Humar *et al.*, 1999a; Keenan *et al.*, 1991; Koskinen *et al.*, 1996; Smith *et al.*, 1998).

Determinants of EC tropism

The dependence of HCMV replication in ECs on the virus strain suggests that specific viral genes are required for efficient replication in this cell type (Kahl *et al.*, 2000; MacCormac and Grundy, 1999; Sinzger *et al.*, 1999). However, until the recent ability to clone CMV genomes as BACs (for review see: (Wagner *et al.*, 2002)), the instability of EC tropism during in vitro culture of HCMV posed a major problem to the identification of EC tropism determinants. Although, most low passage clinical isolates can initially replicate in both ECs and fibroblasts, these isolates consistently lose their ability to replicate in ECs following repeated passage in fibroblasts (MacCormac and Grundy, 1999; Sinzger *et al.*, 1999). However, initial plaque purification of EC tropic strains and isolation of single clones results in stable maintenance of EC tropism (even after long-term passage in fibroblasts). This result suggests that loss of EC tropism results from selection of viral variants within the initial clinical isolate rather than from viral mutants derived by *de novo* mutation or from non-genetic alterations of the virus (Sinzger *et al.*, 1999). The presence of multiple

genetic determinants directing EC tropism is suggested by the observation that recent clinical isolates exhibit a gradation in their ability to replicate in ECs (Sinzger *et al.*, 1999). Alternatively, this observation could be explained by differences in expression level of a single gene or the existence of polymorphic forms of a single genetic determinant. However, the existence of multiple genes for EC tropism is further supported by the observation that co-infection with two distinct non-EC tropic strains resulted in production of a genetically stable EC-tropic recombinant virus (Sinzger *et al.*, 1999). This result could be explained by two mutations present in the same gene having been repaired by a recombination event. Alternatively, a more likely explanation is one of recombination relocating two distinct genetic loci required for EC tropism within the same recombinant genome.

More recently, BAC-based deletional mutagenesis studies have identified a "genomic tropism island" composed of three HCMV ORFs: UL128, UL130 and UL131A that is required for replication in ECs (Hahn *et al.*, 2004). Deletional mutagenesis identified UL128, UL130 and UL131A as each individually required for replication in human umbilical vein ECs (HUVECs). The inability of a number of laboratory strains to replicate in ECs was also consistent with these viruses encoding inactivated forms of UL128, UL130 and UL131A. Heterologous expression of products of each these ORFs recovered EC tropism of viruses that expressed inactivated versions of the respective ORF, identifying the product of each ORF as individually required for EC tropism. The pUL130 and pUL128 proteins are components of the virion envelope (Patrone *et al.*, 2005; Wang and Shenk, 2005b) that form a complex with two essential envelope glycoproteins (gH and gL) (Wang and Shenk, 2005b). The gH and gL glycoproteins had previously been known to complex with a third glycoprotein, gO, and to be required for replication in fibroblasts (Hobom *et al.*, 2000). Two distinct complexes have been identified in EC-tropic virions comprised of gH/gL complexed with either pUL128/pUL130 or gO (Wang and Shenk, 2005b). Antibodies directed against either pUL130 and pUL128 inhibit infection of ECs (HUVECs), but not fibroblasts. Together, these results support a model wherein the pUL128/pUL130 and the gO containing gH/gl complex are required for infection of ECs and fibroblasts, respectively. The pUL131A has not been detected in the gH/gl complex with pUL128 and pUL130. However, a functional UL131A ORF is required for incorporation of pUL128 and pUL130 into the gH/gl virion associated complex (Wang and Shenk, 2005b), and UL131A is required for an early stage of the virus replication cycle in ECs (Wang and Shenk, 2005a). These observations suggest that UL131A is also probably involved in mediating virus entry into ECs, but may be required at submolar levels, or perhaps is more weakly associated with the complex. UL131A is also required for HCMV replication in lung microvascular ECs and a variety of epithelial cell types (Wang and Shenk, 2005a), as well as monocyte-derived dendritic cells (GM-CSF and IL-4 derived) (Gerna *et al.*, 2005). The requirement of these ORFs for replication in other biologically relevant types of ECs as well as MDM is unknown.

Studies in the closely related MCMV model have also identified a number of viral genes required for growth in ECs as well as macrophages (see below). These studies have similarly relied heavily on BAC-based technology and further emphasize the strength of bacterial-based genetic approaches to address these questions. A recent forward genetic approach identified the MCMV encoded ribonucleotide reductase R1 subunit homologue, M45, as necessary for MCMV growth in murine ECs in vitro (Brune *et al.*, 2001). M45 was also required for normal in vitro replication in macrophages, but not fibroblasts, bone marrow stromal cells or hepatocytes. ECs infected with M45 deletion mutants died rapidly from apoptosis indicating that this gene enabled MCMV replication in ECs by preventing apoptosis of the infected cell. Since ECs represent a site of persistent virus infection, the ability to prevent the normal apoptotic death response of these cells to viral infection may be crucial for CMV replication in this cell type. However, a subsequent study showed that the HCMV M45 homologue (UL45) is not required for growth of a BAC cloned recent clinical isolate (RVFIX) in ECs (HUVEC) indicating that homologous genes in HCMV and MCMV may not always be functionally interchangeable (Hahn *et al.*, 2002). Alternatively, given the heterogeneity of ECs, the function of UL45 during infection of HUVEC may not accurately reflect the role of this gene during HCMV replication in EC types normally infected in vivo. The specific level within the apoptotic pathway that the M45 product functions is unknown. A study from our laboratory investigating determinants of rhesus cytomegalovirus (RhCMV) cellular tropism has identified a virally encoded cyclooxygenase 2 (vCOX-2; Rh10) as a critical determinant of RhCMV EC tropism (Rue *et al.*, 2004). The vCOX-2 appears to mediate EC tropism by inhibiting production of the cellular antiviral molecule, nitric oxide (NO). Although HCMV does not encode a COX-2 homologue, the virus is known to induce cellular COX-2 expression, suggesting that COX-2-mediated inhibition of NO synthesis may be an important determinant for EC tropism.

Myeloid lineage cells are a site of HCMV latency

In addition to ECs as a site of HCMV persistent infection, specific subpopulations of cells of the myeloid lineage have

been identified as potential sites of HCMV latency. Within the periphery, CD14+ monocytes are a known site of latent HCMV infection. The ability to reactivate virus from naturally infected CD14+ monocytes by differentiation into MDM in vitro definitively identifies these cells as a site of latent HCMV infection. Within the bone marrow, CD34+ hematopoietic progenitors and GM-Ps have also been identified as potential sites of HCMV latency. However, reactivation of HCMV from these cell types has been observed only following *in vitro* infection. Consequently, the role of these cell types as sites of HCMV latency in vivo remains unclear.

CD14+ monocytes and MDM

The high level of HCMV transmission associated with the transfusion of blood products (Bowden, 1995; Bowden *et al.*, 1995; Hersman *et al.*, 1982; Tegtmeier, 1989), and specifically with cells of the leukocyte fraction, was the initial indication that leukocytes represented a significant source of latent or persistent virus (Adler *et al.*, 1983, 1983; Tegtmeier, 1986). Subsequently, PCR analysis for HCMV DNA identified CD14+ monocytes as the predominant HCMV-infected cell type in the blood of normal immune competent HCMV seropositive individuals (Taylor-Wiedeman *et al.*, 1991, 1993). PCR analysis showed that only a small number of monocytes in the peripheral blood contained HCMV DNA (<1 in 10^4) (Slobedman and Mocarski, 1999), and viral gene expression in these cells was shown either to be undetectable or restricted to immediate-early gene expression (Dankner *et al.*, 1990; Taylor-Wiedeman, *et al.*, 1991, 1993). These in vivo infection results were consistent with findings from in vitro studies, wherein HCMV infection of monocytes was inefficient, with viral replication being absent or restricted to early events of gene expression (Einhorn and Ost, 1984; Rice *et al.*, 1984; Söderberg *et al.*, 1993). Importantly, the ability of the leukocyte fraction to transmit infection, combined with the absence of viral gene expression in the major infected cell type within this population (CD14+ monocytes), identified CD14+ monocytes as a potential site of viral latency. Consistent with monocytes representing a site of HCMV latency, the HCMV genome in these cells was shown to be maintained at a relatively low copy number (6–13 copies/cell) (Slobedman and Mocarski, 1999) and in an episomal circular form (Bolovan-Fritts *et al.*, 1999) comparable to the latent genome structure of other herpesviruses.

Definitive evidence identifying CD14+ monocytes as a site of HCMV latency requires demonstration of an ability to reactivate virus from naturally infected cells. However, initial attempts to reactivate virus from naturally infected monocytes (Ibanez *et al.*, 1991; Taylor-Wiedeman *et al.*, 1994), or even to establish productive replication following in vitro infection were unsuccessful (Einhorn and Ost, 1984; Rice *et al.*, 1984; Söderberg *et al.*, 1993). In one study, productive HCMV replication following in vitro infection was detected, but infection was extremely inefficient with levels of virus progeny at 0.1% of the level observed in fibroblasts (Maciejewski *et al.*, 1993). A major break-through came with a series of experiments that revealed the importance of monocyte/MDM differentiation-state for HCMV replication (Fig. 42.2) (Ibanez *et al.*, 1991). Specifically, differentiation of monocytes into MDM by co-culture with concanavalin A (Con A)-stimulated non-adherent cells dramatically increased the ability of HCMV to replicate in these cells with approximately 40% of MDM (designated Con A-MDM) supporting productive HCMV replication following in vitro infection (Ibanez *et al.*, 1991). Subsequent studies demonstrated that differentiation of naturally infected peripheral CD14+ monocytes into MDM (designated Allo-MDM) by allogeneic stimulation with non-adherent peripheral blood mononuclear cells (PBMC) was able to reactivate virus from these cells (Söderberg-Naucler *et al.*, 1997b). This report was the first study to conclusively identify myeloid lineage cells as a reservoir for HCMV latency, and has enabled the study of mechanisms of reactivation of latent virus from naturally infected cells.

Growth of HCMV in Con A-MDM

The initial studies using cocultivation with Con A-stimulated autologous non-adherent PBMCs to induce monocyte differentiation resulted in production of the Con A-MDM phenotype that was permissive to HCMV, and resulted in a nonlytic infection that produced exclusively cell-associated virus (Ibanez *et al.*, 1991; Söderberg-Naucler *et al.*, 1997a). Generation of this Con A-MDM phenotype was shown to require CD8+ T-lymphocytes and the proinflammatory cytokines IFN-γ and TNF-α (but not IL-1, IL-2, TGF-β or GM-CSF) (Söderberg-Naucler *et al.*, 1997a). Addition of recombinant IFN-γ or TNF-α alone to monocyte cultures was sufficient to produce MDM that were comparable to Con A-MDM in their level of virus production (Söderberg-Naucler *et al.*, 1997a). These observations suggest a model wherein production of IFN-γ and TNF-α by Con A-activated CD8+ T-lymphocytes induces monocyte differentiation into HCMV permissive Con A-MDM (Fig. 42.3), and indicate a critical role for immune stimulation in the production of HCMV-permissive MDM. Interestingly, IFN-γ and TNF-α were also shown to reactivate HCMV from latently in vitro infected GM-Ps (Hahn *et al.*, 1998) identifying a common requirement for these cytokines in the production of an HCMV-permissive cellular phenotype. A more direct role of TNF-α in HCMV

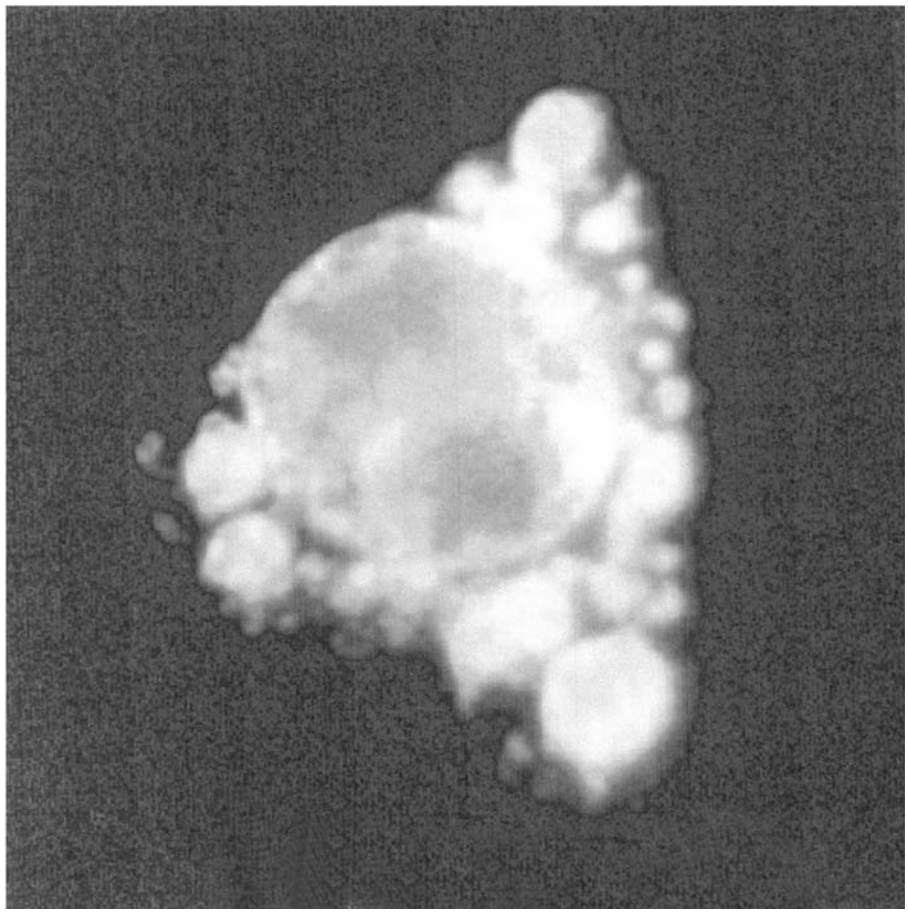

Fig. 42.2. Immunofluorescent micrograph of HCMV-infected MDM. MDM were infected with HCMV. Cells were fixed and stained for the presence of HCMV proteins, pp65 (an early late product; green) and IE-2 (an immediate-early product; red). (See color plate section.)

reactivation is also suggested by the ability of this cytokine to stimulate the IE promoter in myeloid cells by activation of NFκB. Activated NFκB translocates to the nucleus and binds directly to NFκB binding motifs in the IE enhancer thereby activating expression of the two main transcriptional activators of the virus (Prösch *et al.*, 1995, 2001; Ritter *et al.*, 2000; Stein *et al.*, 1993; Zhang *et al.*, 2001). The Con A-MDM model was a major advance in understanding mechanisms of HCMV reactivation. However, the inability to reactivate HCMV from naturally infected Con A-MDM prevented the definitive identification of CD14+ monocytes as a site of HCMV latency in vivo.

Growth of HCMV in Allo-MDM

Allogeneically stimulated PBMC have recently been used to induce MDM differentiation in a cellular microenvironment more closely resembling the milieu believed to exist during in vivo reactivation of HCMV from monocytes. In this system, coculture of HLA-mismatched donor PBMC populations resulted in the production of MDM (designated Allo-MDM) that were permissive to HCMV infection and enabled reactivation of latent virus from CD14+ monocytes naturally infected in vivo (Söderberg-Naucler *et al.*, 1997b). Allo-MDM express both macrophage (CD14/CD64) and dendritic (CD1a/CD83) cell markers. In contrast to Con A-MDM, in vitro infection of Allo-MDM is characterized by vigorous lytic replication in a large number of cells (>50%) and results in accumulation of extracellular virus (Söderberg-Naucler *et al.*, 2001). Importantly, latent HCMV can be reactivated from naturally infected Allo-MDM, which is not possible using other MDM culture systems (Söderberg-Naucler *et al.*, 1997a, b, 2001) and emphasizes the importance of the specific MDM differentiation pathway for HCMV reactivation.

