Congenital cytomegalovirus infection and the placenta

Congenital CMV infection

Human cytomegalovirus (CMV) is a ubiquitous virus that causes asymptomatic infections in healthy individuals (for review see Pass, 2001). Because breast feeding (Stagno *et al.*, 1980), exposure to young children (Pass *et al.*, 1987) and sexual contact (Fowler and Pass, 1991) are major risk factors for infection, most adults are seropositive. Diverse organs and specialized cells, including polarized epithelial cells (Tugizov *et al.*, 1996) and endothelial cells (Fish *et al.*, 1998; Maidji *et al.*, 2002), are susceptible to CMV infection. CMV establishes latent infection in granulocyte-macrophage progenitors (Kondo *et al.*, 1996) and reactivates upon cellular differentiation (Hahn *et al.*, 1998; Soderberg-Naucler *et al.*, 1997). Congenital CMV infection is estimated to affect 1 to 3% of infants in the United States annually and remains an important public health problem causing significant morbidity and mortality (for review see Britt, 1999).

It has long been appreciated that maternal neutralizing antibodies reduce the risk of symptomatic congenital disease in the fetus (Ahlfors *et al.*, 1984; Boppana and Britt, 1995; Fowler *et al.*, 2003; Stagno *et al.*, 1982). The importance of adaptive immunity to CMV is apparent in women with primary infection, often with low-avidity neutralizing antibodies (Boppana and Britt, 1995; Lazzarotto *et al.*, 1998; Revello *et al.*, 2002). Approximately 15% of these women spontaneously abort in early gestation (Griffiths and Baboonian, 1984). Examination of placentas infected with CMV in vitro and in utero has suggested potential routes of virus transmission from the uterus to the placenta (Fisher *et al.*, 2000; Pereira *et al.*, 2003). Importantly, these studies suggest that placental involvement precedes virus transmission and infection of the embryo/fetus. Progression of infection hinges on maternal immunity to CMV, the mechanics of cytotrophoblast development and the presence of other pathogens at the maternal–fetal interface. In this chapter, we describe patterns of CMV infection in early gestation, routes of viral transmission at the maternal-fetal interface and dysregulation of cytotrophoblast differentiation and function secondary to CMV infection in vitro.

CMV infects specialized cells in the placenta

Numerous reports indicate that placentas from pregnancies complicated by congenital CMV infection contain viral DNA and proteins (Benirschke and Kaufmann, 2000; Muhlemann *et al.*, 1992; Nakamura *et al.*, 1994; Sinzger *et al.*, 1993). Later in pregnancy, CMV infection is associated with premature delivery and, in 25% of affected infants, intrauterine growth retardation (Istas *et al.*, 1995), outcomes that are often associated with placental pathologies. CMV replicates in cytotrophoblasts isolated from early and late gestation placentas in vitro (Fisher *et al.*, 2000; Halwachs-Baumann *et al.*, 1998; Hemmings *et al.*, 1998). The routes of virus transmission and the types of immune responses elicited are likely linked to the unusual nature of cytotrophoblast interactions with maternal cells at the uterine-placental interface. A diagram of the maternal-fetal interface midway through gestation with potential sites of CMV infection is shown in Fig. 45.1.

Placental development in early gestation

Diverse cell types in the uterus

Immunologically competent cells are detected in the uterine endometrium and decidua (Kamat and Isaacson,

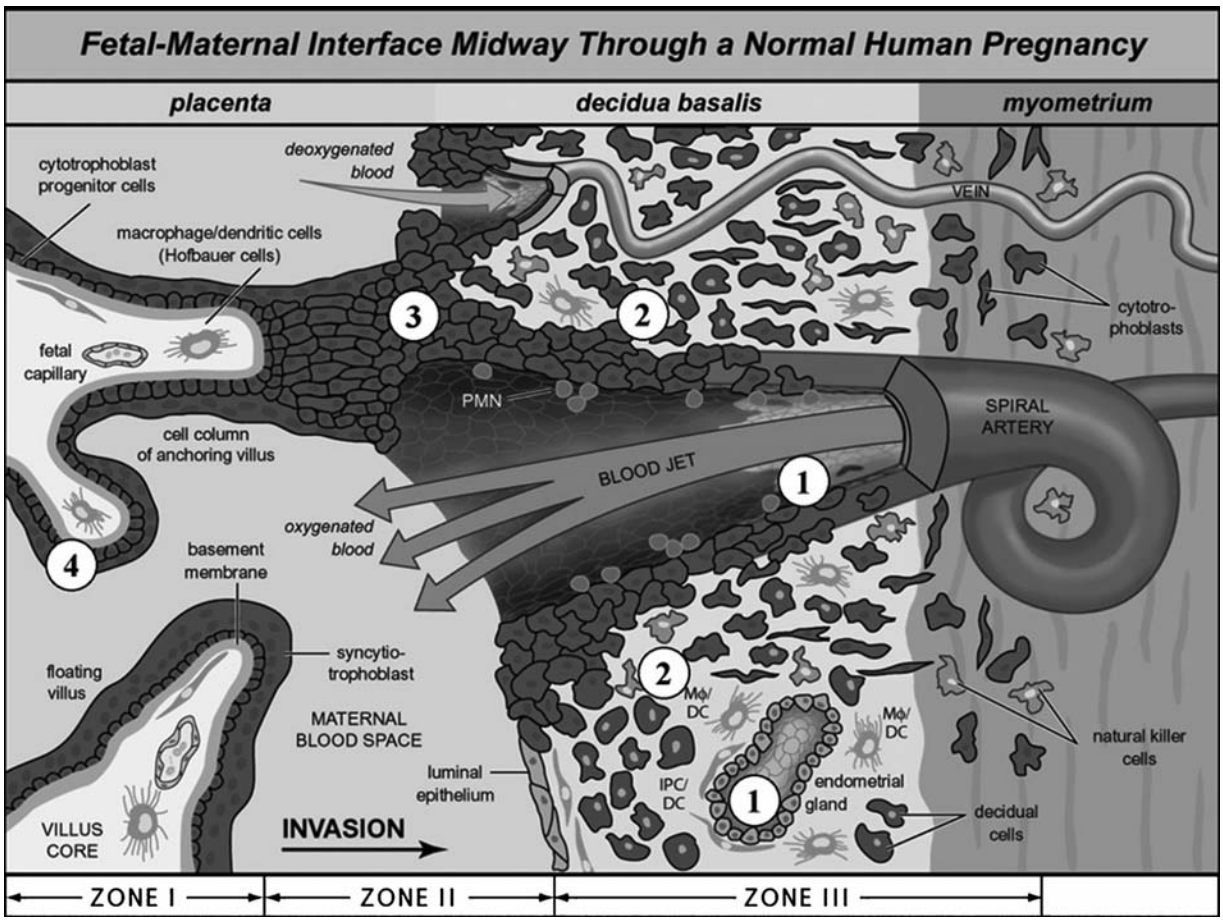

Fig. 45.1. Diagram of the histologic organization of the human maternal-fetal interface at midgestation. In this location, cytotrophoblasts, which are specialized (fetal) epithelial cells of the placenta, differentiate and invade the uterine wall, where they also breach maternal blood vessels. The basic structural unit of the placenta is the chorionic villus, composed of a stromal core with blood vessels, surrounded by a basement membrane and overlain by cytotrophoblast progenitor cells. As part of their differentiation program, these cells detach from the basement membrane and adopt one of two lineage fates. They either fuse to form the syncytiotrophoblasts that cover floating villi or join a column of extravillous cytotrophoblasts at the tips of anchoring villi. The syncytial covering of floating villi mediates nutrient, gas, and waste exchange and transfer of IgG from maternal blood to the fetus (Zone 1). The anchoring villi, through the attachment of cytotrophoblast columns, establish physical connections between the fetus and the mother (Zone II). Invasive cytotrophoblasts penetrate the uterine wall up to the first third of the myometrium (Zone III). A portion of the extravillous cytotrophoblasts home to uterine spiral arterioles and remodel these vessels by destroying their muscular walls and replacing their endothelial linings. To a lesser extent they also remodel uterine veins. At term, few cytotrophoblast progenitor cells remain, the syncytiotrophoblast layer thins, and the volume of the stromal cores expand. Sites proposed as routes of CMV infection in utero are numbered 1 to 4. Diagram modified from (Hoang *et al.*, 2001).

1987). Early studies of leukocyte antigens by using immunohistologic approaches suggested that cells in the endometrium of cycling women in the mid-secretory phase (7–10 days after ovulation) resemble leukocytes in early gestation decidua (King *et al.*, 1989). Granulated lymphocytes with an unusual antigenic phenotype (CD56+ high, CD16–), known as natural killer (NK) cells, constitute a substantial proportion of these cells (Bulmer *et al.*, 1991; Starkey *et al.*, 1988), increasing from the proliferative endometrium to the late secretory endometrium. Macrophages increase prior to menstruation (Kamat and Isaacson, 1987). CD83+ dendritic cells in the uterine stratum basale are present in the non-pregnant and pregnant uterus (Kammerer *et al.*, 2000; Soilleux *et al.*, 2002).

In response to implantation, the uterine lining develops into the decidua, which is maintained by progesterone

(Norwitz *et al.*, 2001). Interglandular tissues increase in quantity, and the cytoplasm of resident stromal cells is distended with glycogen, lipid and vimentin-type intermediate filaments (Fig. 45.1, Zone III). Temporal and spatial expression of growth factors and cytokines (e.g., insulin-like growth factor 1 and its binding protein) suggests that these molecules may influence decidualization (Crossey *et al.*, 2002). Decidual granular leukocytes intermingle with resident maternal cells and invasive fetal cells (Zone III) (Drake *et al.*, 2001; Kamat and Isaacson, 1987; Red-Horse *et al.*, 2001; Starkey *et al.*, 1988). These immune cells are involved in innate pattern recognition, mostly NK cells with some macrophages, dendritic cells and T-lymphocytes. Novel patterns of cytokine/chemokine expression in the decidua, as well as specialized adhesion molecules on uterine vessels (Kruse *et al.*, 1999), probably attract this unusual leukocyte population, which functions in immunity and cytotrophoblast differentiation. Dendritic cell protein ICAM-3-grabbing non-integrin (DC-SIGN+) cells, occasionally found in the endometrium, are abundant in the decidua and associate with NK cells (Kammerer *et al.*, 2003, 1999; Pereira *et al.*, 2003; Soilleux *et al.*, 2002). The unusual immune cell population in the decidua suggests that when macrophage/dendritic cell progenitors (MΦ/DC) latently infected with CMV are attracted to the endometrium and early gestation decidua, CMV could be reactivated in the presence of inflammatory stimuli.

Development of the hemochorial human placenta

The embryo's acquisition of a supply of maternal blood is a critical hurdle in pregnancy maintenance. The mechanics of this process are accomplished by the placenta's specialized epithelial cells, termed cytotrophoblasts. The histology of the maternal-fetal interface is diagrammed in Fig. 45.1. The placenta is composed of individual units termed chorionic villi, each with a connective core that contains fetal blood vessels and numerous macrophages (Hofbauer cells) that often lie under a thick basement membrane (Fig. 45.1, Zone I). Placentation is a stepwise process whereby cytotrophoblast progenitor cells, attached to the basement membrane as a polarized epithelium, leave the membrane to differentiate along one of two independent pathways depending on their location. In floating villi, they fuse to form a multinucleate syncytial covering attached at one end to the tree-like fetal portion of the placenta (Zone I). The rest of the villus floats in a stream of maternal blood, which optimizes exchange of substances between the mother and fetus across the placenta. In the pathway that gives rise to anchoring villi, which attach the placenta to the uterine wall (Zone II), cytotrophoblasts aggregate into cell columns of non-polarized mononuclear cells that attach to and then penetrate the uterine wall. The ends of the columns terminate within the superficial endometrium, where they give rise to invasive cytotrophoblasts. During interstitial invasion a subset of these cells, either individually or in small clusters, comingles with resident decidual, myometrial and immune cells. During endovascular invasion, masses of cytotrophoblasts open the termini of uterine arteries and veins they encounter, then migrate into the vessels, thereby diverting maternal blood flow to the placenta (Zone III). In arterioles, cytotrophoblasts replace the endothelial lining and partially disrupt the muscular wall, whereas in veins, they are confined to the portions of the vessels near the inner surface of the uterus. Together, the two components of cytotrophoblast invasion anchor the placenta to the uterus and permit a steady increase in the supply of maternal blood that is delivered to the developing fetus.

Invasive cytotrophoblasts modulate the expression of stage-specific antigens

During uterine remodeling, cytotrophoblasts switch from an epithelial to a mesenchymal type (Table 45.1). Cytotrophoblasts express novel adhesion molecules and proteinases that enable the cells' attachment and invasion, as well as immune modulating factors that play a role in maternal tolerance of the hemiallogeneic fetus (Cross *et al.*, 1994; Norwitz *et al.*, 2001). Interstitial invasion requires downregulation of integrins characteristic of epithelial cells ($\alpha6\beta4$) and novel expression of $\alpha1\beta1$, $\alpha5\beta1$ and $\alpha V\beta3$ (Damsky *et al.*, 1994). Endovascular cytotrophoblasts that remodel maternal blood vessels transform their adhesion receptor phenotype to resemble the endothelial cells they replace (Fig. 45.1, site 1) turning on the expression of VE-(endothelial) cadherin, platelet-endothelial adhesion molecule-1 and vascular endothelial adhesion molecule-1 (Damsky and Fisher, 1998; Zhou *et al.*, 1997).

Degradation of the basement membrane and extracellular matrix of the uterine stroma is precisely regulated during placentation (Fisher *et al.*, 1985). Cytotrophoblasts upregulate urokinase-type plasminogen activator (uPA) (Queenan *et al.*, 1987; Solberg *et al.*, 2003), matrix metalloproteinase-9 (MMP-9) (Librach *et al.*, 1991) and inhibitors such as tissue inhibitor of metalloproteinases-3, a likely regulator of proteolytic activity and invasion depth (Bass *et al.*, 1997) (Table 45.1). Molecules that may function in maternal immune tolerance are also produced, such as the non-classical major histocompatibility complex (MHC) class Ib molecule HLA-G (Kovats *et al.*, 1990; McMaster *et al.*, 1995) and interleukin-10 (IL-10) (Roth *et al.*, 1996; Roth and Fisher, 1999). This remarkable transformation, evidenced by novel expression of differentiation molecules

and invasiveness, underscores the extraordinary plasticity of cytotrophoblasts.

CMV infects the placenta in vitro and in utero

Potential routes for CMV transmission

The cellular organization of the placenta suggests potential routes by which CMV infection spreads from the uterus, first to the placenta and then to the embryo/fetus (Fig. 45.1) (Fisher *et al.*, 2000; Pereira *et al.*, 2003). One likely site of transmission is within the uterine wall (sites 1 and 2). Interstitial invasive cytotrophoblasts could encounter infected endometrial glands, uterine blood vessels and decidual granular leukocytes. Endovascular cytotrophoblasts could encounter infected endothelial and vascular smooth muscle cells, as well as maternal immune cells. Once cytotrophoblasts within the uterine wall become infected (site 2), CMV might spread in a retrograde manner through the cell columns to the anchoring chorionic villi (site 3). In the villus stromal cores, virus could be transmitted from infected cytotrophoblasts to fibroblasts, fetal macrophages and possibly endothelial cells that line chorionic vessels. This conjecture is based on focal patterns of CMV protein expression in the placenta (Fisher *et al.*, 2000; Muhlemann *et al.*, 1992). Infected MΦ/DC and sloughed endothelial cells seem likely candidates for entering the venous circulation of the placenta and subsequently carrying the infection via the placental circulation to the fetus. Another likely site of transmission is across the syncytiotrophoblast layer that covers floating chorionic villi (site 4). These placental cells, in direct contact with maternal blood, express the neonatal Fc receptor (FcRn), a molecule that facilitates maternal IgG transfer and passive immunization of the fetus (Simister *et al.*, 1996). The syncytium may allow passage of CMV virions complexed with maternal IgG to the underlying layer of cytotrophoblast progenitor cells that could become infected in the presence of virus-binding antibodies with low avidity (Boppana and Britt, 1995; Fisher *et al.*, 2000; Lazzarotto *et al.*, 1997; Pereira *et al.*, 2003; Revello *et al.*, 2002). Accordingly, adaptive and innate immune responses that reduce infectious virions at the uterine–placental interface likely play a central role in preventing transmission.

CMV protein expression in placental cells in chorionic villi infected in vitro and in utero

Clues about potential routes of prenatal CMV infection emerged from a model tissue culture system (Fig. 45.2(a)). Chorionic villi are plated on filters coated with Matrigel, an extracellular matrix, infected with virus and then cultured from 2 to 4 days. Experiments that used this model revealed an unexpected pattern of CMV infection (Fisher *et al.*, 2000). Briefly, tissue sections of villus explants that were infected for several days were double-stained with anti-cytokeratin to identify trophoblast cells and with a monoclonal antibody to CMV immediate-early (IE) proteins to identify infected cells. Notably, syncytiotrophoblasts that cover the villus surface were not infected and failed to stain for CMV IE proteins, whereas nuclear staining of small, isolated clusters of underlying cytotrophoblast progenitor cells was observed (Fig. 45.1, site 4). In some tissues, CMV IE protein expression was also detected in cytotrophoblasts

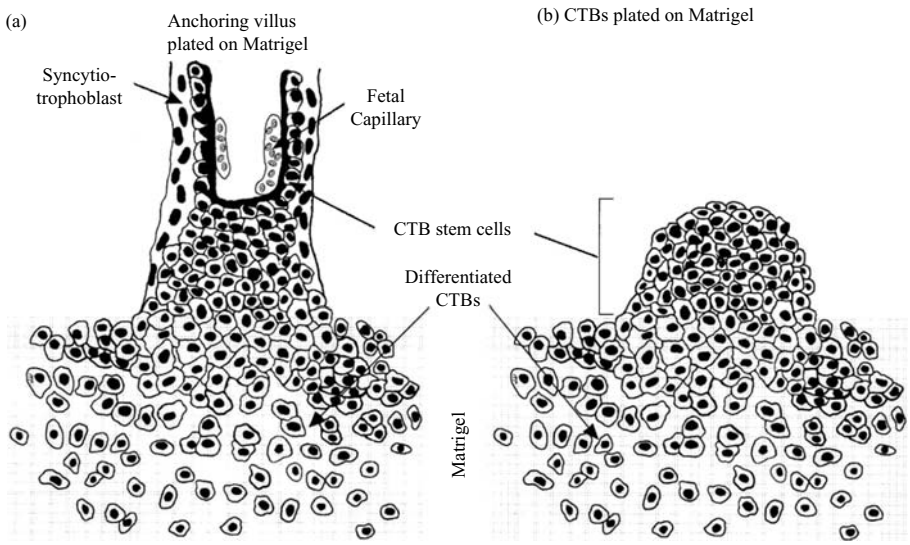

Fig. 45.2. Culture models for studying CMV infection of placental explants and cells. (a) Diagram of an anchoring villus explant attached to a Matrigel substrate via cytotrophoblasts (CTBs) that migrate from the cell columns. (b) Diagram of purified differentiating cytotrophoblasts cultured on Matrigel. The cytotrophoblast progenitor cells aggregate, invade the matrix, and express stage-specific molecules (see Table 45.1). For infection, CMV is added to the medium bathing the explants and purified cytotrophoblasts.

in the cell columns of anchoring villi (Fig. 45.1, site 3). The staining patterns observed when placentas were infected in utero had remarkable similarities to and differences from those observed after infection in vitro. Sometimes, patterns of CMV-infected cells were virtually indistinguishable from those found after infection in vitro; in some locations, isolated clusters of cytotrophoblasts underlying the syncytium were the only cells infected (Fig. 45.3(b)). At other times, nearly all the cytotrophoblast progenitor cells, in highly infected tissues, expressed CMV IE proteins (Fig. 45.3(c), (d)). Comparatively fewer syncytial nuclei stained, but numerous cells within the villus cores stained for viral proteins, including fibroblasts, endothelial cells and macrophages. These studies suggested that in vitro infection is a model for the initial steps in placental infection, whereas in utero infection shows virus transmission from trophoblasts to other cell types in the villus core. The interplay between pathogens and immune responses in other tissues suggest that CMV infection might often occur in the context of the microbial ecology of female reproductive tissues.

Pathogenic microorganisms at the placental–decidual interface

In a study using PCR-based strategies, the presence of viral and bacterial DNA was assessed in biopsy specimens of the decidua and adjacent placentas of 282 healthy pregnancies (McDonagh *et al.*; Pereira *et al.*, 2003). Overall, CMV DNA was detected in 69% of specimens, and CMV with bacteria was detected in 38%. When found in isolation, CMV was detected in 27% of placental samples. Other pathogens included herpes simplex virus type 1 (HSV-1) in 3%; HSV-2 in 9%, and more than one bacterium in 15%. Sixteen percent of placental samples were negative for these pathogens. These findings suggest that early gestation placentas frequently contain DNA from viral and bacterial pathogens.

Detailed analysis of paired first-trimester decidual and placental biopsy specimens from individual pregnancies showed that some pathogens were present in both. CMV DNA was detected in 89% of the decidual samples and 63% of the placentas. When CMV was found in isolation in the decidua (40%), virus was also sometimes present in the placenta (26%). In contrast, when bacterial DNA was detected in the placenta (11%), signals were less frequently found in the decidual samples (6%). Together these results suggest that CMV can be selectively transferred from the decidua, a potential reservoir, to the adjacent placenta. When the effects of gestational age were examined, CMV DNA, with or without other pathogens, was detected in 63% of first-trimester placentas and 74% of second-trimester placentas. Together, samples with both CMV and bacterial DNA increased from 31% in the first trimester to 44% in the second trimester, whereas CMV alone was reduced in the second trimester. Fewer second-trimester placentas were negative for all pathogens. These studies suggested that (a) CMV is commonly present at the uterine-placental

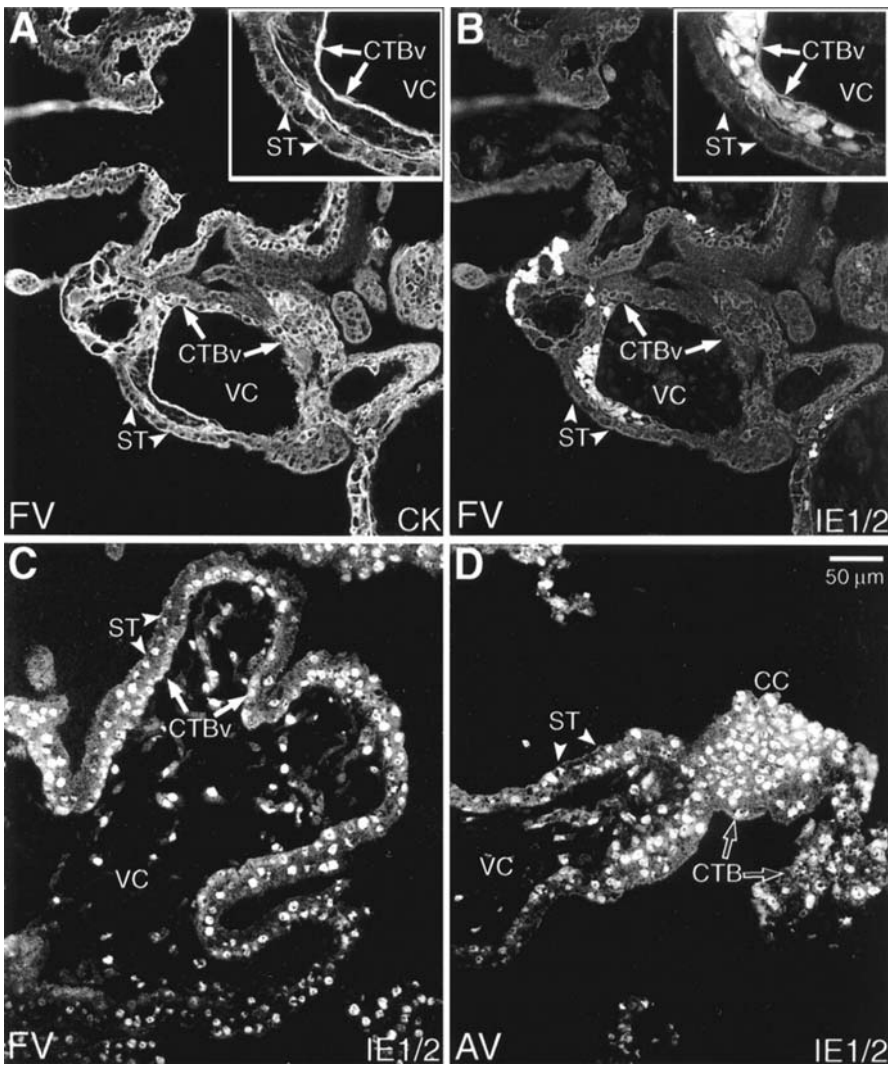

Fig. 45.3. Natural infection of chorionic villi with CMV in utero in cytotrophoblasts and other cells. Both floating villi (FV) (a–c) and anchoring villi (AV) (d) are shown. Tissues were analyzed by using immunolocalization techniques for expression of (a) cytokeratin (CK) and (b, d) CMV IE proteins. (b) In some floating villi, clusters of CMV-infected villous cytotrophoblast progenitors (CTBv) (arrows) underlying the syncytium (ST) (arrowheads) were the only sites of antibody reactivity. Sometimes, numerous cells throughout the villi stained with anti-CMV antibody. (c) Nuclei of syncytiotrophoblasts, villous cytotrophoblasts and stromal components expressed CMV proteins. (d) The same pattern of immunoreactivity was seen in infected anchoring villi. Additionally, cytotrophoblasts in cell columns (CC) stained brightly. VC, villus core.

interface together with pathogenic bacteria, (b) infection tends to increase in the second trimester, and (c) virus is selectively transmitted to the adjacent placenta.

Neutralizing antibodies to CMV gB in placental syncytiotrophoblasts

Development of neutralizing antibodies is delayed when primary CMV infection occurs shortly before or during gestation (Boppana and Britt, 1995; Lazzarotto *et al.*, 1997; Revello *et al.*, 2002), whereas high titers indicate resolution of acute infection and/or reactivation. Antibody responses to CMV in the group of donors from whom paired biopsy specimens were obtained showed that, with one exception, the donors were seropositive with a range of neutralizing activity. Briefly, neutralizing activity in IgG purified from the conditioned medium of biopsy specimens was evaluated. Ten women had low neutralizing titers (0% to 32%), nine had moderate titers (43% to 67%) and four had high titers (70 to 98%).

Some serologic evidence suggests that reinfection with new CMV strains in seropositive women might be associated with symptomatic fetal infection (Boppana *et al.*, 1999). To determine whether multiple strains colonize the placental-decidual interface, a region of the gB gene with characteristic nucleotide differences was sequenced. Sequence analysis of a small number of CMV-positive samples revealed that the gB genotypes were similar to variants in groups 1, 2 and group 3 (Chou and Dennison, 1991). Paired decidua and adjacent placenta from a seropositive donor without detectable neutralizing antibodies contained a mixture of gB genotypes, suggesting that different CMV strains could infect the maternal-fetal interface early in the course of maternal infection.

Patterns of CMV-infected-cell proteins in the decidua and placenta

Decidual biopsy specimens that contained CMV DNA were studied by immunofluorescence confocal microscopy to determine whether viral proteins could be detected (McDonagh *et al.*, 2004; Pereira *et al.*, 2003). Tissue sections of decidual biopsy samples were incubated with a pool of monoclonal antibodies to CMV-infected-cell proteins and to gB, an abundant virion envelope glycoprotein. Staining revealed islands of infected resident uterine and fetal cells, as well as innate immune cells among much larger uninfected areas. Several common staining patterns emerged. In the most highly affected samples, CMV-infected-cell proteins were found in the nuclei and cytoplasm of glandular epithelium (Fig. 45.4(a), *a–c*), vascular endothelium and endovascular cytotrophoblasts (Fig. 45.4(a), *d–f*). Resident decidual cells positive for insulin growth factor binding protein 1 (IGFBP-1) also stained brightly (Fig. 45.4(a), *g–l*). These data indicate that CMV infects a diverse population of maternal cells within the uterine wall and fetal invasive cytotrophoblasts. Innate immune cells showed a staining pattern that was distinctly different from that of CMV-infected cells, suggesting phagocytosis of enveloped virions. Macrophages (CD68+) contained cytoplasmic vesicles that stained strongly for CMV gB (Fig. 45.4(b), *a–c*). Some gB-positive cells also stained for DC-SIGN (Kammerer *et al.*, 2003; Soilleux *et al.*, 2001) (Fig. 45.4(b), *d–f*). NK (CD56+) cells were often dispersed among Mφ/DC that were filled with gB-positive vesicles (Fig. 45.4(b), *g*). Occasionally, striking numbers of NK cells and Mφ/DC intermingled (Fig. 45.4(b), *h* and *i*). Additionally, neutrophils inside uterine blood vessels were found near endothelial cells and decidual cells that expressed CMV-infected-cell proteins, suggesting phagocytosis (Fig. 45.4b, *j–l*). These observations suggested that the uterus serves as a reservoir for CMV virions that could potentially infect the placenta.

Different patterns of CMV infection in the decidua mirrored in the adjacent placenta

Examination of CMV proteins in paired decidual and placental biopsy specimens showed three staining patterns (Pereira *et al.*, 2003). In the first, islands in both decidual and placental compartments stained strongly for CMV-infected-cell proteins. This pattern predominated in samples from donors with low neutralizing titers and a few with intermediate titers and other pathogens. In the decidua, cytokeratin-positive glandular epithelial cells, endovascular cytotrophoblasts in remodeled uterine blood vessels, and interstitial cytotrophoblasts were sometimes positive. Resident decidual cells strongly stained for viral proteins, suggesting that these cells were permissive for viral replication. In the adjacent portions of the placenta, floating villi contained syncytiotrophoblasts and cytotrophoblast progenitor cells expressing CMV-infected-cell proteins that localized to the nuclei and cytoplasm. Abundant vesicles amassed close to the plasma membrane of the villus surface and contained gB. In regions with infected syncytiotrophoblasts, fibroblasts and fetal capillaries in the villus core expressed infected-cell proteins. Invasive cytotrophoblasts in developing cell columns that anchor the placenta to the uterine wall also stained. In contrast, Mφ/DCs within the villus stromal cores contained infected-cell proteins in cytoplasmic vesicles but not in the nuclei, suggesting phagocytosis.

In the second group of paired biopsy specimens, the number of cells that stained for CMV-infected-cell proteins was reduced in the decidua, and occasional focal infection was found in the placenta. This pattern predominated in samples from donors with low to intermediate neutralizing titers, several of which contained other pathogens. In the decidua, CMV replication was detected in some glandular epithelial cells and decidual cells. In the interstitium, Mφ/DCs were abundant throughout, especially near infected glands and blood vessels. These cells contained gB-positive cytoplasmic vesicles but were not infected. Sometimes the adjacent placentas contained small clusters of cytotrophoblast progenitor cells that expressed CMV-infected-cell proteins. Isolated gB-containing vesicles were present in the overlying syncytiotrophoblast layer. In the villus core, Mφ/DCs containing CMV gB-positive vesicles were often observed. In other placental biopsies, only gB-containing vesicles were detected in syncytiotrophoblasts and villus core Mφ/DCs without infection.

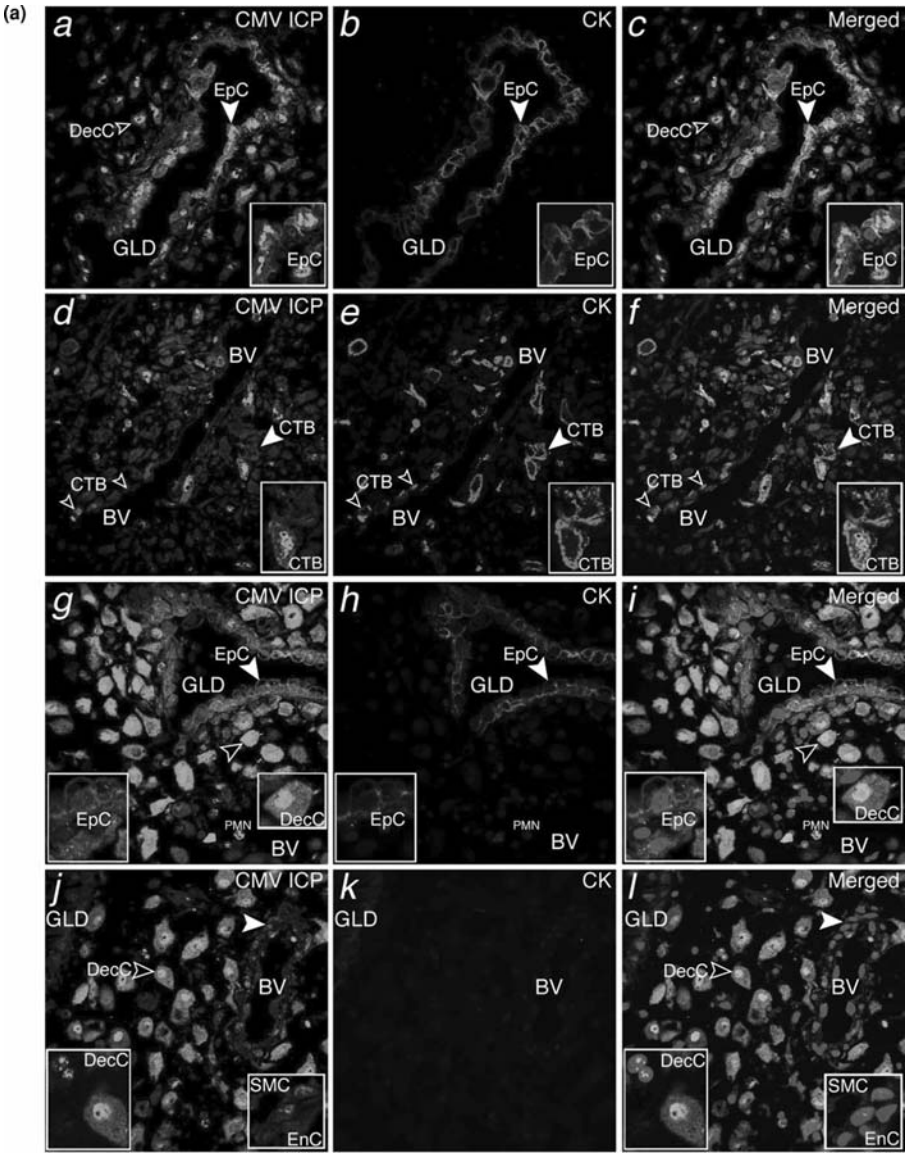

Fig. 45.4. Panel (a): CMV replicates in diverse cell types in uterine decidua. CMV infects endometrial glands (GLD), uterine blood vessels (BV), resident decidual cells (DecC) and cytotrophoblasts (CTB) in the decidua. (*a*)–(*c*), Decidual biopsy specimens stained for CMV-infected-cell proteins (ICP, green) and cytokeratin (CK, red), which identified epithelial cells (EpC). (*d*)–(*i*), CMV-infected interstitial and endovascular CTB and DecC. (*j*)–(*l*), Endothelial cells (EnC) and smooth muscle cells (SMC) of uterine blood vessels (BV) are infected. Panel (b): Abundant innate immune cells infiltrating the decidua contain CMV proteins. (*a*)–(*c*) CMV gB (green), macrophages (Mφ/DC, CD68, red). (g)–(h) DC-SIGN+ (green) macrophage/dendritic cells (Mφ/DC) take up CMV gB (red). (*g* (and) *h*) CD56+ (green) natural killer (NK) cells target infection sites. (*i*) DC-SIGN+ cells containing gB. (*j*)–(*l*) Neutrophils (PMN) with phagocytosed proteins from virus-infected cells and endothelial cells (EnC) positive for von Willebrand factor (vWF) in blood vessels (BV). "Merged" indicates colocalized proteins (yellow). Large arrowheads indicate area shown in insets. (See color plate section.)

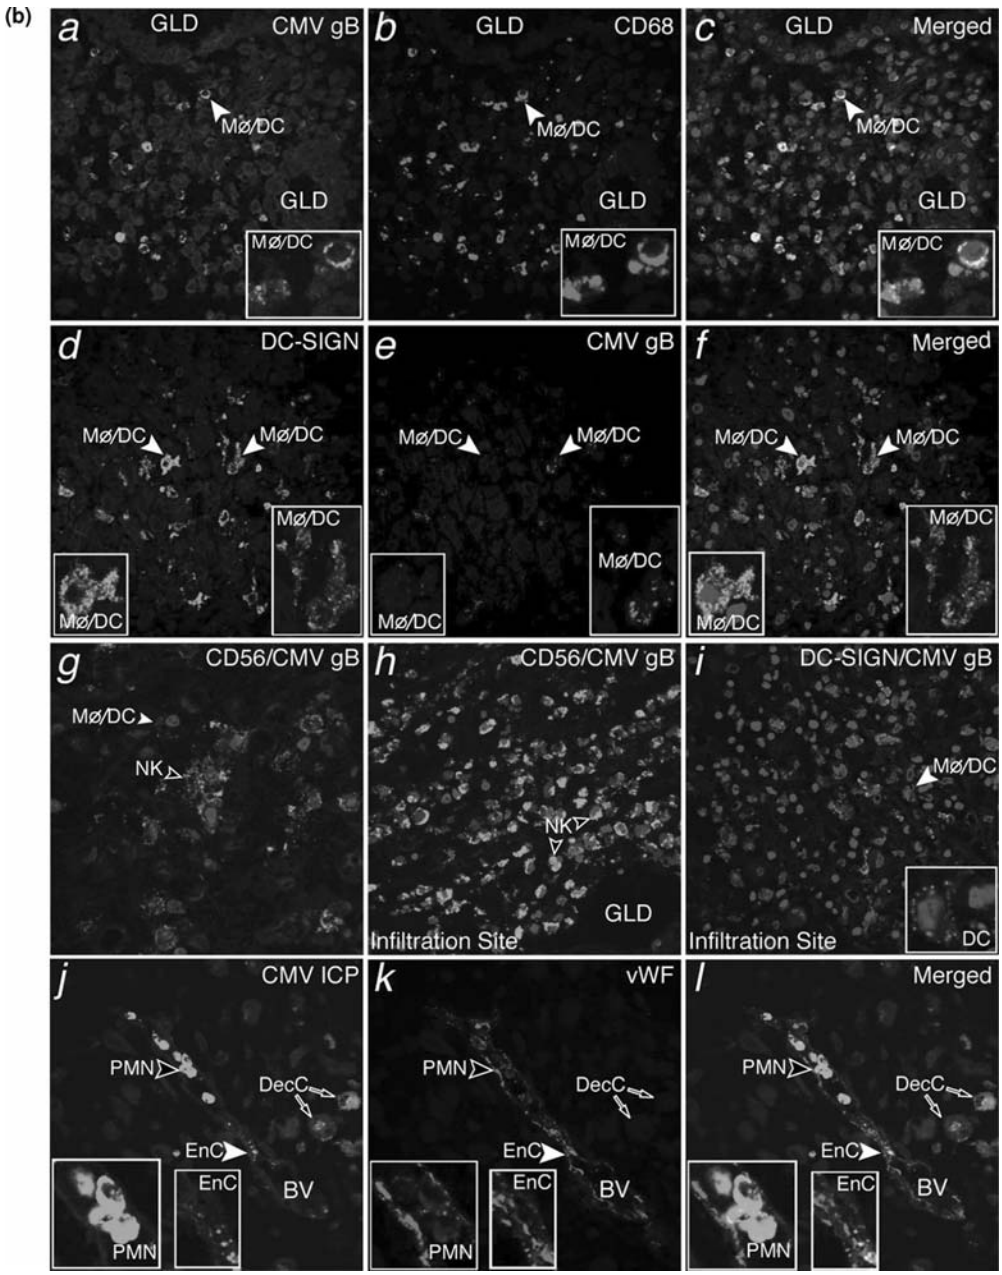

Fig. 45.4. (*cont.*) (See color plate section.)

In the last group of paired biopsy specimens, few cells stained for CMV-infected-cell proteins in the decidua, and none were found in the placenta. This pattern predominated in samples from donors with intermediate to high neutralizing titers, several of which contained other pathogens.

In the decidua, neutrophils with viral proteins were found in uterine blood vessels near infected cells. In the adjacent portions of the placenta, syncytiotrophoblasts contained numerous CMV gB-positive vesicles but were not infected. In villus core Mφ/DCs, gB accumulated in large cytoplasmic vesicles. When placentas were stained for IgG, syncytiotrophoblasts contained many positive vesicles, and gB colocalized with a small subset of them. In villus core Mφ/DCs, some gB-staining vesicles colocalized with the more abundant IgG-positive

vesicles. FcRn-positive vesicles at the apical and basolateral membranes suggested IgG transcytosis in syncytiotrophoblasts (Simister and Story, 1997). In some cases, the presence of viral nucleocapsids in syncytiotrophoblasts was confirmed by electron microscopy.

These studies concluded that CMV is commonly present at the maternal-fetal interface, one possible explanation for why pregnant women shed virus from the cervix (Collier *et al.*, 1995; Shen *et al.*, 1993; Stagno *et al.*, 1975). Bacteria were often found in donors with intermediate to high neutralizing titers whose uninfected placentas contained virion proteins suggesting limited CMV replication in the decidua. Reactivation from decidual MΦ/DCs might occur as a consequence of inflammatory responses to pathogenic bacteria and could depend on the number of latently infected MΦ/DCs infiltrating the uterus (Cook *et al.*, 2002; Hahn *et al.*, 1998; Soderberg-Naucler *et al.*, 2001). Placentas from healthy pregnant donors contained isolated areas of infection that were a small part of the whole tissue. Since these tissues were from normal pregnancies, placental infection that leads to fetal transmission likely involves the decidual and placental components that stained for infected-cell proteins, i.e., an exacerbation of the situation found in samples from women with the lowest neutralizing titers and some with intermediate titers as well as bacterial pathogens.

Coordinated immune responses suppressed CMV infection of the placenta in women with intermediate to high neutralizing titers, one explanation for a correlation between high-avidity IgG and protection against vertical transmission (Boppana and Britt, 1995; Revello *et al.*, 2002). The most remarkable result is that women with uncomplicated pregnancies had suppressed infection in the decidua. Virion-IgG complexes may be transported to the placenta without infection, a process that demonstrates the efficacy of innate and adaptive immunity. CMV infection of the decidua is a novel paradigm and further illustrates how this virus utilizes host immunity (Mocarski, 2002) by exploiting maternal hyporesponsiveness.

Analysis of CMV DNA and proteins expressed in placentas from uncomplicated deliveries by PCR and immunohistochemistry showed evidence of transplacental transmission (McDonagh *et al.*, 2006). CMV DNA was detected in 62% of term placentas examined. In biopsy specimens from placentas with high levels of CMV DNA and low maternal neutralizing titers, fetal blood vessels contained leukocytes with viral replication proteins. Some cord blood samples contained CMV DNA, confirming viral replication. In placentas with low levels of viral DNA and high neutralizing titers, villus core macrophages and dendritic cells contained CMV gB, comparable to infection in early gestation, suggesting virion uptake without transmission. Together the results showed that CMV infection spreads from villus cytotrophoblasts to stromal fibroblasts, placental blood vessels and fetal leukocytes in late gestation. Over 5% of uncomplicated deliveries contained CMV replication proteins, suggesting a higher incidence of transplacental transmission and asymptomatic congenital infection than previously thought.

Complexes of IgG and CMV virions transcytosed from maternal circulation across syncytiotrophoblasts to underlying cytotrophoblasts

Immunohistochemical analysis of early gestation biopsy specimens showed an unusual pattern of CMV replication proteins in underlying cytotrophoblast progenitor cells. Whereas syncytiotrophoblasts were spared in placentas with low to moderate CMV neutralizing titers, cytotrophoblasts were infected, suggesting virion transcytosis from maternal blood (Pereira *et al.*, 2003). Early steps of CMV infection and the role of FcRn were examined using the villus explant model (Fig. 45.2(a)) and polarized epithelial cells (Tugizov *et al.*, 1996). The results showed that (i) maternal IgG modulates CMV infection in chorionic villi, (ii) FcRn transcytoses IgG–virion complexes that retain infectivity with low neutralizing antibodies, (iii) villus core macrophages capture transcytosed IgG-virions, (iv) IgG and gB accumulate in caveolae and (v) CMV DNA is present in syncytiotrophoblasts without viral replication. Receptor-mediated transport and caveolar endocytosis explain the infection patterns in villus cytotrophoblasts and CMV virion gB accumulation in vesicular compartments in utero (Pereira *et al.*, 2003). The rapid kinetics of receptor-mediated transport of IgG–virions was similar in syncytiotrophoblasts and polarized T-84 intestinal epithelial cells expressing FcRn: transcytosed immune complexes were detected in villus core macrophages (explants), underlying cytotrophoblasts or the basal medium (cells). In villus explants, IgG–virion transcytosis and macrophage uptake were blocked with trypsin treatment and soluble protein A. The results suggest that CMV virions could disseminate to the placenta by co-opting the receptor-mediated transport pathway for IgG. It was recently reported that passive immunization with hyperimmune IgG at midgestation prevents congenital disease and growth restriction in infected infants of mothers with primary CMV infection (Nigro *et al.*, 2005). This remarkable outcome suggests once CMV replication has been interrupted, functional villi develop that transport neutralizing IgG to the fetus, reducing dissemination.

Receptors for CMV virions are developmentally regulated in cytotrophoblasts

CMV replication in distinct cytotrophoblast populations suggests that virion receptors could be developmentally regulated as these specialized cells proceed along the differentiation pathway from the fetal to the maternal compartment (Fig. 45.1). Function-blocking methods and immunohistochemical analysis were used to correlate infection with expression of CMV receptors in cytotrophoblasts in situ and in vitro (Maidji *et al.*, 2006). In placental villi, syncytiotrophoblasts express a virion receptor, epidermal growth factor receptor (EGFR) (Wang *et al.*, 2003), but lack integrin coreceptors, and endocytosis occurs without replication. IgG–CMV virion complexes transcytosed by FcRn reach underlying cytotrophoblasts (Maidji *et al.*, 2006). Some EGFR-expressing cells selectively initiate expression of a coreceptor, αV integrin (Feire *et al.*, 2004; Wang *et al.*, 2005), and focal infection can occur. In cell columns, proximal cytotrophoblasts lack receptors, and distal cells express integrins α1β1 and αVβ3 but remain uninfected. In the uterine decidua, invasive cytotrophoblasts expressing integrin coreceptors upregulate EGFR, thereby dramatically increasing susceptibility. These findings indicate that virion engagement with receptors in the placenta (i) changes as cytotrophoblasts differentiate and (ii) correlates with spatially distinct sites of CMV replication in maternal and fetal compartments in utero.

CMV infection dysregulates cytotrophoblast differentiation/invasion in vitro

CMV replicates in placental cytotrophoblasts in vitro

Several groups have reported that cytotrophoblasts isolated from early gestation (Fisher *et al.*, 2000; Hemmings *et al.*, 1998) and term placentas (Halwachs-Baumann *et al.*, 1998) are susceptible to CMV infection. A detailed examination of the viral life cycle was done using an in vitro model of progenitor cytotrophoblasts from chorionic villi plated as a monolayer on Matrigel and cultured from 2 to 4 days after infection (see Fig. 45.2(b)) (Fisher *et al.*, 2000; Librach *et al.*, 1991). Under these conditions the cells form aggregates, analogous to cell columns, and differentiate along the invasive pathway. In CMV-infected cells, nuclear staining for IE proteins was detected by 24 hours and cytoplasmic staining for gB was detected by 72 hours in 20 to 40% of the cells. There was an increase in the titers of intracellular and progeny virions released during the culture period, establishing that differentiating cytotrophoblasts are fully permissive for CMV replication.

Investigation of the effects of viral infection in cytotrophoblasts showed considerable changes, evidenced by dysregulated expression of stage-specific adhesion and immune molecules, as well as metalloproteinases and their inhibitors (Fisher *et al.*, 2000; Maidji *et al.*, 2002; Yamamoto-Tabata *et al.*, 2004). Importantly, the cells' central function, invasion, was significantly impaired following infection.

CMV infection in vitro downregulates cytotrophoblast expression of HLA-G

In healthy placentas, the non-classical MHC class Ib molecule HLA-G is expressed in differentiating cytotrophoblasts, particularly cells in anchoring villi with an increasing gradient of expression in the distal columns that is maintained once the cells enter the uterine wall (Kovats *et al.*, 1990; McMaster *et al.*, 1995). Immunolocalization experiments showed that CMV infection of differentiating cytotrophoblasts in vitro downregulates expression of HLA-G (Fisher *et al.*, 2000). At late times when high levels of CMV gB were detected (Fig. 45.5(a)), staining for HLA-G was either greatly reduced or lost (Fig. 45.5(b)). This was in contrast to cells that were not infected with CMV and stained with anti-HLA-G.

Several CMV genes downregulate expression of classical MHC class Ia molecules (for review see Ploegh, 1998). Studied in the context of cytotrophoblasts infected with CMV mutants in which all of the genes known to downregulate cell surface expression of MHC class Ia molecules are deleted, Jones and Muzithras, (1992), showed that HLA-G expression was not rescued (Fisher *et al.*, 2000). Others reported that HLA-G is resistant to the effects of CMV protein US11, which binds to class I heavy chains and mediates their dislocation to the cytosol and subsequent proteasomal degradation (Schust *et al.*, 1998). Subsequent analyses using chimeric molecules of MHC class Ia and Ib showed that the degradation efficiency depended on sequences in the heavy-chain cytosolic tail that HLA-G lacks (Barel *et al.*, 2003). Since the mechanism of HLA-G downregulation does not involve CMV glycoproteins that alter class Ia expression, it is most likely novel.

CMV infection in vitro downregulates α1β1 integrin expression and impairs cytotrophoblast invasion

Congenital CMV infection is associated with abnormal placentation at a morphological level and intrauterine growth restriction (Benirschke *et al.*, 1974), likely related to impaired remodeling of uterine arterioles by invasive

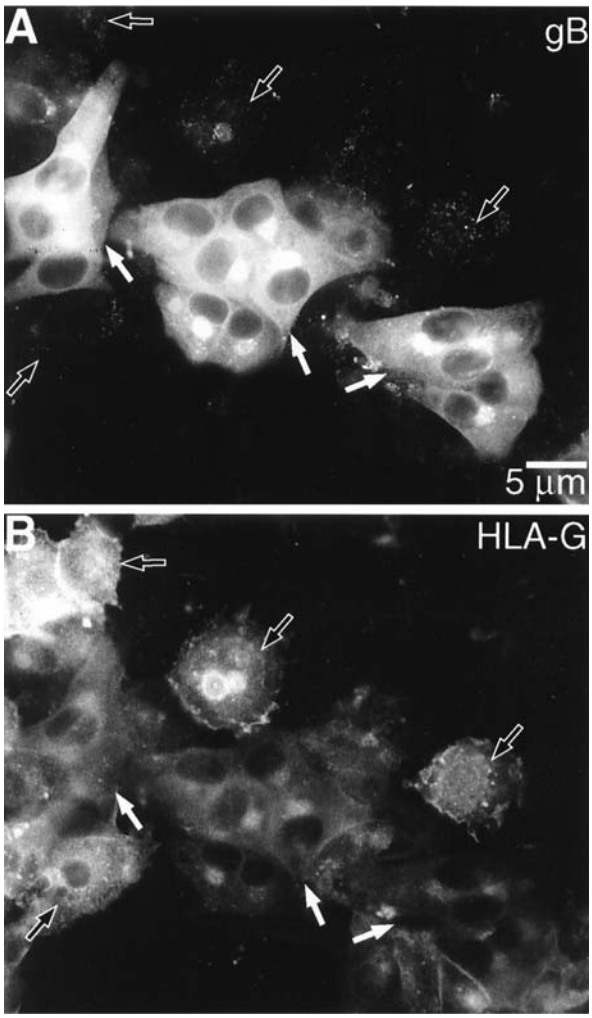

Fig. 45.5. CMV infection impairs cytotrophoblast expression of HLA-G in vitro. Purified cytotrophoblasts were isolated and infected with CMV. At 72 h, the cells were stained for (a) gB and (b) HLA-G expression. Cells that did not express gB (black arrows) expressed HLA-G, and staining for gB (white arrows) was associated with a marked reduction in HLA-G expression.

cytotrophoblasts. This prompted examination of the expression of the laminin/collagen receptor integrin α1β1 in the context of CMV infection. This extracellular matrix receptor is both a stage-specific antigen whose expression is preferentially associated with cytotrophoblasts inside the uterine wall (Damsky *et al.*, 1992) and an adhesion molecule that mediates invasion in vitro (Damsky *et al.*, 1994). Co-localization of CMV gB (Fig. 45.6(a) and (c)) and integrin α1 expression (Fig. 45.6(b) and (d)) showed that cells that did not stain for gB (Fig. 45.6(a)) expressed integrin α1 in a plasma membrane-associated pattern (Fig. 45.6(b)). Diffuse cytoplasmic staining for gB in infected cytotrophoblasts was also correlated with integrin α1 expression (see cell marked with an asterisk in Fig. 45.6(c) and (d)), but accumulation of gB in vesicles (Fig. 45.6(c)) at late times after infection was associated with the absence of staining for integrin α1 (Fig. 45.6(d)). In contrast, immunostaining for another integrin whose expression is upregulated as the cells invade, the fibronectin receptor α5 that functions to inhibit invasion, was not affected.

Flow cytometric analysis and RT-PCR were used to quantify proteins expressed on the surface of freshly isolated cytotrophoblasts from term placentas and changes in differentiating cells infected with VR1814, a pathogenic clinical strain (Tabata *et al.*, 2006). Significant downregulation of HLA-G at the protein level shown by immunohistochemistry was confirmed, and transcription was reduced in infected cells. Likewise, infected cytotrophoblasts significantly dysregulated integrin α1 and α5 proteins. Integrin α9 and VE-cadherin, which promote cell-cell adhesion, were also reduced by infection. Cytotrophoblasts isolated from placentas with CMV DNA and virion gB in syncytiotrophoblasts and in villus core macrophages were uninfected and showed similar expression of the differentiation molecules studied.

The impact of CMV infection on cytotrophoblast invasion was examined using an in vitro assay (see Fig. 45.2(b)) (Fisher *et al.*, 2000). This functional assay tests the ability of isolated cytotrophoblasts plated on the upper surfaces of Matrigel-coated filters to penetrate the surface, pass through pores in the underlying filter, and emerge on the lower surface of the membrane (Damsky *et al.*, 1994; Librach *et al.*, 1991). Invasion is quantified by determining the number of cytokeratin-positive cell processes that emerge through the filter pores. The invasion ability of cells infected with CMV was dramatically impaired, as compared with control uninfected cells, suggesting that functional defects could result from a constellation of virus-induced changes that impair cell–matrix and cell–cell adhesion. Interestingly, the effect on invasion was greater than could be accounted for by the number of CMV-infected cells, suggesting that the presence of infected cells in the invading aggregates influences the behavior of the population as a whole.

CMV infection downregulates MMP activity altering cell-cell and cell–matrix interactions

MMPs are a family of degradative enzymes that remodel the extracellular matrix during many processes, including cell migration, vascularization, and invasion (Chang and

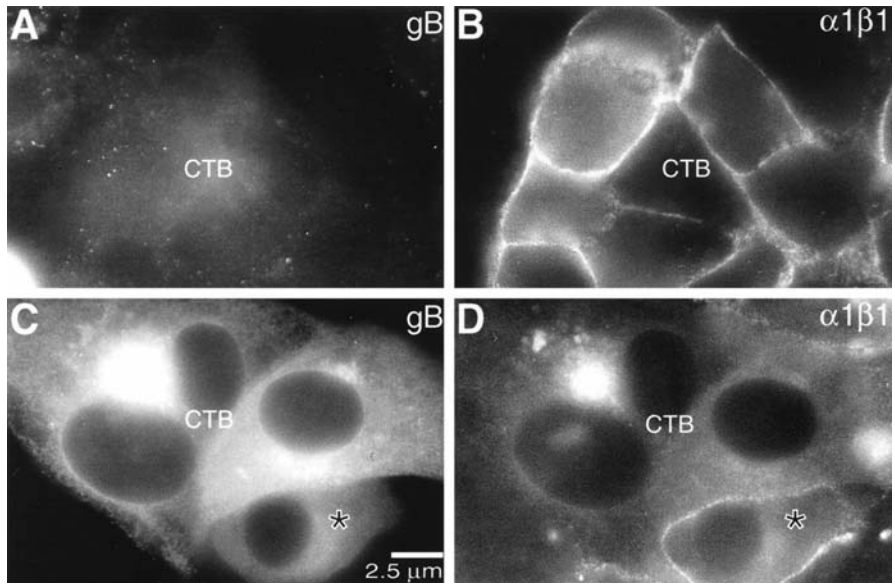

Fig. 45.6. CMV infection in vitro eventually downregulates cytotrophoblast expression of integrin α1. Purified cytotrophoblasts were infected with CMV in vitro. At 72 h, the cells were fixed and stained for expression of gB and integrin α1. Cytotrophoblasts that did not express gB (a) displayed prominent staining for integrin α1 in a plasma membrane-associated pattern (b). Likewise, cells that stained in a diffuse cytoplasmic pattern for gB (c) also reacted with the anti-integrin antibody (d, cell marked with an asterisk). However, when gB was localized in a vesicular pattern, integrin staining was not detected (d).

Werb, 2001). MMPs are highly regulated during translation and post-translationally by activation and secretion. Invasive cytotrophoblasts secrete relatively large amounts of MMP-9 in early gestation, when invasion peaks; later, when invasion is complete, MMP-9 levels fall (Librach *et al.*, 1991). Accordingly, cytotrophoblast invasion is also regulated by factors controlling MMP activation. The inactive proenzyme is activated by cleavage and removal of an inhibitory domain. Activated MMP-9 is absolutely required for invasion, whereas pro-MMP-9 is associated with non-invasive cells (Fisher *et al.*, 1989; Librach *et al.*, 1991).

Examination of cytotrophoblasts and endothelial cells infected with CMV in vitro showed altered MMP protein and activity (Yamamoto-Tabata *et al.*, 2004). Infection with VR1814, an endothelial cell-tropic CMV strain, but not AD169, a laboratory strain, reduced MMP-9 activity, thereby decreasing the cells' capacity to degrade the extracellular matrix. Likewise, MMP-2 activity in uterine microvascular endothelial cells was reduced. Since VR1814-infected endothelial cells transmit infection to cocultured differentiating cytotrophoblasts in vitro (Maidji *et al.*, 2002), infection could undermine contacts between endothelial cells and cytotrophoblasts (Fig. 45.2, site 1). The observation that uterine arterioles are infected by CMV in utero (Pereira *et al.*, 2003) suggests that virus could spread to cytotrophoblasts and in a retrograde direction to the placenta proper (i.e., floating chorionic villi) and to fetal blood vessels in the villus core.

CMV IL-10 dysregulates MMP activity

Several cytokines and growth factors regulate MMP expression and activity. For example, IL-1β is an autocrine stimulator of MMP-9 secretion and cytotrophoblast invasion of Matrigel in vitro (Librach *et al.*, 1994). In contrast, human IL-10 (hIL-10) downregulates these processes and impairs cytotrophoblast invasion (Roth *et al.*, 1996; Roth and Fisher, 1999). Recent reports indicated that CMV IL-10 (cmvIL-10) (Kotenko *et al.*, 2000) binds the hIL-10 receptor 1 (hIL-10R1) with affinity similar to that of natural ligand (Jones *et al.*, 2002) and has comparable immunosuppressive activity (Spencer *et al.*, 2002). Analysis of the cmvIL-10 genes from several strains showed very high sequence conservation, suggesting conserved functions (Kotenko *et al.*, 2000; Spencer *et al.*, 2002). Like other intracellular pathogens that infect macrophages, CMV exploits the IL-10 signaling pathway, expressing an IL10 homologue and upregulating the cell's production of the cytokine (Kotenko *et al.*, 2000; Redpath *et al.*, 2001). Although cmvIL-10 shares only 27% sequence identity with hIL-10, the proteins have essentially identical affinity for the receptor, IL-10R1, and similarly

reorganize the cell surface receptor complex (Jones *et al.*, 2002).

Both cytotrophoblasts and endothelial cells express IL-10R1, suggesting possible autocrine and paracrine regulation by its ligand (Cattaruzza *et al.*, 2003; Roth and Fisher, 1999). hIL-10 in cytotrophoblasts' culture medium can suppress allogeneic lymphocyte reactivity (Roth *et al.*, 1996), an important link between immune protection of the fetus and cytotrophoblast invasion of the uterus. Likewise, recombinant cmvIL-10 can inhibit proliferation of mitogen-stimulated peripheral blood mononuclear cells and production of proinflammatory cytokines at a level comparable to that of hIL-10 (Spencer *et al.*, 2002). Together these findings suggest that cmvIL-10 might, like the cellular molecule, impair invasion of differentiating cytotrophoblasts. MMP activity was examined in uterine microvascular endothelial cells and differentiating cytotrophoblasts in vitro treated with purified recombinant cmvIL-10 or hIL-10 (Yamamoto-Tabata *et al.*, 2004). Culture medium and cell lysates of treated endothelial cells contained less MMP activity than untreated contols, suggesting that the viral cytokine inhibits proteinase production in the absence of infection and that cmvIL-10-and hIL-10 have comparable effects. Likewise, levels of MMP-9 activity in differentiating cytotrophoblasts treated with these cytokines were significantly reduced in a dose-dependent fashion, confirming previous results (Roth and Fisher, 1999).

CMV IL-10 impairs endothelial cell migration and cytotrophoblast invasiveness in vitro

Having shown that cmvIL-10 downregulates MMP-2 and MMP-9 activity, the effect of reduced proteinase activity on fibroblast and endothelial cell function was examined in cell wound healing assays. Briefly, subconfluent cells were scratched ("wounded") and then incubated until control cells closed the wound. Infection with VR1814 or treatment with hIL-10 and cmvIL-10 had impaired endothelial cell wound closure but had no inhibitory effect on fibroblast migration. To assess the effect on cytotrophoblasts, the frequency with which the cells passed through narrow pores in a Matrigel-coated filter was quantified. Treatment with cmvIL-10 alone impaired invasion to a level comparable to that of hIL-10-treated cells, and significantly fewer cells traversed the filter pores after treatment with cmvIL-10 as compared with control untreated cells. Together these results indicated that, like hIL-10, cmvIL-10 impairs endothelial cell migration in wound closure assays and cytotrophoblast invasion as previously observed in CMV-infected cells in vitro (Fisher *et al.*, 2000). These studies suggest that CMV exploits an immune mechanism to dysregulate endothelial cell migration and cytotrophoblast invasion (Yamamoto-Tabata *et al.*, 2004).

Concluding remarks

We are just beginning to appreciate how the unusual anatomy of the maternal-fetal interface is advantageous for CMV spread to the placenta and how innate and adaptive immunity often precludes transplacental transmission. These studies open the door to testing a variety of hypotheses regarding CMV infection of placental tissues. Numerous questions and challenges remain. What is the functional significance of the static picture we obtained of immune defenses and viral proteins at the placental-decidual interface? Does coinfection with viruses and pathogenic bacteria in the decidua and adjacent placenta correlate with fetal transmission in early and late gestation? Additionally it will be interesting to decipher the network of cytokines and chemokines that regulates trafficking of immune cells in the infected decidua. Finally, identifying the molecules used for virion attachment and entry into cytotrophoblasts and syncytiotrophoblasts is crucial to the development of therapeutic strategies. One key to the puzzle of resolving infection *in utero* will be the capacity to gauge the threshold for maternal hyporesponsive. Onset of inflammation could trigger CMV reactivation and processes whereby NK cells, macrophages and dendritic cells control infection in the decidua. We theorize that detailed studies will resolve the serious dichotomy between the devastating consequences of congenital CMV infection and our lack of knowledge, at the molecular level, of the mechanisms involved.

HHV-6A, 6B, and 7

46

HHV-6A, 6B, and 7: pathogenesis, host response, and clinical disease

Yasuko Mori and Koichi Yamanishi

Department of Microbiology, Osaka University Graduate School of Medicine, Japan

Human herpesvirus 6(HHV-6) is a human pathogen of emerging clinical significance. HHV-6 was first isolated from patients with lymphoproliferative disorders in 1986 (Salahuddin *et al.*, 1986). HHV-6 isolates are classified into two groups as variants A(HHV-6A) and variant B(HHV-6B) (Schirmer *et al.*, 1991. The two variants are closely related but show consistent differences in biological, immunological, epidemiological, and molecular properties. HHV-6B is the major causative agent of exanthem subitum (ES) (Yamanishi *et al.*, 1988), but no clear disease has yet been associated with HHV-6A.

Human herpesvirus 7 (HHV-7) was isolated in 1990 from a healthy individual whose cells were stimulated with antibody against CD3 and then incubated with interleukin-2 (Frenkel *et al.*, 1990). This virus is one of the causative agents of ES (Tanaka *et al.*, 1994). Therefore, HHV-6 and HHV-7 are also called Roseolovirus. HHV-6 and HHV-7 are ubiquitous, and more than 90% of adults have antibody to both viruses. These viruses have extensive homology and belong to the β-herpesvirus subfamily.

The genome of HHV-6A is 159 321 bp in size, has a base composition of 43% G + C, and contains 119 open reading frames. The overall structure is 143 kb bounded by 8 kb of direct repeats, DRL (left) and DRR (right), containing 0.35 kb of terminal and junctional arrays of human telomere-like simple repeats (Gompels *et al.*, 1995). A total of 115 potential open reading frames (ORFs) were identified within the 161 573-bp contiguous sequence of the entire HHV-6B genome (HST) (Isegawa *et al.*, 1999). The HHV-6B(Z29) genome is 162 114 bp long and is composed of a 144 528-bp unique segment (U) bracketed by 8793-bp direct repeats (DR). The genomic sequence allows prediction of a total of 119 unique open reading frames (ORFs), 9 of which are present only in HHV-6B. The overall nucleotide sequence identity between HHV-6A and HHV-6B is 90%. The most divergent regions are DR and the right end of the unique region, spanning ORFs U86 to U100. These regions have 85 and 72% nucleotide sequence identity, respectively (Dominguez *et al.*, 1999).

Virus entry and establishment of infection

Cell tropism in vitro

HHV-6A and HHV-6B replicate most efficiently in vitro in peripheral blood mononuclear cells (PBMCs) or cord blood lymphocytes (CBL), and several isolates have been adapted to grow efficiently in continuous T-cell lines. HHV-6 replicates in activated CD4 T lymphocytes in vivo. HHV-6A and HHV-6B differ in their capacities to replicate in specific transformed T-lymphocyte cell lines. Of the two most widely used strains of HHV-6A, strain GS is most commonly propagated in the T-cell line HSB-2 and strain U1102 is usually propagated in J JHAN cells. HHV-6B (Z29 or HST) is grown most often in primary lymphocytes and has been adapted for growth in the Molt-3 or MT-4 –T cells line. While T cells are most widely used for propagation of HHV-6A and HHV-6B, cell lines of neural, epithelial, and fibroblastic origin have different levels of permissiveness for HHV-6 growth in vitro. However, none of these cells are in general use for routine propagation of the virus. In patients with dual infection, only HHV-6A persisted in CSF, which suggests that HHV-6A has greater neurotropism (Hall *et al.*, 1998). Furthermore, CD8 T-lymphocytes, gamma/delta T-lymphocytes and natural killer (NK) cells support HHV-6 replication in association with surface expression of CD4 (Lusso *et al.*, 1991a,b, 1995; Hall *et al.*, 1998).

Grivel et al. showed that HHV-6A and HHV-6B replicate in human lymphoid tissue, but have significant differences in effects on cellular viability and immunological phenotype (Grivel *et al.*, 2003). There is productive infection of both

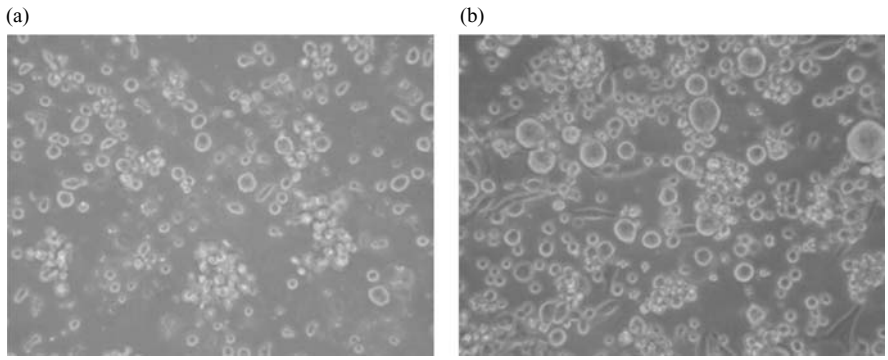

Fig. 46.1. Cytopathic effects of HHV-6A or HHH-7. (a) HSB-2 cells were infected with HHV-6A. (b) SupT1 cells were infected with HHV-7.

CD4+ and CD8+ T-cells, although HHV-6B is markedly less efficient than HHV-6A in targeting CD8+ T-cells. CD46 and CD3 are down-modulated in HHV-6 infected tissues. However CD3 down-modulation is restricted to infected cells, while the loss of CD46 expression is generalized. Thus, the down-modulation of CD46 in HHV-6 negative cells most likely represents an authentic bystander effect. Moreover, HHV-6 infection markedly enhanced the production of CC chemokine RANTES.

In contrast, HHV-7 has a narrow tropism for CD4+ T-cells, associated with infectivity for PHA-stimulated PBMCs, CBLs and in an immature T- cell line SupT1 (Cermelli *et al.*, 1997). Both HHV-6 and HHV-7 induce a cytopathic effect in infected cells which is characterized by ballooning degeneration (Fig. 46.1).

Cell tropism in vivo

The in vivo host tissue range of HHV-6 is broader than its in vitro host range might suggest and includes lymph nodes, lymphocytes, macrophages and monocytes, kidney tubule endothelial cells, salivary glands, and CNS tissues, where viral gene products have been localized to neurons and oligodendrocytes.

HHV-6 genomes and/or antigens are detetable in lymph nodes of patients with sinus histiocytosis with massive lymphadenopathy (SHML) (Levine *et al.*, 1992), tubular epithelial cells, endothelial cells and histiocytes in kidney (Kurata *et al.*, 1990), salivary glands (Fox *et al.*, 1990), and central nervous system (CNS) tissues, where viral gene products have been localized to neurons and oligodendrocytes (Luppi *et al.*, 1994). HHV-6 is also detected in lesions of Langerhans cell histiocytosis in the syndrome of Langerhans cell histiocytosis (Leahy *et al.*, 1993).

HHV-6 was isolated from CD4+ CD8− and CD3+ CD4+ mature T-lymphocytes but could not be isolated from CD4− CD8+, CD4− CD8−, and CD3− T-cells in the peripheral blood of exanthem subitum patients. HHV-6 predominantly infected CD4+ CD8+, CD4+ CD8-, and CD3+ CD4+ cells with mature phenotypes and rarely infected CD4- CD8+ cells from cord blood mononuclear cells, which suggested a predominant tropism of HHV-6 for mature CD4 T-lymphocytes (Takahashi *et al.*, 1989).

So far, two cell types have been recognized as sites of HHV-7 infection in vivo, including CD4+ T-lymphocytes and epithelial cells of salivary glands (Black *et al.*, 1993). HHV-7 is frequently isolated from saliva of healthy adults (Wyatt and Frenkel, 1992). A recent study showed that cells expressing the HHV-7 structural antigen were also detectable in lungs, skin, and mammary glands. Liver, kidney, and tonsils were also positive, although the number of HHV-7-positive cells was low. Large intestine, spleen, and brain were negative for HHV-7 infection (Kempf *et al.*, 1998).

Entry

HHV-6 is characterized by a broad tropism for human cell types but a narrow range of host species. Santoro *et al.* (1999) identified human CD46 as the cellular receptor for HHV-6. CD46 is a ubiquitous type 1 glycoprotein expressed on the surfaces of all nucleated human cells (Seya *et al.*, 1990). It was originally purified as a complement (C) regulatory protein; it binds C3b and C4b on host cells to allow factor I-mediated inactivation of these C fragments, and it plays an important role in protecting host cells from autologous C protein (Seya *et al.*, 1990). CD46 is also a cellular receptor for measles virus. Evidence for CD46 receptor activity included (i) A selective and progressive down-regulation of the surface membrane expression of CD46 in activated human CD4+ T-cells in the course of HHV-6A and HHV-6B infection, (ii) inhibition of HHV-6

infection and associated cell fusion by Mab against CD46 and by soluble CD46, and (iii) non-human cells being rendered susceptible to HHV-6-mediated membrane fusion and HHV-6 entry by expression of CD46. However, the expression of CD46 was not sufficient for HHV-6 fusion and infection in all human cell types, suggesting either that a specific co-receptor is needed or that some cells express an inhibitor of the CD46 receptor activity. Mori *et al.* (2002) found that HHV-6A, but not HHV-6B can mediate fusion-from-without (FFWO) in a variety of human cells, including Vero cells which are an old world monkey cell line. Chinese hamster ovary (CHO) cells are highly resistant to infection by HHV-6 and cell-cell fusion induced by HHV-6A. However HHV-6A, but not HHV-6B induced cell–cell fusion in CHO cells expressing human CD46 without virus replication. Thus, the induction of cell- cell- fusion in the target cells by HHV-6A requires human CD46. Thus, HHV-6A mediates syncytia formation in target cells expressing human CD46 without associated virus replication. Human CD46 is composed of four short consensus repeats (SCRs), a Ser/Thr(ST)-rich domain, 13-amino-acid sequence of unknown significance (UK), a transmembrane domain, and a cytoplasmic tail (CYT) (Seya *et al.*, 1990). The SCR2, -3 and - 4 of the CD46 ectodomain were essential for the HHV-6A induced cell-cell fusion. Another report indicates that the SCR domains 2 and 3 are required for HHV-6 receptor activity (Greenstone *et al.*, 2002).

The products encoded by the U100 gene of HHV-6A have been reported to form a complex containing polypeptides. The U100 gene complex is a major component of the HHV-6 virion and a target for virus-neutralizing antibodies. The gene has an intron-exon structure, resulting in a highly spliced mRNA transcript, and is unique to HHV-6 and HHV-7 (Pfeiffer *et al.*, 1995; Skrincosky *et al.*, 2001). U100 gene products of HHV-6A are mainly composed of 80- and 78-kDa glycoproteins and furthermore, the 80-kDa gene product is the third glycoprotein component of the gH-gL complex in HHV-6A infected cells (Mori *et al.*, 2003a,b). Based on these characteristics, U100 gene products were designated as glycoprotein Q(gQ). The gH-gL-gQ complex is identified as a viral ligand for human CD46 (Mori *et al.*, 2003a,b). The gH-gL complex alone or gQ alone in a transient expression system were unable to bind to CD46. The interaction with CD46 might require additional associations or modification in HHV-6 infected cells. Santoro et al. showed that gH of HHV-6 is a ligand for human CD46, however gH alone does not bind to CD46, and the interaction between gH and CD46 requires HHV-6 infection (Santoro *et al.*, 2003). Therefore, to date, whether one glycoprotein of the gH–gL–gQ complex binds to CD46 directly or whether the steric conformation of the complex itself is required for the interaction with CD46 is unknown.

The entry of herpes viruses into cells is a complex process that is still incompletely understood. In several cases, it appears to require not only a cellular receptor to interact with the virus attachment protein but also at least one additional molecule to interact with the virus and facilitate penetration. Studies on other herpesviruses have provided indirect evidence of a role for homologue of the gH-gL and gB molecules in membrane fusion. In HHV-6, specific monoclonal antibodies against glycoprotein H (gH) and glycoprotein B (gB) inhibited virus-induced cell fusion event and infection (Foa Tomasi *et al.*, 1991; Mori *et al.*, 2002). Considering the previous reports, it seems likely that the process involves several steps. First, HHV-6 gH-gL-gQ complex binds to CD46 and at the same time, gB binds to an unknown cellular molecule, thereby triggering fusogenic activity. Subsequently, viral envelope glycoproteins, probably gB and gH-gL-gQ may act to induce envelope–cell or cell–cell fusion. gB or gH or both are candidates for the actual fusogenic glycoprotens. HHV-7 infects CD4+ T-lymphocye in vitro. The glycoprotein CD4, a member of the immunoglobulin superfamily, is a critical component of the receptor for HHV-7 (Lusso *et al.*, 1994). A selective and progressive downregulation of the surface membrane expression of CD4 was observed in human CD4+ T-cells in the course of HHV-7 infection. Various murine monoclonal antibodies (MAbs) to CD4 and the recombinant soluble form of human CD4 caused a dose-dependent inhibition of HHV-7 infection in primary CD4+ T-lymphocytes. Moreover, radiolabeled HHV-7 specifically bound to cervical carcinoma cells (HeLa) expressing human CD4. However, HHV-7 can infect cells that do not express detectable CD4. It is likely that other host molecules act as receptors; the need for multiple sequential receptors to enable cell-to-cell migration of the virus in tissues is a well-documented phenomenon in other herpesviruses.

The human immunodeficiency virus type 1 (HIV-1) co-receptors, CXC-chemokine receptor (CXCR)4 and CC-chemokine receptor(CCR)5, have been studied to determine whether they serve similar functions for HHV-6A, HHV-6B and HHV-7. Cells from individuals lacking CCR5 were able to support growth of all three viruses, and these individuals were seropositive for the viruses, indicating that this molecule is not essential for viral replication. HHV-7 infection also causes a progressive loss of the surface CXCR4 in CD4(+) T-cells, accompanied by a reduced intracellular Ca2+ flux and chemotaxis in response to stromal cell-derived factor-1 (SDF-1), the specific CXCR4 ligand. Moreover, CXCR4 is downregulated from the surface of HHV-7-infected T-cells independently of CD4. Because

intracellular CXCR4 antigen and mRNA levels are unaffected in productively HHV-7-infected cells, the down-regulation of CXCR4 apparently does not involve a transcriptional block (Secchiero *et al.*, 1998). However, another report demonstrates that CXCR4 is not involved in HHV-7 infection. The natural ligand of CXCR4, SDF-1alpha, was not able to inhibit HHV-7 infection in SupT1 cells or in CD8(+) T-cell-depleted peripheral blood mononuclear cells. Also, a specific CXCR4 antagonist with potent antiviral activity against T-tropic HIV strains (50% inhibitory concentration IC(50), 1 to 10 ng/ml), completely failed to inhibit HHV-7 infection (IC(50), >250 μ/ml) (Zhang *et al.*, 2000). Unlike HIV-1, HHV-6 and HHV-7 infections do not require expression of CXCR4 or CCR5, whereas marked down-regulation of CXCR4 is induced by these viruses (Yasukawa *et al.*, 1999).

Two HHV-7 glycoproteins have been identified as being able to bind the cell surface proteoglycans heparan and heparan sulfate (Secchiero *et al.*, 1997a,b; Skrincosky *et al.*, 2001). They are the virion glycoprotein, gB and spliced glycoprotein encoded by U100. Thus, soluble heparin was found to block HHV-7 infection and syncytium formation in the SupT1 cell line. The CD4 antigen is a critical component of the receptor for the T-lymphotropic HHV-7 suggesting that heparin-like molecules also play an important role in the HHV-7-entry process. As described above, gB is one of the HHV-7 envelope proteins involved in the adsorption of virus-to-cell surface proteoglycans (Secchiero *et al.*, 1997a,b). Analysis of the biochemical properties of recombinant gp65, (U100 gene products), also revealed a specific interaction with heparin and heparan sulfate proteoglycans and not with closely related molecules such as N-acetylheparin and de-N-sulfated heparin, suggesting that HHV-7 gp65 may contribute to viral attachment to cell surface proteoglycans (Skrincosky *et al.*, 2001). The products of U100 are targets for complement-independent neutralization.

Envelope glycoproteins for entry process

The genes U39 and U48 of HHV-6 and HHV-7 encode the conserved surface glycoproteins gB and gH, which contribute to virus-cell fusion.

HHV-6 gH forms complexes with glycoprotein L (gL, encoded by U82), resulting in the formation of a gp100 complex (Liu *et al.*, 1993). Recently, gQ (encoded by U100) was shown to be a third component of gH-gL complex in HHV-6 (Mori *et al.*, 2003a,b). This gQ is unique to the genus of HHV-6 and HHV-7. The gQ gene is subject to differential splicing, and a number of enveloped glycoprotein –encoding genes, gQ genes of HHV-6A and –6B demonstrate only 72.1% sequence identity. This glycoprotein may have a role in the differential consequences of HHV-6A and B infections. Along with gB and gH, gQ contains epitopes recognized by variant specific neutralizing antibodies.

An unusual feature of HHV-6 in comparison to other herpesviruses is the lack of viral glycoproteins in the plasma membrane (Cirone *et al.*, 1994). HSB-2 T-lymphoid cells and human cord blood mononuclear cells infected with HHV-6 reveal the presence, in the cell cytoplasm, of annulate lamellae (AL), which are absent in uninfected cells (Cardinali *et al.*, 1998). Viral glycoproteins are stored in newly formed annulate lamellae, which function as a viral glycoprotein storage compartment and as a putative site of O-glycosylation. It is proposed that, during viral morphogenesis, nucleocapsids released from the nucleus have a primary envelope that lacks glycoproteins but, in the cytoplasm, this is removed and replaced by a secondary envelope containing glycoproteins acquired from the annulate lamella. Further modification of glycoproteins by glycosylation during transit through the Golgi apparatus occurs before mature virions are released.

Spread in host, mechanisms of tissue damage

Growth properties

HHV-6 and HHV-7 replication cycles are approximately 3 days in activated CBLs grown in the presence of IL-2or PHA. Even in most permissive systems, the infectious yields are relatively low, commonly ranging from 10^3 to 10^5 infectious units per ml. Centrifugal infection increases the infectious titer.

Effects of virus infection on host cells

HHV-6 infection has profound effects on host cells. These lead to the development of the classic cytopathic effect of ballooning and multinucleated giant cells.

In the case of HHV-7, multinucleated giant cells occur, not by fusion of cells into syncytia, but by polyploidization (Secchiero *et al.*, 1998). The giant cells, which represent the hallmark of in vitro HHV-7 infection, arise from single CD4(+) T-cells undergoing a process of polyploidization that is linked to disregulation of cyclin-dependent kinase cdc2 and cyclin B. This leads to an accumulation of cells in the G_2 to M phase of the cell cycle, with nuclei continuing to reproduce in the absence of cell division (Secchiero *et al.*, 1998).

Several cytokines can be induced by HHV-6 and HHV-7 infection. Interferon-alpha, interleukin 1 beta, and tumor necrosis factor are induced by HHV-6 (Kikuta *et al.*, 1990; Flamand *et al.*, 1991). But, exposure of human macrophages to HHV-6 profoundly impairs their ability to produce IL-12 upon stimulation with IFN-gamma and LPS, providing a novel potential mechanism of HHV-6-mediated immunosuppression (Smith *et al.*, 2003). HHV-6 can infect NK cells and T lymphocytes. HHV-6 and HHV-7 induces IL-15 in human PBMC and increases their NK activity (Flamand *et al.*, 1996; Atedzoe *et al.*, 1997; Gosselin *et al.*, 1999). The induction of NK cell activity by HHV-6 is abrogated by monoclonal antibodies to IL-15 but not by mAbs to other cytokines (IFN-alpha, IFN-gamma, TNF-alpha, TNF-beta, IL-2, IL-12). IL-15 protein synthesis is increased in response to HHV-6, and addition of IL-15 to PBMC cultures is found to severely curtail HHV-6 expression. Taken together, the host responds to HHV-6 and HHV-7 infection by up-regulating IL-15 production, which then results in an enhancement of NK cell activity; this, in turn, may play a major role in the control of the viral infection (Flamand *et al.*, 1996; Atedzoe *et al.*, 1997; Gosselin *et al.*, 1999).

HHV-6 affects HIV-1 infection in a coreceptor- dependent manner, suppressing CCR5-tropic but not CXCR4-tropic HIV-1 replication. HHV-6 increases the production of the CCR5 ligand RANTES CC-chemokine, the most potent HIV-inhibitory CC chemokine, and that exogenous RANTES mimics the effects of HHV-6 on HIV-1, providing a mechanism for the selective blockade of CCR5-tropic HIV-1 (Grivel *et al.*, 2001). HHV6 infection induces de novo synthesis of the RANTES in endothelial cells as well (Caruso *et al.*, 2003).

HHV-6A infection induces cell-surface expression of CD4, which then allows infection by HIV-1 of cells such as gamma/delta T cells that were previously refractile to infection (Lusso *et al.*, 1991a,b, 1995; Caruso *et al.*, 2003). HHV-6A, but not HHV-6B or HHV-7, down-regulates cell surface expression of CD3, and HHV-7 predominantly down-regulates CD4 (Furukawa *et al.*, 1994).

HHV-6A, HHV-6B and HHV-7 were evaluated for their effects on in vitro colony formation of hemopoietic progenitor cells derived from CBLs. Formation of both granulocyte/macrophage and erythroid colonies was suppressed after infection with HHV-6B. Although HHV-6A suppressed the formation of erythroid colonies as efficiently as HHV-6B, HHV-6A did not exhibit significant suppressive effect on the formation of granulocyte/macrophage colonies. HHV-7 had no effect on either lineage (Isomura *et al.*, 1997). Furthermore, the suppressive effects of HHV-6 on thrombopoiesis in vitro was evaluated. Using CBLs as the source of hematopoietic progenitors, two types of colonies, megakaryocyte colony-forming units and non-megakaryocyte colony-forming units colonies, were established. HHV-6A and HHV-6B inhibited thrombopoietin-inducible both megakaryocyte and non-megakaryocyte colony formation. In contrast, HHV-7 had no effect on thrombopoietin-inducible- colony formation (Isomura *et al.*, 2000). More differentiated CD34+ cells, which were a major source of hematopoietic progenitor cells, were more susceptible to the effects of HHV-6, indicating that the targets for hematopoietic suppression by HHV-6 are the differentiated cells (Isomura *et al.*, 2003). In contrast, in bone marrow-derived cells, both HHV-6A and HHV-6B suppressed erythroid, granulocyte-macrophage, and multipotential precursors of the granulocyte, erythrocyte, monocyte, and megakaryocyte lineages (Carrigan and Knox, 1995). The mechanisms of cell death in the human CD4+ T-cell line J JHAN mediated by HHV-6 were investigated (Inoue *et al.*, 1997) by transmission electron microscopy infected cells showed characteristics of apoptosis, such as chromatin condensation and fragmentation of nuclei, but few virus particles were detected in apoptotic cells. Two-color flow cytometric analysis revealed that DNA fragmentation was present predominantly in uninfected cells but not in cells that were productively infected with HHV-6 (Inoue *et al.*, 1997). Acute in vitro HHV-7 infection induced (i) the formation of giant multinucleated syncytia, which eventually underwent necrotic lysis, and (ii) single-cell apoptosis. Using electron microscopy analysis, all syncytia contained large amounts of virions and most cells within syncytia them exhibited clear evidence of necrosis, whereas apoptosis was predominantly observed in single cells. Although empty viral capsids could be identified in the cytoplasm of approximately 25% of single cells exhibiting an apoptotic morphology, few mature virions were observed in these cells. Thus, it appears that apoptosis occurred predominantly in uninfected bystander cells but not in productively HHV-7-infected cells (Secchiero *et al.*, 1997a,b). Apoptosis induced by HHV-6 in cord blood mononuclear cells (CBMCs) was also investigated. CBMCs prestimulated with phytohemagglutinin (PHA) were infected with HHV-6 and cultured with interleukin 2 (IL-2) for 5 days. The percentage of the hypodiploid fraction by cell cycle analysis and the percentage of cells showing apoptosis determined by terminal deoxytransferase (TdT)- mediated dUTP nick end-labeling (TUNEL) assay were significantly higher in HHV-6-infected CBMC compared with uninfected CBMC. 7A6 antigen, induced on the mitochondria membrane in apoptotic cells, was mainly expressed in CD4+ cells; 7A6 antigen was also detected in HHV-6-infected cells as determined by expression of gH.

Thus, HHV-6 induces apoptosis in HHV-6-infected CBMCs different from T-cells lines (Ichimi *et al.*, 1999). In order to confirm that apoptosis of CD4+ T lymphocytes also occurs in HHV-6 infection in vivo, apoptosis of lymphocytes isolated from nine patients with exanthem subitum and from an adult patient with severe HHV-6 infection was examined (Yasukawa *et al.*, 1998). PBMCs were cultured for 3 days and apoptosis of lymphocytes was examined by flow cytometry of propidium iodide-stained DNA. The percentages of hypodiploid DNA, indicating apoptosis, in lymphocytes from 10 patients with HHV-6 infection were significantly higher than those from five infant patients with non-infectious diseases and five healthy adults ($P < 0–0002$). DNA fragmentation was also detected in lymphocytes from patients with HHV-6 infection. Apoptosis appears to occur predominantly in CD4+ T-lymphocytes and HHV-6 is isolated from the CD4+ T lymphocyte fraction (Yasukawa *et al.*, 1998).

Accordingly, in CBLs, infected cells are apoptotic, while in transformed cells, infected cells die by necrotic lysis and apoptosis is triggered in non-productively infected cells. The latter observation suggests that the virus may be able to inhibit apoptosis in at least some cells and that its replication might be enhanced by suppression of apoptosis.

To dissect the underlying molecular events, the role of death-inducing ligands belonging to the tumor necrosis factor (TNF) cytokine superfamily was investigated (Secchiero *et al.*, 2001a,b). HHV-7 selectively up-regulated the expression of TNF-related apoptosis-inducing ligand (TRAIL), but not that of CD95 ligand or TNF-alpha in SupT1 or primary activated CD4(+) T-cells. Moreover, in a cell-to-cell-contact assay, HHV-7-infected CD4(+) T-lymphocytes were cytotoxic for bystander uninfected CD4(+) T-cells through the TRAIL pathway. By contrast, HHV-7 infection caused a marked decrease of surface TRAIL-R1, but not of TRAIL-R2, CD95, TNF-R1, or TNF-R2. Of note, the down-regulation of TRAIL-R1 selectively occurred in cells coexpressing HHV-7 antigens that became resistant to TRAIL-mediated cytotoxicity. These data suggest that the TRAIL-mediated induction of T-cell death may represent an important immune evasion mechanism of HHV-7, helping the virus to persist in the host organism throughout its lifetime (Secchiero *et al.*, 2001a,b).

Disease consequences

Clinical features in hosts

Primary infection

Both HHV-6 and HHV-7 are ubiquitous viruses, and infection occurs during infancy. HHV-6B is a causative agent of ES (Yamanishi *et al.*, 1988). In most cases, ES is benign; it is associated with other symptoms including diarrhea, cough, lymph node swelling as bulging fontanel. ES is a common disease of infants all over the world. Typically, the infant gets sudden fever, which lasts for a few days, and a rash appears on the trunk and face and spreads to the lower extremities as the fever subsides. In adults, primary infections can cause mononucleosis like disease and hemophagocytic syndrome (Akashi *et al.*, 1993). HHV-7 can also cause ES and was isolated from PBMCs of a infant with typical ES (Tanaka *et al.*, 1994). The median age of children with primary HHV-7 infection was 26 months, which is significantly older than that of children with primary HHV-6 infection (median, 9 months).

Immune response during primary infection

The early immune response was studied by assessing interferon (IFN) and natural killer cell activity in 13 patients with ES associated with HHV-6 infection during the acute and convalescent phases (Takahashi *et al.*, 1992). Only IFN-alpha was significantly increased in the plasma of patients during the acute febrile phase compared with the convalescent period. The inhibitory effect of IFN-alpha and IFN-beta on HHV-6 replication was demonstrated in vitro with cord blood mononuclear cells. Natural killer cell activity was also significantly augmented in the acute phase, especially in the exanthem period, compared to in the convalescent phase. These results suggest that the enhanced IFN-alpha response and natural killer cell activity in the acute early phase of the disease may play pivotal roles in the recovery from ES.

Other symptoms associated with primary HHV-6 and 7 infection

The primary infection by HHV-6 and HHV-7 can cause a highly febrile illness in childhood, complicated by seizures (Torigoe *et al.*, 1996). Cases of possible HHV-6-associated encephalitis in young children have been reported (Asano *et al.*, 1992). Self-limited involvement of the central nervous system (CNS) is a relatively common complication of primary infection with HHV-6 in normal children. Liver dysfunction (Asano *et al.*, 1990; Tajiri *et al.*, 1990), idiopathic thrombocytopenic purpura (Yoshikawa *et al.*, 1993) are also associated with HHV-6 infection.

Reactivation of HHV-6 and its clinical symptoms

Since HHV-6 and HHV-7 establish latency following primary infection, they are important pathogens in immunocompromised hosts. Reactivation of HHV-6 and HHV-7 ocurres in patients after bone marrow transplantation,

solid organ transplantation such as liver, renal and heart transplantation, and AIDS.

Bone marrow transplantation (BMT)

Asymptomatic HHV-6 reactivations appear to be common following allogeneic BMT (Cone *et al.*, 1999), but HHV-6 reactivation associated with symptoms such as bone marrow suppression, encephalitis (Drobyski *et al.*, 1994; Tsujimura *et al.*, 1998; Rodrigues, 1999), pneumonitis (Cone *et al.*, 1993) and acute graft-versus-host disease (GVHD) in BMT recipients has also been recognized. Idiopathic marrow suppression occurred frequently in patients with concurrent HHV-6 viremia (Drobyski *et al.*, 1993). Infection with HHV-6 has been correlated with the development of skin rashes. HHV-6 DNA was detected in skin and/or rectal biopsies more frequently in allogeneic recipients with severe GVHD (92%) than in those with either moderate (55%) or mild GVHD (22%), suggesting that the presence of HHV-6 DNA in the skin or rectum may be a factor in determining GVHD severity (Appleton *et al.*, 1995).

Solid organ transplantation

HHV-6 infection after liver transplantation is associated with an immunosuppressive state (Singh *et al.*, 1995, 2002a,b). Acute febrile illness characterized by life-threatening thrombocytopenia, progressive encephalopathy and skin rash occurred with invasive HHV-6 infection in a liver transplant recipient (Singh *et al.*, 1995). Prolonged suppression of the HHV-6 memory response, but not overall T-helper cell function was documented and may play a role in the pathogenesis of HHV-6 infection in liver transplant recipients (Singh *et al.*, 2002a,b). The memory response to CMV after liver transplantation was significantly more robust than to HHV-6 (Singh *et al.*, 2002a,b). Griffiths et al. conducted a prospective study of the possible relationship of HHV-6 and HHV-7 infection with clinical symptoms after liver transplantation (Griffiths *et al.*, 1999). Although the virus load for HCMV was significantly greater than that for HHV-6 or HHV-7, HHV-6 and HHV-7 may be the cause of some episodes of hepatitis and pyrexia (Griffiths *et al.*, 1999). HHV-6 and CMV are significantly and independently associated with biopsy-proven graft rejection after liver transplantation (Griffiths *et al.*, 2000).

AIDS

Reactivation of HHV-6 has been reported to be possibly associated with interstitial pneumonia, encephalitis, and retinal disorder in AIDS patients, but specific clinical syndromes associated with reactivation are rare.

The other possible associated diseases

Multiple sclerosis (MS)

Several studies have suggested an association between HHV-6 and MS (Challoner *et al.*, 1995; Soldan *et al.*, 1997). However, negative results were also seen in other reports (Coates and Bell, 1998). There was no significant difference between MS patients and non-MS-patients by staining brains immunocytochemically (Coates and Bell, 1998). Therefore, whether HHV-6 contributes to MS pathogenesis in unclear.

Drug hypersensitivity

Drug-induced hypersensitivity syndrome is characterized by a severe, potentially fatal, multi organ hypersensitivity reaction that usually appears after prolonged exposure to certain drugs. Its delayed onset and clinical resemblance to infectious mononucleosis suggest that underlying viral infections may trigger and activate the disease in susceptible individuals receiving these drugs. Reactivation of HHV-6, possibly in concert with HHV-7 may contribute to the development of a severe drug-induced hypersensitivity syndrome (Suzuki *et al.*, 1998; Tohyama *et al.*, 1998).

HHV-6A, 6B, and 7: molecular basis of latency and reactivation

Kazuhiro Kondo[1] and Koichi Yamanishi[2]

[1]Department of Microbiology, The Jikei University School of Medicine, Tokyo, Japan
[2]Department of Microbiology, Osaka University Graduate School of Medicine, Japan

Introduction

The human β-herpesvirus subfamily consists of human cytomegalovirus (HCMV), human herpesvirus 6 (HHV-6), and human herpesvirus 7 (HHV-7). HHV-6 and HHV-7 belong to the Roseolovirus genus of the β-herpesviruses, and the HHV-6 species are divided into two variants: HHV-6A and HHV-6B. These viruses establish a lifelong infection of their host, reactivate frequently, and reactivated viruses are shed into the saliva (Jordan, 1983; Krueger *et al.*, 1990). Some evidence suggests that the molecular mechanisms of viral latency and reactivation are shared among these viruses. HHV-6B is reactivated from latency after coinfection with HHV-7 (Katsafanas *et al.*, 1996), and HCMV disease is frequently associated with concurrent HHV-6 and HHV-7 reactivation in transplant patients (Lautenschlager *et al.*, 2000; Mendez *et al.*, 2001)

The sites of these viruses during latency are not completely defined. For HHV-6B, viral DNA is detected predominantly in the peripheral blood monocytes/macrophages of seropositive healthy adults (Kondo *et al.*, 1991). Furthermore, primary cultured macrophages support latent HHV-6B infection, and viral reactivation is induced in them by treatment with 12-0-tetradecanoylphorbol-13-acetate (TPA) (Kondo *et al.*, 1991). HHV-6B also establishes latency in myeloid cell lines (Yasukawa *et al.*, 1999), and that HHV-6B is detectable in CD34 (+) peripheral blood progenitor cells (Luppi *et al.*, 1999). Therefore, HHV-6B appears to establish latency in hematopoietic progenitor cells.

HHV-6A is detectable in the peripheral blood of seropositive adults (Drobyski *et al.*, 1993); however, a cell population that might harbor latent HHV-6A has not been identified. Unlike HHV-6B, HHV-6A does not establish latency in cultured macrophages (K. Kondo *et al.*, unpublished data).

Some evidence suggests that latent HHV-6 infection in the brain may be involved in the pathology of certain neurological diseases, such as recurrent febrile figures (Hall *et al.*, 1994; Kimberlin and Whitley, 1998; Kondo *et al.*, 1993), multiple sclerosis (MS) (Challoner *et al.*, 1995; Sola *et al.*, 1993) and encephalitis (Caserta *et al.*, 1994). However, the site of HHV-6 latency in the brain has not been identified.

HHV-7 can be reactivated from latently infected peripheral blood mononuclear cells by T-cell activation, and it was first isolated from the purified CD4 (+) T-cells of a healthy individual; however, the range of cell types in which HHV-7 can establish true latency is not clear (Frenkel *et al.*, 1990; Katsafanas *et al.*, 1996). A variety of tissues contain infected cells at a late stage of HHV-7 infection, suggesting that HHV-7 might cause a persistent infection rather than a true latent infection (Kempf *et al.*, 1997a). Since HHV-6B can be recovered after the latently infected cells are superinfected with HHV-7, these viruses may use similar mechanisms to maintain their latency (Katsafanas *et al.*, 1996).

The investigation of latency-associated transcripts is important for understanding the molecular basis of herpesvirus persistence; however, the latency-associated transcripts of HHV-6A and HHV-7 have not yet been identified. In this chapter, we discuss the molecular mechanisms of HHV-6B latency and reactivation that are suggested based on its latency-associated transcripts (Kondo *et al.*, 2002, 2003b).

Latency-associated transcripts of HHV-6

Two types of HHV-6B latency-associated transcripts (H6LTs) have been identified in the gene locus of the immediate early (IE) 1/2 genes (Kondo *et al.*, 2002). They are detected only in latently infected cells in vitro and in vivo. Although they are encoded in the same direction as the immediate early (IE) 1/2 genes and share their

protein-coding region with IE1/2, their transcription start sites and exon(s) are different from those of the productive-phase transcripts (Mirandola *et al.*, 1998; Schiewe *et al.*, 1994) (Fig. 47.1). Type I H6LTs originate at the latent start site (LSS) 1, which is located 9.7 kilobases upstream of the IE1/2 start site, and Type II H6LTs originate at LSS2, which is located between exons 2 and 3 of IE1/2 (Fig. 47.1). In addition, novel short ORFs with latency-associated exons are encoded at the 5 proximal region of the H6LTs (ORF99, ORF142, and ORF145 in Fig. 47.1) (Kondo *et al.*, 2002).

The structures of the H6LTs are similar to those of HCMV latency-specific transcripts (Kondo and Mocarski, 1995; Kondo *et al.*, 1996); the latter encode IE1/IE2 ORFs, and short ORFs appear in the latency-specific exon. Furthermore, in the case of the HCMV latent transcripts, the translation of the IE1/IE2 protein is probably prevented by the existence of latency-specific ORFs upstream of the IE1/IE2 ORFs. Similarly, the HHV-6 IE1/IE2 protein is not detectable in latently infected macrophages. These findings suggest that viral replication of HCMV and HHV-6 may be suppressed at the point of translation of the major immediate early proteins during latency. The function of these upstream ORFs is discussed below.

Consistent with these findings, HHV-6 and HCMV exhibit similarities in their latent infections: (i) Both viruses can establish latency in cells of the monocyte/macrophage lineage (Kempf *et al.*, 1997b; Taylor-Wiedeman *et al.*, 1991); (ii) both viruses tend to persist in the latent state but are reactivated frequently, and the reactivated viruses are shed into the saliva (Jordan, 1983; Krueger *et al.*, 1990); (iii) methylation of the immediate-early gene locus is observed similarly in HHV-6 and HCMV, suggesting that the latent viral genome of these two viruses is locally methylated (Gompels *et al.*, 1995; Honess *et al.*, 1989); and (iv) viral reactivation of HHV-6 is associated with HCMV reactivation (DesJardin *et al.*, 1998; Humar *et al.*, 2000).

The HHV-6 late gene U94, which is a homologue of the adeno-associated virus type 2 (AAV-2) rep gene (Rapp *et al.*, 2000; Thomson *et al.*, 1991), has also been reported to be expressed during latency (Rotola *et al.*, 1998). Because other human β-herpesviruses, such as HCMV and human herpesvirus 7, do not encode homologues of U94 in their genomes (Chee *et al.*, 1990; Megaw *et al.*, 1998; Nicholas, 1996) the U94 gene may play some role that is specific to HHV-6. The Rep protein of AAV-2 is a site-specific endonuclease and helicase that is involved in site-specific integration of the viral genome into the host genome. Chromosomally integrated HHV-6 DNA has been observed in lymphomas (Luppi *et al.*, 1993), and the integrated viral DNA is reportedly transmitted stably in the germ line (Daibata *et al.*, 1998). These findings suggest that the U94 gene may relate to HHV-6 integration. However, no evidence has been reported so far to support this possibility.

Gene regulation of latency-associated transcripts

In the gene regulation of the latency-associated transcripts, a similarity between HHV-6 and HCMV has been observed using a recombinant HHV-6 (Kondo *et al.*, 2003b). The recombinant virus has an enhanced green fluorescent protein-puromycin gene cassette containing the CMV major immediate-early promoter (HCMV-MIEP) (Fig. 47.2). Neither viral replication in T-cells nor latency/reactivation in macrophages is impaired in this recombinant virus. During HHV-6 latency, however, no expression of EGFP driven by the HCMV-MIEP is detected (Fig. 47.3(A)).

Gene expression from the HCMV-MIEP was investigated using the 5'-rapid amplification of cDNA ends (RACE) method (Fig. 47.3(B)), which showed the EGFP mRNA is transcribed from the latent infection transcription start sites (LSSs) 1 and 2 of HCMV (Fig. 47.3(C)), which are used to express the latency-associated transcripts of HCMV (Kondo *et al.*, 1996). The finding that the HCMV MIEP showed a latency-associated activity in the context of HHV-6 latency suggested that the transcriptional control of HHV-6 latency may share some common mechanism with that of HCMV latency (Kondo *et al.*, 2003a).

First molecular event of HHV-6 reactivation

To identify the first molecular event of HHV-6 reactivation, the latent infection system of HHV-6 was used. In this system, macrophages are infected with HHV-6B and cultured for 4 weeks. At 4 weeks postinfection, macrophages show no signs of viral replication, such as viral protein expression or infectious virus production. Viral reactivation is induced by treatment with TPA (20 ng/ml) for 7 days (Kondo *et al.*, 1991).

At the early stage of the induction (3 and 5 days after the treatment with TPA), the proportion of cells that express the type I H6LTs significantly increases; however, transcription of productive-phase IE1/IE2 is not detected at days 0, 3, and 5 (Fig. 47.4). At this phase, IE1 protein is detectable in the cells without the production of infectious virus. Because productive-phase IE1 mRNAs are not detectable, the H6LTs, which contain the IE1 ORF (Fig. 47.1), are thought to be translated into IE1 protein at the first stage of viral reactivation. A similar molecular event has been

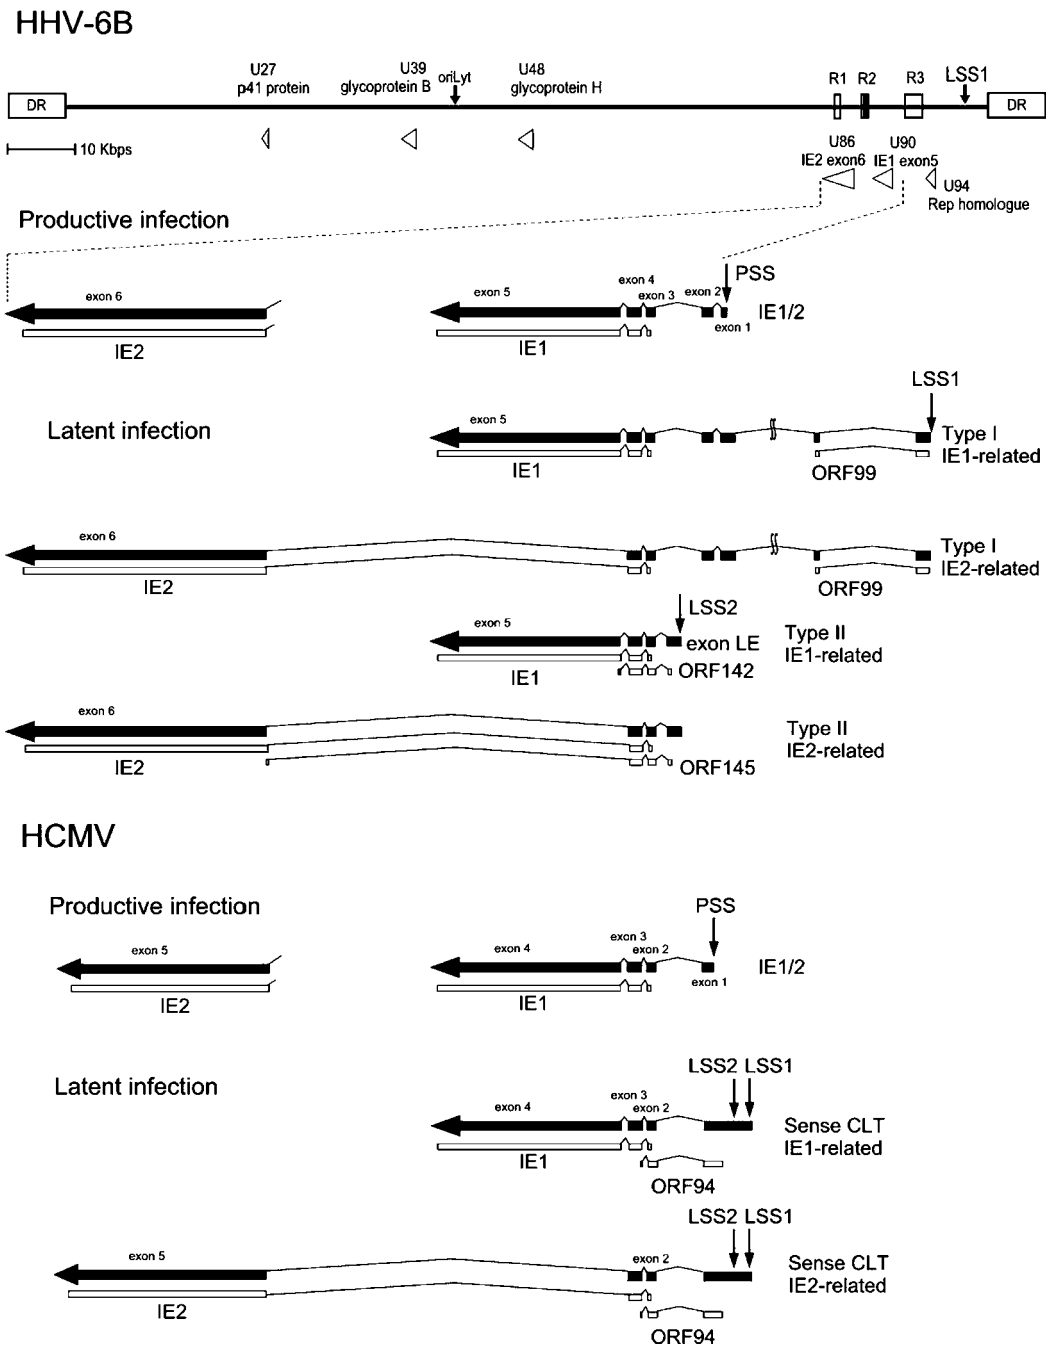

Fig. 47.1. Structures of the HHV-6 and HCMV latency-associated transcripts. Schematic drawings of the H6LT structures are shown. Productive-phase transcripts are also shown. The drawings of the mRNAs are in the same orientation relative to the viral genome. Thin lines represent introns; thick arrows represent exons. All exons and introns are drawn to scale. Latency-associated exons starting from latent start site (LSS) 1 and LSS2 are depicted. The position of the productive start site (PSS) is also shown. In HHV-6, exon 1 of the type I latent transcript is 138-bp longer than that of IE1/2. Two additional exons of the type I latent transcripts are located approximately 7.8 kb and 9.7 kb upstream from the PSS. ORFs of IE1, IE2, and putative latency-associated proteins ORF99, ORF142, and ORF145 are depicted. In HCMV, exon 1 of the cytomegalovirus latency-associated transcript (CLT) is longer than that of IE1/2. Latency-associated exons starting from LSS1 and LSS2 are depicted. ORFs of IE1, IE2, and putative latency-associated proteins ORF94 are depicted.

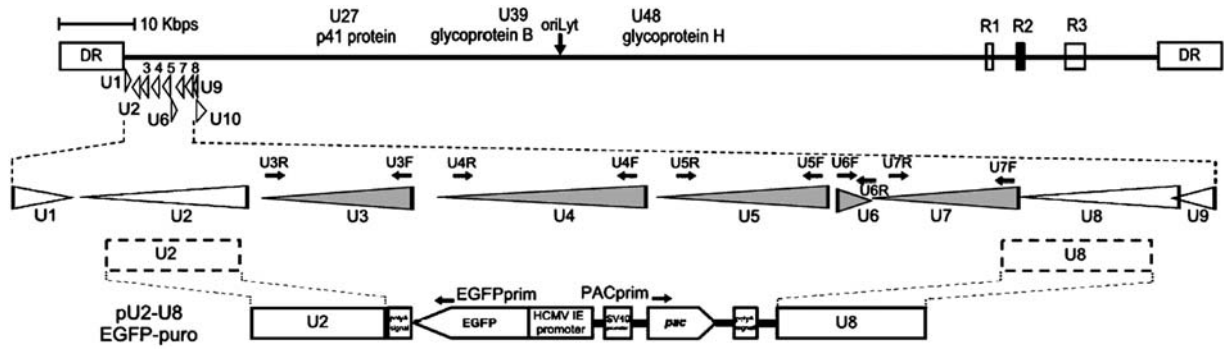

Fig. 47.2. Structure of recombinant HHV-6. At the top is a map of the HHV-6B genome, with the region U1-U9 expanded below. In the middle, shaded arrows show the U3-U7 ORFs that were replaced by the EGFP-puro cassette. The bottom diagram represents the EGFP-puro cassette pU2-U8 EGFP-puro. The open box represents the EGFP gene and human cytomegalovirus major immediate-early promoter. The puromycin-N-acetyl-transferase gene (*pac*) and SV40 early promoter are depicted.

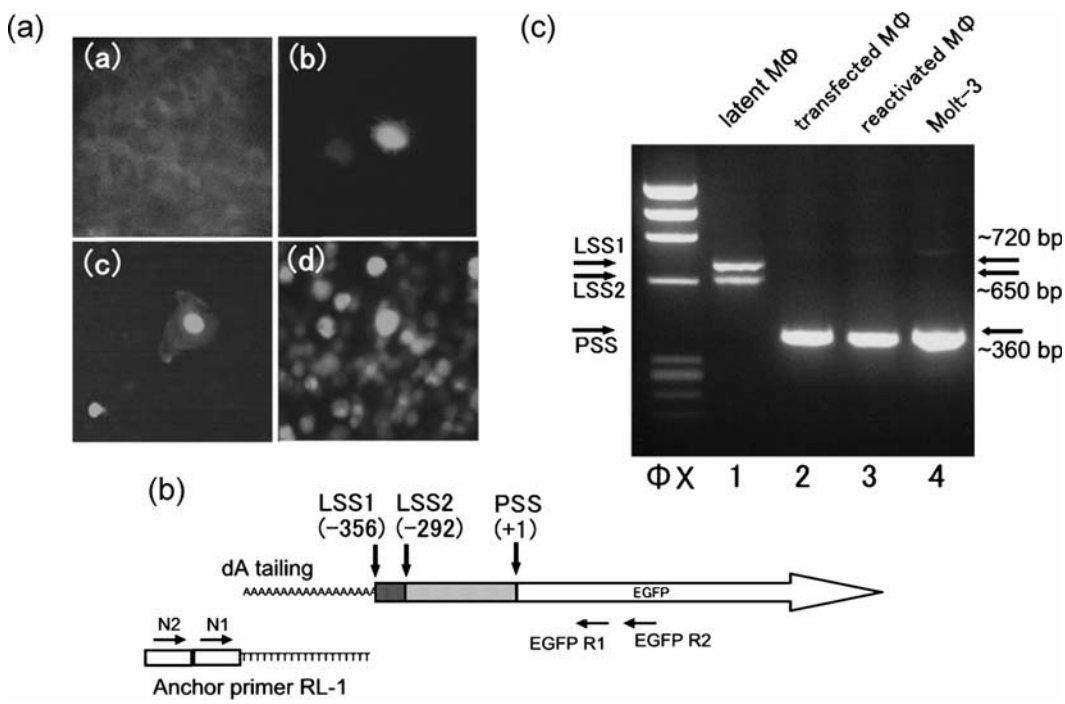

Fig. 47.3. (a) EGFP expression in various types of cells. Live cultured cells were observed under fluorescence. (a) Macrophages that were latently infected with EGFP-HHV-6; (b) latently infected macrophages that were(transfected with plasmid pU2-U8 EGFP-puro shown in Fig. 47.2(c) reactivation-induced macrophages; (d) productively infected Molt-3 cells.
(b) HCMV IE1/IE2 promoter and PCR primers. The EGFP gene and transcription start sites are drawn to scale. The productive infection transcription start site of IE1/IE2 mRNA (PSS indicated as +1) and two latent infection transcription start sites (LSS1 and LSS2: ref. 21) are shown. The locations of the PCR primers are depicted, and a schematic drawing shows the usage of the anchor primer RL-1.
(c) 5'-RACE amplification of the EGFP transcripts. RNA from latently infected macrophages (Mφ) (lane 1), latently infected macrophages that were transfected with plasmid pU2-U8 EGFP-puro shown in Fig. 47.2 (lane 2), reactivation-induced macrophages (lane 3), and productively infected Molt-3 cells (lane 4), was analyzed by the 5'-RACE method. The 5'-end of the transcript initiating at each of PSS (~360 bp), LSS1 (~720 bp), and/or LSS2 (~650 bp) was detected. Hae III-digested φX174 DNA fragments were used as size markers (φX).

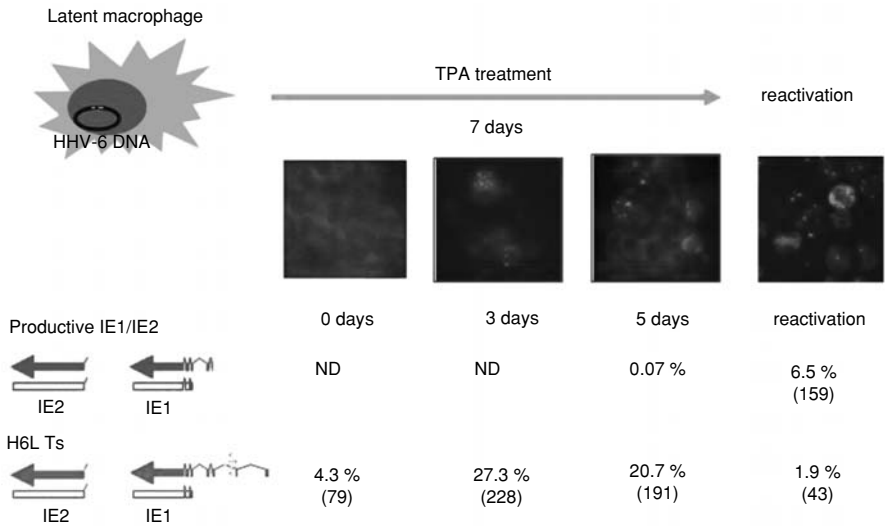

Fig. 47.4. mRNA and protein expression in latently infected macrophages. Latently infected macrophages were treated with TPA for 3, 5, and 7 days (reactivation). Cells were then stained with a mono-specific antibody against IE1. Percentage of H6LT-expressing cells during viral latency and reactivation. The percentages of H6LT-positive cells during viral reactivation were estimated. The copy number of each type of transcript in one H6LT-positive cell is shown in parentheses. The percentage of cells that showed the productive IE1/IE2 is also shown.

observed in transplant patients: approximately two-thirds of reactivation-positive patients express the type I H6LTs 1–3 weeks before the onset of HHV-6 reactivation (Kondo *et al.*, 2003b). This intermediate phase of viral reactivation is different from the complete reactivation phase that is characterized by the expression of productive-phase IE1/IE2 transcripts (Hummel *et al.*, 2001; Soderberg-Naucler *et al.*, 2001), and this intermediate phase seems to be relatively stable (Kondo *et al.*, 2003b).

Transfection of an IE1-expression vector into latent macrophages stimulates HHV-6 reactivation. As described above, H6LTs have latency-associated small ORFs upstream of the IE1/IE2 ORFs (Fig. 47.1). For certain other mRNAs that have small upstream ORFs (uORFs) that restrict the translation of the downstream ORFs, regulation at the translational and mRNA level is important for release from the uORF control (Hoffman *et al.*, 2001; Nomura *et al.*, 2001). An alteration in the regulation of translation as well as the increase in H6LTs might contribute to increased IE1 protein expression and viral reactivation (Kondo *et al.*, 2003b).

Since the reactivation of HHV-6 and HHV-7 is related to graft-versus-host disease in transplant recipients (Yoshikawa *et al.*, 2002) and to drug-induced hypersensitivity syndrome, these viruses might be reactivated by a strong generalized immunological response. However, the trigger that induces viral reactivation has not been identified.

Summary

In the Roseolovirus genus, some of the latency-associated transcripts of HHV-6B have been identified. Since HHV-6B and HCMV have some similarities in their latent transcripts and latent gene regulation, latency-associated transcripts of HHV-6 and HCMV might be involved in mechanizing that are common to β-herpesviruses latency. If so, similar transcripts may be identified in HHV-6A and HHV-7. Investigation of these transcripts should increase our understanding of the molecular bases of Roseolovirus latency and reactivation, about which little is known.

Introduction

The discoveries of *Human herpesvirus 6* variant A (HHV-6A), *Human herpesvirus 6* variant B (HHV-6B) and *Human herpesvirus 7* (HHV-7) followed the development of methods for activation and long-term culture of peripheral blood T lymphocytes. Based on their shared biological properties and nucleotide sequences, HHV-6A, HHV-6B, and HHV-7 are classified as members of the roseolovirus genus of the betaherpesvirus subfamily. HHV-6A and HHV-6B are very closely related, with most of their encoded proteins sharing greater than 90% amino acid sequence identity; most HHV-7 protein sequences share 30% to 60% amino acid sequence identity with their HHV-6 counterparts (for review, see Yamanishi *et al.*, 2007 and elsewhere in this volume). Roseoloviruses share many genetic and biologic properties with the more distantly related cytomegaloviruses. All of the roseoloviruses infect T lymphocytes in vivo and in vitro, cause similar damage to infected cells, and have overlapping but distinct disease spectra.

Primary infection with HHV-6B is the major cause of roseola infantum (also known as roseola, exanthem subitum, 3-day-fever, or sixth disease), a febrile rash illness common in early childhood (for review, see Braun *et al.*, 1997; Yamanishi *et al.*, 2007 and elsewhere in this volume); primary HHV-7 infections can also cause roseola, albeit less frequently. Roseoloviruses can affect the central nervous system; patients with HHV-6 primary infection sometimes develop seizures or convulsions. HHV-6A and HHV-6B infect various types of neural cells and in some studies have been associated with demyelinating diseases, including multiple sclerosis (MS) and progressive multifocal leukoencephalopathy (for review see Caserta *et al.*, 2001; Tyler, 2003). HHV-6 associated pneumonia, encephalitis, hepatitis, and hematopoietic stem cell suppression have been observed after stem cell transplantation, more often in association with HHV-6B than HHV-6A (for review see Clark and Griffiths, 2003; Ljungman, 2002; Yoshikawa, 2003). In addition, HHV-6 and HHV-7 immune suppressive activities may also indirectly contribute to fungal, bacterial, or human cytomegalovirus (HCMV) infections (Boeckh and Nichols, 2003; Ljungman, 2002). A role for HHV-6 infections in the progression of HIV disease has been debated (Braun *et al.*, 1997; Caserta *et al.*, 2001; Clark and Griffiths, 2003). Obviously, many questions remain about the pathogenesis of these viruses, with many of these questions revolving around their immunobiology.

Much of our consideration of these viruses, and justification for studying them, is based on their roles as human pathogens. This has led many experiments to be interpreted in the context of how the results might explain a pathogenic outcome that might be considered negative from the perspective of the infected host, that is, how the virus avoids the immune system and how it creates disease. Usually overlooked is the fact that, by far, the most common outcome of infection with these viruses is not disease, but a lifelong dynamic biological interaction between the virus and host that seldom manifests as disease. Thus, while the processes by which the virus evades or otherwise delays immune responses during the early stages of infection, avoids being eliminated during latency, and causes disease are important, it is worth considering that much of the immunobiology of these viruses is likely to involve a highly regulated process of *stimulation* of host responses. This stimulation must be balanced with the immunoevasive tactics to achieve a state that has almost been idealized by the roseoloviruses: healthy infected hosts capable of lifelong transmission.

Cell tropism

In this section we discuss the effects of HHV-6A, HHV-6B, and HHV-7 on cells of the hematopoietic lineage in the

context of the immunobiology of these viruses. HHV-6A and HHV-6B have apparently broader host ranges than does HHV-7; this is likely due to their choices of cellular receptors (for review, see Yamanishi *et al.*, 2007). The cellular receptor for both HHV-6A and HHV-6B is CD46, a member of the family of regulators of complement activation, which is expressed on all nucleated cells; co- or alternative receptors remain to be identified. CD4, the marker of helper T lymphocytes, is a critical component of a receptor for HHV-7. As for HSV, CMV, and HHV-8, heparan sulfate-like molecules mediate the initial HHV-7 attachment to target cell surfaces.

In vitro

All three viruses can productively infect primary CD4+ T-lymphocytes; activation of these cells is required for efficient viral replication (Table 48.1). HHV-6A, but not HHV-6B, can also efficiently infect primary CD4−/CD8+ T-lymphocytes (Table 48.1) (Grivel *et al.*, 2003; Lusso *et al.*, 1991a; Takahashi *et al.*, 1989). T-lymphocyte cell lines are widely used for cultivating these viruses: the HSB-2 and J JHAN cell lines for HHV-6A, Molt-3 and MT-4 cells for HHV-6B, and Sup-T1 cells for HHV-7. HHV-6A can also productively infect primary NK cells (Lusso *et al.*, 1993). Both HHV-6A and HHV-6B replicate in human peripheral blood monocyte-derived immature dendritic cells, and in intrathymic T progenitor cells in SCID-Hu mice (Asada *et al.*, 1999; Gobbi *et al.*, 1999; Kakimoto *et al.*, 2002; Kondo *et al.*, 1991). Although HHV-6A can productively infect terminally and incompletely differentiated cells, the virus can enter CD34+ hematopoietic stem cells and express virally encoded genes (including *U16–17* and *U91*), but not produce viral progeny (Isomura *et al.*, 2003; Knox and Carrigan, 1992; Luppi *et al.*, 1999). HHV-6 infection of fresh monocyte/macrophages does not produce virus either, although many of these cells contain viral DNA (Clark, 2000; Kondo *et al.*, 1991); as described below, these represent latent infections (Kondo *et al.*, 2002b).

In addition to cells of the immune system, HHV-6 also replicates in many other cells (summarized in Table 48.1; for review, see Braun *et al.*, 1997; Clark, 2000). Our understanding of the cell tropism of HHV-6A and HHV-6B is complicated by the fact that in the various studies, only one or the other variant was used and end points have differed, from expression of specific virally encoded mRNAs or proteins, to detection of infectious progeny.

In vitro, HHV-7 growth is restricted to activated cord blood lymphocytes, purified T lymphocytes, and CD4+ immature SupT1 cells (for review see Black and Pellett, 1999).

In vivo

An important recent observation based on improved methods for cultivation of monocytes/macrophages was that during the acute phase of primary infection, HHV-6B load (both DNA and virus titer) is nearly one log greater in these cells than in CD4+ T-lymphocytes (Kondo *et al.*, 2002a). This extends earlier work in which HHV-6B was frequently detected in CD4+ T lymphocytes obtained both during the acute phase of primary infection and from healthy adults. During the convalescent phase of primary infection and in healthy adults, HHV-6 DNA is detected primarily in monocytes/macrophages, and phorbol ester treatment induces lytic infection; this confirms that the virus establishes latency in these cells (Kondo *et al.*, 1991, 2002b). Another possible site of HHV-6B persistence is in epithelial cells that line tonsillar crypts (Roush *et al.*, 2001).

Because cells that harbor latent HHV-6 can be induced to the lytic state upon exposure to various activating stimuli, virus activity that could contribute to pathogenesis might be found in association with diverse immune stimulation events. For example, drug hypersensitivity syndrome (DHS), or drug rash with eosinophilia and systemic symptoms, presents as fever, rash, and internal organ lesions. A number of case reports have described active HHV-6 infection during DHS, but the exact role played by the virus is not clear. Two mechanisms of virus involvment have been hypothesized. Some drugs reduce B-cells and cause hypogammaglobulinemia, which has been hypothesized to trigger HHV-6 reactivation (Kano *et al.*, 2004). Alternatively, immune responses to some drugs may activate cells harboring HHV-6, leading to virus reactivation. Cases of DHS have also been linked to EBV and CMV (for review see Wong and Shear, 2004).

Little is known of the in vivo cellular distribution of HHV-6A. It has been infrequently detected in peripheral blood mononuclear cells (PBMC) and in over 50% of lungs (Cone *et al.*, 1996), but the type of cells it inhabits is not known.

HHV-6B and HHV-7 (but not HHV-6A) antigens are frequently detectable in salivary glands (Fox *et al.*, 1990; Kempf *et al.*, 1998), but only HHV-7 has been frequently cultured from saliva (Wyatt and Frenkel, 1992).

HHV-7 has been detected in over 50% of PBMC specimens collected from healthy individuals and from patients prior to bone marrow transplantation. In addition, HHV-7 antigens have been detected in a variety of lymphoid and non-lymphoid cells. The virus may establish latency

in CD4+ T-lymphocytes in vivo since it can be activated from PBMC by PHA or anti-CD3 stimulation.

Antigens

Roseolovirus genomes encode about 90 genes. The immunogenicity of individual viral proteins depends on their level of expression, novelty to the host, some aspects of their structure and/or composition, and degree of exposure to the immune system. In addition, adaptive immune effects can target different stages of the viral life cycle. For example, proteins expressed on the virion surface during lytic infection can be targets for neutralizing antibodies, and proteins needed intracellularly for virus replication can be targets of cytotoxic T-lymphocytes (CTL). Important questions relate to what antigens are presented to the immune system during latency, and how this contributes to regulation of latency and reactivation.

HHV-6A and HHV-6B antigens

Latent antigens

Latent transcription has been studied in greatest detail for HHV-6B. Kondo and co-workers identified four species of HHV-6B latency-associated transcripts (H6LTs) that are expressed from the ie1/ie2 region (Kondo *et al.*, 2002b). It remains to be determined whether the proteins encoded by these latent transcript open reading frames are expressed as protein and whether any portion of the immune response is directed at them. The HHV-6 latency transcripts are similar in structure to some CMV latency-associated transcripts that originate from both DNA strands in the ie1/ie2 region (Kondo *et al.*, 1996) and express proteins recognized by sera from healthy CMV seropositive individuals (Landini *et al.*, 2000).

Di Luca and colleagues have identified transcripts from *U94*, the HHV-6 homologue of adeno-associated virus type 2 rep gene, as the only HHV-6 transcripts detected in PBMC from healthy individuals (Rotola *et al.*, 1998). HHV-6 viral replication was blocked in cells transfected with plasmids encoding U94, further supporting a potential role for this gene during latency. Levels of anti-U94 antibodies in serum from healthy individuals are very low (Caselli *et al.*, 2002; Rapp *et al.*, 2000), but their prevalence and titers are higher in patients with MS (Caselli *et al.*, 2002).

Lytic antigens

Most of the virally encoded proteins are expressed during the lytic cycle of viral replication. Lytic antigens present in purified virion particles or infected cell lysates have been analyzed by immunoprecipitation and/or immunoblot analyses with serum from immunized mice or rabbits, or from infected humans.

HHV-6B virions are composed of more than 29 polypeptides that range in size from 30 to 280 kDa, of which about 25–30 peptides, including 8 glycoproteins, are recognized by positive human sera (Balachandran *et al.*, 1989; Shiraki *et al.*, 1989). Human immune responses to HHV-6B IE antigens were detected by immunofluorescence, although the

NT (not tested)

[a]Several other MAbs to the same protein were described simultaneously, but the relationships among them are not clear.

[b]Neutralization only in the presence of complement.

Many other HHV-6 MAbs have also been produced, but their viral protein targets are not as well characterized.

individual protein targets were not identified (Eizuru and Minamishima, 1992).

Monoclonal antibodies (MAbs)

HHV-6-specific MAbs have been used to identify specific virally-encoded proteins and their functions (Table 48.2). Some of the MAb are variant specific, while others recognize both variants; a few also react with HHV-7 antigens.

Targets of complement independent neutralization

Anti-gB antibodies neutralize HHV-6A and HHV-6B infection and cell fusion (Mori *et al.*, 2002; Santoro *et al.*, 1999; Takeda *et al.*, 1996). The epitope of one neutralizing gB MAb (87-Y-13) is in the vicinity of amino acid 134 (Takeda *et al.*, 1996).

As for other herpesviruses, HHV-6A gH and gL depend on each other for proper processing and expression on the cell surface or viral envelopes. The epitope for the OHV3 MAb to HHV-6B gH maps near amino acid 389 (Takeda *et al.*, 1997). MAb 2E4, 5E7 and 1D3, react with gH from both HHV-6 variants via conformational epitopes that include sequences between amino acids 145 to 230, plus residue 652 (Anderson *et al.*, 1996; Anderson and Gompels, 1999). A complex of gH, gL, and gQ appears to be required for binding to the

HHV-6 cellular receptor, CD46, since neither the gH-gL complex nor gQ expressed alone binds to CD46 (Mori *et al.*, 2003b; Santoro *et al.*, 2003). MAbs against gH neutralize viral infectivity and block formation of polykaryocytes (Balachandran *et al.*, 1989; Foa-Tomasi *et al.*, 1991; Qian *et al.*, 1993).

Targets for diagnosis

Essentially all individuals positive by immunofluorescence for HHV-6 mount a readily detectable serologic response to the U11 protein, which can be used as a marker of HHV-6 infection with respect to the other human herpesviruses, including HHV-7 (Black *et al.*, 1996b; Neipel *et al.*, 1992; Yamamoto *et al.*, 1990). HHV-6B *U11* (homologous to HCMV *UL32*/pp150) encodes a tegument protein of 101 kDa, which shares 81% amino acid identity with its HHV-6A counterpart (p100) (Neipel *et al.*, 1992; Pellett *et al.*, 1993). U11 antigenic epitopes recognized by human serum have been mapped to near its carboxyl-terminal region, which has only limited sequence similarity and no cross-reactivity with its HCMV counterpart (Neipel *et al.*, 1992). MAb C3108–103 against U11 is HHV-6B specific; the epitope is in the vicinity of amino acid 723 (Pellett *et al.*, 1993).

75% of HHV-6 positive sera reacted with the gH-gL complex expressed in transfected T-lymphocytes, but use of these glycoproteins for diagnosis has not been established (Liu *et al.*, 1993b). An ELISA based on a 110 kDa glycoprotein affinity-purified with monoclonal antibody 2E2 was reactive with 56% to 96% of human sera from different serum donor categories (Iyengar *et al.*, 1991); it is not known which HHV-6 glycoprotein this corresponds to. HHV-6 positive human sera that had high titer by IFA reacted very weakly with bacterially expressed HHV-6 major capsid protein (UL57) in immunoblots (Littler *et al.*, 1990).

Non-structural proteins are also targets of the humoral response. About 10%–30% of human sera react with HHV-6 p41, the DNA polymerase processivity factor encoded by gene *U27*; higher rates of both IgG and IgM reactivity to p41 have been observed in some patient populations (Patnaik *et al.*, 1995; Soldan *et al.*, 1997), but the basis for this is not understood. As mentioned above, responses to undefined HHV-6B IE antigens have been detected by immunofluorescence (Eizuru and Minamishima, 1992).

HHV-7 antigens

About 20 polypeptides were identified in HHV-7 infected cell lysates, seven of which were glycoproteins (Foa-Tomasi *et al.*, 1994; Nakagawa *et al.*, 1997). Two prominent HHV-7 antigens are encoded by the *U11* and *U14* genes, which encode the tegument proteins, pp89 and pp85, respectively (Stefan *et al.*, 1999).

HHV-7 monoclonal antibodies

Table 48.3 summarizes HHV-7 MAbs that have been generated in several laboratories.

Targets of complement independent neutralization

HHV-7 infection can be neutralized by MAb 5E12 and 5F12, which react with glycoproteins of 78 kDa and 85 kDa, respectively (Nakagawa *et al.*, 1997). HHV-7 gB (U39) and gQ (U100/gp65) bind to heparan sulfate-like molecules on cell surfaces, consistent with a role in viral entry; anti-gp65 antibodies block HHV-7 infectivity (Skrinkosky *et al.*, 2000).

Targets for diagnosis

Although serologic reactivity to intact HHV-7 gB is generally weak, an ELISA based on amino acids 129–152 of gB was both sensitive and specific (Franti *et al.*, 2002). U11/pp89 and U14/pp85 are sensitive and specific serologic markers for HHV-7 (Foa-Tomas: *et al.*, 1994; Stefan *et al.*, 1999), with pp85 being recognized somewhat more frequently than pp89. MAb 5E1, which recognizes U14 (pp85) is a useful marker for HHV-7 since it does not cross-react with HHV-6 antigens and can be used on formalin-fixed, paraffin-embedded tissue (Foa-Tomas: *et al.*, 1996; Kempf *et al.*, 1997).

Immunologic cross-reactivity

The most commonly used serologic methods (e.g., IFA and ELISA) cannot reliably differentiate HHV-6A from HHV-6B infections. There is limited antigenic cross-reactivity between the HHV-6 variants and HHV-7; under the conditions of most assays, this cross-reactivity can occasionally lead to false-positive determinations of an individual's serostatus.

HHV-6A and HHV-6B

A major criterion for defining and distinguishing the HHV-6 variants is their patterns of reactivity with panels of variant-specific MAbs (Table 48.2). Most MAbs generated against one HHV-6 variant react with the other, but some are variant-specific. Similarly, more than 90% of HHV-6-specific CD4+ T lymphocyte clones react with both HHV-6A and HHV-6B (Yasukawa *et al.*, 1993) (the target antigens have not been identified). This is consistent with the extensive amino acid sequence conservation between the viruses (Dominguez *et al.*, 1999). By IFA, 95% of 234 healthy adult Malaysians had similar IgG titers to HHV-6A and HHV-6B (Yadav *et al.*, 1991), as did 80% of 136 healthy adults in the United States (Chandran *et al.*, 1992). The titer differences in some individuals may reflect different responses to unique antigens of either virus, differential responses to common antigens of both viruses, or the nature of primary infection or reactivation. A reliable variant-specific serologic test is needed to better understand the biology of the two variants.

HHV-6 and HHV-7

There is some antigenic cross-reactivity between HHV-6 and HHV-7. Hyperimmune mouse sera against one virus reacts to the other (Black and Pellett, 1999). Adsorption of serum with either HHV-6A or HHV-6B antigens removes about 20–40% of HHV-7 IgG reactivity. Similarly, about 30% of CD4+ T lymphocyte clones that react with both HHV-6A and HHV-6B react with HHV-7 (Yasukawa, *et al.*, 1993), consistent with the level of their amino acid sequence conservation (Dominguez *et al.*, 1999). Some weak or uncertain cross-reactions have also been observed for some MAbs against HHV-6 or HHV-7 (Tables 48.2 and 48.3).

This limited cross-reactivity does not generally lead to HHV-6 seroconversion in individuals naïve for HHV-6 at the time of their primary HHV-7 infection. Anti-HHV-6 IgG titers increased in about 60% of individuals with prior HHV-6 infection, suggesting possible reactivation of HHV-6 by HHV-7, and/or restimulation of reactivity with shared antigens (Caserta *et al.*, 1998; Hall *et al.*, 1994; Huang *et al.*, 1997; Tanaka *et al.*, 1994; Torigoe *et al.*, 1995). Similarly, primary HHV-6 infection does not lead to HHV-7 seroconversion, and HHV-7 primary infection can occur in the presence of high titers of HHV-6 antibodies (Hidaka *et al.*, 1994; Wyatt *et al.*, 1991). However, in HHV-6 naïve individuals, primary HHV-7 infection can transiently induce cross-reactive HHV-6 IgM (213) (Fig. 48.1). In one of two patients who had HHV-7 infections that preceded HHV-6 infection, HHV-7 IgG levels rose slightly after HHV-6 infection (Yoshida *et al.*, 2002b). Simultaneous high-titer increases in HHV-6 and HHV-7 antibody titers in young children are most likely due to dual primary infection rather than cross-reactivity (Ward *et al.*, 2001). Ward and colleagues provide evidence that IFA titers above 32 can be accepted as true positives (Ward *et al.*, 2002).

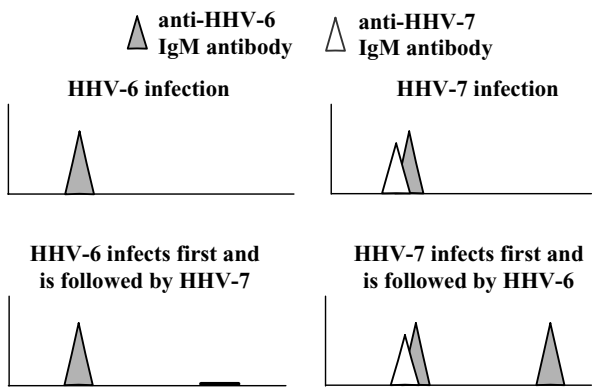

Fig. 48.1. Summary of the IgM cross-reactive responses between HHV-6 and HHV-7. From Yoshida *et al.* (2002a), courtesy of Dr. Mariko Yoshida, with permission from the American Society of Microbiology.

Roseoloviruses and other viruses

About 4% of HHV-6 specific CD4+ T lymphocyte clones responded to HCMV (Yasukawa *et al.*, 1993). HCMV vaccination or natural infection led to 4-fold or greater titer rises to HHV-6, with most of the cross reactivity in this assay being traced to the conserved gB proteins of the two viruses (Adler *et al.*, 1993). Primary infections with HHV-6 or HHV-7 can be clinically misdiagnosed as measles or rubella in children aged younger than 5 years (Black *et al.*, 1996a; Oliveira *et al.*, 2003). To complicate the matter, confirmed infections of measles, HCMV, or EBV have been associated with induction of HHV-6 reactive IgM and significant rises in HHV-6 specific IgG levels, possibly due to reactivation of HHV-6 by the other virus or a more general non-specific immune activation (LaCroix *et al.*, 2000; Linde *et al.*, 1988; Suga *et al.*, 1992a). The cross-reactivity between HCMV and HHV-7 does not confound the results of most serology assays (Black *et al.*, 1996b).

Immune response

In spite of the clear ability of these viruses to infect and kill a variety of immune effector cells both in vitro and in vivo, and to trigger a variety of mechanisms that can be seen as immunoevasive (described below), an immune response sufficient to control the infection develops rapidly following primary HHV-6 and HHV-7 infections. Thus, the likely transient and localized immune evasion or immune manipulation tactics are sufficient to allow establishment of the viral infection (including latency), but in the end have no discernable adverse long-term effects in otherwise healthy hosts. In this section, we describe immunologic outcomes such as antibody titers. In the following section we discuss regulation of these responses.

Immune response after primary infection

Innate immune response

HHV-6 and HHV-7 infections induce production of immune-regulatory chemokines and cytokines (Table 48.4). Among them, regulated upon activation, normal T expressed and secreted (RANTES), a proinflammatory β-chemokine, is known for inducing local responses by selectively attracting monocytes (the target for HHV-6 latency) and lymphocytes (a vehicle for virus spread). Interleukin-1β (IL-1β) enhances inflammatory and interferon-γ (IFN-γ) responses, and is needed for IL-6-dependent, B-lymphocyte immune responses. Both IFN-α and IFN-β inhibit HHV-6 replication in vitro (Takahashi *et al.*, 1992). However, tumor necrosis factor-α (TNF-α), normally an antiviral cytokine, may enhance release of extracellular HHV-6 by stimulating monocyte differentiation (Arena *et al.*, 1997).

HHV-6 and HHV-7 infections also enhance NK cell activity, possibly by inducing IL-15 production, which stimulates the proliferation of T lymphocytes and NK cells (Atedzoe *et al.*, 1997; Flamand *et al.*, 1996). NK cells are very effective in killing autologous HHV-6 infected cells, which may play a major role in controlling viral infection (Malnati *et al.*, 1993).

Antibody response

Given their high seroprevalence in adults, almost all infants have maternal antibodies against these viruses at birth. Antibody titers decline sharply from birth to a nadir at 3 to 6 months of age (Fig. 48.2). HHV-6 seroprevalence increases sharply from 6 months after birth into the second year, when the seroprevalence begins to approximate that in healthy adults; this is the period in which almost all HHV-6B primary infections occur (for review see Braun *et al.*, 1997; Yamanishi *et al.*, 2007). HHV-7 primary infection most often occurs after HHV-6, with seroprevalence not accumulating to adult levels until the early teens (Yamanishi *et al.*, 2007).

IgM antibodies

IgM antibodies develop 5 to 7 days after the onset of clinical symptoms, reach their highest titers in 2–3 weeks and disappear by 2 months post infection. At least one target of the IgM response is the 101K antigen encoded by

[a]HHV-6B has a similar effect.
[b]HHV-7 has a similar effect.

HHV-6 *U11* (LaCroix *et al.*, 2000). An HHV-6-specific neutralizing IgM response develops after HHV-6 primary infection, regardless of whether it happens before or after HHV-7 infection. In contrast, while HHV-7 primary infection of HHV-6-naïve individuals induces IgM antibodies that can neutralize both HHV-6 and HHV-7, there is no IgM response to either virus when HHV-7 infection follows HHV-6 (Yoshida *et al.*, 2002b) (Fig. 48.1).

IgG antibodies

HHV-6 IgG antibodies usually appear within 10 days to two weeks after the onset of clinical symptoms, increase in avidity over time, and remain at measurable levels for many years (Braun *et al.*, 1997). The initial IgG response is of low avidity. Antibody avidity increases with time, making it a useful marker for identifying recent infections and for discriminating primary infections from reactivations (Ward *et al.*, 1993, 2001). HHV-6-specific IgG4 was detected in all bone marrow transplant recipients whose HHV-6 IgG antibody titers increased by at least 8-fold, whereas in pregnant women and in children less than three years of age, HHV-6-specific IgG4 was never detected (Carricart *et al.*, 2004). The possibility that IgG4 antibodies may be a marker for HHV-6 reactivation warrants further study.

Neutralizing antibodies

HHV-6 neutralizing antibodies are present at the time of birth and during and after the rash period of primary infection, but not during the febrile stage (Asada *et al.*, 1989; Suga *et al.*, 1990; Yoshida *et al.*, 2002b), suggesting that maternal antibodies have the capacity to block viral infection. Additional mechanisms may also contribute to the

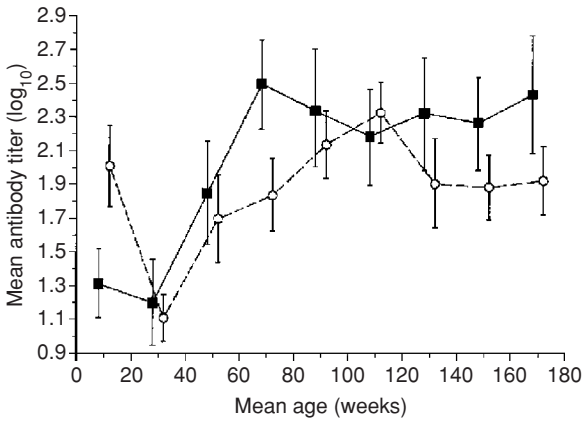

Fig. 48.2. Comparison of the change with age of the geometric mean titers of IgG antibodies to HHV-6 and HHV-7 in children. Geometric mean titers for HHV-6 (black squares) and HHV-7 (open circles) were calculated for 20-week age intervals from birth to 179 weeks. When the titer was <10 it was given a nominal value of 5. Bars represent the mean ± twice the standard error of the mean. The numbers of serum samples tested in each group were as follows: 0 to 19 weeks, 26; 20 to 39 weeks, 36; 40 to 59 weeks, 36; 60 to 79 weeks, 35; 80 to 99 weeks, 31; 100 to 119 weeks, 35; 120 to 139 weeks, 27; 140 to 159 weeks, 24; 160 to 179 weeks, 19. From Ward *et al.* (2001), courtesy of Dr. Katherine Ward, with permission from the American Society of Microbiology.

resistance to infection early in life, because antibody alone is seldom sufficient to prevent infection, as exemplified by the incomplete protection afforded by transfer of high-titered anti-CMV immunoglobulins to organ transplant recipients. Thus, in immunocompetent infants in the early months after birth, protection from HHV-6 infection and disease is the result of a combination of maternally derived antibodies (initially transplacental, then via mother's milk, some of which are neutralizing), and the child's innate immune functions.

Despite the close genetic and antigenic relationship between HHV-6B and HHV-7, their complement-independent IgG neutralizing antibodies, as detected in vitro, do not cross react with each other; this is a reflection of the differences in the viral ligands that interact with the receptors (CD46 and CD4, respectively) used by these viruses to infect target cells (Lusso *et al.*, 1994; Santoro *et al.*, 1999; Yoshida *et al.*, 2002a, b). This does not exclude the possibility that antibodies against one virus provide some protection against the others in vivo. In contrast to neutralizing IgG, HHV-7 specific IgM antibodies neutralize HHV-6 infection (Yoshida *et al.*, 2002b), but the targets have not been identified.

T lymphocyte response

HCMV nucleocapsid proteins and tegument proteins are better than the membrane glycoproteins at inducing T lymphocyte proliferation (Ljungman *et al.*, 1985). Similarly, neither HHV-6A nor HHV-6B membrane glycoproteins induce T-lymphocyte proliferation in healthy adults; instead, these antigens inhibit T-lymphocyte proliferation to mitogens or antigens (Horvat *et al.*, 1993). Antigen preparations mainly composed of the nucleocapsid proteins and tegument proteins of HHV-6A and HHV-6B induce T-lymphocyte proliferation responses of healthy seropositive children and adults (Soldan *et al.*, 2000; Yakushijin *et al.*, 1991); the response peaks later after primary HHV-6 infection (4 weeks) than for other herpesvirus infections (1 to 2 weeks) (Kumagai *et al.*, 2006). More HHV-6 seropositive, healthy adults responded to HHV-6B antigen than that to HHV-6A antigen.

As with VZV, both HLA dependent and independent cytotoxicity have been observed for HHV-6-specific CD4+ T-lymphocyte clones, suggesting heterogeneous functions of CD4+ T-lymphocytes (Arvin *et al.*, 1991; Yakushijin *et al.*, 1992).

CTLs are a product of the Th1 pathway, which is regulated in part by IL-12. HHV-6 virions are sufficient to inhibit the ability of macrophages to produce IL-12 in response to IFN-gamma or lipopolysaccharide (Smith *et al.*, 2003). Although a CTL response eventually develops, it is easy to imagine that a short deferral in the development of the response helps the infection get established.

Possible role of reactivation

About 5% of healthy adults have anti-HHV-6 IgM antibodies, suggesting periodic reactivation in the absence of clinical sequelae (Balachandra *et al.*, 1989; Ohashi *et al.*, 2002; Suga *et al.*, 1992b). During pregnancy, HHV-6 reactivation, as identified by HHV-6 DNAemia, was associated with higher IgG titers, but had no effect on IgM levels (Dahl *et al.*, 1999).

Immune responses in immunocompromised hosts

Allogeneic bone marrow and blood stem cell transplantation

HHV-6 activity is very common after blood stem cell transplantation (SCT), with HHV-6B being more commonly detected than HHV-6A. HHV-7 activity is not detected as often in PBMC, possibly due to the low CD4+ cell counts after transplantation (Boutolleau *et al.*, 2003; Miyoshi *et al.*, 2001; Wang *et al.*, 1996). Because of their high prevalences, most of the post-transplant activity of these viruses is due to either reactivation or reinfection; primary infections are

rare. It is difficult to interpret serological data in these patients because they are often severely immune suppressed and exposed to many blood products. HHV-6 antibody titers do increase (including neutralizing antibodies), but often this is not linked to the presence of viral DNAemia or infectious virus in bodily fluids (Molden *et al.*, 1997; Wilborn *et al.*, 1994; Yoshikawa *et al.*, 1991). Geometric mean antibody titers were significantly higher in recipients without HHV-6 viremia than in those with viremia (Yoshikawa *et al.*, 2002), consistent with a stronger immune response being linked to reduced virus activity. Anti-HHV-7 antibody titer increased in an allogeneic SCT patient with HHV-7-associated meningitis (Yoshikawa *et al.*, 2003b).

After SCT, reconstitution of antigen specific T-lymphocyte responses to HSV, VZV, and CMV do not correlate with the recovery of lymphocyte population levels, nor with the ability to proliferate in response to mitogens. Specific responses develop only after reactivation, reinfection, or vaccination. After allogeneic SCT, more patients showed higher levels of HHV-6B- than HHV-6A-specific T-lymphocyte proliferation responses, in agreement with HHV-6B infection being more common in this setting (Wang *et al.*, 1999). In addition, HHV-6 DNAemia was associated with a lack of HHV-6 specific T lymphocyte responses, regardless of the presence of HHV-6-associated disease, again suggesting a role of immunity in regulating viral activity.

Solid organ transplantation

As with allogeneic SCT, HHV-6B activity is common in the early stages after liver transplantation. Both reactivation and primary infection lead to HHV-6 specific IgM and IgG responses after liver transplantation, but these responses are frequently transient, the instability of the response possibly being due to a lingering immune deficit or other clinical issue (DesJardin *et al.*, 1998; Yoshikawa *et al.*, 2000). Fatal primary HHV-6A infection has been reported in the face of IgM and IgG responses after renal transplantation (Rossi *et al.*, 2001).

HHV-6 specific T-helper lymphocyte proliferation was suppressed after liver transplantation and recovered slower than for HCMV (Singh *et al.*, 2002a). Similar to patients after SCT, HHV-6 specific T lymphocyte responses are weaker in patients with HHV-6 viremia. Nonetheless, responses were normal to the T lymphocyte mitogen, Concanavalin A, suggesting a more specific deficit. Studies on transplanted livers showed that HHV-6 increases vascular expression of adhesion molecules like ICAM-1 and VCAM-1, thus inducing lymphocyte infiltration that may contribute to graft rejection (Lautenschlager *et al.*, 2002).

Multiple sclerosis (MS)

MS is considered to be an autoimmune disease of the central nervous system, in which myelin is destroyed by autoreactive T cells that target certain myelin-specific proteins. The trigger for this activity is not known, but several viruses have been suggested as potential causes or contributors, among them, HHV-6A and HHV-6B. As reviewed in detail elsewhere, experimental approaches to questions of HHV-6 involvement in MS have included (i) PCR analyses of blood, cerebrospinal fluid, and brain tissues, (ii) testing for the presence of viral antigens by immunohistochemistry, (iii) and virus-specific immune responses in blood and intrathecally. The results have been mixed and are difficult to interpret. Thus several studies have noted elevated frequencies of detecting HHV-6 infection in MS patients and in affected brains relative to other neurologic diseases or healthy controls, while others have found no differences. One tenet relating to proof of etiology is consistency of association, which certainly has not been attained with respect to observations among the several groups that have studied this problem. Nonetheless, there has been sufficient consistency of overlapping and complementary data from multiple studies from some research groups and between several groups, to preclude dismissing the possible association. Importantly, studies that have looked the closest at the affected tissues have found some of the strongest associations (Cermelli *et al.*, 2003; Goodman *et al.*, 2003). Thus, we consider this an important area for continued research.

There are several connections to immunobiology. HHV-6 is a constitutive inhabitant of brains, and MS is an inflammatory disease. It is not a stretch to imagine that the immunomodulatory activities of the virus might affect the biology of T-cells in the brain. It is also possible that unusual activity of the virus in the course of the disease might manifest itself in measurable changes in various immune markers. The virus could thus play roles in either as the direct causative agent of the disease or by modulating the course of pre-existing disease. Some recent results consistent with these possibilities are as follows.

(i) In a study that found an association between HHV-6 activity and MS activity, serum IL-12 levels were elevated during the periods of simultaneous disease and virus activity (Chapenko *et al.*, 2003). IL-12 regulates some cytokines and development of Th1 responses. Perplexing in this regard is the contemporaneously published report that HHV-6A markedly suppresses IL-12 expression in macrophages (Smith *et al.*, 2003), the discrepancy possibly being rooted in the differences between the complex in vivo situation and the in vitro purified cell population.

(ii) Cell culture supernatants from HHV-6A- and HHV-6B-infected SupT1 cells induced a non-apoptotic death in

cultured primary dendrocytes but not in primary astrocytes (Kong *et al.*, 2003).

(iii) MS patients had somewhat elevated rates of generating T cell lines that were cross-reactive between HHV-6 antigens and myelin basic protein (Cirone *et al.*, 2002). Possibly related to this, a seven amino acid segment of myelin basic protein is identical to a sequence encoded by *U24* (a protein of unknown function) of both HHV-6A and HHV-6B. This sequence is a more frequent target of cross-reactive CD4+ cytotoxic T cells in MS patients than in controls (Tejada-Simon *et al.*, 2003).

(iv) In a study in which HHV-6 DNA was detected more frequently in serum and cerebrospinal fluid of MS patients than controls, MS patients had lower frequencies of T cells that recognize the major HHV-6 antigen (101K or p100, encoded by *U11*), slightly lower IgG titers against 101K, and markedly elevated serum IgM to the same protein (Tejada-Simon *et al.*, 2002). When infected cell lysates were used as the antigens, HHV-6A specific T-lymphocyte proliferation response were detected more often in patients with relapsing-remitting MS than in the healthy controls, with no differences in the frequency of HHV-6B or HHV-7 specific responses (Soldan *et al.*, 2000). Again, these differences were not found in patients who were mainly in the chronic progressive stage (Enbom *et al.*, 1999).

(v) Results of comparisons of serologic responses to the complex array of HHV-6 antigens present in infected cells by immunofluorescence assays have shown little difference between MS cases and controls (Ablashi *et al.*, 1998, 2000; Enbom *et al.*, 1999). Interestingly, differences have consistently been seen in some studies when defined antigens (IgG to U94/rep and IgM to p41/38) have been used (Caselli *et al.*, 2002; Soldan *et al.*, 1997). IgG antibodies against HHV-6 are often detected in cerebral spinal fluids from MS patients, but it is still unclear whether this reflects real viral activity or non-specific immunoactivation (Ablashi *et al.*, 1998; Enbom *et al.*, 1997). No differences were found in HHV-6-specific IgG subclasses in sera from MS patients compared with healthy controls (Enbom *et al.*, 1999).

In sum, the accumulated diverse results suggest that in at least some MS patients, disease activity and progression are somehow connected to HHV-6 activity and immunobiology; the question remains of whether the virus contributes to the disease or is a fuzzy marker for some aspect of the disease process.

Virally mediated immune modulation

HHV-6 affects almost all the components of the immune system, including both innate and adaptive immune functions. Having discussed some of the end points of these functions, we will now discuss the underlying mechanisms. For heuristic reasons, we will trace these effects outward from the effects on infected cells, to the induction and expression of viral and cellular cytokines, and then the responses triggered by these molecules.

Cell surface markers

As summarized in Tables 48.4, 48.5, and 48.6, the roseoloviruses each trigger mechanisms that result in changes in expression of cell surface markers and other immunomodulators, leading to profound effects on immune-related cell functions and the organismal response to the infection.

Effects on specific cell types

NK cells

HHV-6 infects and kills NK cell clones cultured in vitro. In addition, HHV-6 also induces NK cells to express CD4, the helper T lymphocyte surface marker and the major cellular receptor for HIV-1, which can render NK cells permissive to HIV infection; this has led to speculation that HHV-6 not only causes immune suppression but also contributes to AIDS progression (Emery *et al.*, 1999; Lusso *et al.*, 1993). However, HHV-6 infection of PBMC, which include a variety of cell types, results in enhanced NK activity and NK-mediated killing of HHV-6 infected cells (Flamand *et al.*, 1996; Malnati *et al.*, 1993). Thus, virus-mediated killing of NK cells and NK-mediated killing of virus infected cells is regulated in part by the other cells in the system.

Stem cells

Although none of the roseoloviruses kill blood stem cells, they do affect their growth (Table 48.6). In vitro, HHV-7 inhibits the growth of granulocytic/erythroid/monocyte/megakaryocytic progenitors, but not their more differentiated progeny. In contrast, HHV-6 has less effect on the progenitors, but inhibits the growth of the more differentiated progeny (Isomura *et al.*, 1997, 2003; Knox and Carrigan, 1992; Mirandola *et al.*, 2000). Exposure of bone marrow precursors to HHV-6 inhibited their ability to respond to growth factors such as granulocyte-macrophage colony-stimulating factor and interleukin-3, and also reduced the outgrowth of macrophages from bone marrow (Burd and Carrigan, 1993). This may be due to induction of IFN-α by HHV-6 (Knox and Carrigan, 1992). HHV-6 also infects monocytes/macrophages, although these cells are not as prone to develop the typical CPE seen in CD4+ T-cells after HHV-6 infection. Nonetheless, the virus does cause dysfunction of blood monocytes and blocks their differentiation to macrophages (Burd *et al.*,

1993; Burd and Carrigan, 1993). There is disagreement as to whether HHV-6A or HHV-6B is the more potent inhibitor of hematopoietic stem cell growth (Carrigan, 1995; Isomura *et al.*, 1997, 2003). The mechanism for HHV-7 inhibition of blood stem cells is unknown.

T-lymphocytes

HHV-6 and HHV-7 infected T lymphocytes form balloon-like cells. These cells are usually mono- or binucleated and short-lived (Lusso *et al.*, 1991b). HHV-6A can induce cell fusion via its cellular receptor (CD46) in the absence of viral protein synthesis (Mori *et al.*, 2002; Santoro *et al.*, 1999). HHV-7 infection also induces formation of giant, multinucleated CD4+ T-cells, possibly due to polyploidization of infected cells because of interrupted cell cycles (Secchiero *et al.*, 1997, 1998a). HHV-6B infection shuts off host cell DNA synthesis, but stimulates host cell protein synthesis, which possibly also interferes with the cell cycle and creates a proper intracellular milieu for viral replication (Black *et al.*, 1992; Øster *et al.*, 2005). In SCID-Hu thymus/liver mice, HHV-6A and HHV-6B infection affects almost all of the major lymphoid cellular

Table 48.6. Effects of HHV-6 or HHV-7 infection on immune-related cell functions

Function	Cells	Effect	Virus tested	References
Growth	CD34+ stem cells	R	HHV-6B	(Isomura *et al.*, 2003)
	macrophage	R	HHV-6B	(Burd *et al.*, 1993)
Respiratory burst capacity	monocytes	R	HHV-6A, HHV-6B	(Burd and Carrigan, 1993)
Migration	PHA + lymphocytes	R	HHV-7	(Secchiero *et al.*, 1998c)
Survival				
SCID-hu Thy/Liv mice	thymocytes	R	HHV-6A, HHV-6B	(Gobbi *et al.*, 1999)
tonsilar culture	CD4+ lymphocytes	R	HHV-6A, HHV-6B	(Grivel *et al.*, 2003)
	CD8+ lymphocytes	R	HHV-6A, HHV-6B	(Grivel *et al.*, 2003)
Apoptosis				
in vitro	JJHAN cells	15%	HHV-6A, HHV-6B	(Inoue *et al.*, 1997)
	CBL + PHA	0%	HHV-6B	(Ichimi *et al.*, 1999)
	CBL + PHA + IL2	51%	HHV-6B	(Ichimi *et al.*, 1999)
in vivo (ES patients)	CD4+ T lymphocytes	31%		(Takahashi *et al.*, 1989; Yasukawa *et al.*, 1998)
	CD8+ T lymphocytes	11%		(Yasukawa *et al.*, 1998)

R (reduced)

subsets including CD4 and/or CD8 positive T-cells, but most severely depletes CD4 negative and CD8 negative intrathymic T-progenitor cells (Gobbi *et al.*, 1999). HHV-6A replicates in and kills CD4+ and CD8+ T-cells with almost equal efficiency, while HHV-6B predominantly replicates in and depletes CD4+ T-cells (Grivel *et al.*, 2003).

HHV-6A and HHV-6B induce a dramatic and generalized down modulation of the CD46 molecule in both infected and non-infected cells, while CD3 was downmodulated only in infected lymphocytes, with some differences in this activity between HHV-6A and HHV-6B (Furukawa *et al.*, 1994; Grivel *et al.*, 2003). In contrast, CD4 is upregulated after HHV-6A and HHV-6B infection, possibly via direct activation of the CD4 promoter in infected cells (Flamand *et al.*, 1998; Grivel *et al.*, 2003). HHV-6A showed a stronger effect on CD3 expression in CD4+ lymphocytes than HHV-6B, but the two viruses had similar effects on lymphoid tissues cultured ex vitro (Furukawa *et al.*, 1994; Grivel *et al.*, 2003). HHV-7 uses CD4 as its cellular receptor; CD4 but not CD3 expression is reduced after HHV-7 infection (Furukawa *et al.*, 1994; Lusso *et al.*, 1994; Secchiero *et al.*, 1998c). Down modulation of CD46 may lead to spontaneous complement activation and cytotoxicity of the affected cells. CD3 is an important component of the T-cell antigen receptor and is critical for transduction of the T-cell activation signal upon interaction with the antigen peptide-HLA complex. HHV-6 or HHV-7 infected lymphocytes lose their ability to proliferate in response to anti-CD3 antibodies and to kill virus infected cells (Furukawa *et al.*, 1994).

T-cell apoptosis

Like other herpesviruses, HHV-6 and HHV-7 lytic infections lead to host cell death via necrotic lysis (Inoue *et al.*, 1997; Secchiero *et al.*, 1997; Yasukawa *et al.*, 1998). In addition, CD4+ T-lymphocytes die from virus-triggered apoptosis. This induction is dependent on viral replication for HHV-7 and is independent of viral replication for HHV-6 (Inoue *et al.*, 1997; Secchiero *et al.*, 1997). HHV-6-mediated apoptosis is regulated by the Fas–Fas ligand system and the apoptosis induced by HHV-7 seems to be controlled by bcl-2 (Inoue *et al.*, 1997; Secchiero *et al.*, 1997). In support of this, inhibition of the apoptotic pathway by enhanced expression of bcl-2 enhances HHV-7 infection, as observed for other viruses including Epstein–Barr virus (Razvi and Welsh, 1995; Secchiero *et al.*, 1998b). Both HHV-6A and HHV-6B incorporate the important cell regulatory protein, p53, into virion particles; p53 regulates the cell cycle and protects a portion of infected cells from apoptosis (Takemoto *et al.*, 2005, Øster *et al.*, 2005). The basis for the choice between the two distinct fates (necrosis or apoptosis) of infected cells is unknown.

HHV-7 infection also induces tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) production, which provides a trans-acting signal that triggers apoptosis of nearby uninfected cells (Secchiero *et al.*, 2001). Simultaneously, TRAIL receptor 1 (TRAIL-R1) is down modulated in HHV-7 infected T lymphocytes. Thus, the virus triggers the death of nearby cells, which may protect it from the activity of immune effector cells such as NK cells and CTL, while protecting infected cells from similarly triggered death.

Proliferation

HHV-6A and HHV-6B viral envelope proteins inhibit T lymphocyte proliferation induced by phytohemagglutinin (PHA), IL-2, or antigens (Horvat *et al.*, 1993). Interaction of inactivated HHV-6A viral particles with PBMC inhibits proliferation of both CD4+ and CD8+ T lymphocytes and their responses to IL-2. This defect is apparently due to induction of defective IL-2 receptors or defects in IL-2 induced signaling pathway in these cells, as exogenous IL-2 does not correct the HHV-6 induced proliferation defect (Flamand *et al.*, 1995).

Dendritic cells

Dendritic cells are important antigen presenting cells for CD4 and CD8 T lymphocytes. Immature dendritic cells support HHV-6A or HHV-6B replication (Hirata *et al.*, 2001; Kakimoto *et al.*, 2002). Most of the infected cells are not killed, and differentiate into the mature forms, but these cells are functionally deficient and incapable of supporting lymphocyte proliferation (Kakimoto *et al.*, 2002). This is in contrast to HCMV, which selectively infects mature dendritic cells and down-regulates their cellular markers, thus impairing their function.

Histiocytes

Langerhans cell histiocytosis and hemophagocytic histiocytosis are characterized by dysregulated proliferation and migration of histiocytes (tissue macrophages). These diseases can be triggered by other diseases, use of certain drugs, or infections including HSV, HCMV and EBV. Cases of hemophagocytic histiocytosis have been associated with HHV-6 activity following organ transplantation and in previously healthy individuals (Rossi *et al.*, 2001; Tanaka *et al.*, 2002).

Cytokine production

HHV-6A, HHV-6B, and HHV-7 have profound influences on cytokine production by various immune cells (Table 48.4 and Fig. 48.3).

An important issue in the organismal response to infectious agents is the balance between the Th1 and Th2 arms of the immune system. There have been many studies of the effect of HHV-6 infection on the ability of target cells to produce cytokines that affect this balance, with sometimes diametrically opposed results. As discussed in detail by Lusso and colleagues (Smith *et al.*, 2003), this is probably due, at least in part, to the use of different cell types or cell populations in ex vivo conditions that do not fully represent in vivo regulatory circuits. IL-12 plays a pivotal role in

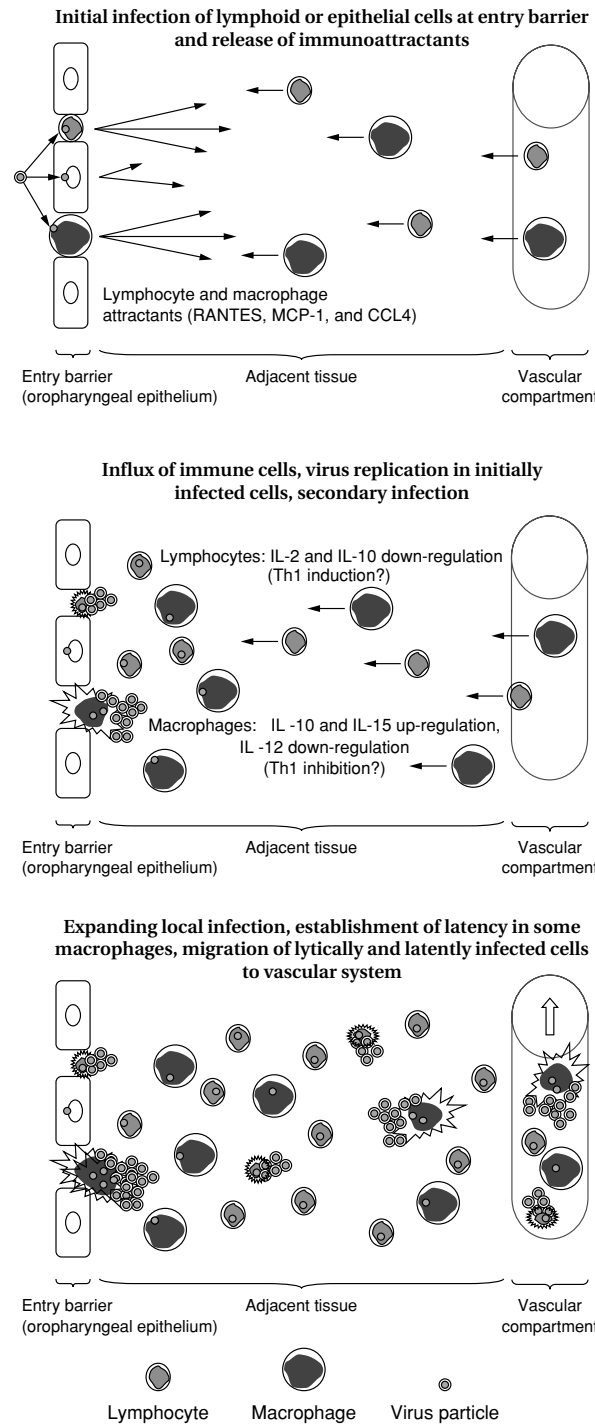

Fig. 48.3. Immunobiological events during early primary HHV-6 infection and establishment of latency. (See color plate section.)

inducing Th1 responses, and IL-10 is one of the key effectors in shifting the balance toward Th2 responses. Under some conditions, HHV-6 infection of PBMC induces IL-10 expression, which inhibits IL-12 production (Arena *et al.*, 1999; Li *et al.*, 1997). Both HHV-6A and HHV-6B infection of monocytes transiently induce low levels of IL-12 production; simultaneously, these same infections substantially restrict the level of IL-12 induction in response to IFN-γ and lipopolysaccharide; the sum is a net reduction in IL-12 production (Li *et al.*, 1997; Smith *et al.*,2003). From these results, it has been argued that HHV-6 infection might lead to inhibition of Th1-polarized immune responses. This is supported by microarray experiments involving HHV-6B infection of a T cell line that harbors HTLV-1 (Takaku *et al.*, 2005). In contrast, five days after HHV-6 infection, SupT1 cells expressed higher levels of IL-18 and other proinflammatory genes, while the level of IL-12 was unchanged and IL-10 was down-regulated (Mayne *et al.*, 2001). In addition, HHV-6 infection induces proinflammatory chemokines, including RANTES, despite encoding a beta chemokine receptor that down-regulates RANTES transcription (Caruso *et al.* 2003; Grivel *et al.*,2001, 2003; Milne *et al.*, 2000). From these data, it has been argued that HHV-6 infection leads to induction of a Th1 response (Mayne *et al.*, 2001). We have summarized these activities in a model of some of the early events following HHV-6 infection (Fig. 48.3).

Interaction of HHV-6A virions with CD4+ T-lymphocytes inhibits IL-2 mRNA synthesis and IL-2 production induced by PHA or OKT3 (Flamand *et al.*, 1995). IL-2 plays a major role in regulating T-lymphocyte and NK cell functions. HHV-6A, HHV-6B, and HHV-7 each downregulates the CXCR4 chemokine receptor leading to loss of response to the CXCR4 specific ligand, stromal cell-derived factor-1 (Hasegawa *et al.*, 2001; Secchiero *et al.*, 1998c; Yasukawa *et al.*, 1999).

Infection of primary astrocytes had only modest effects on expression of inflammatory genes. Interestingly, when the HHV-6A-infected astrocytes were treated with a pro-inflammatory mixture of TNF-α, IL-1β, and IFN-γ, anti-inflammatory genes were strongly induced (Meeuwsen *et al.*, 2005). There was very little overlap between the genes induced by infection of astrocytes vs. the HSB-2 T cell line.

Virally encoded immune modulators

Several herpesviruses, including CMV and HHV-8, encode genes homologous to human cellular chemokines or chemokine receptors, which may play important roles in pathogenesis and immune evasion. *U12* of both HHV-6 and HHV-7 encodes a functional beta-chemokine receptor (Isegawa *et al.*, 1998; Nakano *et al.*, 2003). HHV-6 *U51* encodes a functional chemokine receptor and is expressed in HHV-6 infected human endothelial cells (Caruso *et al.*, 2003; Milne *et al.*, 2000). While the product of *U12* interacts with beta-chemokines (also called CC chemokines) and activates, at least, the calcium-related signaling pathway, expression of HHV-6 U51 suppresses the transcription of RANTES, which recruits T-lymphocytes, NK cells, monocytes and eosinophils to inflammatory sites. Down-regulation of RANTES may compromise the function of these cells, as has been suggested for CMV US28. HHV-6B *U83* encodes a highly active CC chemokine that has been tested against the known chemokine receptors and interacts only with CCR2, a receptor present on macrophages and monocytes (Luttichau *et al.*, 2003; Zou *et al.*, 1999). HHV-6A U83 encodes two different forms of CC chemokines (full length being an agonist and the spliced form being an antagonist) that interact with a wide array of receptors other than CCR2 (Dewin *et al.*, 2006). These activities may contribute to the process by which the virus establishes latency in such cells.

Other immune evasion mechanisms

HHV-6 gB and gH-gL complexes are not detectable on the plasma membrane of infected lymphocytes (Cirone *et al.*, 1994), which may constitute an immune avoidance strategy. It has been reported that HHV-6A down-regulates HLA class I antigen in dendritic cells which may prevent the cells from HLA-I dependent killing, but the opposite was found in another paper (Hirata *et al.*, 2001; Kakimoto *et al.*, 2002).

HHV-7 *U21* encodes a type I membrane protein that binds to class I HLA-1 molecules and reduces their level of cell surface expression by diverting them to lysosomes (Hudson *et al.*, 2001). Unexpectedly, the redirection is not mediated by the cytoplasmic tail of U21, but by its ER-lumenal domain (Hudson *et al.*, 2003). This represents a novel mechanism for lysosomal sorting and for immune evasion.

Clinical significance of immunomodulation

A lot of interest has been concentrated on identifying the pathologic role of these viruses in immunocompromised patients. The rationale is that all the other herpesviruses cause significant diseases in this group of patients. In addition to directly causing pathologic lesions, it is also possible that these three viruses may indirectly contribute to other infectious pathogens by inhibiting the immune system (Griffiths, 2003).