In the Allo-MDM system, cellular depletion and cytokine neutralization experiments showed that both CD4+ and

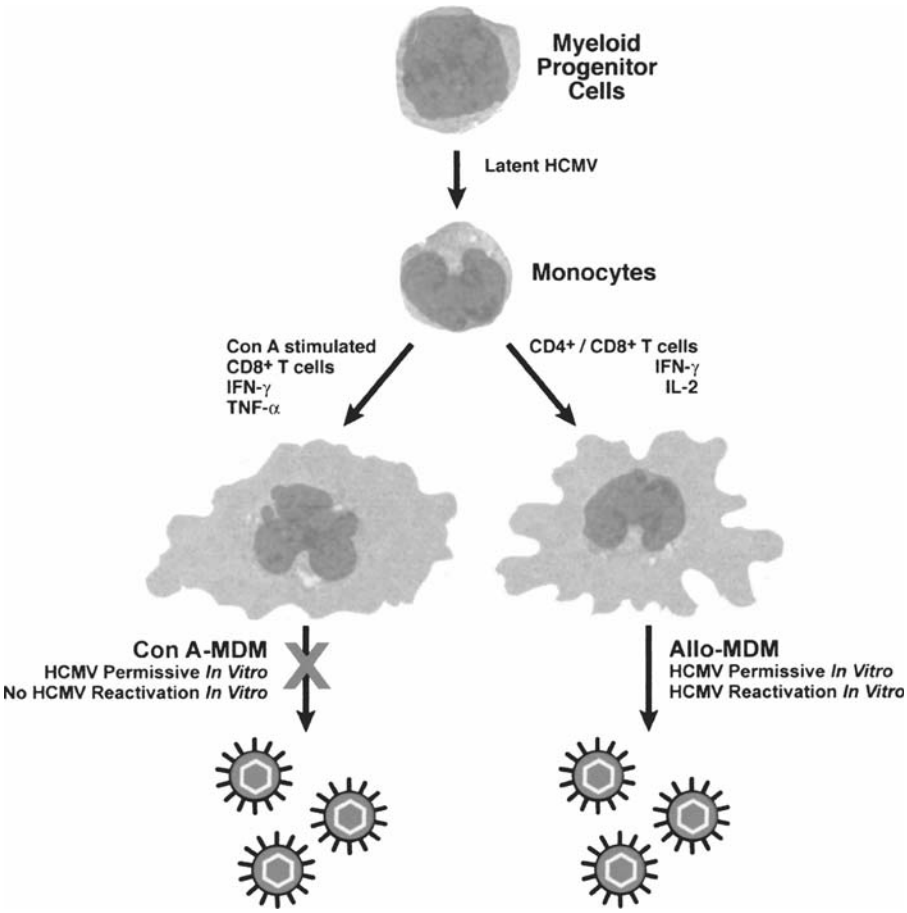

Fig. 42.3. Schematic showing cellular and cytokine factors necessary for generation of Con A- and Allo-MDM.

CD8+ T lymphocytes and the cytokines IFN-γ and IL-2 (but not IL-1, TNF-α or TGF-β) were required for generation of the HCMV-permissive phenotype (Fig. 42.3) (Söderberg-Naucler *et al.*, 2001). These cytokines were required for induction of an Allo-MDM phenotype able to support HCMV replication following in vitro infection. However, reactivation of latent virus from naturally infected cells required additional factors. Conditioned media from Allo-MDM cultures stimulated reactivation of HCMV in the absence of allogeneic stimulation. Thus, soluble factors released during allogeneic stimulation are sufficient to produce a MDM phenotype capable of HCMV reactivation. The presence of IFN-γ (but not IL-1, IL-2, TNF-α, TGF-β or GM-CSF) within the first 48 hours of allogeneic stimulation was necessary for efficient reactivation of latent HCMV. However, IFN-γ alone was not sufficient for the induction of a MDM phenotype capable of reactivating virus. Analysis of the cytokines released during Allo- compared to Con A-MDM differentiation has revealed considerable differences in the kinetics as well as in the type of cytokines released by the two differentiation pathways. IL-13 was observed only in Allo-MDM cultures. IL-13 has previously been shown to increase, albeit at low levels, HCMV gene expression and replication in in vitro infected alveolar macrophages and may be important in the reactivation of HCMV from latency (Hatch *et al.*, 1997). These studies suggest a model (Fig. 42.4) wherein latently infected CD14+ monocytes in the peripheral blood are activated by an immune response (ie., allogeneic organ transplantation or blood transfusion). During this activation, CD4+ and CD8+ lymphocytes play a critical role, with IL-2 released from CD4+ lymphocytes inducing the release of soluble factors from CD8+ lymphocytes. These soluble factors, which include IFN-γ, induce differentiation of CD14+ monocytes into the Allo-MDM phenotype required for reactivation of latent virus.

Consistent with the Allo-MDM in vitro model, a number of studies support a role for immune activation accompanied by release of proinflammatory cytokines

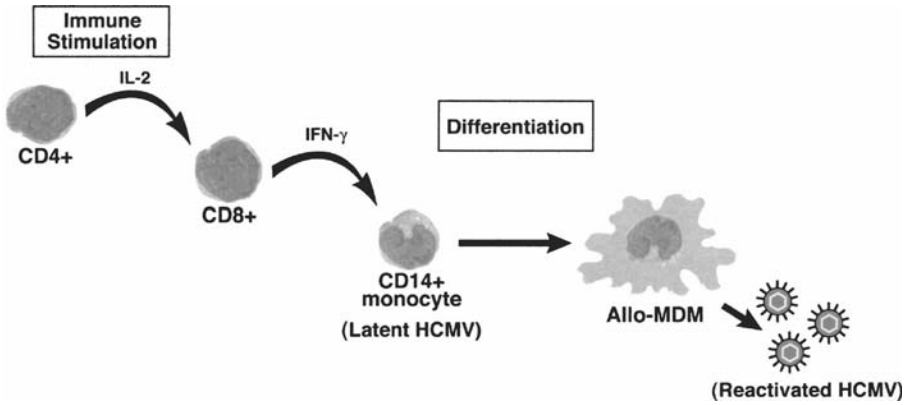

Fig. 42.4. Model for reactivation of latent HCMV in vivo. Allogeneic reaction during transplantation or blood transfusion results in IL-2 production by CD4+ T cells with subsequent stimulation of IFN-γ secretion by CD8+ T cells. In concert with other factors, IFN-γ induces CD14+ monocyte differentiation into Allo-MDM, reactivating latent virus and resulting in the production of infectious virus.

in HCMV reactivation and replication in vivo. In SOT patients, the recipient immune system launches a vigorous allogeneic immune response within the graft in an attempt to remove the transplanted tissue. This response is associated with the release of proinflammatory cytokines, chemokines and an increased expression of adhesion molecules. High levels of HCMV reactivation and disease are consistently observed in allogeneic graft tissue, and elevated plasma levels of IFN-γ and TNF-α are found in patients with HCMV disease (Docke *et al.*, 1994; Fietze *et al.*, 1994; Humar *et al.*, 1999a,b). This association of HCMV disease with proinflammatory cytokine levels is also observed in SOT patients receiving anti-lymphocyte γ globulin (ALG). In these cases, increased TNF-α levels associated with ALG treatment correspond to an increase in severity of HCMV disease (Tolkoff-Rubin and Rubin, 1994). The clinical significance of this extensive reactivation and induction of viral replication within the graft is illustrated by the high incidence of HCMV cytopathology and disease within the transplanted organ (Ho, 1990). For example, HCMV hepatitis is normally asymptomatic in non-hepatic SOT patients; however, in liver transplant recipients, HCMV hepatitis is frequently observed. Similarly, in heart–lung transplant recipients the incidence of HCMV pneumonia is significantly elevated as compared to other SOT patients (Ho, 1990). Since blood transfusion is commonly performed over histocompatibility barriers, reactivation of HCMV through allogeneic stimulation of PBMC would also be expected to play a role in HCMV transmission following transfusion. The high levels of HCMV antigenemia observed in patients with chronic plaque psoriasis are also consistent with the increased TNF-α expression observed in these patients (Asadullah *et al.*, 1999). In experimental studies of MCMV, allogeneic transplantation induces expression of CMV IE genes in vivo, which is accompanied by an increased expression of transcripts for IL-2, TNF-α, IFN-γ and activation of NFκB (Hummel *et al.*, 2001). Although the ability to reactivate productive virus was not determined, a separate study showed that MCMV IE expression could be induced in the lung of latently infected mice in vivo by treatment with TNF-α without immune suppression (Koffron *et al.*, 1999).

Other inflammatory cytokines and chemokines have also been associated with increased HCMV replication and disease following transplantation (Nordoy *et al.*, 1999; 2000a, b). IL-8 was shown to increase HCMV replication in MRC-5 fibroblasts (Murayama *et al.*, 1998), and may be of particular importance due to the high levels of IL-8 that are secreted from a variety of cells in response to proinflammatory cytokines released from allogeneically activated MDM within the graft (Harada *et al.*, 1994). HCMV has also been shown to induce IL-8 expression (Murayama *et al.*, 1998), and studies suggest that IL-8 may function by inhibition of the antiviral IFN-γ response pathway or by increasing neutrophil-mediated HCMV dissemination by attracting neutrophils to sites of HCMV replication (Grundy *et al.*, 1998). High levels of the anti-inflammatory cytokine IL-10 have been shown to be associated with HCMV disease in renal SOT recipients (Nordoy *et al.*, 2000b). An HCMV encoded IL-10 homologue (cmvIL-10) encoded by ORF UL111a was recently identified (Kotenko *et al.*, 2000). The cmvIL-10 shares low sequence homology (27%) with cellular IL-10; however, cmvIL-10 binds to the cellular IL-10 receptor and competes with cellular IL-10 for binding to this receptor. The biological activity

of cmvIL-10 and cellular IL10 also appear comparable (Spencer *et al.*, 2002). Paradoxically, IL-10 has been shown to inhibit monocyte and macrophage function, including inhibiting the release of TNF-α from activated MDM (Oswald *et al.*, 1992). However, recent studies indicate that IL-10 is involved in macrophage differentiation (Allavena *et al.*, 1998), and therefore high IL-10 levels may induce differentiation of MDM into a phenotype that is permissive for HCMV. Together, results from these studies suggest that immune activation with concomitant production of proinflammatory cytokines plays a critical role in virus reactivation and replication in vivo in naturally infected patients, which is recapitulated in vitro in the Allo-MDM system.

CD34+ hematopoietic and CD33+ GM-Ps

Peripheral blood monocytes are clearly an important site of HCMV latency. However, these cells are short-lived, nonreplicating and are present in the circulation for only a brief period of time before entering the tissue and differentiating into MDM. These characteristics suggest another site of HCMV latency existing in a myeloid progenitor population that gives rise to latently infected CD14+ monocytes in the peripheral blood. HCMV has previously been reported to infect CD34+ pluripotent stem cells both in vitro (Goodrum *et al.*, 2002; Maciejewski *et al.*, 1992; Minton *et al.*, 1994; Movassagh *et al.*, 1996; Sindre *et al.*, 1996) and in vivo (Mendelson *et al.*, 1996; Torok-Storb *et al.*, 1992; von Laer *et al.*, 1995a,b). However, since CD34+ stem cells are a common precursor for all peripheral blood cell types, the absence of virus from many peripheral blood cell lineages suggests that CD34+ stem cells may not represent a major site for HCMV latency (Brytting *et al.*, 1995; Schrier *et al.*, 1995; Söderberg *et al.*, 1993; Taylor-Wiedeman *et al.*, 1993; von Laer *et al.*, 1995a,b). This observation would predict that a precursor population further differentiated along the myeloid pathway would be a more biologically significant site of HCMV latency in vivo. Alternatively, HCMV may alter CD34+ cell differentiation, leading to differentiation of only specific cell lineages, or the HCMV genome may be maintained only within specific cell lineages during differentiation.

CD33+ GM-Ps have been identified as one possible precursor population representing a more differentiated site of HCMV latency. Following in vitro infection, HCMV has been shown to infect and establish a latent infection in fetal liver-derived CD33+ GM-Ps (Kondo *et al.*, 1994; 1996; Hahn *et al.*, 1998). Virus was reactivated from CD33+ cells co-expressing either CD15 (granulocyte marker), CD14 (monocyte marker) or CD15 and CD1a (dendritic lineage marker) (Kondo *et al.*, 1994; Hahn *et al.*, 1998). IFN-γ and TNF-α reactivated HCMV from latently in vitro infected GM-Ps (Hahn *et al.*, 1998), closely linking reactivation with immune activation and cellular differentiation state as had been observed with Allo-MDM (Söderberg-Naucler *et al.*, 1997b). However, for both CD34+ precursors and CD33+ GM-Ps, conclusive evidence that these populations represent a site of HCMV latency in vivo awaits demonstration of HCMV reactivation from these cells in vitro following their natural infection in healthy individuals.

The mechanisms controlling HCMV latency and reactivation in these cell types are currently unknown. CMV latency-associated transcripts (CLTs) have been detected in latently infected GM-Ps suggesting a possible role of CLTs in the control of latency. CLTs are represented by sense (ORF94) and antisense transcripts (ORF152 and 154), expressed from the UL122/UL123 region of the genome. This region is normally involved in the expression of transcriptional activators (IE1 and IE2) that are required for lytic replication (Kondo *et al.*, 1996). The presence of CLTs in bone marrow aspirates from healthy HCMV seropositive individuals, as well as the presence of antibodies directed against proteins encoded by ORF94 and ORF152 in the serum of healthy HCMV seropositive individuals (Kondo *et al.*, 1996), have implicated CLTs in the control of HCMV latency in vivo. However, in the in vitro GM-P latency model, only a small proportion of latently infected GM-Ps have been shown to contain detectable CLTs (1.8%–3.6%) even though greater than 90% of GM-Ps are latently infected (Slobedman and Mocarski, 1999). Furthermore, inactivation of ORF94 does not affect the ability of latent HCMV to reactivate in this latency model (White *et al.*, 2000) and CLTs have never been observed in the Allo-MDM model. Together, these observations suggest that CLTs play a minimal role in the regulation of HCMV latency and reactivation. Recently, DNA array analysis using an *in vitro* CD34+ latency model has revealed an expression profile of HCMV genes that is unique to the latent, compared to lytic, state of infection (Goodrum *et al.*, 2002). The role of this latency-associated gene expression profile for the maintenance of latency in these cells is currently unknown. Further investigation may lead to the identification of HCMV ORFs involved in regulating virus reactivation.

Determinants of myeloid lineage cell tropism

Early studies identified differences in the ability of individual HCMV strains to infect monocytes and macrophages indicating that HCMV tropism for monocyte/MDM is genetically determined (Einhorn and Ost, 1984; Rice *et al.*, 1984). Although the genetic determinants for HCMV growth in MDM have not been identified, the MCMV model has provided considerable insight into the role of specific genes in CMV replication in MDM. In the murine model, initial

studies identified M45, M140 and M141 as virally encoded genetic determinants necessary for normal MCMV replication in macrophages in vitro (Brune *et al.*, 2001; Hanson *et al.*, 1999a,b 2001). In animal studies, M140 and M141 were shown to be essential for normal virus replication in the MDM-rich spleen, but not liver, indicating a role of these genes for determination of tropism in vivo (Hanson *et al.*, 2001). Importantly, viruses deleted of M140 and M141 had reduced pathogenicity indicating a role of MDM tropism in virus pathogenicity. Individual deletion of M140 and M141 resulted in decreased viral replication in macrophages; however, a low level of replication remained suggesting a redundancy of function or the existence of additional genes mediating virus replication in MDM. The M140 and M141 gene products are homologues of the HCMV US22 gene family. A study utilizing BAC-based technology has analyzed the function of the 12 US22 MCMV homologues in mediating macrophage tropism (Menard *et al.*, 2003). Results from this study confirmed the role of M140 and M141 as determinants of macrophage tropism, and identified two additional MCMV genes necessary for MCMV growth in macrophages (M36 and m139) (Menard *et al.*, 2003). However, M36 alone was required for growth in primary macrophages as well as macrophage cell lines. The identification of m139 as necessary for growth in macrophages contrasts with results from the earlier studies. This may be a consequence of sequence differences between viruses used by the different laboratories. The function of the HCMV US22 gene family members in mediating HCMV macrophage tropism has not been determined.

Role of apoptotic inhibitors in EC and MDM tropism

Similar to M45 (see above), the M36 product exhibits an anti-apoptotic function suggesting that an ability to inhibit apoptosis may be a common requirement for growth of cytomegalovirus in ECs and macrophages. Studies using a BAC-cloned recent clinical isolate (RVFIX) have shown that the HCMV M45 homologue (UL45) is not involved in the modulation of apoptosis and is dispensable for replication in HUVECs (Hahn *et al.*, 2002) (see above). However, the function of UL45 for replication in macrophages remains to be determined. Four additional HCMV genes, IE1, IE2, UL36/viral inhibitor of caspase-8-induced apoptosis (vICA) and UL37x1/viral mitochondria-localized inhibitor of apoptosis (vMIA) have also been shown to inhibit apoptosis following over-expression of recombinant protein (Goldmacher *et al.*, 1999; Skaletskaya *et al.*, 2001; Zhu *et al.*, 1995). All of these genes except UL36/vICA are essential for virus replication in fibroblasts (Goldmacher, 2002; Marchini *et al.*, 2001; Patterson, and Shenk, 1999) (observed at only low multiplicities of infection for IE1) (Greaves and Mocarski, 1998). The requirement of the HCMV M36 homologue (UL36/vICA) for replication in macrophages or ECs is unknown. However, the M36 and UL36/vICA products appear to share a similar function, with the products of both genes (pM36 and pUL36/vICA, respectively) inhibiting apoptosis at a comparable level within the apoptotic pathway (Menard *et al.*, 2003).