Organ transplantation

HHV-6, but not HHV-7, infection is related to graft rejection in both adult and pediatric liver transplant patients (Feldstein *et al.*, 2003; Griffiths *et al.*, 1999). HHV-6 infection is related to higher CMV viral loads, CMV syndromes and diseases, bacteriemia, fungal disease, and mortality (DesJardin *et al.*, 1998, 2001; Humar *et al.*, 2000, 2002; Rogers *et al.*, 2000). HHV-6 negative patients may experience primary infection, and these patients are more likely to develop fungal infections (Dockrell *et al.*, 1999). In addition, HHV-6 may lead to hepatitis due to hepatitis C virus, and acute liver failure after liver transplantation (Harma *et al.*, 2003; Rogers *et al.*, 2000; Singh *et al.*, 2002b). Similar findings have also been made in lung and heart-lung transplant patients (Jacobs *et al.*, 2003), although HHV-6 infection was associated only with fever in one study of liver transplant recipients (217). After renal transplantation, HHV-7, but not HHV-6 DNAemia is related to graft rejection, higher plasma CMV DNA loads, CMV disease and graft dysfunction (Kidd *et al.*, 2000; Osman *et al.*, 1996; Tong *et al.*, 2000, 2002).

Prophylaxis with valacyclovir or ganciclovir, two effective anti-herpesvirus agents, lead to reduced staphylococcal, candida and other fungal infections after renal and heart transplantation (Lowance *et al.*, 1999; Wagner *et al.*, 1995). In addition to the effects such therapy may have on CMV activity, the effects of this therapy on HHV-6 and HHV-7 may have contributed to the observed benefit. Future work on therapy targeted at roseoloviruses is needed, because these viruses frequently become active earlier than CMV in many patients.

HIV disease

Because of its impact on the immune system, HHV-6 has long been hypothesized to accelerate the progress of HIV infection. HIV disease is more likely to progress in HHV-6 infected infants and active HHV-6A and HHV-6B replication is frequently observed in patients with late stage AIDS (Clark *et al.*, 1996; Emery *et al.*, 1999; Kositanont *et al.*, 1999). While this argues for either or both of the HHV-6 variants being copathogens for HIV, some data runs counter to this. Differences in methods and patient groups may account for some of the disagreement. In several studies there was no relationship between the presence of HHV-6 DNA in saliva or peripheral blood cells, or serological responses and AIDS pathogenesis (for review see Braun *et al.*, 1997).

Future directions

Several areas of roseolovirus immunobiology seem ripe for further study, including (i) events during the earliest stages of primary infection, including identification of the target cells, modulation of immune responses, and establishment of latency, (ii) interactions with innate immune functions, including triggering of innate responses by engagement of receptors such as the Toll-like receptors, (iii) further study of the targets of cellular immunity and the effectiveness of these responses during disease, (iv) the relationship between virus-mediated immune suppression and other infections, (v) the possible contributions of HHV-6 immunomodulation to MS, (vi) interactions of these viruses with the various apoptotic pathways, (vii) the circumstances under which these viruses might affect the balance between the Th1- and Th2-type responses, (viii) mechanisms for modulating HLA-1 expression or activity, and (ix) identification of the mechanisms by which the virus regulates stimulation of immunity. It will be important to extend studies that are done in cultured purified cells to systems that more fully represent the complexity of in vivo regulatory mechanisms.

HHV-6A, 6B, and 7: persistence in the population, epidemiology and transmission

Vincent C. Emery and Duncan A. Clark

Department of Virology, Royal Free and University College Medical School of UCL, London, UK

Introduction

In common with all human herpesviruses, HHV-6 and HHV-7 establish lifelong infection following initial exposure and seroconversion. True latency as exemplified by HSV-1 and VZV, in which the genome is maintained in a transcriptionally restricted state, has not been conclusively shown for HHV-6 or HHV-7. However, the betaherpesviruses may persist in individuals via low grade replication which is continuously suppressed by a functional immune response. In this chapter we will summarize the current understanding of the epidemiology and persistence of HHV-6 and HHV-7 in the human host and its relevance to transmission. In addition, we will highlight a novel form of persistence for HHV-6 which involves integration into host chromosomal DNA.

Persistence of HHV-6 and HHV-7 in individuals

In the case of both HHV-6 and HHV-7, PCR analysis of peripheral blood mononuclear cells (PBMC) shows that a sensitive nested assay and an adequate quantity of input DNA (at least equivalent to approximately 150000 mononuclear cells or 1μg DNA) can detect viral DNA in healthy immunocompetent individuals suggestive of low levels of latent/persisting virus in peripheral blood (Jarrett *et al.*, 1990; Clark *et al.*, 1996; Kidd *et al.*, 1996). In contrast, viral loads are maintained at high levels in saliva of seropositive individuals, particularly in the case of HHV-7 (Kidd *et al.*, 1996; Fujiwara *et al.*, 2000; see Fig. 49.1). Since the salivary glands are a major site of replication following primary infection with both HHV-6 and HHV-7, saliva is likely to be an important fluid mediating transmission of virus within the community. An investigation of separate salivary glands (submandibular, parotid and lip) in multiple patients has revealed that the submandibular gland is most likely to contain HHV-6 (88%) and HHV-7 DNA (100%) compared to the other anatomic salivary glands, 50%–60% of which were infected (Sada *et al.*, 1996).

However, as described in more detail in Chapter 48 HHV-6 and HHV-7 may exist in a true latent state within cells of the lymphoreticular system and in the case of HHV-6, the central nervous system, i.e., exhibiting transcription patterns restricted to specific genomic regions without undergoing full genomic replication (Kondo *et al.*, 2002).

HHV-6 is neurotropic and analysis of postmortem brain tissue by PCR has shown that up to 85% of individuals harbor HHV-6 DNA (Chan *et al.*, 2001). In this study, HHV-6 variant B predominated in the brain although variant A was detected in 27.5% of brains and coinfections were also observed. Whether a latent transcriptionally silent or restricted expression pattern is present in this anatomic site or whether local replication can occur which facilitates viral persistence in the central nervous system, has not been determined. Following primary infection ~29% of children have HHV-6 DNA in the CSF which is consistent with the central nervous system being an important site of latency (Caserta *et al.*, 1994).

Other studies have revealed widespread distribution of HHV-6 and HHV-7 DNA in organs derived from both immunocompetent and immunocompromised hosts (Clark *et al.*, 1996; Emery *et al.*, 1999) with low viral loads detected in most tissues. However, HHV-6 viral loads were significantly increased in autopsy tissues from AIDS patients compared to controls suggesting upregulation of HHV-6 replication in the latter (Clark *et al.*, 1996).

Epidemiology of HHV-6 and HHV-7

Seroepidemiologic studies of HHV-6 and HHV-7 have used indirect immunofluoresence assays and more recently

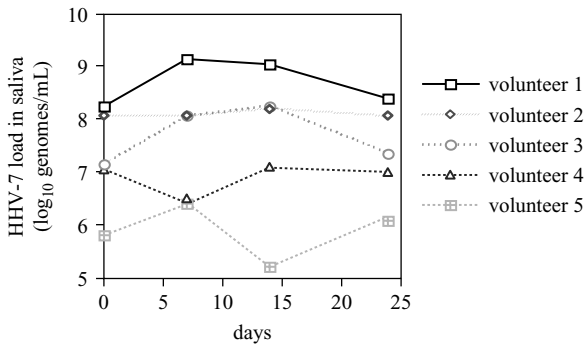

Fig. 49.1. Determination of HHV-7 loads in saliva by quantitative PCR from 5 volunteers showing temporal variation in individuals. Viral loads are expressed as HHV-7 genomes/mL saliva. Adapted from Kidd *et al.*, 1996.

ELISA based assays, with the latter deemed to be more sensitive. Antigenic similarity between HHV-6 and HHV-7 creates the potential problem of cross-reactive HHV-6 and HHV-7 antibodies in human sera (Black *et al.*, 1996). Nevertheless, many studies have consistently shown that HHV-6 and HHV-7 infections are almost universal within the adult population and the viruses have a worldwide distribution. The very close homology between the two HHV-6 variants has hindered attempts to distinguish antibodies to each variant.

Infection with both HHV-6 and HHV-7 occurs early in life. The peak of seroconversion for HHV-7 occurs after 24 months of age (Tanaka-Taya *et al.*, 1996) and is slightly later than seroconversion for HHV-6 which peaks at 13 months (Okuno *et al.*, 1989). Antibody titers are higher in children compared to adults reflecting recent primary infection. Viral loads in blood are also high during this period of acute infection and in the case of HHV-7 can reach 10^7 genomes/μg PBMC DNA. In comparison, HHV-6 loads in blood during primary infection appear to peak at around 10^5 genomes/μg PBMC DNA (Clark *et al.*, 1997; Chiu *et al.*, 1998).

HHV-6 variants A and B

HHV-6 exists as two distinct variants (HHV-6 A and B). Comparative genomic analysis of the prototypes of these variants reveals the number of highly homologous genes but also reveals significant differences in viral proteins (Gompels *et al.*, 1995; Dominguez *et al.*, 1999; Isegawa *et al.*, 1999). At present, the full implications of these differences have not been determined although it is clear that the biological phenotypes can have profound effects. The variants differ with respect to their ability to grow in a range of cell types although both use CD46 as a cellular receptor (Santoro *et al.*, 1999). Interaction with the cellular receptor has been reported to include the participation of the viral glycoproteins gH, gL and gQ (Santoro *et al.*, 2003; Mori *et al.*, 2003). gQ has only 79% amino acid identity between variants which may influence the ability of variants to target different cells. HHV-6 variant A but not variant B has also been shown to induce fusion from without in a variety of human cells mediated through the gB and gH glycoproteins and CD46 (Mori *et al.*, 2002).

A number of PCR systems that allow differentiation between HHV-6 variant A and B have been used extensively in epidemiologic studies. Some of these methods have relied on variant common primers with differentiation of variant type by differences in the presence of restriction endonuclease sites (Dewhurst *et al.*, 1992; Kidd *et al.*, 1998) or hybridization with variant specific probes (Cone *et al.*, 1996). Other studies have used variant specific primers (Chou & Marousek, 1994; Cone *et al.*, 1996).

When the prevalence of each variant is examined at different anatomical sites, HHV-6B is frequently detected in saliva (Aberle *et al.*, 1996; Tanaka-Taya *et al.*, 1996) and it is also the predominant variant in PBMC (Di Luca *et al.*, 1994) and brain tissue (Chan *et al.*, 2001). Co-infection with both variants was found in 22 of 34 lung tissue specimens (Cone *et al.*, 1996) and HHV-6A was more frequently detected in skin biopsies (Di Luca *et al.*, 1996) and CSF (Hall *et al.*, 1998). The absence of HHV-6A in clinical samples most amenable to epidemiologic investigations (blood and saliva) have prevented the true prevalence of this variant from being determined. Although HHV-6B is almost exclusively the cause of febrile illness in young children in the US (Dewhurst *et al.*, 1993), one study has suggested that active HHV-6A infection in young children with febrile illness is more common in Africa (Kasolo *et al.*, 1997).

HHV-6 and HHV-7 genotypes

HHV-6 isolates can clearly be classified as either variant A or variant B, although both are closely related with an overall nucleotide identity of 90%. There is little evidence for HHV-6 intrastrain variation although subgroups within HHV-6B have been suggested by analysis of specific regions of the viral genome (IE-A region and gH) (Chou & Marousek, 1994; Gompels *et al.*, 1993). However, examination of the U94 gene from 13 HHV-6B isolates from the US, Africa and Japan showed 100% amino acid identity (Rapp *et al.*, 2000) suggesting an intolerance of variation in this particular gene. Comparison of the two fully sequenced HHV-7 isolates (RK and JI) shows that intrastrain variation is low although

(a)

Sample time (weeks)	0	1	4	6	10	14	36	45
HHV-6 viral load (log_{10} genomes/μg PBMC DNA)	6.08	5.90	6.04	5.85	6.08	6.00	6.15	6.18

(b)

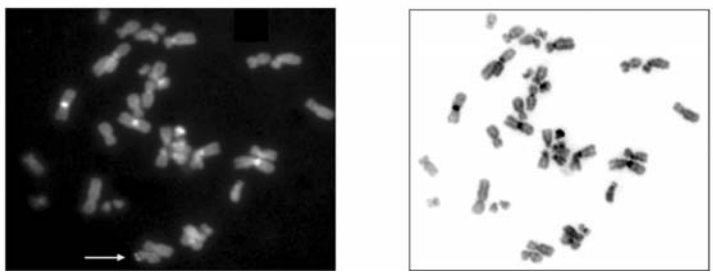

Fig. 49.2. HHV-6 integration into host cell chromosomes. (a) Consistently high viral loads detected in the peripheral blood of an individual at multiple time points by quantitative PCR (adapted from (Clark *et al.*, 1996). (b) FISH analysis using a fluorescently labeled HHV-6 specific probe showing integration of HHV-6 sequences on the short arm of chromosome 11 in V1-LCL (arrowed). (Adapted from Clark *et al.*, 2006.)

more apparent in repeat regions close to either ends of the genome (Megaw *et al.*, 1998). However, analysis of 3 genes encoding the phosphoprotein p100, gB and major capsid protein in 297 people derived from populations in Africa, Asia, Europe and America has suggested the presence of distinct variants (Franti *et al.*, 2001).

HHV-6 integration

An alternative form of HHV-6 persistence characterized by very high viral loads in PBMC and integration of viral sequences into host cell chromosomes is present in a small subset of the population. Luppi *et al.*(1993) first reported three individuals with very high viral loads in PBMC with viral DNA detectable by Southern blotting. Subsequently fluorescent in situ hybridization (FISH) with HHV-6 specific probes identified integrated viral sequences on the short arm of chromosome 17 in all three cases (B cell lymphoma, Hodgkin's disease and a patient with multiple sclerosis) (Torelli *et al.*, 1995). Follow-up studies suggested that the sites of integration were close to or in the telomeres of chromosome 17 (Morris *et al.*, 1999). Of possible relevance, HHV-6 variants have telomere-like repeat sequences in the direct repeat regions that flank the viral genome (Gompels *et al.*, 1995; Dominguez *et al.*, 1999; Isegawa *et al.*, 1999) which may facilitate integration within the telomere. The integrated viral sequences were typed as variant B in all three cases.

More recently, Daibata *et al.* (1998) described a cell line derived from a Burkitt's lymphoma patient with integrated viral sequences (variant B) on chromosome 1q44 and in a follow-up study showed that the asymptomatic husband of this case had integrated virus on chromosome 22q13 (Daibata *et al.*, 1999). Intriguingly, the daughter of this couple had integrated HHV-6 DNA sequences on both chromosomes 1q44 and 22q13 suggesting entry of viral sequences into the germline and chromosomal inheritance. The concept of an "endogenous herpesvirus" is novel and inheritance of viral sequences has only been described for endogenous retroviruses or related genetic elements. In the absence of inheritance, high viral loads found in PBMC may represent integration of viral sequences in a bone marrow progenitor cell which gives rise to a large number of cells/cell types in peripheral blood carrying copies of the viral genome. In the studies by Torelli *et al.* (1995) and Daibata *et al.* (1999), it was suggested that the entire HHV-6 genome was present.

We have also investigated HHV-6 loads in the PBMC of healthy individuals (Clark *et al.*, 1996). Using an input of 1μg DNA (equivalent to 150000 diploid cells) in a quantitative competitive PCR assay, 9 of 25 blood samples were HHV-6 DNA positive with viral loads in 8 ranging from 5–32 HHV-6 genomes/μg DNA. The remaining person (V1) had a consistent viral load of around 6 log_{10} genome copies/μg DNA in multiple samples over a ten month period (Clark *et al.*, 1996). An EBV-transformed B-lymphoblastoid cell line was established and FISH analysis using a fluorescently labeled 9 kbp HHV-6 specific probe identified integrated virus close to the end of the short arm of chromosome 11 (Fig. 49.2). The viral sequences were shown to be HHV-6B using variant typing PCR. A more extensive series of

individuals with a variety of sites of integration have now been investigated by quantitative PCR showing high viral loads are present in whole blood, serum and hair follicles (Ward *et al.*, 2006). The mean HHV-6 DNA load in whole blood was 7.0 $\log_{10}$ copies/milliliter, in serum it was 5.3 $\log_{10}$ copies/milliliter while in hair follicles it was 4.2 $\log_{10}$ copies/hair follicle.

The expression of HHV-6 genes in vivo in patients with integrated viral sequences has not been studied extensively. Daibata *et al.* (Daibata *et al.*, 1998) reported the detection of immediate early and late HHV-6 genes in an integrated HHV-6, EBV negative cell line following treatment with TPA (a commonly used stimulator of herpesvirus lytic infection). No non-integrated linear or episomal forms of the HHV-6 genome were detected by Gardella gel analysis suggesting an absence of viral DNA replication (Daibata *et al.*, 1998).

It is important to consider whether integrated HHV-6 is of clinical relevance. Although the biological effects of HHV-6 integration are unknown, integrated virus is a potential confounder in studies investigating HHV-6 disease associations and also in the medical management of infection. There have been a number of false leads and unproven associations between HHV-6 and disease, some of which may have reflected the unrecognized detection of integrated virus and interpreted as a high viral load. To date, there have been no controlled trials of antiviral therapy against HHV-6 infection, but a number of studies have shown the ability of ganciclovir and foscarnet to suppress HHV-6 replication in vitro. This information has been applied clinically to treat suspected cases of HHV-6 disease. From a management perspective, it will be important to differentiate patients with active HHV-6 infection from those patients with integrated HHV-6 to prevent the latter receiving unnecessary exposure to potentially toxic antiviral drugs.

Transmission of HHV-6 and HHV-7

Although primary infection with these viruses usually occurs in early childhood there is evidence that infection with HHV-6 occurs slightly earlier than HHV-7 (Wyatt *et al.*, 1991). Saliva is the most likely vehicle for transmission of both viruses. HHV-6 and HHV-7 DNA can frequently be detected by PCR in the saliva of both adults and children (Jarrett *et al.*, 1990; Kidd *et al.*, 1996; Suga *et al.*, 1995; Tanaka-Taya *et al.*, 1996) and although there are very few HHV-6 isolates derived from saliva, HHV-7 is readily cultured from this source (Wyatt & Frenkel, 1992). Molecular characterization of HHV-6 strains detected within a limited number of families suggest that the virus may be transmitted primarily from mother to child (Yoshikawa *et al.*, 1993; van Loon *et al.*, 1995). For HHV-7, genetic analysis of virus within families also suggests transmission within the family unit from both mothers and fathers (Thawaranantha *et al.*, 2002), and through multigenerational families in the same household (Takahashi *et al.*, 1997).

HHV-6 and HHV-7 have been detected by PCR in 20% and 3% respectively of the cervixes of women in the later stages of pregnancy (Okuno *et al.*, 1995) suggesting the potential for perinatal transmission. This observation is consistent with the identification of active HHV-6 infection during the neonatal period (Hall *et al.*, 1994). PCR analysis of cord blood suggests a prevalence of HHV-6 congential infection of 1%–2% of births (Aubin *et al.*, 1992; Adams *et al.*, 1998; Dahl *et al.*, 1999) and there are case reports of associated disease (Lanari *et al.*, 2003). HHV-6 reactivation has also been suggested to be more common during pregnancy which may facilitate transmission of virus to the fetus (Dahl *et al.*, 1999). HHV-7, but not HHV-6, was detected in 3 of 29 breast milk samples suggesting that breast feeding may also be a route of transmission for HHV-7 (Fujisaki *et al.*, 1998).

HHV-6 and HHV-7 are now recognized as being common infections in the post-transplant period. In the majority of cases, particularly adults, reactivation of the recipient's virus is the most probable source of active infection. However, transmission from the donor graft is a distinct possibility and has been reported for HHV-6 in a bone marrow transplant recipient (Lau *et al.*, 1998). HHV-6 and HHV-7 DNA have also been detected by PCR in 28% and 50%, respectively, of bone marrow samples from healthy individuals highlighting a possible source of virus for transmission through transplantation (Gautheret-Dejean *et al.*, 2000). There is also evidence suggesting transmission of HHV-6 to infants through living-related liver transplantation from their HHV-6 seropositive mothers (Yoshikawa *et al.*, 2001) and transmission of integrated virus following stem cell transplantation (Clark *et al.*, 2006).

Although HHV-6 and HHV-7 are frequently detected by PCR in PBMC including those of blood donors (Wilborn *et al.*, 1994, 1995), there is no evidence that HHV-6 at least is a cause of post-transfusion hepatitis (Lunel *et al.*, 1991).

Concluding comments

Progress is being made in understanding the persistence of HHV-6 and HHV-7 in the human host and the molecular basis for different forms of persistence. It is clear that both HHV-6 and HHV-7 are well adapted to their human

host since even in the developed world seroprevalence rates are almost universal and they are rarely pathogenic in the immunocompetent host.

Clinical and pathological aspects of EBV and KSHV infection

Richard F. Ambinder[1] and Ethel Cesarman[2]

[1]Johns Hopkins School of Medicine Departments of Oncology, Pathology, and Pharmacology Baltimore, MD, USA
[2]Weill Medical College of Cornell University Department of Pathology and Laboratory Medicine New York, NY, USA

The human γ-herpesviruses Epstein–Barr virus (EBV) and Kaposi's sarcoma herpesvirus (KSHV) establish latency in cellular reservoirs that are maintained for the life of the infected individual. Intermittent reactivation leads to infection of new cells within the host and secretion of virions in saliva. Primary infections are usually asymptomatic. However, in immunocompromised patients and in other special but poorly understood circumstances, tumors and other virus-associated diseases may manifest. Both human γ-herpesviruses were first identified in tumors and primary effusion lymphomas are typically dually infected (Cesarman *et al.*, 1995; Chang *et al.*, 1994; Epstein, 2001). For all their similarities, however, there are also striking differences between the viruses. EBV is nearly ubiquitous whereas KSHV is restricted to particular populations. EBV is most commonly associated with B-, T- and NK-cell tumors and epithelial tumors, whereas KSHV is associated with endothelial and B-cell tumors. In this chapter, aspects of virus–disease associations and therapies will be explored.

EBV

Transmission of EBV generally involves oral contact (Cohen, 2000). This might occur through the maternal chewing of food for young infants such as occurs in some cultures, the sharing of eating utensils, or kissing (Niederman *et al.*, 1976). Infection may also occur through genital transmission, blood transfusion, and organ or bone marrow transplantation (Crawford *et al.*, 2002). By adulthood more than 90% of adults show serologic evidence of EBV infection. Primary infection is usually asymptomatic in infancy or childhood, but is commonly associated with the syndrome of infectious mononucleosis when infection first occurs in adolescence or adulthood (Henke *et al.*, 1973). Symptomatic or not, infection is generally lifelong. Following initial exposure, antibody responses to some latent and lytic antigens persist indefinitely (Henle *et al.*, 1979). Thereafter, infectious virus is shed intermittently in saliva and viral DNA can be detected in peripheral blood mononuclear cells (Ling *et al.*, 2003a,b; Sitki-Green *et al.*, 2004).

Infection in the normal host

Symptomatic infection (infectious mononucleosis also referred to as glandular fever) occurs in less than half of new seroconverters during the late teenage years. The classic manifestations are fever, pharyngitis, cervical lymphadenopathy (often tender), hepatosplenomegaly, malaise and fatigue. The former symptoms and signs usually last one to three weeks, but malaise and fatigue often persist for weeks or months (Rea *et al.*, 2001).

An initial proliferation of EBV-infected B-lymphocytes is followed by the development of NK and T-cell responses (Hislop *et al.*, 2002; Tosato *et al.*, 1979) Laboratory findings include a reactive lymphocytosis (reflecting the proliferation of NK cells and T-cells), hypergammaglobulinemia and the presence of heterophile antibodies (Jenson, 2004). "Monospot" or "slide" tests are in common use and detect antigens on sheep, horse or goat erythrocytes. The appearance of heterophile antibodies appears to reflect broad spectrum B-cell activation rather than cross reaction between erythrocyte antigens and viral antigens. Heterophile antibodies typically persist for several months. Very young patients may not mount heterophile responses. In cases where the diagnosis of primary infection is in doubt, serology to assess the presence of an IgM anti-VCA response is useful. Traditionally determinations of antiviral antibodies have involved immunofluorescence, but now more commonly involve enzyme-linked immunosorbent assays.

The histologic findings in the lymph nodes range from non-specific follicular hyperplasia to a proliferation of large cells resembling lymphoma. In addition, the morphologic features may also resemble those seen in other viral infections, in particular associated with cytomegalovirus, herpes simplex or zoster, or that seen in lymph node draining sites of vaccinations. Lymph nodes from patients with infectious mononucleosis frequently have an immunoblastic proliferation of varying severity, which gives a mottled appearance to a variably expanded paracortex. Plasma cells and plasmacytoid cells are also admixed with immunoblasts and lymphocytes, so there is a polymorphous appearance. Sometimes the immunoblasts form clusters, or even sheets, partially effacing this lymph node, which may be confused with malignant lymphoma (Isaacson *et al.*, 1992).

A multitude of other manifestations are sometimes associated with primary EBV infection. These include: maculopapular rash, particularly common in patients treated with ampicillin; hepatitis; autoimmune hemolytic anemia; genital ulcers; tonsilar enlargement; aplastic anemia; and a variety of neurologic complications including encephalitis, aseptic meningitis, transverse myelitis and others (Ahronheim *et al.*, 1983). Neurologic syndromes may occur in the absence of classic signs, symptoms and laboratory findings described above (Domachowske *et al.*, 1996; Grose *et al.*, 1975; Sumaya, 1987).

In unusual circumstances, primary infection may be fatal. This may occur in the setting of congenital immunodeficiency as elaborated below or it may occur sporadically. Hemophagocytosis is often a prominent feature of fatal infectious mononucleosis (Okano and Gross, 1996).

Therapy

There is no specific therapy for infectious mononucleosis other than supportive care. Antiviral agents such as acyclovir and valacyclovir have been shown to reduce oral viral shedding but not to shorten the course of symptomatic disease (Jenson, 2004; Torre and Tambini, 1999). This lack of clinical efficacy is consistent with the idea that it is the inflammatory response to EBV rather than the destructive effects of the virus per se that are associated with symptoms. In this regard, corticosteroids which have anti-inflammatory properties and are lympholytic have been used to control pharyngitis, lymphadenopathy, splenomegaly and autoimmune manifestations such as severe thrombocytopenia or hemolytic anemia (Roy *et al.*, 2004; Tynell *et al.*, 1996).

Infection in patients with congenital immunodeficiencies

Patients with X-linked agammaglobulinemia lack B cells and seemingly lack the ability to harbor the virus (Faulkner *et al.*, 1999). Neither infectious virus nor viral DNA is detected in either saliva or peripheral blood mononuclear cells. In contrast, various forms of severe combined immunodeficiency (SCID) predispose to fatal infectious mononucleosis, hemophagocytosis, dysgammaglobulinemia and EBV-driven lymphoproliferative diseases (Elenitoba-Johnson and Jaffe, 1997; Filipovich *et al.*, 1994). Whereas SCID patients are vulnerable to many infections and are generally recognized as immunodeficient before primary EBV infection, patients with X-linked lymphoproliferative disease (XLP) often first come to medical attention in association with EBV infection (Seemayer *et al.*, 1995). The genetic defect has been mapped to the SLAM – associated protein (SAP) gene which is expressed on natural killer (NK) cells, CD4+ T-cells and CD8+ T-cells. This molecule is thought to be involved in the coordination of the immune response to EBV and other viral infections (Coffey *et al.*, 1998; Sharifi *et al.*, 2004).

Chronic active EBV

Primary infection that evolves into a severe progressive illness characterized by major organ involvement such as hepatitis, lymphadenitis and hemophagocytosis; extreme elevations of EBV antibody titers; and situations in which EBV is detected by in situ hybridization, immunohistochemistry or PCR (at high copy number) are referred to as chronic active EBV infection (Katano *et al.*, 2004). The disease is much more common in Asia with most reports coming from Japan, Taiwan, Korea and China. Mutations in the SAP gene have not been linked with chronic active EBV infection (Sumazaki *et al.*, 2001). However, in one instance chronic active EBV has been associated with a genetic defect in both alleles of the perforin gene (Katano *et al.*, 2004). Perforin is present in the granules of cytotoxic T-lymphocytes and NK cells and is required for their cytotoxic activity.

Allogeneic transplantation and EBV-specific adoptive T-cell immunotherapy have each been used alone or in combination in the treatment of chronic active EBV infection (Hagihara *et al.*, 2003; Savoldo *et al.*, 2002; Taketani *et al.*, 2002). The experience is limited, however, and reports are mixed.

Infection in HIV patients

Patients with HIV infection typically have increased antibody titers to EBV antigens, increased viral DNA copy number in peripheral blood mononuclear cells and increased viral shedding in oropharyngeal secretions (Ling *et al.*, 2003a,b; Van Baarle *et al.*, 2002). EBV is associated with a variety of malignancies in HIV-infected patients as discussed further below. It is also associated with a benign disorder, oral hairy leukoplakia (Walling *et al.*, 2003). This is a hyperplastic lesion of the oral mucosa, most commonly arising on the lateral aspect of the tongue. Occasionally these raised, white lesions occur in other immunosuppressed populations such as organ transplant recipients. Molecular analysis has revealed that several strains of virus are often present in a single lesion. The lesion is distinctive in that EBER expression is absent and there is high level expression of lytic genes (Cruchley *et al.*, 1997; Gilligan *et al.*, 1990; Webster-Cyriaque *et al.*, 2000). The condition is generally not symptomatic. However, when there are indications for treatment, lesions resolve with acyclovir or valacyclovir therapy (Walling *et al.*, 2003). Therapy is suppressive rather than curative, and recurrence following discontinuation of drug treatment is common.

Other illnesses

A variety of other chronic illnesses have been linked to EBV. In several autoimmune diseases, evidence supporting a link of some sort continues to accrue and the associations are under active investigation. These include systemic lupus erythematosus, multiple sclerosis and rheumatoid arthritis (James *et al.*, 2001; Kang *et al.*, 2004; Levin *et al.*, 2003; Yang *et al.*, 2004). Epitope spreading, cross-reactivity with autoantigens and virus-driven immortalization of autoreactive B cells have all been invoked as mechanisms whereby viral infection might precipitate autoimmunity. The possibility that autoimmunity might lead to increased EBV lytic infection in rheumatoid arthritis has also been considered (Yang *et al.*, 2004). One of the characteristic findings in rheumatoid arthritis is rheumatoid factor, an anti-immunoglobulin autoantibody. Anti-immunoglobulin antibodies lead to lytic activation in latently infected cell lines such as the Akata Burkitt's cell line. Rheumatoid factors from patients' sera have also been found to lead to lytic reactivation.

Chronic fatigue syndrome and lymphoid interstitial pneumonitis are two other illnesses that have been linked to EBV by some investigators. Chronic fatigue syndrome is a poorly understood illness in which patients have chronic fatigue and often sore throat, tender lymphadenopathy, arthralgias, memory loss or headaches (Soto and Straus, 2000; Straus, 1993). These patients often have slightly elevated antibody titers to EBV and other viruses. Lymphoid interstitial pneumonias represent a spectrum of poorly characterized diseases that include idiopathic inflammatory processes and pulmonary lymphoproliferative disorders including malignant lymphomas (Swigris *et al.*, 2002). Lymphoid interstitial pneumonia often occurs in association with other diseases, particularly Sjogren's syndrome and childhood HIV infection. EBV infected lymphocytes are often among the cells in the characteristic infiltrates, particularly in HIV-infected children but the relevance of the virus to the pathogenesis of the process is very uncertain.

EBV-associated tumors

EBV is associated with a variety of malignancies. The association between virus and tumor varies with regard to immunodeficiency, the time between primary infection and tumorigenesis, the importance of geographic factors, the importance of genetic factors, and the malignant tissue itself (lymphoid, epithelial, or smooth muscle) (Fig. 50.1).

The importance of immunodeficiency is illustrated by the observation that organ and hematopoietic stem cell transplant recipients, patients with congenital immunodeficiencies and HIV-infected patients are all at increased risk for EBV-associated B cell malignancies and the much rarer EBV-associated leiomyosarcoma (Knowles, 1999; Loren *et al.*, 2003; McClain *et al.*, 1995). In contrast, no increased risk of EBV-associated nasal lymphoma, nasopharyngeal carcinoma, or gastric carcinoma has been documented in these populations (Filipovich *et al.*, 1994; Grulich *et al.*, 2002; Hsu and Glaser, 2000; Loren *et al.*, 2003; Penn, 1996).

The time between primary infection and malignancy is typically weeks or months in organ transplant recipients, several years in Hodgkin's lymphoma patients, and several decades in nasopharyngeal carcinoma and nasal lymphoma patients (Hjalgrim *et al.*, 2003; Loren *et al.*, 2003; Raab-Traub, 2002). Environmental factors such as exposure to malaria seem to play a role in the pathogenesis of EBV-associated Burkitt's lymphoma in Africa. In regions of Africa where malaria is endemic, Burkitt's lymphoma is a common childhood neoplasm and is uniformly associated with

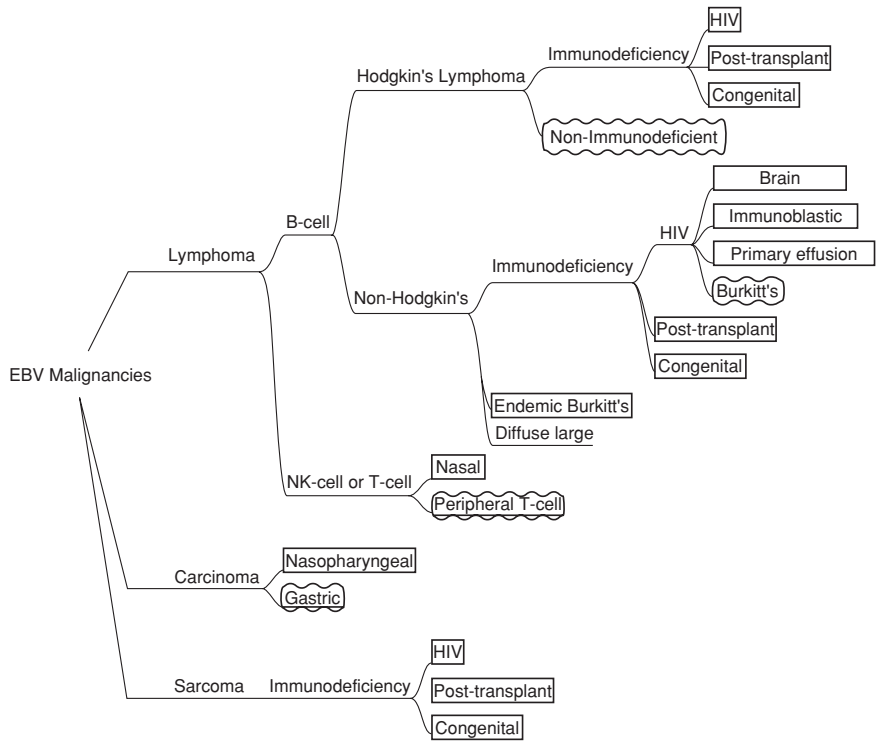

Fig. 50.1. EBV Malignancies. Rectangular boxes indicate malignancies that are almost uniformly associated with EBV. Wavy line boxes indicate malignancies that are associated with EBV in 5%–50% of cases. Blue boxes indicate an association with immunodeficiency.

EBV. In North America and Europe, Burkitt's lymphoma is much less common and is usually not associated with EBV. Populations of African descent in North America seem not to be at increased risk for the tumor (Hsu and Glaser, 2000).

A mix of environmental and genetic factors are implicated in nasopharyngeal carcinoma which is particularly common in Cantonese and Eskimo populations (Yu and Yuan, 2002). In contrast to Burkitt's lymphoma, undifferentiated nasopharyngeal carcinoma is always associated with EBV – even when it occurs in a low risk environment. When high risk Chinese populations emigrate, their risk falls but not to the Caucasian baseline. High risk families are recognized and twin studies confirm a genetic contribution (Jia *et al.*, 2004).

Finally, there is variability in the genetics of the EBV-associated tumors themselves. Burkitt's lymphomas show simple chromosomal translocations that juxtapose immunoglobulin loci, most commonly the heavy-chain locus on chromosome 14, and the c-Myc oncogene. These translocations are recognized as among the defining characteristics of the malignancy. Post transplant lymphoproliferative disorders generally lack karyotypic abnormalities. Hodgkin's lymphoma, primary effusion lymphoma and nasopharyngeal carcinoma show very complex karyotypes.

The determination of EBV association typically involves in situ hybridization for EBER RNA (abundant EBV polymerase III transcripts), or immunohistochemical detection of viral antigens (Ambinder and Mann, 1994). With the exception of peripheral T-cell lymphomas, evidence of viral infection is generally found in most of the tumor cells if any of the tumor cells harbor virus (Anagnostopoulos *et al.*, 1995). This is true at presentation and at relapse, at the primary site and in metastases. In nasopharyngeal carcinoma, several investigators have called attention to heterogeneity in the tumor, with the apparent absence of viral products from sub-populations of cells (Wu *et al.*, 1991; Yao *et al.*, 2000). With the exception of some of the lymphoid proliferations arising in profoundly immunocompromised patients, these tumors are all clonal. Clonality in lymphoid malignancies is readily established by studying antigen receptor rearrangements and in tumors in general by studying a variety of polymorphisms in X chromosomes (where in women, one or the other X will be inactivated). For the EBV-associated malignancies, it is also possible to infer clonality from the study of the viral terminal repeat sequences.

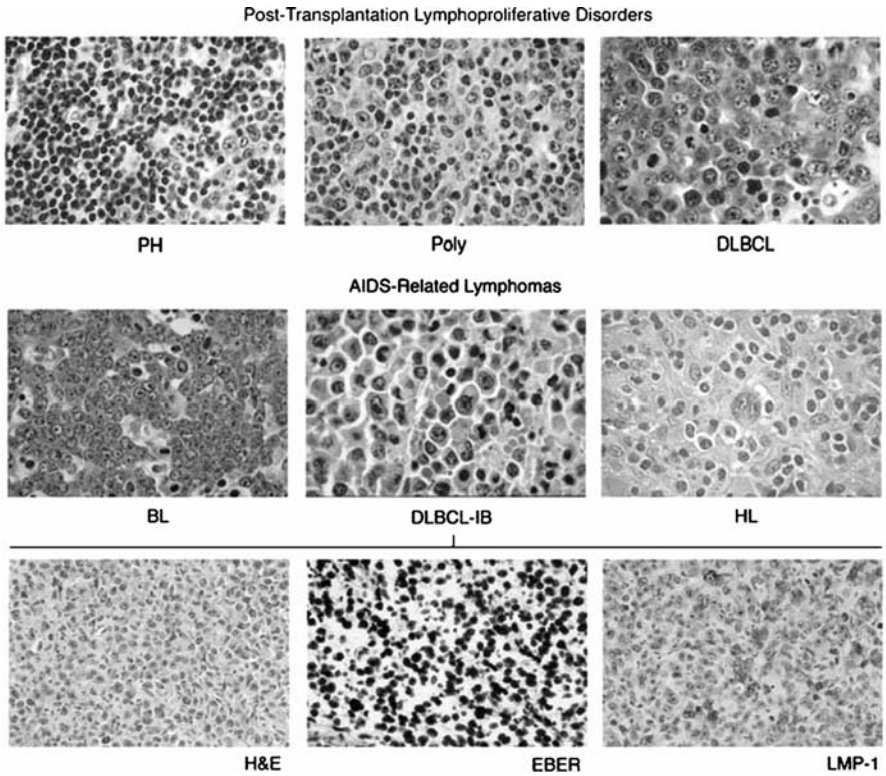

Fig. 50.2. Histopathology of EBV-associated diseases. Top row: Hematoxylin- and eosin- (H&E) stained sections of tissues involved by post-transplantation lymphoproliferative disorders are shown. These include an example of a plasmacytic hyperplasia, showing a majority of mature reactive lymphocytes with some immunoblasts and plasma cells; a polymorphic lymphoproliferative disorder, with a heterogeneous (polymorphic) cell population with atypical immunoblasts; and a diffuse large B-cell lymphoma, or monomorphic PTLD showing sheets of large neoplastic cells (original magnification 630 ×). Middle row: Examples of AIDS-related lymphomas, including: a Burkitt's lymphoma with sheets of medium-sized cells and a "starry sky" pattern due to macrophages with necrotic debris and mitotic figures; a diffuse large B-cell lymphoma with immunoblastic features (large atypical cells with an eccentric nucleus with a central prominent nucleolus and abundant cytoplasm); and an example of a Hodgkin's lymphoma with a classic Reed–Sternberg (original magnification 630 ×). Bottom row: EBV-positive AIDS-related lymphoma, H&E staining shows diffuse infiltration of neoplastic lymphocytes; in situ hybridization for EBER shows dark purple positivity in the majority of the nuclei; and immunohistochemistry for LMP-1 shows cytoplasmic positivity (brown) in many of the tumor cells (original magnification 100 ×).

Burkitt's lymphoma

This is a common childhood neoplasm in areas of Africa that are malarial (Magrath, 1997). The tumor typically arises in the jaw of young boys at the time that adult teeth are erupting. Orbital, abdominal and central nervous system involvement are common. The tumors grow exceedingly rapidly and respond to cytotoxic chemotherapy rapidly. They consist of a diffuse monotonous infiltration of B cells with many mitotic figures, as well as a high rate of spontaneous apoptosis (Fig. 50.2). A "starry sky" pattern is usually present, reflecting the presence of macrophages that have ingested apoptotic tumor cells. Immunophenotypically and genetically all morphologic forms of BL are similar: they express pan B-cell antigens such as CD19 and CD20 and are CD10 and BCL6 positive. Nearly 100% of the cells express the proliferation-associated marker Ki-67 (MIB-1).

In the endemic region, virtually all of the tumors are EBV associated. Studies suggest that antibody titers rise in anticipation of diagnosis. However, serology is not used clinically. The pattern of viral gene expression is very restricted (Niedobitek *et al.*, 1995). Most tumor cells express only latency genes. EBNA1 is expressed but not the other latency nuclear antigens or LMP1. LMP2 mRNA is detected by RT-PCR as well (Tao *et al.*, 1998). Molecular investigation of tumor tissue has shown that the promoters that drive expression of the latency nuclear antigens are densely

CpG methylated (Robertson *et al.*, 1996). In some instances, deletions of latency antigens have been documented (Kelly *et al.*, 2002). Burkitt's lymphoma cell lines are resistant to CD8 T-cell killing in vitro. This reflects their very restricted pattern of viral gene expression, a lack of surface adhesion molecules that facilitate recognition by T-cells, and a failure to process antigens for presentation in MHC class I complex (Moss *et al.*, 1999).

Although there is little doubt that malaria perturbs immune responses, it is not yet clear whether its contribution is mainly as a stimulus to B cell proliferation, as an immunosuppressive factor disrupting T-cell or NK-cell immune surveillance, or perhaps through an entirely different mechanism. Outside the endemic region of Africa, Burkitt's lymphomas are only variably (25%–80%) associated with EBV (Bacchi *et al.*, 1996). The limits of our knowledge are highlighted by the observation that in AIDS patients, the incidence of Burkitt's lymphoma is dramatically increased but these tumors occur in the least immunocompromised AIDS patients (CD4 T-cell >400) and are generally not EBV-associated (Carbone, 2003).

Post transplant lymphoproliferative disorders (PTLD)

Lymphoproliferative diseases arise in approximately 0.5 to 10% of solid organ and bone marrow or hematopoietic stem cell transplant recipients (Swinnen, 2001). The transplanted organ, the immunosuppressive regimen, and previous exposure to EBV are all determinants of risk. In organ transplant recipients tumor typically develops in host B-lymphocytes. The highest risk is associated with bowel transplantation, immunosuppression with OKT3 (a murine monoclonal antibody targeting CD3), and lack of prior exposure to EBV. In bone marrow transplant recipients, tumor typically develops in donor B-lymphocytes and the highest risk is associated with T-cell depletion of the bone marrow graft, high dose immunosuppression (again OKT3) and graft vs. host disease. The recipients' previous exposure to EBV appears to be irrelevant.

Lymphoproliferative diseases in transplant recipients have been classified as plasmacytic hyperplasia, polymorphic B-cell post-transplant lymphoproliferative disease, and monomorphic post-transplant lymphoproliferative disease (Chadburn *et al.*, 1995, 1998; Knowles *et al.*, 1995; Swerdlow, 1997). Histologically, plasmacytic hyperplasia resembles infectious mononucleosis, and is also referred to as infectious mononucleosis-like post-transplant lymphoproliferative disease. The main features are retention of the overall architecture of the tissue and presence of a mixed lymphoid population consisting primarily of lymphocytes, plasmacytoid lymphocytes, plasma cells and scattered immunoblasts; however, little or no cytologic atypia is present. The polymorphic lesions are characterized by destruction of the underlying architecture. These lesions are composed of a polymorphic (or heterogeneous) cell population, and vary from those that show extensive plasmacytic differentiation and minimal cytologic atypia to proliferations that lack plasmacytic differentiation and contain atypical immunoblasts. Individual cell necrosis to large areas of coagulative necrosis may be present. The monomorphic category includes diffuse large B cell lymphoma, Burkitt or Burkitt-like lymphoma, plasma cell myeloma, plasmacytoma and some peripheral T-cell lymphoma. In monomorphic lesions the histologic features are like those seen in immunocompetent individuals, and are classified according to standard criteria most recently described by the World Health Organization (Harris *et al.*, 1997).

EBV is usually associated with B cell lymphoproliferative disease in this setting with the exception of lesions arising several years after transplantation, which are most frequently monomorphic. T-cell lymphomas and Hodgkin's lymphoma in the post-transplant setting are also often EBV associated. As the classification implies these tumors are quite heterogeneous and many different patterns of viral antigen expression are recognized. In most series these tumors are associated almost exclusively type 1 virus (Frank *et al.*, 1995; Tao *et al.*, 2002). Some of these tumors, particularly the plasmacytic hyperplasias and polymorphic B cell post-transplant lymphoproliferative disease, express the full spectrum of antigens expressed by EBV-immortalized lymphoblastoid cell lines. They also express adhesion molecules, class I and class II molecules and are thus particularly susceptible to immune interventions.

The observation that in some cases of post-transplant lymphoma, tumor will regress if immunosuppression is withdrawn or reduced first suggested that lack of immune surveillance plays a critical role in the pathogenesis of these lesions (Porcu *et al.*, 2002; Starzl *et al.*, 1984). This idea was strengthened when it was demonstrated that adoptive cellular immunotherapy was effective in treatment and in the prevention of these tumors, particularly in the bone marrow transplant setting (Papadopoulos *et al.*, 1994; Rooney *et al.*, 1998).

Monitoring viral copy number in peripheral blood mononuclear cells, plasma or whole blood has shown that patients with post-transplant lymphoproliferative disease generally have higher copy numbers – although some patients without tumor also sustain very high viral loads (Rowe *et al.*, 2001; Yang *et al.*, 2000). Several investigators have advocated monitoring viral load as a guide to

immunosuppression or to "pre-emptive therapy" (Rowe *et al.*, 2001).

Anti-B cell antibodies have proven very useful in the management of post-transplant lymphoproliferative disease (Gruhn *et al.*, 2003; Yang *et al.*, 2000). A chimeric antibody directed against CD20, rituximab, is widely used in the treatment of B-cell lymphomas in general and is useful in the treatment of post-transplant lymphoma as well. This antibody rapidly depletes B cells in the peripheral blood and thus treatment is virtually always associated with a fall in EBV load as measured in peripheral blood mononuclear cells. However, this fall is independent of tumor response.

AIDS lymphomas

A large fraction of AIDS lymphomas are EBV associated. Brain lymphomas in AIDS patients are virtually always EBV-associated (Camilleri-Broet *et al.*, 1997; MacMahon *et al.*, 1991). Diffuse large B-cell lymphomas with immunoblastic features are also usually EBV-associated (Knowles, 1999).

Many of these tumors express the full spectrum of viral latency genes. In contrast, AIDS Burkitt's lymphoma and primary effusion lymphoma show highly restricted pattern of EBV gene expression (Horenstein *et al.*, 1997). The latter, while usually EBV associated are consistently KSHV associated and are discussed in more detail below. EBV-associated AIDS lymphomas are most common in patients with low CD4 T cell counts. In the case of primary central nervous system lymphomas, CD4 T cell counts were 10/ul in a recent cooperative group study (Ambinder *et al.*, 2003). However, it should be noted that this generalization only applies to non-Hodgkin's lymphomas in HIV patients. Hodgkin's lymphoma typically arises in HIV infected patients with CD4 T cell counts greater than 200 (Glaser *et al.*, 2003). EBV serology has not been found to be useful in identifying patients at risk for lymphoma insofar as virtually all HIV-infected patients with the exception of infants are EBV seropositive. Furthermore, EBV serology has not been helpful in the diagnosis of lymphoma in this setting. Similarly EBV copy number in peripheral blood mononuclear cells is elevated in HIV-infected patients and this elevation is not restricted to those with tumors (Van Baarle *et al.*, 2002). However, detection of viral DNA in cerebrospinal fluid is useful in the differential diagnosis of brain lymphoma in HIV patients (Antinori *et al.*, 1999; De Luca *et al.*, 1995).

Extranodal T/NK cell tumors

These lymphomas are often EBV-associated. They have been classified into nasal, intestinal, and subcutaneous panniculitis-like (Chan *et al.*, 1997; Chiang *et al.*, 1996; Jaffe *et al.*, 1999). Extranodal NK/T-cell lymphomas are characterized histologically by a diffuse lymphomatous infiltrate that is frequently angiocentric and angiodestructive. Coagulative necrosis and mucosal ulceration are common. The degree of association with EBV appears to be determined by both anatomic site and geography. Nasal lymphomas that express CD56 are most common in Asia and are almost always associated with EBV (Cheung *et al.*, 2003). EBV gene expression is similar to that of EBV-associated Hodgkin's lymphoma (EBNA1, LMP1 and LMP2 are expressed but not EBNA2, 3A, 3B, or 3C) (Chiang *et al.*, 1996). The presence of virus helps to distinguish the aggressive NK cell leukemias from more indolent NK lymphoproliferative disease (Gelb *et al.*, 1994).

Nasopharyngeal carcinoma

Most common in Cantonese, nasopharyngeal carcinoma also occurs in Arab, and Eskimo populations (Yu and Yuan, 2002). They typically present in middle age but sometimes occur in adolescents. EBV is consistently associated with the non-keratinizing and undifferentiated subtypes of nasopharyngeal carcinomas. Biopsies show lesions composed of large neoplastic epithelial cells disposed in a syncytium-like array. Abundant, normal appearing lymphocyes are admixed with the epithelial cells, giving rise to the misnomer of lymphoepithelioma. Well-differentiated tumors are often EBV associated as well (Pathmanathan *et al.*, 1995).

Nasopharyngeal carcinoma grows along nerve sheaths and invades the base of the brain and metastasize to lymphatics. Localized tumors are curable with radiation therapy. Metastatic tumors often respond to chemotherapy.

Nasopharyngeal carcinoma expresses a narrow spectrum of viral antigens with EBNA1, LMP2 and sometimes LMP1. NPC is associated with high antibody titers against many EBV antigens including lytic viral antigens (Connolly *et al.*, 2001; Milman *et al.*, 1985). The antibody profile is particularly distinctive because of the presence of IgA antibodies. Antibody titers begin arising years in advance of diagnosis and are sometimes used clinically in the evaluation of patients at high risk (perhaps because of several affected family members).

Viral DNA is present in plasma in patients with nasopharyngeal carcinoma and has emerged as a highly reliable guide to determining prognosis and monitoring therapy (Lin *et al.*, 2004; Lo *et al.*, 2000). This DNA is not encapsidated but is fragmented DNA released from tumor cells undergoing apoptosis (Chan *et al.*, 2003). Spontaneous apoptosis is an ongoing process in most rapidly growing

tumors. Radiation and chemotherapy accelerate the process. High levels of viral DNA in plasma at the start of therapy has emerged as the single most important prognostic factor, persistence of high levels in the face of therapy has emerged as a marker of relapse or progression (Chan *et al.*, 2002).

Except in Eskimo populations, these tumors are almost exclusively associated with type 1 virus (Raab-Traub, 2002). A "Chinese strain" has been identified with the number of variations, most notably in the carboxyterminus of the LMP-1 gene where a 30 bp deletion is characteristic.

Adoptive T cell therapy has been explored without much success, perhaps reflecting the very limited antigenic targets (Chua *et al.*, 2001; Moss *et al.*, 1999). There is an interesting preliminary report suggesting the possibility that peptide vaccination is efficacious (Lin *et al.*, 2002). Standard therapy involves external beam radiation often with cytotoxic chemotherapy.

Hodgkin's lymphoma

Approximately one third of Hodgkin's lymphomas are EBV-associated in North America and Western Europe, with a higher fraction in the rest of the world approaching 100% in areas of Africa and Latin America (Ambinder *et al.*, 1993; Chang *et al.*, 1993; Glaser *et al.*, 1997). The tumor usually arises in young adults (15–35 years) with the age incidence curve varying somewhat in different regions of the world. The disease most commonly presents as cervical or supraclavicular lymphadenopathy, may be associated with fevers and night sweats and can often be cured with chemotherapy, radiation therapy or combined modality therapy.

Infectious mononucleosis was recognized as a risk factor long before EBV was recognized as the cause of infectious mononucleosis (Grufferman and Delzell, 1984). A recent study has shown that infectious mononucleosis is associated with an increased incidence of EBV-associated Hodgkin's lymphoma but not other Hodgkin's lymphoma (Hjalgrim *et al.*, 2003). The typical interval between symptomatic primary infection and diagnosis of Hodgkin's lymphoma is 2 to 3 years, but increased risk continues for up to 20 years.

The diagnostic hallmark of Hodgkin's lymphoma is the presence of a minority of neoplastic cells, Reed–Sternberg cells, in a background of non-neoplastic cells. The two major subtypes of Hodgkin's lymphoma are the classical and the lymphocyte predominant forms, but only the former is associated with EBV infection. The histologic subtypes of classical HL are nodular sclerosis, mixed cellularity, lymphocyte rich classical, and lymphocyte depleted. EBV is most frequently associated with the mixed cellularity subtype, and also lymphocyte depleted, especially in the context of HIV infection. While the tumor cells are of B cell origin, B cell antigens like CD20, CD79A and immunoglobulin are frequently negative or weakly expressed. The B cell-specific activator protein (BSAP)/PAX5 can usually be detected by immunohistochemistry. EBV can be detected by in situ hybridization for EBER when present. In these cases, immunohistochemistry can detect expression of LMP-1 and EBNA-1, without EBNA-2.

Although viral antibody titers in patients with newly diagnosed Hodgkin's lymphoma differ from healthy counterparts, the differences are sufficiently small that they have no clinical utility (Chang *et al.*, 2004). Studies are ongoing to determine whether viral DNA in plasma has the same significance in Hodgkin's lymphoma that it does in nasopharyngeal carcinoma.

Gastric cancers

Carcinomas of the stomach, particularly those arising in the gastric antrum carry EBV episomes and express EBNA1 in approximately 10–15% of cases. The incidence of this malignancy varies widely with higher incidences particularly in Japan. However, the percentage of cases associated with virus seems to be relatively constant whether tumors from high or low incidence populations are being studied (Fukayama *et al.*, 1998; Takada, 2000). Although only a minority of these tumors are EBV associated, gastric carcinoma is one of the more common tumors world wide and EBV-associated gastric cancers may well be the most common EBV-associated malignancy when considered globally.

Other EBV-associated tumors

Leiomyosarcomas in the immunocompromised (organ transplant recipients, HIV-infected patients and patients with congenital immunodeficiency) are extraordinarily rare tumors but seem to be commonly EBV-associated (McClain *et al.*, 2000; Reyes *et al.*, 2002; van Gelder *et al.*, 1995). Their pattern of viral gene expression has only had limited study due to their rarity but appears to be distinctive with expression of EBNA-2 but not LMP-1. Lymphomatoid granulomatosis is an EBV-associated B cell lymphoproliferative disease that often involves skin, lungs, brain, kidney and other organs. It is associated with systemic symptoms and areas of necrosis within the tumor. The disease generally arises in older patients. As with leiomyosarcomas the disease is so rare that studies of antigen expression are quite limited. Undifferentiated thymic carcinomas resemble nasopharyngeal carcinomas histologically and are generally EBV-associated.

Breast cancer, hepatocellular cancer, thymoma and other tumors

A multitude of other tumors have been linked with EBV. Breast cancer in particular has received a great deal of attention (Bonnet *et al.*, 1999; Labrecque *et al.*, 1995). Reports suggested that viral nucleic aids and proteins could be found in a large percentage of tumors by Western blot and by in situ hybridization. However, a whole series of studies have either failed to confirm the initial reports or have offered alternate explanations such as cross-reacting antibodies or increased tendency to lytic infection in malignant tissues (Glaser *et al.*, 1998; Huang *et al.*, 2003; Murray *et al.*, 2003). Similarly, there have been reports of EBV in hepatocellular cancer, thymoma and several other malignancies that have not generally been confirmed.

The clinical importance of the viral association

Many of the tumors above are only sometimes associated with EBV, with the determinants of association varying from cofactors such as malaria (Burkitt's lymphoma) to AIDS (brain lymphoma) to other factors (Hodgkin's lymphoma). Although the detection of EBV in the tumor is sometimes useful in helping to establish a diagnosis (as in brain lymphoma in AIDS patients), there are few clinical settings in which the detection of virus per se clearly alters the prognosis or therapy. Evidence has been presented that survival in older patients may be poorer in Hodgkin's lymphoma associated with EBV than in that not associated, but definitive studies in this regard are still lacking and no one has yet advocated different primary therapy for Hodgkin's as a function of EBV status (Clarke *et al.*, 2001). For patients who have failed standard therapies, novel approaches to therapy are being explored. In some instances these approaches involve adoptive immunotherapy, in others activation of viral gene expression. Activation of viral gene expression might lead either to direct cell killing, to expression of dominant viral antigens that might render tumor cells more susceptible to immune surveillance or to sensitization to ganciclovir or similar agents whose cytotoxic activity is dependent on phosphorylation by viral kinases (Chan *et al.*, 2004; Moore *et al.*, 2001; Feng *et al.*, 2004; Ambinder *et al.*, 1996).

KSHV

Endemic in sub-Saharan Africa and in regions near the Mediterranean Sea, KSHV-seropositivity is rare in most parts of the world (Chatlynne *et al.*, 1998; Gao *et al.*, 1996). The virus is transmitted in childhood within families in endemic regions, through sexual contacts in adults in high risk groups (Kedes *et al.*, 1996; Martin *et al.*, 1998; Smith *et al.*, 1999). KSHV is commonly detected in the saliva in seropositives and salivary transmission is likely (Ablashi *et al.*, 2002; Koelle *et al.*, 1997). Some investigators have specifically implicated receptive anal intercourse, oral-genital contact, or oral-anal contact in virus transmission (Dukers *et al.*, 2000; Grulich *et al.*, 1999). Although viral DNA has been detected in seminal fluid, relatively infrequent detection in comparison with saliva and low copy number make the role of seminal fluid in transmission uncertain (Pellett *et al.*, 1999).

Primary KSHV infection

A febrile illness and maculopapular rash may be associated with primary infection in children without immunocompromise (Andreoni *et al.*, 2002). Lymphadenopathy has been associated with seroconversion in men who have sex with men (Casper *et al.*, 2002). Fever, lymphoid hyperplasia, splenomegaly and pancytopenia have been reported in organ transplant recipients (Luppi *et al.*, 2003).

KSHV-associated angioproliferative and lymphoproliferative disorders

The virus was originally discovered in Kaposi's sarcoma (Chang *et al.*, 1994). It is also present in multicentric Castleman's disease and associated plasmablastic lymphoma, and primary effusion lymphoma (PEL).

Kaposi's sarcoma

First described in older men of Mediterranean descent, Kaposi's sarcoma also occurs in regions of Africa where it afflicts children as well as adults, in immunocompromised organ transplant recipients and in HIV-infected individuals. In the latter setting, it is one of the defining illnesses of AIDS and is the most common associated malignancy.

Kaposi's sarcoma lesions often involve the skin or mucous membranes and appear as flat violaceous plaques or nodules. Lesions are generally not painful (except occasionally when they involve the plantar surface of the feet). Skin lesions often appear on the lower legs and it has been hypothesized that this reflects a predilection for relatively hypoxic regions of the body (Haque *et al.*, 2003). Although Kaposi's sarcoma lesions are often disfiguring, and associated edema may be a source of discomfort, they are rarely painful and rarely a cause of death (Fig. 50.3). Lesions commonly involve the gastrointestinal tract and the lungs. The appearance is sufficiently characteristic that

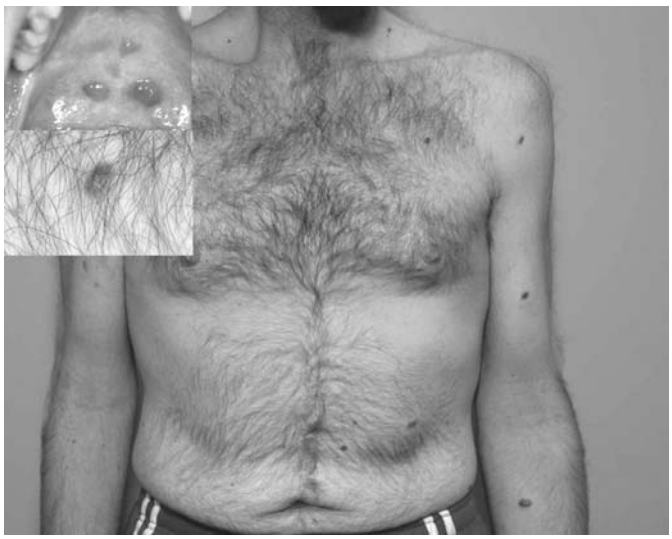

Fig. 50.3. Kaposi's sarcoma. Lesions are often scattered over the trunk and lower extremities. Their appearance is violaceous as a consequence of their neovascularity. The insets show Involvement of the hard palate (top) and a close up of a cutaneous lesion (bottom).

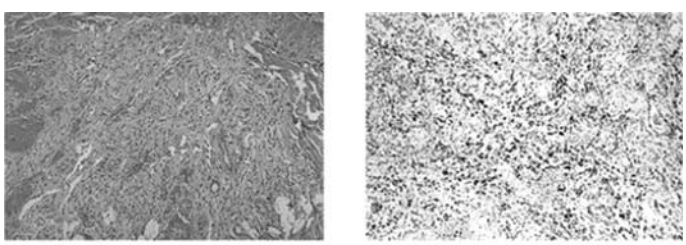

Fig. 50.4. Histological section stained with hematoxylin and eosin of a nodular tumor stage lesion of KS. Note the spindle cell proliferation and abundant vasculature. KSHV LANA (ORF-73) expression in KS. Staining with a rat monoclonal antibody revealed LANA positivity (diaminobenzidine, brown) in the nuclei of many spindle cells in a KS lesion. Positivity was also identified in endothelial cells lining the larger vascular spaces that may represent lymphatic vessels (original magnification 100 ×).

biopsy confirmation is not always necessary. Gastrointestinal lesions may be associated with hemorrhage, diarrhea, or obstruction; while pulmonary lesions may lead to fatal respiratory compromise.

The histologic characteristics of the lesions are similar across different affected populations. There are variable mixtures of ectatic, irregularly shaped, round capillary and slit-like endothelial-lined vascular spaces and spindle-shaped cells often with an inflammatory mononuclear cell infiltrate (Fig. 50.4). Red blood cells and hemosiderin pigment are frequently present, often extravasated between the spindle cells. Small granules of intracytoplasmic or extracellular hyalin material may be identified. In early lesions, the spindle cells are low in number compared to the surrounding inflammatory cells. Sometimes the earliest patch and plaque stage lesions are difficult to distinguish from granulation tissue. The spindle cells eventually become the predominant cell population, forming fascicles that compress the vascular slits, and the lesions become progressively nodular (Cockerell, 1991; Lever and Schaumburg-Lever, 1990).

Immunohistochemistry using monoclonal antibodies to LANA, shows that the viral protein is invariably expressed in Kaposi's sarcoma lesions. Nuclear staining with a speckled pattern can be seen in a variable proportion of the spindle cells, endothelial cells lining vascular spaces and in a very small proportion infiltrating CD45+/CD68+ monocytes (Katano *et al.*, 1999; Kellam *et al.*, 1999a,b; Parravicini *et al.*, 2000). Most spindle cells show expression of a restricted set of viral proteins, although a small percentage of cells express lytic antigens (Cannon *et al.*, 1999; Chiou *et al.*, 2002). It has been suggested that these lytic proteins may exert a paracrine effect on surrounding cells.

Spindle cells are thought to originate from circulating peripheral-blood hematopoietic precursor cells (Dupin *et al.*, 1999). In organ transplant recipients, tumor spindle cells may be of donor origin (Barozzi *et al.*, 2003). KS lesions are clonal in at least some instances Rabkin *et al.*, 1997; Gill *et al.*, 1998). There is the possibility that KS begins as a polyclonal inflammatory lesion that sometimes progresses to oligoclonal or monoclonal neoplasia.

Treatment

Asymptomatic lesions do not always require treatment. In AIDS patients, lesions may regress or stabilize with control of HIV (Krown, 2004). Lesions may be treated topically, with a retinoid cream, injections of cytotoxic agents, or irradiation. Disseminated and visceral disease may respond to systemic treatment with alpha interferon or cytotoxic chemotherapy. Liposomal formulations of anthracyclines have proven particularly useful. These agents which are generally not associated with either nausea or alopecia are generally very well tolerated. Paclitaxel is also very active but is often reserved for second-line treatment because of its toxicity profile with severe myalgias and nausea common. There is no established role for antiherpesviral agents such as foscarnate, ganciclovir or cidofuvir in the management of KS, although there is an intriguing report that

ganciclovir may reduce the incidence of KS in HIV patients being treated for cytomegalovirus retinitis (Robles *et al.*, 1990; Martin *et al.*, 1990).

Castleman's disease and plasmablastic lymphomas

Castleman's disease is a poorly understood atypical lymphoproliferative disorder, usually described as a polyclonal, non-neoplastic condition. Two distinct histopathologic subtypes had been reported before the identification of KSHV. The hyaline vascular type, by far more common, and the plasma cell type.

Castleman's disease can be localized or may be multicentric involving many lymph node groups and spleen. Multicentric Castleman's disease (MCD) is characterized by recurrent fevers, lymphadenopathy, hepatosplenomegaly, autoimmune phenomena and not infrequently progresses to lymphoma or Kaposi's sarcoma, consistent with an association with KSHV infection (Soulier *et al.*, 1995). MCD, also called multicentric angiofollicular hyperplasia, is characterized by a vascular proliferation in the germinal centers, which is reminiscent of KS (Fig. 50.5). In fact, the presence of a lymph node containing both KS and Castleman's disease is not uncommon in HIV-positive patients.

The histologic appearance of Castleman's disease is quite different in the hyaline vascular and plasma cell types. The former is characterized by enlarged lymphoid follicles, small hyalinized germinal centers within an expanded concentric mantle of small lymphocytes, as well as a highly vascularized interfollicular network. In contrast, in the plasma cell type the germinal centers resemble those of follicular hyperplasia, and are composed of a mixture of cleaved and non-cleaved small and large lymphocytes with varying numbers of tingible body macrophages and mitotic figures. The mantle zone is usually intact, and is surrounded by sheets of mature-appearing plasma cells. Transition cases can occur. Both hyaline vascular changes and classic reactive follicles can occur in continuity, both follicle types exhibit the diagnostic onion-skinning of the mantle zones. There is a blurring of the histotypes and these may represent in many cases temporal manifestations of the same disease. Early studies reported the plasma cells to be polytypic in the majority of cases, but in close to 40% of the cases they have been shown to be monotypic, almost always restricted to expression of lambda light chains (Hall *et al.*, 1989).

Since the identification of KSHV in MCD, the understanding of the histology of this disease has changed. While KSHV has been reported in MCD with both hyaline vascular and plasma cell morphology (Larroche *et al.*, 2002), it appears that the majority of cases described in the literature more closely resemble the plasma cell type of MCD. One report indicates that the KSHV-positive cases showed the highest intensity of angiosclerosis and germinal center and perifollicular vascular proliferation, while plasmacytosis is less pronounced than in the KSHV-negative

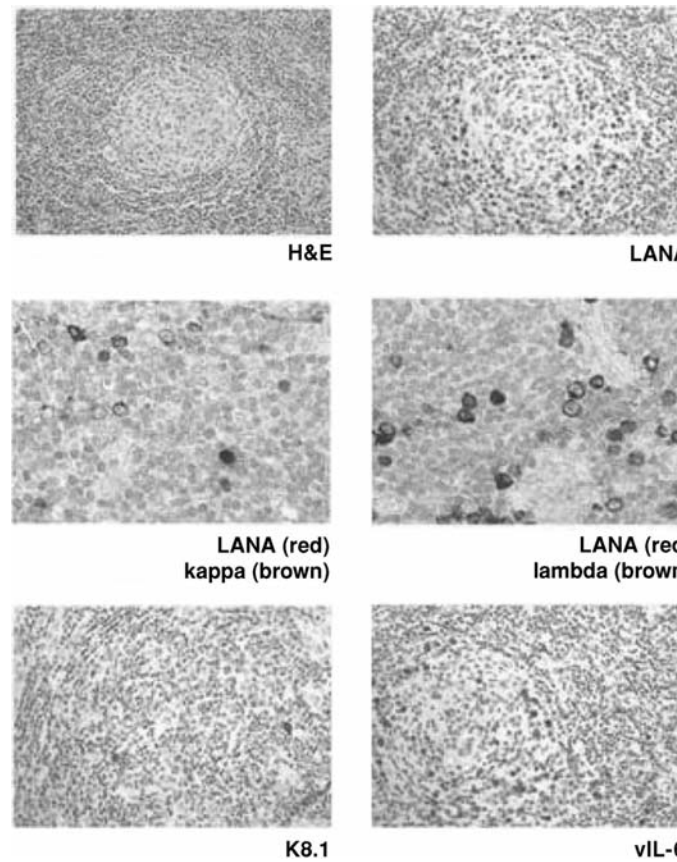

Fig. 50.5. Multicentric Castleman's disease: hematoxylin- and eosin- (H&E) stained section of a lymph node with HIV-associated Castleman's disease showing a single follicle with a large, concentrically arranged mantle zone surrounding a germinal center. The interfollicular area contains a network of small vessels (original magnification 100 ×). Immunohistochemical staining with the following antibodies is shown: LANA (ORF 73), a monoclonal rat antibody was used, showing brown nuclear positivity in cells in the mantle zone (original magnification 100 ×); LANA and kappa, double staining showed nuclear positivity (red staining) in cells that are negative for cytoplasmic kappa (brown staining); LANA and lambda, double staining shows cells that are positive for nuclear LANA (red staining) as well as cytoplasmic lambda (brown staining) (original magnification 400 ×); K8.1, a monoclonal antibody shows cytoplasmic positivity (brown staining) in two cells that are undergoing lytic viral replication (original magnification 100 ×); vIL-6, cytoplasmic staining using a rabbit polyclonal antiserum shows positivity in numerous cells in the mantle zone (original magnification 100 ×).

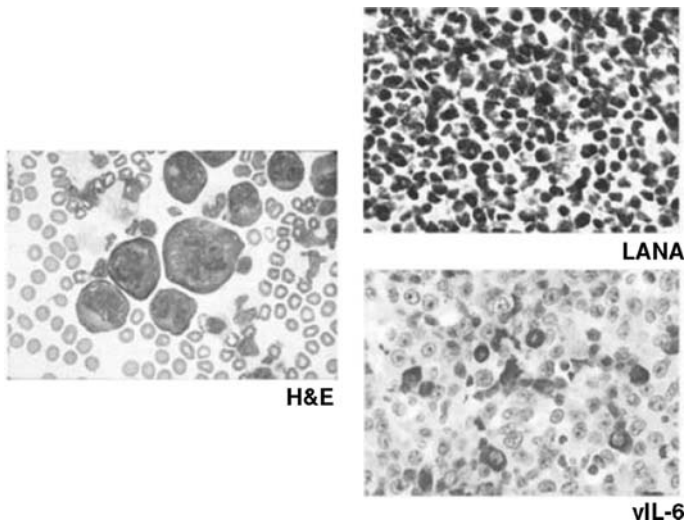

Fig. 50.6. Primary effusion lymphoma: Wright-Giemsa stain air-dried cytocentrifuge preparation of a KSHV-positive primary effusion lymphoma. The tumor cells in this image are considerably larger than normal benign lymphocytes and monocytes. The cells display significant polymorphism and possess moderately abundant basophilic cytoplasm. A prominent, clear perinuclear Golgi zone can be appreciated in several cells. The nuclei vary from large and round to highly irregular, multilobated, and pleomorphic and often contain one or more prominent nucleoli (original magnification 1000 ×). Immunohistochemical staining with the following antibodies is shown: LANA (ORF 73), a monoclonal rat antibody was used, showing brown speckled nuclear positivity in all the neoplastic cells; vIL-6, immunohistochemical staining with a polyclonal rabbit antiserum shows abundant cytoplasmic expression (brown) in many lymphoma cells (original magnification 400 ×).

cases of the plasma cell type (Suda *et al.*, 2001). It now appears that the KSHV-positive cases represent a distinct morphologic variant, resembling more the plasma cell type, but in addition showing the presence of larger cells in the mantle zones, which are approximately twice the size of mantle zone lymphocytes, and characterized by a moderate amount of amphophilic cytoplasm and a large vesicular nucleus containing one or sometimes two prominent nucleoli. These cells have been called plasmablasts, although they frequently have immunoblastic features (Dupin *et al.*, 2000). Expression of IgM can be used to distinguish these plasmablasts from the interfollicular plasma cells that don't express IgM. These cells can be numerous and coalesce.

Immunohistochemistry for KSHV has become a useful diagnostic method for MCD. Monoclonal antibodies to LANA (Dupin *et al.*, 1999) show the presence of KSHV-positive cells, which are the plasmablasts located mostly in the mantle zones of lymph nodes of patients with MCD. These KSHV-infected plasmablasts are B cells that for some unknown reason are monotypic but polyclonal, almost invariably expressing IgMλ (Du *et al.*, 2001). KSHV-positive lymphocytes can also be seen spilling into the germinal centers and in interfollicular areas. One study showed that KSHV-positive endothelial cells can also be found in MCD lymph nodes, in both HIV-positive and -negative patients (Brousset *et al.*, 2001). In addition antibodies to vIL-6 are useful, as this viral protein is also frequently expressed in MCD in scattered plasmablasts surrounding the lymphoid follicles (Cannon *et al.*, 1999a,b; Parravinci *et al.*, 1997; Staskus *et al.*, 1999), and expression of this viral cytokine may confer a worse prognosis (Menke *et al.*, 2002). Lytic antigens are also expressed more frequently in KSHV-infected cells in MCD that in other disorders associated with this virus, suggesting that lytic viral replication may be a feature of MCD (Katano *et al.*, 2000).

Therapy for Castleman's disease remains ill-defined. However, evidence of lytic viral expression has led some to advocate ganciclovir or other antiviral therapy. Indeed, there are small anecdotal reports that indicate responses to ganciclovir (Casper *et al.*, 2004). Other therapies targeting the tissue compartment harboring the virus have also been associated with responses. These include the use of an anti-B-cell antibody rituximab or splenectomy (Corbellino *et al.*, 2001; Lerza *et al.*, 1999; Marcelin *et al.*, 2003).

Primary effusion lymphoma and related lymphomas

Primary effusion lymphomas arise mainly in patients with HIV infection and preferentially involve body cavities and occasionally extranodal sites. These tumors always carry KSHV and are commonly coinfected by EBV. The classical presentation is with signs and symptoms of an effusion in the absence of a tumor mass (Nador *et al.*, 1996). The cells in the effusion are large, have abundant cytoplasm, usually amphophilic to basophilic, and nuclei that range from large, round and regular to highly irregular and pleomorphic, with one or more large prominent nucleoli (Fig. 50.6) (Cesarman *et al.*, 1995). Many cells have plasmacytoid or immunoblastic features. Binucleated or multinucleated cells resemble Reed–Sternberg cells can be seen. Mitotic figures are typically numerous. The immunophenotype is characteristic, as PEL cells express of CD45, CD138 and one or more activation-associated antigens in the frequent absence of B cell-associated antigens and immunoglobulin expression. A B cell origin can be demonstrated by the presence of clonal immunoglobulin gene rearrangements, and the immunoglobulin genes show somatic hypermutation indicating a postgerminal cell stage of differentiation.

Immununohistochemistry shows the presence of LANA and other KSHV proteins in a variable proportion of neoplastic cells, in particular vIL-6. In addition, the majority of PELs are coinfected with EBV, which can be detected by in situ hybridization to EBERs.

Lymphomas containing KSHV can also present as solid tissue masses, usually extranodally, similar to other AIDS-related non-Hodgkin's lymphomas. While some of these lymphomas subsequently develop an effusion, others apparently do not. They usually present as solid extranodal lymphomas and are diagnosed as diffuse large cell, immunoblastic, or anaplastic large cell lymphomas, in which the presence of KSHV in practically all the lymphoma cells could be demonstrated by immunohistochemistry or molecular techniques (Chadburn *et al.*, 2004; Engels *et al.*, 2003). Most of these are immunoblastic in appearance, have a high mitotic rate and variable amounts off apoptotic debris. These lymphomas appear to fall in the spectrum of PEL, as they usually lack expression of B cell antigens and immunoglobulin, they have a similar morphology, and they are frequently co-infected with EBV.

Survival with conventional chemotherapy is dismal, with the reported median survival time less than 6 months (Boulanger, 2005).

Several diseases have been purportedly linked to KSHV. In multiple myeloma patients, the virus was not reported to be in tumor cells but in the associated bone marrow stroma (Rettig *et al.*, 1997; Said *et al.*, 1997). There was the suggestion that production of viral interleukin-6 or cellular interleukin-6 by the stromal cells drove B-cells in the marrow to malignancy. However, many investigators have failed to confirm these findings (Ablashi *et al.*, 2000; Bellos *et al.*, 1999; Brander *et al.*, 2002; Corbellino *et al.*, 1999; Dominici *et al.*, 2000; Drabick *et al.*, 2002; Tarte *et al.*, 1999; Pan *et al.*, 2001). Similarly associations of KSHV with sarcoidosis (Di Alberti *et al.*, 1997) and pulmonary hypertension (Cool *et al.*, 2003) have been reported. Confirmation of a general association with either disease process is lacking (Henke-Gendo *et al.*, 2004; Lebbe *et al.*, 1999; Maeda *et al.*, 2000; Moore, 1998; Regamey *et al.*, 1998; Sugaya *et al.*, 1999).

Conclusions

The human gammaherpesvirus-associated diseases are quite distinct from those associated with other herpesviruses. Rather than tissue destruction in association with lytic infection such as is characteristic of the alpha and beta herpesviruses, the gammaherpesviruses are associated with proliferative diseases and malignancies. The seroprevalence of EBV and KSHV is much more widespread than the associated proliferative diseases. Several of these are most common in immunocompromised patients, but other gammaherpesvirus-associated tumors arise in hosts that are not globally immunocompromised. The host genetic and environmental determinants of disease beyond immunocompromise are poorly understood. Detection of viral nucleic acid or proteins is important in the diagnosis of some of the lymphomas and lymphoproliferative disease. Treatment with virus-specific therapies is still in its infancy. Antivirals that target the viral DNA polymerase such as acyclovir and ganciclovir have very limited if any impact on benign or malignant disease, although there is a hint that these agents may reduce the incidence of tumorigenesis in high risk populations. Two exceptions might be noted: oral hairy leukoplakia clearly responds to antiviral therapy and anecdotal reports suggest that Castleman's disease may also. Adoptive cellular immunotherapies appear to hold promise and have achieved some impressive successes in the bone marrow transplant population in the prevention and treatment of lymphoproliferative disease.

EBV: immunobiology and host response

Denis J. Moss, Scott R. Burrows, and Rajiv Khanna

Infectious Disease and Immunology Division, Queensland Institute of Medical Research and Joint Oncology Program, University of Queensland, Australia

Introduction

The biology and immunology of Epstein–Barr virus (EBV) has continued to fascinate researchers because the lessons learnt provide a platform for understanding the interplay between the biology of this ubiquitous infection, the immune system seeking to restrict its spread and the emergence of a variety of malignancies. As with other gamma herpes viruses, EBV encodes a large set of lytic cycle genes together with a number of latent genes which are associated with expansion of the latent EBV pool in B-lymphocytes. Current evidence suggests that the virus gains entry into the body by infection of B-lymphocytes in the oral cavity via an interaction between the major viral glycoprotein gp340 and the complement receptor CR2 which is expressed on B-cells, although a role for CR2-expressing or non-expressing epithelial and/or T-cells cannot be totally discounted. In either case, evidence suggests that the earliest detectable event following primary infection is the expression of lytic cycle proteins resulting in the release of infectious virus into the oral cavity followed by a generalized seeding of latently infected B-lymphocytes throughout the body. This primary infection results in symptoms of acute infectious mononucleosis (IM) in about 50% of adolescents and is coincident with a marked lymphocytosis (dominated by EBV-specific cytotoxic T-cells) and the appearance of an IgM response to a variety of EBV proteins, most notably the viral capsid antigen, VCA. Current evidence suggests that this cytotoxic T-cell (CTL) response, which includes both CD4+ and CD8+ cells restricts expansion of these latently infected B-cells and results in a long-term carrier state in which there is an equilibrium between the level of secretion of the virus and the number of latently infected B-cells.

Latently infected B cells are of central importance in the overall biology of the virus, and the function of individual latent proteins has been studied in EBV transformed lymphoblastoid cell lines (LCLs). The virus expresses eight EBV latent genes including six nuclear proteins (EBNA1, 2, 3A, 3B, LP and 3C) and two integral membrane proteins (LMP1 and LMP2). Furthermore, virus-infected cells invariably express two small polyadenylated RNAs (EBER-1 and -2) which are often used as a sensitive marker for the presence of EBV within a cell. The nature of the long-term latent infection in vivo has been subject to considerable speculation but is likely to include expression of a limited number of proteins (EBNA1 and LMP1) in a B-cell pool that maintains a phenotype that is poorly recognized by CTL. Thus the virus appears to have evolved so that apart from the clinical effects of IM (which appears to be historically a relatively recent syndrome), most individuals suffer no consequences from carrying a small nucleus of latently infected B-cells which appear to be resistant to CTL recognition and which can, under certain circumstances be reactivated to release relatively low levels of virus into the oral cavity.

The dynamics of the establishment of this small pool of long-lived latently infected B-cells and the CTL response is poorly understood but involves a selection process imposed by the CTL response which recognizes and eliminates B cells with a full complement of latent antigens and a relatively rare differentiation step that permits the emergence of a long-lived memory B cell pool that is resistant to specific lysis and whose phenotype supports the expression of EBNA1 and LMP1. It appears however, that this seemingly elegant balance that ensures the long-term survival of the virus is subject to error on certain occasions resulting in the emergence of EBV-driven B cell malignancies.

These B cell malignancies are classified in terms of the degree of latent antigen expression. Burkitt's lymphoma (BL) is at one end of the spectrum and is characterized by the expression of a single EBV protein (EBNA1 whose phenotype suggests a germinal centre origin (latency 1).

BL cells are well adapted to escape CTL recognition since they have down-regulated expression of class I MHC and of the transporters associated with antigen processing (TAP-1 and/or TAP-2) genes. Furthermore, EBNA1 has a series of glycine-alanine repeat (GAr) sequences that are speculated to exert an inhibitory effect on the endogenous processing of this antigen through class I although it appears this inhibition can be over-ridden in vivo, since both CD4+ and CD8+ EBNA1-specific CTLs have been detected in healthy virus carriers.

Hodgkin's disease (HD) is a second EBV-associated B cell malignancy. In this case, the tumor cell is derived from a post-germinal center B cell and is characterized by expression of EBNA1 and LMP1 and 2 (latency II). It is interesting that the degree of association of HD with EBV is variable according to the histological sub-type ranging from 80% in the case of mixed cellularity to 20% in the case of nodular sclerosing. This difference between histological types presumably reflects the efficiency with which this form of EBV latency has adapted to each of the respective environments associated with these different histological sub-types.

Latency III malignancies have arisen as a result of intense immunosuppression which have prevented the usual efficient culling of B-cells expressing a full spectrum of latent EBV proteins rather than an exploitation of the virus to a new phenotypic niche. These malignancies arise in transplant patients (particularly EBV seronegative graft recipients) and in late stage AIDS patients and in each case the latently-infected B-cell is clearly post-germinal center in origin.

EBV has also adapted to establishing malignancies in a non-B cell environment. Examples of non-B-cell malignancies includes a range of epithelial tumors the clinically most important of which is nasopharyngeal carcinoma (NPC). This malignancy which has a latency II phenotype is most common in south-east Asia, north Africa and Greenland with a low incidence throughout the rest of the world.

The review discusses the role of the EBV-specific CTL response in controlling EBV-infected cells in each of these latency types. Particular attention will be given to newly emerging concepts rather than re-emphasizing historical aspects of EBV immunology which have been well summarized in a series of reviews in the past 10 years (Rickinson and Kieff, 1996; Khanna and Burrows, 2000)

Response during acute infection

The identification of CTL epitopes within EBV proteins was based largely on techniques that favored the definition of $CD8^+$ CTL within EBV latent proteins. In part this has been due to an analysis of the CTL response emerging from *in vitro* cultures of PBMC from healthy immune individuals stimulated with autologous LCLs which express EBV latent rather than lytic proteins. In spite of these limitations and the obvious skewing of defined epitopes towards those in latent proteins, a number of lytic cycle epitopes have been defined and have provided a platform for an analysis of the CTL response seen during acute infection and redistribution of this response in healthy individuals although there are certainly indications that the response during acute compared to silent seroconversion may be fundamentally different. The lymphocytosis seen during acute infection can result in a ten fold increase in T-cell numbers and is characterized by cells with an activated phenotype (CD38, HLA DR and CD69) (Callan *et al.*, 1998; Bharadwaj *et al.*, 2001) (Fig. 51.1). These cells also express surface markers with a memory or effector phenotype (i.e., perforin, CD27, CD45RO), lack of expression of CCR7 (Sallusto *et al.*, 1999; Callan *et al.*, 2000; Hislop *et al.*, 2002) and are known to be susceptible to apopotosis after a brief period of in vitro culture (Moss *et al.*, 1985; Bishop *et al.*, 1985). It is not surprising that, during acute infection, which is characterized by high levels of EBV secretion in the oral cavity and high levels of lytic antigen expression in certain lymphoid tissue, the CTL response is directed largely towards lytic proteins. Immediate early gene products in particular have been shown to generate potent responses when visualized by HLA class I tetramer staining of PBMCs from IM patients (Callan *et al.*, 1998; Hislop *et al.*, 2002). Responses to epitopes from the early gene products, such as those derived from BMLF1 and BMRF1 are generally smaller than responses to the immediate early proteins but can still represent up to 12%

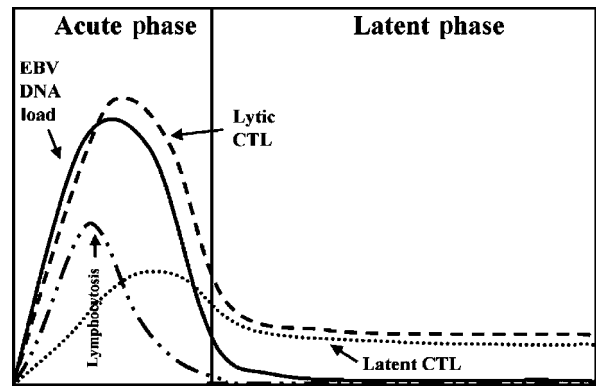

Fig. 51.1. Diagrammatic representation of the dynamics of the activation of a CTL response to EBV lytic and latent proteins in acute primary infection compared to long-term healthy immune individuals. These immune parameters are also shown in relation to EBV viral load and lymphocytosis.

	Gene Name	Protein Name	Function
Immediate early	BZLF1	Zta (Zebra)	Transcription activator
	BRLF1	Rta	Transcription activator
Early	BMLF1	Mta, EB2, SM	mRNA export factor
	BMRF1	EA-D, p54	DNA polymerase processing factor
	BALF2	p138	Single-stranded DNA binding protein
	BALF5	-	DNA polymerase catalytic subunit
	BHRF1	-	Anti-apoptotic protein
	BHLF1	-	oriLyt promoter
Late	BLLF1	gp 350/220	Viral glycoprotein
	BXLF2	gp 85, gH	Virus attachment/penetration
	BDLF3	gp 150	Unknown function
	BALF4	gp 110	Virulence factor/virus maturation
	BCRF1	vIL-10	Inhibits immuneparameters

Fig. 51.2. Diagrammatic representation of the relative strength of EBV immediate early, early and late lytic proteins. The ascribed function of each of these proteins is also listed as an insert.

of the $CD8^+$ population (Annels *et al.*, 2000; Callan *et al.*, 1998; Hislop *et al.*, 2002). Current indications are that the response to late cycle lytic proteins is smaller than the response to either the early lytic cycle proteins or to the latent proteins, although it can contribute up to 3% of the $CD8^+$ response during acute infection (Steven *et al.*, 1996; Annels *et al.*, 2000; Hislop *et al.*, 2001). Overall the relative strength of the CTL response between different EBV lytic proteins (shown diagrammatically in Fig. 51.2) raises the possibility that the magnitude of the response is dictated by their order of synthesis. Although there is the general impression that the overall response in acute infection is extremely focused, it needs to be stressed that there are a relatively modest number of lytic cycle epitopes defined and the contribution of CTL reactivity during acute infection within the majority of these proteins is undefined. However, it should be pointed out that recent results have cast some doubt on the in vivo significance of functional significance of the T cell responses to lytic proteins. These reservations are based on the observation that expression of lytic proteins may result in the down-regulation of both class I MHC and TAP proteins (Ressing *et al.*, 2005).

As mentioned previously, much of what is known about the immune parameters established during primary infection has been inferred from individuals undergoing acute IM. A study (Silins *et al.*, 2001) of a small cohort of adolescent EBV-seronegative individuals undergoing asymptomatic primary infection has provided some insight into the immunobiology of the silent primary infection experienced by the majority of individuals. Such individuals did not develop a significant T-cell lymphocytosis in spite of the presence of EBV viral loads comparable to that seen during acute infection raising the possibility that symptomatic seroconversion is associated with the release of cytokines from the activated T-cell expansions rather than developing as a result of virus-induced pathology. These

studies reveal a striking difference in the degree of TCR diversity seen in those undergoing symptomatic EBV seroconversion compared to those undergoing silent seroconversion. It appears that an oligoclonal TCR repertoire during primary infection is associated with the appearance of clinical symptoms whereas a polyclonal response predisposes towards silent seroconversion..

Response in healthy virus carriers

As the T-cell lymphocytosis resolves during convalescence, there is a reduction in the number of T-cells with activation markers and the relative contribution of the CTL response directed towards latent and lytic proteins is diminished (Fig. 51.1). Although a wide range of HLA alleles have been shown to present EBV T cell epitopes, in most cases, epitope selection is highly allele specific. There are, however, a number of epitopes that show degeneracy in HLA restriction and are immunogenic in HLA mismatched individuals, thus broadening their potential population coverage if included in a CTL-based EBV vaccine. This includes the PYLFWLAAI epitope from LMP2A that is moderately to strongly immunogenic in HLA A*2301$^+$ individuals and weakly immunogenic in most individuals expressing the more common HLA A*2402 (Burrows *et al.*, 2003). In an earlier example, an EBNA 6 epitope was shown to be presented on three closely related subtypes of the B27 allele (Brooks *et al.*, 1993).

Furthermore, it is clear that the response in healthy immune individuals is not a miniturized version of that seen during acute infection but has been specifically selected to control cell-virus relationships established during long-term latent infection during which the level of EBV secretion is relatively modest and the proportion of latently-infected B cells is less than 1% of that present during acute infection. Analysis of CTL responses using tetramer staining, ELISPOT assays and cytokine production has allowed an estimate of the relative immunodominance in responses in healthy EBV immune individuals. This analysis has revealed that the intensity of the lytic antigen-specific response has waned compared to that seen during acute infection and that the response to latent antigens has increased. It is curious that this increased response is not consistent across all EBV latent proteins but is focused particularly to epitopes within EBNA3A, 3B and 3C with a subdominant response in the case of the two membrane-spanning proteins, LMP1 and 2 and a level of response towards EBNA1 that is controversial (see below). Overall, this relative level of immunodominance within the EBV latent proteins does not appear to be determined by their order of synthesis suggesting that other immunobiological factors are more important. The nuclear location of the EBNA3 proteins ensures their efficient processing and presentation through the endogenous pathway. However, in the case of LMP1 and 2 proteins, evidence suggests that their structure and location frequently favors processing through TAP-independent pathway(s). For example, LMP2 is a membrane-spanning protein with a 119 amino acid cytoplasmic N-terminus domain followed by 12 membrane-spanning segments with minimal, if any projection into the cytoplasm, and a 27 amino acid cytoplasmic C-terminus domain. Several reports (Khanna *et al.*, 1996; Lee *et al.*, 1996) have indicated that many, but not all of the epitopes within LMP2 are TAP-independent and that these epitopes lie within the transmembrane stretches of the protein whereas the TAP-dependent epitopes are markedly less hydrophobic (Lautscham *et al.*, 2003). These observations raise the possibility that processing and presentation by a TAP-independent, proteosome-dependent pathway might be linked either to the transmembrane location of this protein or its extreme hydrophobicity.

Role of CD4+ and CD8+ CTL in control of EBV infection

Under the experimental conditions used for the identification of EBV CTL epitopes, class I-restricted CD8$^+$ CTL effectors have been more commonly recognized than CD4+ effector cells. During IM, expansions of activated CD4$^+$ T-cells are observed; however relatively little is known about their specificity or importance in controlling EBV replication either in terms of provision of direct effector function or as a source of immunological help. Direct *ex vivo* cytolytic assays from IM patients have demonstrated CD4 T-cell-mediated EBV-specific cytotoxicity, and in one case this response has been mapped to an epitope in BHRF1 (Schmidt and Misko, 1995). Given the importance of CD4$^+$ T-cells in maintaining CD8$^+$ T-cell responses, it will be of great value to further characterize these cells and their target epitopes to define their role in IM.

In healthy immune individuals, CD4+ responses to epitopes from BHRF1, EBNA1 and EBNA3C have been described and cells specific for epitopes derived from these proteins have been found to be cytotoxic effectors and can produce interferon-γ (Schmidt and Misko, 1995; Leen *et al.*, 2001) regardless of the expression of the co-stimulatory molecules CD27 or CD28. Overall, the hierarchy of CD4+ CTL responses appears to be EBNA3C > EBNA1 > LMP2 >> LMP1 while in contrast the hierarchial

T-helper responses for the same proteins is EBNA1, EBNA3C >> LMP1, LMP2 (Leen *et al.*, 2001). It should be pointed out that the CD4+ assays to detect helper function are based on the release of interferon-gamma and are detecting T-helper activity of a kind thought to reflect CD8 T-cell induction rather than T-cell help associated with a humoral response which would involve analysis for cytokines such as IL-4, IL-5 and IL-13.

The CD4+ and CD8+ CTL response to EBNA1 has received particular attention in recent years. As already mentioned, the pronounced GAr repeat sequences have been reported to inhibit processing and degradation of this protein. Interestingly, most of these CD8+ responses are directed towards epitopes that are COOH-terminal of the GAr domain. The CD8+ response is not derived from full length EBNA1 but from proteins that are prematurely truncated during translation or mal-folded after translation (referred to as defective ribosomal products or DRiPs (Tellam *et al.*, 2004). These DRiPs are apparently subject to proteosomal- and serine protease- mediated (Voo *et al.*, 2004) degradation and class I presentation. In contrast, it is likely that the CD4 response is derived from full length EBNA1 released from dying cells which is subsequently exogenously processed through the class II pathway.

Role of CTL effector cells in resolution of acute IM

This background information on the CTL responses during primary EBV infection and in healthy immune individuals provides some insight into the protective role of these individual responses in resolution of disease. This issue is of central importance in designing a prophylactic vaccine to prevent the clinical symptoms of IM or a therapeutic vaccine to induce regression of the EBV-associated malignancies. The dynamics of latent compared with a lytic antigen-specific responses in acute EBV infection suggests that the latter strong response is incapable of reducing clinical symptoms and might, be driving symptomology. Generally, waning clinical symptoms are coincident with an increasing latent CTL response (Fig. 51.1). Furthermore, there are several studies that suggest that the induction of a potent CTL response to latent proteins might be the preferred strategy in relation to an IM vaccine and that a response to lytic proteins might be associated with pathology. Firstly, in a detailed study of a patient treated by adoptive immunotherapy of autologous CTL, it was noted that there was a correlation between the induction of a strong latent antigen-specific response and the cessation of disease, while a sustained lytic response was coincident with disease progression (Sherritt *et al.*, 2003). Secondly, a study of HLA identical individuals, one of whom sustained prolonged clinical symptoms from primary EBV infection and the other who recovered after a brief period, has been useful in ascribing the link between the CTL response and the severity of acute symptomology. It was clear that rapid recovery was associated with the induction of a broad latent antigen-specific response and that acute disease corresponded with a sustained and focused lytic-antigen response. Thus, provided that we can assume that the lessons from EBV infection of B lymphocytes in vitro are relevant in vivo and that the initial event in primary infection is contact between the virus and a B lymphocyte, a strong case can be mounted in favor of directing an IM vaccine towards latent rather than lytic proteins. Such a vaccine would restrict the latently-infected B cell pool expansions some of which presumably progress towards expression of lytic proteins which appear to be responsible for the lymphocytosis associated with acute infection.

T-cell receptor usage

It is now clear that acute EBV infection is associated with dramatic perturbations within the peripheral TCR repertoire, particularly within the $CD8^+$ compartment (Callan *et al.*, 1996). Prospective studies on IM patients that have investigated the clonal composition and dynamic regulation of the EBV-specific CTL response have provided an important opportunity to track the developmental process that T-cells undergo from primary to persistent infection (Silins *et al.*, 1996; Callan *et al.*, 1998; Silins *et al.*, 1997). Importantly, these studies have demonstrated different levels of TCR diversity selection depending on the viral epitope that is the target of the response. For example, the TCR repertoire utilized in the response to two HLA-B8-restricted epitopes from the latent antigen EBNA3A (FLRGRAYGL and QAKWRLQTL) was found to be oligoclonal in one IM patient, with preservation of distinct clonotypes into the memory T cell pool (Silins *et al.*, 1996). In contrast, T-cell populations raised against an HLA-B8-binding epitope from the lytic antigen BZLF1 (RAKFKQLL) was highly diverse in several IM patients, with no dramatic signs of repertoire focussing over time (Silins *et al.*, 1997). Studies by Callan *et al.* have indicated that the larger the $CD8^+$ clonal burst size during IM, the greater the decay observed after symptoms resolve (Callan *et al.*, 2000; Callan, 2003). Thus clonal dominance and immunodominance are less marked in healthy virus carriers than in IM patients. These findings may be related to a limit in the number of cell divisions a T-cell clone can undergo; thus the progeny of clones that have expanded massively during a primary immune

response may be more prone to die as a result of senescence (Callan, 2003). Overall, the developing picture in IM is that a broad range of TCRs are selected and maintained within the composite CTL response against natural EBV infection. A relatively diverse T-cell response may be especially important in the quick recovery from IM and the establishment and maintenance of effective lifelong CTL control.

In the persistent virus carrier state, the influence of EBV infection on the peripheral TCR repertoire remains significant but is much less dramatic than during the acute infection. EBV-specific CTL frequencies are surprisingly high in healthy EBV-seropositive individuals, presumably as a consequence of antigen persistence. Since the CTL response to some EBV epitopes is oligoclonal, it was proposed that infection with viruses such as EBV and CMV contribute to the decreasing diversity in the $CD8^+$ T-cell repertoire that occurs with age. Indeed, a report from Silins *et al.* (1998) supports this contention by demonstrating that the frequently monoclonal response to the EBNA3A epitope FLRGRAYGL is often large enough to dramatically skew the entire TCRBV6 blood repertoire towards oligoclonality.

As in acute IM, EBV-specific $CD8^+$ T cell responses can be either highly focused or restricted in TCR usage depending on the target viral epitope, and it is not clear what controls this variability. For example, a high degree of clonotypic diversity has been shown for the potent CTL response directed towards the HLA B8- and B*4002-binding epitopes from the BZLF1 lytic antigen, with multiple TCRs sharing very few obvious structural features employed in each case (Couedel *et al.*, 1999; Silins *et al.*, 1997). In contrast, a recent analysis of the equally strong response to an HLA B*3501-binding BZLF1 epitope has revealed that a single CTL clonotype often dominates this response in $B3501^+$ individuals (Miles *et al.*, 2005), with almost identical TCRs used by some unrelated individuals (unpublished observation). The basis for the selection of such immunodominant or "public" TCRs is unclear, although it does not appear to be the result of preferential expansion of high avidity TCRs. Other selection pressures may be involved such as cross-reactive stimulation with another foreign epitope or with a positively selecting self-peptide. Another recent proposal based on the crystal structure of an EBV-specific "public" TCR suggests that immunodominant T cell antigen receptors are selected as a result of certain structural properties that may confer better signaling upon ligation (Kjer-Nielsen *et al.*, 2003).

Negative selection pressures can also theoretically limit the diversity of T-cell responses, such as might occur if a viral epitope was highly homologous with a self peptide. However, this is clearly not the explanation for the dominance of the highly conserved TCR structure that is commonly utilized in response to the B8-binding FLRGRAYGL epitope. This TCR can mediate cross-reactive lysis of EBV-positive and EBV-negative target cells expressing the HLA B*4402 alloantigen (Burrows *et al.*, 1994). Not surprisingly, T-cells with this particular TCR are not detected within the EBV-induced memory CTL population in individuals who co-express HLA B8 and B*4402 due to their potential for self-reactivity (Burrows *et al.*, 1995). Interestingly, however, such individuals do still make a response to the FLRGRAYGL–B8 complex through a variety of different TCRs, illustrating the flexibility and reserve strength of the TCR repertoire in the response to a target epitope.

Virus-driven immune modulation

EBV, like many other herpes viruses, has successfully adapted as a persistent infection by developing various strategies to avoid the potentially hostile effects of host immunity. One such adaptive strategy employed by many oncogenic viruses (such as EBV) involves restricted expression of viral genes, thereby minimizing the potential recognition of target antigens (as seen in many EBV-associated malignancies). On the other hand, viruses (including EBV) are also known to interfere more directly with the host immune response by encoding viral genes, that are homologous to cellular effector molecules. Candidate immune evasion strategies against CTL-mediated control have been recognized which act at the level of cytokine regulation and antigen processing and presentation (Cohen, 1999; Khanna *et al.*, 1995; Spriggs *et al.*, 1996). In the last few years, a number of EBV encoded immunomodulators have been identified within the lytic and latent phases of viral infection which may interfere with virus-specific T-cell responses and enhance EBV-infected B-cell proliferation, thus facilitating pathogen dissemination and survival early in the infectious process.

Modulation of the cytokine network

Previous studies have shown that cytokines contribute directly towards the clearance of viral infections. To counter this potential threat, many viruses have evolved to express novel homologues of these cytokines that can act as antagonists. These homologues can be either positive or negative regulators of T cell-mediated immune responses. The EBV encoded, BCRF1 protein expressed during lytic infection exhibits 78% identity to the deduced amino acid sequence of human IL-10 and shares a similar function to its human homologue (Moore *et al.*, 1990). Recombinant BCRF1, like human IL-10 negatively regulates IL-12 which

promotes IFN-γ production by T-cells. In addition, BCRF1 also abrogates the inhibitory capacity of T-cells which blocks the outgrowth of EBV-infected B-cells. This effect may be mediated through suppression of T-cell activation-induced IL-2 and IFN-γ production (Bejarano and Massuci, 1998). Apart from its effect on IL-2 and IFN-γ production, it has also been proposed that BCRF1 acts directly on T cells to inhibit co-stimulatory signals mediated via B7 receptors such as CD28 or CTLA-4 (Muller *et al.*, 1998). Since BCRF1 is mainly expressed during the replicative phase of the virus cycle, the role of IL-10 in the modulation of latent infection has remained largely unresolved until recently. Studies carried out by Marshall and colleagues showed that LMP1 preferentially activates regulatory T-cells that secrete IL-10 (Marshall *et al.*, 2003). These IL-10 responses inhibit T cell proliferation and IFN-γ secretion by EBV-specific CD8+ T cells.

Another example of modulation of the cytokine network by EBV comes from studies by Strockbine and colleagues (Strockbine *et al.*, 1998) who have identified a novel EBV-encoded modulator of colony stimulating factor (CSF1). Their studies showed that BARF1 protein, when added into the culture medium, neutralizes the proliferative effects of human CSF-1 which is a pleiotropic cytokine best known for its differentiating effects on macrophages. Thus BARF1 may function to modulate the host immune response to EBV infection by blocking CSF-1 function through inhibition of interferon a (IFN-a) secretion from mononuclear cells (Cohen and Lekstrom, 1999) which is the first cytokine produced in response to virus infection. Recent studies have shown that IFN-a activates the p53 gene in virus-infected cells leading to apoptotic death of infected cells (Takaoka *et al.*, 2003). Based on these studies, we hypothesize that BARF1-mediated blockade of IFN-a would protect EBV-infected cells from death during the early stages of infection thus promoting latent infection. In addition to its potential role in promoting latent infection, the role of BARF1 in modulating innate and adaptive immunity should not be ignored since IFN-a activates NK cells and is necessary for both NK cell blastogenesis and cytotoxicity during herpes virus infections (Brion *et al.*, 1995). Furthermore, preliminary studies carried out in our laboratory have shown that recombinant BARF1 protein can inhibit activation and expansion of memory T-cells from healthy virus carriers (S. Pai and R. Khanna, unpublished observations).

Regulation of antigen processing and presentation

T-cell-mediated immune control of EBV infection can act at either latent or lytic phases. The pattern of viral gene expression at each phase determines the potential target antigens. When considering immune evasion strategies for latent infection, EBNA1 remains one of most comprehensively studied proteins. Levitskaya and colleagues have shown that EBNA1 resists CTL mediated immune recognition through a unique inhibitory mechanism which blocks endogenous processing of CTL epitopes within this antigen (Levitskaya *et al.*, 1995, 1997). It was proposed that this GAr sequence within EBNA1 may influence the folding pattern of this protein and affect its capacity to associate with various components of the ubiquitin/proteasome pathway, including ubiquitin conjugation enzymes and/or regulatory subunits of the proteasome. More recent studies have shown that this inhibitory effect may be overridden in certain types of epithelial cells (Jones *et al.*, 2003). When EBNA1 is expressed in immortalized epithelial cells (SSC12F, SVK), it not only inhibits cell growth but is also endogenously processed through the class I pathway for immune recognition by CD8+ T-cells. On the other hand, neither of these phenomena is observed when EBNA1 is expressed in fully transformed epithelial cells (Hela, Ad/AH).

LMP1 is another latent protein known to modulate the function of immune regulatory proteins in B-cells. This protein has recently been recognized as a functional homologue of human CD40 (Uchida *et al.*, 1999). First evidence for a potential role of EBV latent antigens in the regulation of MHC class I expression came from the observation that LMP1 was capable of reversing down-regulated expression of TAP and HLA class I in BL cells which are characterized by defective antigen processing (Khanna *et al.*, 1995). Recent studies from our laboratory have shown that the c-terminal domain of LMP1 plays an important role in translocating relB from the cytoplasm to the nucleus with a consequent effect on the upregulation of antigen processing genes (Pai and Khanna, 2002). This observation raises the intriguing question of why an EBV protein has evolved with the capacity to up-regulate antigen processing function in the host cells, thereby potentially increasing the chances of its elimination by virus-specific CTLs. A possible explanation is that the virus uses the LMP1 protein to hyper-regulate the antigen processing function of B-cells, and that this not only results in efficient presentation of viral peptides, but also increases the levels of self peptides presented by these cells. Increasing self peptide presentation has two potential consequences (i) these self peptides may compete with viral peptides thus reducing the levels of EBV peptides presented to CTLs thereby allowing immune escape or alternatively (ii) increased self peptide presentation may also contribute towards the development of autoimmune reactivity which is often seen as one of the symptoms in individuals

with acute EBV infection. Another plausible hypothesis to explain why EBV modulates antigen processing gene expression via LMP1 involves the long-term host-virus relationship whereby some advantage is gained from deliberately enhancing the chance of EBV-infected B-cells being lyzed by immune surveillance thus protecting the host from an overwhelming infection and maintaining a stable host-virus relationship.

Although much of the emphasis on the immune control of EBV has focused on CD8+ T-cells, recent studies have demonstrated that CD4+ T-cells also play an important role in both primary and latent EBV infection (Precopio *et al.*, 2003). It is not surprising that EBV has evolved immune evasive strategies to counter the potential threat from this effector arm of the immune system. Thus Spriggs and colleagues (Li *et al.*, 1997) have proposed a novel mechanism of blocking peptide presentation through the MHC class II pathway. They showed that, during the late lytic cycle, EBV encodes a type II membrane glycoprotein that specifically binds to the ß chains of MHC class II particularly the HLA DR heterodimer both intracellularly as well as on the cell surface resulting in the retention of MHC class II molecules in the ER thus blocking presentation of class II-restricted T-cell epitopes. Interestingly, subsequent studies have shown that BZLF2 specific antibodies that block the interaction of this protein with MHC class II can also prevent the infection of MHC class II positive B lymphocytes (reviewed in (Spear and Longnecker, 2003). It is possible therefore that BZLF2 plays a dual role, modulating class II-restricted antigen presentation as well facilitating infection of class II positive cells.

T-cell control of EBV-associated malignancies

The EBV-associated malignancies have evolved unique strategies to evade immune recognition allowing them to expand in the face of an existing EBV-specific CTL response (Khanna, 1998; Khanna and Burrows, 2000). Thus, in the case of endemic BL, viral gene expression is restricted to EBNA1 with a phenotype resembling that of resting cells. This combination of properties makes these cells highly resistant to T-cell-mediated immune recognition rendering them incapable of stimulating an EBV or allospecific T-cell response (Rooney *et al.*, 1995). This non-immunogenic phenotype of BL cells is linked to down-regulated expression of MHC class I and TAP-1 and/or TAP-2 genes, whereas expression of the proteasome genes, LMP2 and LMP7 is normal in most cases (Khanna *et al.*, 1994, 1995). It is important to mention here that loss of antigen processing function is not only seen in EBV-positive BL cell lines but also in EBV-negative BL cells. Thus it is likely that the CTL resistant phenotype of BL is a reflection of the nature of the cell type from which the malignant cells are derived. Indeed, Gregory and colleagues have identified normal B-cells which display a phenotype identical to BL cells (Gregory *et al.*, 1987).

While considerable significance has been placed on the apparent loss of MHC class I-molecules in the immune escape of tumor cells, evidence from other human tumors has accumulated that CD4+ T-cells can also play a critical role in immune surveillance (Topalian *et al.*, 1994). Surprisingly, analysis of MHC class II-restricted antigen processing function in TAP-deficient BL cells has revealed that EBV-specific CD4+ CTLs can efficiently recognize these tumor cells (Khanna *et al.*, 1997). Furthermore, in contrast to the consistently low levels of surface MHC class I expression on BL cells, MHC class II expression is normal and quite comparable to that on EBV-transformed normal B-cells. Consistent with these observations, BL cells also show normal levels of the HLA DMB gene product which is an essential component for class II processing. The importance of these studies has been further strengthened by the observation that CD4+ EBNA1-specific CTLs from healthy virus carriers can efficiently recognize not only virus-infected normal B-cells but also BL cells (Munz et al., 2000; Paludan *et al.*, 2002).

In spite of distinct pathologies, NPC and HD share a number of phenotypic features which provide a unique opportunity to study the immune responses to viral antigens expressed in these malignancies. Molecular analysis of fresh biopsies and laboratory-established tumor lines indicate that malignant cells in both NPC and HD express normal levels of HLA class I and TAP1/2 (Khanna *et al.*, 1998; Lee *et al.*, 1998) and express only a limited number of latent proteins (LMP1, LMP2 and EBNA1). A number of studies have shown that, as in the case of healthy virus carriers, the EBV-specific CTL repertoire in HD and NPC patients is strongly focused through the EBNA3A, EBNA3B and EBNA3C proteins and thus have a limited capacity to control these tumors in vivo. Lee and colleagues conducted an exhaustive analysis of EBV-specific T-cell responses in a large panel of HD patients which showed no obvious suppression of the EBV-specific T-cell responses in HD patients when compared to the healthy virus carriers (Lee *et al.*, 1998). These observations were in direct contrast to earlier studies which showed that HD patients often possess a generalized defect in cell-mediated immunity, including impaired responses to mitogens and a decreased capacity of T-cells to respond in a mixed lymphocyte response (Slivnick *et al.*, 1990). Although the precise reason for this loss of T-cell immunity is not known, a recent study by

Marshall and colleagues have shown that the $CD4^+$ T-cell response to the LMP1protein is dominated by regulatory T-cells which express high levels of IL-10. These responses inhibited T-cell proliferation and INF-γ production by both mitogen and EBV antigens (Marshall *et al.*, 2003). Furthermore, Dukers and colleagues have also shown that LMP1 includes two novel retrovirus homologous sequences within the transmembrane domain which showed strong inhibition of T-cell proliferation and NK cell cytotoxicity (Dukers *et al.*, 2000). These authors proposed that HD or NPC tumor cells may actively secrete LMP1 and thus mediate immunosuppressive effects on tumor infiltrating lymphocytes.

Future prospects for an EBV vaccine

Our understanding of the immune response to EBV appears to be at a point where serious consideration can now be given towards a vaccine to at least some of the EBV-associated diseases. It appears that the best prospects relate to allowing the development of vaccine to prevent the clinical symptoms of IM. As already discussed, a strong argument can be drawn that this vaccine should be directed towards activating a response to epitopes within EBNA3A, 3B and 3C. The hope is that the same vaccine might be effective against the emergence of PTLD in transplant patients. The method of delivering this vaccine is open to question, but given the fact that the recipients of an IM vaccine will be largely healthy adolescents, it is unlikely that a live vaccine delivery system will be used.

As already discussed, the latent antigens expressed in the latency II diseases (NPC and HD) are poorly immunogenic. This consideration, when seen in concert with the fact that these patients are suffering a life-threatening disease means that live vaccine delivery vectors might be acceptable.

There appears to be little prospect for the development of an effective vaccine against latency 1 diseases. This conclusion is based on the relative low frequency of these malignancies and their non-immunogenic phenotype.

Immunobiology and host response to KSHV infection

Dimitrios Lagos and Chris Boshoff

Cancer Research UK Viral Oncology Group, Wolfson Institute for Biomedical Research, University College London, London, UK

Introduction

The interplay between malignancy, infection and immunity is best illustrated by the neoplasms related to KSHV (Boshoff and Weiss, 2002): Kaposi sarcoma (KS) is approximately 100 times more common during immunosuppression and can be resolved when iatrogenic immunosuppression is stopped (Euvrard *et al.*, 2003) and during highly active antiretroviral treatment (HAART) of HIV-1 infected individuals (Boshoff and Weiss, 2002). Primary effusion lymphoma (PEL) and plasmablastic multicentric Castleman's disease (MCD) also occur predominantly during immunosuppression. Like other gammaherpesviruses, KSHV persists as a latent episome in B-lymphocytes (Ambroziak *et al.*, 1995; Cesarman *et al.*, 1995; Renne *et al.*, 1996), without provoking host responses that would eliminate infected cells. KSHV acquired a fascinating repertoire of decoys to trick the host immune response enabling establishment of lifelong infection in humans with very few clinical manifestations. When the balance between viral infection and host immunity is disturbed, some of the molecular pathways employed by KSHV to evade host immune responses are directly involved in driving oncogenesis (Moore and Chang, 2003). KSHV is an excellent model to study the coevolution of pathogen attack and mechanisms of host counter attack.

KS is most aggressive in the immunosuppressed and resolves with partial restoration of the immune system (Gill *et al.*, 2002). Since the introduction of HAART, there has also been a dramatic fall in the incidence of KS (Jacobson *et al.*, 1999). Although non-immune mechanisms may contribute to this drop in KS cases and the resolution of established lesions, it is reasonable to propose that immune reconstitution is a major factor in the control of this neoplasm (Box 52.1).

We are only starting to understand how KSHV avoids these host responses, which viral epitopes are targets for adaptive immune responses, and how anti-KSHV immunity is altered during immunosuppression (Table 52.1).

Primary infection

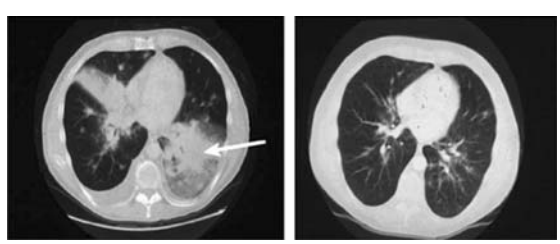
It is thought that KSHV is mainly transmitted by oral exposure to infectious saliva (Pauk *et al.*, 2000), suggesting that mucosal cells are the first port of call. These could be mucosal-associated dendritic cells, macrophages, lymphocytes and/or epithelial cells. KSHV can infect and establish latency in CD34+ hematopoietic progenitors, macrophages and B-lymphocytes in experimental models (Dittmer *et al.*, 1999; Bechtel *et al.*, 2003; Luppi *et al.*, 2005; Wu *et al.*, 2006), but the exact cell type that is predominantly infected at viral exposure is still unknown. KSHV is also present in cells of the endothelial lineage (EC), specifically cells differentiating towards lymphatic endothelium (Dupin *et al.*, 1999; Wang *et al.*, 2004). This microvascular environment is specifically adapted to rapidly eliminate invading pathogens and KSHV must therefore have evolved specific mechanisms to replicate successfully in this niche.

Case reports and epidemiological surveys provide some clues to the consequences of an inadequate immune response to primary KSHV infection: Although primary KSHV infection among immunocompetent individuals can be symptomatic (Andreoni *et al.*, 2002), the development of KSHV-related malignancies is generally associated with immunosuppression. Lymphadenopathy associated with microscopic KS lesions (that is expansion of KSHV-infected EC), occurs in HIV-1 infected individuals, who are thought to be exposed to KSHV for the first time (Oksenhendler *et al.*, 1998). This infers that the lympadenopathic KS seen in African children may also represent primary infection with KSHV, similar to childhood Hodgkin's disease

Box 52.1. Kaposi's sarcoma, immunity and anti-retroviral treatment

For most individuals, living with KSHV is uneventful. However, during immunosuppression the consequences can be severe.

In 1981, Kaposi's sarcoma (KS) became the sentinel of the AIDS epidemic. During the 1980s, prior to the use of any antiretroviral treatment, KS often presented as widespread lesions affecting skin, mucosal surfaces and sometimes internal organs. Periorbital edema was also frequently seen with advanced HIV-1 infection. (Image kindly provided by A. E. Friedman Kien.)



How does HAART prevent KS?

Since the introduction of HAART, the incidence of KS has decreased dramatically, and HAART also leads to rapid KS resolution. The computed tomographic lung scans (Image kindly provided by N. Dupin) show a patient with a large pulmonary KS lesion (left panel) and the improvement in this patient during HAART (right panel).There are several mechanisms by which HAART could lead to KS resolution:

HAART leads to immune reconstitution against KSHV (Wilkinson *et al.*, 2002; Bourboulia *et al.*, 2004). This hypothesis could also explain the resolution of Kaposi's sarcoma in HIV-negative post-organ transplant individuals when immunosuppressive drugs are stopped.Both humoral and cellular immunity might contribute to this.

HIV-1 circulating Tat levels and HIV-1 induced immune activation (including levels of circulating cytokines) are reduced on HAART leading to KS regression (Ensoli *et al.*, 1990; Gallo, 1998). This could explain the often rapid resolution of KS when HAART is initiated, but not the resolution of KS in HIV negative individuals when immunosuppression is stopped (e.g., after an organ transplant).The observation that proangiogenic growth factor (e.g. vascular endothelial growth factor, VEGF) levels decrease during HAART and correlate with KS resolution, supports this theory.

Protease inhibitors (PIs) have a direct anti-spindle cell and/or anti-angiogenic effect (Sgadari *et al.*, 2002) PIs block KS spindle cell growth and angiogenesis in experimental models. Retrospective studies showing that HAART leads to a decreased incidence of Kaposi's sarcoma -and to the resolution of established lesions- were all conducted at a time when PIs were routinely used as part of HAART. However, because of side-effects their use in HAART is now more restricted. Non-PI containing combination anti-retroviral therapy also leads to KS resolution and the incidence of KS remains low in the UK and USA (Gill *et al.*, 2002). However, reports that KS can relapse when a PI-containing regimen is substituted for a non-PI containing regimen (Bani-Sadr *et al.*, 2003) do suggest that PI's directly, or indirectly, play a role in the control of KSHV-infected EC proliferation.

thought to be due to inadequate control of primary EBV infection (Macsween and Crawford, 2003). Furthermore, KS develops more commonly in HIV-1 infected individuals who acquired KSHV after primary HIV-1 infection (Goudsmit *et al.*, 2000), suggesting that an inadequate host response during primary KSHV infection confers the propensity of infected EC to expand, and that EC are one of the first KSHV targets during primary infection. Circulating spindle cells, expressing endothelial and macrophage markers, have been identified from healthy

Table 52.1. Overview of host responses to KSHV infection and future questions

	Cell type	Major findings[a]	Major questions
INNATE IMMUNITY	Dendritic cells	• KSHV infects DC *in vitro* and impairs their antigen presenting properties (Reppocciolo *et al.*, 2006) • Decreased number of pDC in AIDS-KS (Stebbing *et al.*, 2003b) and mDC and pDC in classic KS (Della Bella *et al.*, 2006)	Determine the mechanisms employed by KSHV to regulate DC maturation and function
	Natural Killer cells	• Restoration of NK function correlates with KS resolution on HAART (Sirianni *et al.*, 2002) • KSHV protects KSHV-infected cells from NK cell attack (reviewed in Orange *et al.*, 2002)	Investigate the role of KSHV driven NK cells in control of infection and KS development
	Complement	• Essential for MHV68 control (Kapadia *et al.* 2002) • KSHV ORF4 is a regulator of complement activation (Spiller *et al.* 2003)	Determine the role of complement in KSHV infection
ADAPTIVE IMMUNITY	Cytotoxic T cells	• KSHV sepcific CTL epitopes identified[b] • CTL restoration on HAART correlates with viral clearance (Bourboulia *et al.* 2004)	Determine KSHV specific CTL phenotype and identify further CTL epitopes
	T helper cells	• $CD4^+$ T cells proliferate in response to KSHV (Strickler *et al.* 1999) • $CD4^+$ T cell count below 200/mm^3 is a risk factor for KS development[c]	Determine CD4+ T cell KSHV epitopes and subsets
	B cells	• LANA, K8.1, and ORF65 elicit significant humoral responses[d] • Increase in number of individuals with detectable anti K8.1 responses coincides with plasma KSHV clearance during HAART (Bourboulia *et al.* 2004) • KSHV neutralizing antibodies reduced in AIDS-KS (Kimball *et al.* 2004) • Polymorphisms of FCγRIIIA confer protection against KS (Lehrnbecher *et al.* 2000)	Investigate the neutralizing and effector functions of anti-KSHV antibodies

donors and in higher frequency from individuals with KS (Browning *et al.*, 1994). When isolated from the latter group, these spindle cells are infected with KSHV (Sirianni *et al.*, 1997). During HIV-1 infection, all arms of the immune system are affected. Suboptimal NK cell-, humoral- and cellular immune responses may therefore contribute towards the expansion of KSHV-infected EC to precipitate KS, and KSHV-infected plasmablasts to precipitate MCD or PEL.

Innate immunity

The innate arm of the immune system is the first host defence against invading pathogens. The interactions between KSHV and innate immunity are only starting to be explored.

Dendritic cells

Dendritic cells (DC) are professional antigen presenting cells with a pivotal role in the initiation of innate and adaptive immune responses. DC originate from CD34+ haematopoietic stem cells in the bone marrow and differentiate into the myeloid and lymphoid (or plasmacytoid) DC lineages (mDC and pDC respectively). mDC express myeloid lineage markers, remain in the circulation, or differentiate into immature DC (iDC) after migration to skin

(Langerhans cells, CD1a$^+$) and other tissues (interstitial DC, CD1a$^-$). mDC constantly sample their environment and upon foreign antigen encounter they migrate to the lymph nodes where they mature and present antigens to T lymphocytes. In parallel, pDC express lymphoid markers, remain in circulation or cluster around the high endothelial venules of inflamed lymph nodes. These cells migrate into the lymph nodes in response to inflammatory cytokines and they are considered to be the main type I interferon-producing cells during host defence against viral infections. In addition to these typical functions, DC exhibit an extraordinary plasticity and multi-potency in their ability to interact with all cells of the immune system to initiate and orchestrate efficient innate and adaptive immune responses (Banchereau and Steinman, 1998; Patterson, 2000; Shortman and Liu, 2002).

The key role of DC in host responses against viral infections makes them a major target for viral mechanisms to evade host immunity. The development of efficient in vitro iDC generation methods from peripheral blood monocytes (moDC) (Sallusto and Lanzavecchia, 1994) or bone marrow CD34$^+$ stem cells (Caux *et al.*, 1997) has allowed studies of the effects of viruses on DC generation, maturation, and function. Members of the herpesvirus family such as HSV, HHV6, CMV, and EBV use a variety of mechanisms to block DC generation and/or maturation, e.g., CMV directly infects DC and impairs their function and also blocks differentiation of monocytes to DC, whereas EBV induces apoptosis of monocyte DC progenitors (Chapters 31 and 43).

Currently, little is known about the interaction of DC and KSHV. In vitro, although infection of CD34$^+$ hematopoietic progenitors does not affect differentiation to DC (Larcher *et al.*, 2005), KSHV uses the DC-SIGN receptor to directly infect DC resulting in a decrease of their antigen presenting properties (Rappocciolo *et al.*, 2006). In vivo, the importance of DC in the host response to KSHV can be hypothesized based on the high occurrence of KSHV related malignancies in immunosuppressed individuals and the critical role that DC play in the pathogenesis of other herpesviral infections. Moreover, KS occurs at sites rich in DC: Langerhans cells in the skin and interstitial DC in the mucosal surfaces. In the context of HIV-1 infection, the number and function of both DC lineages decrease after primary infection and during high viraemia (Donaghy *et al.* 2001, 2003). A further reduction in the numbers of pDC has been reported in AIDS-KS in comparison to HIV-1 infected individuals (Stebbing *et al.*, 2003b). Low numbers of both DC subsets (but not CD34$^+$ hematopoietic progenitors) are also reported in classic KS and this decrease correlates with advanced disease (Della Bella *et al.*, 2006). Finally, the number of Langerhans cells is significantly decreased in KS lesions when compared with normal skin, suggesting that KSHV might influence DC maturation or migration (Valcuende-Cavero *et al.*, 1994). However, it is still not clear whether DC are infected by KSHV in vivo and the exact mechanisms that KSHV employs to effect DC maturation and function are yet to be determined.

Natural killer cells

Natural killer (NK) cells are lymphocytes that do not undergo genetic recombination events and thus do not express clonally distributed receptors for antigen. They are found mostly in peripheral blood, spleen, and bone marrow, but can migrate to inflamed tissues in response to various chemoattractants. NK cells mediate direct lysis of target tumor or infected cells by release of perforin and granzymes or by binding to apoptosis inducing receptors on the target cell. Upon activation, NK cells release inflammatory cytokines, which influence the type of adaptive responses. The mechanism of NK function is described by the "missing self" hypothesis (Medzhitov and Janeway, 2002): NK activity is switched off by a set of inhibitory receptors, which are expressed on their cell surface, including killer-cell immunoglobulin-like receptors (KIRs), immunoglobulin-like inhibitory receptors (ILT) and the lectin-like heterodimer CD94-NKG2A. All these receptors are involved in HLA molecule recognition. Each type of KIR is expressed only by a subgroup of NK cells allowing the constant sampling of every single HLA allele. Down-regulation of MHC-I molecules, which occurs in tumor and virally infected cells, results in the withdrawal of the KIR inhibitory signal and subsequent activation of NK cells through a group of receptors termed natural cytotoxicity receptors (NCR) (Medzhitov and Janeway, 2002; Moretta *et al.*, 2002). It has been shown that individuals with decreased or depleted NK activity are prone to HSV, CMV, and EBV infections (Biron *et al.*, 1999). Moreover, herpesviruses evade NK cell-mediated immunity using mechanisms that target every step of NK cell activation (Chapter 31 and Orange *et al.*, 2002).

At least four different mechanisms by which KSHV regulates NK activity can be proposed (for review see Orange *et al.*, 2002): Inhibition of NK activating receptor ICAM-1 by the viral gene K5, selective modulation of MHC-I molecules (HLA-A and HLA-B only) by K5, secretion of viral antagonists (vMIP-I and II) that block chemotactic responses of leukocytes, and decreased number of pDC (see DC section), which are the main type I IFN producers and fundamental for NK function. However, apart from the latter, these mechanisms involve lytic KSHV gene products and do not explain how KSHV latently infected cells that express low levels of MHC-I are protected from NK cells.

There is some evidence for the importance of NK cells in the control of KSHV infection and KS development: first, PEL cell lines are preferentially lyzed by NK cells from healthy blood donors when compared with KSHV$^-$/EBV$^+$ Burkitt lymphoma cell lines. Second, NK cell activity is decreased in individuals with aggressive AIDS-KS in comparison with individuals with indolent classic KS. Finally, NK cell activity is restored within 6 months of HAART in individuals with complete KS resolution and coincides with cell associated KSHV clearance (Sirianni *et al.*, 2002). However, it is still not clear whether NK cell activity is specifically driven by KSHV in infected individuals, as NK cell activity does not differ between HIV-1 infected individuals with and without KS. Further studies should investigate the role of NK cells in the control of KSHV infection and in the pathogenesis of KSHV-related neoplasms.

Complement

Complement activation occurs due to differences in pathogen envelope or membrane composition (alternative pathway), or existence of pathogen specific antibodies (classical pathway) (Walport, 2001a,b). Viruses have evolved evasion mechanisms of complement activity by incorporating complement regulatory proteins into their envelope or by having structural and functional or just functional viral homologues of such regulators (termed regulators of complement activation RCA). The importance of these regulatory homologues was demonstrated in a mouse model of γ-herpesvirus infection. Murine γ-herpesvirus 68 (MHV68) encodes for an RCA, which inhibits complement activation at the level of C3 (the point of convergence of all complement pathways). It was demonstrated that deletion of this protein resulted in decreased virulence and that this was reversed in C3$^-$/C3$^-$ mice. In addition, complement was shown to have a direct effect on viral latency (Kapadia *et al.*, 2002). Furthermore, and similarly to the MHV 68 KSHV encodes for a lytic product (ORF4) that inhibits complement activation at the level of C3 (named KSHV complement control protein, KCP) (Spiller *et al.*, 2003). Based on these observations, it seems reasonable to speculate that KCP plays an important role in the protection of KSHV virions and/or infected cells, against opsonisation, complement mediated virolysis, and humoral immune responses, in particular during cell-to-cell transmission.

Adaptive immunity

T-lymphocytes

T-lymphocytes are in the forefront of the battle of the host's immune system with invading pathogens. Activation of the innate arm of the immune system results in the direct killing of invading pathogens and the initiation and direction of efficient adaptive immune responses, which, if successful, lead to the establishment of immunological memory. Through the MHC machinery CD8+ and CD4+ T-lymphocytes specifically recognize viral peptide antigens, proliferate, and either directly lyze the infected cells (cytotoxic CD8+ T-lymphocytes, CTL) or further orchestrate the adaptive immune response (helper CD4+ T-lymphocytes, Th cells). However, during infection a variety of mechanisms are used by herpesviruses to escape T-cell responses (Ploegh, 1998; Yewdell and Hill, 2002).

Cytotoxic T-lymphocytes

CTL are primed by dendritic cells (DC) and by other professional antigen presenting cells, which present viral antigens through the MHC-I machinery. Following clonal expansion, the primed CTL act against virus by killing infected cells via perforin- and/or Fas-dependent pathways, before new virus particles are made, whereas they also release cytokines and chemokines with antiviral activity.

CTL epitopes

Considering the size of the KSHV genome, only a relatively small number of KSHV specific MHC class I-restricted CTL epitopes have been identified thus far (Fig. 52.1(a)) (Osman *et al.*, 1999; Wang *et al.*, 2000, 2001, 2002; Brander *et al.*, 2001; Micheletti *et al.*, 2002; Wilkinson *et al.*, 2002; Stebbing *et al.*, 2003a; Ribechini *et al.*, 2006). Although the use of these epitopes led to the detection of KSHV-specific CTL responses, these responses are in general weak compared to those seen against other herpesviral antigens. Whether this is due to viral immune escape from CTL, or whether help from autologous antigen presenting cells is necessary for efficient CTL responses (as shown for DC (Wang *et al.*, 2002)) or whether the KSHV genome has just not yet been exhaustively screened for CTL epitopes remains to be elucidated. One difficulty is that in the West, KSHV is predominantly present in HIV-1 infected individuals who exhibit suppressed CTL activity. The majority of CTL epitopes have therefore been identified in HIV-1 infected individuals during HAART, where the immune system is partly restored. Interestingly, T cell responses to LANA and ORF 65 are also detectable, even in KSHV-seronegative HIV-1 infected individuals, implying that KSHV-specific cellular immunity can occur in the absence of antibody responses (Woodberry *et al.*, 2005). However, the peptide epitopes present in these two viral proteins were not identified and it is not clear whether the observed responses were due to CTL or CD4$^+$ cells.

In KSHV, as in other herpesviruses, most of the CTL epitopes have been identified in conserved sites. It was demonstrated that functional CTL epitopes cluster in a

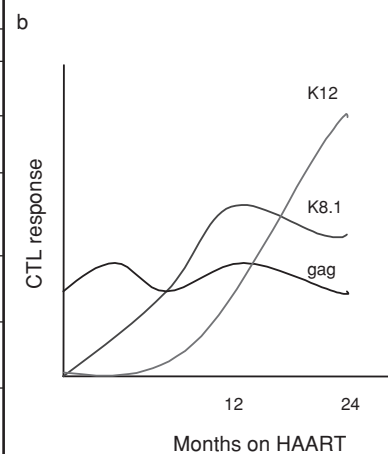

Fig. 52.1. KSHV specific CTL epitopes and CTL recovery during HAART. **(a)** KSHV specific CTL epitopes: CTL peptide epitopes have been identified in five KSHV encoded proteins. The K1 epitopes all cluster in the most variable region (VR1) and are associated with specific KSHV strains (associated strains are shown in brackets next to the epitopes). No HLA class A epitopes have thus far been identified in K1. K12 (Kaposin A) is the only latent KSHV protein thus far shown to elicit CTL responses. **(b)** Effects of HAART on the recovery of anti-KSHV CTL responses: CTL activity increases during HAART in HIV-1 infected individuals, with or without KS, against lytic and latent epitopes (K8.1 and K12, epitopes, respectively. HIV-1 gag responses also shown). CTL responses against K12 continue to increase after 12 months on HAART (Bourboulia *et al.*, 2004). These CTL responses could contribute to the observed drop in the incidence of KS in the West since the widespread introduction of HAART. CTL, cytotoxic T-lymphocyte; HAART, highly active anti-retroviral therapy.

positively selected region of the most variable KSHV gene. K1 is a positional homologue of LMP-1 of EBV and contains the two most variable regions (VR1 and VR2) across the entire KSHV genome which are used to classify KSHV into four clades (A, B, C, and D) (Zong *et al.*, 1999). Every viral isolate studied thus far is unique to an infected individual. However, unlike the situation in retroviruses, K1 mutations have not been detected within an infected individual over time. Several, HLA class I restricted epitopes within the VR1 were identified with the use of autologous overlapping peptides corresponding exactly to a patient's own viral sequence (Fig. 52.1(a)). These CTL epitopes are conserved within a specific strain (e.g. A or B), but not between strains. Based on these observations it appears that part of the genetic variability occurring in K1 is driven by a positive selection for CTL recognition, rather than due to CTL escape (Stebbing *et al.*, 2003a). Furthermore, the observed variability does not appear to be due to escape from humoral immunity (a mechanism employed by other viruses such as influenza and HIV-1 where variability in viral surface proteins is driven by escape from humoral immunity resulting a 'antigenic shift'). It seems likely that this selection prevents the complete evasion of all host immune control mechanisms, which would lead to overwhelming viral infection with subsequent death of the host and, therefore, of the virus. It seems that K1, which is an

early-lytic product, serves as a "suicide" protein allowing CTL recognition of cells reactivating from latency. Of note, CTL epitopes were also identified in vMIR1 and vMIR2 (Ribechini *et al.*, 2006), two lytic KSHV genes that down-regulate expression of MHC-I and other co-stimulatory proteins (Chapters 31 and 62), whereas vFLIP is able to upregulate expression of MHC-I and ICAM-1 (Lagos *et al.*, unpublihsed data). In addition to K1 recognition by CTL, the above findings reveal two more mechanisms employed by KSHV to regulate immune escape, limit viral dissemination and establish equilibrium in the virus–host co-speciation.

Effects of HAART on CTL

HAART promotes long-term immune reconstitution in patients with and without KS. This reconstitution is also KSHV-specific (Wilkinson *et al.*, 2002; Bourboulia *et al.*, 2004). It has been demonstrated that there is a significant decline of KSHV DNA load in PBMC and plasma during HAART and this correlates with a significant increase of anti-KSHV-specific CD8+ T-cell responses (Bourboulia *et al.*, 2004) (Fig. 52.1(b)). It appears that prolonged HAART (more than 12 months) is necessary for these anti-KSHV effects to be established and maintained in most HIV-1 infected individuals. In individuals with KS, resolution of KS is also associated with significant increases of KSHV specific CD8+ T-cell responses during the first 6–9 months on HAART. Future work has to determine whether other KSHV specific epitopes are able to elicit more potent CD8+ T cell responses and contribute to the restoration of KSHV specific T-cells and whether such responses are stronger and occur earlier than those observed for K8.1 and K12. Moreover, detailed phenotyping of KSHV-specific CD8+ T-cells would give further insight into the anti-KSHV responses in comparison to other viruses that establish persistent infections (Appay *et al.*, 2002).

Helper T-lymphocytes

The final stages of herpesvirus virion assembly occur in endosomal cellular compartments with extensive targeting of viral proteins to endosomes. During this process viral proteins can be efficiently sampled by the MHC-II, leading to the presentation of viral antigens to CD4+ T-lymphocytes.

The association of KS with low CD4+ T-cell count (mainly below 200/mm^3; although on average these values are higher than those associated with other AIDS-associated cancers) (Crowe *et al.*, 1991; Cannon *et al.*, 2003; Engels *et al.*, 2003; Mbulaiteye *et al.*, 2003) and the rapid KS resolution during HAART suggest a potential role for anti-KSHV CD4+ T-cell responses in the control of KSHV infection. However, although CD4+ T-cell proliferation as a response to KSHV has been reported (Strickler *et al.*, 1999), a correlation between CD4+ T-cell number and KS resolution during HAART has not been observed (Gill *et al.*, 2002). Future studies should determine the KSHV specific CD4+ T-cell epitopes and the patterns of these responses during primary and persistent infection comparing also with other herpesviruses (Amyes *et al.*, 2003).

B-lymphocytes

Antibody responses from B lymphocytes play a major role in anti-viral immunity (Burton, 2002). Antibodies can bind to viral proteins and block viral entry to the host cells (neutralizing antibodies), inhibit release of viral particles from infected cells, or trigger effector functions through their Fc domain causing the lysis of free virions or infected cells by NK cells (antibody-dependent cellular cytotoxicity, ADCC) or by the complement (complement dependent cytotoxicity, CDC).

The importance of humoral immune responses against human herpesviruses has been shown (Chapters 34, 43, 51 and 72). Furthermore, antibody responses against MHV68, in the absence of CD8+ and CD4+ T-cells, can efficiently control MHV 68 replication (Kim *et al.*, 2002).

Antibody responses are recognized and detectable against KSHV latent and lytic proteins. However, the role of these antibodies in controlling KSHV replication or infection remains to be elucidated.

Antibody epitopes and serological assays for anti-KSHV antibody detection

The ORF73 of KSHV encodes for the major latent nuclear antigen of KSHV. More than 70% of infected individuals have detectable anti-LANA antibodies (Gao *et al.*, 1996; Kedes *et al.*, 1996). These humoral immune responses are directed against epitopes in the C-terminus. Detection of anti-LANA antibodies correlates in different populations with the KS burden (Chapter 54), and the detection of anti-LANA antibodies by indirect immunofluorescence is a useful assay for serological surveys (Fig. 52.2(a)). Several studies have suggested that seroconversion and/or a high antibody titer against LANA correlates with risk of KS development in HIV-1 infected individuals (Gao *et al.*, 1996; Sitas *et al.*, 1999; Sitas and Newton, 2001; Ziegler *et al.*, 2003). However, the association between KSHV load in sera or in PBMC and anti-LANA antibody titer is still unclear.

Strong anti-lytic antibody responses are directed against K8.1, which encodes for an envelope glycoprotein that is the positional homologue of EBV gp220/350 (Chandran *et al.*, 1998). Anti-K8.1 antibodies are detectable in approximately 80% of individuals with AIDS-KS and in more than 90% of

Fig. 52.2. Humoral responses to KSHV and reconstitution during HAART (a) Immunofluorescent assay for anti-LANA antibodies: The KSHV LANA elicits antibody responses and is used for serological studies in an indirect IFA. Sera from KSHV infected individuals recognize LANA and a typical nuclear stippling pattern is observed. **(b)** Several KSHV proteins have been shown to elicit potent humoral responses and used in the development of serological assays for the detection of KSHV infection: Sensitivity and specificity of various serological assays as described in comparative studies (see main text) or unpublished results. Sensitivity is calculated based on the assumption that all individuals with KS should be positive for KSHV. In general, assays combining different proteins (e.g. ELISA combining K8.1 and ORF65 epitopes) are more sensitive than single assays. **(c)** The detection of anti-KSHV antibodies in different populations correlated with KS burden: Various serological assays have been employed to conduct KSHV epidemiological. Although the sensitivity and specificity of these assays vary, overall the global seroprevalence correlated with the incidence of KS: White bars correspond to countries with a low KS incidence (mainly AIDS-KS). Light gray to Mediterranean countries where classic KS occurs, and dark grey to Sub-Saharan Africa with a high prevalence of non-HIV-1 (endemic-) and AIDS-KS, West Africa remains a conudrum, because KS is seldom seen, despite a high seroprevalence of KSHV (reviewed in Ablashi *et al.*, 1999; Sarid *et al.*, 1999; Dedicoat and Newton 2002; Dukers and Rezza 2003; Martin 2003; figure courtesy of Dimitra Bourboulia). (d) The effect of HAART on anti-KSHV humoral responses: LANA and K8.1 epitopes have been used to assess the effect of HAART on KSHV specific humoral responses (Bourboulia *et al.*, 2004). Reconstitution of humoral immunity during HAART, and in particular an increase number of individuals with detectable anti-K8.1 antibodies, coincides with a reduction of plasma KSHV viraemia. However, the role of these humoral responses in controlling KSHV replication is still not elucidated. LANA latent nuclear antigen; IFA, immunofluorescence; ORF, open reading frame, ELISA, enzyme linked immunosorbent assay; MAP, multiple antigenic peptide

individuals with non-AIDS KS (Fig. 52.2(b)). A K8.1 peptide epitope, with no known sequence similarity to any other pathogen has been used in the form of a multiple antigenic peptide (MAP) for the development of a highly sensitive and specific ELISA to detect KSHV infection (Lam *et al.*, 2002). The sensitivity of this ELISA is improved by combining the K8.1 epitope with a known LANA epitope in a MAP (D.Lagos, unpublished data).

Another lytic antigen that generates humoral responses is the small viral capsid antigen encoded by ORF65 (Simpson *et al.*, 1996; Lin *et al.*, 1997). A combination of an ORF65 peptide epitope with a K8.1 epitope is employed in one of the most sensitive and specific, commercially available assays (Schatz *et al.*, 2001) (Fig. 52.2(b)).

Specific antibody responses among individuals with KS have also been reported against ORF26 and K12, although

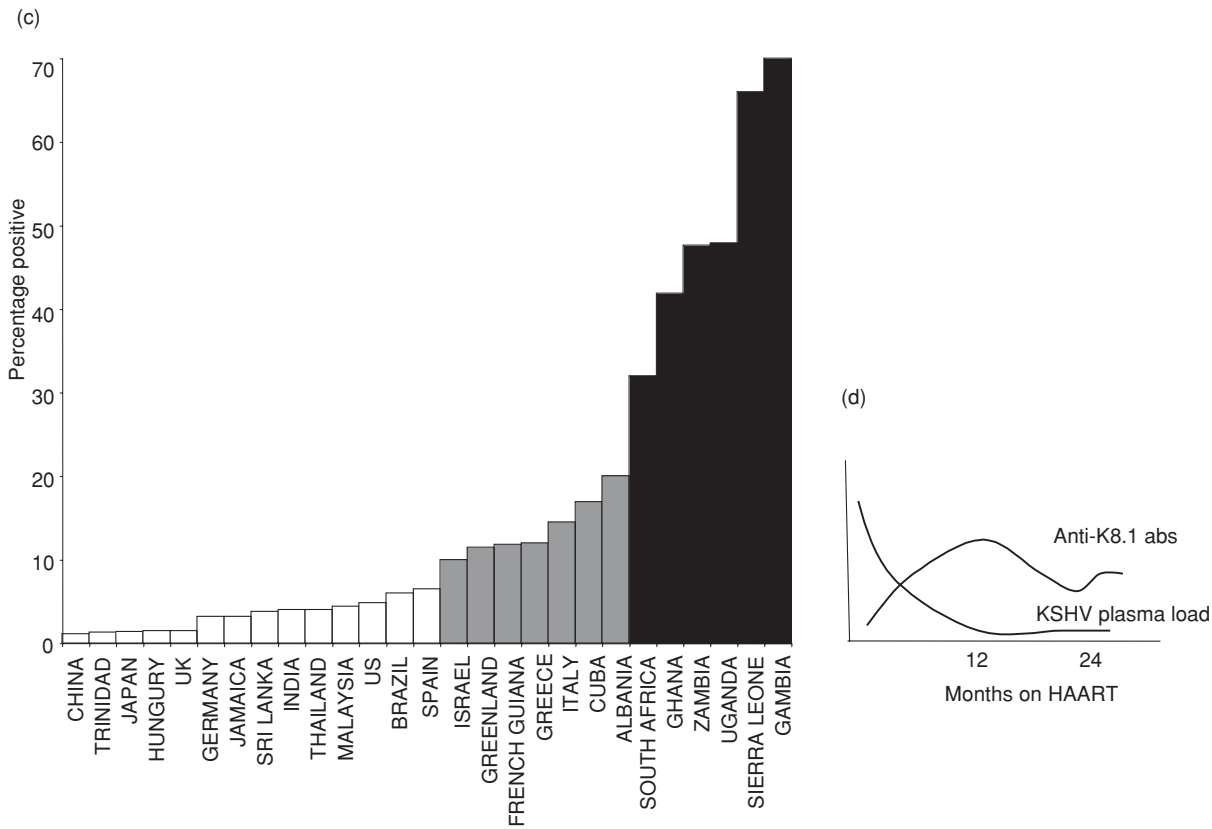

Fig. 52.2. (*cont.*)

significantly less common than LANA, K8.1, and ORF65 (Schatz *et al.*, 2001).

A variety of serological assays for KSHV detection have been described. These include immunofluorescent assays using PEL cell lines and ELISA using virions, purified recombinant proteins, peptide epitopes, mixtures of peptide epitopes, and multiple antigenic peptide epitopes as antigens. These assays have been successfully used in large epidemiological studies providing insight into KSHV biology, transmission, risk factors for KSHV infection and KS development (Ablashi *et al.*, 1999; Sarid *et al.*, 1999; Dedicoat and Newton, 2002; Dukers and Rezza, 2003; Martin, 2003) (Fig. 52.2(c)). The sensitivity of these assays ranges from less than 80% for individuals with AIDS-KS to more than 90% for HIV-1 negative individuals with KS (Rabkin *et al.*, 1998; Enbom *et al.*, 2000; Spira *et al.*, 2000; Schatz *et al.*, 2001; Dukers and Rezza, 2003; Pellett *et al.*, 2003) (Fig. 52.2(b)). There are some AIDS-KS cases where anti-latent and anti-lytic antibodies are not detectable, but KSHV copies can be detected in plasma and/or PBMCs by quantitative PCR (Lallemand *et al.*, 2000). Whether this is due to low sensitivity of the current serological assays or the defect in the humoral immunity of these individuals remains to be elucidated.

Effects of HAART on humoral responses

Although it is not clear if HAART has any significant effect on anti-LANA antibody titer (Wilkinson *et al.*, 2002; Bourboulia *et al.*, 2004), an increase in the number of individuals with detectable anti-K8.1 antibodies coincides with plasma virus clearance during HAART (Bourboulia *et al.*, 2004) (Fig. 52.2(d)). Based on these results it could be proposed that the humoral arm of the immune system plays an important role in the control of the KSHV replication.

How antibodies contribute to KSHV immunity

It has been shown that sera from KSHV-seropositive individuals can block KSHV infection in vitro (Dialyna *et al.*, 2004; Kimball *et al.*, 2004). Moreover, individuals with AIDS-KS display reduced levels of neutralizing antibodies,

Box 52.2. Transmission of cancer, immunity and Kaposi's sarcoma

Until the end of the eighteenth century, it was believed by many that cancer was a contagious disease. James Nooth, an English surgeon, and Jean Louise Alibert, the founder of the French School of Dermatology and personal physician of King Louis XVIII, were the first to independently challenge this hypothesis: both injected themselves with breast cancer cells, which resulted in short-lived local inflammatory responses, but no tumour establishment. They concluded that cancer was not contagious.

The discovery in 1908 by Peyton Rous that cell-free filtrates from tumors could transmit cancer between Plymouth Rock hens heralded the era of viral oncology and sparked a debate whether viruses were responsible for most cancers. The first evidence that a virus was indeed involved in the pathogenesis of a human cancer only emerged in 1964 with the discovery of Epstein–Barr virus. Two years later Peyton Rous was awarded the Nobel Prize in Physiology of Medicine for his discovery of "tumor inducing viruses."

In the 1950s, selective immunosuppressant drugs were developed and organ transplantation became a life-saving reality. However, the first case of a kidney transplant recipient who developed iatrogenic Kaposi's sarcoma was reported soon afterwards. It was also noticed that Kaposi's sarcoma can disappear when immunosuppression is stopped, linking immunity closely with Kaposi's sarcomagenesis. The transmission of other cancers during organ transplantation, e.g., melanoma, has also been documented.

Until recently, it was widely accepted that iatrogenic Kaposi's sarcoma was due to the loss of immunesurveillance against KSHV: It was thought that KSHV could be transmitted from donor to host, or that immunosuppressive drugs led to the reactivation of KSHV in already infected recipients. The provocative finding in 2003 that certain cases of post-organ transplant Kaposi's sarcoma are due to the transmission of KSHV-infected precancerous cells, revived the debate on the transmission of cancer. Ironically, this is a tumor induced by a virus, where both host cell and pathogen are transmitted simultaneously. These findings infer that KSHV not only infect endothelial cells during periods of immunodeficiency, but that KSHV-infected circulating endothelial cells are present in otherwise healthy individuals. Notably, the concept of cancer cell transmission is further supported by the identification in 2006 of the oldest known somatic mammalian clonal cell population as the causative agent of the canine transmissible venereal tumor.

The wider implications of this are that in populations such as certain sub-Saharan African countries with a large HIV-1 burden where many are immunosuppressed, the transmission of cancer cells between infected individuals, e.g., Kaposi's sarcoma or anogenital cancer may represent a reality. The study of iatrogenic Kaposi's sarcoma would provide further insight into the immunological control of cancer.

despite the fact that higher total binding antibody levels are observed in this group (Kimball *et al.*, 2004). This implies that the humoral immunity plays a crucial role in the prevention of KS development and that the most immunogenic KSHV antigens are not necessarily the targets of neutralizing antibodies. However, the contribution of KSHV neutralizing antibodies in controlling in vivo infection needs to be addressed further, as the neutralizing titers are low and the specific epitopes not known. K8.1 could be such a neutralizing antibody target as it is directly involved in the process of viral entry into host cells by binding to heparan sulfate (Birkmann *et al.*, 2001; Chapter 23) and reconstitution of anti-K8.1 humoral responses during HAART coincides with virus clearance. Of note, gp 220/350, the EBV positional homologue of K8.1, elicits neutralizing antibody responses and has been investigated as a target for development of an EBV vaccine (Chapter 72). Another candidate for KSHV-specific neutralizing antibodies is glycoprotein B, which is also involved in viral entry (Chapter 23). Rabbit polyclonal antibodies raised against glycoprotein B

neutralize infectivity in vitro (Akula *et al.*, 2002). In addition to their neutralizing potential, antibodies can control KSHV infection through their effector functions. It has been reported that the genotype of the low affinity Fc receptor FcγRIIIA can contribute protection or conversely be a risk factor for KS development (Lehrnbecher *et al.*, 2000). This receptor is expressed on the surface of NK cells and could be an important factor influencing ADCC activity. Further studies are necessary to elucidate the role of the humoral immunity in the host defense against KSHV.

Conclusions and future perspectives

Excluding pox viruses, KSHV has pilfered an unprecedented array of cellular genes, mainly to impede the function of host antiviral immune responses. During immunosuppression, both the innate and adaptive anti-KSHV immune responses are hampered, allowing the uncontrolled proliferation of KSHV-infected cells that belong to the B-lymphocyte and EC lineages.

KSHV proteins that elicit humoral and cellular immune responses are being identified and the consequences of immunodeficiency (HIV-1 induced or iatrogenic) and immune-restoration are being elucidated. Such studies will allow the understanding of the anti-KSHV host defence mechanisms and could eventually lead to the generation of an effective vaccine. During the next couple of years, the study of KSHV immunobiology should also provide further insight into tumor and transplant immunology.

The epidemiology of EBV and its association with malignant disease

Henrik Hjalgrim, Jeppe Friborg, and Mads Melbye

Department of Epidemiology Research, Statens Serum Institut, Artillerivej 5, 2300 Copenhagen S. Denmark

EPSTEIN-BARR VIRUS EPIDEMIOLOGY

Epidemiology of primary Epstein-Barr virus infection

Epstein-Barr virus (EBV) is an ancient virus, and has probably coevolved with its different hosts over the last 90–100 million years (McGeoch *et al.*, 1995). With the ability to establish lifelong latency and intermittent reactivation after primary infection and with limited clinical symptoms in the majority of infected individuals, EBV has become ubiquitous in all human populations

Age at primary infection

Children in developing countries acquire the infection in the first few years of life, and universal seroconversion is often seen by ages 3–4 years, whereas infection in developed countries often is delayed until adolescence (de The *et al.*, 1975; Haahr *et al.*, 2004; Henle and Henle, 1967; Melbye *et al.*, 1984a,b) (Figure 53.1). In some developed countries a bimodal infection rate, with peaks in children below 5 years and again after 10 years of age, has been described (Edwards and Woodroof, 1979; Henle and Henle, 1967; Lai *et al.*, 1975). Oral EBV excretion between parents and infants, and from intimate partners in adolescence and early adulthood is the likely explanation for the observed bimodality (Crawford *et al.*, 2002; Fleisher *et al.*, 1979).

EBV antibody titers in seropositive individuals vary according to age following a U-shaped pattern, with high titers among infants and in the elderly (above 50 years) (Glaser *et al.*, 1985; Venkitaraman *et al.*, 1985). High antibody titers in infants probably reflect primary infection, whereas in the elderly it may be due to an age-dependent reactivation due to a reduced cellular immune response (Wick and Grubeck-Loebenstein, 1997).

Geographic variation

EBV has been detected in all populations and all areas of the world (IARC, 1997), but with noticeable geographical variation in the distribution of EBV genotypes. Two major types of EBV, type 1 and 2, have been described in humans, varying in the genes that encode some of the nuclear proteins in latently infected cells (Sample *et al.*, 1990). Both types are detected all over the world, with type 1 being the most prevalent. However, in some regions (e.g. central Africa, Papua New Guinea and Alaska) type 2 is more prevalent (Table 53.1) (Gratama and Ernberg, 1995; Zimber *et al.*, 1986). It is assumed that the geographical distribution of the two types in EBV-associated diseases reflects the general prevalence in the areas involved (Gratama and Ernberg, 1995). Thus, there seems to be no clear association between the two types and specific diseases.

In most areas recovery of type 2 is unusual, except in immunodeficient (HIV+ individuals and transplant recipients) carriers. The increased detection in immunodeficent individuals has been explained by an increased exposure to exogenous virus combined with deficient EBV-specific cellular immunity, leading to long-term carriage of multiple EBV genotypes (Gratama and Ernberg, 1995). The frequency of the type 2 genotype in HIV-positive haemophiliacs is comparable to the frequency in healthy individuals, which indicates that the immunodefiency *per se* is not responsible for increased type 2 detection (Yao *et al.*, 1998).

The distribution of specific DNA sequence polymorphisms also shows geographic variation, with the epidemiology of the EBV-encoded oncogene LMP-1 being the most thoroughly studied. Numerous sequence variations have been identified in LMP-1 genes from different EBV isolates, some of which have been associated with an increased risk of nasopharyngeal carcinoma (Jeng *et al.*, 1994).

Table 53.1. Distribution of EBV types 1 and 2 in various clinical conditions and among healthy patients. (Partly reproduced from Gratama and Ernberg, 1995 with permission from Elsevier.)

Country	Patients	N	Type 1 (%)	Type 2 (%)	Both types (%)
China (Hu *et al.*, 1991)	Nasopharyngeal carcinoma	37	86	14	0
Taiwan (Shu *et al.*, 1992)	Nasopharyngeal carcinoma	53	94	4	2
Korea (Kim *et al.*, 2002)	Healthy	26	81	15	4
Japan (Kunimoto *et al.*, 1992)	Healthy	21	95	5	0
USA (Frank *et al.*, 1995)	Post-transplant lymphoproliferative disease	24	100	0	0
USA (Goldschmidts *et al.*, 1992)	HIV-positive	22	55	45	0
Alaska (Abdel-Hamid *et al.*, 1992)	Nasopharyngeal carcinoma	3	0	100	0
Argentina (Correa *et al.*, 2004)	Healthy	183	78	15	7
Brasil (Klumb *et al.*, 2004)	Burkitt's lymphoma	21	86	14	0
Central Africa (Goldschmidts *et al.*, 1992)	Burkitt's lymphoma	16	50	50	0
Papua New Guinea (Aitken *et al.*, 1994)	Burkitt's lymphoma	56	42	53	5
Western Europe (Sandvej *et al.*, 1994)	Hodgkin's disease	55	93	5	1
Australia (Kyaw *et al.*, 1992)	HIV-positive	56	27	30	43
Australia (Kyaw *et al.*, 1992)	Cardiac transplants	18	39	33	28

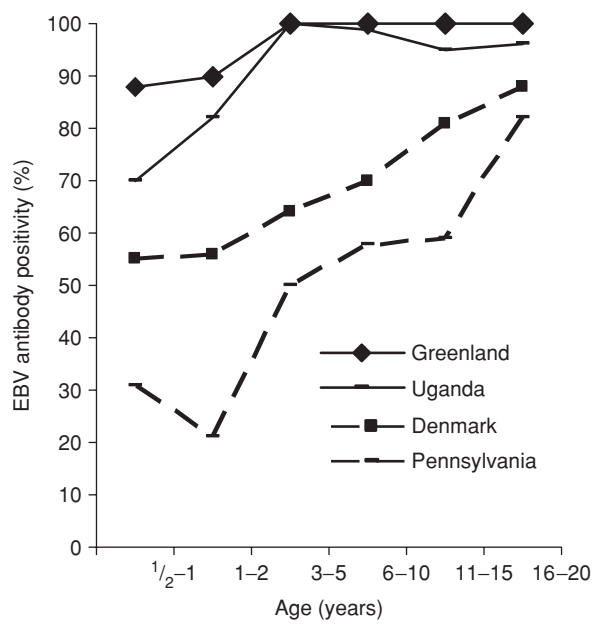

Fig. 53.1. Age-specific distribution of EBV antibody positive individuals in four populations. Reproduced from de The *et al.*, 1975; Henle and Henle, 1967; Melbye *et al.*, 1984.

Studies indicate that LMP-1 sequence variants from nasopharyngeal carcinoma high-incidence areas in Southeast Asia have evolved distinct from LMP-1 variants in nasopharyngeal carcinoma low-incidence areas such as areas of Australia, Papua New Guinea, and Africa (Burrows *et al.*, 2004) suggesting that positive selection pressure on the LMP-1 sequences may enhance the oncogenic potential of virus isolates from nasopharyngeal carcinoma endemic areas.

Sex differences

There is no consistent difference in EBV seroprevalence by sex in children (Golubjatnikov 1973; Lang *et al.*, 1977; Sumaya *et al.*, 1975). In developed countries, this similarity continues into early adolescence, when a higher seroprevalence and an earlier occurrence of infectious mononucleosis among girls indicate earlier exposure to the virus (Crawford *et al.*, 2002).

Generally, antibody titers seem to be higher in females than in males (Biggar *et al.*, 1981; Levine *et al.*, 1982; Wagner *et al.*, 1994). This difference, which also has been observed for other viruses, is in accordance with the notion that women in general mount more vigorous antibody- and cell-mediated immune response following infection or vaccination than men (Beagley and Gockel, 2003).

Socioeconomic factors

Poor socioeconomic conditions have been associated with early primary EBV infection, whereas late primary EBV infection is seen in populations of high socioeconomic status. Based on father's education and the family's living conditions, Henle and colleagues documented a seroprevalence of 60% among young American school children (aged 5 to 10 years) of low socioeconomic status compared to less than 20% in children with high socioeconomic level (Henle

et al., 1969). Low income and crowded family conditions have also been found to increase the likelihood of being EBV seropositive in children from other geographical locales, such as Thailand (Mekmullica *et al.*, 2003), Turkey (Ozkan *et al.*, 2003), Ghana (Biggar *et al.*, 1978) and Denmark (Hesse *et al.*, 1983). In an early work by Lang and colleagues (Lang *et al.*, 1977) three genetically different Melanesian populations with differences in living conditions and social patterns were found to have similar patterns of early EBV infection. In all three populations the mothers chew the food before feeding the children. Thus, exposure to saliva either directly or via for example unclean toys are believed to explain differences in socioeconomic conditions. This is in line with the observation that socioeconomic associated differences in sero-prevalence are greatly diminished in age groups who have become sexually active.

Genetic and racial factors

Differences in prevalence and more generally the infection patterns have never been clearly associated with race, but merely seen as differences in socioeconomic, hygienic, and cultural behavior. The high prevalence of EBV infection in populations around the world would indicate that the influence of host-specific characteristics on natural resistance to EBV infection is limited. Yet, the distinct distribution of nasopharyngeal carcinoma (NPC) with high incidence figures observed in Inuits from the Arctic and in South-East Asian populations suggests the existence of a particular immunologic control of EBV in these ethnicities, though the exact mechanism remains to be described (Hildesheim *et al.*, 2002; Yu and Yuan, 2002). Supportive of a genetically determined response to the EBV carrier state is the finding among Greenlandic Inuits of remarkably high titers throughout life of IgG antibodies to EBV-VCA (Melbye *et al.*, 1984a,b).

Transmission

Most frequently, EBV transmission takes place through oropharyngeal secretion. In adolescent and adult cases of IM intimate kissing has been the main route of transmission whereas saliva on, for example, toys and fingers is believed to be major routes of transmission among smaller children. However, 40 years into the discovery of EBV we still need data to better explain the exact determinants of infection. Among EBV seronegative adults, close contact with IM cases (Sawyer *et al.*, 1971), or longer stays together with seropositive persons in a restricted space (Storrie and Sphar, 1976) only infrequently leads to secondary cases. On the contrary, EBV infection frequently takes place among smaller children of low socioeconomic status, in nurseries (Chang *et al.*, 1981) and when sharing a room (Crawford *et al.*, 2002).

Shedding of EBV in saliva among seropositive individuals ranges from 22% to 90% (Apolloni and Sculley, 1994; Haque and Crawford, 1997; Ikuta *et al.*, 2000; Sixbey *et al.*, 1984;Yao *et al.*, 1991). Ling and colleagues observed that shedding of EBV in saliva among adults at any given time over a 12 months period varies between 32% and 73% (Ling *et al.*, 2003). These and other authors were unable to detect any correlation between viral shedding frequency or viral load in saliva and the presence of EBV in PBMCs (Haque and Crawford, 1997; Ling *et al.*, 2003), suggesting that the factors responsible for EBV reactivation in the oropharynx are different from those governing viral load in the blood.

EBV has been detected in cervical secretions in between 8 and 28% of teenage girls and adult women, and in semen samples and samples scraped from the penile sulcus of men (Enbom *et al.*, 2001; Israele *et al.*, 1991; Kapranos *et al.*, 2003; Naher *et al.*, 1992), but evidence on whether EBV is transmitted through genital contact is limited. A recent study found EBV type 2 among homosexual men to be significantly more prevalent than among heterosexual men and to be correlated with the number of sexual partners (van B. D. *et al.*, 2000). However, the exact mode of transmission in these studies remains unknown since it is difficult to distinguish between genital transmission, orogenital contact and kissing.

Transplacental transmission and transmission through breast milk have been reported in rare circumstances, but are considered non-significant modes of transmission (Fleisher and Bologonese, 1984; Kusuhara *et al.*, 1997; Meyohas *et al.*, 1996). EBV may be spread through blood transfusion and as a result of organ transplantation (Alfieri *et al.*, 1996; Scheenstra *et al.*, 2004). One transfusion unit of erythrocytes contains an average of two EBV genomes, in contrast to a whole blood unit which harbored on average 600 to 700 EBV genomes (Wagner *et al.*, 1995). Transmission is of particular concern in association with organ transplantations where primary EBV infection is a major risk factor for post-transplant lymphoproliferative disease (PTLD) (Aguilar *et al.*, 1999; Bodeus *et al.*, 1999; Scheenstra *et al.*, 2004).

EBV viral load epidemiology

During the recent decade, methods for detecting and quantifying cellular and extracellular EBV in peripheral blood have improved significantly. Initially applicable only to small series of patients, modern techniques such as

real-time PCR have now made large studies feasible. However, the majority of these have been performed to investigate EBV viral loads in specific diseases, and knowledge on EBV viral load in healthy individuals has mainly been generated from the control groups, rarely selected randomly from the population.

EBV viral load in peripheral blood mononuclear cells (PBMCs) is the combined result of the number of infected B cells and the number of EBV genomes per B-cell. A roughly constant number of infected B cells (1–50 *per* 1,000,000) is present in peripheral blood in the healthy latently infected host, but the number seems to vary considerably between individuals (Khan *et al.*, 1996). Differences in detection methods, sample preparation and measurement units make comparisons of EBV viral loads from different studies difficult. But the EBV viral load appears to be transiently elevated at the time of primary EBV infection (Fan and Gulley, 2001). In general, the viral load observed in PBMCs from healthy individuals is low (<100 DNA genome copies *per* ug DNA) compared to the high EBV loads observed in some EBV-associated diseases (ex. post-transplant lymphoproliferative disease (PTLD)) (Stevens *et al.*, 2002a,b). The low EBV viral loads in most healthy EBV-infected individuals reflect the low frequency of EBV-positive B cells in the circulation, whereas the high EBV loads observed during PTLD and immune suppression are the result of increased numbers of EBV infected B cells (Babcock *et al.*, 1999; Yang *et al.*, 2000), together with an increased number of EBV genomes in some of the infected B cells (Rose *et al.*, 2002). However, EBV viral load in PBMCs in the single healthy individual does not appear to be static. As healthy individuals are followed over time, short episodes of increased viral load can be observed, suggestive of EBV reactivation (Maurmann *et al.*, 2003), and measurement of EBV viral load in PBMCs and plasma seem to detect episodes of EBV reactivation earlier and with greater sensitivity than the traditional serological methods (Figure 53.2). EBV detection in whole blood and serum/plasma is becoming the 'gold standard' and most commonly utilized test, as it is less laborious and more reproducible than PBMCs.

The correlation between EBV viral load in PBMCs and serological response is not obvious (Gartner *et al.*, 2000). Increased anti-p18-VCA, suggestive of lytic viral replication, and decreased anti-EBNA-1 IgG levels has been associated with high EBV loads in HIV carriers (Stevens *et al.*, 2002a,b).

EBV in plasma or serum, which is frequently detected in patients with nasopharyngeal carcinoma or PTLD, is only rarely detected in healthy individuals, although EBV viremia can be detected in association to episodes of EBV reactivation (Lechowicz *et al.*, 2002;).

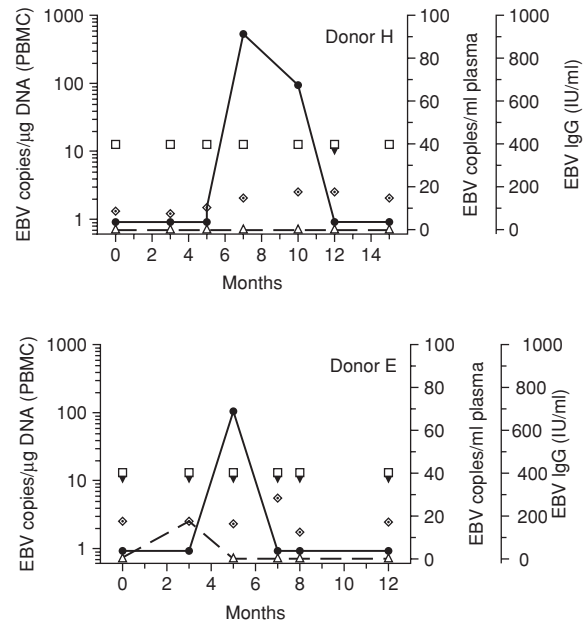

Fig. 53.2. Healthy individuals with serological evidence of EBV reactivation during 15 months of follow-up. -_- viral load (PBMC), -△- Viremia (plasma), ◇ EBV IgG (IU/ml). Partly reproduced from Maurmann *et al.*, 2003.

Infectious mononucleosis

Primary EBV infection is usually considered asymptomatic when occurring in infants and small children, and most of the knowledge on primary infection is derived from studies of adolescent patients with infectious mononucleosis. However, the assumption that primary EBV infection in childhood is always subclinical is probably fallacious, as when looked for, infectious mononucleosis symptoms may also occur in infants in association with primary EBV infection (Chan *et al.*, 2003). Although symptoms may be milder, primary infection in infants is not presumed to be fundamentally different from the characteristic picture of infectious mononucleosis (IARC, 1997).

Primary EBV infection in adolescence causes infectious mononucleosis in more than half of the infected individuals. Symptoms of infectious mononucleosis (glandular fever) commence after an incubation period of 4–7 weeks, and typically (in more than 50%) include fever, lymphadenopathy and pharyngitis (Chang, 1980).

Confirmation of the diagnosis has traditionally been based on the detection of heterophil antibodies, which are present in 86% of adolescents and adults with infectious mononucleosis (Fleisher *et al.*, 1983), but less frequently in acutely infected small children (Chan *et al.*, 1998). However,

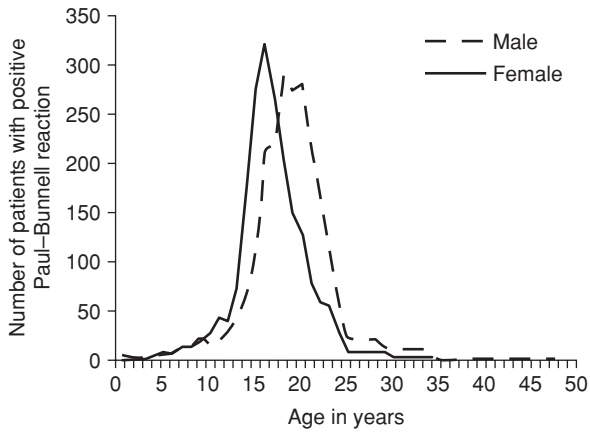

Fig. 53.3. Age-and sex-specific distribution of positive Paul–Bunnell reactions at Statens Serum Institut in Denmark 1965–1969. Reproduced from Rosdahl *et al.*, 1973 with permission from Taylor & Francis Scandinavia.

positive detection of heterophil antibodies can occur in other conditions, including HIV infection, Systemic Lupus Erythematosus, and other viral diseases (Hendry and Longmore, 1993; Horwitz *et al.*, 1979; Macsween and Crawford 2003). Detection of IgM to the viral capsid antigen (VCA) is both more sensitive and specific, and is present at time of onset of clinical symptoms. Both heterophil antibodies and anti-VCA IgM are transient and disappears within months, and detection of EBV-DNA in serum might be useful as a supplement to serology for the diagnosis (Chan *et al.*, 2001).

Epidemiology

The majority of infectious mononucleosis patients are not hospitalized, but reliable data on the population incidence is available from sentinel systems, centralized laboratories or from areas where infectious mononucleosis is a reportable disease. Incidence rates between 60–100 *per* 100,000 person-years in Caucasian populations seem consistent (Evans *et al.*, 1997; Morris and Edmunds, 2002; Rosdahl *et al.*, 1973). In these populations the incidence of infectious mononucleosis increases from the age of 2–4 years to reach a maximum in adolescence and early adulthood, after which the disease incidence decreases, to become rare after 40 years of age (Figure 53.3) (Auwaerter, 1999; Rosdahl *et al.*, 1973). The age-specific distribution of cases reflects the clinical disease ratio of primary EBV infection which is low in children, and may reach 74% among college students (Sawyer *et al.*, 1971). The low incidence among older adults reflects the low number of EBV-uninfected individuals. There seems to be no seasonal variation in incidence rates.

Table 53.2. Factors influencing the development of infectious mononucleosis

EBV immune status
Age at time of infection
IL-10 polymorphisms

The difference in infectious mononucleosis incidence rates between ethnic groups within the same region, probably reflects variation in social and economic factors, influencing age at primary infection (Heath *et al.*, 1972; Melbye *et al.*, 1984a,b), and there is no evidence of racial differences in infectious mononucleosis susceptibility.

Risk factors for infectious mononucleosis

The factors influencing clinical disease are summarized in Table 53.2.

The marked difference in infectious mononucleosis incidence in comparable settings with an equal number of susceptible individuals, indicates that determinants other than immune status and age at infection are involved. As intimate contact appears to account for most cases of infectious mononucleosis (Crawford *et al.*, 2002), age-specific incidence of infectious mononucleosis in otherwise comparable settings can differ due to behavioural differences.

In children, carriage of the ATA haplotype in the promoter of interleukin (IL)-10, is associated with high levels of spontaneous IL-10 and a late age of primary EBV infection. Thus, the ATA haplotype may increase the age at primary infection and perhaps also the risk of symptomatic disease (Helminen *et al.*, 2001).

Studies on HLA-alleles and infectious mononucleosis have produced conflicting results. A higher frequency of HLA-B-3501 among infectious mononucleosis cases compared to controls has been reported, however, the association between infectious mononucleosis, HLA-B-3501 and other HLA-alleles has not been reproduced in other populations (Chang, 1980).

Viral factors, including EBV strain variation, have not been associated with a different ability to cause infectious mononucleosis.