Results from a number of studies have given considerable insight into the mechanisms by which pUL36/vICA and the product of UL37×1/vMIA (pUL37×1/vMIA) inhibit the apoptotic pathway (Goldmacher, 2000; Skaletskaya *et al.*, 2001). The pUL36/vICA and pUL37×1/vMIA appear to function at distinct steps in the apoptotic pathway. During apoptosis, death stimuli (e.g., Fas-ligation) activate caspase 8 resulting in permeabilization of the mitochondrial membrane leading to the release of mitochondrial proteins into the cytoplasm. These mitochondrial proteins activate downstream caspases and nucleases leading to the apoptotic death of the cell. The pUL36/vICA appears to function early in the apoptotic pathway by binding to the prodomain of caspase 8 and inhibiting activation. In contrast, pUL37×1/vMIA is localized to mitochondria (Colberg-Poley *et al.*, 2000; Goldmacher *et al.*, 1999), and has been shown to prevent apoptosis by inhibition of BID-mediated permeabilization of the mitochondrial membrane (Goldmacher, 2002). The function of pUL36/vICA and pUL37×1/vMIA at separate steps in the apoptotic pathway is further supported by the ability of pUL36/vICA, but not pUL37×1/vMIA, to inhibit Fas-mediated apoptosis in type I cells where caspase 8 can directly activate caspase 3 and thereby bypass the mitochondria (Skaletskaya *et al.*, 2001). As indicated above, deletional analysis has shown that UL37×1/vMIA, but not UL36/vICA, is essential for HCMV replication in fibroblasts (Borst *et al.*, 1999; Goldmacher, 2002). Although UL37×1/vMIA is required for oriLyt-dependent viral DNA synthesis (Smith and Pari, 1995), the anti-apoptotic function of pUL37×1/vMIA appears to be critical for replication in fibroblasts, since pUL37×1/vMIA-deficient HCMV replication was rescued by co-expression of other apoptosis inhibitors (Goldmacher, 2002; Reboredo *et al.* 2004). Although the requirement of IE1, IE2, pUL36/vICA and pUL37×1/vMIA for HCMV replication has been determined in fibroblasts, the role of these proteins as determinants of HCMV tropism in other permissive cell types has not been investigated.

Summary

ECs and myeloid lineage cell populations are important sites of HCMV persistence and latency within the host.

The use of cells of the myeloid lineage as a virus reservoir closely links HCMV replication to the immune system, and the virus has exploited immune activation to provide the necessary signals for reactivation of latent virus. The utilization of in vitro culture systems is beginning to increase our understanding of reactivation, persistence and replication of HCMV within EC and myeloid cell populations. The ability of CMV to replicate in EC and MDM is determined by genetic determinants of the virus. The MCMV model has enabled identification of a number of genes that are critical for virus replication in these cells. Ongoing studies in a number of laboratories, in large part using BAC-cloned CMV, are further defining viral determinants of CMV tropism. Recently, a tropism island comprising UL128, Ul130, and UL131A has been identified as necessary for HCMV replication in ECs. These studies are expected to yield exciting insights into the necessary requirements for virus replication in these cells.

Immunobiology and host response

Mark R. Wills, Andrew J. Carmichael, J. H. Sinclair, and J. G. Patrick Sissons

Department of Medicine, School of Clinical Medicine, University of Cambridge, UK

Introduction

HCMV, as all persistent viruses, has to survive in the host in the face of an immune response. Antibody, and probably T-cells in particular, contain the infection in the normal host but impaired T-cell immunity is associated with HCMV disease. The virus encodes functions which can counter this immune response and may also use immune cells as sites of latency. Although our knowledge of many aspects of the virus/host relationship is still incomplete, studies on HCMV over the past 20 years have given insight into how a large DNA virus achieves this coexistence with the normal immune response. Other chapters also contain relevant material.

Cells of the immune system as sites of latency and reactivation for HCMV

Consideration of the immune response to HCMV has to take account of the fact that some cells of the immune system are strong candidates for being sites of latency (see elsewhere in this volume). It is a longstanding clinical observation that HCMV can be transmitted by blood transfusion, but the most sensitive PCR based techniques do not detect HCMV DNA in plasma or serum of healthy virus carriers (although they do in patients with active HCMV disease), implying HCMV is most likely transmitted by cells in peripheral blood. Evidence from several laboratories suggests that HCMV is latent in myeloid lineage cells (Sinclair and Sissons, 2006). Using highly sensitive PCRs (of considerably greater sensitivity than those used for diagnostic assays) HCMV DNA can be detected in CD14+ peripheral blood mononuclear cells and in CD34+ cells in bone marrow (Mendelson *et al.*, 1996; Taylor-Wiedeman *et al.*, 1991). HCMV DNA is also reported in CD33+ cells in bone marrow (Hahn *et al.*, 1998; Kondo *et al.*, 1994). No infectious virus can normally be detected in freshly isolated peripheral blood monocytes or myeloid lineage progenitors, although the induction of HCMV immediate early gene expression can be detected by highly sensitive RT PCR when peripheral blood monocytes are differentiated with interferon-γ (IFN-γ) and GM CSF (Taylor-Wiedeman *et al.*, 1994). In order to demonstrate that a particular cell type is really harboring latent virus capable of reactivation, it is necessary to show that infectious virus can be rescued from such putatively latently infected cells. One group has reported that differentiation of peripheral blood monocytes from seropositive subjects to monocyte-derived macrophages in vitro in the presence of allogeneic T cells results in detection of infectious HCMV by co-cultivation of the cells with fibroblasts (Soderberg-Naucler *et al.*, 1997, 2001). There is also evidence that dendritic cells (DC) may be a specific site of latency and that their differentiation to mature DC in vitro may be associated with reactivation (Reeves *et al.*, 2005).

These observations all relate to the detection of endogenous HCMV DNA in cells of normal seropositive subjects, rather than the detection of HCMV which has been exogenously added to such cells during in vitro culture. Although the latter type of experiment with exogenous HCMV in general supports the evidence from detecting endogenous HCMV DNA that myeloid lineage cells are a site of persistence, it is always difficult to exclude the possibility that low level virus replication (rather than true latency) is maintaining HCMV DNA in such experimental in vitro systems.

Considering all of the current evidence from the literature, the most plausible picture of HCMV latency and reactivation in cells of the bone marrow and blood is that HCMV is carried in myeloid lineage progenitor cells in the bone marrow and is maintained in the cells as they divide down the myeloid lineage into peripheral blood monocytes and dendritic cells, albeit at a very low frequency – perhaps 0.01% of mononuclear cells – and

virus then reactivates when latently infected monocytes differentiate into macrophages (probably after exiting the circulation into tissues) under the influence of cytokines. However, unanswered questions include the following. (i) Is there a reservoir of HCMV in bone marrow which maintains virus in some stem cell population ? (ii) What is the mechanism by which viral DNA is maintained in myeloid lineage cells as they divide ? (iii) Is there a subpopulation of mononuclear cells, particularly DC, which is critical for maintenance of HCMV latency? (iv) What are the precise cytokines and pathways which differentiate peripheral blood mononuclear cells into the cell phenotype needed to permit reactivation of latent virus ? (v) Are there a limited set of HCMV RNA transcripts that are necessary for the maintenance of HCMV latent DNA (analogous to the LATs of HSV)?. There are reports of HCMV latency-associated transcripts in myeloid lineage cells in both natural and experimental infection, but it is unclear whether they are truly specific for latency and what their function might be (White *et al.*, 2000; Bego *et al.*, 2005). The subject is further discussed in the chapter by Nelson and colleagues.

The balance of evidence suggests that HCMV is not latent in other cell types in peripheral blood (Taylor-Wiedeman *et al.*, 1993). In healthy carriers, lymphocytes and peripheral blood neutrophils appear not to carry virus – although neutrophils may contain CMV antigens during active HCMV disease, there is no evidence they do this in normal seropositive subjects and the evidence is against their being a site of replication for the virus (Sinzger *et al.*, 1996).

The immune response to HCMV in the human host

Lessons from animal models of CMV disease

Murine cytomegalovirus (MCMV) infection of inbred mice has been extensively utilized as a model system to help to further understand HCMV infections, including aspects of immune responses, latency and immunopathology. This work has generated a substantial literature and made an important contribution to our understanding of the immunobiology of HCMV. The work cannot be reviewed here but is well summarized in several excellent recent reviews on the immune response to (Polic *et al.*, 1998; Reddehase, 2002), and latency of (Reddehase *et al.*, 2002), MCMV.

Antibody and complement

Following primary infection, antibodies specific to numerous HCMV encoded proteins are readily detectable in serum (for review see Britt, 1991; Landini and Michelson, 1988). These include structural tegument proteins (such as pp65 and pp150), envelope glycoproteins (predominantly gB and gH) as well as non-structural proteins such as the Immediate Early 1 protein (IE1, UL123) and a DNA binding protein (UL44). Viral neutralizing activity in vitro is predominantly mediated by antibodies specific for gB and gH (Britt *et al.*, 1988; Urban *et al.*, 1996). Both mouse and guinea pig animal models suggest that antibody is important in protection from a lethal infective dose and in reducing fetal infection (Rapp *et al.*, 1992; Harrison *et al.*, 1995). In humans, pre-existing humoral immunity to cytomegalovirus also plays an important role in preventing congenital infection of the fetus during pregnancy (Fowler *et al.*, 1992) and in preventing transfusion-associated infection in premature infants (Yeager *et al.*, 1981). The role of humoral immunity in the pathogenesis of HCMV disease in immunosuppressed patients is uncertain. Prior infection and thus the existence of preformed antibody to HCMV may be an important factor in limiting reactivation and protecting from re-exposure: however there is very limited evidence for the benefits of administration of HCMV-specific antibody to immunosuppressed transplant patients who are undergoing a primary infection or reactivation, with some studies reporting beneficial results and others suggesting no benefit (Guglielmo *et al.*, 1994; Munoz *et al.*, 2001).

gB in its mature form is composed of two disulfide bonded subunits gp116 and gp58 derived by the proteolytic cleavage of a glycosylated precursor molecule (Britt and Mach, 1996). The vast majority of HCMV-infected individuals mount an antibody response directed against gB, and a large proportion of neutralizing antibodies produced in response to viral infection are gB-specific (Britt *et al.*, 1990; Gonczol *et al.*, 1991; Marshall *et al.*, 1992; Schoppel *et al.*, 1997). The antibody response to gB has consequently been extensively studied, and three antigenic domains have been identified AD-1 (aa 552–635), AD-2 (aa50–77) and AD-3 (aa783–906). AD-2 has been further defined and is composed of two antibody binding sites, Site I (aa68–77) and Site II (aa50 to 54). Antibodies which bind AD-1 and AD-2 site II mediate viral neutralization (Kniess *et al.*, 1991; Meyer *et al.*, 1992; Wagner *et al.*, 1992). The AD-1 site is large, consisting of a run of 75 amino acids: within this run, cysteine residues at positions 573 and 610 form a disulfide bond which is required for binding of antibodies directed at AD-1 (Speckner *et al.*, 1999).

Of possible relevance to humoral immunity to HCMV is the existence of virus-associated Fc receptors. It has been recognized for some time that HCMV-infected cells are able to bind IgG isotype from human and other species, independent of any specific antibody activity to HCMV (Furukawa *et al.*, 1975; Keller *et al.*, 1976; Mackowiak and

Marling-Cason, 1987). However only recently has this IgG Fc binding activity been ascribed to viral encoded gene products rather than virus-induced cellular Fc binding proteins. Two proteins have been described to date. The first is a 34 KDa Fc binding protein (Fc-BP) encoded by the TRL11 and IRL11 ORFs and predicted to be a type I membrane glycoprotein with no homology to other herpesvirus encoded viral Fc binding proteins (Lilley *et al.*, 2000). The second protein is 68KDa and also a type I membrane glycoprotein encoded by the UL119-UL118 genes involving mRNA splicing (Atalay *et al.*, 2002). These may represent one of the many levels at which HCMV is modulating the host immune response – it has been suggested that binding of IgG could reduce the levels of neutralizing antibody directed at the virus. These Fc-BPs proteins have a rapid rate of endocytosis and endolysosomal degradation providing for an efficient antibody capture and disposal system. Binding of HCMV-specific IgG via the Fc region might also interfere with complement activation and antibody-dependent cellular cytotoxicity (Atalay *et al.*, 2002).

The HCMV specific CD8+ T-cell response

Given the inferential evidence for the importance of T cell immunity in controlling HCMV infection, and the evidence for the importance of the CD8+ T-cell response to MCMV, more attention has focussed on the CD8+ T-cell response to HCMV than on any other aspect of the immune response. HCMV specific CD8+ cytotoxic T-lymphocytes (CTL) were first detected in the peripheral blood lymphocytes (PBL) of patients with overt HCMV infection in the early 1980s and a short time later MHC restricted HCMV specific CTL precursors (CTLp) were stimulated to grow and mediate cytotoxicity from the PBL of normal healthy HCMV carriers (Borysiewicz *et al.*, 1983). Since then a large body of work has identified individual viral encoded proteins which are recognized by T-cells, defined minimal antigenic peptides within these proteins together with their MHC Class I restrictions, enumerated the frequency of HCMV-specific CD8+ T-cells in normal healthy carriers as well as immunosuppressed transplant patients, and analyzed in detail the clonal composition of HCMV specific CD8+ T-cells and the phenotypic characteristics of these long-term memory T-cells.

The cytomegalovirus gene products that are targets for the human CD8+ T cell response have been studied for over 20 years. Most recently a study produced overlapping peptides to the whole HCMV proteome (213 open reading frames) in order to comprehensively map all CD8 and CD4 epitopes. Previous to this work.

CD8+ T-cells specific for IE1 (UL123), the viral matrix proteins (pp65 (UL83), pp150 (UL32), pp28 (UL98), pp50 (UL44)), the surface viral glycoproteins (gB (UL55), gH (UL75)) and a number of other viral proteins (US2, US3, US6, US11, UL16 and UL18) have been detected using either interferon-γ secretion (ELISPOT or intracellular flow cytometry), or cytotoxicity using either bulk polyclonal T cell populations or T-cell clones as effector cells in radioactive Chromium release cytotoxicity assays (Borysiewicz *et al.*, 1983; Wills *et al.*, 1996; McLaughlin-Taylor *et al.*, 1994; Elkington *et al.*, 2003; Kern *et al.*, 2002; Longmate *et al.*, 2001).

The work of Riddell and colleagues first suggested a large proportion of the CD8+ T-cell response to HCMV was directed at the lower matrix protein pp65: these workers generated CD8+ T-cell clones for infusion into bone marrow transplant recipients by secondary in vitro restimulation of PBMC from their HCMV seropositive donors, and found the majority of clones were specific for this protein (Walter *et al.*, 1995). A number of subsequent studies concluded that the majority of the CD8+ T-cell response to HCMV in a given virus carrier is directed at pp65 (Wills *et al.*, 1996; Boppana and Britt, 1996). By comparing the killing of target cells infected with AD169 strain HCMV or a pp65 gene deletion mutant (RVAd65) in limiting dilution assays, the contribution of pp65-specific CTLp to the total HCMV-specific CTLp frequency was quantified in healthy seropositive virus carriers at between 70 and 90%, suggesting that pp65 is an immunodominant viral antigen. CD8+ T-cells specific for IE1 have also been isolated from seropositive carriers, although the frequencies of IE1-specific CTLp have been estimated as being on average ten fold lower than those for pp65-specific CTLp (Wills *et al.*, 1996). pp150-specific CTL have also been isolated from some donors at about a four fold lower frequency as compared to pp65. The frequency of CTLp specific for gB, gH, pp50 or pp28 has been reported as < 10 CTLp/million CD8+ T cells which is at the limit of detection of this assay (Boppana and Britt, 1996).

Estimations of the frequency of virus-specific CTLp in assays based on in vitro restimulation with antigen depend on the CTL precursors being exposed to all the appropriate CTL epitopes. When autologous HCMV-infected fibroblasts are used for restimulation in vitro, viral encoded proteins (US2, US3, US6 and US11) which interfere with antigen processing and presentation (Reddehase, 2002) may lead to selective presentation of particular virus peptides by surface MHC Class I, with a consequent underestimation of CTLp frequencies against certain antigens. The view that pp65 is immunodominant has been refined in the light of further data over the past few years. Panels of synthetic peptides spanning complete proteins combined with rapid epitope screening assays (based on intracellular

IFN-γ production detected by flow cytometry) have been used to reassess the frequency of IE1-specific CD8+ T-cells (Kern *et al.*, 2002). Previous observations that only a proportion of virus carriers have CD8+ T-cell responses to IE1 were confirmed, but this work also found much higher frequencies of IE1-specific T-cells similarly high to those specific for pp65 (Kern *et al.*, 2002). It has been shown that *de novo* protein synthesis is not required to sensitize target cells to killing by pp65-specific CTL (McLaughin-Taylor *et al.*, 1994): pp65 is present in virions as a preformed structural protein which is delivered to the cytosol during virus infection, from which pp65 can enter the MHC Class I antigen processing pathway. In contrast IE1 has to be synthesized *de novo* after virus infection at a time in the virus replication cycle when the ability of the infected cell to present new MHC Class I-peptide complexes is impaired. Direct stimulation of CD8+ T-cells using synthetic peptides in the absence of any influence of other viral proteins, has demonstrated much higher frequencies of IE1-specific CD8+ T-cells than previously reported and this may hold true for other HCMV antigens. A recent investigation utilizing a bioinformatics approach to predict CD8+ T-cell epitopes has described dozens of new HCMV T-cell epitopes within 14 HCMV encoded proteins. The new epitopes were verified using an ELISPOT assay measuring IFN-γ production, and some of the epitopes were also used to generate functional CTL (Elkington *et al.*, 2003). Although this approach clearly indicates that many other HCMV-encoded proteins can act as CD8+ T cell antigens, this work also confirms the previous findings that pp65-specific and IE-specific T-cells dominate the CD8+ T-cell response in most individuals.