EBV dynamics during infectious mononucleosis

In healthy seropositive individuals EBV DNA in serum is only occasionally detected, but in the acute phase of infectious mononucleosis high loads of EBV DNA in serum is

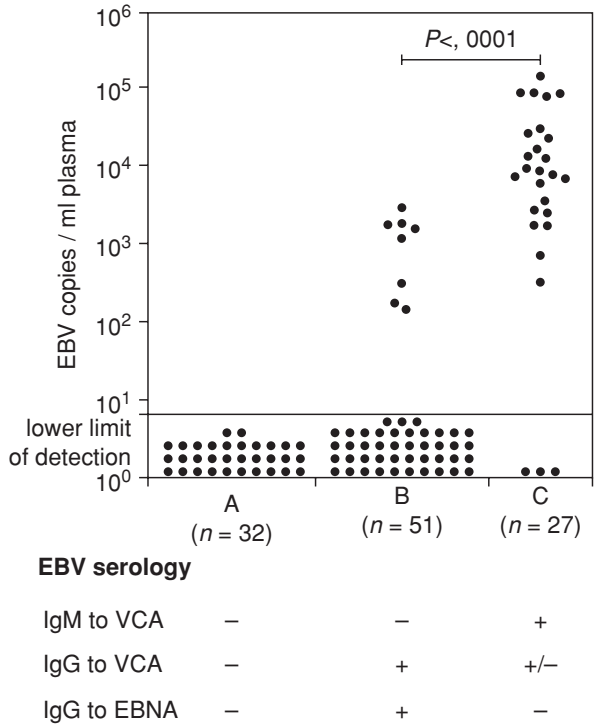

Fig. 53.4. EBV DNA levels in sera from individuals with different EBV-antibody patterns. A: sero-negative, B:sero-positive, C: acute EBV-infection. Reproduced from Berger *et al.*, 2001 with permission from John Wiley & Sons, Inc.

present in most patients (Fig. 53.4) (Berger *et al.*, 2001). The peak in serum viral load is observed in the first seven days of disease, thereafter viral load decreases with resolution of symptoms, although there seem to be considerable inter-individual differences in the decline (Berger *et al.*, 2001). Parallel with the increase in serum viral load, the EBV viral load in peripheral blood mononuclear cells (PBMC) increase to a maximum within the first weeks of the disease, and thereafter declines (Kimura *et al.*, 1999). However, sustained high levels of EBV DNA is found in saliva for at least 6 months after onset of clinical disease, associated with persistent infectivity of saliva (Fafi-Kremer *et al.*, 2005).

Despite the lack of massive expansion in numbers of T lymphocytes in asymptomatic primary EBV infection, both patients with IM and asymptomatic primary infection have similar high EBV viral loads in PBMC. Thus the large T cell expansion seen in IM patients may represent an overreaction, not associated with the control of the primary EBV infection (Silins *et al.*, 2001).

Studies on EBV viral load in primary infection have focused on the time around the infection, and the importance of early versus delayed primary EBV infection on long-term EBV viral load is unknown.

Table 53.3. Proposed guidelines for diagnosing CAEBV (all conditions must be fulfilled). Adapted from Okano *et al.*, 2005 with permission from John Wiley & Sons, Inc.

I.	Persistent or recurrent infectious mononucleosis-like symptoms
II.	Unusual pattern of anti-EBV antibodies with raised anti-VCA and anti- EA, and/or detection of increased EBV genomes in affected tissue, including the peripheral blood
III.	Chronic illness which cannot be explained by other known disease processes at diagnosis*

* EBV-associated diseases such as hemophagocytic lymphohistiocytosis or lymphomas mainly derived from T-cells or NK-cells often develop during the course of illness.

Chronic active EBV infection

Chronic active EBV infection (CAEBV) was first described in the late 1970s, and is characterized by chronic or recurrent infectious mononucleosis-like symptoms and by an unusual pattern of EBV antibodies. Criteria's for diagnosing CAEBV has been suggested earlier, and recently a new set of guidelines has been proposed (Table 53.3) (Okano, *et al.*, 2005; Straus, 1988).

The antibody pattern resembles acute infection and is characterized by high titers of IgG-VCA and IgG-EA, and absence of EBNA antibodies. Patients with CAEBV also have lower frequencies of EBV-specific $CD8^+$ T-cells, compared to infectious mononucleosis patients and healthy individuals (Sugaya *et al.*, 2004). Methods for measuring EBV viral load can be included, as high EBV viral loads in peripheral blood lymphocytes and serum are present (Kimura *et al.*, 2001). There is no known hereditary background, and CAEBV is not associated with mutations in the gene responsible for X-linked lymphoproliferative syndrome (Sumazaki *et al.*, 2001).

CAEBV seem to constitute a disease spectrum with unusual EBV activation, from chronic symptomatic EBV infections with moderately elevated EBV antibodies and a generally good prognosis, to severe chronic active EBV infection with extraordinarily elevated EBV antibodies, clonal expansion of EBV-infected T cells and NK cells, severe clinical and hematological findings, and a generally poor prognosis with high mortality from pancytopenia, lymphoma and hepatic failure (Fig. 53.5) (Kimura *et al.*, 2001; Okano, 2002).

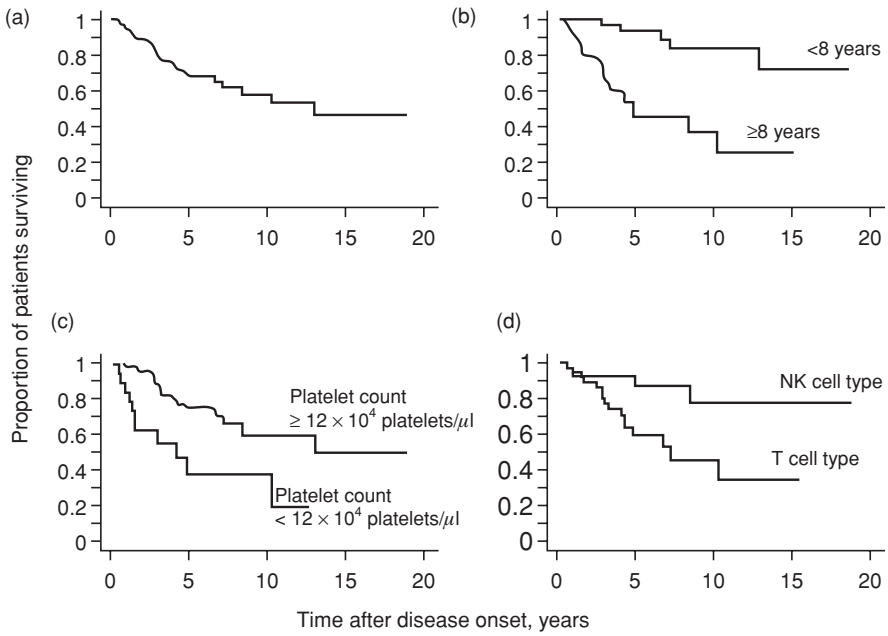

Fig. 53.5. Survival after onset of severe CAEBV. All patients (A), and according to age (B), platelet count (C) and T/NK cell-type of disease (D). Reproduced from (Kimura *et al.*, 2001) with permission from The University of Chicago Press.

Thrombocytopenia and age> = 8 years at onset of disease are associated with a poorer outcome (Kimura *et al.*, 2003).

Epidemiology

Studies on CAEBV have been based on case series, and estimates of population incidences are not available. The disease is very rare, and in 2002 a national survey of severe CAEBV in Japan identified 82 patients (Kimura *et al.*, 2003). Mean age at onset of disease in this survey was 11.3 years with men and women equally represented. Many of the studies on CAEBV have originated in Japan, but whether this reflects a true difference in incidence, or an increased awareness is unknown. However, CAEBV in different geographical areas may be of different entities, as CAEBV in Western populations appears to be milder (Savoldo *et al.*, 2002).

X-linked lymphoproliferative syndrome

X-linked lymphoproliferative syndrome (XLP) or Duncan's disease is a rare, primary immunodeficiency that was first described as a familial disorder affecting males with a rapidly fatal course in response to EBV infection (Purtilo *et al.*, 1975). XLP is characterized by three major phenotypes (Table 53.4): fulminant infectious mononucleosis, B cell lymphoma and dysgammaglobulinemia. Occasionally aplastic anemia, vasculitis and pulmonary lymphomatoid granulomatosis are seen (Engel *et al.*, 2003). A patient can develop more than one phenotype.

Table 53.4. Phenotypes of X-linked lymphoproliferative syndrome. Adapted from Engel *et al.*, 2003 with permission from Nature Publishing Group.

Phenotype	Proportion (%)
Fulminant infectious mononucleosis	50
Following infection with Epstein–Barr virus, patients mount a marked polyclonal expansion of B and T cells leading to destruction of the liver and bone marrow	
B-cell lymphoma	30
Extranodal non-Hodgkin's B-cell lymphomas, usually Burkitt's type, most of which involve the ileocecal region of the intestine	
Dysgammaglobulinemia	30
Acquired dysgammaglobulinemia and other abnormalities in immunglobulin synthesis	

A lack of immune surveillance of EBV in patients with the infectious mononucleosis phenotype of XLP is assumed, however, the phenotypes with B-cell lymphoma and dysgammaglobulinaemia can be observed in patients with or without signs of previous infection with EBV, suggesting

Table 53.5. Effect of EBV infection on clinical phenotype in XLP. Adapted from (Sumegi, *et al.* 2000) with permission from the American Society of Hematology

Phenotype	EBV+ (n = 114)	EBV− (n = 38)	P
Fulminant infectious mononucleosis	70	0	0.0001
Dysgammaglobulinaemia	19	15	0.30
Lymphoproliferative disease	20	21	0.24
Aplastic anemia	5	2	0.03

other antigenic stimuli are also involved in the development of XLP (Table 53.5) (Engel *et al.*, 2003; Sumegi *et al.*, 2000).

Treatment is difficult, haematopoietic stem cell transplantation for fulminant infectious mononucleosis and B-cell lymphomas, and immunoglobulin treatment for agammaglobulinemia has been suggested, but the mortality by the age of 40 years is nearly 100% (Gross *et al.*, 1996; Morra *et al.*, 2001).

The genetic basis for XLP has been identified as an alteration or deletion of the gene SH2D1A, that codes for a cytoplasmatic protein, SAP (SLAM-associated protein, where SLAM is 'signalling lymphocytic activation molecule') (Coffey *et al.*, 1998; Nichols *et al.*, 1998). SAP interacts with several signaling molecules of the SLAM (CD150) family, and is expressed by all T and NK cells. Defective SAP causes selective alterations of the T-/NK-cell function that compromise the ability of these cells to control infection with EBV (Benoit *et al.*, 2000; Engel *et al.*, 2003). Elevated EBV antibody titers are observed in mothers to boys with XLP, although, normal levels of circulating EBV-DNA in XLP patients surviving the initial phase suggest that SAP function is not essential for proper control of EBV replication after primary infection (Sumazaki *et al.*, 2001).

Mutations of SH2D1A are detected in nearly all cases of XLP with a previous family history of XLP, however, mutations of SH2D1A are frequently missing in XLP cases without a family history (Sumegi *et al.*, 2000), although de novo mutations can occur (Sumazaki *et al.*, 2001).

Epidemiology

XLP is estimated to affect approximately 1 in 1,000,000 males (Purtilo *et al.*, 1975). However, this number is likely to be an underestimate, due to the similarity of disease manifestations with other clinically related disorders, such as common variable immunodefiency and the hemophagocytic syndromes (Nichols *et al.*, 2005). The age at onset of clinical disease vary considerably from less than one year to 40 years, with a median of three to eight years (Sumegi *et al.*, 2000). An international XLP registry was established in 1978 and contains over 300 patients from more than 80 families, with up to 17 affected males reported from a single family (Hamilton *et al.*, 1980; Sumegi *et al.*, 2000). XLP patients have been reported from North and South America, Europe and Japan, but it is unknown whether the geographical distribution reflects true differences in incidence or differences in awareness.

Epstein–Barr virus and malignant neoplasms

EBV has been implicated in the development of a wide variety of benign and malignant diseases (Table 53.6). In the following, only the virus' association with malignant diseases will be described. Accordingly, the association between EBV and autoimmune conditions such as multiple sclerosis (Wekerle and Hohlfeld, 2003) or systemic lupus erythematosus (Kang *et al.*, 2004), or immune deficiency-related conditions, such as oral hairy leukoplakia (Niedobitek *et al.*, 1991) and lymphoid interstitial pneumonitis (Swigris *et al.*, 2002) will not be discussed. Focus will be on the main characteristics of EBV-associated cancers and on the evidence linking them with the virus. Nasopharyngeal carcinoma, Burkitt's lymphoma, and Hodgkin's lymphoma will be described in some detail, whereas the association between EBV and other malignant disorders are described more cursorily.

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma is derived from the epithelial lining of the nasopharynx. It typically develops in the lymphoreticular tissue rich area in the fossa of Rosenmüller, and less frequently in the roof and wall of the nasopharynx (IARC, 1997). Histopathologically, two major groups of nasopharyngeal carcinomas are recognized, i.e. keratinizing squamous cell carcinoma (WHO type I), and non-keratinizing carcinoma, the latter being further split up into differentiated (WHO type II) and undifferentiated carcinomas (WHO type III) (Shanmugaratnam, 1991).

Epidemiology

The occurrence of nasopharyngeal carcinoma is characterized by a remarkable geographical and ethnic variation as reflected in the combined occurrence of all types of cancer in the nusopharynx (Table 53.7). (Yu and Yuan, 2002). The

Table 53.6. Evidence for an association between different types of cancer and EBV. Adapted from Hsu and Glaser, 2000

Malignancy	Lines of evidence
Nasopharyngeal carcinoma	• Elevated anti-EBV antibody titers preceding and at diagnosis • Elevated levels of free EBV DNA at diagnosis • Correlation between anti-EBV antibodies and free virus DNA in plasma, and tumor burden and prognosis • Demonstration of monoclonal EBV in tumor cells
Lymphomas Burkitt's lymphoma variants	• Elevated anti-EBV antibody titers preceding and at diagnosis • Demonstration of monoclonal EBV in tumor cells • Increased occurrence in immune suppressed patients
AIDS associated lymphoma [other than Burkitt' lymphoma	• Increased occurrence compared with general population • Overall risk correlates with immune function • Demonstration of monoclonal EBV in malignant cells
Post-transplant lymphoma	• Increased occurrence compared with general population • Overall risk correlates with immune function • Demonstration of monoclonal EBV in malignant cells
Nasal T/NK lymphoma	• Demonstration of monoclonal EBV in tumor cells
Hodgkin's lymphoma	• Increased risk in infectious mononucleosis patients • Increased risk in immune suppression • Elevated anti-EBV antibody titres preceding and at diagnosis • Demonstration of mononclonal EBV in malignant cells
Gastric adenocarcinoma	• Elevated anti-EBV antibody titers preceding and at diagnosis • Demonstration of monoclonal EBV in tumor cells
Lymphoepithelioma-like carcinoma	• Demonstration of monoclonal EBV in malignant cells
Leiomyosarcoma	• Increased risk with immunosuppression • Demonstration of mononclonal EBV in malignant cells

tumor is quite rare in most Western countries with incidence rates less than 1 per 100 000 persons per year, as is it indeed in most parts of the world, but high incidence rates are observed in certain ethnic populations in South-East Asia and North Africa and in the circumpolar indigenous populations (Table 53.7). Common to both low-and high incidence areas, nasopharyngeal carcinoma is seen two-to-three times more often in men than in women (Table 53.7). Different age-specific incidence patterns are observed in endemic and non-endemic regions (Parkin *et al.*, 2002; Lee *et al.*, 2003; Yu and Yuan, 2002): In non-endemic regions nasopharyngeal carcinoma occurrence increases continuously with age, whereas in endemic regions the incidence increases with age to peak around the age of 50 years and decrease thereafter. A third bimodal age pattern with a minor incidence peak in adolescents and young adults has been described in some populations with low to intermediate nasopharyngeal carcinoma incidence (Yu and Yuan, 2002; Daoud *et al.*, 2003).

Even within regions where nasopharyngeal carcinoma is endemic considerable variation in disease occurrence can be observed between different ethnic subpopulations. For instance, in the Chinese province of Guangdong the incidence of nasopharyngeal carcinoma is twice as high in Cantonese as in other ethnic groups (Li *et al.*, 1985; Yu *et al.*, 1981; Yu and Yuan, 2002). Familial clustering of nasopharyngeal carcinoma and other cancers is well-established from a plethora of case-reports (Zeng and Jia, 2002). The familial accumulation in turn translates into increased risks for nasopharyngeal carcinomas, e.g., first degree-relatives of Greenlandic Inuits with nasopharyngeal carcinoma have an eight-fold higher risk of the tumor than the general population (Friborg *et al.*, 2005). Epidemiologically, these observations may indicate a genetic predisposition to nasopharyngeal carcinoma, a suspicion that has been supported by genetic studies. Specifically, a meta-analysis of published data for Chinese patients showed increased risk for HLA alleles A2, B14, B46, and decreased

Table 53.7. Incidence rates for nasopharyngeal cancer (all types combined) in different regions. Adapted from Yu and Yuan, 2002 and updated from Parkin, *et al.*, 2002. Data for Greenland from Friborg *et al.*, 2003

	Age-standardized (world) incidence rates (per 100,000)		
Population	Males	Females	Calendar period
Chinese, Hong Kong	21.4	8.3	1993 to 1997
Chinese, Tapei	8.9	3.4	1997
Chinese, Shanghai	4.2	1.5	1993 to 1997
Chinese, Tianjin	1.7	0.5	1993 to 1997
Inuits, Greenland	10.3	8.0	1988 to 1997
Inuits, Athabascans, and Aleuts, Alaska	11.9	5.6	1980 to 1987
Thais, Chiang Mai	3.2	1.3	1993 to 1997
Vietnamese, Hanoi	10.4	4.6	1993 to 1997
Malays, Singapore	6.8	2.0	1993 to 1997
Filipinos, Manila	7.2	2.5	1993 to 1997
Kuwaits, Kuwait	2.6	0.9	1994 to 1997
Algerians, Setif	8.0	2.7	1990 to 1993
Israeli Jews born in Morocco, Algeria or Tunisia	2.8	1.3	1961 to 1981
U.S. Whites (SEER)	0.5	0.2	1993 to 1997

risks for HLA alleles A11, B13 and B22 (Goldsmith *et al.*, 2002). Moreover, susceptibility *loci* have been reported on chromosomes 3 (Xiong *et al.*, 2004), 4 (Feng *et al.*, 2002), 14 [Diehl *et al.*, unpublished observations quoted in (Pickard *et al.*, 2004)] and near the HLA-locus (Lu *et al.*, 1990). Polymorphisms in genes coding for certain enzymes involved in nitrosamine metabolism [Gluthathione S-transferase M1 and cytochrome P450 2E1] also have been reported to correlate with risk for nasopharyngeal carcinoma [reviewed by (Zeng and Jia, 2002; Hildesheim *et al.*, 1997)].

There is good evidence, however, that environmental factors are also significant to the risk of nasopharyngeal carcinoma. Accordingly studies of families emigrating from high to low risk regions have shown that the risk of nasopharyngeal carcinomas decreases between successive generations (IARC, 1997). Among environmental factors, the evidence is particularly strong against certain diets including Cantonese-style salted fish and other preserved foods (for review, see IARC, 1997). Accordingly, a high intake of preserved foods is a common characteristic of the populations where nasopharyngeal carcinoma is endemic, and case-control studies in endemic as well as non-endemic regions have demonstrated an association between intake of such food items and nasopharyngeal carcinoma risk. Moreover, the risk for nasopharyngeal carcinomas seems to be inversely correlated with the age of first exposure. Consistent with the role of diet, the incidence of nasopharyngeal carcinoma in Hong Kong has decreased over the last decades concomitantly with changes in lifestyle towards a western-world pattern (Lee *et al.*, 2003). Other suggested risk factors have included low socioeconomic status (possibly correlated with high intake of preserved food items), tobacco, and alcohol, and occupational exposure to formaldehyde and wood dust (Hildesheim *et al.*, 2001; IARC, 1997).

It is noteworthy that the association between preserved food and risk for nasopharyngeal carcinoma gains biological plausibility in the context of the familial accumulation of the tumor and its association with EBV. Accordingly, the preserved foods contain carcinogenic nitrosamines, as well as EBV-activating substances (IARC, 1997).

Evidence of association with EBV

Infection with EBV has been implicated in the development of nasopharyngeal carcinoma by several different lines of evidence (Table 53.6). Historically, the first indication was the observation that sera from African and American patients with nasopharyngeal carcihoma were often more positive for precipitating antibodies to antigens prepared from cultured Burkitt's lymphoma cells than controls (Old *et al.*, 1966). This observation has since been confirmed in serological studies showing elevated titers of IgG and in particular IgA antibodies against EBV viral capsid, early and nuclear antigens in nasopharyngeal carcinoma patients data being less compelling for type I than types II and III, manifesting as apparent ethnic variations (IARC, 1997; Raab-Traub, 2000). Antibody titers correlate with stage of disease and has been shown to return to normal levels in long-term disease-free survivors (Yu and Henderson, 2004). More compelling than the sero-prevalence surveys in patients are, however, the results of a prospective study of 9699 persons which showed that presence of IgA anti-EBV viral capsid antigen antibodies or neutralising EBV specific anti-DNase antibodies correlated with subsequent risk for nasopharyngeal carcinoma (Fig. 53.6) (Chien *et al.*, 2001).

The serological findings are corroborated by the demonstration of monoclonal EBV in the malignant nasopharyngeal carcinoma cells (Raab-Traub and Flynn, 1986). This line of evidence is most consistent for nasopharyngeal carcinoma types II and III, but the virus has also been demonstrated in type I carcinomas (Nicholls *et al.*, 1997; Raab-Traub, 2000). Consistent with the assumption of a causal role for the virus in development of the tumor, monoclonal

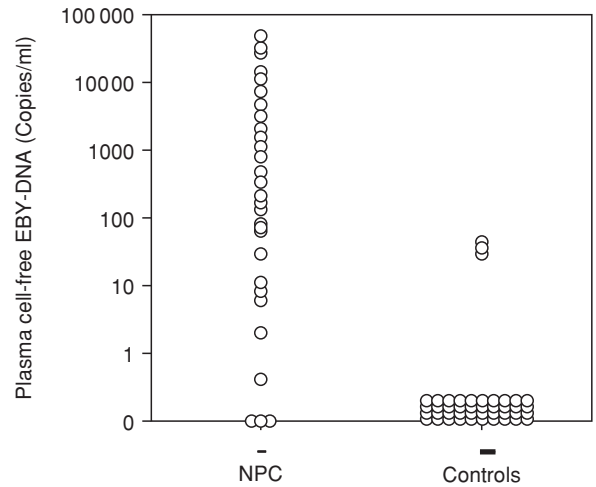

Fig. 53.7. Comparison of plasma cell-free EBV DNA in NPC patients and control subjects. The categories (NPC patients and control subjects) are plotted on the X-axis. The Y-axis denotes the concentration of cell-free EBV DNA (copies of EBV DNA/ml of plasma) detected by the BamHI-W region PCR system). Reproduced from (Lo *et al.*, 1999) with permission from the American Association for Cancer Research.

EBV has also been demonstrated in pre-invasive dysplastic and carcinoma *in situ* lesions (Pathmanathan *et al.*, 1995) as has the virus been demonstrated in nasopharyngeal carcinoma metastases (Lee *et al.*, 2000).

More recently, the detection and quantification of circulating EBV DNA have attracted interest. In one study, such DNA was demonstrated in 96% of patients with nasopharyngeal carcinoma as compared with only in 7% of controls, and levels of DNA moreover correlated with disease stage (Figure 53.7) (Lo *et al.*, 1999) and, independently hereof, also with prognosis (Lo *et al.*, 2000; Lin *et al.*, 2004).

Tumors of the lymphoid tissues

The tumors of the lymphoid tissues constitute a clinically and epidemiologically heterogeneous group of malignancies with the common characteristic that they are derived from cells belonging to the lymphoid lineage. Three major categories of lymphoid malignancies are recognized today, i.e. B-cell lymphomas, T and NK-cell lymphomas, and Hodgkin's lymphomas (Harris *et al.*, 2001a,b). Within each of these categories, distinct disease entities are recognised based on morphologic, immunophenotypic, genetic and clinical characteristics.

The occurrence of non-Hodgkin's lymphoma generally increases with age and overall lymphomas are more often seen in men than in women with a male : female incidence ratio of 1.5–2:1 (Parkin *et al.*, 2002). Incidence rates vary internationally, age-standardized (world) rates ranging from typically 3–8 and 2–6 per 100 000 Asian men and women to 10–15 and 5–10 per 100 000 in European men and women (IARC, 2002). An as yet unexplained remarkable increase in the incidence of all types of non-Hodgkin' lymphomas combined was apparent in the latter half of the twentieth century in most regions of the world, amounting to 3%–4% increase annually (Devesa and Fears, 1992). Recent data from Scandinavia suggest that the increase has just as inexplicably begun to subside (Sandin *et al.*, 2006).

Relatively few risk factors have been established for non-Hodgkin's lymphomas (Scherr and Mueller, 1996; Grulich and Vajdic, 2005; Ekstrom-Smedby, 2006). In part, this may reflects that the composite nature of the malignant lymphomas including possible etiological heterogeneity has not always been taken into consideration previously. The most consistently observed risk factor is immune suppression, primary as well as acquired. Other risk factors include familial aggregation (Chang *et al.*, 2005; Goldin *et al.*, 2005), autoimmune conditions (Zintzaras *et al.*, 2005) and exposure to certain hair dyes (Takkouche *et al.*, 2005) and herbicides (Fritschi *et al.*, 2005; Scherr and Mueller, 1996). Several infectious organisms are known or suspected to be etiologically linked to lymphoma development including both bacteria, e.g., *Helicobacter pylori* (Wotherspoon *et al.*, 1991), *Borrelia burgdorferi* (Cerroni *et al.*, 1997), *Campylobacter jejuni* (Lecuit *et al.*, 2004), *Chlamydia psittaci* (Ferreri *et al.*, 2004) and viruses, e.g., human herpesvirus-8 (Cesarman *et al.*, 1995), human T-cell lymphotropic virus type I (Hinuma

et al., 1981), hepatis C virus (Pozzato *et al.*, 1994), and EBV (Epstein *et al.*, 1964).

The evidence for an association with EBV infection is the strongest for Burkitt's lymphomas, NK/T-cell lymphomas of the nasal cavity, for malignant lymphomas in immune incompetent patients, and for a subset of Hodgkin's lymphomas. The virus may, however, also be encountered in other types of malignant lymphomas, though less regularly (IARC, 1997). It is noteworthy, therefore, that in a prospective serological investigation elevated IgG ($\geq$ 1:320) and IgM ($\geq$ 1:5) titres of anti-viral capsid antigen antibodies were associated with 2.5-(IgG)and 3.2-fold (IgM) increased risks for non-Hodgkin's lymphoma overall with no apparent difference between different lymphoma subtypes (Mueller *et al.*, 1991).

Burkitt's lymphoma/leukemia

Burkitt's lymphoma is a highly aggressive lymphoma that often presents extranodally or as acute leukemia (Diebold *et al.*, 2001). The presumed cell of origin is a germinal centre B-cell. Based on clinical and epidemiological characteristics, three variants of Burkitt's lymphoma are recognized, i.e., endemic, sporadic, and immunodeficiency-associated Burkitt's lymphoma. Histologically, the tumor is generally characterized by monomorphic cytoarchitecture composed of medium-sized B cells with basophilic cytoplasm and numerous mitotic figures with variations between the tumor variants. A constant feature shared by all Burkitt's lymphoma variants is chromosomal translocations involving the MYC oncogene on chromosome 8 (i.e., either t(8:14), t(2:8) or t(8:22) (Diebold *et al.*, 2001)).

Epidemiology of endemic Burkitt's lymphoma

The endemic variant of Burkitt's lymphoma is primarily a childhood malignancy seen in Papua, New Guinea and in equatorial Africa, where in certain areas it is the most common childhood cancer (van den Bosch, 2004). The tumor occurs two-to-three times as often in boys as in girls and in both genders the incidence of endemic Burkitt's lymphoma peaks at ages 5–9 years (Diebold *et al.*, 2001). Precise incidence rates are difficult to obtain, but data suggest crude incidence rates of 4.6 and 2.9 per 100 000 in Ugandan boys and girls < 15 years (IARC, 2002).

One of the most striking characteristics of endemic Burkitt's lymphoma is the correspondence between its geographical distribution and measures of prevalence of malaria infection, a correlation that is apparent both between and within regions and over time (IARC, 1997). Moreover, the peak ages for endemic Burkitt's lymphoma is also the age interval during which anti-malarial antibodies peak (IARC, 1997). These ecological similarities have been interpreted as reflecting a role for malarial infection in development of endemic Burkitt's lymphoma, as discussed below. Other suspected risk factors, the effects of which are also related to EBV infection, are certain groups of plants used in traditional medicine that may stimulate viral replication. The direct evidence of the role of such is, however, limited (IARC, 1997).

Epidemiology of sporadic Burkitt's lymphoma

Sporadic Burkitt's lymphoma occurs predominantly in children and young adults, and is seen throughout the world (Diebold *et al.*, 2001). The tumor make up a few percent of all lymphomas in industrialized countries, but constitutes up to 50% of all lymphomas in children (Diebold *et al.*, 2001). Like the endemic variant, sporadic Burkitt's lymphoma is seen two-to-three times as often in males as in females. Generally, the incidence of sporadic Burkitt's lymphoma is much lower than that of the endemic variant, e.g., rates of 0.38 and 0.08 per 100 000 are observed in white US boys and girls <15 years (Parkin, 2002). Familial accumulation of the lymphoma has been reported in a few instances, but otherwise few risk factors have been established (IARC, 1997).

Epidemiology of AIDS-related Burkitt's lymphoma

Burkitt's lymphoma frequently is the AIDS defining malignancy in HIV-infected patients (Diebold *et al.*, 2001). The tumor and its association with EBV are described later. Burkitt's lymphoma is also seen in organ transplant recipients.

Evidence of association with EBV

EBV was originally identified in an endemic Burkitt's lymphoma cell culture (Epstein *et al.*, 1964), and of the three lymphoma variants, the endemic type has remained the most strongly associated with the virus. The evidence of an association between Burkitt's lymphoma and EBV includes both serological and molecular biological studies (Table 53.6).

An early classical paper describes a prospective serological investigation set in the Uganda West Nile District, where Burkitt's lymphoma is endemic. Based on an initial collection of blood samples from nearly 42 000 healthy children, children who subsequently developed Burkitt's lymphoma displayed statistically significantly higher titres of antiviral capsid antigen antibodies than their peers, who remained healthy (geometric mean titre 425.5 vs. 125.8). No differences were observed between the two groups of children for anti-early antigen or anti-EBV nuclear antigen antibodies (de-Thé *et al.*, 1978). In a later update of the study, each twofold dilution of antiviral capsid antigen antibody titer

was associated with a five-fold in Burkitt's lymphoma risk overall and a nine-fold increased risk of EBV-positive lymphomas (Geser *et al.*, 1982).

Employing different serological techniques, studies have suggested that African Burkitt's lymphoma patients are more often infected with EBV than their peers and also display higher anti-EBV antibody titres (IARC, 1997). Similar patterns have also been observed in sporadic Burkitt's lymphoma patients, in particular children, though with less striking differences *vis à vis* controls (IARC, 1997).

Large case-series have since the original observation confirmed the presence of EBV in endemic Burkitt's lymphoma cells. Accordingly, virus has been demonstrated in more than 95% of investigated endemic Burkitt's lymphoma cases (IARC, 1997). In contrast, the prevalence of EBV in sporadic Burkitt's lymphoma in general appears to be less than 30% (IARC, 1997; Diebold *et al.*, 2001), albeit with considerable variation in reported estimates ranging between 15 and 88% (Hsu and Glaser, 2000). In AIDS-related Burkitt's lymphoma, the prevalence of EBV is 25 to 50% (Diebold *et al.*, 2001; Raphael *et al.*, 2001).

The mechanism by which EBV contributes to the development of Burkitt's lymphoma is not entirely understood, but the virus's absence in many cases either suggests that it is neither sufficient nor necessary for the tumor to develop or, alternatively, that EBV-positive and -negative tumors are different biological entities (Bellan *et al.*, 2005). For EBV positive tumors, age at infection with the virus and the ability to control infected cells seem critical (Mueller *et al.*, 1996). For endemic Burkitt's lymphoma it has been suggested that early EBV infection may lead to transformation and replication of a large subset of B-lymphocytes. This process in turn may be augmented by recurrent malaria infections that act both as B-cell mitogen and T-cell suppressant. Translocation involving chromosome 8 may then result from the increased cell replication (Klein, 1979; de The, 2000). Some support for the interaction between malaria and EBV comes from studies showing that the number of EBV infected cells is higher during acute malaria than after recovery (Lam *et al.*, 1991) and that the number of EBV infected cells correlate with the intensity of malaria transmission in the area of residence (Moormann *et al.*, 2005). It is noteworthy, however, that in the aforementioned prospective serological investigation, the children who developed endemic Burkitt's lymphoma and children who remained healthy had similar rates of malaria parasitemia before tumor development (de-Thé *et al.*, 1978). Accordingly, other models for the role of EBV in Burkitt's lymphoma development have also been proposed (Hecht and Aster, 2000; van den Bosch, 2004). The occurrence of EBV-positive Burkitt's lymphoma in AIDS patients and in organ transplant recipients would also be consistent with a critical role for immunological control of EBV-infected cells in the lymphoma development, as would an inverse correlation between socioeconomic status and Burkitt's lymphoma occurrence (Hsu and Glaser, 2000).

NK/T-cell lymphomas

EBV is associated with certain types of NK/T-cell lymphomas. These include in particular the extranodal NK/T-cell lymphoma of the nasal type, but also aggressive NK-cell leukemia (Nava and Jaffe, 2005) and possibly angioimmunoblastic T-cell lymphoma (Anagnostopoulos *et al.*, 1992; Chan *et al.*, 1999; Huh *et al.*, 1999; Weiss *et al.*, 1992) and extranodal enteropathy-type T-cell lymphoma (Huh *et al.*, 1999; Quintanilla-Martinez *et al.*, 1997; Zhang *et al.*, 2005). Histologically, extranodal NK/T-cell lymphomas of the nasal type are characterized by a broad morphological spectrum, but an angiodestructive pattern with frequent necrosis and apoptosis is a characteristic finding (Chan *et al.*, 2001; Nava and Jaffe, 2005). As signaled by the name the malignant cells are either of NK-cell (the majority) or T-cell origin. The nasal region is the most frequent site of involvement, but the tumor may also present at other extranodal sites such as skin testis, kidney, upper gastrointestinal tract, and the orbit (Chan *et al.*, 2001; Rizvi *et al.*, 2006).

Epidemiology of mature T- and NK-cell lymphomas

Mature T- and NK-cell tumors are generally rare tumors, and NK/T cell lymphomas of the nasal type even more so. In an international series comprising lymphoma patients from the US, Europe, Asia and South Africa peripheral T-cell lymphoma made up 9.4% of all non-Hodgkin's lymphomas, however, with considerable geographic variation, ranging from 1.5% in Vancouver, Canada to 18.3% in Hong Kong (Rudiger *et al.*, 2002). In the same series, NK/T-cell lymphomas of the nasal type constituted a mere 1.4% of the all investigated lymphomas (Rudiger *et al.*, 2002), all cases except three diagnosed in Hong Kong. Thus, NK/T-cell lymphomas of the nasal type are rare in the Western world, and is more commonly seen in Asia, Mexico and in Central and South America countries (Hsu and Glaser, 2000). In a recent Chinese case series from Hong Kong, NK/T-cell lymphomas of the nasal type made up 6.3% of all non-Hodgkin's lymphomas (Au *et al.*, 2005), and similar proportions have been reported from Peru (Quintanilla-Martinez *et al.*, 1999). Generally, the incidence is held to be higher in men than in women (Hsu and Glaser, 2000). Besides the ethnic variation little is known about risk factors for this small

group of lymphomas, but the entity has been described in immune dysfunctional individuals (Stadlmann, 2001).

Evidence of association with EBV

EBV has been incriminated in NK/T-cell lymphoma development exclusively by the demonstration of the virus in the tumor cells (Table 53.6). Accordingly, patient series have shown that the NK/T-cell lymphomas of the nasal type almost invariably (90%) harbor EBV, irrespective of the patient's ethnicity (Chan *et al.*, 2001a,b; Kanavaros *et al.*, 1993; Miyazato *et al.*, 2004; Quintanilla-Martinez *et al.*, 1997); in Asians also when presenting outside the nasal cavity (Chan *et al.*, 1997).

Hodgkin's lymphoma

Hodgkin's lymphoma develops from germinal center B-lymphocytes in the vast majority (> 98%) of all cases, and in rare instances from post-thymic T-cells (Stein *et al.*, 2001). Histologically, the tumor typically contains a small number of malignant cells, which are large mono- and multinucleated cells (Hodgkin's or Reed–Sternberg cells), surrounded by T-lymphocytes in a rosette-like pattern and dispersed in an abundant mixture of reactive inflammatory and accessory cells (Stein, 2001). Based on clinical and biological criteria, two main types of Hodgkin's lymphoma are recognized, i.e., nodular lymphocyte predominant (5%) and classical (95%) Hodgkin's lymphoma, the latter being further divided into four histological subtypes [nodular sclerosing (70%), mixed cellular (20–25%), lymphocyte rich (∼ 5%) and lymphocyte depleted (<5%) classical Hodgkin's lymphoma (Stein, 2001).

Epidemiology

Hodgkin's lymphomas constitute 10%–15% of all malignant lymphomas [slighty more when chronic lymphocytic leukemia is disregarded] (Parkin *et al.*, 2002). In Western countries, age-standardized (world) incidence rates are typically in the range of 2–4 per 100 000 in men and 1.5–3 per 100 000 in women, whereas incidence rates < 1 per 100 000 in both men and women are typical for Asia (Parkin *et al.*, 2002). Geographical differences also exist with respect to age-specific incidence rates. In industrialized countries a conspicuous bimodal age distribution with cases accumulating in young adults and the elderly has become one of the lymphomas distinguishing characteristics (Fig. 53.8). In Hodgkin's lymphoma epidemiology literature, this pattern has been referred to as Pattern III, implying the existence of Patterns I and II (Correa and O'Conor, 1971). Of these, Pattern I was seen in developing countries and was characterized by relatively high incidence of Hodgkin's lymphoma in children, low incidence in the third decade and high incidence in the elderly. Pattern II was perceived as an intermediate between Pattern I and III. A Pattern IV describing a general paucity of Hodgkin's lymphoma in all age groups was also suggested based on data originally reported from Asian countries (Correa and O'Conor, 1971). A more recent survey of register data indicate that, with the possible exception of Asian countries, these archetypical incidence patterns may no longer be as clearly distributed geographically (Macfarlane *et al.*, 1995).

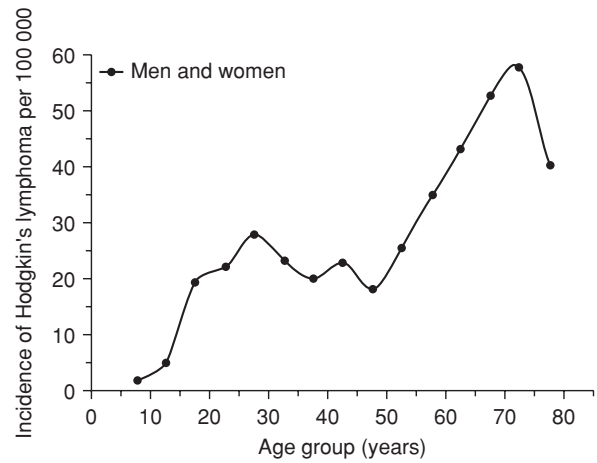

Fig. 53.8. Age-specific incidence of Hodgkin's lymphoma in the white population of Brooklyn, U.S., 1943–52. Reproduced from MacMahon, 1957 with permission from John Wiley & Sons, Inc.

The bi-modal age distribution in Pattern III reflects the age-related distributions of the different subtypes of Hodgkin's lymphoma with the nodular sclerosis subtype making up the bulk of the young adult age peak, and mixed cellularity subtype increasing in frequency with age, but has nevertheless also been used to define epidemiologically (meaningful) disease entities (MacMahon, 1957; MacMahon, 1966). Accordingly, studies of risk factors for Hodgkin's lymphoma have often focused on specific age-groups, i.e., children [<15 years], young adults [15–ca. 44 years], and elderly [≥ca. 45 years], rather than specific Hodgkin's lymphoma subtypes. Presumably reflecting the age distribution of cases, most epidemiological studies have concentrated on Hodgkin's lymphoma in young adults, the risk of which has been associated with an affluent childhood social environment, as measured by long maternal education, small sibling size and housing (Mueller, 1996). In contrast, Hodgkin's lymphoma in children appears to be associated with low socioeconomic status, whereas it plays little if any role for the risk for Hodgkin's lymphoma in the elderly (Mueller, 1996). It has long been suspected that the

association with childhood environment in young adults cases reflects a surrogate for loads of infectious diseases in childhood, and that, in young adults, the lymphoma might arise as an untoward reaction to delayed exposure to a common childhood infectious agent (Gutensohn and Cole, 1977). Consistent with this notion, attendance of nursery school or day care for more than 1 year was associated with a reduced risk (odds ratio = 0.64; 95% confidence interval 0.45 to 0.92) for Hodgkin's lymphoma at ages 15–54 years in a recent investigation (Chang *et al.*, 2004). Patients suffering from immune incompetence, whether acquired or inherited, are at increased risk for Hodgkin's lymphoma. In AIDS patients, for instance, the increase in the order of 10-fold (Frisch *et al.*, 2001). Hodgkin's lymphoma is also known to cluster within families suggesting a genetic predisposition to the disease (Goldin *et al.*, 2004). Also, smoking has recently been incriminated in two large case-control studies, suggesting relative risks of around two for current smokers (Briggs *et al.*, 2002; Chang *et al.*, 2004), although previous studies have yielded conflicting results (for review see Briggs *et al.*, 2002). Among investigated occupational exposures, wood working and formaldehyde exposure have frequently been associated with risk for Hodgkin's lymphoma (Mueller, 1996).

Evidence of association with EBV

Epidemiological, serological, and molecular biological studies have all suggested that EBV is involved in the development of at least a proportion of Hodgkin's lymphomas (Table 53.6). Consistent with suspected mechanisms underlying the association with affluence in childhood, history of infectious mononucleosis has been associated with an increased risk for Hodgkin's lymphoma in cohort as well as case-control studies, relative risks typically in the order of two-to-threefold increased (Alexander *et al.*, 2003; Hjalgrim *et al.*, 2000; IARC. 1997). The risk increase seems to be specific to Hodgkin's lymphoma and inversely correlated with time since infectious mononucleosis, in practice restricting it to the young adult age group (Hjalgrim *et al.*, 2000). Serological investigations have also pointed to a role for EBV in Hodgkin's lymphoma pathogenesis. Specifically, though patients with Hodgkin's lymphoma appear not to be more frequently infected with the viruses (as measured by prevalence of antiviral capsid antigen IgG antibodies at diagnosis) than comparable controls, the patients have higher mean titres of these antibodies (IARC, 1997). In case-control studies the patients also demonstrate antibodies against the early antigen complex and at higher titres more often than normal persons (IARC, 1997). Perhaps the most compelling evidence, however, comes from a prospective serological investigation, in

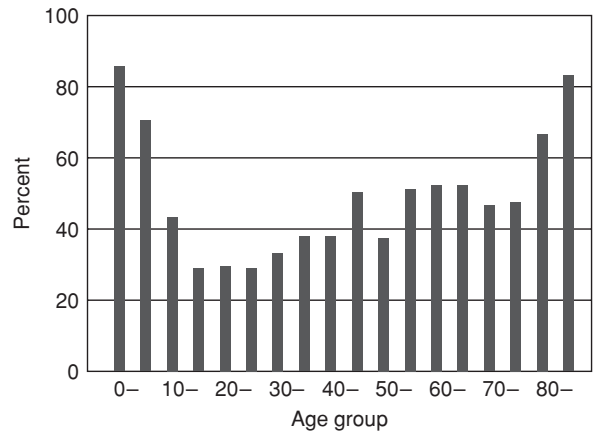

Fig. 53.9. Percentage of Hodgkin's lymphomas positive for EBV by five-year age group (Reproduced from (Glaser *et al.*, 1997)) with permission from John Wiley & Sons, Inc.

which prediagnostic elevated titres of antiviral capsid antigen IgG antibodies (relative risk = 2.6; 90% CI 1.1 to 6.1), anti-diffuse early antigen antibodies (relative risk = 2.6; 90% CI 1.1 to 6.1) and anti-restricted early antigen (1.9; 90% CI 0.90–4.0) were all associated with risk of Hodgkin's lymphoma (adjusted for IgM). In multivariate analyses including all types of anti-EBV antibodies, risk for Hodgkin's lymphoma was associated with high titers of anti-EBV nuclear antigen antibodies (relative risk = 6.7; 90% CI 1.8 to 25) and inversely associated with IgM antibodies (relative risk = 0.07; 90% CI 0.01 to 0.53) (Mueller *et al.*, 1989). The third line of evidence of an association between EBV and Hodgkin's lymphoma is the demonstration of the virus in the malignant cells (Weiss *et al.*, 1987). Importantly, however, the virus is not invariably present in the malignant cells, and the proportion of EBV-positive tumors varies by histological subtype (more common in mixed cellularity than nodular sclerosis Hodgkin's lymphoma), age (less common in young adults than other age groups), sex (more common in men than in women), and geography (more common in developing than developed countries) (Figures 53.9 and 53.10) (Cartwright and Watkins, 2004; Glaser *et al.*, 1997).

The role of EBV in Hodgkin's lymphoma pathogenesis remains uncertain from epidemiological evidence, but there is some evidence to suggest that risk factors may differ between virus-positive and -negative tumors. Accordingly, in some investigations the increased risk for Hodgkin's lymphoma following infectious mononucleosis may be restricted to virus-positive subtypes (Alexander *et al.*, 2000; Hjalgrim *et al.*, 2003), although other investigations have reported no particular predilection for

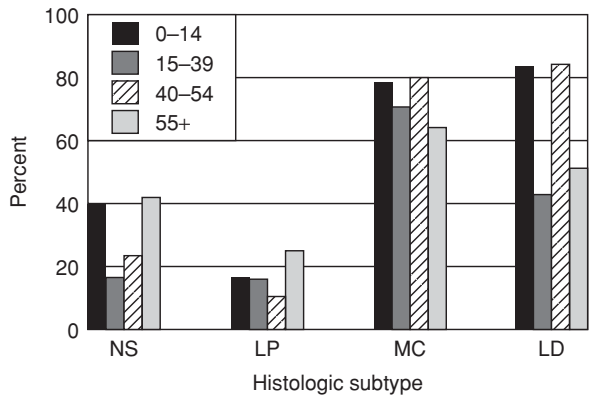

Fig. 53.10. Distribution of EBV positive tumors by histological subtype (Reproduced from (Glaser *et al.*, 1997)) with permission from John Wiley & Sons, Inc.

virus-positive tumors after infectious mononucleosis (Alexander *et al.*, 2003; Sleckman *et al.*, 1998).

It has been speculated that the Hodgkin's lymphoma-mononucleosis association may merely reflect the significance of high socioeconomic status. This speculation is, however, not easily compatible with observations showing that first-degree relatives of mononucleosis patients either have no increased Hodgkin's lymphoma risk (Hjalgrim *et al.*, 2002), or an increased risk for only for virus-positive tumors (Alexander *et al.*, 2003). Also, titres of antiviral capsid antigen antibodies have recently been found to correlate with Hodgkin's lymphoma virus status in both case-control (Alexander *et al.*, 2003; Chang *et al.*, 2004a,b) and prospective studies (Levin *et al.*, 2002). There is also evidence to suggest that smoking is particularly associated with an increased risk for EBV-positive Hodgkin's lymphoma (Briggs *et al.*, 2002; Chang *et al.*, 2004a,b; Glaser *et al.*, 2004), as is low socioeconomic status and race for Hodgkin's lymphoma in childhood (Flavell *et al.*, 2001) and immune-incompetence (Audouin *et al.*, 1992). Finally, inherited susceptibility to EBV-positive Hodgkin's lymphoma has also recently been proposed (Diepstra *et al.*, 2005). None of these different lines of evidence can, however, rule out the simple explanation that the proportion of virus-positive lymphomas merely reflect the number of circulating EBV-infected cells at initiation of lymphoma development (Thorley-Lawson and Gross, 2004).

Lymphoproliferative disease associated with immunodeficiency

The recent WHO classification for tumors of the hematopoietic and lymphatic tissues recognizes four broad clinical settings of immune deficiency that are associated with an increased risk for malignant lymphomas and other lympoproliferative disorders. These are (1) primary immune disorders and deficiencies (Borisch *et al.*, 2001), (2) infection with human immunodeficiency virus (HIV) (Raphael *et al.*, 2001), (3) iatrogenic immune suppression in organ or bone marrow transplant recipients (Harris *et al.*, 2001a,b), and (4) iatrogenic immune suppression associated with methotrexate treatment (Harris and Swerdlow, 2001), typically for auto-immune conditions. With the exception of post-transplant lymphoproliferative disorder, the malignancies observed in these settings are largely similar to sporadic occurring neoplasms.

Primary immune disorders

Primary immune disorders are associated with a substantial risk for malignant disease, reported absolute risks ranging from 12%–25% in patients with Wiskott-Aldrich syndrome, ataxia telangiectasia, and common variable immunodeficiency (Filipovich *et al.*, 1992). Hematopoietic malignancies make up nearly 70% of the observed tumors, clearly different from the normal 8% (Mueller, 1999). Onset of disease is typically in childhood (Borisch *et al.*, 2001). EBV infection plays a significant role in many, though not all, of the malignant lymphomas occurring in patients with primary immune deficiencies (Filipovich *et al.*, 1992) Specifically, loss of immunological control of EBV-infected lymphocytes allows their continued proliferation and malignant transformation, possibly promoted by defective immune regulation and chronic immune stimulation (Filipovich *et al.*, 1992).

Post-transplant lymphoproliferative disease

"Post-transplant lymphoproliferative disorder" (PTLD) in reality defines a spectrum of lymphoid hyperproliferative states that may be observed in solid organ and bone marrow transplant recipients (Loren *et al.*, 2003). PTLDs are most often but not invariably of B-lymphocyte origin, and manifest heterogeneously, possibly reflecting serial development of the disorder (Harris *et al.*, 2001a,b) (Table 53.9). Histologically, it has been suggested that EBV-associated PTLD should include two of the following three features: disruption of underlying architecture by a lymphoproliferative process, presence of monoclonal or polyclonal cell populations, and evidence (typically by *in situ* hybridization for virus-encoded RNA) of EBV in many of the cells (Paya *et al.*, 1999). Although it also includes reactive hyperplasia, the term PTLD is normally used in reference to the malignant end of the PTLD spectrum unless otherwise specified (Green, 2001; Loren *et al.*, 2003).

Table 53.8. Distribution of tumors by primary immunodeficiency syndrome in a combined series of patients with inherited immune deficiencies (Reproduced from Filipovich *et al.*, 1992; Mueller, 1999.) The table is not exhaustive with respect to immune deficiencies carrying increased cancer risk

Immunodeficiency	Total tumors	NHL	Hodgkin's disease	Leukemia	Other tumors
Severe combined immunodeficiency	42	31 (73.8)[a]	4 (9.5)	5 (11.9)	2 (4.8)
Hypogammaglobulinemia	21	7 (33.3)	3 (14.3)	7 (33.3)	4 (19.0)
Common variable immunodeficiency	120	55 (45.8)	8 (6.7)	8 (6.7)	49 (40.8)
IgA deficiency	38	6 (15.8)	3 (7.9)	0 (0)	29 (76.3)
Hyper-UgM syndrome	16	9 (56.3)	4 (25.0)	0 (0)	3 (18.8)
Wiskott-Aldrich syndrome	78	59 (75.6)	3 (3.8)	7 (9.0)	9 (11.5)
Ataxia telangiectasia	150	69 (46.0)	16 (10.7)	32 (21.3)	33 (22.0)
Other immunodeficiencies	25	12 (48.0)	1 (4.0)	4 (16.0)	8 (32.0)
Total immunodeficiency categories	500	252 (50.4)	43 (8.6)	63 (16.0)	142 (28.4)

[a]Percentage of total tumors.
NHL, non-Hodgkin's lymphoma.

Table 53.9. Post-transplant lymphoproliferative disorders (reproduced from Harris *et al.*, 2001 with permission from IARC).

Categories of post-transplant lymphoproliferative diseases (PTLD)
Early lesions
Reactive plasmacytic hyperplasia
Infectious mononucleosis-like
Polymorphic PTLD
Monomorphic PTLD (classified according to the WHO nomenclature)
B-cell neoplasms
Diffuse large B-cell lymphoma (immunoblastic, centroblastic, anaplastic)
Burkitt's/Burkitt's-like lymphoma
Plasma cell myeloma
Plasmacytoma-like lesions
T-cell neoplasms
Peripheral T-cell lymphoma, not otherwise specified
Other types
Hodgkin's lymphoma and Hodgkin's lymphoma-like PTLD

In solid organ transplant recipients, PTLD is typically of recipient origin (>90%), whereas in hematopoietic stem cell transplant recipients it is most often of donor origin (Harris *et al.*, 2001a,b). The organ graft is frequently involved in PTLD (e.g., in 80% of lung transplanted, 33% of liver transplants, and 32% of kidney transplants in children) (Holmes and Sokol, 2002).

Epidemiology The epidemiology of PTLD remains scantily characterized. Occurrence varies by type of transplantation, ranging from a few percent or less in renal transplant recipients to ~20% in recipients of HLA mismatched, T-cell depleted bone marrow, and even 33% of child-recipients of combined liver-kidney transplants (Curtis *et al.*, 1999; Harris *et al.*, 2001a,b; Holmes and Sokol, 2002; Loren *et al.*, 2003).

PTLD may develop as soon as the first week or as late as 9 years after transplantation, but the median latency period is around 6 months in solid organ recipients and 70–90 days in hematopoietic stem cell recipients (Loren *et al.*, 2003). PTLD occurs in all age groups, but is seen in more men than women, which could, however, reflect gender differences in transplantation frequency (Hsu and Glaser, 2000). Inadequate T-cell control of EBV-infected B-lymphocytes is thought to be critical to the development of EBV-positive PTLDs. Consistent with this theory, established risk factors for PTLD include recipient EBV seronegativity (in particular if the donor is EBV-seropositive), primary or reactivated EBV infection following transplantation, high levels of immune suppression (cyclosporine, tacrolimus, antithymocyte globulin, or antilymphocyte antibodies), cytomegalovirus infection, transplanted organ (renal < non-renal) and – less certain – younger age (Aguilar *et al.*, 1999; Loren *et al.*, 2003; Swinnen, 2000).

Evidence of association with EBV The significance of EBV to PTLD development is implied first and foremost by demonstration of the virus in approximately 80% of cases (Harris *et al.*, 2001a,b). EBV-negative PTLDs have been described, and tend to occur with longer latency periods than their virus-positive counterparts (Nalesnik, 2002).

Because early recognition of developing PTLD may affect prognosis, attempts have been made to develop techniques

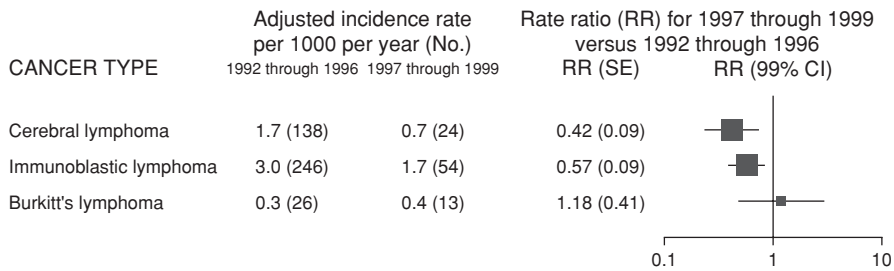

Fig. 53.11. Incidence rates of certain types of non-Hodgkin's lymphoma in 1992 through 1996 (before HAART) and in 1997 through 1999 [after HAART] and rate ratios (RRs) of incidence rates in 1992 through 1996 compared with 1997 through 1999. Reproduced from International Collaboration on HIV and Cancer 2000 with permission from Oxford University Press.

for monitoring EBV infection activity. Decreased anti-EBV nuclear antigen antibody levels have been associated with an increased risk for PTLD (Cen *et al.*, 1993; Riddler *et al.*, 1994). A more useful measure of EBV activity is, however, the assessment of the burden of virus infection in peripheral blood mononuclear cells and serum which, by a wide variety of different assays, have been found to correlate with risk for PTLD (Stevens *et al.*, 2002a,b).

Lymphomas in HIV

EBV infection is involved in different diseases in HIV-infected individuals, in particular malignant lymphomas and leiomyosarcomas.

Malignant lymphoma in people with HIV The risk for malignant lymphomas is increased massively in patients with acquired immune deficiency syndrome (AIDS). Accordingly, aggressive B-cell non-Hodgkin's lymphoma has been an AIDS-defining condition almost since the recognition of the HIV epidemic and is the second most common tumor associated with HIV (Dal Maso and Franceschi, 2003; Lim and Levine, 2005).

The magnitude of reported increases in risk for non-Hodgkin's lymphoma in persons with AIDS have varied somewhat, but generally have been in the order of 100-fold for all types of non-Hodgkin's lymphoma combined in the period before the introduction of Highly Active Anti-Retroviral Therapy (HAART) (Dal Maso and Franceschi, 2003), relative risks possibly being more increased in children (Biggar *et al.*, 2000) and less increased in elderly (Biggar *et al.*, 2004). Particularly elevated relative risks have been reported for high grade diffuse immunoblastic (652-fold increased) and Burkitt's lymphoma (261-fold increased) (Cote *et al.*, 1997). While some uncertainty has existed for Hodgkin's lymphoma, recent data have suggested that the risk for this lymphoma is also increased in HIV-infected persons, although to a much lesser extent, i.e., around 10-fold (Frisch *et al.*, 2001; IARC, 1996).

The risk of non-Hodgkin's lymphoma varies by level of immune suppression as measured by CD4 count and typically is a late manifestation of HIV infection (IARC, 1996). Consistent with this, the introduction of HAART seems to have accompanied by a decrease in AIDS-malignant lymphoma occurrence, notably of the subtypes most strongly associated with EBV (see below) (International Collaboration on HIV and Cancer, 2000; Lim and Levine, 2005) (Fig. 53.11).

In contrast to AIDS-related Kaposi's sarcoma, a human herpesvirus 8-associated malignancy that occurs predominantly in homo- or bisexual men, the occurrence of malignant lymphomas show no predilection for mode of HIV acquisition (IARC, 1996).

HIV itself appears not to be directly involved in the lymphoma development as illustrated by its absence in the malignant cells. Rather, through chronic antigenic stimulation causing B-cell proliferation, and through cytokine dysregulation, the virus may create an environment conducive for the development of malignant lymphomas (Levine, 2000; Knowles, 2001).

The range of different types of malignant lymphomas in HIV-infected persons is wide, but can be categorized according to whether they also occur in immune-competent individuals (Burkitt's lymphoma, diffuse large B-cell lymphoma, extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue type (MALT lymphoma), peripheral T-cell lymphomas and classical Hodgkin's lymphoma), whether they are seen in other immune dysfunctional conditions (polymorphic B-cell lymphoma) or whether they are more specific to HIV infected individuals (primary effusion lymphoma, plasmablastic lymphoma of the oral cavity) (Raphael *et al.*, 2001). However, the various lymphoma subtypes are not equally frequent and a few of these make up the vast

majority of cases in AIDS, i.e., Burkitt's lymphoma (50%–60% of all HIV-related lymphomas) and diffuse large B-cell lymphomas (25% of all HIV-related lymphomas many of which present in the central nervous system), primary effusion lymphoma (less than 5% of all HIV-related lymphoma) and plasmablastic lymphoma of the oral cavity (Raphael *et al.*, 2001).

Evidence of association with EBV As for other lymphomas, the primary evidence of EBV involvement in development of HIV-related lymphomas is the demonstration of monoclonal virus in the tumors (Table 53.6). Overall, EBV is present in approximately 60% of HIV-related lymphomas, but the proportion of virus-positive tumors varies considerably with site of presentation and histological subtype. Thus, EBV is almost invariably present in Hodgkin's lymphomas, in (primary) central nervous system lymphomas and in primary effusion lymphomas (so-called PEL), in 80% of diffuse large cell lymphomas with immunoblastic features, in more than 50% of plasmablastic lymphomas of the oral cavity, in 30%–50% of AIDS-related Burkitt's lymphomas, and in 30% of diffuse large B-cell lymphomas of the centroblastic variant (Raphael *et al.*, 2001). As the risk of the various types of non-Hodgkin's lymphoma correlating with level of immune deficiency, a similar correlation arises with respect to prevalence of EBV in the lymphoma (Carbone and Gloghini, 2005).

Gastric carcinoma

Gastric carcinomas are tumors derived from the epithelium of the stomach mucosa with glandular differentiation (Fenoglio-Preiser *et al.*, 2000). Histologically, the tumors either are gland-forming with tubular, acinary, or papillary structures or display a complex mixture of dis-cohesive, isolated cells with variable morphologies, sometimes in combination with glandular, trabecular, or alveolar solid structures (Fenoglio-Preiser *et al.*, 2000). The current WHO classification of tumor of the digestive system distinguishes between tumors occurring at the junction between esophagus and the stomach, many of which would previously have been classified as cancers of the gastric cardia, and gastric cancer differing epidemiologically.

Epidemiology

The incidence of gastric cancer has been decreasing worldwide for several decades (Parkin *et al.*, 2002), yet with an estimated 876 000 incident cases annually it remains the fourth most common cancer worldwide, and because of its relatively poor prognosis the second most common cancer-specific cause of death attributed 647 000 deaths annually (Parkin *et al.*, 2000). There is considerable (more than 10-fold) geographical variation in the incidence of gastric cancer, with high rates in the Andean regions of South America, Eastern Europe, and Eastern Asia, and low rates in Northern Europe, most African countries, and North American whites (Fenoglio-Preiser *et al.*, 2006). For instance, world standardized incidence rates of 6.6 per 100 000 are observed in white American men as compared with rates between 60 and 90 per 100 000 observed in Japanese men (IARC, 2002). Irrespective of this geographical variation, the cancer is twice as common in men as in women (Parkin *et al.*, 2002; Nyren and Adami, 2002). In contrast to decreasing occurrence of gastric cancer, there is evidence to suggest that cancer of the esophageal–gastric junction may be increasing (Newnham *et al.*, 2003; Wijnhoven *et al.*, 2002), although this is still debated (Ekstrom *et al.*, 1999).

Both gastric cancer and cancers of the esophageal–gastric junction are rare before the age of 30 years, but increase with older age (Parkin *et al.*, 2002). Besides age, established risk factors for gastric cancer include familial occurrence, tobacco smoking, certain diets, alcohol, and infection with *Helicobacter pylori* (Nyren and Adami, 2002). With respect to familial occurrence of gastric carcinoma, it has been estimated that familial clustering of gastric cancer occurs in approximately 1% of patients (Shinmura *et al.*, 1999). Increased gastric cancer risk has been described in a number of hereditary conditions, notably the Li–Fraumeni syndrome and hereditary non-polyposis colorectal cancer, but other syndromes may exist (Nyren and Adami, 2002). Familial clustering of gastric cancer may reflect shared genetic or environmental factors, or both. Accordingly, in a study of more than 44 000 Scandinavian twins, compared to men whose twin did not have stomach cancer 7- and 10-fold increased risks for gastric cancer were observed in dizygotic and monozygotic male twins, whose twin had stomach cance. For women, the corresponding relative risk estimates were 6 and 20 respectively (Lichtenstein *et al.*, 2000). This corresponded to inherited factors accounting for 28%, shared environmental factors 10%, and non-shared environmental factors to 62% of the overall gastric cancer risk.

Smoking is associated with stomach cancer risk, in cohort studies amounting to 1.5 to 2-fold increased risk (Tredaniel *et al.*, 1997). Certain dietary items are suspected to be of importance for gastric cancer risk. Accordingly, salt intake and, in some populations, smoked or cured meats have been associated with increased risk of gastric cancer, whereas intake of fresh fruit and vegetables have been associated with a reduced gastric cancer risk (Nyren and Adami, 2002). Finally, several studies have shown that infection

with *Helicobacter pylori* carries an increased risk of gastric cancer. Thus, in a Japanese cohort study, 36 cases of gastric carcinoma was observed during follow-up in 1246 *Helicobacter pylori* infected persons compared with no cases among 280 uninfected men (Uemura *et al.*, 2001). Analogously, a meta-analysis of 42 studies showed *Helicobacter pylori* infection to be associated with a two-fold increased risk of gastric cancer (Eslick *et al.*, 1999).

Evidence of an association with EBV

The scientific evidence incriminating EBV in development of gastric carcinoma encompasses the demonstration of monoclonal virus in the malignant cells and aberrant anti-virus antibody patterns before and at diagnosis (Table 53.6).

The first suggestion of an involvement of EBV in gastric carcinoma development came in the early 1990s by the demonstration of the virus in lymphoepithelioma-like carcinomas of the stomach (Burke *et al.*, 1990). Subsequent investigations indicate that the virus is present in the vast majority of this specific subgroup of gastric carcinomas, i.e., 80+% (Fukayama *et al.*, 1998). Importantly, however, the association with EBV is not restricted to lymphoepithelioma-like gastric carcinomas as the virus can also be demonstrated in varying proportions (typically less than 10%) of carcinomas of more common histologies (Fukayama *et al.*, 1998; Imai *et al.*, 1994; Koriyama *et al.*, 2004; Shibata and Weiss, 1992; van Beek *et al.*, 2004).

EBV has also been implicated in gastric carcinoma development by serological studies. Specifically, elevated seroprevalence of anti-viral capsid antigen IgA and IgGy and elevated anti-early antigen antibies and (elevated IgG viral capsid antigen antibody titers) have been described at and before diagnosis of EBV-associated gastric carcinomas (Imai *et al.*, 1994; Levine *et al.*, 1995).

Besides, by histology the proportion of EBV-positive gastric carcinomas appears to vary by gender, age, tumor location, and possibly geography. EBV-positive gastric carcinomas seem to be more common in men than in women. In a large Japanese investigation of 1918 cases, EBV was demonstrated in 83 (6.8%) of 1212 male and in 17 (2.4%) of 706 female cases (Koriyama *et al.*, 2004). Likewise, in a recent Dutch series 38 (11.7%) of 324 gastric carcinomas in men and 3 (1.2%) of 242 carcinoma in women harbored EBV (van Beek *et al.*, 2004), and from smaller US series EBV prevalence of 15%–21% and 3%–5% are reported for gastric carcinomas in men and women, respectively (Shibata, 1998). Overall, the proportion of EBV-positive tumors seems to correlate inversely with age, but the age pattern may differ between gastric carcinoma subtypes (Koriyama *et al.*, 2004; van Beek *et al.*, 2004).

Interestingly, the EBV-positive tumors are not evenly distributed topographically in the stomach. Accordingly, the virus can more often be demonstrated in carcinomas of the cardia and the middle stomach than in the antrum, proportions varying 3–4 fold or more (Koriyama *et al.*, 2004; Takada, 2000; van Beek *et al.*, 2004). Of interest, EBV-positive tumors have been reported to make up a relatively large proportion of gastric carcinomas after partial gastrectomy for non-malignant diseases, published estimates ranging between 27% and 42% (Baas *et al.*, 1998; Chang *et al.*, 2000; Koriyama *et al.*, 2004; Nishikawa *et al.*, 2002; Yamamoto *et al.*, 1994). It has been suggested that this distribution of the EBV-positive tumors reflect that the non-neoplastic mucosa of the proximal stomach may be conditioned to develop EBV-related tumors (Fukayama *et al.*, 1998).

As illustrated in Fig. 53.12 the proportion of EBV-positive gastric carcinomas appears to differ between countries and may even vary within countries (Tashiro *et al.*, 1998). However, so far it has been difficult to define a clear geographic pattern in the distribution of EBV-related gastric carcinomas like those known for nasopharyngeal carcinoma and Burkitt's lymphoma. The precise siginificance of variation in referral patterns, case selection or possible variation in other risk factors for gastric carcinomas is difficult to evaluate in this context (Hsu and Glaser, 2000; Levin and Levine, 1998).

Lymphoepithelioma-like carcinomas may have a better prognosis than other gastric lymphomas, and recently, it has been suggested that other types of EBV-positive gastric carcinomas may also have better prognosis than virus-negative tumors (van Beek *et al.*, 2004).

Given the high incidence of gastric adenocarcinoma worldwide [around 870 000 incident cases annually (Parkin *et al.*, 2001), EBV-related gastric carcinoma, estimated to amount to at least 50 000 cases per year may be the most common of all EBV-associated malignancies (Takada, 2000) (Table 53.10).

Other malignancies associated with EBV infection

EBV has been shown, or is suspected, to be involved in the development of a series of other malignancies, much less frequently occurring than those described in the above sections. These include lymphoepithelioma-like carcinomas and soft tissue sarcomas, for which an association with EBV is compelling, and carcinomas of the breast, thymus, and liver, for which the evidence is less evident.

Lymphoepithelioma-like carcinomas

Lymphoepithelioma-like carcinomas are tumors that morphologically resemble undifferentiated carcinoma of the

Table 53.10. Estimated number of neoplasms associated with EBV (reproduced from Levin and Levine, 1998.)

Malignancy	Estimate of EBV genome positivity	Estimated number of cancers worldwide in 1990	Estimated number of EBV associated neoplasms
Gastric adenocarcinoma	6–12%	876 000	78 840
Nasopharyngeal cancer			
Developed countries	95%	5 500	5 225
Economically developing countries	99%	53 000	52 470
Hodgkin's lymphoma			
Developed countries	30–50%	25 000	10 000
Economically developing countries	60–90%	37 000	27 750
Non-Hodgkin's lymphomas	6–10%	223 000	17 840
Burkitt's lymphoma			
Developed countries	20–30%	600	7 440
Economically developing countries	95%	9 000	8 550
AIDS-related lymphoma	50–90%	9 000	6 300
Smooth muscle sarcomas	Case reports (rare malignancy)		
Lymphoepithelioma like carcinomas of the salivary gland, lung, stomach, thymus	Case reports (rare malignancies)		

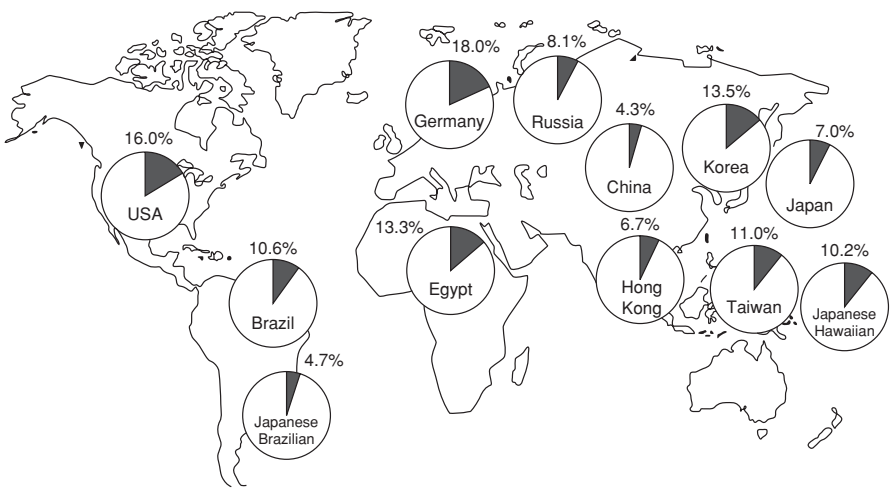

Fig. 53.12. World distribution of proportions of gastric cancers that are EBV-related. Reproduced from Tashiro *et al.*, 1998.

nasopharynx. In addition to the stomach (see above) the tumor has been described in the salivary glands, oral cavity, larynx, thymus, trachea, lungs, breast, uterine cervix, vagina, urinary bladder, skin, stomach (Iezzoni *et al.*, 1995), thyroid (Shek *et al.*, 1996), esophagus (Mori *et al.*, 1994), kidney (Elzevier *et al.*, 2002), ureter (Chalik *et al.*, 1998), and liver (Jeng *et al.*, 2001).

The tumor attracts interest because, in addition to the morphological similarity with nasopharyngeal carcinoma, EBV has been reportedly demonstrated in the malignant cells in some, but not all of the affected organs (Chalik *et al.*, 1998; Elzevier *et al.*, 2002; Iezzoni *et al.*, 1995; Jeng *et al.*, 2001; Mori *et al.*, 1994; Shek *et al.*, 1996).

Also, the prevalence of the virus in the malignant cells follows the same geographical distribution as observed nasopharyngeal carcinoma for salivary gland and lung lymphoepithelial-like carcinomas, being higher in Asian than in Western patients, thereby further underscoring the analogy between the two groups of tumors (Hsu and Glaser, 2000).

Leiomyosarcoma

Leiomyosarcomas are malignant neoplasms of smooth muscle tissues. They are exceedingly rare tumors, occurring at rates around 1 per 100 000, slightly higher in women than in men (Levi *et al.*, 1999; Zahm *et al.*, 1996) The connection with EBV is fairly recent and initially arose from the apparent accumulation in HIV infected children and organ transplant recipients (see for review Jenson, 2000 of cases reported until 1998). Epidemiologically, the association for HIV-infected children has been supported by surveys of cohorts of such children demonstrating excessive occurence of the tumor (Biggar *et al.*, 2000; Granovsky 1998). The conclusive piece of evidence for the association with EBV is, however, the demonstration of the virus in the tumors of immunocompromised hosts (Jenson, 2000).

Other malignancies

In recent years, the involvement of EBV in other malignancies than those discussed above has been debated. These include breast carcinomas (Glaser *et al.*, 2004a,b), hepatocellular carcinoma (Sugawara *et al.*, 1999), and thymomas (Chen, 2002). As yet, however, the evidence for the association with EBV remains controversial.

The epidemiology of KSHV and its association with malignant disease

Jeffrey N. Martin

Department of Epidemiology and Biostatistics, University of California, San Francisco, 185 Berry Street, Suite 5700 San Francisco, CA, USA

Introduction

In 1872, Moritz Kaposi, a Hungarian dermatologist, described six patients with multifocal brown–red or blue–red nodules or plaques on the feet and hands (Kaposi, 1872). Initially called "Idiopathisches multiples Pigmentsarcoma der Haut" (multiple idiopathic sarcoma of the skin) by Kaposi, the condition later became known as Kaposi's sarcoma (KS). Decades later, after the epidemiology of KS began to be investigated, its uneven geographic distribution suggested that exogenous factors were etiologically important. Subsequently, as the AIDS epidemic unfolded in the early 1980s, homosexual men were found to be up to 20 times more likely than other risk groups to develop KS, a markedly disproportionate risk that led to the hypothesis that the exogenous factor was a sexually transmitted infectious agent (Beral *et al.*, 1990). Numerous microbial candidates were proposed (Drew *et al.*, 1982; Huang *et al.*, 1992; Wang *et al.*, 1993) but for none was convincing evidence demonstrated until Kaposi's sarcoma-associated herpesvirus (KSHV), or human herpesvirus 8 (HHV-8), was discovered in 1994 (Table 54.1) (Chang *et al.*, 1994). In a short period following the discovery of KSHV, consensus rapidly developed that it is a necessary, albeit not sufficient, causal agent of KS (Whitby *et al.*, 1995; Gao *et al.*, 1996a,b; Martin *et al.*, 1998; Renwick *et al.*,1998; O'Brien *et al.*, 1999). This discovery was more than academic in that, because of the AIDS epidemic, KS is now worldwide the fourth most common cancer caused by an infectious agent, following gastric, cervical, and hepatic cancer. Subsequently, it was also determined that KSHV has a potentially causal role in primary effusion lymphoma (PEL) (Cesarman *et al.*, 1995), also known as body cavity-based lymphoma, and multicentric Castleman's disease (Soulier *et al.*, 1995). Now that the clinical importance of KSHV has been established, attention has turned towards unraveling of what is proving to be a complicated epidemiologic profile for the virus.

Diagnosis of KSHV infection

While nucleic acid amplification techniques were originally used to identify the presence of KSHV DNA in KS tissue, when applied to peripheral blood these techniques are much less sensitive as compared to detection of KSHV-specific antibodies. Even among patients with KS, of whom virtually all have detectable KSHV DNA in their KS lesions, only approximately 40 to 60% have detectable KSHV DNA in either plasma or peripheral white blood cells (IARC Working Group, 1997). Among persons without KS, the group for which a diagnostic test for KSHV is most needed, the prevalence of KSHV DNA in blood is much lower, especially in HIV-uninfected populations, and is always less common than the detection of KSHV-specific antibodies. For this reason, there is currently little role for nucleic acid-based testing of peripheral blood in the diagnosis of KSHV infection (Spira *et al.*, 2000). Instead, the primary means of KSHV diagnosis is antibody testing, which is described in detail in Chapter 52. What follows is a brief overview of antibody testing that provides the requisite perspective for which to interpret epidemiologic studies of the distribution and transmission of KSHV infection.

Initial serologic assays for KSHV antibodies

After the finding that DNA from PEL biopsy specimens contains KSHV sequences (Cesarman *et al.*, 1995), the original assays for KSHV antibodies were developed using cell lines obtained from patients with PEL (Miller *et al.*, 1996; Kedes *et al.*, 1996; Gao *et al.*, 1996a,b; Simpson *et al.*, 1996) One of the first platforms were indirect immunofluorescence assays (IFAs) that utilized the cell lines in an

Table 54.1. Original detection of KSHV DNA by polymerase chain reaction in various tissue specimens

Tissue type	No. evaluated	No. (%) positive for KS330
KS, AIDS-related	27	25 (93)
Lymphoma, AIDS-related	27	3 (11)
Lymph nodes, AIDS-related	12	3 (25)
Lymphoma, non-AIDS	29	0
Lymph nodes, non-AIDS	7	0
Vascular tumors, HIV unknown	5	0
Opportunistic infections	13	0
Consecutive surgical biopsies, HIV unknown	49	0

From Chang *et al.* (1994).

uninduced state where KSHV is primarily in its latent phase. These assays detect antibodies to KSHV latency-associated nuclear antigen (LANA or LNA-1), the product of open reading frame (ORF) 73 (Rainbow *et al.*, 1997; Kedes *et al.*, 1997a,b). Extensive evaluation of these assays determined that anti-LANA seropositivity is found in approximately 80% of persons with KS and less than 5% of non-male-homosexual adults in the USA or Northern Europe (i.e., specificity of at least 95%) (Kedes *et al.*, 1996; Gao *et al.*, 1996a,b; Simpson *et al.*, 1996). Subsequently, it was determined that induction, using phorbol ester, of KSHV into a lytic phase resulted in IFAs with greater, albeit not complete, sensitivity (approximately 95%) in terms of identifying KS patients, while maintaining seropositivity of less than 10% in non-homosexual adults in the USA (Chandran *et al.*, 1998). In an attempt to improve throughput and eliminate the subjective interpretation inherent in IFAs, a variety of other first-generation assays with comparable performance characteristics were developed. These include enzyme immunoassays (EIA) detecting antibodies against (a) bacterially derived recombinant portions of a minor capsid protein (ORF 65) (Simpson *et al.*, 1996), LANA (Renwick *et al.*, 1998), and glycoprotein K8.1 (Raab *et al.*, 1998; Engels *et al.*, 2000); (b) synthetic peptides portions of K8.1 and ORF 65 (Spira *et al.*, 2000; Pau *et al.*, 1998); and (c) whole virus (Chatlynne *et al.*, 2001; Martin *et al.*, 2000).

Methodologic challenges in serologic assay development

Although first-generation antibody assays, particularly those detecting anti-LANA antibodies, have been useful in epidemiologic work, no single first-generation serologic assay has demonstrated very high sensitivity and specificity, and agreement between assays has been suboptimal. In a study of seven first-generation antibody assays examining 143 serum specimens, the percentage of KSHV-seropositive specimens determined by the different assays ranged from 0% to 54% for the subset of specimens from blood donors, 27% to 60% for HIV-infected persons without KS, and 49% to 93% for KS patients (Rabkin *et al.*, 1998). More recently, a comparison of KSHV antibody testing from six laboratories, using newly developed assays or second-generation versions of previously examined assays, found improved agreement when testing serum specimens from persons with KS (all six laboratories found all 21 specimens to be positive) but only modest agreement when evaluating 1000 specimens from blood donors (a low risk group for KSHV infection) (Pellett *et al.*, 2003).

In part, the interassay disagreement that has been observed may be because certain assays target different antibodies for which inherent sensitivity and specificity for KSHV infection may differ (e.g., antibodies against lytic-phase versus latent-phase antigens). In other instances, however, assay calibration (i.e., differentiating positive from negative results) has not been done in a standardized fashion across assays with reference to a wide spectrum of gold standard KSHV-infected (true positive) and KSHV-uninfected (true negative) subjects. Determining assay sensitivity by limiting the true positive reference group to persons with KS, as has been typically done in the initially described assays, may result in estimates of sensitivity that are unrealistically inflated. This is because it is now recognized that, among KSHV-infected persons, antibody titer is highest and therefore easier to detect in KS patients (Gao *et al.*, 1996a,b). One attempt to reduce this "spectrum bias" (Ransohoff and Feinstein, 1978) was by Engels *et al.*, who used diluted serum from KS patients in an attempt to mimic KSHV-infected persons without KS and found rapidly diminishing sensitivity with only minimal dilution (Engels *et al.*, 2000). However, how much dilution is needed to mimic infected but non-diseased persons is not known. Another attempt was the use of homosexual men without KS but who had detectable KSHV in their saliva (Casper *et al.*, 2002a,b). These persons, however, may be enriched for antibody-positivity if the presence of KSHV antigen drives antibody production. Therefore, more work is needed in identifying gold standard KSHV-infected reference subjects without KS for the evaluation of assay sensitivity.

While early serologic investigators at a minimum had the presence of KS as a basis for forming a true positive reference group, assembling a true negative (KSHV-uninfected) reference group has been particularly vexing because of the lack of any analogous gold standard certifying absence of

infection. For example, the use of blood donors (Simpson *et al.*, 1996; Pau *et al.*, 1998; Rabkin *et al.*, 1998; Tedeschi *et al.*, 1999) is problematic because they may include men with undisclosed homosexual activity, the primary risk factor for KSHV infection in developed countries (described below). Approaches used in more recent work to optimize the assembly of a true negative reference group have capitalized on what is now known about the epidemiology of KSHV infection and of KS *per se*. In the USA, for example, this includes the use of virginal women and of young children who are just past the age of harboring maternal antibodies (Martin *et al.*, 2000), HIV-infected hemophiliacs and their female sexual partners, both of whom were known not to subsequently develop KS after a substantial period of observation (Engels *et al.*, 2000), and homosexual women (Casper *et al.*, 2002a,b).

In addition to the uncertainties in assembling the reference populations for assay calibration, other technical differences have likely contributed to poor interassay agreement. For example, the method of cut-off generation for a positive versus negative result has varied considerably. Some investigators have set cut-offs *a priori* by taking the mean of between 5 and 40 individuals considered to be uninfected and then adding two to five standard deviations (Renwick *et al.*, 1998; Simpson *et al.*, 1996; Pau *et al.*, 1998; Chatlynne *et al.*, 2001; Rabkin *et al.*, 1998; Tedeschi *et al.*, 1999; Davis *et al.*, 1997). The small sample sizes used in these calculations and the wide range of standard deviations employed likely result in substantial variation across assays. An improved approach to cut-off generation has been used in more recent work where receiver-operating characteristic (ROC) curves were described (Engels *et al.*, 2000; Martin *et al.*, 2000; Casper *et al.*, 2002; Corchero *et al.*, 2001; Laney *et al.*, 2006). ROC curves are not dependent upon an *a priori* cut-off, but instead show the paired sensitivity and specificity estimates associated with various empiric cut-offs. However, what has not yet been performed is an assessment of interassay agreement by having each assay examine sera from a panel of well-conceived true negative and true positive subjects and then compare ROC curves, generated in a standard fashion for each assay. Until this is done, it will not be possible to compare agreement between contemporary assays.

Approaches using a combination of antibody assays

An approach featuring a highly sensitive high-throughput serologic screening assay followed by a more labor-intensive confirmatory assay with both very high sensitivity and specificity, akin to what is done for the diagnosis of HIV infection, cannot yet be performed for KSHV infection because of the lack of a such confirmatory assay. Nonetheless, use of a combination of assays has been investigated in an attempt to improve assay accuracy compared to individual assays used in isolation (Engels *et al.*, 2003; Casper *et al.*, 2002; Laney *et al.*, 2006). In the most comprehensive analysis of assay combinations, joint use of EIAs featuring K8.1, ORF 73, ORF 65, and whole virus lysate antigens and a latent-phase IFA only marginally improved sensitivity (while holding specificity constant) compared to the best performing individual assays (Engels *et al.*, 2000). Rather than parallel use of multiple assays, the same degree of improvement in accuracy can be obtained when assays are used serially, with the use of a high-throughput EIA first, reserving the more time-intensive IFA in an attempt to resolve specimens scoring in the indeterminate range in the EIA (Engels *et al.*, 2000). Not only is this more cost-efficient than simultaneous testing with both assays, the improvement in accuracy can be substantial depending upon the initial EIA used (Casper *et al.*, 2002a,b).

Recently developed eukaryotically derived recombinant antigen-based serologic assays

While the use of induced PEL cell IFAs increases assay sensitivity, the lack of a KSHV-uninfected isogeneic control cell line hinders the discrimination of KSHV-specific antibody binding vs. non-specific binding to cellular components. Furthermore, because PEL cell IFAs express most or all of the KSHV-encoded genes, including those conserved across all herpesviruses, there is the threat of cross-reactivity with other herpesviruses. To address this, Inoue *et al.* used a mammalian expression system with BHK-21 cells infected with recombinant Semliki Forest virus (SFV) carrying individual KSHV proteins that are unique to KSHV (Inoue *et al.*, 2000). This approach has the advantage of having an isogeneic control, very high antigen expression, and, because it is a mammalian system, protein glycosylation, which may be an important component of epitope antigenicity. To date, separate BHK-21-based IFAs expressing ORF K8.1, ORF 73, and ORF 65 have been established. (Inoue *et al.*, 2000; Quinlivan *et al.*, 2001). Among these, the K8.1SFV IFA has exhibited the best performance. Among 72 KS patients, the K8.1SFV IFA detected antibodies in 94.4%, and among 30 blood donors, 2 (6.7%) were reactive, thus indicating an estimated specificity of at least 93.3%. These approaches will offer greatest utility when they are available in high throughput formats, and in this regard, Laney *et al.* have recently developed an EIA featuring a baculovirus-insect cell system-derived full length LANA protein as the antigen substrate (Laney *et al.*, 2006).

Seroreversion

Further complicating the interpretation of serologic testing is the phenomenon of a negative result following a positive result, termed seroreversion, noted in longitudinal observation of individual subjects. For example, Quinlivan *et al.* found that 27 (82%) of 33 subjects who had at least one time point seropositive for antibodies to LANA had at least one subsequent time point exhibiting seroreversion (Quinlivan *et al.*, 2001). This has also been reported by others (Chohan *et al.*, 2004 and Minhas *et al.*, 2006). Whether seroreversion is the result of assay measurement error (i.e., inadequate reproducibility) or whether it reflects true biologic diminution or loss of antibody is not known. In any case, its presence clouds the interpretation of a single seronegative serologic test result in a cross-sectional study.

Differential reactivity to KSHV antigens over time

Related to the idea that biologic phenomena may be responsible for seroreversion is the finding that KSHV-infected persons may develop antibodies to different antigens at different points in time. There are few longitudinal studies available, especially those with adequate lead-in periods that first establish seronegativity, but in work that has been done with antigen-specific assays, it appears that seroconversion to different antigens can occur at different times (Quinlivan *et al.*, 2001; Biggar *et al.*, 2003; Spira *et al.*, 2001). This further highlights how the currently available assays targeting single antigens are likely not optimally sensitive for detecting infection.