In a recent and comprehensive study 13 687 consecutive 15-mer peptides overlapping each other by 10 amino acids and comprising 213 potential ORFs were synthesized and used in intracellular IFN gamma assays in order to identify all ORFs from HCMV that could be recognized by either CD4+ or CD8+ T cells derived from a cohort of 33 HCMV positive donors of diverse HLA haplotypes. The results showed that 47% of HCMV ORFs were recognized by CD8 T cells from at least one of the 33 donors, and on average, each donor exhibited CD8+ T cell responses to 7 different ORFs. Traditionally studied ORFs like pp65 (UL83) and IE1 (UL123) were among the most common, being recognized by more than half the subjects: however this study showed that many other ORFs are also commonly recognized and pp65 and IE1 are by no means universally immunodominant in such a diverse cohort (Sylwester *et al.*, 2005).

The production of soluble tetrameric MHC class I molecules loaded with specific viral peptide, then biotinylated and labeled with a fluorescent tag, provides a reagent which binds directly to the T-cell receptor (TCR) of peptide-specific CD8+ T-cells. These labelled Class I tetramers allow the visualization of antigen-specific T-cells by flow cytometry and have made an important contribution to the analysis of virus-specific T-cell responses to many human virus infections including HCMV. Tetramers have been constructed to pp65 peptides presented by HLA-A0201, A2402, B0702 B0801 and B3501 (Gillespie *et al.*, 2000; Hassan-Walker *et al*, 2001; Kuzushima *et al.*, 2001), and IE1 peptides presented by HLA-A0201 and B0801 (Khan *et al.*, 2002a,b; Wills *et al.*, 2002), and used to determine the frequencies of virus-specific CD8+ T-cell frequencies in a large number of HCMV seropositive subjects. The results confirm the very high frequency response to pp65 and IE1 in most HCMV seropositive subjects and also demonstrate that functional assays such as LDA tend to underestimate the HCMV-specific frequency (as has been noted in other virus sytems).

It is clear that primary HCMV infection elicits strong virus-specific CD8+ responses to numerous viral proteins: evidence suggesting that these specific CD8+ responses are protective is provided both by murine models of CMV, and by data obtained from patients undergoing reconstitution of their immune systems following bone marrow transplantation (BMT) or stem cell transplantation. Mice are protected from lethal MCMV challenge by CD8+ cells specific for immediate early antigens (Reddehase *et al.*, 1987). In a murine model of CMV reactivation (deficient in B-cell responses) it has been demonstrated that CD4+ and NK cells can substitute for CD8+ T-cells. However in murine models of BMT, removal of reconstituted CD8+ cells leads to lethal disease and reconstituted CD8+ cells transferred to immunocompromised mice could prevent disease (Polic *et al.*, 1998). Following BMT in humans there was a strong correlation between the recovery of cytolytic T-cell activity and recovery from HCMV infection. Subsequent studies quantifying T-cell recovery using virus-specific tetramers estimate that a recovery of virus-specific cells of >10 per μl of blood was protective against serious HCMV disease (Cwynarski *et al.*, 2001).

The availability of HCMV-specific MHC Class I tetramers, monoclonal antibodies against cell surface molecules and multi-parameter flow cytometry, and techniques for T-cell receptor analysis have made possible the detailed characterization of antigen-experienced HCMV-specific CD8+ T-cells.

Analysis of the clonal composition of the memory CD8+ T-cells specific for defined pp65 epitopes by sequencing of the TCRs of multiple independently derived epitope-specific CTL clones, reveals a high degree of clonal focusing: in a given virus carrier, the majority of CTL clones

specific to a defined pp65 peptide use only one or two different TCRs at the level of the nucleotide sequence. Thus in a given carrier the large population of circulating HCMV peptide-specific CD8+ T cells is in fact composed of only a few individual CD8+ clones that have undergone extensive clonal expansion in vivo (Weekes *et al.*, 1999). It is also clear that cells of an individual antigen-experienced pp65-specific clone persists in the virus carrier for years, because the same clones can be repeatedly isolated over time. CD8+ T-cells obtained from unrelated subjects that recognize the same defined peptide–MHC complex often use the same TCR Vβ segment, and have similar amino acid sequences within the hypervariable VDJ region of the TCR that binds to the viral peptide. Similar observations of clonal T cell focusing have also been made for CTL specific for a number of IE1 peptides (Khan *et al.*, 2002a,b). Other persistent virus infections (EBV and HIV) are also associated with this tendency to develop large oligoclonal T-cell populations. The focused pp65-specific and IE-specific CD8+ T-cell response observed in HCMV carriers may be the result of repeated exposure to viral antigen upon periodic reactivation of HCMV, with selection of CD8+ T-cells that express certain high affinity TCRs, and persistence of these clones in long-term memory. It is interesting to note that a study of HCMV-specific T-cell responses in elderly subjects showed that the frequency can increase over time to very large numbers (up to 25% of all CD8+ cells in an individual) and that the T-cell repertoires become more oligoclonal (Khan *et al.*, 2002a,b). It remains unclear how soon after primary HCMV infection the pattern of CD8+ T cell clonal focussing develops and to what extent the relative clonal dominance changes in long-term virus carriers. Following allogeneic BMT from HCMV-seropositive donors to HCMV-seropositive recipients, individual dominant HCMV-specific CD8+ clones present in the donor are typically transferred in the allograft, undergo expansion and are maintained long-term in the recipient; in addition, delayed emergence of different donor-derived clonotypes can be observed more than 6 months after transplantation (Gandhi *et al.*, 2003).

Detailed analysis of the phenotype of peptide-specific CD8+ T-cells has been undertaken using oligonucleotide clonotype probing (which can quantify a virus-specific T-cell receptor rearrangement directly from peripheral blood) or HCMV-specific tetramers, in combination with monoclonal antibodies to cell surface markers. The expression of the CD45RA and CD45RO isoforms of CD45 was previously thought to distinguish naïve (CD45RAhigh) from memory T-cells (CD45ROhigh). However in healthy carriers, cells of a single antigen-experienced HCMV-specific CD8+ T-cell clone are present in both the CD45RO(high) and CD45RA(high) T-cell subpopulations. During primary HCMV infection, all the highly activated effector HCMV-specific T-cells express CD45RO, but during convalescence they accumulate in the CD45RA(high) subpopulation consistent with reversion from CD45RO(high) cells (revertant memory) (Wills *et al.*, 1999). The same phenomenon has also been described following primary EBV infection (Faint *et al.*, 2001). Further analysis of the CD45RA(high) HCMV-specific T-cells using markers to cell surface adhesion, costimulation and chemokine receptor molecules has shown that they lack the costimulatory molecule CD28 and the chemokine receptor CCR7. However, in contrast to previous suggested models of CD8+ T-cell memory, these CD28(−) CD45RA(high) CCR7(−) cells are not terminally differentiated, because following stimulation in vitro with specific HCMV peptide these cells undergo sustained clonal proliferation, up-regulate CD45RO and CCR5, and show strong peptide-specific cytotoxic activity. In an individual with acute primary HCMV infection, HCMV pp65-specific CD8+ T-cells are predominantly CD28(−) CD45RO(high) CCR7(−). During convalescence, an increasing proportion of pp65-specific CD8+ T-cells were CD28(−) CD45RA(high) CCR7(−). Thus CD8+ T-cell memory to HCMV is maintained by cells of expanded HCMV-specific clones that show heterogeneity of activation state and costimulation molecule expression within both CD45RO(high) and CD28(−)CD45RA(high) T-cell pool (Wills *et al.*, 2002). Similar techniques have been used by a number of groups to examine the memory T-cells generated in response to EBV: it is interesting to note that T-cells specific for lytic EBV antigens display very similar phenotypic profiles to HCMV pp65-specific T-cells. It is also of interest that this does not hold for all persistent virus infections (Faint *et al.*, 2001; Appay *et al.*, 2002).

The capacity of viruses to encode functions which may enable them to evade the effector function of cytotoxic T-cells has generated enormous interest over the last 5 years. Investigation of the ways in which HCMV can disrupt the normal MHC Class I antigen processing pathways has revealed a surprising number of mechanisms: these include the degradation of newly synthesised MHC Class I heavy chains (mediated by US2 (Wiertz *et al.*, 1996b) and US11 (Wiertz *et al.*, 1996a; Jones *et al.*, 1995), retention of MHC Class I peptide complexes in the endoplasmic reticulum (ER) (mediated by US3 (Jones *et al.*, 1996) and blockade of peptide translocation into the ER (mediated by US6 (Ahn *et al.*, 1997). Further details are available elsewhere in this volume and in a recent review by Reddehase *et al.* (2002). The sequential expression of the US3 and US11 gene products which would lead to MHC Class I-peptide complex retention in the ER (US3)

followed by degradation of de novo MHC Class I heavy chains (US11) may be very efficient. The combination of US2 and US11 may allow many different MHC Class I heavy chains (as would be found in an outbred population) to be redirected to the cytosol for degradation. HCMV infects and becomes latent in a number of different cell types in vivo and it is conceivable that some of these viral gene products are more efficient in some cell types as compared to others. The human immune system and HCMV have co-evolved to a considerable extent, and it is possible that the diversity of immune evasion mechanisms reflects this co-evolution of the virus and the immune system, and that some of the immune evasion mechanisms are vestigial.

It is clear that in spite of viral immune evasion genes, upon primary HCMV infection the host mounts a strong T-cell response composed of both CD8+ CTL and CD4+ helper T-cells which produce antiviral cytokines: the outcome is that acute primary infection is resolved, although HCMV is not cleared from the host but becomes latent with periodic reactivation and production of new virions. It is also clear that during long term carriage of the virus there is a balance between the cell-mediated immune response and viral activity. This balance is lost in the immunocompromised host where reactivation of latent virus or primary infection can lead to uncontrolled viral replication which may cause serious disease and death. Although the functional significance of the immune evasion genes in vivo remains to be determined, a plausible hypothesis is that the immune evasion mechanisms give the virus a "window of protection" during reactivation from latency in the face of an expanded population of antigen-experienced T-cells, enabling the virus to complete its life cycle to produce new virions. During reactivation the IE proteins are abundant at a time when the virus is retaining MHC Class I complexes in the ER, blocking antigen presentation and preventing T-cell surveillance. The virus may thus be able to replicate and release progeny virus from the cell: however, subsequent infection of neighboring cells will deliver preformed viral structural proteins to the cytosol which can enter the antigen processing pathway and be presented at the infected cell surface for T-cell recognition, resulting in local containment of the reactivation episode.

The HCMV-specific CD4+ T-cell response

CD4+ T-cells play a key role in the control of virus infections, by the activation of dendritic cells (by ligation of CD40 on the dendritic cell by CD154 on the T-cell), by providing help for virus-specific B-cells (ligation of CD40 on the B-cell induces immunoglobulin gene somatic hypermutation and class switching), and by secreting cytokines that facilitate the proliferation and differentiation of virus-specific CD8+ T-cells. In murine CMV infection, long-term selective depletion of CD4+ T-cells in vivo is associated with persistent virus replication at specific sites (Jonjic *et al.*, 1989). Analysis of the HCMV-specific CD4+ T-cell response in humans has been greatly enhanced by the development of flow cytometry methods to detect intracellular cytokine expression by antigen-specific T cells (Waldrop *et al.*, 1997, 1998). At present the production of peptide-MHC Class II tetramers to identify HCMV-specific CD4+ T-cells is technically demanding; when such tetramers become widely available, not only the analysis but also the therapeutic manipulation of HCMV-specific CD4+ T-cells may become possible in the future.

Using in vitro restimulation of PBMC with whole HCMV antigen and detection of intracellular cytokine expression by flow cytometry, in healthy HCMV carriers typically 1%–2% of all circulating CD4+ T-cells are specific for HCMV (Waldrop *et al.*, 1998; Rentenaar *et al.*, 2000) with one report of much higher frequencies (Sester *et al.*, 2002). In approximately 60% of HCMV carriers, virus-specific CD4+ T-cells recognize the lower matrix protein pp65, and in a given carrier, CD4+ T-cells typically focus on one or a few peptide epitopes within pp65 (Beninga *et al.*, 1995; Kern *et al.*, 2002). The recent examination of the whole HCMV proteome for CD8 T cell specific responses also included CD4+ T cell responses: the results show that 44 unique ORFs are antigens for CD4+ T cells and that 81 ORFs are targets for both CD4 and CD8 responses (Sylwester *et al.*, 2005). In part because fewer peptide binding motifs are known for MHC Class II alleles than for MHC Class I alleles, relatively few MHC Class II restricted epitopes within pp65 have been identified (Kern *et al.*, 2002; Khattab *et al.*, 1997; Le Pira *et al.*, 2004; Weekes *et al.*, 2004).

In healthy virus carriers, the surface phenotype of HCMV-specific CD4+ T-cells has been analyzed by staining of HCMV-stimulated PBMC with two or three different fluorochrome-linked monoclonal antibodies. CD4+ T-cells responding to stimulation by whole HCMV are enriched within CD45RO+, CD27−, CD62L−, CD11a^{high} and CCR7− subpopulations (Rentenaar *et al.*, 2000; Sester *et al.*, 2002; Bitmansour *et al.*, 2002). Most peripheral blood HCMV-specific CD4+ T-cells secrete IFN-γ, a proportion of which also secrete TNFα and IL-2; very few HCMV-specific CD4+ T-cells secrete IL-4 (Rentenaar *et al.*, 2000; Bitmansour *et al.*, 2002). Many HCMV specific CD4+ cells are also cytotoxic and MHC Class II restricted (van Leeuwen *et al.*, 2006; Weekes *et al.*, 2004).

In healthy HCMV carriers, the circulating population of HCMV-specific CD4+ T-cells is oligoclonal. Following in

vitro stimulation with whole HCMV antigen, responding HCMV-specific CD4+ T-cells showed striking focussing of TCR Vβ segment usage by monoclonal antibody staining. When HCMV-specific CD4+ T-cells were sorted and analyzed by RT-PCR, the TCR Vβ expansions were composed of a limited number of clonotypes in which 1–3 clones dominated the response together with a cohort of subdominant clones and numerous minor clones. The same dominant clonotypes were identified when CD4+ T-cells were stimulated with individual pp65 peptides (Bitmansour *et al.*, 2002). Cells of an individual expanded clone showed a spectrum of triggering thresholds consistent with TCR-independent threshold regulation, including different thresholds for secretion of IFN-γ and IL-2, but the triggering thesholds did not differ between CD27+ and CD27− cells of the given clonotype. These results indicate that a given antigen-experienced CD4+ clonotype can give rise to qualitatively distinct functional responses depending upon epitope dose and availability of costimulation (Bitmansour *et al.*, 2002).

To study the CD4+ T-cell response during natural primary HCMV infection in immunocompetent subjects is difficult; usually the time at which infection began is uncertain, and subjects have often had symptoms for a number of days before primary HCMV infection is confirmed by detection of anti-HCMV IgM. Longitudinal studies of primary HCMV infection have been performed in the setting of HCMV-seronegative individuals who received a renal transplant from a HCMV-seropositive donor (D+/R−) without prophylactic Ganciclovir treatment, although the introduction of HCMV via a solid organ that lacks lymphatic drainage and the concurrent use of immunosuppressant therapy (to prevent graft rejection) may modify the kinetics of infection and of the host T cell response (Rentenaar *et al.*, 2000; Gamadia *et al.*, 2003). HCMV DNAemia was first detected at a median of 25 days (range 18–29 days) after transplantation, and HCMV-specific IFN-γ-producing CD4+ T-cells were first detected (by intracellular cytokine staining following in vitro restimulation with whole HCMV antigen) at a median of 7 days (range 4–14 days) after first detection of HCMV DNAemia. In four of five subjects, HCMV-specific CD4+ T-cells were detected 3–10 days before anti-HCMV IgM. The HCMV-specific CD4+ T cell response developed rapidly, reached peak frequencies of 0.46% to 2.5% of peripheral blood CD4+ T-cells, and decreased rapidly to a low level over at least the next 10 weeks. In contrast to the phenotype observed in long-term virus carriers, during primary infection HCMV-specific CD4+ T-cells were predominantly CD38+, many were CD27+, and most showed co-expression of CD45RO and CD45RA. During primary infection a proportion of HCMV-specific CD4+ T cells were in cell cycle, as indicated by Ki67 expression (Rentenaar *et al.*, 2000). In a second study, compared to asymptomatic primary infection, symptomatic primary HCMV infection was associated with delayed appearance of HCMV-specific CD4+ T-cells in peripheral blood. Among nine subjects who developed primary HCMV infection following D+/R– renal transplantation, four subjects had symptomatic infection that required Ganciclovir treatment, while the other five subjects had asymptomatic infection. In the symptomatic subjects the time at which HCMV DNAemia was first detected after transplantation (median 27 days) was similar to that in asymptomatic subjects, but the peak viral load and duration of HCMV DNAemia was greater in the symptomatic subjects. The time from first detection of HCMV DNAemia to first detection of HCMV-specific CD4+ T-cells by intracellular cytokine staining was significantly longer in symptomatic infection (median 39 days, range 28–53) compared to asymptomatic infection (median 10 days, range 0–17). In symptomatic subjects, HCMV-specific CD4+ T-cells only became detectable after starting Ganciclovir therapy, and reached peak frequencies of 0.36% to 1.42% of peripheral blood CD4+ T-cells. There were no differences in the kinetics of antibody or CD8+ T-cell responses between symptomatic and asymptomatic subjects; the time from first detection of HCMV DNAemia to first detection of either anti-HCMV antibody (15 days vs. 17 days) or HCMV-specific CD8+ T-cells by peptide MHC Class I tetramer staining (21 days vs. 24 days) was similar in symptomatic and asymptomatic subjects (Gamadia *et al.*, 2003).