Utility of currently available serologic assays

For epidemiologic work where between group comparisons are the primary focus, even using first-generation serologic assays, despite their poor inter-laboratory agreement, has resulted in reproducible and plausible inferences (described below). Use of currently available serologic assays for individual-level diagnosis, however, be it in an epidemiologic study in the determination of seroconversion among individual subjects, or in the clinical setting, requires greater caution. The lack of gold standards in the development of assays, the apparent lack of concurrent high-level sensitivity and specificity among those first-generation assays that have been evaluated most extensively, and the phenomenon of seroreversion make definitive diagnosis of the presence or absence of KSHV infection problematic at an individual level. The only exception is persons who test positive on a very specific assay, such as the anti-LANA IFA (at least as performed in experienced laboratories). Currently, there is no Food and Drug Administration-licensed assay for KSHV antibodies; testing is limited to research laboratories. Clinicians who seek to use the avaible assays should be aware of their pitfalls and knowledgeable about their performance characteristics. Finally, the recent success in developing an essentially 100% sensitive and specific serologic assay for HIV infection, has raised expectations for the serologic detection of all newly described pathogens, including KSHV. Although not directly studied, the sensitivity and specificity of currently available KSHV antibody assays may not appreciably differ from antibody assays for other herpesviruses, none of which by virtue of their earlier discovery was investigated with the serologic expectations of the contemporary era. Whether or not the recently developed eucaryotically-derived recombinant antigen-based assays will demonstrate very high and reproducible specificity and sensitivity upon wide scale testing or whether there exist inherent biologic limitations to the serologic detection of KSHV infection remains to be determined.

Epidemiology of KSHV infection

Prevalence of infection Geographic distribution

Extensive worldwide surveys of KSHV seroprevalence using the same serologic assay and same method of sampling of subjects (e.g., similar age groups) have not been performed. Even with this limitation, three major patterns of seroprevalence have reproducibly emerged: high-level endemic, intermediate-level endemic, and non-endemic. High-level endemic areas are defined by those with seroprevalences between 30% and 70% among general adult populations and are found in many parts of Africa (Olsen *et al.*, 1998; Mayama *et al.*, 1998; Gessain *et al.*, 1999) and the Middle East, e.g., Egypt (Andreoni *et al.*, 1999). As is discussed below, it is the catastrophic intersection between the endemic nature of KSHV and the HIV epidemic in sub-Saharan Africa that has resulted in KS becoming the most common adult malignancy in many areas there (Chokunonga *et al.*, 2000; Wabinga *et al.*, 2000).

However, even within these geographically constrained areas there nonetheless exists important differences in KSHV seroprevalence from region to region. For example, recent work using a standardized approach to antibody testing found considerably higher seroprevalence in Uganda than compared to South Africa (Butler *et al.*, 2006).

Intermediate-level endemic areas feature KSHV seroprevalences between 10 and 25% in the general population and are found primarily in the Mediterranean area (Angeloni *et al.*, 1998; Whitby *et al.*, 1998; Cattani *et al.*, 2003) Again even within this defined geographic area, there

is considerable heterogeneity. For example, among blood donors in Italy, prevalence was estimated to be 7.3% in Northern and Central Italy and 24.6% in Southern Italy (Whitby *et al.*, 1998).

Non-endemic areas are those with seroprevalences less than 10% in the general population. These include North America, Central America, South America, Northern Europe, and Asia. In these non-endemic areas, however, certain population groups have seroprevalences that rival those in high and intermediate-level prevalence regions. In particular, it is homosexual men across these non-endemic areas that have consistently been shown to have the highest seroprevalence; between 30% and 60% of HIV-infected homosexual men in these areas and 20% and 30% of HIV-uninfected homosexual men are KSHV-infected (Martin *et al.*, 1998; O'Brien *et al.*, 1999; Kedes *et al.*, 1996; Chandran *et al.*, 1998; Melbye *et al.*, 1998; Dukers *et al.*, 2000). This contrasts with less than 10% prevalence in most reports of women and non-homosexual men in the general population of these areas (Martin *et al.*, 1998; Kedes *et al.*, 1996; Smith *et al.*, 1999; Kedes *et al.*, 1997a,b). Other notable pockets of concentrated prevalence (not all of which have been confirmed by other investigators) in otherwise non-endemic areas include an estimated seroprevalence of 65% among Brazilian Amerindians >30 years of age (Biggar *et al.*, 2000), 33% among adults in Papua New Guinea (Rezza *et al.*, 2001), 20% among adults of the Noir-Marron, an ethnic group of African origin residing in French Guiana (Plancoulaine *et al.*, 2000), and 25% among Hispanic children in South Texas in the USA (Baillargeon *et al.*, 2002). Although considerable work has now firmly established the marked geographic differences in KSHV seroprevalence, it is notable (as will be discussed below) that the explanation for this is unknown. Whether the answer rests in host genetic or behavioral differences, influences from other exogenous environmental influences, or viral variants is unresolved.

Temporal patterns

Studies of genomic strain variability have concluded that KSHV is an ancient human virus, introduced at least tens of thousands of years ago (Hayward, 1999) (and discussed below). Descriptions of KS in the 1800s and the finding of high KSHV seroprevalences in geographically distinct and remote isolated populations (Biggar *et al.*, 2000; Rezza *et al.*, 2001; Whitby *et al.*, 2004) substantiate this. There is, however, debate as to the introduction of KSHV in sentinel populations such as homosexual men in the USA and Northern Europe. Two initial reports hypothesized that an epidemic of KSHV infection in homosexual men took place concurrently with that of HIV infection (O'Brien *et al.*, 1999; Melbye *et al.*, 1998). This hypothesis was based upon the finding of an initial high incidence of KSHV infection in these studies at the beginning of their observation in 1981 and 1982, respectively. However, a more direct examination of homosexual men in San Francisco as early as 1978, prior to the HIV epidemic, found that seroprevalence was already 24.9% (Osmond *et al.*, 2002). An endemic state of KSHV infection in homosexual men has also been suggested in Denmark in the 1970s, both in a study directly measuring KSHV seroprevalence (Hjalgrim *et al.*, 2001) and in a study of KS which found that never-married men (a crude surrogate for homosexual men) were significantly at risk (Hjalgrim *et al.*, 1996). Therefore, the introduction of KSHV infection appears to have substantially preceded that of HIV, although how long KSHV has been transmitted at high rates among homosexual men is not known.

There is little information on the patterns of KSHV infection in different populations over time. In Africa, among samples collected between 1972 and 1978 in Uganda and Tanzania, the seroprevalence of KSHV infection was similar to that found in the 1980s and 1990s, suggesting there has been little influence from the emerging HIV epidemic (de-The *et al.*, 1999). In homosexual men in developed countries, there had been speculation, based upon the report of either decreased incidence of AIDS-associated KS or a decline in KS as a proportion of new AIDS cases, that the prevalence of KSHV infection had fallen in the late 1980s and early 1990s (Rutherford *et al.*, 1990; Dore *et al.*, 1996; Jones *et al.*, 1999). However, a decline in the overall KS incidence rate could have been caused by reduced HIV transmission alone, resulting in fewer immunocompromised persons available to develop KS. Similarly, a decline in KS as a proportion of new AIDS cases could be caused by a decline in the proportion of new cases occurring in homosexual men since KS is uncommon in risk groups other than homosexual men. Direct examination of KSHV seroprevalence in homosexual men in San Francisco (including both HIV-infected and uninfected men) found a stable prevalence between 26% and 29% in the periods spanning 1978–80, 1984–85, and 1995–96 (Osmond *et al.*, 2002). Similarly, KSHV seroprevalence was stable at approximately 60% in the period spanning 1985 to 1995 among homosexual men in Italy who had recently acquired HIV infection (Rezza *et al.*, 2000a,b).

Genotypic diversity of infection

The entire KSHV genome was sequenced shortly after its detection (Russo *et al.*, 1996; Neipel *et al.*, 1997), and considerable work thereafter has documented extensive genotypic heterogeneity across populations. Initial work

examining genotypic diversity focused on segments of ORF 26 and ORF 75, and although there was not extensive overall variation (only 1.5% of nucleotide positions), there was enough clustering to form three distinct but narrow subtypes in the initial 12 specimens examined (Zong *et al.*, 1997). Subsequently, ORF K1, K12, 73, K14.1, and K15 have also been examined in many more specimens, resulting in the finding of significantly more genotypic heterogeneity and a much more complicated interpretation. Of these regions, the far left hand (ORF K1) and right hand (ORF K15) sides of the genome are most interesting. ORF K1 is the most heterogenous, with up to 44% amino acid differences across strains, allowing for the formation of at least five major subtypes and at least 24 subgroups, many of which indicate intertype recombination (Biggar *et al.*, 2000; Nicholas *et al.*, 1998; Zong *et al.*, 1999; Cook *et al.*, 1999; Meng *et al.*, 1999; Zong *et al.*, 2002). This degree of diversity has been seen with relatively few isolates examined thus far (less than 250); as more are sequenced, it is apparent that even more distinct subtypes will be identified (Whitby *et al.*, 2004). ORF K15 features two highly diverged alleles, termed P (for predominant) and M (for minor) corresponding to their prevalence in isolates examined to date, which have only 33% amino acid homology to one another (Poole *et al.*, 1999). The two alleles are so disparate that it has been suggested the minor form was introduced via a recombination event with a related but as yet undocumented primate virus (Poole *et al.*, 1999).

While there is an impressive degree of between-subject genotypic diversity, the data on within-subject heterogeneity are conflicting. The majority of initial reports examining sequence variability within individuals either at one time point with multiple samplings or over time did not find evidence of strain (Meng *et al.*, 1999; Zong *et al.*, 1999; Stebbing *et al.*, 2001; Codish *et al.*, 2000), and even among those that did (Gao *et al.*, 1999; Lacoste *et al.*, 2000a,b), intrahost variability was very low. More recently, however, work examining three different types of oral fluid collection, as well as blood, and using a high-fidelity PCR approach, found that among 24 Malawians, 16 had evidence of strain variability in ORF K1 (Beyari *et al.*, 2003). Seven of the subjects harbored two or more subtypes. The reasons for the discrepancy between this and prior work is not clear, but if these findings are confirmed, they will demand significant caution in performing and interpreting future molecular epidemiology studies, particularly those focusing on interpersonal transmission.

Nomenclature schemes for the genotypic diversity of KSHV are still in evolution and not yet standardized between authors. Based on ORF K1 typing alone, at least three approaches have been proposed. Zong *et al.* (1997) proposed naming subtypes A–D, with numerical subgroups within subtypes (e.g., A1–A5′). Cook *et al.* (1999) proposed subtypes A–C with two forms of subgroups, one denoted with numbers (e.g., A3 and A5) and another with superscripts (e.g., A′). Finally, Meng *et al.* (1999) proposed genotypes I–IV with subtypes (e.g., I–A to I–F). To each of these schemes, a fifth major subtype (termed subtype E) was subsequently described among remote isolated South American populations (Biggar *et al.*, 2000; Whitby *et al.*, 2004). Overall genotypic classification is even more complicated because there is not complete linkage in strain diversity across the genome. For example, diversity in ORF K15, although limited to the P vs. M nomenclature, is largely independent of ORF K1 genotype (Zong *et al.*, 2002; Lacoste *et al.*, 2000a,b). When the internal coding regions (e.g., ORF 26, K12, 73, 75) are also considered, there becomes the need to describe at least three or four segments to fully describe a strain (e.g., as C3/A/A2/M) (Zong *et al.*, 2002).

Despite the complexity in nomenclature, there do appear to be emerging patterns in the geographic distribution of the different subtypes. Following the classification scheme proposed by Zong *et al.* for ORF K1 (Zong *et al.*, 1997, 2002), it has been observed that B subtypes are found almost exclusively in sub-Saharan Africa, D subtypes in South Asia/Australia/Pacific, and A and C subtypes in the U.S./Europe/North Asia (with a notable exception being the presence of A5 subtypes in Africa). This has led to the speculation that KSHV was present in the origins of modern humans in Africa (B subtype), and that the separation into the three main branches (A/C, B, and D) is explained by isolation and founder effects associated with the original migrations of human out of Africa, first to the Middle East, and then South Asia (D subtype), and later to Europe, North Asia, and the Americas (A and C subtypes) (Hayward, 1999; Zong *et al.*, 2002). Notable examples of this geographic association are seen in immigrants whose KSHV sequences match those of their countries of origin rather than their adopted residence (Zong *et al.*, 2002). The story is not entirely consistent, however, because of the unexpected finding of subtype E in isolated South American populations (Biggar *et al.*, 2000; Whitby *et al.*, 2004). Whereas it would have been expected that novel subtypes in South America would be most closely related to subtypes A and C (or even B), subtype E is most closely related to subtype D. Finally, the finding of M allele types for ORF K15 in ORF K1 A, B, or C strains further complicates the explanation regarding the geographic spread of the virus over time.

Aside from tracing the spread of KSHV over time and across human populations, the other implications of the substantial genotypic diversity are not well understood.

Table 54.2. Current strength of evidence[a] for various routes of KSHV transmission in endemic vs. non-endemic areas

Route of transmission	Endemic areas	Non-endemic areas
Sexual transmission among homosexual men	++	+++
Sexual transmission among heterosexual men and women	++	+
Non-sexual horizontal transmission in childhood	+++	n.s.
Injection drug use	n.s.	+++
Vertical transmission	+	n.s.
Blood transfusion	+++	+
Solid organ transplantation	+++	+++

[a] + denotes weak evidence; ++ denotes moderate evidence; +++ denotes definitive or strong evidence; – denotes presence of studies but no supportive evidence; n.s. denotes not yet studied.

First, while it is likely that the considerable heterogeneity in ORF K1 is providing clues regarding a powerful biological selection process, whether this involves immune evasion or some other mechanism is not known. Second, it is not known whether genotype plays a role in the ease of transmissibility and acquisition of KSHV. For example, it has not been established whether the localization of the B subtype in Africa can explain the high KSHV seroprevalence there compared to other regions. If genotype is important in viral transmission, high transmissibility is likely not limited to subtype B, as E subtypes in remote South American populations are also associated with very high community seroprevalences (Biggar *et al.*, 2000; Whitby *et al.*, 2004). Third, there has thus far been no convincing evidence for the importance of genotype in either the development of KSHV-related disease per se, the type of KSHV-related disease manifestation (KS vs. primary effusion lymphoma vs multicentric Castleman's diseases), or clinical severity once disease occurs. Of these potential questions, data are most abundant, but not yet definitive, on the issue of association with type of disease where work to date finds no correlation (Zong *et al.*, 2002; Lacoste *et al.*, 2000a,b). One report found an association between single nucleotide polymorphisms (SNPs) at nucleotide positions 1032 and 1055 of ORF 26, but this was among many SNPs evaluated and requires confirmation (Endo *et al.*, 2003). The lack of evidence for the importance of genotype in these various questions should not be interpreted as no role for genotype, but rather a lack of definitive data owing primarily to study designs that have focused on convenience samples of virus obtained from diseased patients (most of whom have a poorly characterized clinical course), rather than systematic sampling of asymptomatically-infected individuals (Whitby *et al.*, 2004) and well-characterized diseased individuals. The current inability to detect and sequence KSHV DNA from all KSHV-infected individuals (as defined by antibody-positivity) is a substantial obstacle to addressing these questions.

Routes of transmission

Current knowledge about KSHV transmission can be summarized as follows (Table 54.2). There is definitive evidence that it is transmitted by some form of intimate contact between homosexual men and equally persuasive evidence that it is transmitted in childhood by a horizontal non-sexual route in high-level endemic areas. There is also strong evidence that it is transmitted by infected organs in transplantation, by sharing of equipment among injection drug users, and by transfusion of whole unprocessed blood in high-level endemic areas. What is not known are the specific sexual behaviors that transmit KSHV among homosexual men, the exact means of horizontal spread to children in endemic areas, whether KSHV is transmitted vertically, and whether transmission occurs via transfusion of blood products that have undergone conventional processing techniques.

Transmission in non-endemic areas

Sexual transmission

Initial seroepidemiologic studies postulated that KSHV was sexually transmitted by showing that, other than in KS patients, seroprevalence was highest in homosexual men and other groups at highest risk for sexually transmitted disease (STD). For example, Kedes *et al.* (1996) using an IFA for antibodies directed against LANA, found among STD clinic clients in San Francisco that 6% of heterosexuals, 13% of HIV-uninfected homosexual men, and 35% of HIV-infected homosexual men were seropositive; seroprevalence in screened blood donors was 1%. Reports of this type, however, describing an association between risk of STD and KSHV seroprevalence, provide only indirect evidence for sexual transmission. More definitive evidence is found in studies with direct measurement of sexual activity, controlled for other potential routes of spread. Among a population-based sample of homosexual men in San Francisco, KSHV seroprevalence increased linearly with the number of male intercourse partners in the previous two years (Fig. 54.1) (Martin *et al.*, 1998). This association was independent of recreational drug use, transfusion history, CD4 lymphocyte count, and HIV serostatus. The strength of this association, confirmed by others (O'Brien *et al.*, 1999;

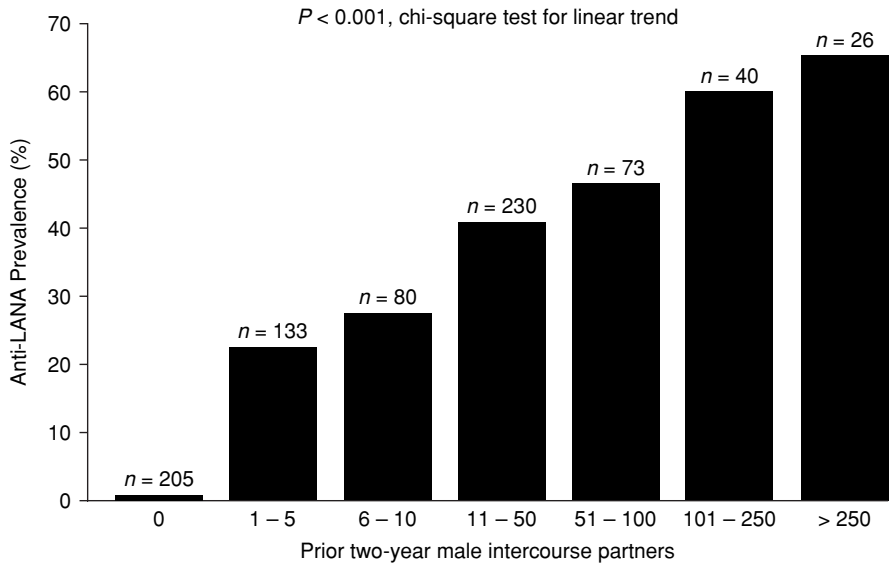

Fig. 54.1. Prevalence of antibodies to KSHV latency-associated nuclear antigen (LANA) by number of prior two-year male intercourse partners among men in San Francisco. Number atop each column signifies number of subjects in each group. From Martin *et al.*, 1998.

Melbye *et al.*, 1998; Dukers *et al.*, 2000; Pauk *et al.*, 2000; Jacobson *et al.*, 2000a,b; Diamond *et al.*, 2001; Casper *et al.*, 2002a,b), leaves little doubt that some form of intimate contact transmits the virus among homosexual men. However, because "sexual partner" is defined broadly in most of these reports to include a variety of practices (e.g., insertive and receptive penile-anal intercourse, penile–oral intercourse, and oral–anal contact), these data alone do not pinpoint the specific route of sexual transmission.

Even prior to the discovery of KSHV, many studies had sought to identify the specific route of transmission for the putative KS agent. Some (Jacobson *et al.*, 1990; Beral *et al.*, 1992; Grulich *et al.*, 1997), but not all (Archibald *et al.*, 1990; Lifson *et al.*, 1990; Page-Bodkin *et al.*, 1992; Elford *et al.*, 1992) found that insertive oral–anal sexual practices ("rimming") were a risk factor for KS and, by extension, were a risk factor for the as-yet-undiscovered KS agent. The discovery of KSHV was hoped to bring clarity to this question, but initial studies among homosexual men have been conflicting, variously reporting the strongest association for penile–anal intercourse, penile–oral intercourse, oral-anal contact, or kissing. To date, at least 8 studies have evaluated specific practices (Table 54.3) (O'Brien *et al.*, 1999; Melbye *et al.*, 1998; Dukers *et al.*, 2000; Pauk *et al.*, 2000; Jacobson *et al.*, 2000a,b; Diamond *et al.*, 2001; Casper *et al.*, 2002a,b; Grulich *et al.*, 1999). For almost all of the acts, at least one study has reported an association. However, for no act have all (or nearly all) studies found an association. Receptive penile-anal intercourse, the act that has attracted the most support, is paradoxically one in which the apparent culprit body fluid, semen, is now known to rarely harbor KSHV (Pauk *et al.*, 2000; Diamond *et al.*, 1997; Koelle *et al.*, 1997).

There are numerous potential biases, reviewed elsewhere (Martin and Osmond, 2000), inherent in the work to date that might explain the inconsistency among studies evaluating specific routes of KSHV sexual transmission. One potential bias is inaccuracy in measuring exposure, in this case the self-report of sexual acts, which is complicated in cross-sectional studies by not knowing the relevant period of exposure to query. A second problem, deficiencies in sensitivity and/or specificity of KSHV serologic assays, particularly with the first-generation assays used to date, results in both misclassification of who is infected and mistaken ascertainment of sexual practices in longitudinal studies by querying for sexual behavior during the incorrect time period. Finally, because sexual acts are correlated in homosexual men, failure to adjust for all of the relevant acts can lead to confounding. In other words, finding an association for a particular act may simply be because that act is correlated with another act that is the true culprit in transmission. All but one (Pauk *et al.*, 2000) of the studies to date were assembled to study HIV infection, and hence in general did not record acts, such as kissing, where saliva is passed. Moreover, no study recorded information on less obvious uses of saliva in various sexual acts such as a lubricant for penile-anal intercourse or when a finger is inserted into an anus (Butler *et al.*, 2003).

Table 54.3. Studies evaluating specific sexual practices as routes of KSHV transmission in homosexual men

		Specific Sexual Practice						
		Penile–anal intercourse		Penile–oral intercourse		Oral-anal contact		
Study	Design	Ins.[a]	Rec.[a]	Ins.	Rec.	Ins.	Rec.	Kissing
Melbye, 1998 (Melbye *et al.*, 1998)	cohort	ne[c]	+[b]	ne	−[b]	−	−	−
O'Brien, 1999 (O'Brien *et al.*, 1999)	cohort	+	+	−	−	+	−	ne
Grulich, 1999 (Grulich *et al.*, 1999)	cross-sectional	−	−	−	−	−	−	ne
Dukers, 2000 (Dukers *et al.*, 2000)	cohort	−	−	+	+	−	−	ne
Jacobson, 2000 (Jacobson *et al.*, 2000)	cohort	ne	+	−	−	ne	ne	ne
Pauk, 2000 (Pauk *et al.*, 2000)	cross-sectional	ne	ne	ne	ne	ne	ne	+
Diamond, 2001 (Diamond *et al.*, 2001)	cross-sectional	−	+	ne	ne	ne	ne	ne
Casper, 2002 (Casper *et al.*, 2002a,b)	cross-sect/cohort	−	−	ne	ne	−	−	ne

[a] "Ins." denotes insertive practice of the act; "Rec." denotes receptive practice of the act
[b] "+" indicates an association was found; "−" indicates no association
[c] "ne" denotes the act was not evaluated

Recording of acts where saliva is exchanged is important because, unlike semen, saliva is now known to be the body fluid that most commonly harbors KSHV (Pauk *et al.*, 2000; Koelle *et al.*, 1997). Careful work from Seattle, for example, found that among KSHV-seropositive homosexual men, 30% of oral samples contained KSHV DNA, vs. 1% of genital and anal samples (Pauk *et al.*, 2000). Therefore, failure to record all of the relevant acts may result both in the inability to find the true culprit act of transmission and the spurious assertion of the importance of a correlated but non-transmitting act.

Recognition that saliva is the body fluid that most commonly harbors KSHV has naturally focused attention on transmission by kissing (Pauk *et al.*, 2000). However, because kissing is common in all population groups, the low prevalence of KSHV in the general population argues against kissing as a dominant route of spread. Indeed, other herpesviruses transmitted by kissing (e.g., EBV) are highly prevalent in the general population. One scenario where kissing could be the major route of spread but still not result in high prevalence in the general population is if KSHV was recently introduced into homosexual men and has not yet spread to others. Data from San Francisco, however, show that KSHV was not recently introduced into homosexual men. Seroprevalence among homosexual men in San Francisco in 1978–80 was estimated to already be high at 28.4% and stable over the next 15 years (26.4% in 1995–96), arguing against kissing as the dominant route of spread. (Osmond *et al.*, 2002).

The most recent US Public Health Service guidelines for the prevention of KSHV infection reflect the uncertainty in the literature about its transmission (US Public Health Service and Infectious Disease Society of America, 2002). They state that the major routes of KSHV transmission appear to be "oral (via) semen, and through blood via needle sharing" and that patients should be counseled that "kissing and sexual intercourse with persons who have high risk of being infected with KSHV (e.g., persons who have KS or who are HIV–infected), might lead to acquisition of the agent that causes KS." Admittedly, this guideline is rated CIII (meaning evidence for efficacy is insufficient), but it poses a quandary for homosexual men, leaving great uncertainty about whether any form of contact is safe.

In contrast to the data for sexual transmission in homosexual men, evidence for sexual transmission in heterosexual men or women is less convincing. In a large study of 2718 STD clinic attendees in London, KSHV seroprevalence in heterosexual men and women was 4.6% compared to 18.5% in (mostly HIV-uninfected) homosexual men (Smith *et al.*, 1999). Among the heterosexual men and women, there was no association between KSHV seropositivity and either number of sexual partners or current or prior history of STDs. Several other studies have found associations between KSHV seropositivity and STD history (either HIV, genital warts, syphilis, gonorrhea, herpes simplex virus 2, or chlamydial infection) among women (Sosa *et al.*, 1998; Tedeschi *et al.*, 2000; Cannon *et al.*, 2001; Greenblatt *et al.*, 2001; Janier *et al.*, 2002; Goedert *et al.*, 2003), but whether this truly represents sexual transmission rather than a surrogate for other types of incompletely controlled for behavior (e.g., injection drug use) is not clear. Among the two

studies which best controlled for injection drug use by restricting to those women who denied either injection drug use (Cannon *et al.*, 2001) or who were seronegative for hepatitis C virus infection (Goedert *et al.*, 2003), one study reported an association between STD history and KSHV seropositivity (Cannon *et al.*, 2001) but the other did not (Goedert *et al.*, 2003). To date, although one report found a trend towards higher seropositivity in women with earlier sexual debut (de Sanjose *et al.*, 2002), no study has revealed the same unequivocal direct relationship between KSHV seropositivity and number of sexual partners as seen in homosexual men. Moreover, in what should be the most powerful evaluation of heterosexual transmission among women, a history of sex with male bisexual partners has not been associated with KSHV seropositivity (Cannon, *et al.*, 2001; Greenblatt *et al.*, 2001). Given the scarcity of KSHV in semen, the lack of significant heterosexual transmission of KSHV is not surprising. Finally, given the general uncertainty as to whether heterosexual transmission occurs to any appreciable extent in non-endemic areas, there has been no enlightening work as to which specific sexual practices might be operative.

Injection drug use

The paucity of KS among HIV-infected non-homosexual injection drug users (Beral *et al.*, 1990) led to the prediction that the putative agent of KS would be low among injection drug users. Indeed, KSHV seroprevalence in injection drug users is much lower than in homosexual men (Renwick *et al.*, 1998; Simpson *et al.*, 1996) but whether injection drug use can transmit KSHV to any extent is under active investigation. The strongest evidence comes from Cannon *et al.* who evaluated women in the US-based HIV Epidemiology Research Study (HERS) (Cannon *et al.*, 2001). Compared to non-users, injection drug users were more likely to be KSHV-infected in a dose-response manner depending on drug use frequency. Furthermore, when restricted to women with low-risk sexual behavior, those who were hepatitis C virus-infected were 20 times more likely to be KSHV-infected. The inference that KSHV can be transmitted through injection drug use has subsequently been supported in at least 3 other studies in women and men (Diamond *et al.*, 2001; Goedert *et al.*, 2003; Atkinson *et al.*, 2003). In contrast, no association for injection drug use was reported among women in the Women's Interagency HIV Study (WIHS), but this cross-sectional analysis evaluated only the prior 6-month injection drug use history and did not evaluate dose-response trends or an association with HCV seropositivity (a better marker of lifetime injection drug use) (Greenblatt *et al.*, 2001). Similarly, no association was found among injection drug users in Baltimore, but again the study lacked accurate measurement of the lifetime magnitude of injection drug use behavior, critical in a population where everyone has practiced at least some of this behavior (Bernstein *et al.*, 2003). Finally, a study of both male and female drug users in Amsterdam also failed to show an association for injection drug use (Renwick *et al.*, 2002), but admittedly lacked adequate statistical power. Taken together, the available data do support that injection drug use can transmit KSHV. Nonetheless, the efficiency of spread by injection drug use (defined as the probability of transmission per each contact with a KSHV-infected person where injection drug use equipment is shared) is likely very low as evidenced by the markedly lower prevalence in injection drug users as compared to homosexual men. This is consistent with the biological data finding KSHV DNA far more commonly in saliva, a body fluid commonly exchanged during male homosexual activity, than in whole blood, the culprit fluid exchanged among injection drug users.

Blood transfusion

The possibility of transmission by blood transfusion was raised by Blackbourn *et al.* (1997) who recovered KSHV from peripheral blood mononuclear cells from a single blood donor and were able to propagate the virus in previously uninfected target cells. Further concern was introduced with the finding, reviewed above, that injection drug use (i.e., exposure to minute quantities of blood) can apparently transmit KSHV. Confirmation of an actual transmission event in non-endemic areas via blood transfusion, however, has to date not been demonstrated. The most suggestive evidence comes from a study of 284 initially KSHV-seronegative individuals who received a blood transfusion and were followed for 6 months. Two persons developed KSHV seroreactivity by 6 months, compared to no such seroconversions among 75 individuals who did not receive a transfusion (Dollard *et al.*, 2005). If the seroconversions were indeed from the blood transfusion, then the risk of HHV-8 infection per transfused unit was estimated to 0.082% (95% Cl, 0.05 to 0.20%). However, because linked donor specimens were not available and the control group was small in number, it is not possible to definitively prove that the seroconversions were due to the transfusion and not from other sources. Two other smaller look-back studies of a total of 32 known KSHV-antibody-positive blood donors and their associated transfusion recipients failed to detect a seroconversion among the recipients (Operskalasi *et al.*, 1997; Engels *et al.*, 1999). Hence while at this time it cannot be definitively proven or disproven if transmission via blood transfusion occurs in non-endemic settings where modern blood-banking techniques are practiced,

if transmission does occur efficiency is likely to be low. Other epidemiologic data support this view. For transfusion of non-cellular components (e.g., fresh frozen plasma, cryoprecipitate, or factor concentrates), that the risk from transfusion, at least in non-endemic areas, is very low is substantiated by indirect data in (a) hemophiliacs where KSHV seroprevalence is very low (0% to 3%) (Kedes *et al.*, 1996; Gao *et al.*, 1996a,b; Simpson *et al.*, 1996), and (b) HIV-infected hemophiliacs in the 1980's who had a very low incidence of KS. For transfusion of cellular components (e.g., red blood cells), the low incidence of KS among the initial cohort of persons in the 1980s, other than hemophiliacs, who acquired HIV via blood transfusion similarly argues for a very low risk of transmission (Beral *et al.*, 1990). Both the hemophiliacs and red blood cell transfusion recipients were in many cases infected by blood donations from homosexual men who harbored HIV and likely also had a high prevalence of KSHV infection. That so few developed KS strongly suggests that KSHV is very inefficiently spread via transfusion in non-endemic areas with modern blood-banking practices. As such, there has been to date no forceful movement in the US blood banking community to universally screen for KSHV (Dodd 2005). This stance has been further substantiated by the apparent very low seroprevalence of KSHV infection in individuals who have passed the standard medical and behavioral screening for blood donation. In a study of 1000 representative blood donors, KSHV seroprevalence was estimated to be approximately 3% (Pellett *et al.*, 2003). Among the blood donors found to antibody-positive, no donor had detectable evidence of KSHV DNA upon testing of their whole blood.

That KSHV transmission by injection drug use (where only minute quantities of blood are exchanged) has been established in non-endemic areas but transmission by transfusion (where large quantities are exchanged) has not is seemingly inconsistent. The paradox may be explained by the composition of the material exchanged. In injection drug use, fresh whole blood is exchanged, which is replete with mononuclear cells, the host cells for KSHV when it is present in the circulation. In contrast, mononuclear cells are intentionally (albeit not completely) removed in all forms of blood transfusion in most non-endemic areas. Although elements of blood plasma are exchanged in both injection drug use and transfusion, cell-free KSHV DNA is rarely found in plasma. In addition, it has required the presence of multiply exposed injection drug users (e.g., daily drug use over several decades) to delineate a risk associated with this practice. The only comparably exposed group in non-endemic areas to be examined in transfusion medicine were 19 persons from France with thalessemia or sickle cell disease who received a mean of 326 red blood cell transfusions (Lefrere *et al.*, 1997). No instances of KSHV infection were found in these individuals, but, of note, they received only white-blood-cell-reduced (a more complete technique of white blood cell removal than standard processing) red cells, and they were examined for the presence of KSHV only with PCR techniques, not by antibody testing. In a smaller group ($n = 9$) of patients with sickle cell disease who had over 100 red blood cell transfusions and did have KSHV antibody testing performed, two were seropositive, but the sample size was too small to ascertain whether this was significantly greater than the background seroprevalence in the population (Challine *et al.*, 2001).

Organ transplantation

Several studies have confirmed the ability of KSHV to be transmitted through renal transplantation (Regamey *et al.*, 1998; Diociaiuti *et al.*, 2000; Luppi *et al.*, 2000a,b). The initial sentinel work from Switzerland found that 12% (25/206) of renal transplant recipients negative for antibodies to KSHV prior to surgery seroconverted within one year after transplantation, (Regamey *et al.*, 1998). Two of the 25 developed KS. The inference that most, if not all, of these apparent seroconversions were caused by the allograft was strengthened by finding that serum from five out of six donors to seroconverters was positive for KSHV antibodies compared to nought out of eight donors to nonseroconverters. In addition, transmission through blood products was ruled out in several cases. Subsequently, elegant molecular work performed on eight renal transplant recipients with post-transplant KS determined that, among five patients, individual cells microdissected from KS lesions were of donor origin and were KSHV-infected (Barozzi *et al.*, 2003). This finding not only substantiates the ability of KSHV to be transmitted via renal transplantation but implies that, in at least some cases, the virus is spread not as free virus but instead in a cell-associated form in KS progenitor cells. Finally, although the data are not as conclusive, transmission through liver transplantation has also been reported (Andreoni *et al.*, 2001 and Marcelin *et al.*, 2004). Now that transmission through solid organ transplantation has been confirmed, there are beginning to be calls for routine screening of organ donors and recipients (Moore, 2003; Michaels and Jenkins, 2003). Indeed, it is this setting where there is the most urgent need for the development of commercially available high throughput KSHV diagnostic assays. Difficulties in the assays for KSHV antibodies will make this an imperfect process, but the idea seems most warranted in non-endemic areas where the low prevalence of KSHV infection among donors means that few organs will need to be discarded because of KSHV-seropositivity

Table 54.4. Studies evaluating the association between age and KSHV seroprevalence in pre-pubescent children in Africa, the Middle East, and Italy

			Percent KSHV seropositive	
Country/population (reference)	Age group	*N*	Anti-latent Antibody	Anti-lytic Antibody
Cameroon	Age 7–12 mo	32		12.5[a]
Clinic patients	Age 13–24 mo	28		14.3
(Gessain *et al.*, 1999)	Age 3–4	36		13.9
	Age 5–8	34		23.5
	Age 9–11	36		25.0
	Age 12–14	28		39.2
	Age 15–20	27		48.0
	Pregnant women	189		54.5
Uganda	Age 0–5	35	20[b]	28[b]
Hospital outpatients	Age 5–9	48	38	42
(Mayama *et al.*, 1998)	Age 20–24	53	36	46
Egypt	Age <1	42	7.1	16.6
Vaccinees	Age 1–3	40	10.0	37.5
(Andreoni *et al.*, 1999)	Age 4–6	40	7.5	45.0
	Age 7–9	38	10.5	57.8
	Age 10–12	36	5.5	52.7
Italy	Age 3–5	90	1.1	
Hospital inpatients	Age 6–10	94	6.3

and those that are may be able to be given to recipients who are seropositive.

Transmission in endemic areas

Non-sexual horizontal transmission

In high-level endemic areas, such as the Middle East and Africa, an age-dependent increase in KSHV seroprevalence during childhood provides definitve evidence for some form of non-sexual horizontal transmission (Table 54.4). In intermediate-level endemic areas, e.g., the Mediterranean, fewer comparable data exist (Perna *et al.*, 2000; Whitby *et al.*, 2000); although only one report is suggestive of an age-dependent increase in KSHV seroprevalence before puberty (Whitby *et al.*, 2000), this is substantiated by the finding of increased seroprevalence in the children of patients with KS, relative to persons without KS (Angeloni *et al.*, 1998). Indeed, that prevalence at the time of puberty in some high-level endemic areas is nearly that seen in adulthood suggests that non-sexual horizontal transmission is the dominant route of spread; (this, of course, assumes that seroreversion is not common and therefore not masking the occurrence of a continuing high incidence of infection in adulthood). For example, in Cameroon, Gessain *et al.* demonstrated that after loss of maternal antibody by 6 months of age, there was a monotonic increase in KSHV seroprevalence from 13% in 7- to 24- month olds to 39% in 12- to 14-year-olds (Gessain *et al.*, 1999). There was a similar pattern found among Ugandan children (Mayama *et al.*, 1998). In Egypt, prevalence was 17% in 0- to 1-year-olds ranging to 58% among 7 to 9 years (Andreoni *et al.*, 1999).

That saliva is the body fluid that most commonly harbors KSHV lends the biologic plausibility that some form of non-sexual horizontal transmission is the dominant form of spread in endemic areas. The exact mode of spread, however, is not known. Some of the first reports from sub-Saharan Africa found that maternal KSHV seropositivity was a risk factor for seropositivity among children, leading to the conclusion that mother-to-child spread was the most significant route (Bourboulia *et al.*, 1998; Sitas *et al.*, 1999a,b). These data, however, were not controlled for the family's community of residence (and hence

background prevalence of KSHV infection), and did not consider whether this association might be confounded by father-to-child, sibling-to-sibling, or extrafamilial spread. In a cross-sectional study that evaluated all family members, Plancoulaine *et al.* (2000) found evidence for both mother-to-child and sib-to-sib spread, but not father-to-child or spouse-to-spouse. This, however, was performed in French Guiana, where a seroprevalence of only 15% among persons 15 to 40 years old was reported, even when using a more sensitive induced IFA antibody assay. Whether or not the findings apply to areas with much higher prevalence, such as Africa, is not clear. A similar cross-sectional family study from Israel, where again seroprevalence among adults was only slightly greater than 10%, found a role for mother-to-child spread but did not examine the role of sib-to-sib spread (Davidovici *et al.*, 2001). Most recently, a study of children in a high prevalence area in rural Tanzania found that having a KSHV-seropositive mother, father, or next-older sibling was associated with being KSHV-seropositive and that the magnitude of the risk was about the same across these relatives (Mbulaiteye *et al.*, 2003a,b). Importantly, there was also an age-dependent increase in KSHV seroprevalence among children who did not have a seropositive first-degree relative, suggesting that non-familial transmission also occurs. Transmission emanating from outside of the immediate family has also been reported in initial molecular epidemiologic work performed among family members in Malawi (Cook *et al.*, 2002a, b).

Taken together, these studies suggest that a variety of relationship types (i.e., mother–child, father–child, sib–child, non-family member–child) may be important in KSHV transmission. It is likely that no single relationship type has any universal significance per se in transmitting KSHV but rather that transmission is a product of salivary shedding in the infected individual and as-of-yet undetermined sociocultural practices that promote saliva passage to either interrupted skin or mucosal surfaces in the uninfected child. Some interesting theories have been proposed but for which supportive data are currently lacking. One of the most speculative put forward is the blood-sucking promoter arthropod hypothesis which suggests that the bite of a child by a bloodsucking arthropod triggers two subsequent events: (a) transfer of anti-hemostatic (anticlotting, vasodilators, and anti-platelet agents) and immunodulators from the arthropod to the human skin; and (b) use of saliva by a caregiver to relieave the itch of the bite (Coluzzi *et al.*, 2002, 2003, 2004 and Ascoli *et al.*, 2006). In this theory, the arthropod is not the biological vector for KSHV, but rather a promoter of infection by creating a hospitable microenvironment in the skin for KSHV infection and then facilitating contact with KSHV-containing saliva. As has been the case for horizontal transmission of hepatitis B virus infection in endemic areas, identifying the precise mechanisms by which KSHV is spread to children will be a considerable challenge. The exact mode of spread notwithstanding, why non-sexual horizontal transmission in children is so common in one part of the world but so uncommon in others (e.g., the USA) is not understood. While an association between lower education and KSHV seropositivity in some studies in endemic areas (Sitas *et al.*, 1999a,b; Newton *et al.*, 2003) suggests that region-specific behavioral factors may be important, the role of region-specific differences in host-meditated response to KSHV remains largely unexplored. Although a culprit gene has not yet been identified, segregation analysis in a French Guiana population suggests that a recessive gene controlling susceptibility to KSHV infection may explain the rapidly rising KSHV seroprevalence up to puberty in the population with a subsequent plateau thereafter (Plancoulain *et al.*, 2003).

Sexual transmission

While sexual transmission among homosexual men appears to occur in KSHV-endemic areas just as it does in non-endemic areas (Perna *et al.*, 2000; Rezza *et al.*, 1998), data on heterosexual transmission in endemic areas are conflicting. That sexual transmission may occur is evidenced in some areas where there is a monotonic increase in KSHV seropositivity through adulthood (Olsen *et al.*, 1998; Sitas *et al.*, 1999a,b; Newton *et al.*, 2003; Lavreys *et al.*, 2003) or where risk of KSHV infection among married individuals is associated with KSHV-seropositivity or presence of KS *per se* in their spouses (Mbulaiteye *et al.*, 2003a,b; Brambilla *et al.*, 2000). Alternatively, these finding might simply be explained by continued non-sexual transmission during adulthood. The best evidence for heterosexual transmission in intermediate-level endemic areas comes from one report from Sicily showing an association between prostitution, STD clinic attendance and KSHV-seropositivity (Perna *et al.*, 2000), although others have not confirmed this (Masini *et al.*, 2000). In high-level endemic areas, the best evidence is from two studies from Cameroon (Bestetti *et al.*, 1998, Rezza *et al.*, 2000a,b), two from Kenya (Lavreys *et al.*, 2003; Baeten *et al.*, 2002), and one from Nigeria (Eltom *et al.*, 2002a,b) each showing a relationship between KSHV-seropositivity and prostitution and/or history of at least one STD. The work from Kenya was also notable for associations between KSHV seropositivity and lack of condom use and lack of circumcision. (Baeten *et al.*, 2002). However, several other studies have found no role for heterosexual transmission (Mayama *et al.*, 1998; Newton *et al.*, 2003; Rezza *et al.*, 1998; Enbom *et al.*, 1999; Wawer

et al., 2001; Vitale *et al.*, 2000; Marcelin *et al.*, 2002; Enbom *et al.*, 2002). In particular, there is marked inconsistency in high-level endemic areas between what should be a powerful marker of sexual behavior – HIV infection – and KSHV serostatus with some studies showing an association (Bestetti *et al.*, 1998; Nuvor *et al.*, 2001; Hladik *et al.*, 2003) but others not (Sitas *et al.*, 1999; Rezza *et al.*, 2000; Baeten *et al.*, 2002; Marcelin *et al.*, 2002; He *et al.*, 1998). This is in contrast to the universal association seen between HIV infection and KSHV serostatus in homosexual men in low-level endemic areas (Martin *et al.*, 1998; Renwick *et al.*, 1998; O'Brien *et al.*, 1999). In terms of direct information on number of sexual partners in endemic areas, Sitas *et al.* (1999a,b) found a very small risk associated with lifetime sexual partners but others have not confirmed this (Lavreys *et al.*, 2003; Baeten *et al.*, 2002). Of particular acts examined, the one report that examined kissing did not show an association with KSHV seropositivity (Lavreys *et al.*, 2003).

To date, no longitudinal studies evaluating sexual transmission of KSHV that follow initially seronegative adults have been performed. Given the high prevalence of KSHV infection that is already present by puberty in endemic areas, attempts with cross-sectional studies to assess the role of either current or past sexual behavior in determining KSHV serostatus are methodologically challenging. The expectation of these cross-sectional studies would be associations that are attenuated. Therefore, definitive evidence will likely await longitudinal study.

Vertical transmission

The occurrence of KS in young children, and, in particular, a case report of KS in a 6-day-old child (Gutierrez-Ortega *et al.*, 1989) has suggested that KSHV can be vertically transmitted. Because of the presence of maternal antibody in infants, documentation of vertical transmission relies upon detection of KSHV DNA. Mantina *et al.* (2001) evaluated the newborns of 89 Zambian women who were KSHV-antibody positive. In a blood draw taken at 24 hours of life, 2 of 89 (2.2%) had detectable KSHV DNA in peripheral blood cells by polymerase chain reaction (PCR). Because KSHV DNA sequences could not be detected from the mothers, it cannot be determined whether or not these two cases represent true vertical infection or PCR contamination. Even if they do represent true infection, it would appear that the incidence and efficiency of vertical infection is quite low.

Blood transfusion

Because of the high prevalence of KSHV infection in endemic areas, if transmission via blood transfusion occurred, even if inefficient, it could pose a significant public health concern. A study of Ugandan children with sickle-cell disease found a dose–response relationship between number of transfusions received and KSHV-seropositivity, even after adjustment for age (Mbulaiteye *et al.*, 2003). The overall estimated KSHV transmission risk was 2.6% (95% confidence interval 1.9% to 3.3%) per unit transfusion. If it is assumed that the prevalence of KSHV among donors in Uganda is approximately 50%, then the risk associated with receipt of a transfusion from a KSHV-seropositive donor is 5%. This finding of KSHV transmission via blood transfusion was recently confirmed in a longitudinal study, also conducted in Uganda (Hladik *et al.*, 2006). This work also showed that blood units stored less than 4 days prior to use were associated with a higher risk of KSHV transmission than units stored for more than 4 days. Of note, however, is that in Uganda transfusion recipients are typically given fresh unprocessed whole blood. Whether or not these same per unit risks occur when fractionated blood products (e.g., leukocyte-depleted red blood cells or plasma) are used, as is the case in more developed settings, is not known. The finding of KSHV DNA in the serum of a substantial proportion of blood donors in at least one African population lends credence to the (Enbom *et al.*, 2002) concern.

Disease manifestations

Primary infection syndrome

Very little is known about the clinical manifestations of primary KSHV infection. A major reason for this is the absence of clinically available diagnostic tests that could be used to evaluate large numbers of symptomatic persons. Furthermore, the phenomenon of seroreversion, which occurs with the currently available research-level serologic assays, makes identification of seroconversion uncertain in the absence of long-standing and repeated documentation of seronegativity (as would only be available in a formal cohort study). As such, in adults, all that is known comes from three reports of what are believed to represent primary infection. In the first, an HIV-infected man developed a sudden but transient onset of angiolymphoid hyperplasia with fever, arthralgia, cervical adenopathy, and splenomegaly (Oksenhendler *et al.*, 1998). The second report involved two transplant recipients who each received a kidney from same KSHV-seropositive donor; one recipient developed disseminated KS and the other had fever, splenomegaly, and pancytopenia (Luppi *et al.*, 2000a,b). These reports emphasize the potential severity of primary infection, but because they were identified on the basis of symptoms

they do not indicate what percentage of new infections are associated with clinical symptoms. Moreover, the reports may not represent primary infection in immunocompetent hosts. The third report described five cases of KSHV seroconversion that developed during the longitudinal observation of HIV-uninfected homosexual men (Wang *et al.*, 2001). Four of the five had one or more symptoms of lymphadenopathy, diarrhea, fatigue, or rash. Although the symptoms were self-limiting, their longevity and severity were difficult to ascertain from the retrospective study design. Furthermore, this study reported a KSHV incidence of only 3.7 cases/1000 person–year, which seemingly could not account for the prevalence of 9.2% observed at the beginning of the cohort's observation, raising questions about whether the seroconversions detected represented only the cases that were the most overt immunologically and perhaps clinically. Nonetheless, this 4:1 ratio of symptomatic to asymptomatic infection is intriguing and merits further dedicated prospective study.

In children, a study of 86 one- to four-year olds in Egypt with fever of undetermined origin found six children with KSHV DNA in saliva but without KSHV antibodies, thus presumably representing primary infection (Andreoni *et al.*, 2002). Of the three children for whom a follow-up blood sample was obtained, all developed KSHV antibodies. In addition to fever, five of the six children developed a rash that first appeared on the face and gradually spread to the trunk, arms, and legs. Five of the six also had upper respiratory tract infection symptoms and two had lower respiratory tract infection symptoms. While this report again demonstrates the severity of disease that can occur, its hospital-based sampling precludes an understanding of the overall frequency of symptomatic disease among children with primary infection. There has also been one report of a 1-month-old girl with DiGeorge anomaly, a primary immunodeficiency, who had widespread KSHV dissemination with virus detected in peripheral blood mononuclear cells, bone marrow, spleen, and lymph nodes as well as in endothelial and epithelial cells of the skin, lungs, esophagus, intestine, choroid plexus, and heart (Sanchez-Velasco *et al.*, 2001). She died of multi-organ failure. Of interest from a transmission viewpoint is that there was no evidence of KSHV infection in her mother.

Kaposi's sarcoma

There are four forms of KS, defined on the basis of their epidemiologic context. "Classic" KS is the syndrome originally described by Kaposi (1872), and it has recently been thoroughly reviewed (Iscovich *et al.*, 2002). It is found most frequently in older men (over 50 years) of Mediterranean or Eastern European heritage and is characterized initially by bluish-red painless spots on the feet and lower legs that subsequently progress, if untreated, to form raised, nodular growths that may ulcerate and bleed. In the latter stages of disease, the entire lower extremities as well as the hands and arms may become involved. Although the disease course is typically indolent, internal involvement does occur in approximately 10% of cases.

African or "endemic" KS is most common in sub-Saharan Africa. Even before the AIDS epidemic, portions of sub world Saharan Africa, particularly the Nile-Congo watershed, had among the highest incidences of KS in the world (Davies *et al.*,1964; Hutt and Burkitt, 1965). In these areas, KS represented 4 to 10% of all adult cancers and was mainly a disease of men aged 30 to 50 years old. Like classic KS, endemic KS manifests primarily as localized plaques and nodules on the feet and lower legs, but visceral involvement is more common than in the classic form.

The third form of KS was described shortly after the advent of solid organ transplantation (Siegel *et al.*, 1969; Penn, 1979), and foreshadowed the powerful influence of immunosuppression on KS development. In this form, called "post-transplant" or "iatrogenic" KS, both disseminated cutaneous involvement and visceral disease are common. As noted earlier, recent work has shown that among cases that develop because of de novo transmission of KSHV, cells within the KS lesions are often of donor origin (Barozzi *et al.*, 2003). This implies that either circulating KSHV-infected spindle-like cells or lymphoid cells trapped in the allograft or endothelial cells (or their precursors) residing in the allograft are the critical transplanted element that leads to KS lesion formation. Interestingly, lesions often diminish with lessening of the immunosuppressive regimen (Penn, 1979), but because this reduction is often accompanied by organ rejection, KS is a feared post-transplant complication. The finding that KS lesions are sometimes of donor cellular origin implies that donor-derived KSHV-specific cytotoxic T-cells could be a useful form of therapy that could obviate the need to lessen immunosuppression.

The fourth form of KS, originally described in young homosexual men, heralded the beginning of the HIV epidemic in 1981 (Fig. 54.2) (Friedman-Kien, 1981; Hymes *et al.*, 1981). "Epidemic" or "AIDS-associated" KS became the most common HIV-associated malignancy, particularly affecting persons who acquired HIV via male homosexual behavior (Beral *et al.*, 1990). Prior to the introduction of effective anti-HIV therapy, HIV-infected homosexual men were estimated to have a 20-fold higher risk of KS development than other HIV transmission risk groups (Beral *et al.*, 1990) a lifetime cumulative incidence of

Fig. 54.2. Diffuse cutaneous Kaposi's sarcoma in a homosexual man.

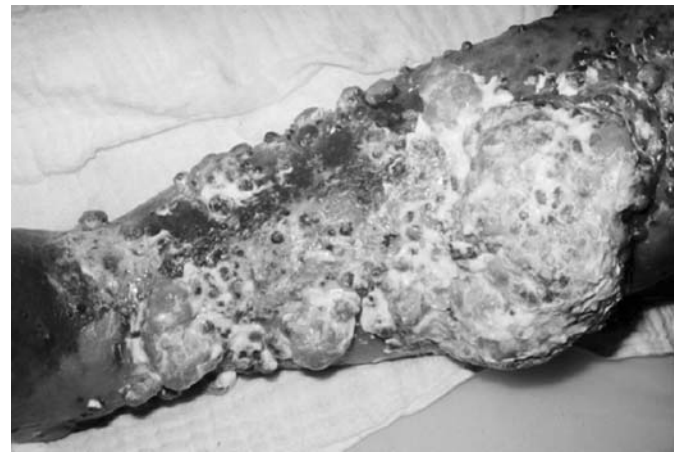

Fig. 54.3. Fulminant nodular Kaposi's sarcoma of the lower extremity in a patient with AIDS.

37% (Hoover *et al.*, 1993). Cutaneous AIDS-related KS, typically the earliest presentation, is often disseminated, cosmetically disfiguring, and complicated by bulky lesions, lymphatic obstruction, and extremity or facial swelling (Fig. 54.3) (Kaplan and Northfelt, 1997). Subsequent visceral manifestations, especially pulmonary and gastrointestinal involvement, are common (Friedman *et al.*, 1985; Mitchell *et al.*, 1992) and convey a poor prognosis. Prior to 1996 (i.e., prior to the era of highly active antiretroviral therapy for HIV and improved chemotherapy for KS), the median survival for HIV-infected persons with visceral involvement was 15 months (Krown *et al.*, 1997). However, even persons with KS confined to the skin and/or lymph nodes also had significant mortality with a median survival of 27 months (Krown *et al.*, 1997). As it has with other complications of HIV infection, the advent of highly active antiretroviral therapy has dramatically altered the prognosis of AIDS-associated KS. In a study of 287 patients with KS from 1990–1999, use of highly active antiretroviral therapy was associated with an 81% reduction in mortality (Tam *et al.*, 2002).

The introduction of potent antiretroviral therapy for HIV infection in the mid-1990s has also led to a dramatic reduction in the incidence of AIDS-associated KS in resource-rich settings (Eltom *et al.*, 2002a,b; Portsmouth *et al.*, 2003). In contrast, in portions of sub-Saharan Africa, where KSHV is endemic and antiretroviral therapy is not widely available, KS is now the most common adult malignancy. For example, in Uganda the incidence of KS has increased more than 20-fold in men between 1964 and 1968 and 1989 and 1991 (Wabinga *et al.*, 1993). A similar situation exists in Zimbabwe, where the HIV epidemic is largely unchecked and where KS is now the most common cancer overall in adults, most common in men (40% of all cancers) and the second most common in women (18% of all cancers) and children (10% of all cancers) (Chokunonga *et al.*, 2000). As is seen in AIDS-associated KS in resource-rich settings, the clinical manifestations of KS in sub-Saharan Africa have also changed. The most common presentations are now more aggressive forms such as lymphadenopathic or visceral KS, for which effective, affordable treatment is generally unavailable (Wabinga *et al.*, 1993; Desmond-Hellmann *et al.*, 1991).

The disproportionate risk of KS among HIV-infected homosexual men led to the hypothesis that a sexually transmitted infectious agent, other than HIV, was etiologically important (Beral *et al.*, 1990). This epidemiologically driven hypothesis re-invigorated an intense laboratory investigation for the causative agent that ultimately resulted in the identification of KSHV (Chang *et al.*, 1994). In a relatively short period of time since the discovery of KSHV, there have been a large number of epidemiologic studies evaluating its causal role in KS (Table 54.5). In the absence of experimental evidence (e.g., Koch's postulates), epidemiologists assess causality using Hill's criteria (Hill, 1965). These

[g]hazard ratio shown is for KSHV seroconverters.

criteria are discussed in Table 54.6 in order of their importance. The overwhelming assessment of these criteria, coupled with the finding that KSHV is invariably present in KS tumor specimens from all forms of KS throughout the world, is that KSHV is a necessary causal agent of KS. However, because only a small fraction of persons infected with KSHV develop KS, it is concluded that KSHV is a necessary, but not sufficient, causal agent of KS.

Of other potential cofactors operating along with KSHV in the etiology of KS, immunosuppression in general, and HIV infection, in particular, confer the greatest risk. Among HIV-infected persons, the magnitude of immunosuppression, as evidenced by CD4+ T-cell count, is predictive of development of KS (Renwick *et al.*, 1998; Jacobson *et al.*, 2000a,b). Timing of KSHV infection relative to HIV infection may be important as well as the risk of developing KS was significantly greater in one study (Renwick *et al.*, 1998), and of similar magnitude but not statistically significant in a second study (Jacobson *et al.*, 2000a,b), in persons who acquire KSHV after as compared to before HIV infection. Studies of this nature have potential methodologic pitfalls (Cannon and Pellett, 2001), however, and could conceivably be explained by what appears to be KSHV seroconversion actually being KSHV reactivation and reappearance of antibody-positivity. Two potential genetic risk factors have also been described and await confirmation. The FF genotype of the low affinity Fc gamma receptor IIIA is underrepresented in patients with KS, whereas the VF genotype confers greater risk (Lehrnbecher *et al.*, 2000). Homozygosity for allele G at amino acid 174 of the IL6 promoter, associated with increased IL6 production, has been related to the development of KS while homozygosity of allele C appears protective (Foster *et al.*, 2000). However, it is not known whether these genetic factors influence development of KS via pathogenic acceleration among KSHV-infected persons or via enhancing the acquisition of KSHV *per se*.

Despite substantial investigation, the identification of cofactors, in addition to KSHV, for development of KS among immunocompetent individuals is largely incomplete. The role of cofactors is particularly evident in Africa, where prior to the AIDS epidemic, there was tremendous heterogeneity in KS incidence; this heterogeneity is not fully explained by underlying geographic differences in KSHV prevalence (Dedicoat and Newton, 2003). The absence of KS among Ethiopian immigrants to Israel compared to Israeli-born residents, despite higher KSHV

Table 54.6. Assessment of the Hill criteria for the role of KSHV infection in the etiology of Kaposi's sarcoma

Criterion	Comment
Temporality	Demonstrating that KSHV infection precedes KS is the *sine qua non* for causality. KSHV infection has been shown to precede KS in several studies (Whitby *et al.*, 1995; Gao *et al.*, 1996; Martin *et al.*, 1998; Renwick *et al.*, 1998; O'Brien *et al.*, 1999; Moore *et al.*, 1996; Lefrere *et al.*, 1996) thus dispelling notions that KS tumors, by being hospitable breeding grounds, result in the subsequent presence of KSHV. Importantly, KSHV infection is temporally associated with KS independent of degree of sexual exposure (Martin *et al.*, 1998) (excluding the possibility that KSHV is just a marker for another as-yet-undiscovered sexually transmitted pathogen) and immunocompromise (Whitby *et al.*, 1995; Gao *et al.*, 1996; Martin *et al.*, 1998; Renwick *et al.*, 1998; O'Brien *et al.*, 1999).
Strength of Association	After adjusting for all known potential confounding factors, statistical associations between a putative cause and disease that maintain a large magnitude are less likely to be explained by unaccounted for confounding factors and hence more likely to be valid associations. In longitudinal studies of KSHV and KS, the relevant association to be evaluated is KS incidence in KSHV-infected persons compared to KSHV-uninfected persons. If it is accepted that KS *per se* does not cause KSHV infection to be detected, associations from case-control studies are also relevant. Of studies of AIDS-related KS that measured KSHV infection by serologic means and directly controlled for number of sexual partners (Martin *et al.*, 1998) or restricted analyses to homosexual men (Gao *et al.*, 1996; Renwick *et al.*, 1998; O'Brien *et al.*, 1999; Miller *et al.*, 1996; Kedes *et al.*, 1996; Gao *et al.*, 1996; Simpson *et al.*, 1996; Lennette *et al.*, 2002) the magnitude of association between KSHV and KS ranges from 2.5 to 5.2 (hazard ratios) in longitudinal studies and 1.8 to 18.9 (odds ratios) in case-control studies.
Consistency	All published epidemiologic reports addressing a possible association between KSHV and, KS, with the exception of one have found a direct association. While it is formally possible that an unrecognized bias in either subject selection or variable measurement could account for the association between KSHV and KS seen in all studies to date, this is improbable because such a bias is unlikely to be consistently present in such a wide array of studies which vary by design, participant selection, and assay formats. Furthermore, the remarkable consistency in results makes chance a very unlikely explanation.
Biologic Plausibility	There are several potential mechanisms by which KSHV may cause, KS, described in Chapter 56.
Dose-Response Relationship	Among HIV and KSHV co-infected homosexual men, this criterion has been satisfied by the finding that detectable peripheral blood mononuclear cell-associated KSHV is associated with the subsequent development of KS (Engels *et al.*, 2003).
Coherence	This criterion implies that a cause-and-effect interpretation for the association in question does not conflict with what is otherwise known about either the disease or the putative causal agent. A causal role for KSHV in KS is compatible with existing knowledge in that the epidemiology of KSHV *per se* matches that long predicted for the agent of KS (e.g., highest prevalences in groups at greatest risk for, KS, and, in developed settings, sexually transmitted).
Analogy	Although a weak criterion, there is analogous evidence for a causal role of KSHV in KS. Two herpesviruses closely related to KSHV, herpesvirus saimiri and Epstein-Barr virus (EBV), are oncogenic.
Specificity	That a single cause must cause a single disease is clearly outdated (Rothman and Greenland, 1998) and likely violated by KSHV which has also at least been associated with primary effusion lymphoma (Cesarman *et al.*, 1995) and multicentric Castleman's disease (Soulier *et al.*, 1995).
Experimental evidence	In SCID mice, injection of KSHV into transplanted human skin results in the formation of lesions that are morphologically and phenotypically consistent with KS (Foreman *et al.*, 2001).

seroprevalence in the Ethiopians, is a well-documented example of some heretofore undiscovered protective factor (Grossman *et al.*, 2002). Studies which have evaluated factors associated with KS that were performed prior to the identification of KSHV have had their interpretations clouded by the possibility that these factors are associated with acquisition of KSHV. This pertains to, for example, genetic studies where in at least some reports an increased risk for classic KS has been observed in persons with HLA DR5 and a protective effect observed for HLA DR3 (Contu *et al.*, 1984). Both male gender and older age have for long been identified as a significant risk factors for KS, and neither can be fully explained by an increased risk for acquisition of KSHV infection. However, mechanistic explanation

Table 54.7. Current strength of evidence* for a causal role of KSHV infection in various diseases

Disease	Strength of evidence
Kaposi's sarcoma	+ + +
Primary effusion lymphoma	+ +
Multicentric Castleman's disease	+ +
Hemophagocytic lymphohistiocytosis	+ +
Pulmonary hypertension	+
Prostate cancer	+
Amyotrophic lateral sclerosis	+
Multiple myeloma	−
Sarcoidosis	−

+ denotes weak evidence; + + denotes moderate evidence;
*+ + + denotes strong evidence;
− denotes that initial claims have been largely refuted.

for these factors is unknown. Higher levels of immune activation, measured by circulating neopterin and beta-2-microglobulin, have also been associated with classical KS, but it has not been determined whether this is a cause or a consequence of KS (Touloumi *et al.*, 1999). More recent studies that were either limited to participants with KSHV infection or adjusted for KSHV infection are most notable for the absence of demonstrable associations. Nonetheless, two new potential behavioral factors have been identified that require further investigation. In classic KS, smoking was found to be protective; the effect of smoking on inflammatory cytokines was the speculated mechanism (Goedert *et al.*, 2002). In endemic KS, going barefoot more than half the time was a risk factor (Ziegler *et al.*, 2003). It has been suggested that fine soil particles might pass through the skin of barefoot individuals and block the lymphatic system, causing local immunosuppression in the lower limbs and predisposing to the development of KS (Ziegler, 1993).

Other diseases

KSHV also has been associated with primary effusion lymphoma (Cesarman *et al.*, 1995), multicentric Castleman's disease (Soulier *et al.*, 1995), and hemophagocytic lymphohistiocytosis (Fardet *et al.*, 2001) (Table 54.7). The rarity of these disorders will likely preclude their ever being scrutinized with Hill's criteria, as was discussed for KS. Among other diseases that have been hypothesized to be caused by KSHV, multiple myeloma (Rettig *et al.*, 1997) has generated the most interest because of its frequency andclinical severity. From an ecological viewpoint, the association lacks plausibility given that multiple myeloma is not more common in populations in which KSHV prevalence is high. In addition, numerous individual subject-level studies (Parravicini *et al.*, 1997; Masood *et al.*, 1997; Whitby *et al.*, 1997; Ablashi *et al.*, 2000; Brander *et al.*, 2002) have failed to confirm the initial claim. Most recently, claims have also been made for an association between KSHV infection and pulmonary hypertension (Cool *et al.*, 2003), prostate cancer (Hoffman *et al.*, 2004), and amyotrophic lateral sclerosis (Cermelli *et al.*, 2003). The clinical impact of these conditions, especially prostate cancer, is sure to prompt much additional work in the next several years seeking to confirm these associations.

EBV-induced oncogenesis

Nancy Raab-Traub

Department of Microbiology and Immunology, Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, USA

Introduction

The Epstein–Barr virus (EBV) is a human herpesvirus that is a ubiquitous infectious agent, infecting greater than 90% of the world's population (Henle *et al.*, 1969). The majority of infections occur early in life without significant illness. However, EBV is clearly an important factor in multiple human cancers. This dichotomy raises the question as to what are the unique aspects of infection in those who develop cancers. The study of EBV and its associated tumors points to specific interactions between environmental, genetic, and viral factors.

Many of the malignancies associated with EBV develop in the setting of immunosuppression or have endemic patterns of incidence (Raab-Traub, 1996). EBV has potent growth transforming properties in vitro where it efficiently induces permanent growth of infected lymphocytes (Nilsson *et al.*, 1971). Therefore it is not surprising that EBV is clearly the etiologic factor in post-transplant lymphoma and a subset of AIDS-associated lymphomas.

The endemic patterns of incidence characteristic of many EBV-associated tumors were initially apparent as EBV was originally isolated from samples of African Burkitt's Lymphoma (BL) (Epstein *et al.*, 1964). This childhood tumor develops with high incidence in subequatorial Africa (Burkitt, 1962a). EBV was subsequently identified in nasopharyngeal carcinoma (NPC), a major tumor that occurs with extraordinarily high incidence in the southern Chinese and with elevated incidence in Inuit populations and in Mediterranean Africa (Henle *et al.*, 1978a; Wolf *et al.*, 1973). EBV has also been identified in a subset of T-cell lymphomas that develop with increased frequency in Taiwan and Japan and in parotid gland tumors that occur most frequently among Inuits (Su *et al.*, 1990; Saemundsen *et al.*, 1982).

Finally, there are the more recently identified tumors associated with EBV, a subset of Hodgkin's lymphoma (HL) and gastric carcinoma (Weiss *et al.*, 1989a,b; Shibata *et al.*, 1991). The factors that contribute to the development of these tumors are unknown but the environmental and immune components may be similar to those that contribute to the development of EBV cancers with endemic incidence patterns or due to immune impairment. It is likely that environmental or genetic factors increase infection of distinct susceptible cell populations and activate cellular pathways that are highly synergistic with EBV genes that affect cell growth.

This chapter will review the pathogenesis of EBV infection, the characteristics of EBV-associated tumors, the molecular biology of latent infection, and biochemical properties of EBV genes as they relate to tumor development.

EBV infection in vivo

EBV is the prototype member of the Herpesvirus subfamily, Gammaherpesviridae, and like other herpesviruses, the virus establishes a latent infection with life-long persistence in the infected host (Kieff and Rickinson, 2001). The virus is transmitted by salivary exchange and may initially infect the epithelial cells of the oropharynx, posterior nasopharynx, parotid gland and duct, and possibly tonsilar lymphocytes (Miller *et al.*, 1973; Wolf *et al.*, 1984; Sixbey *et al.*, 1984). Hybridization in situ has detected evidence of EBV DNA in cells lining the parotid duct and EBV DNA and replicative mRNAs have been detected in sloughed oropharyngeal epithelial cells and tonsilar lymphoid cells (Sixbey *et al.*, 1984). Through infection of trafficking lymphocytes, the virus then establishes a

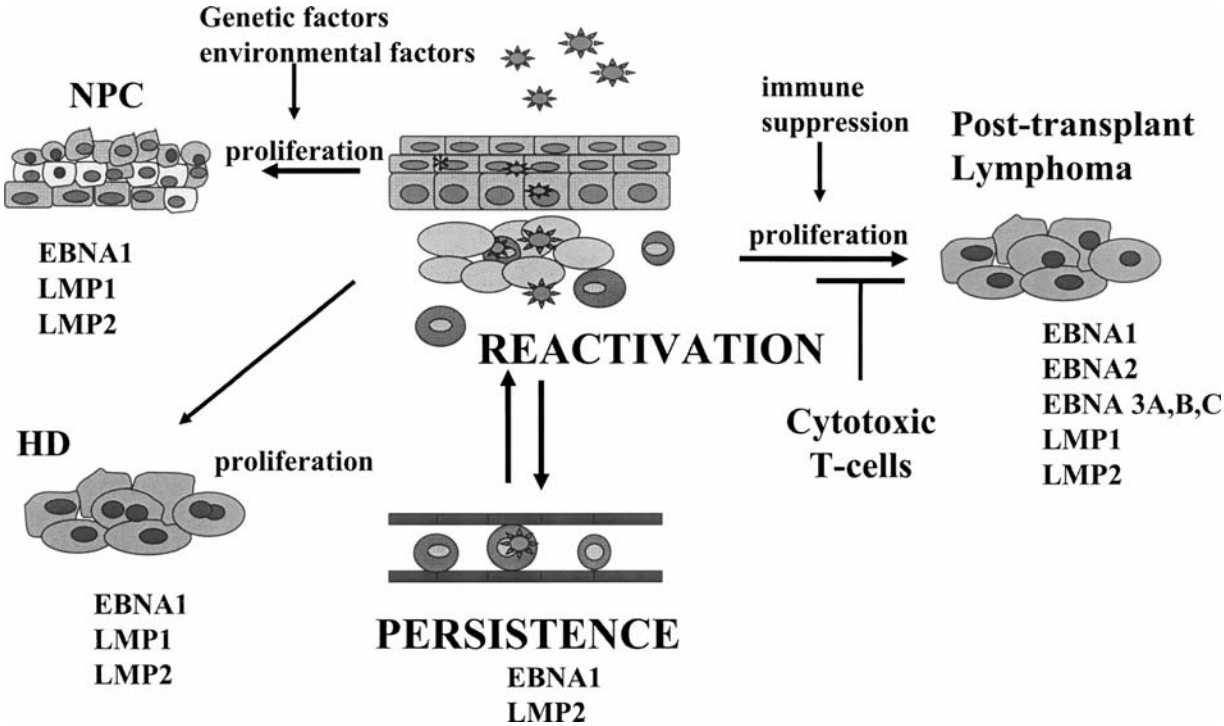

Fig. 55.1. EBV pathogenesis. EBV is transmitted by saliva and infects oropharyngeal epithelial cells and lymphocytes. The virus persists in memory B cells that have limited EBV expression, possibly only EBNA1 or LMP2. The virus frequently reactivates from peripheral blood lymphocytes producing virus and may be directly shed from lymphocytes into the nasopharynx or may replicate in mucosal epithelial cells. In combination with possible genetic changes such as the absence of p16 expression, the virus may establish a latent infection in a basal epithelial cell. Additional genetic changes may enable expression of EBNA1, LMP1, and LMP2 which may not be presented by specific HLA types. The viral episome is maintained in the infected epithelial cell which rapidly becomes malignant in nasopharyngeal carcinoma (NPC). Similar events may occur in the development of Hodgkin Disease (HD). In the context of immunosuppression, the virus can reactivate to full latent expression with expression of EBNA2, 2, 3A,3B,3C, LMP1, and LMP2. The transformed cells may develop into post-transplant lymphoma in the absence of cytotoxic T-lymphocytes.

persistent latent infection in bone marrow and peripheral blood memory B-lymphocytes (Fig. 55.1). Virus expression is tightly restricted in latently infected B-lymphocytes with no viral gene expression or with expression limited to the EBV nuclear antigen 1 (EBNA1), and/or latent membrane protein 2 (LMP2) (Babcock *et al.*, 2000a). The state of EBV latency may reactivate and express additional viral genes that induce cell growth, including the other EBNAs and LMP1 and LMP2. The proliferation of the infected lymphocytes is controlled by cytotoxic T-cells (CTLs) that primarily recognize the EBNA2 and EBNA3 proteins (Murray *et al.*, 1990). Therefore in immunosuppressed patients who lack CTL control, EBV-infected B-lymphocytes may proliferate and develop into B-cell lymphomas (Fig. 55.1). EBV infection also may reactivate into replicative infection at mucosal sites and infectious virus is frequently detected in saliva.

The infected peripheral lymphocytes can be explanted in vitro and established as permanent lymphoblastoid cell lines (LCLs). The majority of the infected cells in the cell lines do not produce virus but instead are latently infected and maintain the EBV genome as a multi-copy episome (Rickinson, 2001). In vitro, an occasional cell in some cell lines may reactivate into viral replication and produce infectious virus. The infectious virus produced by cell lines or virus that is present in throat washings will infect primary B-lymphocytes, establish a latent infection, and induce growth transformation.

The ability of the virus to efficiently transform B-cells in culture to immortalized, transformed cells undoubtedly underlies its connection to human cancers. In B-cell lines grown in vitro, the carefully regulated, coordinate expression of multiple viral gene products induces permanent continuous cell growth.

Characteristics of latent infection

DNA structure

The EBV genome that is encapsidated in the virion is a 185 kb double-stranded, linear DNA molecule that is replicated by a virally encoded DNA polymerase (Kieff and Rickinson, 2001). Within latently infected cells, the viral genome is an extrachromosomal episome that is present in multiple copies (Adams and Lindahl, 1975). The episome has a nucleosomal structure and is replicated by the host DNA polymerase (Shaw, 1985; Shaw *et al.*, 1979). The linear viral genome is largely unique DNA interspersed with short direct tandem repeats. At the ends of the viral DNA there are multiple copies of a 500 bp direct tandem repeated sequence (Given *et al.*, 1979). Due to the variable numbers of this terminal repeat (TR) element the terminal restriction enzyme fragments are heterogeneous in size. Identification of the terminal restriction enzyme fragments of linear virion DNA on Southern blots will reveal ladder arrays of heterogeneous DNA fragments that contain different numbers of TR (Fig. 55.2(a)). After entry into the cell, the linear form circularizes through the TR to form viral episomal DNA. The restriction enzyme fragment representing the fused termini of the episomal form of EBV can be distinguished from the terminal restriction fragments of the linear genomes because the fused fragments are larger and contain the unique DNA sequences adjacent to the terminal repeats from both ends of the genome (Raab-Traub and Flynn, 1986). Therefore the fused termini restriction enzyme fragment will hybridize to DNA probes of unique DNA from either end of the linear genome (Fig. 55.2(a)).

Identification of the EBV termini is particularly useful because it permits discrimination between viral replicative and latent states and also is a predictor of the clonality of the viral genome. In the initial studies, a single band representing the EBV fused termini was detected in NPC and in monoclonal lymphomas (Fig. 55.2(b)). The identification of a single band indicated that all of the EBV episomes were identical to one another with regard to number of TR (Raab-Traub and Flynn, 1986). This indicated that the tumors contained a homogeneous clonal population of EBV genomes and suggested by extension cellular monoclonality. This provided the first evidence that NPC like BL is a monoclonal proliferation and revealed that the malignancy had developed from a single EBV-infected cell. The link between the homogeneity of the EBV genome and cellular clonality has been confirmed in multiple studies of lymphoid tumors where clonality can be determined through analysis of the immunoglobulin joining region (Brown *et al.*, 1988). Most EBV tumors contain a single clonal population of EBV genomes as evidenced by the detection of a single restriction enzyme fragment (Fig. 55.2(b)). Clonal EBV genomes are present in Hodgkin's disease and in many lymphomas that develop in immunosuppressed patients (Weiss *et al.*, 1989a,b). Oral hairy leukoplakia (HLP) is an unusual lesion that may develop on the lateral borders of the tongue in HIV infected or immunosuppressed individuals (Greenspan *et al.*, 1985). It is the only pathologic manifestation of a permissive EBV infection and identification of the EBV termini detects abundant ladder arrays of linear DNA (Fig. 55.2(b)) (Gilligan *et al.*, 1990a).

EBV expression in latent infection

Multiple viral genes are expressed in latently infected lymphocytes maintained in vitro and at least three different patterns of EBV expression have been detected in latently infected cells and tissues (Rowe *et al.*, 1987). In cell lines transformed in vitro and in lymphomas that develop in transplant recipients, six EBNA proteins (EBNA 1, 2, 3A, 3B, 3C, and leader protein, EBNA-LP) are expressed (Rickinson, 2001). These proteins regulate their own expression and also regulate expression of the latent membrane proteins, LMP1 and LMP2 (Wang *et al.*, 1990). In addition, the non-polyadenylated EBER RNAs and rightward transcripts from the BamHI A region are expressed (BARTS) (Brooks *et al.*, 1993). This state of latent infection is termed Type 3 latency. EBV expression is more restricted in other types of latent infections that have been identified in tumors and in peripheral blood lymphocytes. Type 1 latency is the most restricted with expression of EBNA1 and the EBERs and is found in BL. In Type 2 latency found in NPC and HL, EBNA1, LMP1, LMP2, EBERs, and BARTs are expressed. In peripheral blood lymphocytes, EBV may not express any genes or may only express EBNA1 or LMP2. This has been referred to as Type 0 latency (Rickinson, 2001).

The EBNA2 and EBNA3 proteins are the major targets of EBV-specific cytotoxic T lymphocytes (CTL) (Rickinson and Moss, 1997). Expression of these proteins has been detected in tonsillar lymphocytes and during infectious mononucleosis but they have not been detected in latently infected peripheral blood lymphocytes (Babcock and Thorley-Lawson, 2000b). Of the cancers that are associated with EBV, the EBNA2 and 3 proteins are only expressed in lymphomas that develop in immunosuppressed patients such as post-transplant lymphomas (Young *et al.*, 1989). Due to the expression of the EBNA CTL targets, the post-transplant lymphomas can be successfully treated by immune therapy (Rooney *et al.*, 1995) (Fig. 55.1). Reduction

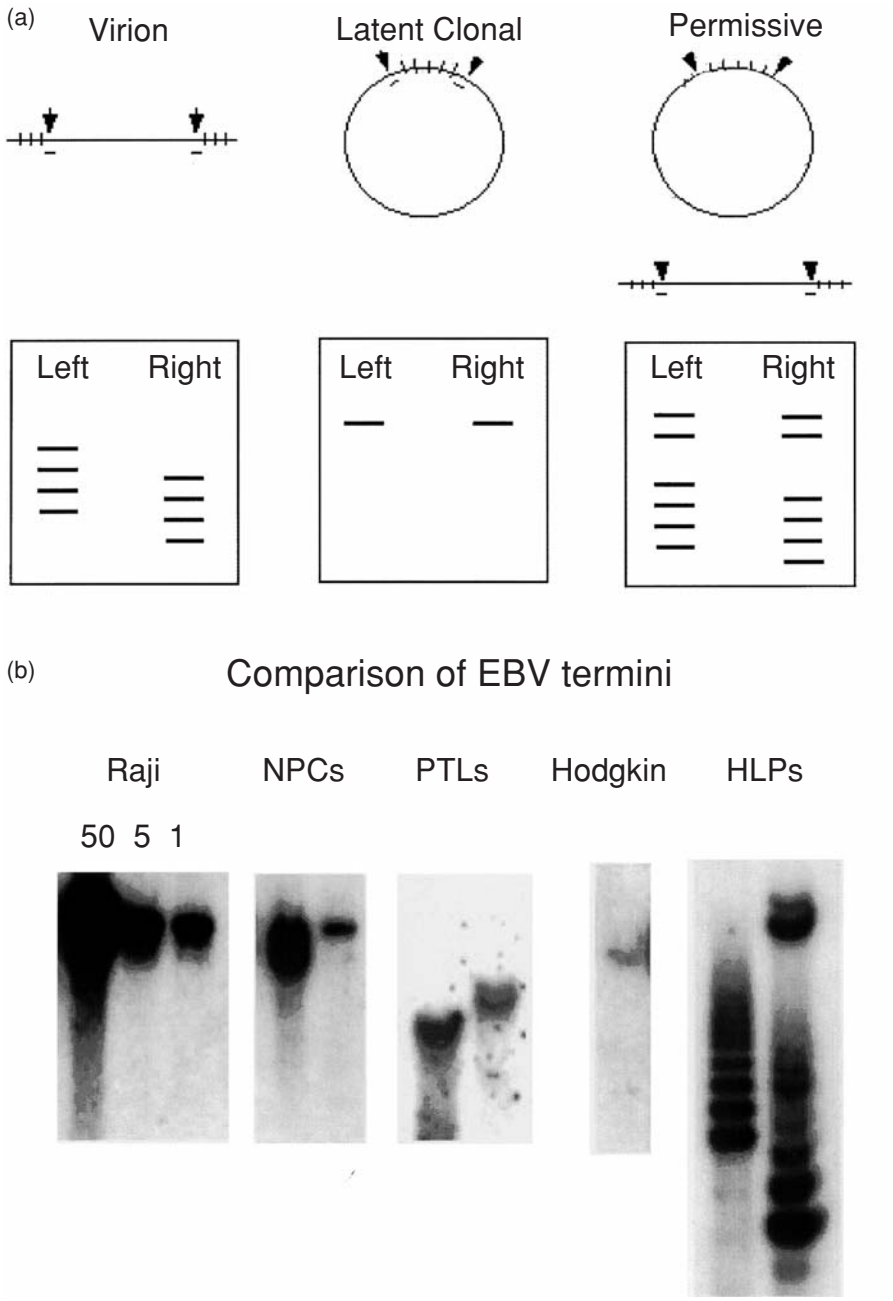

Fig. 55.2. Identification of the EBV termini identifies episomal and linear viral DNA. (a) A is present at the termini of the linear DNA. The number of terminal repeats (TR), homologous direct repeat 500 bp sequence, differs between individual DNA molecules such that the terminal restriction enzyme fragments that contain the TR are heterogeneous in size and form a ladder array on gels representing molecules that have differing numbers of the TR element. Upon entry into the cell, the viral DNA circularizes through the TR to form the intracellular, extrachromosomal episome. This circularization produces a fused restriction enzyme fragment that can be identified with DNA probes representing unique DNA adjacent to the TR from either ends of the linear genome. (b) A single fused restriction enzyme fragment representing the EBV episomal DNA is detected in most EBV malignancies including NPC, PTL, and HD. The Raji cell line and dilutions is used for comparison of copy number. HLP represents a permissive infection.

of immunosuppression or infusion of EBV-specific CTLs that recognize the EBNA proteins can result in regression of the EBV-infected lymphoma. In other EBV associated tumors that develop in non-immunosuppressed individuals and in some patients with AIDS, the EBNA2 and 3 proteins are not expressed (Raab-Traub, 1996). The expression of LMP1 and LMP2 independent of transactivation by the EBNA proteins, the major CTL targets, may be one factor that contributes to the development of these tumors.

The EBNA proteins

The EBNA 1 protein is essential for maintenance and replication of the viral episome by the host DNA polymerase during latent infection (Yates *et al.*, 1985). EBNA1 binds to the origin of replication for the plasmid form of the viral genome and is essential for plasmid replication. EBNA1 also binds to cellular chromosomes and mediates equivalent partitioning of the viral genomes to the daughter cells. Although EBNA1 is expressed in all dividing EBV infected cells, the protein is not recognized by CTLs and the latently infected cells can persist in the presence of a functioning immune system (Levitskaya *et al.*, 1995). The lack of CTL recognition of EBNA1 is due to the presence of a large repeated element of glycine and alanine. This sequence apparently spares EBNA1 from proteosomal degradation and presentation by MHC class I molecules (Levitskaya *et al.*, 1997).

The EBNA 2 protein is essential for growth transformation of lymphocytes and is also a transcriptional transactivator (Cohen *et al.*, 1989). EBNA2 interacts with the RBPJk protein to activate gene expression (Grossman *et al.*, 1994; Henkel *et al.*, 1994). RBPJk is the DNA binding protein and transcription factor that is activated by the Notch signaling pathway. Activated Notch has been shown to partially substitute for EBNA2 in transformation (Hofelmayr *et al.*, 2001). EBNA2 also interacts with multiple cellular transcriptional proteins through which it regulates the viral promoters for the latent membrane proteins, LMP1 and LMP2, for the B-cell activation marker, CD23, and the EBV receptor, CD21 (Johannsen *et al.*, 1995). Two types of EBNA2 have been identified, encoded by quite divergent sequences (Dambaugh *et al.*, 1984). The type of EBNA2 gene, EBNA2A or 2B, distinguishes two types of EBV, EBV1 or 2. EBV1 is more prevalent than EBV2 in Western populations, however, EBV2 infection is prevalent in central Africa, in New Guinea, and among Alaskan Eskimos (Zimber *et al.*, 1986). Coinfection with both EBV types is frequently detected in HIV infected patients and has also been detected in normal individuals (Walling *et al.*, 1992). Recent studies indicate that multiple strains are detected in most individuals (Sitki-Green *et al.*, 2003).

The EBNA3 genes are also encoded by divergent sequences that co-segregate with the EBNA2 type (Sample *et al.*, 1990). Thus the sequence type of the EBNA2 and EBNA3 genes define Type 1 and Type 2 of EBV. All of the EBNA3 proteins interact with the cellular RBPJk protein and may modulate transactivation of the LMP1 promoter and other genes by the EBNA2 protein (Robertson *et al.*, 1996).

Latent membrane protein 1

LMP1 is considered the EBV oncogene as it can transform rodent fibroblasts in vitro and is essential for B-cell transformation (Wang *et al.*, 1985). Transgenic mice that express LMP1 in B cells have increased development of B cell lymphomas (Kulwichit *et al.*, 1998). LMP1 has profound effects on cellular gene expression and induces expression of multiple genes including adhesion molecules, anti-apoptotic functions, growth factors, and growth factor receptors (Wang *et al.*, 1988). The biochemical properties of LMP1 that are in part responsible for these effects on cellular expression are its ability to activate the NFKB transcription factors and to interact with the cellular molecules that mediate signals from the tumor necrosis factor family of receptors (Mosialos *et al.*, 1995). These molecules, entitled TRAFs, form heterotrimeric complexes that transduce signals that depending on the receptor may activate NFKB, induce cellular growth, or induce apoptosis. Thus the activation of the TRAF pathway is likely the key property of LMP1 that mediates its effects on cellular growth regulation.

The LMP1 protein has a short cytoplasmic amino terminus, a six membrane-spanning domain that is responsible for spontaneous aggregation in the plasma membrane, and signaling domains in the carboxyl terminus (Fennewald *et al.*, 1984). The cytoplasmic carboxyl terminus contains two signaling domains, C-terminal activation region 1 (CTAR1) and CTAR2 (Huen *et al.*, 1995). CTAR1 binds TRAFs 1, 2, 3, and 5 while CTAR2 binds the TNF receptor-associated death domain protein (TRADD) and its partner, the TNF receptor-interacting protein (RIP) (Devergne *et al.*, 1996; Izumi *et al.*, 1997). Signaling from these two domains leads to NF-κB activation as well as c-Jun N-terminal kinase (JNK) and p38 mitogen-activated protein kinase (MAPK) activation (Eliopoulos and Young, 1998; Eliopoulos *et al.*, 1999). In reporter assays, LMP1 containing CTAR2 but deleted for CTAR1 (LMP1-CTAR2) induces greater NFκB activity, however electrophoretic mobility shift assays (EMSA) indicate that LMP1 deleted for CTAR2 but containing CTAR1 (LMP1-CTAR1) activates at least 3 heterodimeric forms of NFκB including p50/p50, p50/p52, and p52/p65 dimeric forms (Paine *et al.*, 1995;

Miller *et al.*, 1998). These forms are more abundant than the p50/p65 form that is the predominant form of NFκB activated by CTAR2. EBV containing LMP1-CTAR1 is also capable of transforming lymphocytes (Kaye *et al.*, 1999).