HCMV, innate immunity and natural killer (NK) cells

NK cells were originally described for their ability to mediate cytotoxicity against certain tumors without prior activation; they are characterized by the lack of both T- and B-cell markers, and are a component of the innate immune system. An important role for NK cells in the early control of viral infections is emerging (Tay *et al.*, 1998; Biron *et al.*, 1999). There is only limited evidence for the role of NK cells in the control of HCMV infection (Biron *et al.*, 1989, 1999). However the virus encodes a variety of NK cell evasion mechanisms which are discussed in this section, which provides indirect evidence for the importance of these cells in the innate response to HCMV. In the MCMV murine model system the evidence for their protective role is much stronger. Newborn mice are highly susceptible to lethal MCMV infection until NK responses become apparent at 3 weeks. Adoptive transfer of NK cells into these mice or adult SCID mice can confer protection reviewed in (Tay *et al.*, 1998). Inbred mouse strains have differing

resistance to MCMV (Scalzo *et al.*, 1992), and the dominant Cmv1 resistance locus has been mapped to the NK cell gene complex on chromosome 6. The Cmv1 resistance gene has now been shown to encode an activating NK cell receptor Ly49H (Brown *et al.*, 2001; Lee *et al.*, 2001; Daniels *et al.*, 2001).

Activation of NK cells is promoted by signals from activating NK receptors, but inhibited by signals received through the inhibitory NK receptors which interact with specific MHC class I molecules on the surface of the target cell. Individual NK cell clones express distinct patterns of inhibitory NK receptors, which include immunoglobulin supergene family members and C-type lectin family members (for review see Lanier, 2005). The C-type lectin heterodimer CD94/NKG2A is present on the surface of the NK cell and ligates HLA-E on a normal cell surface (Braud *et al.*, 1998). HLA-E is stabilized and translocated to the cell surface when it binds certain signal sequence peptides derived from the normal turnover of HLA-A, HLA-B and HLA-C molecules (Braud *et al.*, 1997).

As discussed earlier, HCMV encodes a number of genes responsible for the retention and destruction of MHC Class I molecules. Upon HCMV reactivation (Sissons *et al.*, 2002), the early interference with the MHC Class I pathway may impede the presentation of viral derived peptides to the host CD8+ T cells and hence avoid recognition. However, the reduced levels of surface Class I MHC on HCMV-infected cells might be expected to favor activation of host NK cells (Karre *et al.*, 1986). This has led to the suggestion that HCMV would also have to evade NK cell recognition in order to safeguard this window in which a latent genome within a cell can reactivate, and have enough time to assemble and release infectious virus. The observation in a number of experimental systems that HCMV-infected cells are relatively resistant to NK-mediated lysis suggests that HCMV has evolved viral encoded functions to evade NK surveillance (Reyburn *et al.*, 1997; Vales-Gomez *et al.*, 2003; Wang *et al.*, 2002; Cerboni *et al.*, 2000; Fletcher *et al.*, 1998; Arnon *et al.*, 2005; Tomasec *et al.*, 2005; Wills *et al.*, 2005). Six distinct virus encoded proteins and mechanisms have been proposed to prevent NK activation and lysis of HCMV-infected cells.

HCMV expresses a viral MHC Class I homologue gpUL18 which was reported to inhibit NK lysis (Reyburn *et al.*, 1997), although this report has been contradicted by a subsequent investigation which suggested that UL18 may activate NK cells (Leong *et al.*, 1998). These data might now be explicable in the light of the recent identification in MCMV of a new MHC Class I-like molecule (m157) which can engage an inhibitory NK receptor in one strain of mouse and an activating receptor in others (Arase *et al.*, 2002). It has subsequently been shown that HCMV UL18 binds LIR-1/ILT2 which is present on only a subset of NK cells (Cosman *et al.*, 1997). At present it remains unclear whether UL18 expression on HCMV-infected cells activates or inhibits specific populations of NK cells.

The viral protein encoded by HCMV UL40 also includes a signal sequence peptide similar to those of Class I molecules, and expression of UL40 has been reported to stabilize HLA-E (Tomasec *et al.*, 2000). HLA-E expression is not affected by the US2-11 gene products, and the maintenance of surface HLA-E expression by providing an appropriate signal peptide from UL40 has been proposed as another novel NK cell evasion strategy for HCMV (Wang *et al.*, 2002). However other groups have not observed this effect of UL40 in their systems (Falk *et al.*, 2002).

Some activating NK receptors recognize host cell proteins which are upregulated on the surface of stressed cells, for example, the activating receptor NKG2D recognizes MICA and MICB. A third mechanism of NK cell evasion is mediated by the viral membrane glycoprotein UL16 which is able to bind to MICB, ULBP-1 and ULBP-2 and sequester them in the endoplasmic reticulum/cis-Golgi, thereby preventing them interacting with NK cells bearing NKG2D and delivering an activating signal to the NK cell (Dunn *et al.*, 2003; Cosman *et al.*, 2001; Sutherland *et al.*, 2001).

A structural protein (pp65) from the virus tegument has been shown to interact with an activating NK receptor NKp30 leading to dissociation of the linked CD3zeta from NKp30 and thus reducing NK cell mediated killing (Arnon *et al.*, 2005).

In addition to these data, a comparison of the ability of different stains of HCMV to resist NK mediated lysis of infected fibroblasts has demonstrated a striking difference between the laboratory adapted strain AD169, and strains of the virus (including Toledo) that are more closely related to clinical isolates (Cerboni *et al.*, 2000; Fletcher *et al.*, 1998). As both laboratory adapted and clinical strains of the virus possess the UL16, UL18 and UL40 open reading frames these observations imply that other viral genes are responsible for this phenotype. Fletcher *et al.* (1998) reported that clinical strains of the virus downregulated lymphocyte function-associated antigen-3 (LFA-3) whereas AD169 did not, and speculated that this may be responsible for the difference in phenotype: however, Cerboni *et al.* (2000), while also observing the difference between clinical and laboratory strains, were not able to show any correlation with LFA-3 downregulation. It has been recognized since 1996 that clinical isolates of the virus have a larger genome, and comparison of AD169 with Toledo virus shows that Toledo has a 13.5 kb insert which encodes 20 predicted ORFs (Davison *et al.*, 2003) that are absent from AD169. It seems likely that

some of the genes encoded in the UL b' region are responsible for rendering infected fibroblasts resistant to NK lysis Two genes encoded in the Ulb' region have now been shown to mediate inhibition of NK cell lysis. ORF UL141 is able to inhibit NK cell mediated lysis in a clonally dependent manner, by sequestering CD155 in the ER and thus preventing it engaging an NK activating receptor DNAM-1 (Tomasec *et al.*, 2005). ORF UL142 is a novel HCMV encoded MHC class I related molecule which also inhibits NK cell killing in a clonally dependent manner. UL142 is also localized to the ER and it is likely that it sequesters virus induced stress molecules that would otherwise traffic to the cell surface to be recognized by activating NK cell receptors (Wills *et al.*, 2005).

The immune response and pathology in immunocompromised subjects

Immunosuppression by CMV

It is frequently stated that HCMV is "immunosuppressive." At a clinical level, the association is somewhat anecdotal: obviously CMV disease frequently arises in the context of immunosuppression, iatrogenic or otherwise, and it is difficult conclusively to implicate HCMV in the causation of immunosuppression. The disease associated with primary HCMV infection in the normal immunocompetent host is characterized by marked T cell proliferation, but not obviously associated with immunosuppression.

The possession of a large number of gene functions which modulate the expression of MHC molecules, cytokines and NK cell interactions, is really the most specific evidence that HCMV exerts "immunosuppressive" effects, although it is obvious these effects do not prevent the normal host from mounting a sustained and effective immune response against the virus. In the whole organism the effect of HCMV- induced downregulation of MHC molecules may be counteracted by other influences – for instance, it has been shown that IFN-γ and TNFγ can upregulate MHC Class I molecules and counteract the downregulating effect of the HCMV genes referred to above (Hengel *et al.*, 1995).

Much of the in vitro evidence for "immunosuppression" comes from experiments in which investigators have added HCMV to cultures of peripheral blood mononuclear cells and then used a readout such as T cell proliferation in response to exogenous mitogens or a similar assay. Given that HCMV, particularly recent clinical isolates, can infect differentiated macrophages, it can be envisaged that infection in this sort of in vitro system at high multiplicities may well cause impairment of such assays. More recently, it has been shown that HCMV can exogenously infect dendritic cells (DC) in vitro (Raftery *et al.*, 2001), with enhanced expression of their costimulatory molecules and partial downregulation of MHC molecules, with upregulation of apoptosis-inducing ligands CD95L (FasL) and tumor necrosis factor related apoptosis-inducing ligand (TRAIL). This would result in HCMV-infected DC potentially being able to delete activated T-cells. There is emerging evidence that dendritic cells may well be a site of HCMV latency and, although it can be envisaged this sort of mechanism might operate in vivo, it is difficult to know how valid it is to extrapolate from in vitro experiments in which large numbers of DC are infected to the situation likely to obtain in vivo, where HCMV infection of DC would seem likely to be a low frequency event. Murine DC have also been shown to be permissive for murine CMV infection in vitro: again, MCMV infected DC were unable to deliver the signals necessary for T-cell activation and it has consequently been suggested they may be involved in CMV-induced immunosuppression in the mouse (Andrews *et al.*, 2001).

In summary, the issue of whether HCMV can exert generalized immunosuppressive effects in vivo is unresolved. The clinical settings in which disseminated HCMV disease occurs are usually characterized by multiple variables operating simultaneously – such as pre-existing immunosuppression due to other disease or the administration of immunosuppressive drugs, the simultaneous administration of anti-rejection therapy, and other opportunistic infections. Given the in vitro evidence, it is plausible to suggest that CMV disease may be causally associated with immunosuppression but the case has to be regarded as not proven.

Immunopathology in human CMV disease

CMV pneumonitis

Pneumonitis is the most serious manifestation of HCMV infection after bone marrow transplantation (BMT), occurring in 10–15% of allogeneic BMT recipients, with a mortality of 80% prior to antiviral therapy. There is interstitial pneumonitis in the absence of any other identifiable pathogen, with increasing arterial hypoxemia, and progression to respiratory failure. It is suggested that graft versus host disease (GVHD) may contribute to the lung injury in HCMV pneumonitis in BMT recipients. The relationship between HCMV and GVHD is controversial, with proposals both that HCMV may predispose to GVHD, and vice versa. The striking rarity of pneumonitis attributable to HCMV in patients with AIDS, implies that factors other than immunosuppression alone contribute to its occurrence in BMT recipients. It has been hypothesized that CMV pneumonitis is mediated by an immunopathological mechanism, consequent on the regenerating immune system following bone marrow transplantation reacting against CMV infected cells in the lung. It has been suggested that CD4+ T

cells might be particularly involved and that the absence of CD4+ cells in HIV infection might explain the rarity of CMV pneumonitis in that setting: however, in fact cells recovered from bronchoalveolar lavage during CMV pneumonitis in bone marrow transplant patients are mainly NK cells and CD8+ cells. An alternative suggestion has been that uncontrolled virus replication might trigger a dramatic release of cytokines such as TNFγ and this might mediate the pneumonitis – although any direct evidence for this is lacking (Barry *et al.*, 2000).

Reddehase and colleagues (Podlech *et al.*, 2000) have used the model of syngeneic bone marrow transplantation and simultaneous infection of BALB/c mice with MCMV to study the mechanisms of CMV interstitial pneumonitis in a longitudinal fashion. These authors have taken care to adapt the mouse model to mimic as closely as possible the events surrounding allogeneic bone marrow transplantation in humans. When reconstituting CD8+T-cells were depleted, there was a disseminated cytopathic MCMV infection of the lungs with high mortality. When hematopoietic reconstitution with both CD8+ and CD4+ T-cells occurred, viral replication in the lungs was much less and restricted to focal areas – after clearance of the infection, memory CD8+ T-cells persisted in the lung tissue with little MCMV present. These authors concluded there is no evidence for CD8+ T-cells exerting an immunopathological effect, but rather of their protecting against MCMV infection in the lungs. They make the point that the late phase appearances with persisting memory cells in the lung could be misinterpreted as CMV-induced immunopathology and conclude that this mouse model provides no evidence for immunopathologically mediated interstitial pneumonitis in human BMT recipients.

CMV retinitis and immune recovery vitritis

HCMV disease is one of the most frequent opportunistic infections in patients with advanced HIV infection, of whom 40% develop sight or life threatening HCMV disease. A CD4+ T-cell count of $< 50/\mu l$ carries a particular risk of disease, although the widespread use of highly active antiretroviral therapy (HAART) in developed countries means that relatively few patients now have such low CD4+ T-cell counts, and the incidence of HCMV disease in patients with AIDS has consequently declined significantly. The commonest manifestation is HCMV retinitis which was seen in up to 25% of patients with AIDS prior to effective antiretroviral therapy. It is characterized by hemorrhagic retinal necrosis, spreading along retinal vessels, and threatening sight when disease encroaches on the macula (Whitcup, 2000).

However a newly recognized syndrome consequent on the use of HAART is "immune recovery vitritis." This is characterized by posterior segment inflammation and occurs in patients with inactive previously treated CMV retinitis, as the CD4+ T-cell count reconstitutes on antiretroviral therapy. In one series 60% of patients with prior HCMV retinitis who responded to HAART developed the syndrome (Karavellas *et al.*, 1999). Although attributed to infiltrating T-cells reacting to HCMV antigens in the eye, this mechanism (whilst plausible) is not yet proven, although T cells are present in histopathological specimens of epiretinal membrane in the disease. The inflammation responds to steroids alone.

CMV and inflammatory demyelinating neuropathy

The pathogen most frequently associated with acute inflammatory demyelinating neuropathy, also known as Guillain–Barré syndrome (GBS), is *Campylobacter jejuni*. However a proportion (5%–10%) of patients with GBS show serological evidence of primary HCMV infection, and are more likely to have IgM antibodies to the GM2 ganglioside than other patients with GBS (Khalili-Shirazi *et al.*, 1999): a causal relationship is postulated. CMV-infected fibroblasts have been shown to express the GM2 epitope (Ang *et al.*, 2000) and "molecular mimicry" has been postulated as a possible cause of the association (Yuki, 2001).

CMV and organ transplant rejection

The risk of HCMV disease is 3–5 times greater in a seronegative than a seropositive recipient receiving an organ allograft from a seropositive donor, and disease is much more severe. Many centers "match" seronegative donors to seronegative recipients, although this is often thwarted by organ shortage. Disease often presents with specific organ involvement not seen in the normal subject. Interstitial pneumonitis due to HCMV carries a poor prognosis; disease in the gastrointestinal tract includes oesophagitis, gastritis and gastric ulceration, and colitis; HCMV retinitis may occur in severely immunosuppressed patients (Rubin, 2001; van der Bij and Speich, 2001).

There has been much circumstantial suggestion in the literature that CMV, even more so than other virus infections, may be somehow involved in the pathogenesis of rejection of solid organ allografts. There is suggestive epidemiological evidence that clinically significant HCMV infection is commoner in subjects who develop graft rejection, although it can be difficult to dissect out whether HCMV infection is a consequence of the immunosuppressive therapy in use, or preceded the treatment of rejection episodes – the latter would make a causal association more plausible (Kashyap *et al.*, 1999; Borchers *et al.*, 1999). Possible mechanisms which have been invoked to explain how CMV might

be causally associated with rejection have focussed mainly on changes which the virus might induce in endothelial cells and in the expression of Class II MHC molecules. It is postulated that CMV-induced upregulation of adhesion molecules on endothelial cells might promote the infiltration of allospecific T-cells (Borchers *et al.*, 1999; Craigen and Grundy, 1996). There is some evidence for increased expression of Class II MHC molecules on cells in solid organs in association with CMV infection – given the evidence that, if anything, CMV may downregulate class II MHC molecules in isolated cell types in vitro, such upregulation seems more likely to be mediated by cytokine release related to virus infection, such as IFN-γ or others. There is some evidence from the model of rat CMV infection that rat CMV can enhance chronic kidney allograft rejection in a transplant model (Lautenschlager *et al.*, 1997) and that this is associated with increased vascular endothelial and tubular epithelial expression of ICAM-1 and increased interstitial inflammation (Yilmaz *et al.*, 1996).

One group has reported that CD13 (Aminopeptidase N, a cell surface zinc metalloproteinase) is incorporated into virions, and that this may be associated with the development of autoantibodies to CD13. In the allogeneic bone marrow transplant setting, the presence of antibodies to CD13 correlated with the development of GVHD, and it was suggested CMV induced CD13 specific autoimmunity was contributing to the mediation of the GVHD (Moller *et al.*, 1999).

The other aspect of solid organ allograft rejection in which CMV has been implicated is the chronic vasculopathy which may be a feature of chronic rejection. In cardiac transplantation, the most common cause of death following transplantation is cardiac allograft vasculopathy, an obliterative progressive vascular disease of the coronary arteries which is believed to be a form of chronic rejection (Orbaek Anderson, 1999). A number of studies have indicated an association between CMV and cardiac allograft vasculopathy (Weill, 2001), and it has been postulated that CMV may promote vasculopathy by the sort of mechanisms discussed above. Again, these suggestions are largely based on circumstantial evidence, although the virus may enhance the development of allograft vasculopathy in the rat CMV model of heterotopic heart or aortic transplantation, (Hosenpud, 1999; Koskinen *et al.*, 1999).

Introduction

Cytomegaloviruses (CMVs) are ubiquitous but highly species specific agents and are a common cause of infections in many animal species including humans (Weller, 1971). The characteristic cellular changes caused by CMV including cell enlargement with intranuclear inclusions were first reported in 1881 by Ribbert in the kidneys of a stillborn infant with congenital syphilis (Ribbert, 1904). Subsequent reports have described similar findings in the parotid glands of children and in the salivary glands from guinea pigs. It was initially thought that cytomegalic inclusion disease (CID) of the newborn was the sole manifestation of human CMV (HCMV) infection (Goodpasture and Talbot, 1921; Lipschutz, 1921; Cole and Kuttner, 1926; Lowenstein, 1907). Several groups of investigators have simultaneously isolated and propagated HCMV from infants and children with CID and from adenoidal tissue of children undergoing adenoidectomy (Rowe *et al.*, 1956; Smith, 1956; Weller *et al.*, 1957). As tissue culture isolation and serological assays became more widely available, HCMV was linked to a variety of illnesses, many of which have subsequently been shown to be unrelated to HCMV. A common characteristic of patients at risk for invasive HCMV infections is the suppression of host immune responsiveness. The onset of AIDS epidemic in the early 1980s has led to a dramatic expansion of the spectrum of HCMV disease. HCMV was the most common opportunistic infection in patients with AIDS and a major cause of morbidity and mortality in these patients until the introduction of highly active antiretroviral therapy (Jacobson *et al.*, 1988; Gallant *et al.*, 1992; Munoz *et al.*, 1993; Spector *et al.,* 1999). Currently, HCMV continues to cause disease in patients with AIDS, but similar to other opportunistic infections in AIDS patients responding to antiretroviral therapy, the incidence of invasive HCMV disease is extremely low even in those with minimally reconstituted immune systems (Jacobson *et al.*, 2001). Currently, HCMV is a cause of significant morbidity and mortality in newborn infants who acquire HCMV prenatally and in allograft recipients.

Epidemiology of HCMV infection

Human cytomegalovirus infections have been recognized in every human population that has been studied (Krech *et al.*, 1971; Gold and Nankervis, 1976). HCMV infection is endemic without seasonal variation (Gold and Nankervis, 1976). HCMV is acquired early in life in most populations with the exception of people in economically well developed countries of northern Europe and North America. The patterns of HCMV acquisition vary greatly based on geographic and socioeconomic backgrounds of the population and the seroprevalence increases generally with age (Alford *et al.*, 1981). In the developing world, acquisition of HCMV is nearly universal in early childhood. Studies have shown that most preschool children (>90%) in South America, Sub-Saharan Africa, East Asia, and India are HCMV antibody positive (Gold and Nankervis, 1982; Stagno, 2001). In contrast, seroepidemiologic surveys in Great Britain and in certain populations in the United States have found that less than 20% of children of similar age are seropositive (Huang *et al.*, 1980; Gold and Nankervis, 1982).

In Chengdu, China a population survey observed 60% of children 4 to 7 years of age were HCMV seropositive (Liu *et al.*, 1990). Similiarly, 58% of children 4 to 12 years of age in Taipei, Taiwan, 61% of hospitalized pediatric patients from a low income population in Rio de Janeiro, Brazil and 56% of children aged 1 to 4 years in Jamaica were HCMV antibody positive (Prabhakar *et al.*, 1992; Shen *et al.*, 1992; Suassuna *et al.*, 1995). In Finland the HCMV seroprevalence

rate increased from 27% in children 7 months of age to 41% in children 8 years of age in a cohort of children followed for 8 years (Aarnisalo *et al.*, 2003). In a population survey in Parma, Italy, age-specific HCMV seroprevalence increased from 28% in two year olds to 96% in 45–54-year-old residents (Natali *et al.*, 1997). Similiarly, in Spain, the CMV seroprevalence rate in children 2 to 5 years of age was 42% increasing to 79% in adults 31 to 40 years of age (de Ory *et al.*, 2004). Recent studies in blood donors have demonstrated that populations in Asia and Africa continue to have CMV seropositivity rates of 95%–100% (Urwijitaroon *et al.*, 1993; Lu *et al.*, 1999; Pultoo *et al.*, 2001; Kothari *et al.*, 2002) whereas in Germany the HCMV seropositivity rates in blood donors are lower ranging from 30% in 18 to 20 year olds to >70% in adults >65 years of age (Hecker *et al.*, 2004).

Although the exact mode of HCMV acquisition is unknown, it is assumed to be through direct contact with body fluids from an infected person. The differences in age-related prevalence probably reflect differences in child rearing practices, sexual behaviors, and possibly, living conditions. Breastfeeding, group care of children, crowded living conditions, and sexual activity have all been associated with high rates of HCMV infections. Sources of virus include oropharyngeal secretions, urine, cervical and vaginal secretions, semen, breast milk, blood products, and allografts (Hayes *et al.*, 1972; Reynolds *et al.*, 1973; Lang, 1975; Alford *et al.*, 1980). Presumably, exposure to saliva and other body fluids containing infectious virus is a primary mode of spread and because infected infants typically excrete significant amounts of HCMV for months to years following infection. Even older children and adults shed virus for prolonged periods (>6 months) following a primary HCMV infection. In addition, a significant proportion of seropositive individuals continue to shed virus intermittently.

An important determinant of the frequency of congenital and perinatal HCMV infections is the seroprevalence rate in women of child-bearing age. The incidence of congenital HCMV infection is directly related to the seroprevalence rates. Studies from United States and Europe have shown that the seropositivity rates in young women range from less than 50% to 85% (Krech *et al.*, 1971; Gold and Nankervis, 1982). In contrast, most women of child bearing age in less well developed regions are HCMV antibody positive (Schopfer *et al.*, 1978; Stagno *et al.*, 1982; Vial *et al.*, 1985). Prospective studies of pregnant women in the United States have shown that the rate of HCMV acquisition in young women of lower income is about 6% per year compared with about 2% in women of middle to upper income background (Stagno *et al.*, 1986).

Perinatal HCMV acquisition, including congenital infection contributes significantly to the spread of HCMV in the population because infected infants excrete large amounts of virus for prolonged periods of time. An additional and less well appreciated mode of virus spread is through breast milk. It is estimated that over 80% of breast-fed infants of persistently infected mothers will be exposed to HCMV as a result of breast feeding (Hayes *et al.*, 1972; Stagno *et al.*, 1980). Similar to congenital infections, infants infected through breast feeding will excrete virus for prolonged periods of time, making them ideal vectors for the spread of virus. Children continue to acquire HCMV infection throughout childhood and the rate of infection continues to increase during adolescence and early adulthood secondary to sexual exposure. Significant titers of infectious HCMV can be found in semen and cervical secretions, suggesting that exposure to the body fluids could result in the transmission of HCMV (Jordan *et al.*, 1973; Willmott, 1975; Drew *et al.*, 1981; Chandler *et al.*, 1985a,b). The natural history of HCMV infection in adolescents and adults has been shown to parallel sexually transmitted diseases (STDs) (Knox *et al.*, 1979; Sohn *et al.*, 1991). Homosexual men and women attending STD clinics have an increased incidence of HCMV infection (Drew *et al.*, 1981). Thus, HCMV should be considered an STD in adults that can effectively spread through a sexually active population (Table 44.1).

Transmission of HCMV by mothers to infants: perinatal infections

Studies of mothers and infants from various countries in previous decades suggest that HCMV infections in young infants are acquired from their mothers (Numazaki *et al.*, 1970; Hayes *et al.*, 1972; Reynolds *et al.*, 1973; Granstrom and Leinikki, 1978; Alford *et al.*, 1980; Stagno *et al.*, 1980; Dworsky *et al.*, 1983a,b). HCMV may be transmitted from the mother to the infant either through the genital tract at delivery or through breast milk (Hayes *et al.*, 1972; Reynolds *et al.*, 1973; Stagno *et al.*, 1975; Alford *et al.*, 1980; Stagno *et al.*, 1980; Dworsky *et al.*, 1983a,b). As seen in Table 44.2, the rates of HCMV excretion in infants differ by country (Stagno *et al.*, 1980). Children from countries such as Japan, Thailand, and Guatemala, where the practice of breast-feeding is almost universal and the majority of women of childbearing age are seroimmune to HCMV, have higher rates of HCMV excretion during the first year of life than infants from other countries where breast-feeding is less common (Stagno *et al.*, 1980; Stagno and Cloud, 1990). (Table 44.2)

Table 44.1. Sources and routes of transmission of HCMV infection

	Mode of exposure and transmission
Community acquired, age	
Perinatal	Intrauterine fetal infection (congenital); intrapartum exposure to virus; breast milk acquired; mother-to-infant transmission
Infancy and childhood	Exposure to saliva and other body fluids; child-to-child transmission
Adolescence and adulthood	Exposure to young children; sexual transmission; possible occupational exposures
Hospital acquired, source	
Blood products	Blood products from seropositive donors; multiple transfusions; white blood cell containing blood products
Allografts	Allograft from seropositive donors
Donor semen	Artificial insemination using semen from seropositive donors

Breastfeeding practices have a major influence on the epidemiology of postnatal HCMV infections (Stagno and Cloud, 1994; Bryant *et al.*, 2002). HCMV isolation from breast milk was first described over 35 years ago by Diosi *et al.,* (1967). The importance of breast milk as a source of HCMV was first recognized by Hayes *et al.* (1972). HCMV has been detected in breast milk in 13% to 50% of lactating women using conventional virus isolation techniques (Yeager, 1975; Stagno *et al.*, 1980; Dworsky *et al.*, 1983). More recent studies utilizing the more sensitive PCR technology demonstrated the presence of HCMV DNA in breast milk from >90% of seropositive women (Hamprecht *et al.*, 1998, 2001; Maschmann *et al.*, 2001). The mechanisms of HCMV reactivation and excretion of HCMV in breast milk have not been defined. The early appearance of viral DNA in milk whey, the presence of infectious virus in milk whey, and higher viral load in breast milk have been shown to be risk factors for transmission of HCMV infection (Hamprecht *et al.*, 1998, 2001; van der Strate *et al.*, 2001).

In term infants, the consequences of HCMV infection acquired via breast milk has been reported to be negligible (Hayes *et al.*, 1972; Stagno *et al.*, 1980; Dworsky *et al.*, 1983). In contrast, postnatal HCMV infection can lead to symptomatic infection in about 10% to 50% of preterm infants leading to significant morbidity (Alford *et al.*, 1980; Dworsky *et al.*, 1983; Yeager, 1983; Paryani *et al.*, 1985; Hamprecht *et al.*, 1998, 2001). A prospective study of 41 seropositive mothers and their infants revealed that 12/31 infants who were breastfed for >1 month acquired HCMV infection compared with none of the 10 infants who were breastfed for <1 month (Dworsky *et al.*, 1983). Although it is clear that postnatal HCMV infection acquired through breast milk causes symptomatic infection such as sepsis-like syndrome in preterm infants, there is conflicting data on the occurrence of long-term sequelae. The association between postnatal HCMV infection and adverse neurodevelopmental outcome in preterm infants was reported in an earlier study by Paryani *et al.,* (1985). However, a more recent prospective study demonstrated that none of the 22 preterm infants with early postnatally acquired HCMV infection developed hearing loss or other neurologic sequelae (Vollmer *et al.*, 2004).

Table 44.2. Urinary HCMV excretion rates during the first two years of life[a]

Country	Total number of infants	% excreting HCMV by age							
		At birth	1 m	2 m	3 m	6 m	9 m	12 m	24 m
Japan	257	–	6	10	20	56	44	22	7
Thailand	140	–	–	–	38	55	18	15	–
Guatemala	109	–	–	–	23	42	40	35	–

[a]Table used by permission (Stagno *et al.*, 1980).

Children-to-children transmission of HCMV

Young children are a known source of HCMV infection in the population. After early infancy where mother-to-child transmission occurs, young children likely acquire HCMV through horizontal transmission from other children or possibly indirectly through environmental contamination. Children who do not attend day-care centers have rates of HCMV seropositivity that remain generally stable until school age (Alford *et al.*, 1980; Yow *et al.*, 1987; Stagno and Cloud, 1994). However, studies in day-care centers

Table 44.3. HCMV excretion among children in day-care centers

Author	Year	Study location	% (number excreting virus/number of children)[a]
Strangert	1976	Sweden	35 (7/20)
Strom	1979	Sweden	72 (13/18)
Pass	1984	US, Birmingham	57 (59/103)
Adler	1985	US, Richmond	24 (16/66)
Hutto	1985	US, Birmingham	41 (77/188)
Jones	1985	US, San Francisco	22 (31/140)
Murph	1986	US, Iowa City	21 (17/80)

Nelson	1987	UK	27 (32/117)
Adler	1988	US, Richmond	53 (55/104)
Volpi	1988	Italy	13 (33/253)
de Mello	1996	Brazil	52 (31/60)
Ford-Jones	1996	Canada	17 (79/471)
Kashiwagi	1999	Japan	22 (12/54)

[a]Virus excretion either from saliva or urine or both.

throughout the world have demonstrated that young children shed virus in saliva and urine creating exposure opportunities for virus transmission to other children in the day-care setting, to their parents and to the day-care or nursery workers. As illustrated in Table 44.3, HCMV excretion is common in children who attend day-care centers, although the percentage of children excreting virus varies by location (Strangert *et al.*, 1976; Strom, 1979; Pass *et al.*, Adler, Hutto *et al.*, 1985; Jones *et al.*, 1985; Grillner and Strangert, 1986; Murph *et al.*, 1986; Nelson *et al.*, 1987; Adler, 1988a,b; Volpi *et al.*, 1988; de Mello *et al.*, 1996; Ford-Jones *et al.*, 1996; Kashiwagi *et al.*, 2001) (Table 44.3).

Prospective studies in day-care centers have provided evidence of child-to-child transmission by documenting acquisition of HCMV in children previously known to be uninfected upon enrollment in the day care centers (Pass *et al.*, 1984; Adler, 1988a,b; de Mello *et al.*, 1996). Pass *et al.* followed a cohort of children <12 months of age in a day care center and found that <10% were shedding virus at enrollment but 6 to 12 months later 78% of the children in the cohort were shedding virus (Pass *et al.*, 1984). Similarly, Adler followed a group of children for 26 months in a day-care center in Richmond, Virginia and found that virus excretion increased from 25 to 61% in children <3 years of age (Adler, 1988a,b). A study in a day-care center in Sao Paulo, Brasil identified 37 children who were initially HCMV seronegative upon enrollment into the study and demonstrated that 6 to 12 months later, 50% of these children excreted HCMV in either their saliva or urine (de Mello *et al.*, 1996).

Studies that have provided appropriate control groups for comparing the day-care center populations have found that the prevalence of HCMV excretion is significantly higher in the children who attend a day-care center than in the control children who did not attend a day-care center (Hutto *et al.*, 1985; Adler, 1988a,b). In both Richmond, Virginia (odds ratio (OR) = 4.3, 95% confidence interval (CI), 2.2–8.1) and Birmingham, Alabama (OR = 3.9, 95% CI, 1.8–9.0), children attending day-care centers were approximately four times more likely to shed HCMV than children who were not enrolled in day-care centers (Adler, 1985; Hutto *et al.*, 1985).