Expression of LMP1 affects different cellular genes in lymphocytes and epithelial cells. In both cell types, NFKB transcription factors are activated although different forms of NFKB are activated in the two cell types. Activation of NFKB increases expression of B-cell activation markers in lymphoid cells, and expression of the A20 gene in both lymphoid and epithelial cells. In epithelial cells, LMP1 activates transcription of the epidermal growth factor receptor (EGFR), which is also detected at high levels in NPC (Miller *et al.*, 1995b). Several studies have shown LMP1-CTAR1 has unique properties including the ability to induce expression of the EGFR, TRAF1, and CD54 (Miller *et al.*, 1997; Devergne *et al.*, 1998). The ability of CTAR1 to activate NFκB p50/p50 homodimers may be responsible for its unique ability to induce EGFR expression. Chromatin precipitation assays of the EGFR promoter in NPC have detected 50/p50 homodimers in a complex with bcl3 (Thornburg *et al.*, 2003). It is presently unknown if EBV infection affects bcl3 activity or if the activation of bcl3 is a unique event in NPC.

Latent membrane protein 2 (LMP2)

The LMP2 proteins, LMP2A and LMP2B, are expressed in transformed lymphocytes and in NPC and HL (Young *et al.*, 1991; Busson *et al.*, 1992). The LMP2 gene contains exons located at both ends of the linear EBV genome and can be only transcribed across the fused termini of the episomal form or in some rare integrated events (Laux *et al.*, 1988; Sample *et al.*, 1989). Two distinct forms of mRNA encodes the 54 kd and 40 kd LMP2A and 2B proteins. The 2.3 kb and 2.0 kb RNAs have different promoters and the two RNAs each have a unique first exon and share exons 2 to 9 (Sample *et al.*, 1989). The first exon of LMP2A (exon 1A) encodes the hydrophilic N-terminus whereas the first exon of the B form (exon 1B) is non-coding.

Genetic studies have revealed that LMP2A and B are not required for EBV dependent-transformation of B-cells, however, LMP2A is an important factor in maintaining EBV in a non-replicative state (Longnecker and Miller, 1990). This is accomplished by its ability to alter signaling from the B-cell receptor (BCR), to keep the infected lymphocytes in a non-activated state and maintain a latent infection in B-cells . LMP2 is an integral membrane protein with 12 transmembrane spanning regions. The amino terminal domain that is unique to LMP2A is cytoplasmic and contains multiple potential protein recognition sequences and signaling domains. The motifs include an immunoreceptor tyrosine-based activation motif (ITAM) with two spaced tyrosine residues. This motif is recognized by the Lyn/Syk kinases to transduce BCR signaling (Miller *et al.*, 1995a). LMP2 also contains a PY motif that interacts with the NEDD4 family of ubiquitin ligases (Longnecker *et al.*, 2000; Ikeda *et al.*, 2001). LMP2 apparently sequesters the lyn kinase within lipid rich rafts and promotes its degradation thus blocking BCR signaling and B-cell activation (Dykstra *et al.*, 2001).

Studies in transgenic mice have revealed that LMP2 also provides a cell survival signal (Caldwell *et al.*, 1998). A recent study, using microarray analysis, revealed that LMP2 interferes with expression of specific transcription factors that regulate B-cell development resulting in enhancement of cellular survival (Portis and Longnecker, 2003). In studies in the HaCat epithelial cell line, LMP2 induced growth in soft agar and inhibited differentiation through activation of PI3 kinase and the Akt kinase (Scholle *et al.*, 2000). LMP2 also activates Akt in lymphocytes (Swart *et al.*, 2000). One target of the activated Akt in epithelial cells is GSK3β, an important component in the Wnt/β-catenin signaling pathway. GSK3β exists in a cytoplasmic complex with APC and Axin and it is within this complex that GSK3β phosphorylates β-catenin leading to ubiquitination and degradation of β-catenin by the proteosome complex. GSK3β is inactivated by phosphorylation by Akt (Chen *et al.*, 2000; Cross *et al.*, 1995). Therefore Akt activation may inhibit phosphorylation of β-catenin resulting in its stabilization. In epithelial cells expression of LMP2 greatly increases the levels of β-catenin and also induces its nuclear translocation (Morrison *et al.*, 2003). This property requires activation of Akt and phosphorylation of GSK3. Activation of β-catenin occurs frequently in the development of carcinoma frequently through genetic mutations and it is likely that activation of this pathway is an important factor in EBV effects on epithelial cell growth.

The powerful effects of LMP2 on epithelial cell growth are also suggested by a recent study that revealed that EBV infected epithelial cell clones rapidly emerged from primary infected cultures (Moody *et al.*, 2003). This growth advantage was linked to those clones that had fewer numbers of TR, a property that resulted in increased expression of LMP2.

EBV-encoded RNAs (EBER)

In EBV infected cells, two small non-polyadenylated RNA molecules designated EBER 1 and EBER 2 are transcribed by RNA polymerase III (Lerner *et al.*, 1981). These 170 bp RNAs are encoded by adjacent sequences that have considerable homology. The EBERs exist as ribonucleoprotein complexes and are the most abundantly expressed viral transcript with 10^5 or 10^6 copies per infected cell (Howe and Steitz, 1986). Genetic studies indicate that EBER

expression is not essential for lymphocyte transformation and their function remains obscure (Swaminathan *et al.*, 1991). The Akata BL cell line is unique in that it can be cured of EBV infection. The loss of EBV results in the loss of the ability of Akata cells to form tumors in nude mice (Komano *et al.*, 1998). Expression of EBERS partially revert this loss, potentially through effects on bcl2 (Komano *et al.*, 1999). Similar studies of an EBV infected gastric epithelial cell line have shown that the EBERS induce altered growth properties through induction of expression of IGF1 (Iwakiri *et al.*, 2003).

The extraordinary abundance and stability of the EBER ribonucleoprotein complexes in embedded sections makes in situ detection of EBER expression a useful diagnostic tool to identify EBV-associated diseases (Ambinder and Mann, 1994). However, the EBERs are not expressed at all times in all cells and are not expressed in all examples of EBV infection (Gilligan *et al.*, 1990a; Pathmanathan *et al.*, 1995a). Thus the absence of EBER expression does not necessarily indicate that the lesion does not contain EBV (Niedobitek *et al.*, 1991a,b). The EBERs are not expressed in the differentiated form of NPC or in oral hairy leukoplakia (HLP), a site of EBV replication that contains viral particles, replicative gene products, and linear viral DNA (Gilligan *et al.*, 1990a). The lack of EBER expression in HLP revealed that EBERs were not required for viral replication and indicated that the detection of EBER expression denotes latent EBV infection.

BamHI A transcripts (BARTS)

The BamH A RNAs were initially identified by cDNA cloning of EBV RNAS expressed in NPC (Gilligan *et al.*, 1990b; Hitt *et al.*, 1989). These RNAs are transcribed rightward through the BamHI A fragments (BARTs) and are antisense to multiple replicative functions. At least three mRNAs are abundantly expressed in NPC and consistently detected on Northern blots, while in lymphoid cell lines, these RNAs are only detectable by PCR amplification of cDNAs (RT-PCR) (Gilligan *et al.*, 1990b; Brooks *et al.*, 1993; Sadler and Raab-Traub, 1995b).

In NPC the RNAs are also readily detectable by in situ hybridizations and are transcribed in all cells (Gilligan *et al.*, 1990b). The cDNA clones contain distinct exons and patterns of alternate splicing that produce previously unidentified open reading frames (ORFs) (Sadler and Raab-Traub, 1995b). These cDNAs have been detected by RT-PCR in NPC, BL, parotid carcinoma, peripheral blood lymphocytes, and LCL samples. At the 3′ end of all of the mRNAs is an ORF that would encode a 174 amino acid (aa) protein, *B*amHI *A r*ightward *f*rame *0* or BARF0. This is an unusual ORF with the translational stop codon embedded in the polyadenylation signal (Sadler and Raab-Traub, 1995b). An alternatively spliced cDNA, RK-BARF0, was identified that extended the BARFO ORF from 174 to 279 codons and would encode a protein of approximately 30 kDa. This splice was detected in the least abundant mRNA. The amino terminus of RK-BARF0 protein contains a highly hydrophobic region that resembles an endoplasmic reticulum targeting signal peptide sequence. In yeast two hybrid studies, RK-BARF0 and BARF0 interacted with the extracellular domain of Notch 3 and Notch 4 (Kusano and Raab-Traub, 2001).

Notch defines a family of transmembrane receptor proteins found in a variety of organisms including mammals. Notch is synthesized in the endoplasmic reticulum (ER), and further processed in the trans-Golgi network (TGN) to produce two fragments which are then linked through disulfide bonds (Blaumueller *et al.*, 1997). After ligand binding, Notch is proteolytically cleaved releaving the carboxy terminal domains. This activated intracellular form of Notch is then thought to activate effector molecules, such as the DNA binding protein, RBP-Jk (Fortini, 1994). Activated Notch and RBP-Jk activate expression of several mammalian genes including erbB2a and NF-κB2 and as previously described, the EBNA2 and EBNA3 proteins interact with RBP-Jk to activate expression of LMP1 (Henkel *et al.*, 1994; Grossman *et al.*, 1994). The direct interaction of RK-BARF0 with Notch induces the proteosomal degradation of Notch. Although the RK-BARF0 protein has not yet been detected, EBV infected cells have very low levels of Notch suggesting that RK-BARF0 may be expressed during EBV infection.

The cDNA representing the most abundant RNA contains the RB2 or A73 ORF (Sadler and Raab-Traub, 1995b). The RB2 ORF is formed from 4 exons and has been shown to interact with the receptor for activated kinases (RACK1) (Smith *et al.*, 2000). The RK103 ORF, also called RPMS1, encodes a potential protein that also interacts with RBP-Jk (Sadler and Raab-Traub, 1995b; Smith *et al.*, 2000). The specific splice that is unique to RPMS1 is also readily detected in peripheral blood lymphocytes (Chen *et al.*, 1999b). Although the protein products for these novel ORFs have not been identified, the intriguing properties of the possible proteins suggests that these complex RNAs may encode additional proteins expressed in latent infection in epithelial cells or in B-lymphocytes in vivo.

Malignancies associated with EBV

The malignancies associated with EBV are distinct cancers that develop in the setting of immunosuppression, occur with endemic patterns of incidence, or are a discrete

subset of more common cancers. The most consistent and significant associations include post-transplant lymphoma, African Burkitt's lymphoma, Hodgkin's disease, and nasopharyngeal carcinoma (Raab-Traub, 1996).

Post-transplant lymphoproliferative disease

The ability of EBV to cause cancer is most clearly indicated by the development of B-cell lymphoproliferations in patients who are deficient in T-cell mediated immunity following bone marrow or solid organ transplantation. The majority of cases of post-transplant lymphoma (PTL) are EBV-positive. These proliferations are initially polyclonal but frequently progress to oligoclonal or monoclonal lymphoma and clonal or bi-clonal EBV is readily detected (Fig. 55.2). Depending on the degree or regimen for immunosuppression, PTL develops in 5–15% of cardiac transplants, 10% of heart-lung transplants, in 1 to 3% of renal transplants, and approximately 1 to 2% of bone marrow transplants.

EBV infection in post-transplant lymphoma is an example of Type 3 latency that includes expression of the major CTL targets, the EBNA2 and EBNA3 proteins (Young *et al.*, 1989). In some cases, the disease may regress after reduction in immunosuppressive therapy indicating that the cells are still susceptible to EBV-specific cytotoxic T-cells. Adoptive or prophylactic immunotherapy has also been successful (Rooney *et al.*, 1997). However, there is also variability in EBV gene expression and in the monoclonal, more monomorphic post-transplant lymphomas there may be more restricted Type 1 or 2 latency patterns of viral expression. A recent report described an intriguing case of lymphoma that did not respond to CTL infusion. Subsequent analysis revealed that the EBV strain in the tumor contained a deletion in EBNA3B and that the CTL preparation that had been expanded ex vivo and administered was predominantly directed against EBNA3B (Gottschalk *et al.*, 2001). This provided the first evidence of an EBV escape mutant that evaded immune control due to the deletion of a specific protein. EBNA3B has been shown to not be essential for B-cell immortalization in vitro and its loss would provide an immunoselective advantage in vivo (Tomkinson *et al.*, 1993).

Burkitt's lymphoma

EBV was originally detected in cell lines established from the unusual childhood malignancy, Burkitt's lymphoma (BL) (Epstein *et al.*, 1964). Burkitt's lymphoma was first recognized by a British surgeon working in the colonial office in East Africa (Burkitt, 1962b). He described the clinical and epidemiologic features of this tumor and discovered that the tumor occurred with high incidence in an endemic geographic region that was coincident with the endemic malarial belt of Central and East Africa. Fresh tumor biopsies were sent to Dr. Anthony Epstein in London where he succeeded in establishing cell lines. In some lines, herpesvirus particles were detected by electron microscopy. This virus was subsequently shown to be distinct from other known human herpesviruses and subsequent seroepidemiologic studies revealed that EBV infection was widespread in all populations with the majority of adults having antibodies to the virus (Henle and Henle, 1974).

The early seroepidemiologic studies provided additional evidence that EBV was associated with the cancer. In endemic areas, children become infected with EBV during the first two years of life and endemic BL patients had significantly elevated antibody titers to viral antigens, including the viral capsid antigen (VCA) and early replicative functions (early antigen, EA) (Henle *et al.*, 1971). Prospective epidemiologic studies in Uganda indicated that high EBV VCA antibodies preceded the development of the tumor by months or years.

Characteristics of EBV Infection in BL

Although patients with BL have elevated titers to replicative antigens, EBV gene expression in BL is tightly latent and its expression is very restricted (Rickinson, 2001). Most cells express only EBNA1 and the EBERs. This restricted state of expression is only found in BL and was subsequently termed Type 1 latency. The expression of EBNA1 in the absence of the transcriptional transactivator EBNA2 and EBNA3 proteins reflects the use of an alternate promoter for EBNA1 (Sample *et al.*, 1991). This promoter in the BamHI Q fragment, Qp, is regulated by both IRF and STAT transcription factors (Sample *et al.*, 1992; Chen *et al.*, 1999a). The BARTs have also been detected in BL sample by RT-PCR. Recent studies have indicated that expression in BL may be somewhat heterogeneous with some cells expressing LMP1 and the EBNA proteins that are characteristic of Type 3 latency (Niedobitek *et al.*, 1995). EBV expression in BL also changes in vitro and most BL cell lines reactivate into Type 3 latency with expression of the additional EBNAs and the LMPs. In vitro, this change in expression results in an altered growth pattern with rapid growth of clumped cells and elevated expression of lymphocyte activation molecules, adhesion molecules, and HLA antigens (Rowe *et al.*, 1987).

All of the tumors from the endemic areas contain EBV in all of the malignant cells and each tumor contains a clonal form of the EBV episome indicating that the tumor

developed from a single EBV-infected cell (Raab-Traub and Flynn, 1986) (Fig. 55.2).

Contributing factors

The detection of consistent chromosomal rearrangements in many human cancers suggested that these would cause genetic changes that could alter cellular gene's expression or function. BL was one of the first cancers to be shown to have a characteristic chromosomal translocation and these translocations were eventually shown to involve chromosomal rearrangments of the c-myc oncogene with the loci that encode the immunoglobulin heavy and light chains (Dalla-Favera *et al.*, 1982; Magrath, 1990). This rearrangement induced the aberrant activation of the c-myc oncogene, a critical step in the control of cellular proliferation.

Rare childhood lymphomas in Western countries were subsequently shown to resemble Burkitt's lymphoma histologically. These tumors occur 100-fold less frequently than the endemic form but also are marked by the characteristic translocations between c-myc and the immunoglobulin loci. It is intriguing that the sporadic and endemic forms of BL have different breakpoints with regard to c-myc (Pelicci *et al.*, 1986). The endemic form has breakpoints many kb 5′ to c-myc while the breakpoint in the sporadic form usually occurs in the first exon or intron (Magrath, 1990). These differences in the translocation break point may reflect an effect of EBV in the development of the translocation.

Deregulated c-myc expression is found in all forms of BL suggesting that this is an essential step in the development of this lymphoma. As the translocations involve the immunoglobulin loci, it is possible that they occur during variable gene rearrangement or class switching. The cell surface markers, CD10 and CD77, which are characteristic of BL suggest that BL cells may represent a germinal center B-cell (Rickinson, 2001). Germinal centers are greatly expanded in chronic malarial infection and during HIV infection. The elevated titer to EBV replicative antigens that are characteristic of BL suggest that EBV reactivation and replication has occurred. The activation of viral replication and the expansion of germinal centers are likely contributing factors to the increased risk of development of BL in areas of endemic malaria.

AIDS-associated lymphoma

Lymphomas develop in approximately 3% of AIDS patients and the incidence of BL is greatly increased in HIV-infected patients (Ambinder, 2001). Although in HIV infection, many types of lymphoid malignancies may develop, BL tends to develop early in the course of AIDS progression. The tumors resemble classical BL histologically and also possess the characteristic translocations with the chromosomal breakpoints similar to those in the sporadic BL.

Other B-cell malignancies also occur at high incidence in AIDS and approximately 50% of these are EBV-associated. Central nervous system lymphoma is extremely rare in the general population but occurs in 0.5% of patients with AIDS. All of the CNS lymphomas are EBV positive (MacMahon *et al.*, 1992). Possible genetic or environmental factors that contribute to the development of EBV-positive lymphoma or CNS lymphoma have not yet been identified although the effect of HIV infection on the cytokine network may influence lymphoma development. Both IL6 and IL10 are elevated during HIV infection and promote the growth of EBV-infected B cells (Stewart *et al.*, 1994). In addition to the reduced immune control during HIV infection, abnormal synthesis of these cytokines could activate paracrine or autocrine pathways that influence the outgrowth of EBV-infected cells and promote lymphoma development.

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma (NPC) is an epithelial tumor, that similarly to BL, is characterized by marked geographic and population differences in incidence (Raab-Traub, 2002). It develops with high incidence in southern China and southeast Asia where it may represent 20% of all cancer cases, occurring at a rate of $100/10^5$/year in some regions. The tumor also frequently develops in Eskimo populations and occurs with elevated incidence in Mediterranean Africa. The tumor occurs rarely in Caucasian population, however, unlike BL, all cases of NPC that develop in endemic or nonendemic regions contain EBV (Raab-Traub *et al.*, 1987).

Early seroepidemiologic studies revealed that, similar to patients with BL, patients with NPC had elevated antibody titers to the replicative antigens, VCA and EA. However, NPC patients uniquely had elevated IgA antibodies to these antigens. Detection of IgA antibodies to EBV precedes the development of NPC by several years and the levels also correlate with tumor burden and recurrence (Henle and Henle, 1974). These data suggest that EBV reactivation and replication precede the development of NPC while the induction of IgA antibodies indicates that the replication is occurring at mucosal surfaces.

Subsequent studies revealed that viral DNA and the EBV nuclear antigen, EBNA, were detected in the malignant epithelial cells rather than in the abundant infiltrating lymphoid cells (Wolf *et al.*, 1973). This was the first detection of EBV within epithelial cells.

The tumor presents with varying degrees of differentiation and has been classified by the World Health

Organization into three categories (Shanmugaratnam, 1978). Squamous cell carcinomas, WHO1 tumors, are highly differentiated with characteristic epithelial growth patterns and keratin filaments. Non-keratinizing WHO2 carcinomas retain epithelial cell shape and growth patterns. Undifferentiated carcinomas, WHO3, do not produce keratin and lack a distinctive growth pattern. In addition many tumors have mixed degrees of differentiation or may present as WHO3 at the primary site with increased differentiation in metastatic lymph nodes. The WHO2 and WHO3 tumors have elevated IgG and IgA titers to VCA and EA whereas the WHO1 tumors have EBV serologic profiles similar to control populations. This initially suggested that EBV was only associated with the WHO II and III types. However, subsequent studies have also consistently detected EBV in WHO1 tumors from the Orient (Pathmanathan *et al.*, 1995a). However, in other studies, EBV was not detected in WHO1 NPC from some areas (Niedobitek *et al.*, 1991a,b). The consistent detection of EBV in most NPC from both endemic and non-endemic areas suggests that EBV is an essential cofactor in the development of this tumor.

Characteristics of EBV infection in NPC

EBV infection in NPC is primarily latent with expression of replicative antigens in some cells. Identification of the EBV terminal restriction enzyme fragments in NPC revealed that the EBV genomes were homogeneous and clonal with faint ladder arrays representing linear DNA (Fig. 55.2(b)) (Raab-Traub and Flynn, 1986). This confirmed that EBV infection was predominantly latent and suggested that the tumor was also clonal. The detection of linear DNA also indicated that the tumor was likely the site of the antigenic stimulus for the elevated antibody responses to EBV replicative antigens.

Initial studies of viral expression in NPC revealed striking differences in comparison with EBV expression in transformed B cells. The sequences that were subsequently shown to encode EBNA2 and the EBNA3 proteins were not transcribed and there was abundant transcription from the BamHI A and EcoDhet fragments (Raab-Traub *et al.*, 1983). This pattern of expression was subsequently classified Type 2 latency with expression of EBNA1 from the Qp promoter and transcription of LMP1 and LMP2 (Nonkwelo *et al.*, 1996). Two distinct LMP1 mRNAs were identified in NPC and included the standard 2.8 kb mRNA transcribed from the LMP1 EDL1 promoter and a larger 3.7 kb mRNA that initiated within the TR (Gilligan *et al.*, 1990b; Sadler and Raab-Traub, 1995a). This mRNA has been shown to be regulated by SP1 and STAT3 transcription factors (Sadler and Raab-Traub, 1995a; Chen *et al.*, 2001). LMP1 has been suggested to activate STAT signaling and activated nuclear STAT was detected in NPC. This may indicate that LMP1 in NPC is auto-regulated and that perhaps constitutive STAT activation is a factor that leads to tumor development (Chen *et al.*, 2003).

The abundant transcription from the Bam HI A fragment was further characterized and shown to encode a family of 3′ co-terminal, intricately spliced transcripts (BARTs) that contain multiple potential ORFs (Sadler and Raab-Traub, 1995b). The putative protein products of these ORFs have properties that could in part substitute for the EBNA proteins. RK103/RPMS1 interacts with a co-repressor of RBPJk and negatively affects Notch signaling (Zhang *et al.*, 2001). RKBARF0 also increases LMP1 expression and induces Notch degradation (Kusano and Raab-Traub, 2001). Although Notch inhibits differentiation in some cell types, in epithelial cells Notch induces differentiation. The identification of multiple effects on the Notch pathway by the putative BamHI A proteins and the EBNA proteins suggests that EBV usurps this pathway in both lymphoid and epithelial cells.

EBV infection has been shown to be an early event in the development of NPC and has been identified in rare examples of high grade dysplasia and isolated carcinoma in situ (CIS). In an initial survey, the lesions were extremely rare (11/1798 or 0.6%) with coexistent nasopharyngeal intraepithelial neoplasia with invasive cancer in approximately 3% (58/1798). This extreme rarity of lesions without concomitant carcinoma and the development of invasive carcinoma within 1 year indicated a rapid progression of the initiated cell from dysplasia to carcinoma in situ and invasive cancer (Pathmanathan *et al.*, 1995b). Thus the biologic behavior of NPC is quite distinct from that observed in the malignant progression of mammary carcinoma or cervical cancer where intraductal cancer of the breast or carcinoma in situ of the cervix may persist for years. All cells in examples of CIS expressed EBERs and LMP1 revealing that the lesions were homogeneously infected. Clonal EBV episomes were detected without detectable linear forms of the genome indicating that the neoplasias were a predominantly latent infection. The presence of a single clonal form of EBV implies that the hyperplasia or dysplasia represents a focus of EBV-induced cellular proliferation (Pathmanathan *et al.*, 1995b). One extensive study in high-risk Chinese populations revealed that in early dysplasia EBV was present in a subset of cells while EBV infection in high grade dysplasia was homogeneous and uniform. These studies suggest that an early genetic change precedes EBV infection and induces dyplastic growth and that the EBV infected cells apparently overtake the population and the lesion rapidly progress to CIS (Yeung *et al.*, 1993). A genetic

factor may also influence the ability of EBV to establish a latent infection in epithelial cells rather than replicate as is believed to occur in normal oropharyngeal cells (Fig. 55.1).

During primary infection and during reactivated infection, oropharyngeal epithelial cells with evidence of viral replication have been detected and are thought to be the source for viral shedding (Sixbey *et al.*, 1984). The high IgA titers to EBV replicative antigens that precede the development of NPC patients to VCA likely reflect increased viral replication and antigenic stimulation. The elevated IgA titers may actually contribute to the development of NPC by enhancing epithelial infection as it has been shown that secretory IgA facilitates entry into epithelial cells (Gan *et al.*, 1997). In the development of NPC, increased viral replication, perhaps at lymphoid/mucosal epithelial interfaces, increases the likelihood of establishing a latent, transforming infection of an epithelial cell that may have already had an initiating genetic change. This establishment of latent infection and expression of critical viral transforming functions in an epithelial cell in combination with genetic changes that may facilitate latent infection or are synergistic with EBV transforming proteins are likely to be critical events that lead to the development of NPC. This process could be influenced by the genetic or environmental factors (Fig. 55.1). However, the viral transforming functions are likely essential to the malignant outgrowth.

Contributing factors

The incidence of NPC is low in Western populations where it is only 0.25% of all cancers occurring with a rate of $0.1/10^5$ per yr. However in contrast to the relationship of EBV to Burkitt's lymphoma, EBV is consistently detected in NPC regardless of geographic distribution or the racial background (Yu and Yuan, 2002). The consistent association with a ubiquitous herpesvirus and the remarkable patterns of incidence suggests that other genetic or environmental factors contribute to tumor development.

Comparisons of EBV infection among Indians and Chinese living in Singapore revealed that both populations were infected with EBV early in life, usually between the ages of 6 to 9 (Shanmugaratnam, 1970). Although the two ethnic groups were living in the same general area of Singapore, the NPC incidence was only high in the Chinese population. Elevated incidence is retained by second generation Chinese in other nonendemic regions but gradually decreases with subsequent generations (Buell, 1974). This continued elevated incidence suggested that environmental contaminants were not likely to be a cofactor but rather that genetic or cultural and dietary differences contributed to the development of this disease. One dietary component that has been suggested is exposure to salted fish at an early age (Ho, 1976; Yu *et al.*, 1986). Tumor promoting compounds have also been identified in food products in other populations with elevated incidence (Poirier *et al.*, 1989).

Extensive surveys for activated oncogenes or tumor suppressor loss did not reveal characteristic translocations, mutations in p53 or Rb alterations, or activating ras mutations (Effert *et al.*, 1992; Sun *et al.*, 1995, 1993). This suggests that viral genes affect these pathways, directly or indirectly, such that there is no selection for mutation in these genes (Fries *et al.*, 1996). However, additional genetic changes could develop during tumor growth and contribute to tumor progression and metastasis.

To identify potential tumor suppressor genes, screening of NPC samples has detected specific loss of of DNA sequences indicated by loss of heterozygosity in PCR screenings. This approach has shown that the p16 cyclin dependent kinase inhibitor at 9p21 and the RASSF1a gene at 3p14 are frequently lost in NPC samples (Lo, 2002).

Studies in vitro have shown that reintroduction of the RASSF1a gene into an NPC cell line inhibited growth (Lo, and Huang 2002). This finding suggests that inactivation of this ras isoform is an important contributor to NPC development. Other studies have shown that p16 is not expressed in NPC due to specific methylation of the promoter. In vitro studies have shown that LMP1 expression induces methylation of the p16 promoter and that LMP1 also induces cytoplasmic translocation of the ets transcription factor that regulates p16 promoter activity (Ohtani *et al.*, 2003). The loss of p16 may be highly synergistic with LMP1 expression in the induction of NPC.

Hodgkin's lymphoma

Hodgkin's lymphoma (HL) is a common malignant lymphoma characterized by the loss of lymph node architecture with the majority of infiltrating cells of a nonmalignant phenotype. The malignant cells are the unusual Hodgkin and Reed–Sternberg (RS) cells that constitute about 2% of the tumor mass (Ambinder *et al.*, 1999). Dependent on the ratio of RS cells and the type of infiltrate, HL is histologically distinguished as lymphocyte-predominant, nodular sclerosing, mixed cellularity, or lymphocyte depleted. EBV is always found in the lymphocyte depleted form, approximately 70% of mixed cellularity, 10%–40% of nodular sclerosing and never in lymphocyte enriched (Chapman and Rickinson, 1998).

The disease occurs world-wide but has higher incidence in higher socio-economic groups in Western populations where it occurs with two peaks at ages 25 to 30 or again later than age 45. It was observed years ago that the profile of the

early age onset group was similar to patients who developed infectious mononucleosis, the pathologic manifestation occurring in post-adolescent primary EBV infection. A history of IM was noted to be associated with a 2–4 fold increased risk for HL. Retrospective analyses of the serum repository at Yale revealed that elevated EBV titers preceded the development of HL by 2–3 years (Mueller *et al.*, 1989).

The key finding revealing an etiologic association of EBV with HL was the detection of the viral genome and virally encoded proteins in the RS cells (Weiss *et al.*, 1989a,b). Again, the analysis of the EBV genome revealed that HL had clonal EBV episomes, indicating that HL develops from an EBV-infected cell (Fig. 55.2(b)). Monoclonality has also been revealed by immunoglobulin gene rearrangements and in some cases, T-cell receptor rearrangements. The tumors predominantly have expression of B cell markers although T-cell receptor rearrangement has been detected in some cases (Marafioti *et al.*, 2000).

Transcriptional studies have shown that HL has expression of EBNA1, LMP1, LMP2 and the EBERS, indicative of Type 2 latency (Deacon *et al.*, 1993). Several of the genes known to be activated by LMP1 are expressed in HL and activated NFκB has been found in the RS cells (Hinz *et al.*, 2002). The same forms of activated NFκB have been detected in EBV negative RS cells (Knecht *et al.*, 1999). In the EBV negative examples of HL, mutations have been described within the IκB repressor of NFκB (Emmerich *et al.*, 2003). This finding suggests that activation of NFκB is likely an important factor in the development of HD and that it occurs either via LMP1 expression or by other mechanisms.

Although HL frequently responds well to treatment, new methods of targeting EBV infection have been attempted (Bollard *et al.*, 2004). CTL therapy has had some success and new trials are testing inhibitors of NFκB.

T-cell lymphoma

Although long believed to be B-cell trophic, EBV has been detected in an occasional T-cell lymphoma. A particular type of T-cell lymphoma that usually presents in the nasal cavity, also referred to as midline granuloma, is a common tumor in southeast Asians. The first link to EBV was presented in five Japanese cases, all of which were EBV-positive (Harabuchi *et al.*, 1996). The tumors had various T or NK cell markers suggesting EBV infection of a peculiar undifferentiated cell type.

Peripheral T-cell lymphomas that are EBV-positive have also been described in Taiwanese and Japanese populations. In some cases, EBV was only detected in some cells suggesting that the virus infected the tumor secondarily (Kanegane *et al.*, 1999). However, the proportion of EBV infected cells seems to increase over time with emergence of a clonal EBV-infected population indicating that the virally infected cells have some growth advantage and that the fastest growing clone will eventually predominate.

Rare carcinomas

Other undifferentiated carcinomas that develop in other tissues are also associated with EBV. Clonal EBV episomes have been detected in all samples examined of undifferentiated carcinoma of the parotid gland (Raab-Traub *et al.*, 1991). These studies revealed that carcinoma of the parotid gland is also a clonal proliferation of non-permissively infected epithelial cells. Viral shedding is believed to occur in epithelial cells lining the parotid gland without apparent pathology. The establishment of a latent transforming infection in these cells is apparently a rare occurrence that contributes to the development of this tumor. Undifferentiated carcinoma of the parotid gland is an extremely rare cancer that has been most often detected in Alaskan Inuit populations who also have a high incidence of NPC (Lanier *et al.*, 1991).

EBV infection has also been detected in undifferentiated gastric carcinoma, a rare tumor in both Oriental and Caucasian populations (Shibata *et al.*, 1991). These findings indicate that EBV may gain access to epithelial cells outside the naso/oropharynx and that in some instances when this occurs, it leads to the development of carcinoma.

Contributing factors

Genetic factors

Tumor suppressor inactivation

The development of cancer involves multiple oncogenic events and several possibly contributing genetic components have been identified in EBV associated cancers. Loss of heterozygosity (LOH) is a highly informative approach for detecting allelic deletion of potential tumor suppressor functions. This approach has been used most successfully in solid tumors such as NPC. These studies have determined that the highest frequencies of allelic loss occurred on chromosome 3p and 9p (Huang *et al.*, 1991, 1994; Lo and Huang, 2002). Intensive efforts have localized the region on 3p to 3p21.3. Functional evidence of tumor suppressor function within this region have shown that chromosomal transfer into an NPC cell line abrogated growth. The target gene has been demonstrated to be an allelic form of

RASSF1A, a newly discovered gene that contains a ras association domain (Cheng *et al.*, 1998). Thus RASSF1A may modulate ras function.

The site of LOH at 9p21 spans the cyclin-dependent kinase inhibitors (cdki) p15INK4B and p16INK4A and the negative regulator of p53, p14ARF . Loss of p16 has been shown in NPC samples and transfer of p16 induced growth arrest in the NPC cell line HK1 (Lo *et al.*, 1995). Homozygous deletion and promoter methylation of p14 ARF has also been demonstrated in many NPC tumors. The loss of this locus has been shown to occur early in dysplastic nasopharyngeal cells (Lo and Huang, 2002). The loss of this locus in combination with EBV infection likely contributes to the rapid development of invasive NPC.

Similarly, the promoters for p15 and p16 have been shown to be methylated in Hodgkin's lymphoma suggesting that loss of cdki function is also a contributing factor in EBV-associated lymphoid diseases (Garcia *et al.*, 2003).

EBV strain variation

The elevated incidence of EBV-associated malignancies in specific populations suggests that one possibility for these differences in disease incidence may be difference in prevalence of EBV variants. These strains could possess distinct biologic properties or be less immunogenic. The prevalence of specific strains within a population could contribute to these differences in disease incidence. EBV types 1 and 2 are distinguished by sequence changes in the EBV nuclear antigens 2 and 3 (EBNA 2 and 3) and several variants of EBV have been identified by polymorphisms in the viral genome (Abdel-Hamid *et al.*, 1992; Khanim *et al.*, 1996; Lung *et al.*, 1990). Strain specific changes have also been identified in EBNA1, BZLF1, and LMP1 (Miller *et al.*, 1994; Bhatia *et al.*, 1996; Packham *et al.*, 1993; Edwards *et al.*, 1999). The incidence of BL is high in Papua New Guinea with a frequent occurrence of HLA A11. Multiple A11-restricted epitopes have been identified in EBNA3 and analysis of the EBNA3 sequence in the virus prevalent in this area revealed that it contained changes within key positions in the A11 restricted epitopes. These changes and decreased immune recognition may contribute to the prevalence of a given strain within a population and perhaps to a higher viral burden in A11 individuals which might be possible etiologic factor in the development of BL in this region.

Many of these studies have focused on detecting strains possibly unique to NPC. Analyses of strain variation based on restriction enzyme polymorphisms identified a predominant strain in NPC from Southern China (Lung *et al.*, 1990). Various polymorphisms within restriction sites were identified including a loss of an Xho1 restriction enzyme site within the LMP1 gene (Hu *et al.*, 1991). This polymorphism was also present in all NPC from Alaska and in some of the NPC samples from Caucasian Americans but not in samples of NPC from Mediterranean Europe and Africa (Abdel-Hamid *et al.*, 1992).

Further studies of sequence variation within LMP1 revealed that consistent sequence variation distinguished EBV strains and seven phylogenetically distinct strains of LMP1 have been described that have signature changes in the coding sequence (Edwards *et al.*, 1999). Individual isolates differ by these specific base pair (bp) changes, the presence or absence of a 30 bp deletion, the number of 33bp repeats, and a 15 bp insertion within one of the repeats. Strains with or without the deletion have been detected in approximately equal proportions in the various EBV-associated diseases suggesting that all strains can be pathogenic (Miller *et al.*, 1994; Khanim *et al.*, 1996). However, several studies have suggested that LMP1 with the deletion has enhanced transforming potential in vitro and may be present in more aggressive disease forms (Knecht *et al.*, 1992). One study indicated that the enhanced transforming ability of the Chinese strain in BalbC 3T3 cells was transferred with the carboxy terminus that included the 10 aa acid deletion. Deletion of the 10 aa in the B95 LMP1 resulted in the ability to induce transformation and tumorgenicity while insertion of the 10 aa into the Chinese strain eliminated transformation and tumorigenicity (Li *et al.*, 1996).

Heteroduplex tracking assays (HTA) have been useful for distinguishing viral variants and following HIV strain evolution (Nelson *et al.*, 2000). To identify viral variants within a tissue sample, a specific DNA sequence is amplified from the sample, denatured, and reannealed to a single stranded probe of that region (Fig. 55.3(a)). Homoduplexes migrate faster during agarose electrophoresis while the migration of mismatched heteroduplexes is impaired (Fig. 55.3(b)). In the HTA developed for LMP1, the amplified region spans the 30bp deletion (Sitki-Green *et al.*, 2002). Strains are distinguished using a probe that contains the 30bp from the China2 strain (Ch2) and a probe of the same region that spans the deletion (Med-). Probes from two of the strains have been utilized to clearly identify each variant of the LMP1 types, China 1 (Ch1), Mediterranean with the deletion (Med+), Mediterranean without the deletion (Med-), North Carolina (NC) Alaskan (Al), and the prototype, B95. Each form of LMP1 consistently migrates to the same position when hybridized with each probe (Fig. 55.3(b) & 55.3(c)).

Using this approach, HTA revealed that infection with multiple strains of EBV is a frequent occurrence in patients with HIV and also in healthy, asymptomatic carriers

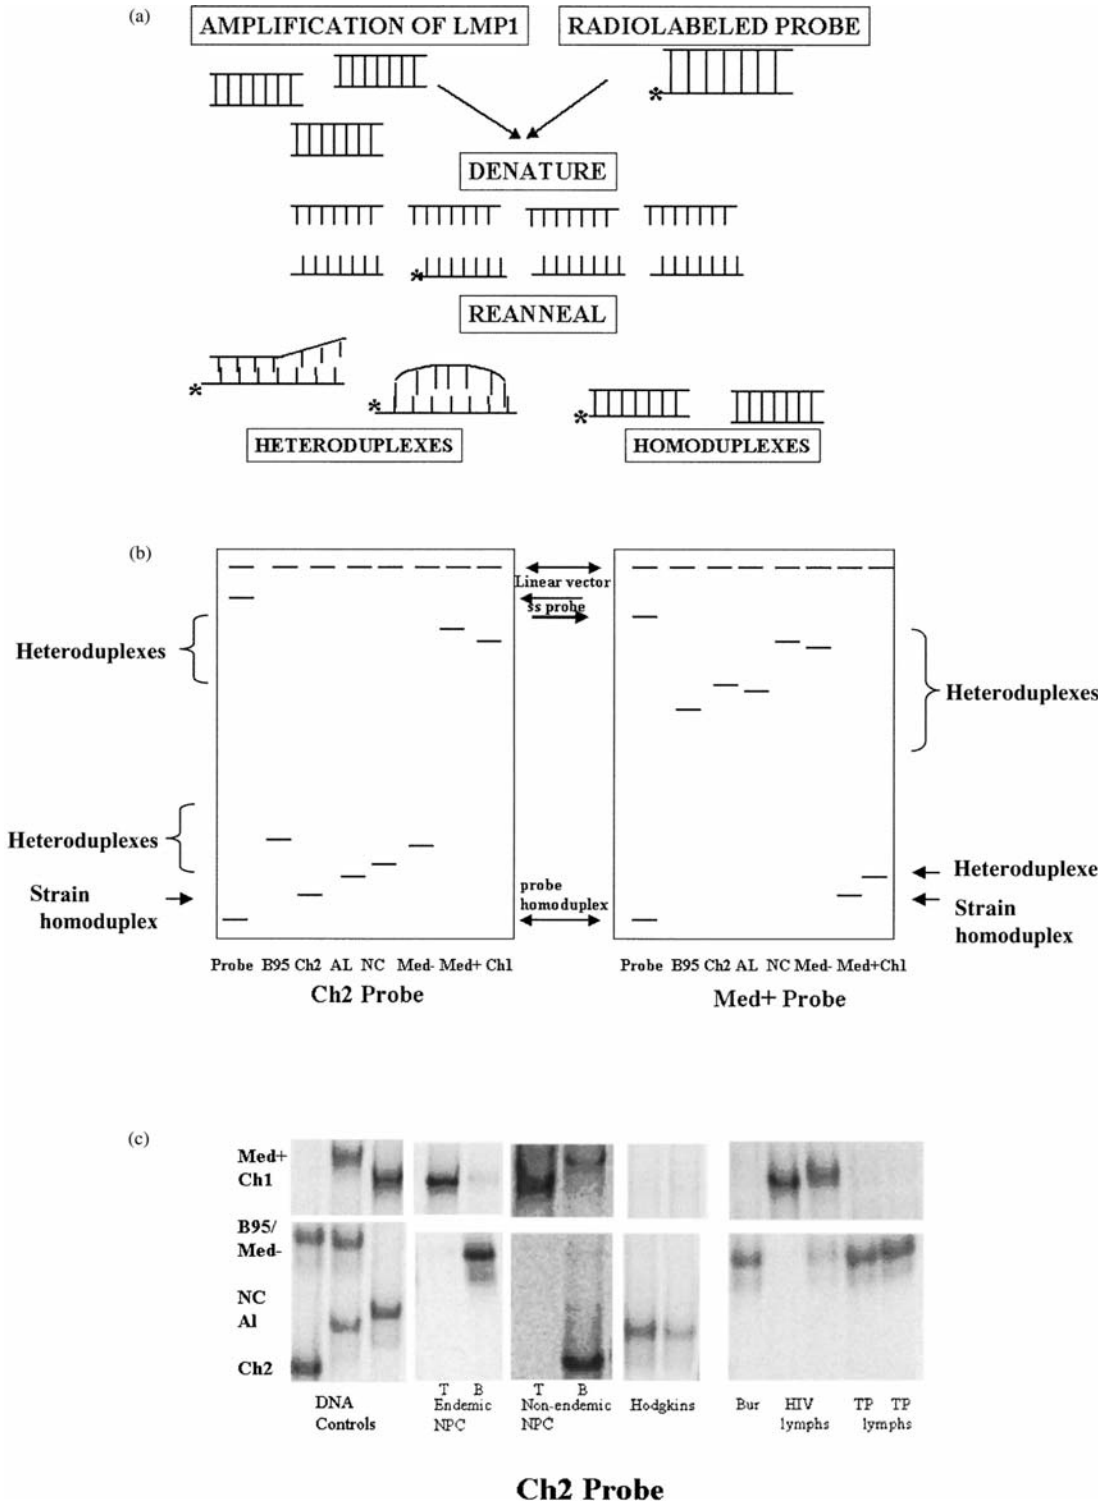

Fig. 55.3. Heteroduplex tracking assay to identify EBV LMP1 variants. (a) HTA analysis is based on the principal that 100% homologous DNA molecules, homoduplexes, will migrate according to size on a polyacrylamide gel, while, heteroduplexes will migrate more slowly because of malformations in the DNA helix corresponding to regions of mismatch. The greater the mismatch of two sequences, the slower the migration of the heteroduplex through a gel matrix. A specific region of LMP1 harboring multiple sequence changes is amplified from each sample, denatured, and hybridized to a single-stranded labeled probe. (b) Diagram of HTA using two probes to form heteroduplexes with each PCR amplified strain that are subjected to electrophoresis through a non-denaturing gel. Distinct migration patterns of heteroduplexes are produced for each strain. (c) HTA analysis reveals single variants in NPC, HD, Burkitt lymphoma (Bur), and HIV and post-transplant (TP) lymphoma samples.

(Sitki-Green *et al.*, 2003). The relative abundance of the strains changes over time with different strains prevalent in the oral cavity than in the peripheral blood at a particular time. HTA analysis of tumor samples has revealed that EBV-associated tumors contain a single strain of EBV while blood and saliva samples usually contain multiple strains of EBV (Fig. 55.3(c)). This provides another perspective of EBV infection in tumors and supports the concept of a homogeneous, clonal infection.

Comparison of the strain prevalence in NPC tumor samples with matching blood samples revealed that the LMP1 variant China1 was almost always in the tumor while other EBV LMP1 variants were present in the blood (Fig. 55.3(c)) (Edwards *et al.*, 2004). In many cases the strain within tumor tissue had changes in the known and computer-predicted HLA restricted epitopes of the HLA type of the patient. Patients with NPC are frequently HLA A2 and A24 and the China 1 strain have been shown to be changed at the strongest A2 epitope. These amino acid substitutions at key positions in these LMP1 epitopes may result in a reduced CTL response that enables immune escape of latently infected cells that express the China 1 LMP1.

The elevated incidence of NPC and BL in restricted populations such as Alaskan Eskimos and Cantonese from Southeastern China may reflect a predominance of a specific MHC type. Higher incidence of a specific MHC haplotype in these populations could have selected for viruses with mutations in putative CTL recognition sequences in LMP-1. The prevalence of such a type in these populations may allow expression of LMP-1 in infected cells to go undetected. Thus a combination of a specific EBV strain in a patient with a particular HLA type could be a contributing factor to tumor development due to decreased immune recognition of a specific LMP1 or perhaps other proteins expressed in the tumor such as LMP2 or the putative BamHI A proteins.

Summary and future considerations

EBV-targeted therapy

The strong association of EBV with major human malignancies provides an opportunity to specifically target EBV or pathways activated by EBV to treat these cancers. A potential vaccine could either protect against infection or possibly eliminate specific pathologic consequences. To prevent viral infection, it would be necessary to completely neutralize EBV at mucosal surfaces through efficient induction of IgA antibodies. This could theoretically be accomplished with a transformation defective EBV that would replicate at mucosal surfaces. Several studies indicate that there are naturally occurring EBV strains that lack the EBNA2 gene and are transformation negative (Sixbey *et al.*, 1991). A genetically engineered strain of EBV that lacked essential transforming proteins yet replicated efficiently at mucosal surfaces might be useful as an attenuated vaccine.

An alternative approach would be a subunit vaccine. The viral glycoprotein gp350, is the most abundant viral glycoprotein and is essential for viral binding and infection. The protective ability of gp350 antibodies has been tested in cotton top marmosets challenged with a lymphoma inducing growth (Finerty *et al.*, 1992). Some protection was provided that seemed to be cell mediated rather than antibody mediated (Wilson *et al.*, 1996). A gp350/vaccinia recombinant was also tested in China in seronegative children. After 1 year, all ten of the control group had seroconverted and had antibodies to VCA, indicating wild-type EBV infection in comparison with the test group where only three had seroconverted (Gu *et al.*, 1995).

A novel approach has developed synthetic peptides representing the predominant CTL epitopes presented by prevalent class I molecules. Expression of a cocktail of EBV epitopes in vaccinia virus indicated that all of the epitopes were processed correctly for the individual HLA classes and that the virus could induce the correct EBV epitope-specific CTLs in vitro (Moss *et al.*, 1996). Many EBV CTL epitopes have been identified and it is possible that an appropriate cocktail could be selected to protect the majority of individuals. It may also be possible to enhance a specific CTL response. In NPC and Hodgkins's disease, the viral proteins which induce the immunodominant CTL response are not expressed. It is possible that the viral expression could be manipulated perhaps through the use of demethylating agents such as azacytidine to induce expression of the viral proteins that would make the cells susceptible to CTL killing (Robertson, 2000). Alternatively, the CTL response to weaker immunogens such as LMP1 or LMP2 could theoretically be enhanced which may enable immune recognition and control of the tumor. Immunotherapy and other approaches to alter EBV expression or induce viral replication are reviewed in other chapters.

The EBV associated cancers are classic examples of the multistep nature of cancer development. The malignancies develop as a combination of a common virus with potent transforming ability, possible immune impairment, increased genetic susceptibility, in part due to HLA type, and genetic changes possibly due to environmental exposure. Potential steps in the pathway to cancer would be some event or exposure that increases the amount of virally infected cells. This might be an increase in viral replication in combination with an expanded population of a specific cell type. Thus in the development of BL or HIV lymphomas,

an expansion of germinal center B-cells due to malaria or HIV and their infection by EBV is likely a contributing early event. Important interactions between the intracellular environment and the virus next occur. These include factors that contribute to establishment of a latent, transforming infection rather than a permissive viral replicative infection and the ability to express LMP1 and LMP2 without expression of the CTL targets, EBNA2 and EBNA3. Important contributing factors include activation of STATs, expression of IL6, and lack of p16 expression. The ability of the growing LMP1-expressing cells to evade immune recognition is critical at this point and specific strains of EBV in certain HLA backgrounds would be able to persist. The EBV transforming proteins would take over multiple cellular signal transduction pathways through direct effects and indirect effects on expression of cellular genes. Multiple other genetic changes may occur during this process and have important effects on cell growth. However, the potent effects of EBV on cell gene expression suggest that the latently infected cells would be rapidly growing and quickly invasive. Importantly, this scenario suggests that EBV and expression of viral proteins are essential to the cancer process, to both initiation and progression. The dependence of tumor growth on viral proteins and activation of specific signaling pathways enables targeting of EBV-associated tumors through immunotherapy and specific inhibitors of activated pathways.

KSHV-induced oncogenesis

Don Ganem

Howard Hughes Medical Institute, Departments of Microbiology and Immunology and Medicine, University of California, San Francisco, CA, USA

Human infection by KSHV is associated with the development of at least three proliferative disorders: Kaposi's sarcoma (KS), primary effusion lymphoma (PEL) and a subset of multicentric Castleman's disease (MCD). In keeping with the classification of KSHV as a lymphotropic ($\gamma 2$) herpesvirus, two of these (PEL and MCD) are primary disorders of the B cell lineage. The third, KS, is a more complex lesion driven by proliferation of cells of endothelial lineage. KSHV is the second human γ-herpesvirus to be linked to neoplasia (EBV being the first). As such, many notions about how KSHV engenders these lesions have been heavily influenced by paradigms derived from the study of EBV-induced malignancies. In EBV, the viral latency program is powerfully immortalizing in vitro, and is thought to be the principal genetic program driving virus-related tumorigenesis. Lytic infection, while presumed important for dissemination of infection to target cells early in infection (and following lytic reactivation at later times), is not thought to play a direct role in the histogenesis of the tumors. As we shall see, although many parallels indeed exist with EBV, the distinctive features of the KSHV-associated diseases makes routine extrapolation from other viral models an enterprise to be undertaken with caution. In this chapter, we will review the biology of the KSHV-associated malignancies and consider the cellular and molecular mechanisms by which KSHV infection contributes to their pathogenesis.

Primary effusion lymphoma (PEL)

PEL is a classical neoplasm involving cells of the B cell lineage (see review by Cesarman, this volume). The malignant cells in PEL are clonal (as judged by VDJ rearrangement; Knowles *et al.*, 1989; Green *et al.*, 1995), fully immortalized, grow readily in culture (Cesarman *et al.*, 1995; Boshoff *et al.*, 1997) and are tumorigenic in nude mice (Picchio *et al.*, 1997). They express few classical B-cell surface markers, but regularly express CD138/syndecan-1 and display somatic hypermutation in Ig and bcl-6 loci, indicating that they are derived from post-germinal center B-cells (Carbone *et al.*, 2001). Consistent with this, transcript profiling suggests that the cells are of plasmablastic lineage (Klein *et al.*, 2003; Jenner *et al.*, 2003). The fact that PEL cells often secrete IL6 and IL10, a feature that is shared with other plasmacyctic neoplasms (Lauta, 2003), also accords with this interpretation.

Virtually all cases of PEL harbor KSHV DNA in every cell; many also display EBV infection as well, though EBV is never found in PEL as the sole pathogen. Where the EBV genome is present, its expression is largely restricted to EBNA 1, EBER RNA and low levels of LMP2a (typical of the so-called Latency I pattern) (Horenstein *et al.*, 1997; Szekely *et al.*, 1998; Schulz, 2001). KSHV infection of PEL cells is predominantly latent, which has made PEL cell lines the most widely studied model for KSHV latency. Most PEL lines also display a small subpopulation of cells staining for markers of lytic reactivation (Staskus *et al.*, 1997; Sturzl *et al.*, 1997). Latently infected PEL cells express at least 5 loci (see below), none of which have been conserved in EBV. Most of these loci were discovered by screening for transcripts or antigens constitutively expressed in PEL cell lines. Their products have been studied intensively for their biochemical and phenotypic properties, usually by overexpression in heterologous cell types. As we shall see, in the aggregate they harbor numerous activities that can deregulate cell growth and augment cell survival, consistent with the notion that KSHV latency drives the generation of PEL. The rarity with which PEL follows KSHV infection, however, also suggests that while viral latency is surely necessary for PEL development, it may not be sufficient for it. Host factors – most likely additional host cell

mutations – must also be involved, but the number and identities of these have not been determined. It is known, however, that PEL cells do not harbor rearrangements of MYC or BCL-2 genes. One study reports that cultured PEL cell lines have frequent reduplications of chromosome 7 and 12, as well as abnormalities at 1q21–25 (Gaidano *et al.*, 1999), but the key genes affected by these processes remain to be identified. In addition, two autocrine or paracrine loops involving host genes have been posited to occur in PEL. One report indicates that both HGF (hepatocyte growth factor) and its receptor (c-Met) are expressed in primary PEL tumors and in PEL cell lines (Capello *et al.*, 2000). More widespread has been the recognition that PEL cells usually express the IL6Rα and gp130 chains that mediate responsiveness to IL6, and often secrete human IL6 itself, raising the possibility of an autocrine loop. However, recent studies suggest that it is a viral homologue of IL6 (v-IL6; see below) that actually functions in this role, together with IL10 (Jones *et al.*, 1999).

The KSHV latency program in PEL

Since both KSHV and EBV are lymphotropic herpesviruses linked to B-cell lymphoma, it is natural to imagine that similar mechanisms must underly their oncogenic programs. However, a closer look reveals many phenotypic differences that challenge this assumption. First, while in vitro EBV infection of primary B-cells is strongly immortalizing, there is little evidence that KSHV infection can immortalize lymphocytes on its own. This issue has been most rigorously addressed by Kliche *et al.* (1998), who showed that under conditions in which EBV efficiently promoted outgrowth of lymphoblastoid cell lines, KSHV failed to do so when the PBMCs were from EBV-negative hosts. Only with B cells from EBV-infected hosts could KSHV infection be linked to B cell outgrowth, and in all cases the resulting LCLs harbored both viral genomes. This would suggest that the KSHV latency program is not strongly immortalizing on its own, and, at least in vitro, either requires one or more cofactors from EBV or acts to stimulate EBV's immortalizing activity. These findings accord well with the finding that most PEL tumors harbor both EBV and KSHV. Nonetheless, it is clear that the *sine qua non* of PEL is KSHV infection, since PEL tumors are not observed in its absence. And since occasional PEL tumors harbor KSHV alone, whatever cofactor(s) are derived from EBV must also be obtainable in some alternative way.

These findings illustrate that KSHV latency must make some genetic contribution to PEL, but do not define the biochemical nature of that contribution or identify the responsible viral gene(s). Two major experimental obstacles have impeded progress on this question. First, KSHV infection of primary B-cells proceeds very inefficiently in vitro, making it difficult to assay biochemical or phenotypic events directly triggered by latency in this lineage. Second, systems for mutating viral genes in the context of the intact KSHV genome are exceedingly inefficient – to date only a few viral genes have been inactivated in this fashion (Delecluse *et al.*, 2001; Xu *et al.*, 2005), though two laboratories have been able to construct genetically marked WT KSHV isolates (Viera *et al.*, 2001; Zhou *et al.*, 2002).

In the absence of such systems, inferences about KSHV's genetic and biochemical contributions to PEL must be derived from studies of the effects of expression of individual latency genes in heterologous cells, usually fibroblasts or other non-lymphoid cells. A previous chapter in this volume described the identification of the viral genes transcribed in latent PEL cell lines; these transcription units and their map positions are pictorially summarized in Fig. 56.1. Here we consider what is known about each of these proteins and how this knowledge might relate to PEL development.

Latency-associated nuclear antigen (LANA)

This large, multifunctional protein is expressed in all latently infected cells in vivo, irrespective of their lineage – it is the universal marker of KSHV latency and is present in KS spindle cells as well as the B-cells of MCD and PEL (Dupin *et al.*, 1999). Studies in Tg mice affirm that its promoter is expressed efficiently in both B-cells and epithelia (Jeong *et al.*, 2002). (Paradoxically, this study failed to demonstrate endothelial expression of LANA, despite its ubiquitous expression in human KS spindle cells. This suggests that either the promoter fragment employed lacked recognition sites for endothelial-specific factors, or there are species differences in LANA gene regulation). The protein has three major domains (Fig. 56.2): a central region composed of variable numbers of highly acidic amino acid repeats, a C-teminal, more basic region involved in DNA binding and oligomerization, and an N-terminal region to which many functions have been ascribed, including chromatin attachment and corepressor recruitment (Krithivas *et al.*, 2000; Piolot *et al.*, 2001; see below). The best-characterized function of LANA is that involved in the establishment and maintenance of the latent viral episome in the nucleus (Ballestas *et al.*, 1999; Cotter and Robertson, 1999). This activity is based upon its ability to (i) bind to sequences in the terminal repeats (TRs) of the genome (Ballestas and Kaye, 2001; Garber *et al.*, 2002); (ii) mediate transient semiconservative DNA replication from TR-containing plasmids (Hu *et al.*, 2002; Lim *et al.*, 2002; Grundhoff and

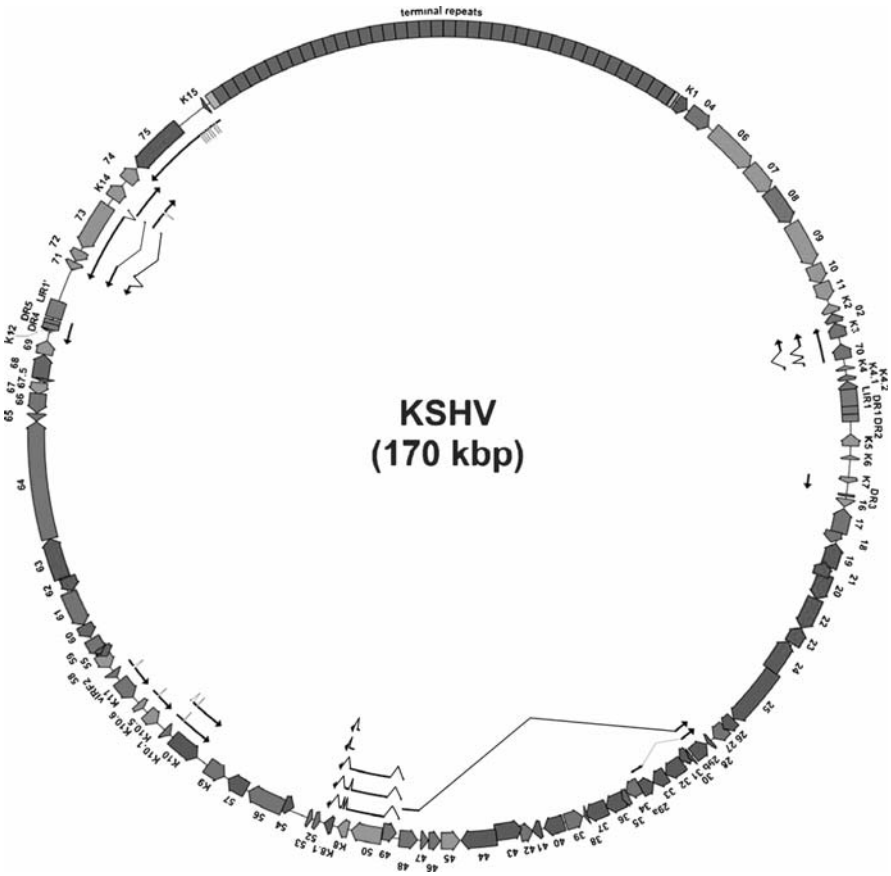

Fig. 56.1. Latency Genes of KSHV. Transcripts of latent genes are depicted as arrows, superimposed on the physical map of the circular, latent viral genome. (See color plate section.)

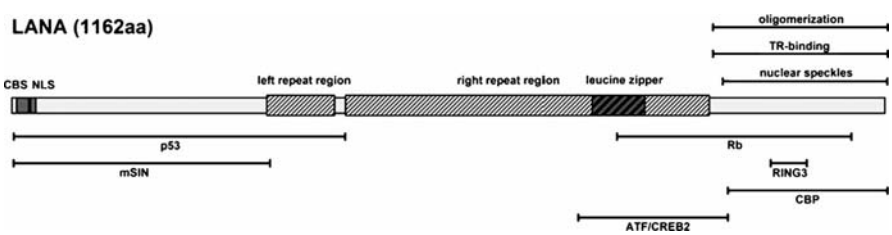

Fig. 56.2. Domain organization of LANA. Regions implicated in binding some of the putative LANA-associated host factors are denoted with lines above or below the name of the corresponding factor. CBS, chromatin binding sequence; NLS, nuclear localization sequence.

Ganem, 2003); and (iii) bind mitotic chromosomes to promote segregation of viral genomes to the progeny of dividing cells (Ballestas *et al.*, 1999; Piolot *et al.*, 2001). However, the story of viral episome maintenance is more complex than this. In many biologically important contexts, while LANA is necessary for plasmid maintenance, it is not always sufficient for it – additional cis-acting epigenetic changes in the viral chromatin appear to be required (Grundhoff and Ganem, 2004). This will be considered more fully in a later section.

Apart from its role in plasmid maintenance, the protein has been suggested to function in several other pathways. Friborg *et al.* (1999) showed that LANA can bind p53, and that cells transfected with LANA displayed reduced activation of p53-dependent reporter genes and increased resistance to p53-dependent programmed cell death

triggered by several stimuli. Such an activity could serve to extend the lifespan of a B-cell, though it seems unlikely (by itself) to be able to account for the B-cell proliferation that characterizes PEL. Although direct tests of this have not been carried out in primary B cells, LANA expression can extend the survival of cultured primary endothelial cells, but it does not fully immortalize them (Watanabe *et al.*, 2003). Similarly, we have found that LANA overexpression in Tg mice in several non-lymphoid lineages does not induce either hyperplasia or neoplasia (Grundhoff and Ganem, unpublished data). However, abrogation of p53 activity may produce more dramatic phenotypes in concert with other viral gene products that affect cell proliferation, like the viral cyclin (see below; and Verschuren *et al.*, 2002).

Another reported activity of LANA is binding to the tumor suppressor Rb (Radkov *et al.*, 2000). While it is unclear what fraction of cellular Rb protein is complexed to LANA, that which is bound is inactivated, as judged by the enhanced activity of E2F reporter genes. LANA can also cooperate in 3T3 cell transformation when coexpressed with activated ras genes, an activity that it shares with other DNA tumor virus oncogenes that inactivate Rb. The significance for PEL of this Rb binding, however, has recently been called into question by the finding that many PEL cell lines display loss of the cyclinD-cdk inhibitor p16INK4a (Platt *et al.*, 2002). Since this protein acts to inhibit cellular cyclind/cdk6 from inactivating Rb, its loss should trigger proliferation – but only in cells with functional Rb. Indeed, PEL cell lines remain sensitive to growth inhibition when p16 INK4a expression is restored by transfection. These results imply that despite expression of LANA, Rb function in PEL cells has not been completely inactivated. The fact that one PEL cell line (BC3) has been identified in which Rb protein is missing altogether (Platt *et al.*, 2002) further sustains this impression. As such, these findings are at variance with what is observed in tumors induced by other DNA tumor viruses that strongly inactivate Rb (Kelley *et al.*, 1995; Wrede *et al.*, 1991); in those cases, lesions in Rb and INK4a loci are very uncommon. The partial inhibition of Rb mediated by LANA may provide a selective advantage early in tumorigenesis, but additional lesions in the pathway appear to be required for full oncogenicity.

Another role for LANA in tumorigenesis stems from recent observations that the protein can interact with GSK-3ß, a kinase that phosphorylates and inactivates ß-catenin by targeting it for ubiquitin-mediated proteolysis (Fujimuro *et al.*, 2003). Binding of GSK-3ß relocates the kinase from the cytosol to the nucleus, allowing cellular accumulation of ß-catenin protein, which can then oligomerize with the transcription factor LEF and turn on a proliferative program of gene expression that includes cyclin D, c- myc, and c-jun. In fact, PEL cells display ß-catenin upregulation, and this can be impaired by siRNAs directed against KSHV LANA (Fujimuro *et al*, 2003). Although the consequences of this for PEL cell growth and survival have not been determined, transient LANA expression in other cell types is associated with enhanced S-phase entry, consistent with the idea that the ß-catenin pathway could be important in KSHV-induced proliferation. And certainly, many other types of cancer are linked to dysregulation of the ß-catenin pathway, including tumors of the colon, esophagus, breast and uterus (Polakis, 2000).

In addition to its effects on ß-catenin/LEF, LANA also can act more directly on the program of host gene expression. Early studies of expression profiling in stably-transfected B cells indicated that many host genes are dysregulated by LANA expression, both positively and negatively (Renne *et al.*, 1996) – though such experiments do not distinguish direct from indirect effects. Other experiments suggest that LANA's principal direct transcriptional activity is repression – for example, LANA will extinguish transcription of reporter genes linked in cis to TR elements containing LANA binding sites; similarly, when LANA is tethered to the DNA binding domain of Gal4, it can repress transcription of GAL4-dependent reporters (Krithivas *et al.*, 2000; Schwam *et al.*, 2000; Garber *et al.*, 2002). This effect is due in part to the recruitment of the mSin3 co-repressor complex via binding to the protein SAP30 (Krithivas *et al.*, 2000). However, it remains unclear how this activity is related – if at all- to oncogenesis (It could, for example, have more to do with the maintenance of viral latency or to the modulation of KSHV chromatin structure.) Similar statements apply to the many other activities described for LANA – such as binding to the nuclear matrix, the bromodomain-containing RING3 protein, me-CpG binding protein 2, heterochromatin protein 1, and various components of the transcription apparatus (Viejo-Borbolla *et al.*, 2003; Platt *et al.*, 1999; Mattsson *et al.*, 2002; Krithivas *et al.*, 2002; Lim *et al.*, 2001, 2003)

v-cyclin

Cotranscribed with LANA from the major latency promoter is a viral homologue of cellular cyclin D. This protein, v-cyclin, is expressed principally from a spliced mRNA from which the upstream LANA gene has been removed (Dittmer *et al.*, 1998; Sarid *et al.*, 1999). V-cyclin is a fully functional cyclin (Chang *et al.*, 1996) in that it can bind to and activate cdk6 (though unlike cellular cyclin D family members, it is much less active on cdk4). The in vitro substrate specificity of v-cyclin/cdk 6 differs

substantially from that of host cyclinD/cdk6; allthough both can phosphorylate Rb, the viral cyclin can also trigger cdk6 phosphrylation of p27, histone H1, Id-2 and cdc25a (Godden-Kent *et al.*, 1997; Li *et al.*, 1997). Forced v-cyclin expression can induce S-phase entry in quiescent 3T3 cells, and also overcome an Rb-mediated growth arrest induced by cdk-inhibitors in cultured cells (Swanton *et al.*, 1997). In fact, the v-cyc/cdk6 complex is less sensitive to inhibition by cdk inhibitors like p27, p21 and p16. For p27, at least, this resistance is further accentuated by the fact that the p27 protein is targeted for degradation by dint of its phosphorylation by v-ccylin/cdk6 (Mann *et al.*, 1999; Ellis *et al.*, 1999).

These activities suggest that v-cyclin might promote cellular proliferation in vivo. However, it has been difficult to document such a role for this gene in viral tumorigenesis in vivo, and the study of gene expression in primary PEL tumors turns up numerous discrepancies with the picture painted by studies of v-cyclin biochemistry. For example, despite the fact that v-cyclin expression destabilizes p27 in cultured cells, PEL tumors routinely display abundant p27 expression (Carbone *et al.*, 2000). And the fact that many PEL tumors delete p16INK4a suggests that despite the action of v-cyclin, Rb function is not fully abrogated in latently infected B-cells; further mutational lesions must accumulate in this pathway for full transformation. What v-cyclin does in the economy of the cell prior to the advent of such mutations remains the province of inference, extrapolation, and analogy.

Compounding the dilemma, we lack many experimental tools that are standardly used to approach such problems in other systems. First, there are no animal models of lymphomagenesis by KSHV in which critical notions about v-cyclin's role could be put to the test – for example, via the study of v-cyclin-deficient mutants. Another impediment has been the difficulty in establishing stable cell lines expressing the protein. This is most likely due to the fact that such cells often undergo apoptosis, particularly if they express elevated levels of cdk6 (Ojala *et al.*, 1999). Such problems are not unexpected: apoptosis often follows overexpression of cellular cyclins, and many viral oncogenes that provoke unscheduled DNA synthesis can similarly induce p53 and trigger programmed cell death. V-cyclin- induced apoptosis is also associated with the inactivation of the antiapoptotic factor bcl2 – which, it turns out, is due to its phosphorylation at the hands of vcyclin/cdk6 (Ojala *et al.*, 2000). It is unclear how this problem is mitigated in vivo, but the low levels of v-cyclin protein accumulation in latency likely represent one viral stratagem for doing so. Alternatively, another viral gene product might nullify this apoptotic effect. In this connection it is of interest that Verschuren *et al.* (2002) have shown that in cultured cells, loss of p53 allowed cells to survive in the presence of elevated levels of v-cyclin. Moreover, when v-cyclin was targeted to the B cell lineage in transgenic mice, lymphomas were observed only when the animals were also p53 -/-. This raises the possibility that the functional inactivation of p53 by LANA expression in KSHV latency (or by v-IRF3; see below) might similarly unmask the oncogenic potential of v-cyclin.

v-FLIP

The third protein encoded by the major latency locus is a viral homologue of the FLICE inhibitory protein, v-FLIP. Transcribed from the same promoter as LANA and v-cyclin, vFLIP is the downstream gene in the spliced, bicstronic mRNA from which v-cyclin is expressed. The failure of attempts to identify moncistronic vFLIP transcripts led to the recognition that an IRES element is embedded within v-cyclin coding sequences (Bieleski and Talbot, 2001; Grundhoff and Ganem, 2001; Low *et al.*, 2001). This implies that both the v-cyclin and LANA mRNAs could template vFLIP translation, though the greater abundance of cyclin mRNA makes it the predominant vFLIP message.

FLIPs as a class are thought to bind adaptor proteins (TRADD and FADD) of the Fas/TNFR signaling pathway via their death effector domains (DEDs) (Thome *et al.*, 1997). This binding impairs the recruitment and activation of caspase 8, leading to blockade of a caspase activation cascade that results in programmed cell death; procaspase 8 can also be directly bound and inhibited. Several other herpesviruses encode v-FLIPs that have been shown to employ this mechanism (Thome *et al.*, 1997). Some papers report that KSHV v-FLIP can function in this fashion (Djerbi *et al.*, 1999, Belanger *et al.*, 2001). However, several laboratories have failed to confirm these findings, and other reports suggest that KSHV v-FLIP can also block cell death via induction of the anti-apoptotic transcription factor NFkB (Chaudhary *et al.*, 1999). vFLIP can be detected in PEL cells complexed wiith NEMO (or IKKγ) (Liu *et al.*, 2002; Field *et al.*, 2003). This complex activates IKK, leading to phosphorylation of IkB and release of active NFkB. These findings are particularly provocative in view of the observations that (i) PEL cells display high levels of NFkB activity, inhibition of which triggers enhanced cell death (Keller *et al.*, 2000); and (ii) that siRNA-mediated inhibition of v-FLIP in PEL cell lines provokes apoptosis (Guasparri *et al.*, 2004; Godfrey *et al.*, 2005). It thus appears that the major role of v-FLIP in PEL latency in the activation of an anti-apoptotic program, principally through upregulation of NFkB activity. However, KSHV vFLIP also binds to TRAF2

and RIP upstream of IKK, and TRAF binding also results in JNK activation (An *et al.*, 2003) – the roles of these activation events in cell proliferation and survival are not yet understood. Very recently, it has been reported that forced overexpression of KSHV vFLIP in rodent fibroblasts results in classical transformation – growth in soft agar and tumorigenesis in nude mice (Sun *et al.*, 2003). These studies raise the possibility that deregulated vFLIP could contribute to an active proliferative program rather than simply extending cell survival. However, such inferences must be made with caution, since (i) the levels of vFLIP in PEL cells are likely much lower than those achieved in these studies, and (ii) the transforming function of vFLIP occurs in the context of antecedent immortalization, and in cells of heterologous species and cell type.

Finally, other studies (Brown *et al.*, 2003) suggest an additional role for NFkB activation by v-FLIP in KSHV biology. Activation of NFkB inhibits lytic cycle gene expression, and inhibition of NFkB activation promotes lytic reactivation. This implies that apart from its role in cell survival, V-FLIP-mediated NfkB activation may be important for maintaining stable KSHV latency.

K10.5/v-IRF3/LANA2

The KSHV genome harbors at least four genes that encode members of the IRF (*i*nterferon *r*egulatory *f*actor) transcription factor family. IRFs are a family of cellular transcription factors, several members of which (esp. IRF3 and IRF 7) are centrally involved in the transcriptional activation of type I interferons – hence their name (Barnes *et al.*, 2002). The KSHV IRF homologues (generically termed v-IRFs) are clustered together in one region of the viral chromosome, suggesting that they arose by duplication of one or more ancestral gene(s) presumably derived from the host genome. Most of the vIRFs are lytic proteins, but one, v-IRF3 (encoded by ORF K10.5), encodes a nuclear protein expressed in latency (Rivas *et al.*, 2001; Lubyova and Pitha, 2000). (For this reason it has also been dubbed LANA-2.) Unlike the LANA/v-cyclin/v-FLIP locus, the vIRF3 gene is not expressed in all latently infected cell types in vivo. Its products are found primarily in latently infected B cells, including PEL cells and cells from MCD, but not in KS spindle cells (Rivas *et al.*, 2001). Like several of its sister vIRFs, vIRF3 expression in mouse fibroblasts inhibits the IRF3/7-mediated induction of the IFN-A4 promoter and impairs the ability of these cells to support IFN induction in response to RNA virus infection – suggesting that vIRF3 can function like a dominant-negative (DN) IRF mutant (Lubyova and Pitha, 2000). However, more recent results in human cells have disputed this simple conclusion, suggesting instead that vIRF3 can actually enhance the binding of IRFs 3 and 7 to the IFN promoters and upregulate IFN release (Lubyova *et al.*, 2003); if so, it is difficult to understand the biological rationale for such an activity, especially since IFNs can be growth-inhibitory in some settings. Easier to relate to the biology of KSHV latency is the observation that vIRF3 protein can also bind and inactivate p53 (Rivas *et al.*, 2001); this activity would be expected to contribute to lifespan prolongation in KSHV-infected B cells, particularly in the context of v-cyclin expression (Verschuren *et al.*, 2002). All of these notions, however, remain to be explicitly tested.

Kaposin

The kaposin locus was initially identified in a screen for genes that are transcibed in uninduced PEL cell cultures (Zhong *et al.*, 1996). In situ hybridization using probes for kaposin mRNA revealed that it is expressed in both uninduced BCBL-1 cells (at a low level) and in variable levels in KS spindle cells lacking markers of lytic reactivation (Staskus *et al.*, 1997; Sturzl *et al.*, 1997). Thus, kaposin transcripts behave as latent mRNAs that, like the LANA/vcyclin/vFLIP mRNAs, can be expressed in both lymphoid and endothelial cells. Recent work from several laboratories has mapped these latent mRNAs and identified their promoter (Li *et al.*, 2002; Pearce *et al.*, 2005; Cai and Cullen, 2006). A second promoter in the kaposin locus is strongly induced during lytic replication (Sadler *et al.*, 1999), owing to the presence of at least one high-affinity binding site for the lytic switch protein RTA (Chang *et al.*, 2002; Song *et al.*, 2003)

Kaposin mRNA encodes at least three proteins via differential initiation of translation (Fig. 56.3(a)) (Sadler *et al.*, 1999). The 3 end of kaposin mRNA bears the coding sequences of ORFK12, initiation at whose AUG directs the synthesis of a 60aa hydrophobic polypeptide known as kaposin A. The protein is found on both the cell surface and on intracellular membranes (Tomkowicz *et al.*, 2002). Interest in this protein was heightened when it was shown that its overexpression in immortalized rodent fibroblasts can trigger morphologic transformation in vitro and tumorigenesis in vivo (Muralidhar *et al.*, 1998). Subsequently it was found that kaposin A can bind cytohesin - 1, a guanine nucleotide exchange factor (GEF) for ARF GTPases and a regulator of integrin-mediated cell adhesion. Binding of kaposin A to cytohesin-1 stimulates GTP binding to ARF1, a process that is implicated in transformation since the transformed phenotype can be reverted by expression of a cytohesin-1 mutant deficient in guanine nucleotide exchange (Kliche *et al.*, 2001). Kaposin A has growth deregulatory potential,

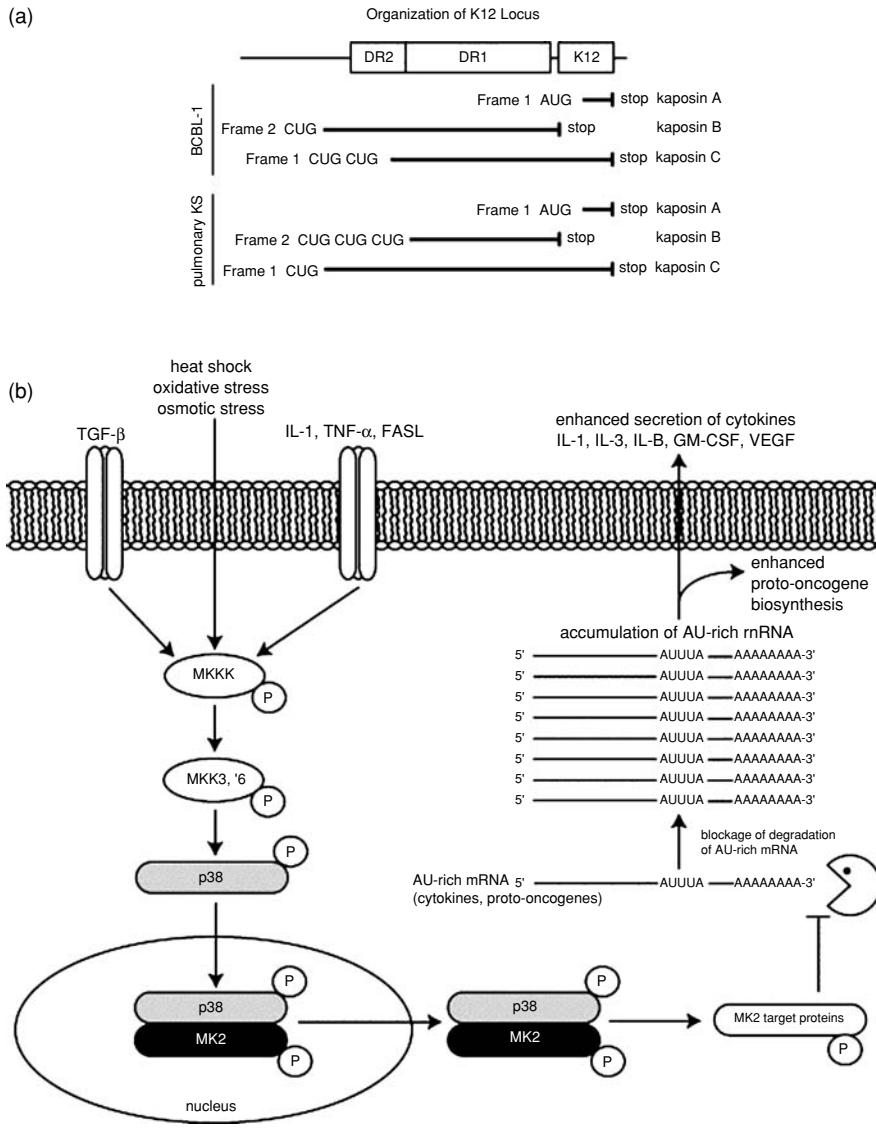

Fig. 56.3. (a) The kaposin locus. Top line, sequence organization of the gene,showing open reading frame (IRF) K12 and the upstream series of tandem direct repeats (DRs) of 23 GC- rich bp. The locus comprises two sets of such Drs(DR1 and DR2) which differ in sequence from each other. Kaposins B and C are derived from translation of the repeats via initiation from CUG codons in different reading frames; kaposin B is encoded solely by the repeats, while kaposin C extends into ORF K12. Sequence differences between different isolates of KSHV result in the production of kaposins B and C from CUGs located at different locations in the locus; shown here to illustrate this is the coding arrangement in KSHV cloned from BCBL-1PEL cells (top), and a primary KS tumor from lung tissue(bottom). (b) Schematic illustration of the p38/MK2 pathway. Activation of p38 via inflammatory or others stresses leads to its nuclear import, where it binds and phoyphorylates MK2 can phosphorylate some nuclear transcription factors. Active MK2-p38 complexes can also be exported from the nucleus to the cytosol, where MK2-p38 complexes can also be exported from the nucleus to the cytosol, where MK@ can phosphorylate additional targets involved in stabilizaton of transcripts bearing AU-rich elements (AREs). Such AREs are typically found in cytokine mRNAs. Kaposin B binds and activates MK2 in a fashion that is independent of upstream inflammatory or oxidative stresses.

especially in cells that have already undergone immortalization. But determination of its role in authentic KSHV tumorigenesis will require examination of its effects in primary cells of lymphoid and endothelial lineage. Such tests should be possible in transgenic mice, though none has yet been reported.

Immediately 5[1] to the K12 open reading frame is a series of tandemly repeated 23-nt GC-rich elements of two families, termed DR (*d*irect *r*epeat) 1 and DR2. Because this region lacks AUG codons, it was initially assumed to be noncoding. However, multiple proteins are produced from this region by initiation at variant CUG codons. (Sadler *et al.*, 1999). One of these, Kaposin B, is encoded predominantly by the repeat sequences; another, kaposin C, expresses the repeats fused in frame to ORF K12, producing a membrane-bound isoform of kaposin B. The functions of kaposins B and C have long been mysterious, but recent findings indicate that they likely function as adapter proteins in signal transduction. Specifically, they bind and activate a kinase, MK2, that is normally a target of p38 phosphorylation (McCormick and Ganem, 2005; Fig 56.3(b) summarizes the key features of the p38-MK2 pathway). The activation mechanism is complex, but appears to require p38, suggesting that kaposin B either increases the sensitivity of MK2 to p38, or decreases the accessibility of p38-phophorylated MK2 to phosphatase action. One result of this activation is the stabilization of mRNAs bearing AU-rich elements in their 3 UTRs (See Fig 56.3(b))– an important result, since such elements are found primarily in the highly regulated transcripts of key cytokines (e.g. IL1,3,4,6, TNF, GM-CSF), growth factors (VEGF) and oncogenes (c-myc). PEL cells are known to produce abundant cytokines (notably IL6, vIL6 and IL10) and many PEL lines are dependent upon one or more of these factors for cell growth or survival in vitro (Aoki *et al.*, 2000; Jones *et al.*, 1999). Cytokines and growth factors also play important roles in KS pathogenesis (see below), and it is likely that kaposin contributes to their production in this disease as well. It is important to point out, however, that post-transcriptional regulation by kaposin is not likely to be the sole modulator of cytokine and growth factor expression in KSHV infection – many of these genes may be controlled transcriptionally as well, by both viral and host factors (see, for example, An *et al.*, 2002).

Latent KSHV miRNAs

Recently it has become clear that in addition to the aforementioned coding RNAs, the latency program of KSHV also generates up to 12 micro RNAs (miRNAs) (Pfeffer *et al.*, 2005; Cai *et al.*, 2005; Samols *et al.*, 2005). These miRNAs are derived primarily from the latent kaposin mRNAs, with all but two emanating from intronic regions of the transcripts (Cai and Ciullen, 2006). (The two encoded in the body of the kaposin mRNA could arise from either latent or lytic kaposin RNAs, but they are only weakly induced during lytic replication.) The function(s) of these miRNAs are not known.

Other KSHV genes and PEL

There is general agreement that the aforementioned genes are *bona fide* products of viral latency. However, there is one viral gene with a likely role in PEL that has not been definitively classified as a latent gene – that for the viral homologue of IL6 (v-IL6). In most cultured PEL cells, this gene is very weakly expressed in the absence of chemical inducers of lytic reactivation, and is strongly upregulated by the latter. This has led most to characterize it as a lytic gene (Nicholas *et al.*, 1997; Staskus *et al.*, 1999; Katano *et al.*, 2000); the low-level expression in the absence of inducers has been ascribed to spontaneous lytic reactivation. However, Parravicini *et al.* (2000) observed by immunohistochemistry on PEL biopsies that a small number of cells in the tumor expressed vIL6 in the absence of another marker of lytic reactivation (vIRF1). They have proposed on this basis that some primary PEL tumor cells can express v-IL6 in the absence of lytic reactivation, though this appears not to be the case for most latently infected PEL cells. Interestingly, when cultured PEL are exposed to IFN-γ, they can express vIL6 without activating any other viral gene (Chatterjee *et al.*, 2002); this lends credence to the idea that the gene can sometimes be expressed outside of the lytic cycle. Whether vIL6 is expressed from a small number of lytically infected cells or is coming from an alternative transcriptional program, there is evidence that its action is important in PEL biology. All PEL cells express the gp130 subunit that allows response to vIL6 (Molden *et al.*, 1997), and in cultured PEL lines, growth can be partially inhibited by anti-vIL6 (but not anti-IL6) antibodies (Jones *et al.*, 1999). (More dramatic inhibition is obtained when both human IL10 and vIL6 are inhibited; Jones *et al.*, 1999.) These results suggest that despite their seeming autonomy, PEL cells do respond to autocrine and paracrine signals, and that these signals can emanate from the host as well as the viral genome.

Multicentric Castleman's disease (MCD)

Castleman's disease is a polyclonal lymphoproliferative lesion that occurs in two histologic types. The first, or

"plasma cell variant" is characterized by extensive plasma cell proliferation but preservation of the nodal architecture. The second or "hyaline-vascular" type, displays prominent, abnormal germinal centers and marked, aberrant neoangiogenesis. Clinically, Castleman's disease occurs in two forms, a localized form involving only a single node or node cluster; this form is unlinked to KSHV and can be treated with local excision of the involved tissue. The second form, multicentric Castleman's disease (MCD), is an aggressive systemic illness characterized by fever, weight loss, splenomegaly and diffuse lymphadenopathy. MCD occurs at increased frequency in AIDS patients, and in this context is nearly always linked to KSHV infection (Soulier *et al.*, 1995); histologically, these cases are usually of the plasma cell type. However, MCD does occur rarely in HIV-negative subjects; in this context, only 40–50% of cases show KSHV DNA in the lesions (Soulier *et al.*, 1995; Parravicini *et al.*, 1997). Although polyclonal (Du *et al.*, 2001), MCD is an aggressive disease that is often treated with chemotherapeutic drugs just like a lymphoma. In fact, microscopic foci of clonal plasmablastic lymphoma have been reported to arise within foci of MCD (Dupin *et al.*, 2000; Oksenhendler *et al.*, 2002).