Besides child-to-child transmission, HCMV is also found on toys and other environmental surfaces in day-cares providing another viral source for HCMV infection (Faix, 1985; Hutto *et al.*, 1986; Schopfer *et al.*, 1986). Although HCMV is usually considered labile under most environmental conditions, a study led by Hutto, found that HCMV survived on toys for up to 30 minutes in a day-care where children aged six to 30 months of age were placing a hand or toy in their mouths every one to two minutes (Hutto *et al.*, 1986). Likely horizontal transmission of HCMV from child to child occurs through saliva on hands and toys. As seen in Fig. 44.1, the highest rates of HCMV excretion in day-care settings are usually seen among toddlers and young children (ages 12–24 months and 25–36 months) supporting the theory that HCMV transmission occurs through saliva on hands and toys as children play together (Strangert *et al.*, 1976; Strom, 1979; Pass *et al.*, 1984; Adler *et al.*, 1985; Jones *et al.*, 1985; Murph *et al.*, 1986; Ford-Jones *et al.*, 1996; Kashiwagi *et al.*, 2001). (Fig. 44.1)

The strongest evidence to support child-to-child transmission of HCMV has been obtained by the analysis of the restriction endonuclease digestion patterns of HCMV DNA of isolates obtained from HCMV infected children attending day-care centers. Adler examined the restriction endonuclease patterns of HCMV isolates obtained from 16 children at a single day-care center and found that one group of seven children and another group of four children were excreting identical strains (Adler, 1988a,b). The seven children in one group were all <29 months of age and all but one of these children shared the same classroom. The four children in the second group were >36 months of age and three of the children were in the same room. In another prospective study by Adler, 104 children from a day-care center were followed and 14 different strains of HCMV were identified by restriction endonuclease analysis (Adler, 1988). Three of the 14 strains infected 44 of the children attending the day-care center. All children infected with one of the three strains of HCMV were younger than 3 years of age indicating frequent child-to-child transmission of

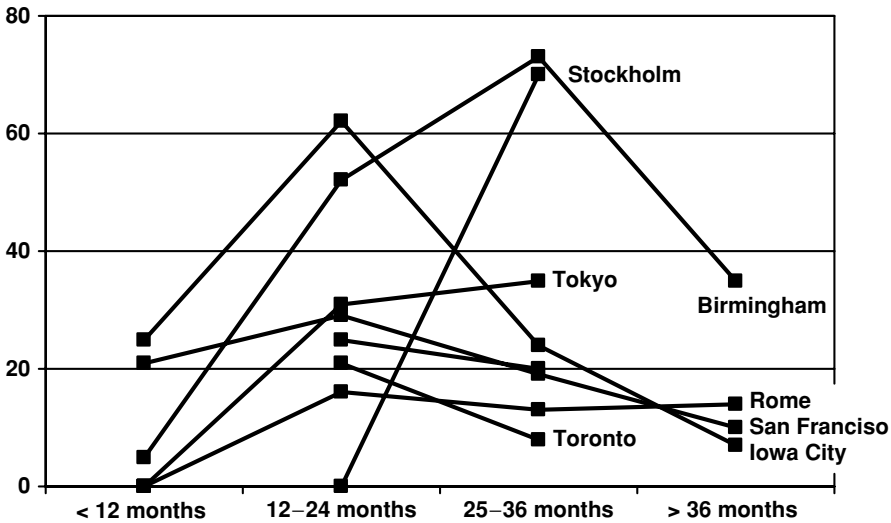

Fig. 44.1. Age-related HCMV excretion in various day-care center populations.

HCMV in these young children within the day-care setting. Other studies using restriction endonuclease analysis of HCMV DNA in different populations have also found identical HCMV strains are shared among children in group day-care confirming that HCMV is efficiently transmitted from child to child in day-care settings (Grillner and Strangert 1986; Murph *et al.*, 1991).

The higher HCMV excretion rates in young children attending day-care centers ranging from 13% to 72% compared to children who do not attend day care; the highest rates of HCMV excretion observed in toddlers and young children; the documentation of HCMV shedding in children previously known to be uninfected after day-care center attendance in prospective studies; the isolation of HCMV from toys and other objects in day-care settings; and the identification of similar strains of HCMV within day-care centers provides compelling evidence for child-to-child transmission among young children in day-care settings.

Transmission of HCMV by children to parents

Children excreting virus often become the source of HCMV infection for susceptible parents and others in the household. Studies by Spector *et al.*, and Dworsky *et al.*, using restriction endonuclease analysis, have demonstrated that infants with perinatal HCMV infections may transmit HCMV to an uninfected parent or other adult family member (Spector and Spector, 1982; Dworsky *et al.*, 1984). Seroconversion rates for parents when children reside in the household are higher than the rates reported for households with only adults in residence. In a study by Yeager *et al.*, infants who were nosocomially infected with HCMV by transfusion transmitted HCMV infection to their seronegative mothers (Yeager, 1975). Of the mothers who were seronegative and exposed to infected infants, 47% (7/15) seroconverted within a year after the child was discharged from the hospital compared to 4% of the mothers whose infants were uninfected at the time of discharge. Dworsky *et al.* studied 372 women between pregnancies and observed these women had an annual seroconversion rate of 5.5% compared to 2.2% for women who were pregnant for the first time (Dworsky *et al.*, 1983). Taber *et al.*, in a family HCMV study, demonstrated an increased seroconversion rate within the family setting (Taber *et al.*, 1985). The annual seroconversion rate for parents with young children in the household was 10.6% for mothers and 10% for fathers in this study. In 10 of 14 families where the initial family member who seroconverted could be identified, the index case was a child. In another study by Pass *et al.*, virus isolates were collected from the members of five families where the mother had evidence of a primary maternal infection during her most recent pregnancy and a child less than three years of age who was excreting HCMV residing in the home (Pass *et al.*, 1987). In each of the five families, the HCMV strains were identical by restriction endonuclease analysis. In two families, acquisition of HCMV by the child in a day-care center was followed by both maternal seroconversion and maternal excretion of the same identical strain of HCMV as shed by her child. This study provides further evidence that children in the household, especially

Table 44.4. Risk factors for primary HCMV infection in women attending an STD clinic (Chandler. *et al.*, 1985a,b)

Factor	Seroconversion (11/84, 13%)	Remained seronegative (15/84, 18%)	*P* value
Age (years)	20.4 ± 0.9	22.3 ± 0.5	NS
>two recent sexual partners	67%	14%	0.01
History of STDs	73%	32%	0.02
STDs during study	73%	63%	NS

those attending group day-care may transmit HCMV to other family members.

Other studies in day-care centers have provided compelling evidence of the acquisition of HCMV by children in day care with the subsequent seroconversion of their parents (Adler, 1985; Pass *et al.*, 1986; Adler, 1991). In a longitudinal follow-up study of seronegative parents with children in day-care centers and a control group of parents whose children were not in day-care centers, 21% (14/67) of the parents whose children were in the day-care centers seroconverted whereas none (0/31) of the controls seroconverted (Pass *et al.*, 1986). All of the parents who seroconverted had a child who was shedding HCMV either in saliva or urine. Parents at greatest risk of HCMV infection were the parents of children who were found to be shedding HCMV (45%, 9/20) and were <18 months of age at enrollment. In a similar study, Adler observed that 39% (7/18) of mothers seroconverted within 3 to 7 months after their children became infected at the day-care center (Adler, 1988a,b). The HCMV strains isolated were identical in both the mothers and their children, and in six of the mothers the HCMV strain was associated with the day-care center. An additional study from Adler prospectively followed 96 seronegative mothers of children attending three day-care centers (Adler, 1991). Among the 50 mothers with HCMV infected children, 19 seroconverted (38%) whereas, only 2 of the 46 seronegative mothers of uninfected children seroconverted (4%). Of the 19 mothers who seroconverted, 9 shed HCMV and the virus was an identical isolate as was shed by their child. All of these studies provide evidence that young children contribute to parental HCMV infections and mothers of these young children are at an increased risk of HCMV infection that might result in congenital infections for their future offspring (Pass *et al.*, 1987).

HCMV transmission through sexual activity

An important source of HCMV infection is through the intimate contact with oral and genital secretions (Britt and Alford, 1996). Salivary glands are a site of virus persistence in humans and it is likely that reactivations leads to the presence of infectious virus in oral secretions. Infectious virus can often be cultured from cervical secretions and semen has been shown to be a rich source of virus in seropositive men (Lang, 1975; Knox *et al.*, 1979; Stagno *et al.*, 1975). High rates of HCMV seropositivity have been reported in women attending STD clinics and couples discordant for HCMV have been shown to readily transmit virus and in some cases, reinfect previously infected partners (Handsfield *et al.*, 1985; Chandler *et al.*, 1985a,b, 1987).

Chandler *et al.*, examined the association between HCMV infection and indices of sexual activity in 347 women attending an STD clinic (Chandler *et al.*, 1985a,b). To determine the annual incidence of primary HCMV infection, 84 seronegative women were followed for a mean duration of 18.4 weeks with documented seroconversion in 11 (13%). Based on this study, the annualized incidence of primary HCMV infection was estimated to be 37% (Table 44.4). As can be seen in Table 44.4, the risk factors acquisition of HCMV infection in seronegative women in this population include the history of STDs and >2 sexual partners in the month preceding seroconversion. However, the majority of subjects included in the study were selected based on the presence of mucopurulent cervical discharge or cervical ectopy which may have resulted in the inclusion of more women with STDs in the study. In a more recent study from Seattle by Coonrod *et al.*, 245 HCMV seronegative women attending an STD clinic were followed for a median duration of 23 months. During the study, seroconversion was documented in 36 (15%) women, an annualized rate of 10%–12% (Coonrod *et al.*, 1998). The risk factors that were associated with seroconversion in that study include young age, younger age at sexual debut, greater number of sexual partners, and more recent sexual partners. In addition, seroconverters were more likely to have gonorrhea, chlamydia or pelvic inflammatory disease. (Table 44.4)

The shedding of HCMV in genital tract secretions was examined in studies of selected populations (Pereira *et al.*, 1990; Fairfax *et al.*, 1994; Shen *et al.*, 1994; Clarke *et al.*, 1996). Collier *et al.*, studied the association between HCMV shedding and sexual activity in 1481 women attending an STD clinic (Collier *et al.*, 1995). HCMV was isolated in cervical secretions from 9.4% of the 951 seropositive women. Cervical HCMV excretion was associated with concomitant gonococcal infection and was less frequent in women using barrier contraception. Higher frequency of HCMV-IgM antibodies were observed in seroconverters, suggesting recent HCMV infection and possible exogenous reinfection. The frequency and the factors associated with cervical shedding of HCMV were compared between a group of 195 licensed prostitutes and 187 women attending an

STD clinic in Taiwan (Shen *et al.*, 1994). About a third of the women in both groups shed HCMV in cervical secretions. The factors that were associated with cervical HCMV shedding are multiple sexual partners, and history of STDs. In another study of STD clinic attendees by Pereira *et al.*, age less than 23 years and concomitant gonococcal infection were independently associated with cervical HCMV excretion (Pereira *et al.*, 1990). Women with another genital tract infection were 6.5 times more likely to have HCMV than those without other genital infections. In a more recent study by Clarke et al., HCMV shedding in HIV seronegative and HIV seropositive women from an urban minority community was examined (Clarke *et al.*, 1996). HCMV seropositivity was >90% in both groups. Cervicovaginal shedding was detected in 4.4% of HIV-negative women and 19.6% of HIV-positive subjects (odds ratio, 5.28; $P < 0.001$). Multiple logistic regression analysis revealed that HCMV shedding was associated with younger age (OR = 0.90; $P < 0.001$), and concurrent chlamydial or gonococcal infection (OR = 3.60; $P < 0.08$). Among HIV-positive subjects, CMV shedding was significantly higher in women with CD4 cell counts $<500 \times 10^6$/L. The data from the studies described above provides evidence that cervicovaginal HCMV infection is related to sexual activity, and the presence of other genital tract infections.

Several studies have identified the risk factors for seropositivity to HCMV in women attending STD clinics, in pregnant women, sexually active adolescent girls, and HIV infected women (Chandler *et al.*, 1985a, b; Collier *et al.*, 1990; Sohn *et al.*, 1991; Shen *et al.*, 1994; Clarke *et al.*, 1996; Coonrod *et al.*, 1998). The results from these studies have been summarized in Table 44.5. In a study of 347 women attending an STD clinic, a stepwise logistic regression analysis showed that HCMV seropositivity was associated with non-white race, number of lifetime sexual partners, and young age at sexual debut (Chandler *et al.*, 1985a,b). However, the majority of women included in the study had cervical abnormalities. A latter study from the same STD clinic including unselected study subjects and larger sample size has attempted to define the relationship between sexual practices and HCMV seropositivity in African American and Caucasian women (Collier *et al.*, 1990). The risk factors associated with HCMV seroprevalence are similar in both African American and Caucasian women and these include more recent new sexual partners, more lifetime sexual partners, and the presence of chlamydial infection. Additional risk factors in Caucasian women included young age at sexual debut and not using barrier contraception. In another study from Seattle, the risk factors for the presence of HCMV antibodies were determined in 1129 pregnant women (Chandler *et al.*, 1985a,b). Fifty seven percent of women were HCMV seropositive. Logistic regression analysis showed the seropositivity correlated with lower socioeconomic status, older age, history of abnormal cervical cytology, infection with *Trichomonas vaginalis*, and greater number of sexual partners.

In a study of 254 adolescent girls attending a contraceptive counseling clinic, Sohn *et al.*, demonstrated a strong association between indicators of sexual activity and the presence of CMV-IgG antibodies (Sohn *et al.*, 1991). Using logistic regression analysis, the presence of two more sexual activity risk factors (young age at sexual debut, years of sexual activity, number of lifetime partners) was the most important predictor of HCMV infection. After controlling for confounders, African-American race was associated

Table 44.5. Risk factors for CMV seropositivity in adolescents, contraceptive and STD clinics

Author and Year published, location	Study population	Risk factors for CMV seropositivity
Chandler, 1985 Seattle, US	347 STD clinic clients (219 with cervical abnormalities	Young age sexual debut More lifetime sexual partners More recent sexual partners
Collier, 1990 Seattle. US	1481 STD clinic clients	*African Americans*: Recent sexual partners New sexual partners Cervical chlamydial infection *Caucasians*: Young sexual debut Recent new sexual partners More lifetime sexual partners Lack of barrier contraception
Sohn, 1991 Birmingham, US	254 adolescent girls (12–18 years)	African American race STDs >2 sexual partners >3 years of sexual activity
Hyams, 1993 Philippines	470 male military personnel presenting at a STD clinic	History of STDs
Shen, 1994 Taiwan	195 licensed prostitutes 187 STD clinic clients 70 women attending a gynecologic clinic	Presence of cervical CMV shedding
Ray, 1997 India	368 in STD and antenatal clinics	Chlamydial endocervicitis
Rosenthal, 1997 Cincinnati, US	399 adolescents	African American race Female sex
Coonrod, 1998 Seattle, US	245 STD clinic clients	More sexual partners New sexual partners Gonorrhea Chlamydia Pelvic inflammatory disease

with an increased risk of infection (OR = 3.4) whereas oral contraceptive use was protective (OR = 0.6) for HCMV infection. The association between sexual activity and the HCMV seropositivity has also been documented in other studies from different geographic regions (Table 44.5) (Berry *et al.*, 1988; Pereira *et al.*, 1990; Hyams *et al.*, 1993; Shen *et al.*, 1994; Coonrod *et al.*, 1998). (Table 44.5)

Further support for the sexual transmission of HCMV was provided by a study of HCMV infection in sexual partners by Handsfield *et al.* (1985). This study demonstrated that 74% of men whose female partners were seropositive were antibody positive compared to 34% of those whose partners were seronegative ($P = 0.008$). Restriction endonuclease analysis of HCMV isolates from three pairs of sexual partners identified that two of the couples were infected with common strains. To determine the frequency of HCMV reinfection, Chandler et al. examined serial isolates from eight women attending an STD clinic and seven women receiving routine prenatal care (Chandler *et al.*, 1987). Using restriction digestion analysis, the authors demonstrated that four of the eight women from the STD clinic were infected with more than one virus strain. Two women shed different strains in serial samples, and two women shed different strains simultaneously from different body sites. These findings provide evidence that reinfection with different virus strains is not uncommon in women with increased exposure to HCMV.

The association between sexual activity and HCMV transmission can be summarized as follows: (a) the prevalence of HCMV antibody more than doubles during the years beginning sexual activity (15–30 yrs) (Wentworth and Alexander, 1971), (b) higher rates of seropositivity in male partners of seropositive women as compared to seronegative women (Numazaki *et al.*, 1970; Handsfield *et al.*, 1985), (c) HCMV has been isolated from cervix of 13% to 35% of women with suspected STDs (Knox *et al.*, 1979; Shen *et al.*, 1994), (d) seropositivity correlated with the presence of other STDs (Chandler *et al.*, 1985a,b; Collier *et al.*, 1995; Coonrod *et al.*, 1998), (e) among seronegative women attending an STD clinic, the annual HCMV seroconversion rate was noted to be 37% vs. 1% to 2% per year in the general population (Table 44.5) (Chandler *et al.*, 1985a,b), (f) seropositivity correlated with number of lifetime sexual partners and young age at onset of sexual activity (Collier *et al.*, 1990; Pereira *et al.*, 1990; Shen *et al.*, 1992) and, (g) a negative correlation between the use of barrier contraception and seropositivity (Collier *et al.*, 1990, 1995).

Thus, there is strong epidemiological evidence that acquisition and transmission of HCMV infection is associated with sexual activity and STDs. However, the mechanisms and pathogenesis of this association have not been defined. Although frequent and repeated exposure is an important determinant for HCMV infection in individuals with STDs, it is also possible that the presence of genital tract inflammation plays an important role by providing a local milieu that is conducive to HCMV replication and transmission. However, the relationship between genital tract inflammation and the local HCMV replication has not been studied.

Transmission of HCMV to child-care providers

Children in day-care settings may be an important source of HCMV infection for child-care personnel. Numerous studies in the past decades have described the risk of HCMV infection for women who provide care for children in an occupational setting, as seen in Table 44.6 (Jones *et al.* 1985; Blackman *et al.*, 1987; Nelson *et al.*, 1987; Adler, 1989; Pass *et al.*, 1990; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996; Bale *et al.*, 1999; De Schryver *et al.*, 1999). Overall, the annual seroconversion rates in day-care workers who care for young children range from 0% to 20%. Variations in seroconversion rates within differing populations may reflect underlying factors such as socioeconomic status and race and their impact on HCMV infection. The populations with the highest seroconversion rates were those that studied day-care providers in various regions of the US and Canada (Adler, 1989; Pass *et al.*, 1990; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996; Bale *et al.*, 1999). Studies in England and Belgium found lower seroconversion rates among individuals who were exposed to children in occupational settings (Nelson *et al.*, 1987; De Schryver *et al.*, 1999). This lower transmission rate may be due to the smaller sample sizes and the shorter follow up periods for the detection of seroconversion. It is also possible that lower levels of virus shedding or the virologic characteristics including the infectivity of the circulating HCMV strains might account for the lower rates of transmission. Another explanation could be that child care personnel in these countries are better educated and adhere to standard hygiene practices when caring for young children thereby interrupting the transmission of the virus. Although HCMV seroconversion rates in child care providers vary in different populations and studies, the higher seroconversion rates observed in the larger cohort studies provide evidence that in some populations, young children play an important role in transmitting HCMV to their care providers (Adler, 1989; Pass *et al.*, 1990; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996; Bale *et al.*, 1999). (Table 44.6).

Table 44.6. Annual HCMV seroconversion rates among child care personnel

Author, year, and location	Population	HCMV seropositivity, %	Annual seroconversion rate, %
Jones, 1985 US, San Francisco	130 infant development center workers	50	0
Blackman, 1987 US, Iowa City	57 preschool workers for physical and mentally impaired children program	35	0
	53 home-based early intervention program workers	40	7.7
	66 hospital clinic staff	38	0

	294 nurses for the elderly	18.4	1.42

[a]NR = Not reported.

Risk factors for HCMV serconversion of child care providers have included workers <30 years of age, not wearing gloves when changing diapers, and caring for children ≤3 years of age for 20 hours a week (Pass *et al.*, 1990; Ford-Jones *et al.*, 1996). However, other studies did not find that seroconversion of day care providers was related to caring for children ≤3 years age (Adler, 1989; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996). None of the studies found that race or the presence of other children in the home were associated with seroconversion in an occupational setting (Adler *et al.*, 1990; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996). In several studies where day care children were evaluated for virus shedding, similar viral isolates were found in both the children and in the day-care providers who seroconverted suggesting that HCMV infection in the workers were acquired from the children in their care (Adler, 1989; Murph *et al.*, 1991; Bale *et al.*, 1999).

Seroprevalence studies of child care personnel have identified factors associated with HCMV seropositivity in these workers as illustrated in Table 44.7 (Blackman *et al.*, 1987; Volpi *et al.*, 1988; Adler, 1989; Pass *et al.*, 1990; Murph *et al.*, 1991; Ford-Jones *et al.*, 1996; Jackson *et al.*, 1996; Bale *et al.*, 1999; De Schryver *et al.*, 1999; Kiss *et al.*, 2002). The risk factors observed for HCMV seropositivity include factors that are associated with HCMV in the general population such as parity, age and race (Chandler *et al.*, 1985a,b; Collier *et al.*, 1990; Sohn *et al.*, 1991) and also additional risk factors related to occupation as a child-care provider. These occupational risk factors suggest that HCMV infection in occupational settings may result from the exposure to young children who are shedding virus. However, none of these studies can provide with certainty that all HCMV infections observed in the day-care personnel are due to child-to-worker transmission since other HCMV exposure opportunities may exist in the environment and the population from other sources. (Table 44.7)

Transmission of CMV in health-care settings

The possibility that CMV may be transmitted in health care settings has been explored over the last three decades. In 1969, Haldane *et al.*, reported a significantly higher incidence of birth defects among the offspring of nurses caring for children with CMV infection (Haldane *et al.*, 1969). Following this report, many studies (Table 44.8) have evaluated the risk of CMV infection in nurses who cared for young infants and children in the newborn nurseries or pediatric wards of hospitals and provided conflicting results (Yeager, 1975; Haneberg *et al.*, 1980; Ahlfors *et al.*, 1981; Dworsky *et al.*, 1983a,b; Friedman *et al.*, 1984; Hatherley, 1985; Adler *et al.*, 1986; Balfour and Balfour, 1986; Hatherley, 1986; Demmler *et al.*, 1987). Overall, the studies with appropriate control groups found the combined risk of CMV infection in nurses who cared for children to be almost three times (risk ratio (RR) 2.7, 95% CI, 1.3 – 5.5) greater than the controls (Yeager, 1975; Ahlfors *et al.*, 1981; Dworsky *et al.*, 1983; Friedman *et al.*, 1984; Balfour and Balfour, 1986; Hatherley,

[a]Borderline significance.
[b]Reported for the combined groups.

1986; Flowers *et al.*, 1988). However, when person–year analysis was performed to take into account the follow-up period, a trend toward an increased risk in nurses remained but failed to reach statistical significance (RR 1.8, 95% CI, 0.9 – 3.6) (Flowers *et al.*, 1988).

Studies of health-care personnel including staff in children's hospitals have shown that CMV seroconversion rates do not differ between the employees, and the general population (Tolkoff-Rubin *et al.*, 1978; Dworsky *et al.*, 1983; Balfour and Balfour 1986; Demmler *et al.*, 1987; Balcarek *et al.*, 1990; Gerberding, 1994). However, all of the studies of health care personnel have low sample sizes, inadequate statistical power and have not provided information on potential confounding factors such as CMV sexual exposure or exposure to children outside of the workplace that could impact their risk for HCMV infection (Flowers *et al.*, 1988; Farr and Torner, 1990). These limitations and also the widespread adoption of universal precautions (CDC, 1987, 1988) in health-care settings in the late 1980s have made it difficult to estimate whether an increased risk of CMV infection exists within occupational settings. As illustrated in Table 44.9, several studies have evaluated risk factors for CMV seropositivity in health-care providers although these studies did not account for other possible non-occupational CMV exposures (Gerberding, 1994; Herbert *et al.*, 1995; Sobaszek *et al.*, 2000). Studies using molecular epidemiologic techniques demonstrated that health care workers are at low risk for occupational CMV transmission (Dworsky *et al.*, 1983; Adler, 1986; Peckham *et al.*, 1986; Demmler *et al.*, 1987). In these studies, molecular analysis of CMV isolates demonstrated that some of the CMV infections identified in the workers were similar to CMV isolates from other family members and were not occupationally acquired (Dworsky *et al.*, 1983; Demmler *et al.*, 1987). Without a large collaborative study or the pooling of results of multiple well-designed studies, the question about the relative contribution of CMV infection in health-care settings cannot be fully elucidated at this time. However,

Table 44.8. Seroconversion rates for personnel in health care settings

Study, year published, and location	Study groups	CMV seroconversion rates % (number/total)
Yeager 1975	Pediatric ward nurses	9.7 (3/31)
Denver, US	Nursery nurses	5.9 (2/34)
	Controls	0 (0/27)
Tolkoff-Rubin, 1978	Hemodialysis staff	0 (0/26)
Boston, US	Hemodialysis patients	13 (10/80)
Haneberg, 1980 Norway	Pediatric student nurses	9.4 (6/64)
Ahlfors, 1981	Pediatric ward nurses	6.9 (2/29)
Sweden	Pediatric nurses	0 (0/31)
	Controls	1.9 (1/52)
Dworsky, 1983	Nursery nurses	3.3 (4/61)
Birmingham, US	Controls (pregnant women)	1.5 (23/1549)
	Medical students	0.6 (1/89)
	Medical house staff	2.7 (1/25)
Friedman, 1984	Pediatric intensive care nurses	8.7 (2/23)
Philadelphia, US	Nursery nurses	7.7 (3/39)
	Pediatric ward nurses	4.6 (3/65)
	Controls	2.9 (1/35)
Hatherley, 1985 Australia	Nursery nurses	4.4 (2/45)
Hatherley, 1986	Nursery nurses	1.9 (3/154)
Australia	Controls	0 (0/12)
Adler, 1986	Pediatric ward nurses	6.5 (2/31)
Richmond, US	Nursery nurses	2.5 (1/40)
Balfour, 1986	Neonatal intensive care nurses	4.2 (4/96)
Minneapolis, US	Student nurses	5.0 (7/139)
	Renal transplant/hemodialysis nurses	1.7 (2/117)
	Controls	1.8 (3/167)
Brady, 1985	Nursery nurses	6.0 (4/67)
Houston, US	Medical house staff	9.5 (2/21)
Demmler, 1987	Nursery nurses	5.4 (2/37)
Houston, US	Pediatric chronic care ward nurses	0 (0/21)
	Pediatric chronic care ward therapists	0 (0/37)
Balcarek, 1990	Children hospital employees, patient care	4.4 (8/183)
Birmingham, US	Children hospital employees, administrative	3.6 (2/56)
		4.1 (2/49)
	Children hospital employees, support	8.3 (1/12)
	Children hospital employees, laboratory	
Gerberding, 1994 San Francisco, US	Health care providers at one hospital	6.6 (25/378)

the existing data suggest that the risk of CMV infection in a health-care setting is low and likely does not differ from the risk of CMV infection in the general population. (Tables 44.8 and 44.9).

Transfusion acquired HCMV infection

Transfusion associated HCMV infection was first described in 1966 and since that time, has been demonstrated to be a cause of significant morbidity and mortality in a wide variety of clinical circumstances (Kaariainen *et al.*, 1966; Hillyer *et al.*, 1990; Meyers, 1991). HCMV infection following transfusion has been associated with transfused red cell, platelet concentrates, and granulocyte concentrates whereas, fresh-frozen plasma and cryoprecipitates have not been reported to cause HCMV transmission (Bowden and Sayers, 1990). HCMV is believed to establish latency in the cells of myeloid lineage and the virus can be reactivated and cause disease in seropositive immunocompromized hosts. Transfusion of unscreened cellular components results in HCMV transmission in approximately 30%

Table 44.9. Risk factors for CMV seropositivity in health care workers

Study, year published, and location	Study groups	Risk factors for CMV seropositivity evaluated	Odds ratio (95% confidence interval)
Gerberding, 1994 San Francisco, US	976 health care providers at San Francisco General Hospital	Older age	1.4 (1.2–1.7)[a]
		Female	1.8 (1.3–2.5)
		Being a physician	0.4 (0.3–0.6)
		Working on an AIDS clinical unit	NS[b]
Herbert, 1995 England	81 preclinical dental students and 81 matched controls 53 clinical dental students and 53 matched controls 103 dental surgeons and 103 matched controls	Protective workwear	NS[b]
Sobaszek, 2000 France	400 female health care workers who had contact with children or immunosuppressed patients	Number of children ≥1	1.9 (1.2–3.0)
		Close contact nursing tasks	2.2 (1.4–3.3)
		Older age	1.7 (1.0–3.0)

[a] For an increase of one decade.
[b] NS, Not significant.

(range 10%–70%) in seronegative recipients, as determined by seroconversion and/or virus isolation (Wilhelm *et al.*, 1986; Preiksaitis *et al.*, 1988). The risk of transfusion associated HCMV infection is directly related the number of components transfused and the quantity of leukocytes transfused. HCMV can also be transmitted via organ or marrow grafts (Wreghitt *et al.*, 1988; Reusser *et al.*, 1991). The use of blood products from seronegative donors and using procedures which limit the quantity of leukocytes in the transfused blood have considerably reduced the risk of transfusion associated HCMV infection (Lang *et al.*, 1977; Brady *et al.*, 1984; Preiksaitis *et al.*, 1988; Miller *et al.*, 1991). These findings suggest that leukocytes are the cellular components of blood products responsible for most transfusion-associated HCMV infection.

Transfusion-associated HCMV infection can result in significant morbidity and mortality in preterm infants, allograft recipients, following cardiac surgery and other immunocompromized hosts (Yeager *et al.*, 1981; Brady *et al.*, 1984; Adler, 1985; Bowden, 1991). The rate of HCMV acquisition in preterm infants of seronegative mothers who received multiple transfusion has been shown be between 9% and 13.5% (Yeager *et al.*, 1981; Adler, 1983). The percentage of units of blood capable of transmitting HCMV has been estimated to be between 2.5% and 12.5%. A controlled trial in low birth weight HCMV seronegative infants born to HCMV-seronegative mothers compared the use of filtered and unfiltered red cell components for the prevention of transfusion associated HCMV infection (Gilbert *et al.*, 1989). Twenty-one percent (9/42) of the recipients of unscreened, unfiltered blood acquired HCMV infection compared with none of 59 infants who received unscreened, filtered components. Additional studies have confirmed the effectiveness of the leukofiltration in reducing the transmission of HCMV in other population groups including immunocompromized hosts (Eisenfeld *et al.*, 1992).

Transplantation and HCMV infection

Allografts from donors previously infected with HCMV represent a major risk factor for HCMV transmission. In all but the bone marrow allograft recipients, the transplantation of an organ from a donor previously infected with HCMV into a seronegative recipient has been shown to be the single most important risk factor for primary HCMV infection (Rubin *et al.*, 1985; Ho, 1991). In solid organ transplantation, primary infections that develop from the allograft have a more profound impact on the outcomes than infections acquired via transfusions (Falagas *et al.*, 1996). The natural history of HCMV infection in transplant recipients suggests that infection is nearly universal in those exposed, but the clinical disease is dependent on specific risk factors, in particular, the immunosuppressive regimen. As the severity of immunosuppression increases, so does the severity of HCMV disease, as evidenced by the often fatal HCMV infections that occur in bone marrow allograft recipients

(Meyers *et al.*, 1982; Winston *et al.*, 1990; Schmidt *et al.*, 1991). In renal allograft recipients following HCMV mismatched donor-recipient transplantation, disease rates as high as 70% have been described (Rubin and Colvin, 1986). Mortality rates in excess of 50% in heart/lung transplantation have limited the mismatched donor-recipient transplantation in some centers (Smyth *et al.*, 1991).

Historically, HCMV interstitial pneumonitis occurred in 10% to 30% of bone marrow transplant recipients, with mortality rates of over 80% in some studies, even after the introduction of ganciclvir (Wingard *et al.*, 1988; Winston *et al.*, 1988). However, the incidence of HCMV infection and disease in hematopoietic stem cell transplant recipients has decreased somewhat over the past 15 years due to changes in patient management. These changes include the avoidance of HCMV positive cellular blood products in susceptible, HCMV-negative recipients, and the use of prophylactic and/or pre-emptive antiviral therapy to limit HCMV reactivation and disease. Since, the advent of prophylactic and pre-emptive antiviral therapy, the onset time of HCMV pneumonia has been delayed from a median time of 44 days after transplant to between 92 and 188 days (Goodrich *et al.*, 1993; Nguyen *et al.*, 1999; de Medeiros *et al.*, 2000; Machado *et al.*, 2000; Ljungman, 2001). In a study of liver transplant recipients, despite the significant increase in the proportion of high risk patients (HCMV recipient-/donor+) and the increase in the rate of HCMV infection, the incidence of HCMV disease has decreased significantly (Singh *et al.*, 2004). The authors of that study noted that the HCMV infection rate neither confounded the use of antiviral prophylaxis nor selective testing for HCMV. In addition to the morbidity and mortality associated with HCMV disease, the survival of the allografts has been adversely affected by HCMV.

HCMV transmission from artificial insemination by donor semen

The advent of artificial insemination with donor semen suggests another possible transmission route for HCMV in the population. HCMV has been cultured from semen even in cases in which urine, saliva or blood specimens have been negative for infectious virus (Lang and Kummer, 1975; Biggar *et al.*, 1983; Mascola and Guinan, 1986; Tjiam *et al.*, 1987). It has been demonstrated that HCMV transmission can occur through therapeutic donor insemination (Prior *et al.*, 1994). However, most of the studies examining the presence of HCMV in semen have included individuals attending STD clinics. In a more recent study from France, Masat et al. examined the presence of HCMV in cryopreserved semen samples collected for therapeutic donor insemination (Mansat *et al.*, 1997). Using cell culture and PCR, HCMV was detected in 5.1% of the semen specimens suggesting that cryopreserved semen from healthy donors may represent a potential source of HCMV infection. The American Fertility Society recommended that all semen donors be screened for the presence of HCMV antibodies and that semen from seropositive donors may only be used to inseminate seropositive recipients. Although the risk to offspring via donor insemination has not been defined, the British Andrology Society recommends that only semen from seronegative donors be stored for clinical use (British Andrology Society, 1999).

Summary

HCMV remains a ubiquitous infectious agent and a cause of significant disease in individuals with immature or suppressed immune responses. In most human populations examined, HCMV is acquired predominantly through exposure to young children, breast feeding and sexual activity. Although a strong epidemiologic association between these risk factor and acquisition of HCMV has been demonstrated, the exact mechanism and pathogenesis of HCMV transmission have not been defined. Furthermore, the roles of virologic characteristics including strain variation and reinfections in the transmission of HCMV have not been delineated. Today, HCMV is primarily a cause of disease in newborn infants and in allograft recipients. Perhaps of even greater potential medical importance is the proposed role of chronic HCMV infections in diseases such as coronary atherosclerosis and human cancers, two areas of active research (Everett *et al.*, 1992; Zhou *et al.*, 1996; Hosenpud, 1999; Zhu *et al.*, 1999; Streblow *et al.*, 2000).