The polyclonality of MCD suggests that the process is being driven by paracrine signaling factors to which a large number of B cells can respond. Consistent with this idea, all forms of MCD appear to be associated with the overproduction of IL6, and there are strong reasons to implicate IL6 signaling in disease pathogenesis. First, IL6 is a known inducer of B cell differentiation, proliferation and survival (Horn *et al.*, 2000). Second, IL6 overproduction in mice leads to an MCD-like illness (Brandt *et al.*, 1990). Third, high levels of circulating IL6 correlate with MCD exacerbations (Oksenhendler *et al.*, 2000). And fourth, administration of neutralizing IL6 mAbs to patients with MCD reverses their fever and other systemic symptoms and ameliorates their splenomegaly (Beck *et al.*, 1994), although this finding has been tested primarily in HIV-negative MCD patients, not all of whom are KSHV-positive.

KSHV infection is localized to the B cells of the "mantle zones" surrounding the germinal centers of MCD (Dupin *et al.*, 1999; Parravicini *et al.*, 2000; Katano *et al.*, 2000). Despite the fact that MCD is a polyclonal lesion, all KSHV-positive cells in the lesion bear lambda light chains, usually on IgM (Du *et al.*, 2001) – the origin of this peculiar finding remains unclear. Many of these cells are latently infected, as judged by the presence of LANA staining – from 10–50% of mantle zone cells (typically around 30%) have been reported to be LANA-positive in various series (Dupin *et al.*, 1999; Parravicini *et al.*, 2000; Katano *et al.*, 2000). In addition to KSHV latency, however, MCD also displays abundant lytic infection. From 5–25% of LANA-positive cells in the mantle zone stain for lytic markers – many more than in PEL or KS (Staskus *et al.*, 1999; Katano *et al.*, 2000, Parravicini *et al.*, 2000). These lytically infected cells stain prominently for v-IL6 – an important finding given the suspected role for IL6 signaling in this disease. (Although IL6 and vIL6 differ in their requirement for IL6Rα, both signal via gp130 and thus induce nearly identical signals in recipient cells (Nicholas 2003).) Clinical evidence also links MCD to lytic KSHV replication. MCD typically occurs in patients with high KSHV loads in the PBMC compartment, a manifestation of extensive lytic growth (Oksenhendler *et al.*, 2000, Grandadam *et al.*, 1997, Boivin *et al.*, 2002). In fact, an MCD-like syndrome has even been seen in primary KSHV infection (Oksenhendler *et al.*, 1998), where lytic infection is typically predominant. (It should be emphasized, however, that most primary infections with KSHV are subclinical and do not engender MCD).

The discovery that vIL6 production is prominent in the expression program of MCD is satisfying, especially given its ability to signal along pathways shared by human IL6 (Nicholas, 2003). Nonetheless, it is clear that human IL6 continues to be overproduced even in KSHV-associated MCD (Oksenhendler *et al.*, 2000), and it is difficult to judge the relative contributions of each of these two proteins to the disease state. Most experts assume that vIL6 is predominant, but there is little direct evidence on either side, and it seems likely that both proteins contribute to the disease. The source of human IL6 in KSHV-linked cases is now starting to become clear. One pathologic study shows that h-IL6-positive cells are found mainly within the follicular centers (Parravicini *et al.*, 1997) – a place with few KSHV-positive cells. This suggests that one source is reactive, uninfected B lymphocytes. However, some mantle-zone cells in that study were also positive, and it has recently been found that lytically infected cells produce high levels of cellular IL6 as well as v-IL6 (Glaunsinger and Ganem, 2004b). Given the extensive amount of lytic replication in MCD, and the correlation of this with both disease progression and circulating human IL6 levels, it is reasonable to suspect that these cells are also contributing to the raised steady-state levels of h-IL6.

Kaposi's sarcoma

The choice of the word sarcoma in the naming of KS is unfortunate, for KS resembles classical sarcomas very little, both in terms of its histology and clinical behavior.

Unlike most classical cancers, which arise as a clonal outgrowth of a single cell type, KS lesions are histologically very complex (Regezi *et al.*, 1993a,b). The main proliferating element is the so-called *spindle cell*, so named after its spindle-like shape. Marker studies indicate that this cell is in the endothelial lineage, though there has been controversy over its exact position in this lineage (Herndier and Ganem, 2001). Some evidence favors it being derived from lymphatic rather than blood vessel endothelium (Beckstead *et al.*, 1985), based upon the expression of markers characteristic of lymphatic endothelium such as VEGF-R3, VEGF-C and podoplanin (Weninger *et al.*, 1999; Skobe *et al.*, 1999; Marchio *et al.*, 1999). However, this conclusion is still inferential, and spindle cells within any given lesion can display variability in the expression of markers (Regezi *et al.*, 1993a,b). Moreover, recent studies show that KSHV infection of vascular epithelial cells can reprogram them to express lymphatic markers (Wang *et al.*, 2004; Hong *et al.*, 2004; Carroll *et al.*, 2004). Irrespective of their precise origin, spindle cells clearly represent the main proliferative element in KS. However, they are not the sole element – all KS lesions also contain (i) variable (but substantial) numbers of infiltrating monocytes, T-cells and plasma cells; and (ii) a profusion of aberrant, slit-like neovascular spaces. These neovascular channels, the most distinctive histologic signature of KS, are only partially lined with KSHV-positive cells (Dupin *et al.*, 1999), lack pericyte or smooth muscle accompaniment, and are prone to leakage and rupture. As a result, KS lesions also often display edema and hemorrhage, giving them a grossly purplish or bruise-like appearance. It is thus useful to think of KS as subsuming three formally separable (but probably interdependent) processes – a *proliferative* component (chiefly involving spindle cells), an *inflammatory* component and an *angiogenic* component. As we shall see, KSHV may make different genetic contributions to each of these components of the disease.

KS can occur in several tissues, but is most commonly localized to the skin, especially in the lower extremities in classical, HIV-negative forms of the disease. In the skin, it involves the dermis, with sparing of the overlying epidermis (Parravicini *et al.*, 2000). Cutaneous involvement, while potentially disfiguring, is not life-threatening. Dermal KS begins as a so-called *patch* lesion, in which spindle cells are clearly demonstrable but are not necessarily the dominant element of the lesion. Inflammatory cells and neovascular elements are prominent at this stage, which can somewhat resemble granulation tissue. Subsequently, the accumulation of spindle cells becomes more apparent, as the lesion progresses through a plaque-like stage to the *nodular* stage, in which masses of spindle cells generate macroscopically visible nodules or masses.

As noted above, the clinical behavior of KS in immunocompetent adult hosts is very indolent- cutaneous KS is typically a disease which people die *with* but not *of*. In fact, spontaneous remissions of classical KS, while not common, are well-documented (However, in immunocompromised hosts – and in young children in KSHV-endemic regions – KS can be more aggressive, involving lymphoreticular structures, the GI tract and the lung.) This indolent behavior suggests that KS is a proliferative state that is on the cusp between the benign and the malignant. Consistent with this inference, analysis of KS clonality has shown that many KS lesions are oligo- or polyclonal (Judde *et al.*, 2000; Gill *et al.*, 1998; Delabesse *et al.*, 1997). While this conclusion has been disputed by some (Rabkin *et al.*, 1997), their own analyses showed evidence of non-clonality in numerous tumors. The heated controversy surrounding KS clonality is misplaced. The pathogenetically important finding is that many macroscopic KS lesions have evidence of oligo- or polyclonality – not that *all* of them do. In any polyclonal process, it is expected that, in some cases, some clones will fare better than others. The instructive feature of the studies of clonality in KS is how different they are from similar studies of classical cancers like breast or colon cancer – in which exceptions to monoclonality are almost never found.

The cell biology of the spindle cell also supports the view that KS is at a (somewhat indistinct) border between hyperplasia and neoplasia. KS spindle cells, unlike many tumor cells, remain highly dependent upon exogenous growth signals when cultured in vitro. Gallo, Ensoli and their colleagues were the first to find methods to reproducibly grow KS spindle cells in culture, and found them to be dependent upon the cytokine-rich conditioned medium of activated T-cells (Caveat: after in vitro culture, the cells produced in this fashion generally lose the viral genome; see below.) (Ensoli *et al.*, 1989, 2001; Miles *et al.*, 1990; Ensoli and Sturzl, 1998). Nor do they display genetic instability, another hallmark of traditional cancers: KS spindle cells are generally diploid, and classical KS lesions do not display microsatellite instability, though some advanced AIDS-KS lesions do (Bedi *et al.*, 1995). Spindle cells also lack classical findings associated with transformation – they do not form foci, grow in soft agar or form tumors in nude mice. However, an interesting phenotype is observed when the cells are injected subcutaneously in nude mice (Salahuddin *et al.*, 1988). They do not grow, but survive for a brief interval – during which slit-like new vessels *of murine origin* appear in the surrounding tissue. When the human implant involutes, these vessels likewise disappear. This suggests a model for KS that involves a complicated paracrine minuet between several partners. In this model,

spindle cells require growth factors from their microenvironment (perhaps from infiltrating inflammatory cells) for their proliferation, but also seem to produce angiogenic (and proinflammatory?) substances to recruit the other components of the lesion. In this view, none of the partners in this process is fully autonomous; each depends upon the other (Ensoli and Sturzl, 1998). If correct, this is a very different biology than most classical cancers – so it should not surprise us if the viral contributions to its pathogenesis turn out to differ from those of classical DNA tumor viruses.

KSHV and KS: the big picture

The epidemiology of KSHV strongly points to a critical role for this infection in KS pathogenesis – KSHV DNA is always found in KS tumors, irrespective of whether they derive from classical or AIDS-related KS (Chang *et al.*, 1994; Moore and Chang 1995; Huang *et al.*, 1995; Schulz 1999). At the population level, KSHV infection tracks strongly with KS risk – the prevalence of infection is high in groups in which KS is frequent, and low in those in which it is rare (Kedes *et al.*, 1996; Gao *et al.*, 1996). This statement applies both to risk groups within the USA and to populations around the globe (Schulz, 1999). At the level of individual HIV-infected patients, infection with KSHV preceeds the onset of KS (Moore *et al.*, 1996a,b) and predicts an elevated risk of KS tumorigenesis (Martin *et al.*, 1998).These data, which in the aggregate derive from the study of thousands of subjects, strongly indicate that KSHV infection is the *sine qua non* of KS – without it, clinical KS does not occur. But to say it is necessary for KS development is not to say it is sufficient – indeed, there is strong evidence that it is not. First of all, 2%–7% of the US population has serologic evidence of infection (Schulz, 1999), yet most of these individuals have no measurable risk of developing KS. This indicates that cofactors are clearly required for tumorigenesis. In AIDS-related KS, that cofactor is clearly HIV infection – a fact that is strongly supported by (i) the dramatic reduction in KS incidence that has accompanied reduction of HIV viremia via antiretroviral therapy (Portsmouth *et al.*, 2003; Gates and Kaplan 2002); and (ii) the remission of clinical KS in patients treated with HAART alone (Lebbe *et al.*, 1998; Cattelan *et al.*, 2001; Gill *et al.*, 2002). HIV-1 infection predisposes to KS much more strongly than does HIV-2 infection (Ariyoshi *et al.*, 1998). How HIV infection promotes KS development is still actively debated. Several in vitro studies have suggested that HIV infection can augment KSHV replication in both cell-autonomous and paracrine fashions (Harrington *et al.*, 1997; Varthavaki *et al.*, 1999, 2002; Huang *et al.*, 2001). Secreted HIV tat protein has also been proposed as a growth factor for KS spindle cells, again on the basis of experiments in cultured cells (for review see Barillari and Ensoli, 2002). However, the in vivo importance of these observations remains to be proven. Cell-autonomous mechanisms of KSHV activation, for example, require that cells be dually infected with both HIV and KSHV – which is exceedingly rare in vivo (Staskus *et al.*, 1997). (This caveat does not apply to paracrine mechanisms of activation). The fact that KS is strongly augmented by therapeutic immunosuppression (e.g., with cyclosporin) makes it likely that T cell depletion by HIV is also centrally involved in the amplification of KS risk, e.g., due to the inability to contain KSHV replication.

The identity of the cofactor(s) in classical KS remain unknown. Their characterization is the last remaining Great Unsolved Problem in the human biology of KS, Unfortunately, though – and in marked contrast to AIDS-KS (Beral *et al.*, 1990) – the epidemiology of classical KS has not proffered strong clues to their identity. There are hints, however, that host genetic factors may play a role. Such hints derive from the identification of populations that have a low risk of classical KS despite a high prevalence of KSHV infection. In one such group (Ethiopians), even after the superventionof AIDS KS developed at a 12-fold lower rate than in other AIDS-afflicted groups (Grossman *et al.*, 2002). In such populations whatever host factors are modulating KS risk, they must operate post the acquisition of KSHV.

KSHV gene expression in KS

As noted above, KSHV DNA is present in all KS tumors, irrespective of clinical type or disease stage. Within the tumor, KSHV specifically targets the spindle cell compartment (Boshoff *et al.*, 1995; Staskus *et al.*, 1997; Dupin *et al.*, 1999), with little or no infection of other cell types. (One report suggests that monocytes in the lesions may be infected (Blasig *et al.*, 1997), but this has not been confirmed in other studies (Parravicini *et al.*, 2000; Staskus *et al.*, 1997.) Using known latency genes (as defined by their pattern of expression in PEL cell lines) as probes in *in situ* hybridization studies, it was shown that most KS spindle cells are latently infected; however, a small subpopulation (1%–2%) express markers of lytic infection (Staskus *et al.*, 1997; Dupin *et al.*, 1999; Sturzl *et al.*, 1997, Katano *et al.*, 2000). Several groups have enumerated the latency genes expressed in KS spindle cells in vivo, using immunohistochemistry or *in situ* hybridization on KS biopsies. In general, all of the genes discussed previously in PEL latency are expressed in latently infected spindle cells, save for v-IRF3 (LANA 2) (Rivas *et al.*, 2001). Careful studies (Katano *et al.*,

2000; Parravicini *et al.*, 2000) also show that, in KS, v-IL6 is produced only in the minor subset of cells that is truly in the lytic cycle – here, there is no suggestion that KS cells can express this gene outside of the lytic cycle.

The discovery that most spindle cells display latent infection is in accord with herpesviral dogma that the latency program drives tumor formation. Consistent with this, examination of early (patch) lesions of KS shows that only 10–30% of spindle-like cells are LANA-positive (Dupin *et al.*, 1999), while in later lesions virtually all such cells are latently infected (Staskus *et al.*, 1997; Dupin *et al.*, 1999). This clearly implies that latently infected cells have a growth (or survival) advantage in vivo. And certainly, many of the in vitro properties of the latency genes are commensurate with this inference. Examples include: the inhibition of p53 and the partial abrogation of Rb by LANA, the induction of NFkB by v-FLIP, the stimulation of cdk6 by v-cyclin, the potentiation of growth deregulation by kaposin A and the upregulation of ß-catenin by LANA. All of these activites could contribute to endothelial cell survival and proliferation, and, as noted earlier, LANA expression can indeed prolong the lifespan of primary endothelial cells in culture (Watanabe *et al.*, 2003). But since most of these activities were discovered in experiments involving overexpression of individual viral proteins in heterologous cell types that were already immortalized, their contributions to the in vivo biology of KS remain to be defined.

Another experimental perspective on this issue comes from examination of cells infected with authentic KSHV. When KSHV virions are applied to most established cell lines, a latent infection results that appears to have no phenotypic consequences (Viera *et al.*, 2001; Lagunoff *et al.*, 2002; Bechtel *et al.*, 2003). However, when KSHV is used to infect *primary endothelial cells*, the situation is dramatically different. In the early days of the culture, there is dramatic lytic replication and fairly efficient spread of infection through the monolayer (Ciufo *et al.*, 2001; Gao *et al.*, 2003; C. Grossman and DG, unpublished data). By 10–14 days, the entire culture is LANA –positive, with most cells being latently infected. These cells also display a dramatic elongation to a spindle morphology (Fig. 56.4) that is remarkably similar to that seen in KS tumors in vivo (Fig. 56.4). Importantly, however, in most experimenters' hands the cells are not immortalized (Gao *et al.*, 2003, Tang *et al.*, 2003; Grossman *et al.*, 2006), though there is one dissenting report (Flore *et al.*, 1998). While they may undergo some prolongation of lifespan, KSHV-infected endothelial cells are not capable of indefinite proliferation – at least not in conventional culture media. The cells fail to grow in soft agar, and no reports of tumorigenesis by KSHV-bearing cells in nude mice have yet appeared. While these results could simply reflect the inadequacy of current culture conditions, they certainly suggest that, at a minimum, the KSHV latency program is much less potent than that of EBV in cell immortalization. This, in turn, raises questions as to whether this more subtle latency phenotype is sufficient to drive KS pathogenesis all by itself.

In fact, independent evidence from clinical studies suggests that lytic replication as well as latency also plays a pivotal role in KS development. Martin *et al.* (1999) showed that in patients with advanced AIDS, addition of parenteral ganciclovir – a drug that blocks lytic but not latent KSHV infection – resulted in a prompt and dramatic decline in the incidence of new KS tumors. This is a powerful and interesting result because most of these patients have carried HIV and KSHV for many years – therefore, the impact of GCV is not likely to be due simply to the reduction of early dissemination to target cells. Rather, it appears that ongoing lytic replication is continuously necessary throughout the entire natural history of KSHV infection in order to support lesion formation. Consistent with this, patients with KS typically have high levels of KSHV DNA in the circulation (Whitby *et al.*, 1995; Campbell *et al.*, 2000; Quinlivan *et al.*, 2002; Cannon *et al.*, 2003a,b, Engels *et al.*, 2003) – just as do patients with MCD, another disease in which lytic KSHV replication is thought to play an important role.

How might lytic replication contribute to KS tumor development? Here I outline three non-exclusive possibilities. The first derives from the observation that latent KSHV infection is not immortalizing. If spindle cells cannot grow indefinitely, then in order for a tumor mass to expand, KSHV-positive cells that die must be replaced by new latently infected cells. The most obvious source of such cells would be from *de novo* infection of endothelia with virus produced by lytic replication. The second model derives from recent observations of Grundhoff and Ganem (2004), who showed that when cells newly latently infected with KSHV are placed under conditions of rapid proliferation, they rapidly segregate the viral genome. With continued passage, at least in some lines, rare subpopulations can emerge in which latent infection has been stabilized. In such cells, the KSHV genome can be maintained indefinitely as an autonomous episomal replicon – just as it is in PEL cells in vivo. Examination of these rare, stably latent subclones reveals that *cis*-acting, epigenetic changes in the viral chromosome are responsible for stabilization (though the biochemical nature of these epigenetic changes is still unknown). Two lines of evidence support the relevance of these observations to the in vivo situation. First, exactly the same phenomena are observed in primary endothelial cells, which reproduce the main features of KS spindle cell biology (Grundhoff and Ganem, 2004). More importantly,

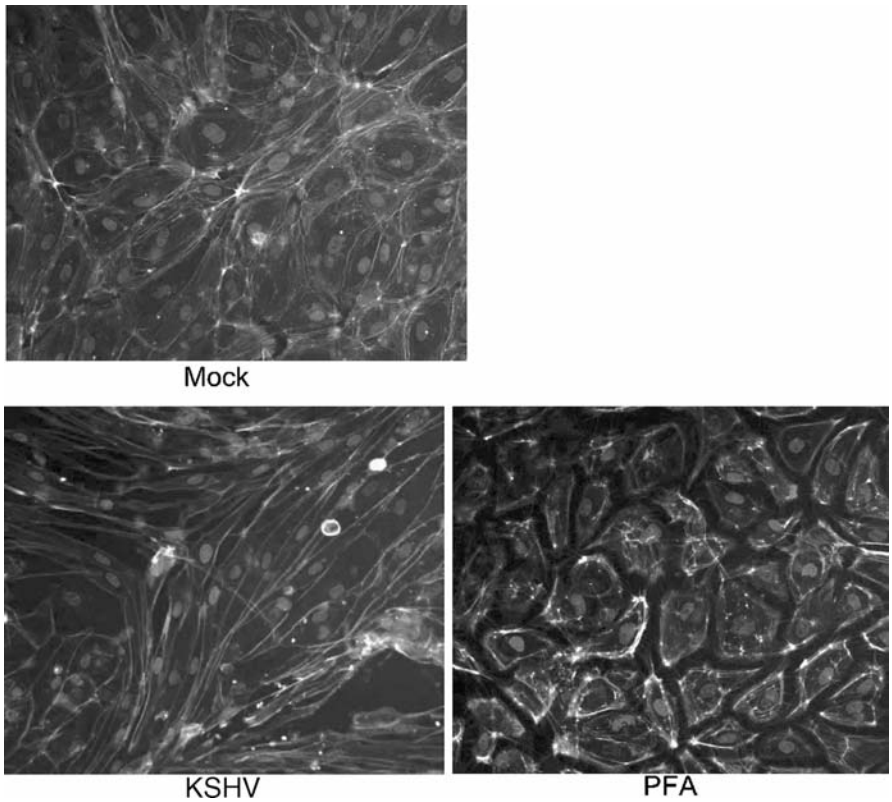

Fig. 56.4. KSHV infection of culture primary endothelial cells results in morphologic changes resembling spindling in vivo. Primary blood endothelial cells were mock infected(top) or infected with KSHV (botttom left); three weeks later, following spread of virus through the culture, the culture was 100% latently infected. Cells were then stained with phalloidin; note extensive spindling of the infected culture.Bottom right: cells were infected with KSHV and immediately carried in Phosphonofomate (PFA), an inhibitor of KSHV replication that blocks spread throught the culture; this blocks widespread establishment of latency and spindling.

when infected KS spindle cells are explanted directly from clinical specimens and placed under conditions favoring their proliferation, they too rapidly – and invariably – segregate their viral episomes (Flamand *et al.*, 1996; Aluigi *et al.*, 1996; Dictor *et al.*, 1996). This instability may be one explanation for the relative clinical indolence of KS, since cells that proliferate aggressively will likely lose their latent infection – and with it their virally endowed growth advantage. Second, it offers another reason why lytic replication is continuously required for KS development – namely, to restore latent infection to spindle cells that have lost their KSHV genomes (or recruit other cells to latency to replace those lost from the latent pool via episome segregation).

The third manner in which lytic KSHV replication may contribute to KS pathogenesis harkens back to the fact that KS is an amalgam of three processes: proliferation, inflammation and angiogensis. Since lytically infected cells die, they cannot contribute importantly to the proliferative component of the disease. However, if lytically infected cells produce paracrine signaling molecules, they could promote both the inflammatory and angiogenic components of the lesion. In fact, examination of the KSHV genome (Russo *et al.*, 1996; Nicholas *et al.*, 1997; Nicholas, 2003) reveals numerous viral genes whose products are secreted signaling molecules – many of which are homoloues of cellular cytokines or chemokines. And interestingly, the majority of these are expressed in the lytic cycle – examples include the three viral CC chemokines and v-IL6. Several of the viral chemokines have been shown to be chemotactic for both Th2 cells (Sozzani *et al.*, 1998; Stine *et al.*, 2000) and endothelial cells (Haque *et al.*, 2001). The former observation suggests that these chemokines may blunt antiviral (and anti-tumor) Th1 responses by favoring Th2 polarization of the local antiviral response – consistent with this, one of these (vCCL2) was shown to extend the survival of cardiac allografts in rodents, in part by impairing CTL infiltration (DeBruyne *et al.*, 2000). The activity on endothelial chemotaxis raises the possibility that KS lesions may be able

to recruit more endothelial targets for infection. Endothelial chemotaxis may also relate to observations that application of several viral chemokines to chick chorioallantoic membranes stimulates angiogensis (Boshoff *et al.*, 1997; Stine *et al.*, 2000), though it is also possible that angiogenesis in these models is due to substances released from inflammatory cells recruited by the chemokines). Another lytic protein, v-IL6, in addition to its known roles in B-cell survival, differentiation and proliferation, has also been suggested to affect local angiogenesis (Aoki *et al.*, 1999), perhaps via induction of VEGF production. Recent studies also indicate that vIL6 signaling can block STAT2 phosphorylation by type I IFN signaling, inhibiting both their growth-arresting potential and also their antiviral action (Chatterjee *et al.*, 2002).

Another viral signaling molecule about which much has been written is the viral GPCR homologue (v-GPCR), a member of the chemokine receptor subfamily of the seven transmembrane G protein coupled receptors (Cesarman *et al.*, 1996). Expression of this protein also is restricted to the lytic cycle (Kirshner *et al.*, 1999; Chiou *et al.*, 2002). The protein displays constitutive signaling activity when expressed in the absence of known ligands, though its activity can be further upregulated by chemokines like GRO-α (Arvanitakis *et al.*, 1997; Gershengorn *et al.*, 1998). The resulting singaling activates the MAPK, PI3-kinase and p38 pathways (Sodhi *et al.*, 2000; Smit *et al.*, 2002), as well as activating NFkB activity (Schwarz and Murphy, 2001), and at least in 3T3 cells can stimulate cell proliferation (Bais *et al.*, 1998). In keeping with this broad signaling activity, many host genes are upregulated in response to vGPCR expression in transfected cells (Polson *et al.*, 2002). Among these is VEGF (Bais *et al.*, 1998; Sodhi *et al.*, 2000), a major mediator of angiogenesis and vascular permeability – and a molecule long suspected of a pathogenetic role in KS based on the prominence of neovascularity and edema in affected tissues. In keeping with these in vitro findings, expression of vGPCR in several different cell lineages in transgenic mice produces focal angioproliferative lesions that share some features with KS (Yang *et al.*, 2000; Guo *et al.*, 2003; Montaner *et al.*, 2003). Because this single viral gene product can be linked to both proliferation and angiogenesis, it is seductive to imagine that it is the key player in KS pathogenesis (Montaner *et al.*, 2003).

Several complicating facts, however, must be reckoned with. First, vGPCR is a lytic cycle gene, and there is no evidence that it is expressed in the majority of proliferating, latently infected KS spindle cells (caveat: for a powerful signaling molecule like this, levels below those detectable by in situ hybridization could still be biologically important). If its expression is restricted to lytic infection, then several conclusions follow. First, its cell-autonomous, pro-mitotic activity is likely to be nullified by the direct cytotoxicity resulting from the lytic cycle. Second, it has recently been found that KSHV lytic replication results in a strong block to *de novo* host gene expression, mediated primarily by virus-induced host mRNA degradation (Glaunsinger and Ganem, 2004a,b). Indeed, in lytically infected endothelial cells in culture, very few of the genes upregulated by vGPCR transfection were found to be expressed – although a limited and transient induction of VEGF-C was observed (Glaunsinger and Ganem, 2004b). It is to be emphasized that these results do not negate a role for vGPCR in KS pathogenesis, but they do place important boundary conditions on its potential roles. For vGPCR to play a role in the proliferative component of the tumor, it will have to be shown that the gene can be expressed outside of the traditional lytic cycle – if not in canonical latency, then in response to some extracellular signal or milieu. While this has not yet been observed, it is not without precedent – recall, for example, that in response to IFN-γ, vIL6 can be expressed by KSHV-positive cells in the absence of any other lyic gene expression (Chatterjee *et al.*, 2002). Even if vGPCR is only expressed in lytic replication, it could still contribute to the angiogenic component of KS, since while the block to host expression is strong, it is not absolute–low levels of host transcripts can still be generated very early in infection, before the establishment of the shutoff. But given the attenuation of its ability to induce VEGF and other genes in this context, it would be predicted that substantial lytic replication would be required to generate KS risk. Interestingly, this is exactly what is observed in vivo – patients with KS generally have very high circulating KSHV loads (Whitby *et al.*, 1995; Campbell *et al.*, 2000; Quinlivan *et al.*, 2002; Cannon *et al.*, 2003a,b, Engels *et al.*, 2003).

Conclusions

The pathogenesis of KSHV-related neoplasms reprises many of the themes struck by other models of herpesviral oncogenesis, but also elaborates variations on them and, more importantly, mandates consideration of entirely new ones. Chief among the latter is the apparent dependence of KS (and likely MCD as well) on continued operation of the lytic cycle. If current notions about this are correct, they have an important potential clinical corollary – namely, that treatment with drugs that block lytic KSHV replication would not only prevent KS development but could potentially arrest or even reverse established KS lesions. Putting this notion into practice, however, may not be simple, as we have no accurate idea of the duration for

which such therapy would need to be administered. This would be expected to depend upon the lifespan of latently infected cells, the frequency with which episomes are segregated in vivo, the levels of KSHV production, and the efficiency of *de novo* infection/reinfection – all factors of which we have little quantitative understanding. Therefore, treatment duration will have to be determined empirically, and is almost certain to be many months. This, in turn, will require therapies that are safe, non-toxic and orally bioavailable. Whether currently available drugs meet these criteria is debatable, and less toxic and expensive drugs may well be required. If such can be found, however, it would allow this notion to be put to its definitive test in a clinical trial.

Monkey B virus

Julia Hilliard

Department of Biology, Georgia State University, Atlanta, GA, USA

Introduction

B virus (Cercopithecine herpesvirus 1, herpesviridae), an alphaherpesvirus endemic in macaque monkeys, has the unique distinction of being the only one of nearly 35 identified non-human primate herpesviruses that is highly pathogenic in humans. B virus has been positively linked with more than two dozen human deaths since the first report describing it in 1933, five of those in the last 12 years, following exposures involving macaques in during acute B virus infection. B virus, unique among the non-human herpesviruses, is included in this volume because it is distinctively neurotropic and neurovirulent in the foreign human host inadvertently exposed by handling macaque monkeys generally used in biomedical research. Untreated B virus infections in humans result in an extremely high mortality rate (~80%) and, consequently, present unique and potentially lethal challenges for individuals handling macaque monkeys or macaque cells and tissues. Infection in humans is associated with breach of primary skin or mucosal defenses and subsequent contamination of the site with virus from a macaque or cells or tissues harvested from this animal. Fomites, contaminated particulates or surfaces, can serve as source of virus as well. In one case, human-to-human transmission was reported and attributed to a shared tube of medication which resulted in contamination at a broken skin site with cream used to treat another patient's bite wound. Later, the same patient autoincoculated one eye during manipulation of a contact lens. In 28 zoonotic cases occurring during the 1980s and 1990s out a total of 46 documented cases confirmed since 1933, 80% have survived infection with the advent of antiviral therapies in contrast to 80% mortality reported in untreated patients. Timely antiviral intervention is an effective means of reducing B virus-associated morbidity and preventing a fatal outcome.

History

The first case to appear in the medical literature was described as follows. A laboratory worker accidentally bitten by a monkey, apparently recovered from the bite, but immediately afterward fell ill of a febrile disease with progressive symptoms of ascending myelitis and died 15 days after the first symptoms of involvement of the central nervous system (CNS). The gross and histological picture included areas of softening in the mid brain and widely diffuse areas of perivascular lymphocytic infiltration. While the brain of this individual was contaminated with a coliform bacterium, it yielded, on rabbit brain passage, a bacteriologically sterile tissue cell culture isolate that killed rabbits with invariably characteristic neurologic symptoms and also caused an exaggerated skin lesion that was subsequently followed by ascending myelitis and death. The virus present in the brains of these animals was thoroughly compared with known strains of herpes viruses by crossed immunity reactions which will be elsewhere described. This agent produced lethargic encephalitis in Cebus but not in rhesus monkeys.

Gay and Holden (1933) reported an ultrafiltrable agent, similar to herpes simplex virus, recovered from this brain tissue as received from Albert Sabin. They initially designated the isolate "W" virus, noting that it caused similar disease in rabbits infected by either intradermal or intracranial routes, but a rhesus macaque exposed to virus showed no illness. Within a year of these first reports by Gay and Holden, Albert Sabin independently reported an ultrafilterable agent that he identified as "B" virus from tissues of this same index patient, naming the virus by using the initial of the last name of the patient. These studies were expanded with the observation that B virus, deadly in this patient, caused disease strikingly different from HSV. Sabin described the case as follows: in 1932, a young physician

(WB) was bitten by a macaque monkey and later developed localized erythema at the site of the animal bite. This apparent localized infection was followed by lymphangitis, lymphadenitis, and ultimately a transverse myelitis, with the demise of WB ascribed to respiratory failure. At the time of WB's death, tissue specimens were obtained for laboratory investigation.

The virus subsequently has been called B virus, herpes B virus, herpesvirus simiae, or Cercopithecine herpesvirus 1. The lethality of B virus infection in rabbits was described by Sabin (1934) who showed that infectivity was independent of route of inoculation. Experimentally infected dogs, mice, and guinea pigs, on the other hand, showed no susceptibility regardless of route of infection. Both Gay and Holden, as well as Sabin, observed that B virus induced immunological reactions in an infected host similar to HSV-1. The virus was noted also to share similarity with pseudorabies as well as with other viruses, including SA8 and two additional herpes non-human primate alpha-herpesviruses recently described, HPV-2, originally described as SA8 (Simian Agent 8)(Eberle *et al.*, 1995) and Langur herpesvirus (J. Hilliard, unpublished data).

Twelve fatalities were identified by 1959 along with five survivors. Detection of antibodies in humans, in the absence of clinical symptoms but with a history of working with macaques, is unreliable; however, these tests early antibody could not discriminate between antibodies induced by HSV types 1 and 2 vs. B virus. Subsequently, with the development of more precise tests, Freifeld *et al.* (1995) observed a high risk population ($n = 325$) that antibodies were rarely, if ever, present in the absence of a history of clinical symptoms. Following another fatal case, however, antibodies were found to be present in at least two coworkers and one additional individual with no previous history of HSV 1 or 2 (J. Hilliard, unpublished data). Two of the three reported a significant illness, describing symptoms commensurate with early stages of B virus infection nearly a decade earlier but with full recovery. These observations suggest B virus may reactivate and be responsible for maintenance of high antibody titers long after acute illness; however, there are too few cases to suggest with certainty that B virus reactivates in humans who survive acute disease.

Distribution in nature

All species of macaques appear to serve as the natural hosts of B virus. There are, in general, genotypic differences associated with B virus depending on the species of macaques from which it was isolated. There is an absence of strong evidence to suggest that there is a difference in the pathogenesic mechanisms of these different genotypes when they infect humans. The macaque host is found most often in the Asian wilds, but colonies of these animals have been exported to a number of other regions, for example, the Isle of Mauritius and Gibralter. B virus can also infect humans (1987, 1987, 1989; Benson *et al.*, 1989; Artenstein *et al.*, 1991), as well as other species of monkeys housed next to macaques (Loomis *et al.*, 1981; Wilson *et al.*, 1990). Other vertebrate species can be infected, including other non-human primates, but in such cases the infected animal serves as a foreign host and frequently succumbs to infection. N/P B virus transmission results from direct contact, whether from animal to animal, animal to person, person to person, or contaminated object to animal or person. There has been only one recognized case of human-to-human transmission observed in 1987 (Palmer, 1987; Weigler, 1992; Weigler *et al.*, 1993).

B virus is highly prevalent in host natural performed reservoirs. Estimations of prevalence have been by a variety of investigators and techniques for both wild and captive macaque populations (Shah and Southwick, 1965; DiGiacomo and Shah, 1972; Kessler and Hilliard, 1990; Weigler, 1992; Freifeld *et al.*, 1995; Sato *et al.*, 1998). Transmission of infection correlates with onset of sexual activity, facilitating transmission of the virus among animals within a group (Weigler *et al.*, 1995). Crowding of animals during transportation seems to accelerate the spread of infection within a community (Keeble *et al.*, 1958; Keeble, 1960). A number of captive colonies worldwide are attempting to define and breed macaques free of B virus, but generally, due to the nature of the virus, antibodies are usually the only measure of prior infection. Investigators will be challenged greatly as they try to eliminate a virus that has coevolved with this host for nearly 30 million years!

As would be expected of an alphaherpesvirus infection in the natural host results is frequently associated with mild clinical signs, if any. B virus infection, however, can have serious consequences under certain immunosuppressive conditions, as observed by a number of investigators and reported by Chellman and colleagues (Chellman *et al.*, 1992). Under these conditions, virus shedding from mucosal membranes can be documented easily by virus isolation in cell culture. In most infected animals, persistent, high antibodies throughout the lifetime of the host provide supportive evidence that B virus, as with HSV, reactivates periodically. N/P Virus can be reactivated in vitro (Boulter, 1975; Vizoso, 1975) from ganglia harvested from asymptomatic seropositve animals. In healthy animals, virus reactivation can be documented by recovery of virus from mucosal samples; however, virus is excreted for only short periods of time (Weigler *et al.*, 1993; J. Hilliard,

unpublished data). Collectively, these observations are not surprising in view of data derived from other alpha herpes viruses.

The virus

Isolation and growth properties of B virus

In 2003, the Department of Justice listed B virus as a Select Agent when it is outside of the natural host further restricting work with this virus, a potential tactical agent of terrorism. Because the agent is capable of causing death in up to 80% of untreated cases, the Center for Disease Control and Prevention (CDC) has undertaken the responsibility of defining agent summary statements for work performed with B virus. Isolation of virus is recommended in BL-3 containment laboratories while growth and propagation is strictly confined to BL-4 maximum containment facilities. Obviously, early work with this agent was done under far less stringent containment.

As noted, B virus was initially isolated from rabbit brain homogenates following fatal zoonotic infections. Within a decade after its discovery, chorioallantoic membranes or embryonated eggs were used for growth and propagation of B virus. By 1954, B virus was reported isolated from primary rhesus kidney tissue used for polio vaccine production. Virus was also noted to be present in rhesus central nervous system tissue. Shortly thereafter, monkey kidney and chick embryo were found to support in vitro replication of virus. In B cells, virus induces syncytial cells uniquely characteristic of this agent.

Following virus isolation, B virus was found to be relatively stable in cell culture media stored at 4 °C. Long-term storage, however, required −80 °C, not −20 °C. These observations have been important for optimizing recoverability of virus from clinical samples to better understand the agent from both the macaque host and others, including humans.

B virus replicates to high titer in cell lines derived from Old World monkeys, particularly in Vero cells derived from African green monkey and vervet kidney cells. Rabbit kidney cells, BSC-1, and LLC-RK also support replication of B virus. Vero cells are an optimal cell line for isolation of virus from clinical specimens. Infected cells balloon, fusing into polykaryocytes that expand outwardly as more cells become infected. Eosinophilic, intranuclear inclusions (Cowdry type A bodies) are observed following fixation and staining of infected monolayers of cells, but inclusions are neither always observed in infected animals nor in some humans with zoonotic infection. As a result, intranuclear inclusion bodies should not be relied upon as a diagnostic marker. In the event this agent is inadvertently isolated in a BL-2 laboratory, cultures should be sealed and forwarded to a registered specialty laboratory that can handle this select agent safely and in accordance with federal guidelines.

In culture, B virus grows with kinetics similar to HSV (Weigler *et al.*, 1993). Virus particles adsorb to cells, resulting in fusion and virus penetration of susceptible cells with suitable receptors. The nature of the cell receptors will be discussed in further detail later. Early in infection (3–4 hours), virus activity eclipses, but cellular responses can be detected by preliminary microarray analysis within the first hour post infection (Zao *et al.*, unpublished data). Although host cell machinery is halted once virus enters the cell, innate immune responses of the cell post infection work presumably to counteract the virus. This, too, will be discussed in more detail later in this chapter. By 4 hours postinfection, DNA synthesis increases dramatically as does synthesis of polypeptides (Hilliard *et al.*, 1987). Morphogenesis of the the virus is also similar to that of HSV, as shown by electron microscopy studies during the time course of infection (Ruebner *et al.*, 1975). Within 6–10 hours after infection, infectious virions are detectable. By 24–28 hours postinfection, intracellular and extracellular virus levels plateau. Similar to HSV, B virus expresses sequential classes of proteins, i.e., immediate early, early, and late proteins (Hilliard *et al.*, 1987). Homologous glycoproteins, as well as structural proteins, are encoded by the B virus genome (Slomka *et al.*, 1995). Previous studies have characterized the antigenic relatedness of many of these proteins to those from HSV types 1 and 2, and to other non human primate alphaherpesviruses (Eberle *et al.*, 1989; Hilliard *et al.*, 1989).

The B virus genome

Two complete B virus genome sequences derived from cynomologus and rhesus monkeys, respectively (Harrington *et al.*, 1992; Perelygina *et al.*, 2003) have been published along with a number of partial sequence analyses (Bennett *et al.*, 1992; Killeen *et al.*, 1992). The total genome length has been calculated to be 156 789 base pairs for rhesus derived B virus and x bp for cynomolgus derived B virus.

B virus contains a double-stranded DNA genome of approximately 162 kbp. One strain of virus originating from a cynomologus monkey has been mapped and subcloned by Harrington *et al.* The genome contains two unique regions (Ul and Us) flanked by a pair of inverted repeats, two of which are at the termini and two internally located, an arrangement allowing four sequence-orientation

isomeric forms. The overall size of the genome is slightly larger than HSV-1 (152 kbp) and HSV-2 (155 kbp). The guanosine:cytosine content of the DNA was calculated to be 75% based on the buoyant density of viral DNA. Eberle *et al.* published data which established the presence in B virus of gene homology to HSV-1 and HSV-2, gB, gC, gD, gE, and gG. Further examination of the sequences of the nine major glycoproteins demonstrated that the 75% of the GC content was conserved within most glycoproteins. Harrington *et al.* showed that the location of genes within the Ul regions of HSV and B virus were collinear; one gene rearrangement was described in an isolate which originated in a cynomolgus macaque. Homologues of HSV Us9 and Us10 genes were noted to be located upstream of the Us glycoprotein gene cluster in contrast to the downstream location of these genes in HSV Us region. This rearrangement was affirmed according to hybridization data and the proposed physical map of Harrington *et al.* Sequence analysis (unpublished) of the prototype strain (E2490) which originated from a rhesus macaque, however, illustrates that B virus DNA is colinear in these same regions with the HSV-1 genomic arrangement (L. Perelygina *et al.*, 2000, unpublished data).

To date, sequences for only a few B virus genes have been submitted to GeneBank, i.e., homologues of gB, gD, gC, gG, gJ, and gI, largely covering the sequence of the Us region. Nonetheless, with a number of laboratories engaged in the sequencing of this virus, the majority of the genome sequence will be accomplished likely within a short time. Each of the glycoproteins for which sequence information is available, except gG, has about 50% identity with HSV, slightly higher for HSV-2 than HSV-1. B virus gG is a homologue of HSV-2 gG and is closer in size to gG-2 (699 kbp) than gG-1 (238 kbp). Glycoprotein sequences demonstrated that all cysteines are conserved as are the majority of glycosylation sites. This conservation suggests that B virus glycoproteins have similar secondary structure to that characterized in HSV. Sequence analyses from these laboratories also suggest that B virus and HSV types 1 and 2 probably evolved from a common ancestor. Using restriction length polymorphisms (RLPs), as a guide, several investigators have shown intrastrain variation among both human and non human primate derived isolates, the significance of which remains to be studied. Eberle *et al.* postulated the possible existence of B virus isolates, which vary with respect to pathogeneicity for non-macaque species, based on the existence of three distinct B virus genotypes found during phylogenetic analyses; however, this postulate must be examined in a suitable animal model. In zoonotic infections, unfortunately little is usually known about the species of most source animals, but where data are actually available many rhesus macaques have been identified targeting this species as the harbinger of a unique, highly pathogenic strain that can cause zoonoses. Published case summaries that implicate other macaque species and in one case a baboon, are difficult, if not impossible to confirm.

Synthesis of viral proteins

Approximately 23 major polypeptides have been identified by electrophoresis in denaturing polyacrylamide gels (Fig. 57.3), but over 50 different polypeptides have been identified by immunoblot analysis. Each has been assigned an infected cell polypeptide number as an initial reference point. The number may be an underestimate of the total produced, but it serves as a basis for comparison in ongoing studies. Molecular weight of these infected-cell polypeptides ranged from about 10 000–250 000 Daltons. Over 75% of the expected coding capacity of the viral DNA was accounted for by these infected cell polypeptides. At least nine bands from electrophoresed infected cell polypeptides containing viral glycoproteins have been thus far identified. Many of these glycoproteins have been cloned and sequenced by two groups. The proteins encoded were mapped to genes by the Us region which was largely colinear to the HSV glycoproteins gD, gI, gJ, and gG, as previously described. Sequence analysis of selected genes show that B virus is most closely related to herpesvirus papio 2 (HVP-2). Although there are protein homologues in herpesviruses of New World monkeys, very little, if any, cross-reactivity exists between B virus and the New World monkey herpesviiruses.

The kinetics of synthesis of the proteins and glycoproteins in infected cells in culture were found to have a course similar to that observed for HSV, although infectious virus was detectable slightly earlier, appearing 6 hours post-infection Both host cell DNA and protein synthesis appeared curtailed during the first 4 hours postinfection. As for glycoproteins, only glucosamine and some mannose were incorporated during the infection in vitro. B virus polypeptides/glycoproteins can be grouped into classes that differ in their relative rates of synthesis at different times throughout the virus replication cycle, as is characteristic of alpha herpesviruses.

Pathology and pathogenesis

During the course of B virus infection, some factors are observed not only in the natural host, but also in the experimentally infected host and the infected human as a result of zoonotic exposure. Those common factors will be

discussed initially, then specific details for each of these host groups will be provided. First, there are various outcomes in infected hosts and evidence can be deduced from the literature that route of infection may play an important role. Specific details are lacking, but some observations can be made. The route of inoculation predicts differences in the time course of infection and spread through the central nervous system and visceral organs, e.g., spleen, adrenal, kidney, and in some cases even heart. Routes of infection are unique to each of the categories of hosts: natural, experimentally infected, and human zoonotic infections. For example, venereal transmission of the virus is common in macaque hosts, whereas intranasal virus can be experimentally delivered to a rabbit, or in the case of zoonotic exposure to a human by accidental aerosolization. However, these routes share one common feature, namely the involvement of mucosal membranes.

The cells that come into contact with the virus initially are another important factor to the permissiveness of the infection. For example, nasal mucosa has been found to be a less ideal site for virus replication than lung. However, nasal mucosa is not entirely resistant since increasing titers of virus can be isolated from these sites. Another important consideration in B virus pathogenesis is the dose of the virus initially introduced. The role of dose remains a challenging issue for study. Both dose and route of inoculation are important factors with respect to the onset of disease. For example, a far greater quantity of virus is required to infect rabbits by aerosolization than by an intradermal route of inoculation, although practically it remains unconfirmed whether these routes and doses parallel human versus nonhuman primate studies. Also, dose may be an important factor in contributing to associated morbidity and mortality. The commonality of each exposure route is generally a mucous membrane. Another common feature of natural, experimental, or zoonotic infection is that B virus can be found in the CNS shortly after the onset of acute infection. But where this virus goes and what it does differs widely in a natural infection versus an infection of a susceptible foreign host, the latter often succumbing to respiratory failure after neurologic deterioration.

The natural host

The macaque, the natural host of B virus, typically suffers little to no morbidity as a consequence of infection. Exceptions appear rarely and seem to involve specific accompanying factors, e.g., immunosuppression. Typically, once a macaque becomes infected following exposure of mucous membranes to virus, infection is relatively self-limiting. The virus may replicate at the site of inoculation and induce a localized erythema. There is also evidence of a limited focal infection of liver and kidney in some macaques. Virus travels via the peripheral nerves subserving the site of inoculation to associated dorsal route ganglia. Latent infection can then be established in the ganglia, with intermittent reactivation of the virus throughout the life of the macaque. In rare cases, viremia has been observed. Virus was also recovered from urine as well as multiple organs. Reactivation from latency has been observed in the natural host as judged by rising antibody titers as well as from recovery of virus by co-cultivation of sensory ganglia with cell monolayers.

During active replication of B virus in the natural host, isolation of virus can be readily accomplished from buccal, conjunctival, or genital mucosa swabs, predictable sites from which an alphaherpesvirus may be recovered during an active infection. The frequency of active infections within a seropositive group of macaques has been observed to be quite low, with relatively brief periods of excretion of virus from mucosal sites. Mucosal ulcers extend down to the papillary layer of the dermis. Two distinct zones have been described, namely a central area of necrosis and a surrounding zone of ballooning degeneration. Around the lesion, "normal" epithelium exists. An eosinophilic polymorphonuclear infiltration characterizes the histopathology of the lesion. Postmortem examination of monkey tissues from animals euthanatized at the time of active virus shedding shows histological evidence of perivascular cuffing of immune infiltrates in sections of spinal cord. Similar examinations of latently infected, healthy animals show no indication of virus from peripheral sites, but virus was recovered from sensory ganglia.

Experimental infections

Rabbits, mice, rats, guinea pigs and chickens have been experimental hosts of B virus as previously mentioned. Disease is not a uniform consequence following inoculation of B virus into mice and guinea pigs; however, several strains of B virus have increased virulence for the mouse. One strain, identified as E2490 was avirulent for white rats and chickens; nonetheless antibody developed after infection. Cotton rats infected by either intraperitoneal, subcutaneous, or intracerebral routes succumbed to infection with selected strains. Rats showed typical hind leg paralysis secondary to transverse meyelitis similar to symptoms in the rabbit. Reagan and colleagues selected, by serial passage human isolates of B virus, strains capable of infecting mice, hamster, and white chicks. With respect to experimental infections, a review of the literature suggests that the rabbit is perhaps the most useful small

animal model since virus replicates in rabbits to high titers, making it a particularly good model for testing antiviral agents.

Using the rabbit, as well as the mouse model, investigators have shown that virus dose was important depending on the route of inoculation. Experimentally infected animals given low doses of intradermal virus developed only erythema that disappeared within a few days and was not associated with further apparent symptoms. In contrast, animals receiving a larger dose developed a necrotic lesion that was generally followed by CNS invasion. B virus subsequently appeared in the regional lymph nodes late after infection. These nodes drained the area of initial infection and with time, necrosis of the infected nodes occurred, as seen upon post mortem. In the CNS focal lesions were seen in pons, medulla, and spinal cord. Spread was most often facilitated by travel through the peripheral nerves, but in rare cases hematogenous route of spread in experimentally as well as inadvertently infected hosts has been described.

Cervical spinal cord and medulla oblongata were the primary sites for virus recovery post mortem. With time post infection, virus was found in olfactory regions of the brain, which may have been due to movement of the virus centripetally through the nerves innervating nasal mucosa. Perivascular cuffing and glial infiltration were characteristic histopathology findings upon examination of brain tissue. Hepatic congestion was accompanied by infiltration of polymorphonuclear and mononuclear cells seen in the periportal areas of the liver. Scattered necrotic foci can be found throughout the lobes of the liver. The presence of inclusions was seen mainly in the regions of inflammation, around pyknotic or karyorrhetic hepatocytes. When lesions were present on skin in the foreign host, the depth of the involved tissue was significantly thicker than that found on mucous membranes, explaining perhaps the reason B virus was recovered weeks or months later from these sites in foreign hosts.

Development of animal models for studies of B virus have been limited by the lack of antiviral drugs or a protective vaccine designed specifically to treat or prevent this infection since there is grave concern for individuals about actively working with this neurovirulent virus should an accident occur even when BL-4 laboratories are available and appropriate protocols are in place.

Human infection

Human infection with B virus generally occurs through an occupational exposure to a macaque shedding virus at a site which comes into contact with broken skin or mucosal membranes. Several cases where no monkey contact occurred in years suggested that virus could be reactivated. Review of all confirmed cases of B virus in humans can be summarized as follows.

The most striking characteristic of human B virus infection is the involvement of the patient's CNS as a target of infection, specifically the upper spinal cord and lower brain.

These areas are the principal sites for virus replication as observed with clinical, laboratory, and post-mortem data, but initially the infected individual generally experiences a flu-like syndrome followed by numbness or parathesias around the site of inoculation. An ascending myelitis occurs during the final stages of the infection in humans, resulting ultimately in respiratory failure. Virus can be recovered at skin sites of inoculation for extended periods of time and viral DNA can be detected generally in cerebrospinal fluid by the time neurological symptoms are experienced. Antibodies can also be detected in the CSF. Generally, death is associated with respiratory complications. Cutaneous lesions, from which B virus can be isolated, sometimes develop late in infection. Edema and degeneration of motor neurons are prominent. Even with advancing disease Cowdry type A eosinophilic intranuclear inclusions can be found in only a few cases, and certainly not uniformly. Gliosis and astrocytosis are late histopathologic findings, thus, there can be evidence of myelitis, encephalomyelitis, or encephalitis, or combinations of each of these conditions.

Pathogenesis of B virus infection has been studied for each of the reported fatal cases and in some surviving cases. With fatal disease, generally, CNS lesions are localized within the upper cervical spinal cord, sometimes extending into the medulla and pons. In some cases hemorrhagic infarcts can be visualized in these areas, whereas in other cases damage appears minimal in spite of the fact that the patient generally succumbs after prolonged ventillatory support. In some cases, patients are alert, but paralyzed and in other cases patients remain in a comatose state which results in respiratory failure. Survivors have varying degrees of morbidity, seen, ranging from little-to-no sequelae to more severe, incapacitating sequelae. Some survivors experience slow progressive neurologic decline, whereas others report few if any effects long term. Several survivors have subsequently given birth to healthy babies with no ill effects for either the mother or infant. Monitoring of the vaginal canal for virus shedding in these individuals prior to delivery has been negative. In several reports, the ocular effects of B virus infection have been reported. Histopathological examination of the patient's eye revealed a multifocal necrotizing retinitis associated with a vitritis, optic

neuritis, and prominent panuveitis. A "herpes-like" virus was identified in the involved retina by electron microscopy in one case. Post mortem vitreous cultures taken from both eyes and retina have been positive for B virus. Thus, B virus can produce infection and destruction of retinal tissue similar to that of other herpesviruses. Ophthalmic zoster-like symptoms have been reported as well and in one particular case, reactivation of latent infection was speculated to have occurred.

To summarize human pathogenesis, the tissues and organs that become infected by B virus vary in some cases perhaps according to the route of infection. If skin is the primary site of infection, the virus usually, but not always replicates in the skin leading in some cases to localized erythema. Knowledge of the site of initial replication is useful for the development of guidelines for disease prevention and also for retrieval of a virus isolate that then allows unequivocal diagnosis. Subsequently, lymphangitis and lymph node involvement are observed. Viremia has not been proven to occur in humans, although with the application of more sensitive assays, e.g., polymerase chain reaction, further insights may be uncovered. With lymphatic involvement, the virus can spread abdominal viscera, where it has been isolated previously. Nevertheless, spread via neuronal routes is the fundamental route of transmission of the virus, as it is with HSV given the involvement of the spinal cord and CNS. Visceral organs, including heart, liver, spleen, lungs, kidneys, and adrenals demonstrate congestion and focal necrosis with variations in the extent of involvement from patient to patient. Recent human cases failed to demonstrate necrosis, but virus was isolated from adrenal, kidney, lung, and liver tissue collected at autopsy. In cases where B virus infection is suspected, medical personnel should follow published guidelines at the time of injury or observation of symptoms of possible infection.

Latency

A characteristic of all herpesviruses is the ability to become latent and reactivate when provoked with the proper stimulus. B virus is no exception. Reactivated infection has been described in both populations of macaques from the wild and captive established colonies. Unequivocal evidence of latent infection caused by B virus in macaques came with studies on frequency of recovery of B virus in monkey kidney cell culture systems. Wood and Shimada obtained six isolates from 650 pools of monkey kidneys, suggesting at least 1% of macaque kidneys contain latent virus that can be reactivated by culturing the cells. Virus was also isolated from rhesus tissues by Boulter and colleagues as well as by cocultivation from a variety of neuronal tissues including gasserian ganglia, trigeminal ganglia, dorsal route ganglia, and spinal cord. Latent virus was also isolated by cocultivation of tissues from experimentally infected rabbits, further supporting the rabbit as a potentially good animal model for B virus infections. Latency likely occurs in human infection as cutaneous recurrences have been documented and there are cases where an individual has not been in contact with macaques for years or even decades but antibodies exist at high levels.

As in HSV infections in humans, a prominent factor associated with reactivation of B virus in the macaque appears to be stress, particularly that associated with the capture and shipment of animals from the wild to captivity. Shedding of virus following reactivation also occurs with illness and during the breeding season of the natural host. No information is yet available on the state of the viral DNA during latency or on the molecular or biochemical events associated with the establishment and reactivation of latent virus.

Epidemiology

Animals

The majority of adult macaques and a very few younger animals in the wild have been reported to be seropositive for antibodies B virus. However, colonies of animals exist in the wild that have been found to be largely seronegative, but each of these colonies was established apart from original natural habitats to meet escalating needs of the scientific community and thus, the epidemiological pattern of virus infection was modified by human intervention. The high seroprevalence in macaques in the wild, the highly infectious nature within captive colonies, and low morbidity in this host confirmed the macaque as the natural host. More recent studies indicate that animals became infected at a higher incidence at the onset of puberty. The increased incidence appears to be associated with sexual transmission within the colony. Infants and juveniles have been reported to demonstrate a very low incidence of infection as judged by the low prevalence of B virus antibodies. Since antibody levels may reflect presence of maternal antibody in animals in contact with dams, it is of importance that both age groups are virus positive, suggesting transmission other than sexual activity occurs.

No particular species of macaque appears to be excluded as a natural host for B virus infection, although there is minimal data available from certain species and absent in

the case of others. Although presence of antibodies has been confirmed in the majority of the different species of macaques, there has been speculation that virus isolated from certain species is less neurovirulent or less neurotropic than virus shed by rhesus macaques. Differences in the restriction endonuclease profiles of the different isolates from different macaque species have been reported, but the lack of available data on the types of macaques involved with each of the documented human cases has not permitted rigorous evaluation of this hypothesis.

Virus shedding during either primary or recurrent infections has been noted to occur at unpredictable frequency with widely variable duration. Analysis of available data indicates that macaques shed virus for a longer duration during primary infection, and for short periods, even hours following reactivation. Levels of shed virus, as measured from mucosal swabs range from 10^2–10^3 pfu/ml in one diagnostic laboratory.

Humans

B virus is an infection that humans rarely contract, but when they do, nearly 80% of untreated cases result in fatality. Epidemiological analysis indicates B virus is usually acquired via zoonotic transmission from either a macaque or infected cells or tissues from the animal. There is, however, one documented case of transmission from human-to-human as previously described, supporting the assumption that B virus can be transmitted similarly to HSV-1 or HSV-2, through mucosal contact with virus which is sometimes present in secretions or wound sites. A recent fatal case which resulted from exposure of ocular membranes to virus from a monkey in the process of being transported refocused attention on an earlier report implicating this type of transmission in the epidemiological analysis of zoonotic transmission of the virus. Current analyses of cases suggest categorization of risk levels with regard to the severity of injury is not useful. The low incidence of B virus infection in humans makes it difficult to reach statistical conclusions, but analysis of cases occuring during the last decade support the fact that first aid of injured or contaminated sites plays a major role in infection control. Only minimal disruption of the protective skin layer or instillation directly to a mucosal membrane can result in initiation of infection when the site is exposed to viable virus. The level of virus needed to initiate an infection in humans remains unknown. Where data are available, rhesus macaques were most frequently implicated as the source of infectious virus in reported human cases, but alone this is insufficient to conclude that the rhesus is uniquely important in the establishment of zoonotic infections. Other species of macaques and even a baboon have been linked to fatal zoonotic infections.

The incidence of zoonotic infections has been correlated retrospectively with periods of increased usage of macaques particularly in biomedical research. Evaluation of past cases underscores that transmission of the virus is often associated with no more than a superficial scratch or puncture, suggesting that once virus gains entry into a host, the ability to initiate disease is perhaps dose independent, at least in some cases. However, this point remains unsubstantiated. Dose and route of entry are topics that require further study to clarify importance in zoonotic infection. Likewise, incidence and prevalence of zoonotic infections must be estimated cautiously since little data regarding the virus source is available from clinically recognized cases.

Host immune responses

Antibodies specific for B virus have been studied in both the natural and the foreign hosts by a wide variety of methods, including serum neutralization with or without complement, competitive RIA, multiple types of ELISA including competition ELISA, and western blot. Limited serial observations have been available from both the natural or foreign host, but comparison of available data have been useful in that relatively consistent responses are induced in both hosts. The time course over which antibodies develop has been measured in wild macaques, captive colony populations, individually imported animals, experimentally infected macaques, zoonotically infected humans, and even in vaccine trial recipients. The ELISA methodologies provide a rapid diagnostic tool with increased sensitivities of detection, and enhanced specificity when competition protocols are utilized. The antibodies which develop in response to herpes B virus infection in both humans and non-human primates are capable of neutralizing HSV-1 and HSV-2, as well as non human primate alpha herpesviruses. The HSV antibodies are not able to neutralize B virus, indicating the presence of virus specific antigens unique to B virus. Sequence data have been useful in confirming the existence of virus specific epitopes.

The humoral immune responses which develop after a B virus infection either in the susceptible host, either natural or foreign, had characteristic patterns of viral antigen recognition throughout the course of infection. The glycoproteins induced antibodies early in the course of infection. Antibodies began to appear within 7–10 days after the infection and consisted of IgM. Within 14–21 days after the onset of acute infection, IgG antibodies were present. In rare cases, the infected host remained persistently

antibody negative in spite of virus isolation. The pattern of the immune response was altered in the cases of humans who have had a previous infection with HSV-1 or HSV-2, since viral antigens that are shared among the three viruses induce an anamnestic response toward shared protein or glycoprotein sequences. Neutralizing antibodies develop in both the natural and foreign host, but at significantly lower levels than the foreign host. The nature and specificity of the humoral responses make it possible to design enhanced serological testing strategies to rapidly identify detectable antibodies and will provide the basis for future diagnostic strategies.

Clinical Manifestations of disease

Observation of the clinical pattern of disease is important for rapid diagnosis of B virus infection in both macaques and humans. In the natural host, recognition of early infection allows removal of infected monkeys from captive colonies that are being established as B virus-free. In B virus-free colonies, it is important to remove seropositive animals and isolate animals with equivocal results to prevent infection of other colony members, or in seropositive colonies to minimize risk to humans who have to handle them. Macaques are not treated with antivirals since the prevalence of infection is generally cost prohibitive. In the case of humans, early recognition of disease facilitates treatment with antivirals, principally nucleoside analogues, a course which appears to significantly lower the morbidity and mortality. Notably, immunosuppression, e.g., administration of corticosteroids, is often associated with reactivated mild disease in the natural host, whereas other agents appear to be capable of facilitating systemic B virus dissemination, culminating in death.

Humans exposed to herpes B virus demonstrate clinically variable signs of infection. Most often, illness after exposure to viable virus is apparent within days to weeks, but in some cases there appears to be a delay in development of acute disease. The reasons for this delay are unknown and, though rare, delays may even range from months to years, making diagnosis difficult. Once symptoms appear, the clinical progression is associated with relatively consistent symptoms, including flu-like illness, lymphadenitis, fever, headache, vomiting, myalgia, cramping, meningeal irritation, stiff neck, limb paresthesias, urinary retention with an ascending paralysis culminating in inability of the patient to maintain respiration, requiring ventillatory support. Cranial nerve signs, e.g., nystagmus and diplopia are also common to most published cases. Sinusitis and conjunctivitis have been observed in some. The array of symptoms may be related to the dose of virus with which the individual was infected or the route of inoculation. Summary descriptions of human cases can be found in two comprehensive reviews.

A summary of reported cases indicates that the highest percentage of deaths post infection occur within weeks postonset. In some cases however life was prolonged artificially for months or years. Incubation times from identifiable exposures to onset of clinical symptoms ranges from days to years, but the majority of cases occur within days to months. Virus has been recovered from throat, buccal, and conjunctival sites, as well as from lesions, vesicles, or injury sites as late as weeks to months post infection. The majority of clinical cases are associated with bites (50%), with fomites (8%) saliva (<5%), and aerosols described as other modes of exposure (10%).

Diagnosis

Non-human primates

B virus infection in macaques is identified by either virus isolation or the presence of specific antibodies or both. The neutralization assay dominated as a diagnostic tool in macaques and humans for many decades. The time required for the results of this test was often a drawback. The dot-blot, RIA, ELISA, and western blots were subsequently developed. Three of these techniques rely on the use of monoclonal antibodies. Each of these tests can be accomplished in less than a day, and are available through commercial laboratories as well as through a national resource laboratory subsidized through NIH's National Center for Research Resources. All of these assays utilize B virus infected cells for antibody detection, making them more effective than other types of assays which rely on HSV-1. This is a particularly important point with respect to diagnostic tools utilized to recognize early laboratory signs of infection for the establishment of B virus-free colonies. Currently, there are no diagnostic serologic tools to identify infected macaques that lack detectable antibodies; however, there are some promising assays being developed for diagnosis of HSV-2 infections in humans that may be adapted for identification of B virus infection in macaques. When selecting an assay for detection of antibodies, the sensitivity and specificity of the test for a specific species of macaque should be known and considered in the final evaluation of the results. Tests dependent on monoclonal antibodies or recombinant reagents should have defined sensitivity and specificity for each macaque species to be tested. Finally, evaluation of a macaque is optimal when

analysis is performed on multiple samples collected at different times, especially in cases when the antibody titer is low (<1:50). A constellation of different tests at numerous time points may be necessary in some cases to correctly determine the status of an animal with low antibody titers, particularly when such an animal is housed in a B virus-free colony.

Virus isolation is the gold standard for diagnosis of infected macaques. Unfortunately, virus isolation is not a particularly sensitive diagnostic tool, with the possibility of many false negatives. Nonetheless, standard cell culture for virus isolation is still a valuable tool for the colony manager and for the veterinarian. Virus positive cultures can be easily recognized with the unique cytopathic effect produced by B virus, but unequivocal confirmation of the identification requires either electrophoretic analysis of infected cell polypeptides or restriction endonuclease digested DNA. More recently, several PCR reactions have been described which can be used to verify the identity of the virus; however, this diagnostic tool is costly for colony management. Nonetheless, when a possible zoonotic infection must be confirmed, PCR may be beneficial for identification of B virus in macaques.

Other species of monkeys become infected infrequently with B virus. These are usually animals that have been co-housed or housed in close proximity to B virus infected macaques at some time. Since many, if not all non human primates harbor indigenous alpha herpesviruses, the important diagnostic point is to differentiate specific antibodies from cross-reactive ones. Euthanasia is generally advised in the case of a B virus infection in a non-macaque monkey since it is likely that the animal will succumb and, in the meantime, would pose a great risk to anyone attempting to treat the infection. B virus has been identified in the patas monkey, colobus monkey, and Debrazza and Thompson *et al.* (in press). In each case, there was a major concern for the people responsible for care of the animal, particularly since these animals often have severe morbidity and are shedding virus. Currently, the most effective assay for diagnosis of B virus in a non macaque monkey would be a competition ELISA to facilitate discrimination between specific and cross-reactive antibodies similar to the challenge faced when diagnosing infection in humans.

Humans

The evaluation of clinical symptoms associated with an antibody or virus positive case is the gold standard for diagnosis of B virus infection in an exposed individual. Both serological and virological techniques are available for diagnosis of B virus infected humans. The CDC has published specified guidelines for recognition and treatment of such infections. In the case of a suspected infection, several emergency resources are available. Contact with the CDC or the laboratories recommended in the CDC guidelines can expedite laboratory support for the clinician suspecting an infection. Generally, a rise in B virus specific antibodies over several days during acute infection can be used to the etiologic agent. However, in other cases, data are equivocal and decisions with regard to the patient must be based on a complex decision table collectively using all diagnostic tools, including clinical symptoms. Virus isolation is again the gold standard for diagnosis, however virus isolation is frequently not possible even under the best of circumstances. Serological diagnosis of B virus in humans is a complex task when an individual with a suspect infection has detectable antibodies as a result of a previous HSV-1 or HSV-2 infection. As discussed in a previous section, significant cross-reactivity exists among these viruses. In the absence of these cross-reactive antibodies, diagnosis is rapid and straightforward, with confirmation using the neutralization assay and/or western blot. This was not the case prior to the development of rapid diagnostic competitive ELISAs and RIAs. The diagnostic tests for humans are performed currently by only a few facilities that have been licensed and have access to BL-4 containment laboratories for the preparation of B virus antigen.

Virus identification can be accomplished by isolation using conventional cell culture, and in clinical emergencies with PCR. The identity of isolates should be confirmed by electrophoretic analysis of infected cell polypeptides or restriction endonuclease digested DNA. The application of PCR is most helpful in the symptomatic patient if virus cannot be recovered. PCR is also a useful tool for monitoring the efficacy of antiviral interventions.

Control of B virus infection

Multiple levels of prevention can be used to prevent B virus infection in both humans and non-human primates, ranging from attempts to eliminate virus to designing methods to work safely in environments where there is increased risk for contracting this agent. The CDC has published detailed guidelines for maximizing protection for individuals working with macaque monkeys. Further, the NIH's National Center for Research Resources has funded the development of B virus-free colonies for NIH-funded research involving these animals in attempt to ultimately eliminate this virus from colonies used for biomedical research. Nonetheless, B virus infected monkeys are plentiful and require

attentive handling adhering to strict guidelines, including barrier precautions.

When B virus is present, it can be inactivated with either heat or formaldehyde. Other inactivators include detergents and bleach. Individuals who work in a decontaminated area should still be alert to injury prevention. Minimizing fomites, however, decreases worker risk and reduces virus spread among animals. One B virus infection in a human was acquired from a cage after sustaining a scratch, underscoring that surface decontamination is important in infection control.

As early as the 1930s, attempts were made to identify an effective vaccine for protection of individuals who could be exposed to this virus while working with macaques or their cells or tissues. Limited vaccine trials were performed in human volunteers and although short-term antibody was induce, it was observed to wane quickly and the vaccine was not pursued further at that time. Recently, a recombinant vaccine was tested and found to induce antibodies in macaques, but the duration of antibodies and protection remain to be studied.

Antiviral therapy has been recognized as an effective prevention of infection progression in humans and animal trials as well, when administered sufficiently early after exposure. Acyclovir and the related family of nucleoside analogues were noted to be effective when given in high doses, e.g., acyclovir at 10–15 mg/kg three times daily for 14–21 days. Efficacy of therapy in cases of infection in humans has been monitored by inhibition of peripheral virus shedding in some cases and by reduction in CSF antibodies or viral DNA load in others. Ganciclovir has a greater efficacy in vitro and thus was used in all proven cases since 1989 with success. Interestingly, prior to 1987, in at least five retrospectively recognized cases, individuals fared well in the absence of antiviral therapy, but overall, the use of acyclovir and ganciclovir remains the recommended therapy by CDC. Generally, antiviral therapy is reserved for human with a clinically apparent infection, however it is also used by an increasing number of facilities for post-injury prophylaxis or after laboratory results indicate an animal may have been actively infected around the time of the exposure. Postinjury prophylaxis has been performed with famciclovir or valcyclovir, as well, both in that have demonstrated efficacy in vitro. Recommendations and guidelines have been published by the CDC, as discussed previously and can be readily accessed. Only a handful of physicians have had experience in the treatment of B virus zoonosis and their participation and expertise were important in the development of the CDC guidelines.

Finally, with respect to prevention, the value of wound cleansing following a potential exposure due to a bite, scratch, splash, or other suspicious injuries is very mandatory. Guidelines for wound cleaning are described in detail in the CDC Guidelines. Every institution working with macaques should have an injury protocol with immediate availability of first aid, a secondary care plan, and last but not least an infectious disease specialist who is a member of the institution's prevention and care response team.

Conclusions

B virus is usually a rapidly advancing, devastating disease which can be interrupted with effective use of antiviral therapies if deployed sufficiently soon after infection. The guidelines for treatment and prevention are widely published and can be rapidly accessed either through CDC or the diagnostic resource using the world wide web address www.gsu.edu/bvirus. Diagnostic techniques are rapidly improving to support clinical diagnosis and information regarding sample collection and evaluation is available at any time to clinical care centers in case of emergencies.

With the newer diagnostic techniques, sensitivity of detection is improving and the barriers posed by the high degree of cross-reactivity among this family of viruses are rapidly being diminished.

Because of the risk of human disease, precautionary methods must be followed in the workplace. Proper attention to the details of housing, management, handling of macaque monkeys, and organized exposure response measures using the CDC guidelines can minimize B virus zoonotic infections. Rapid identification of infection is essential for early inititation of antiviral drug therapy which can prevent further mortality associated with this very interesting alphaherpesvirus.

Simian varicella virus

Ravi Mahalingam[1] and Donald H. Gilden[1,2]

Departments of Neurology[1] and Microbiology[2], University of Colorado Health Sciences Center, Denver, CO, USA

Introduction

After primary infection (chickenpox) in children, varicella zoster virus (VZV) becomes latent in cranial, dorsal root and autonomic ganglia along the entire neuraxis and may reactivate decades later to produce zoster. The incidence of zoster and its attendant neurological complications is related to a natural decline in cell-mediated immunity (CMI) to VZV that occurs with aging, and which also develops in immunocompromised organ transplant recipients, and patients with cancer or AIDS. Yet the mechanism of reactivation and the cascade of events that are precipitated by impaired CMI to VZV are still unknown. To study such events require an animal model of varicella. While experimental animal models of latency and pathogenesis exist for closely related viruses such as herpes simplex types 1 and 2, VZV causes disease exclusively in humans. Thus, lack of a good animal model has hampered the studies of varicella latency and pathogenesis. Several attempts to produce disease by experimental inoculation of animals have led to seroconversion without clinical symptoms (Takahashi *et al.*, 1975; Myers *et al.*, 1980, 1985; Matsunaga *et al.*, 1982; Wroblewska *et al.*, 1982; Walz-Cicconi *et al.*, 1986). Subcutaneous inoculation of the Oka VZV (vaccine strain) into the breast of a chimpanzee has been shown to produce viremia and mild rash restricted to the site of inoculation (Cohen *et al.*, 1996). VZV DNA was detected in blood mononuclear cells (MNCs) of the chimpanzee during the 10-day incubation period. Mild varicella was observed resembling the low-level infection seen in some children vaccinated with VZV, but latency was not studied.

In contrast, simian varicella virus (SVV) causes a natural varicella-like disease of non-human primates. Herein, we describe the biology of SVV, its close similarity to VZV, and its usefulness as a model to study VZV pathogenesis and latency.

Simian varicella virus (SVV) is an alphaherpesvirus that infects Old World monkeys and causes a naturally occurring exanthematous disease similar to human varicella (White *et al.*, 2001). Epidemic outbreaks in African green or vervet (*Cercopithicus aethiops)*, Patas (*Erythocebus patas*), and various species of macaque (*Macaca sp.*) monkeys were first reported in the 1960s and 1970s at five primate centers in both the USA and UK. Virus isolated during these outbreaks was shown to be very similar to VZV in terms of its tissue culture characteristics (Soike *et al.*, 1984a). Clinical (Padovan and Cantrell, 1986; Myers and Connelly, 1992) (Fig. 58.1), immunological (Felsenfeld and Schmidt, 1977,1979) and pathological (Wenner *et al.*, 1977; Padovan and Cantrell, 1986; Dueland *et al.*, 1992) changes produced by SVV infection of primates are similar to those in human varicella. Like VZV, primary SVV infection causes viremia, and infectious virus can be recovered from blood MNCs (Clarkson *et al.*, 1967; Wolf *et al.*, 1974; Soike *et al.*, 1984a). Occasionally, rash becomes hemorrhagic and disseminated (Soike, 1992). Like disseminated varicella in immunosuppressed patients, lung and liver are the most severely affected organs (Roberts *et al.*, 1984). Histological examination of skin and viscera reveals foci of hemorrhagic necrosis, inflammation and eosinophilic intranuclear inclusions (Clarkson *et al.*, 1967; Wolf *et al.*, 1974). Like VZV, SVV becomes latent in ganglia at multiple levels of the neuraxis (Mahalingam *et al.*, 2002).

SVV reactivation has been observed in infected monkeys exposed to social and environmental stress (Soike *et al.*, 1984a). Both the 1968 and 1974 outbreaks of varicella in *Erythrocebus patas* monkeys at the Tulane National Primate Research Center, Covington, LA, were attributed to reactivation of SVV (Soike, 1992). SVV reactivation often appears as a whole-body rash in contrast to VZV reactivation in humans (zoster) which is generally localized to 1–3 dermatomes. Zoster in monkeys is often obscured by fur

Fig. 58.1. Vesicular rash on the abdomen of an African green monkey infected with simian varicella virus. (Reprinted with permission of *Ann. NY Acad. Sci.*)

and the duration of rash is generally less than one week. SVV has been isolated from skin vesicles after reactivation (Fig. 58.2) (Soike *et al.*, 1984a). Identical restriction enzyme profiles have been detected in the genomes of SVV isolated from primary infection and reactivation in the same monkey (Gray and Gusick, 1996). Neither VZV nor SVV has been isolated from blood of otherwise healthy, asymptomatic immunocompetent humans or primates.

Similarities between SVV and VZV

SVV and VZV encode antigenically related polypeptides, and SVV-specific antibodies cross-react with human VZV in serum neutralization and complement fixation tests (Felsenfeld and Schmidt, 1979; Soike *et al.*, 1987; Fletcher and Gray, 1992). Although VZV does not cause disease in non-human primates, it has been used to immunize and protect monkeys from SVV infection (Felsenfeld and Schmidt, 1979). To date, there is no evidence that SVV can infect or cause disease in humans. It seems likely that humans exposed to VZV are protected against SVV infection since nearly all adults in North America are VZV-seropositive and since VZV can protect monkeys from SVV infection.

Simian varicella virus genome

SVV is an enveloped, double-stranded DNA virus. The SVV genome is colinear (Pumphrey and Gray, 1992; White *et al.*, 1997) with that of VZV, sharing similarities in size and structure. The two virus genomes share 70–75% DNA homology (Davison and Scott, 1986; Gray and Oakes, 1984; Clarke *et al*, 1992; Gray *et al.*, 1992). The entire SVV genome has been sequenced, and analysis showed that SVV DNA is 124 784 bp in size, 100 bp shorter than VZV DNA, and its G+C content is 40.4% (Gray *et al.*, 2001, unpublished observations). The left end of the SVV genome contains a small segment (665 bp) that consists of 506 bp of unique sequences flanked on either side by 79 bp inverted repeats; part of this inverted repeat sequence (64 bp) is present at the junction of the long and short segments of the SVV genome. The unique short (U_S) component composed of a 4909-bp region bracketed by 7557-bp inverted repeats (IR_S). The entire short segment of the SVV genome (U_S+IR_S+TR_S) is 147 bp longer than its VZV counterpart. However, the unique short segment (U_S) is slightly shorter than that of VZV.

There are a total of 74 methionine-initiated open reading frames (ORFs) (Fig. 58.3). This includes 71 distinct SVV genes since 3 ORFs (69, 70 and 71) are duplicated within the

repeat regions. The gene organizations of the SVV and VZV genomes are similar if not identical. Of the 70 unique SVV ORFs, 68 share extensive homology with the corresponding VZV genes (Gray *et al.*, 2001). Several SVV genes, including thymidine kinase (Pumphrey and Gray, 1996), uracil DNA glycosylase (Ashburn and Gray, 1999), glycoproteins E (Gray *et al.*, 2001), B (Pumphrey and Gray, 1994), L and H (Ashburn and Gray, 2002) and C (Gray and Byrne, 2003), have been characterized either at the level of RNA or protein and shown to be very similar to their VZV counterparts.

A detailed comparison of the SVV and VZV sequences revealed several important differences at the leftward end (Fig. 58.4): (i) the left end of the SVV genome contains a 660 bp segment that consists of 506 bp of unique sequence flanked on either side by 79 bp inverted segments; (ii) an 879-bp ORF A and a 420 bp ORF (LE) in SVV that are absent in VZV. ORFA has 42% amino acid identity to SVV ORF 4 and 49% to VZV ORF 4; (iii) a 342-bp ORF B in SVV with 35% amino acid identity to a 387-bp ORF located to the left of ORF 1 on the VZV genome; and (iv) a 303-bp ORF in SVV with 27% amino acid identity to VZV ORF 1. No homologue of VZV ORF 2 was detected. Further, all of the known strains of SVV lack a VZV ORF 2 homologue (Mahalingam *et al.*, 2000). Transcripts specific for ORFs A and B have been detected in SVV-infected cells in culture and in acutely infected monkey ganglia. In vitro transcription-translation followed by immunoprecipitation of SVV ORF A showed that it encodes a 35-kD protein (Mahalingam *et al.*, 2000). Thus, the only major difference between SVV and VZV DNA is in the leftward terminus, possibly underlying the species specificity of SVV infection for monkeys.

The U_S of both VZV and SVV DNA invert, resulting in two major isomers of the virus DNA. A small (88-bp) repeat DNA segment brackets the U_L of VZV DNA. Like VZV, ~5% of SVV DNA molecules have an inverted U_L segment in productively infected cells. Further, the SVV genome exists either as circles or concatemers in SVV-infected cells (Clarke *et al.*, 1995), as also shown for VZV (Kinchington *et al.*, 1985). Like VZV, SVV and transfected SVV DNA produce a cytopathic effect in tissue culture, characterized by the formation of syncytia preceding cell lysis, a low virus titer and cell-associated virus (Soike *et al.*, 1984b; Soike, 1992; Clarke *et al.*, 1992).

SVV pathogenesis

Experimental inoculation of SVV in African green monkeys has generated two models of varicella infection. Intratracheal inoculation of 10^4 pfu of SVV into monkeys results in vesicular skin rash at 7–10 days post-infection (p.i.)

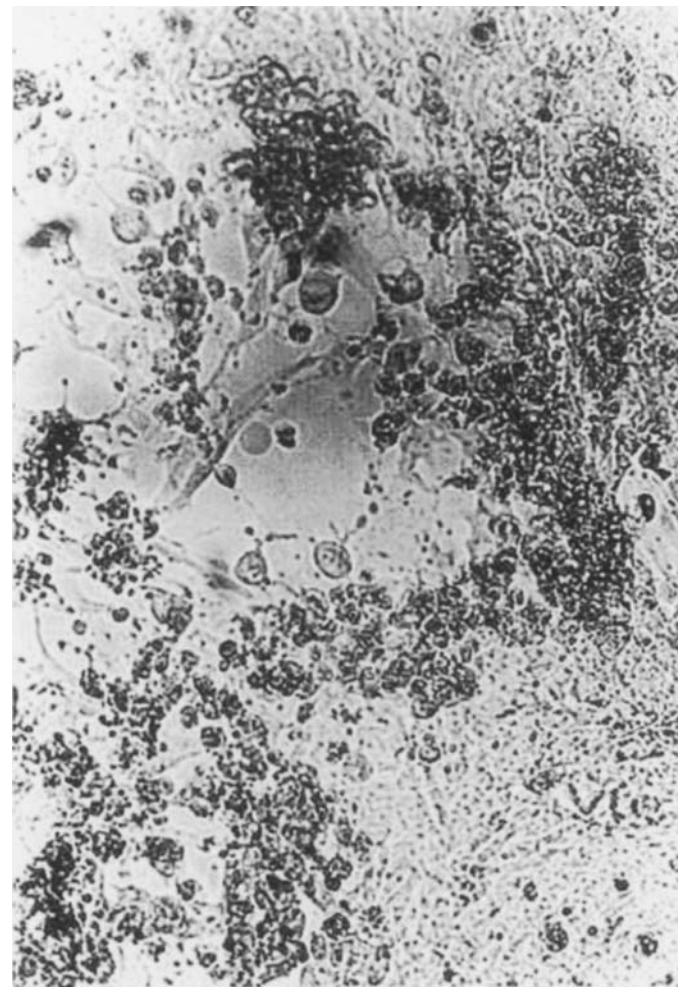

Fig. 58.2. Viral cytopathic effect resulting from infection of Vero (African green monkey kidney) cells using reactivated simian varicella virus isolated from monkeys. (Reprinted with permission of *Ann. NY Acad. Sci.*)

(Figs. 58.1 and 58.5). Viremia can be detected as early as 3 days p.i., peaking at ~5 days p.i., and disappearing by 11 days p.i., indicating hematogenous spread of the virus throughout the body. Hepatitis and pneumonia have been detected at the peak of rash, as suggested in Fig. 58.5. Induction of antibody responses by 12 days p.i correlates with the resolution of rash (Wenner *et al.*, 1977; Iltis *et al.*, 1982; Soike *et al.*, 1984a; Dueland *et al.*, 1992; Gray *et al.*, 1998; Gray, 2003). The time course and route of spread of SVV to ganglia in monkeys after intratracheal or intravenous inoculation was determined by analyzing DNA extracted from monkey tissues 5–60 days later (Mahalingam *et al.*, 2001). SVV DNA was detected in

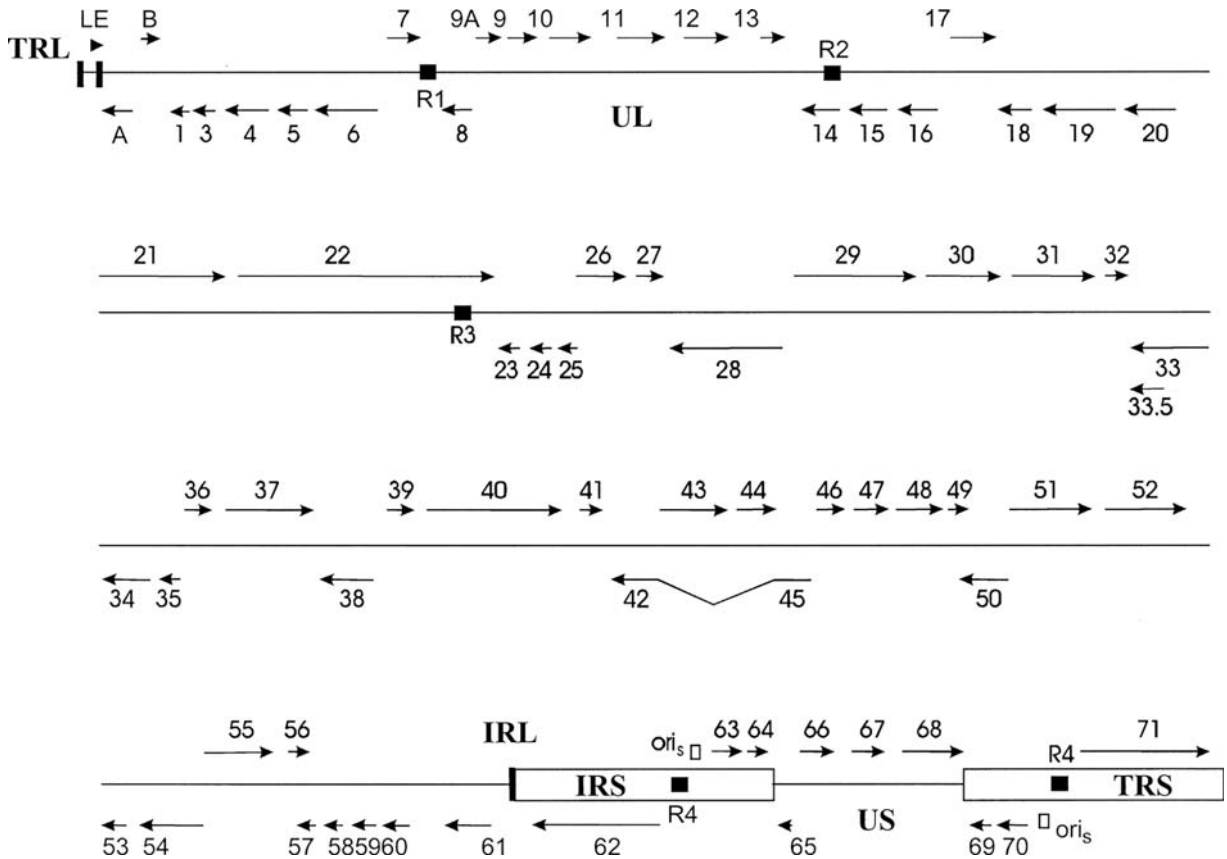

Fig. 58.3. Complete genome map of SVV. The unique long segment (UL) of the genome is flanked by 64-bp of inverted repeats (TRL and IRL). The left end of the SVV genome contains 665 bp segment that contains 506 bp of unique sequence flanked on either side by 79 bp inverted repeats; part of this inverted repeat sequence (64 bp) is present at the junction of the long and short segments (IR_L) of the virus genome. The unique short segment (US) is flanked by 7557-bp of inverted repeats (IRS and TRS). Arrows indicate the direction and location of the 73 SVV ORFS corresponding to the nomenclature conventions of VZV. Black boxes indicate the repeated sequences (R1, R2, R3, and R4). The putative origins of DNA replication (ori_s) are shown. (Reprinted with permission of Virology.)

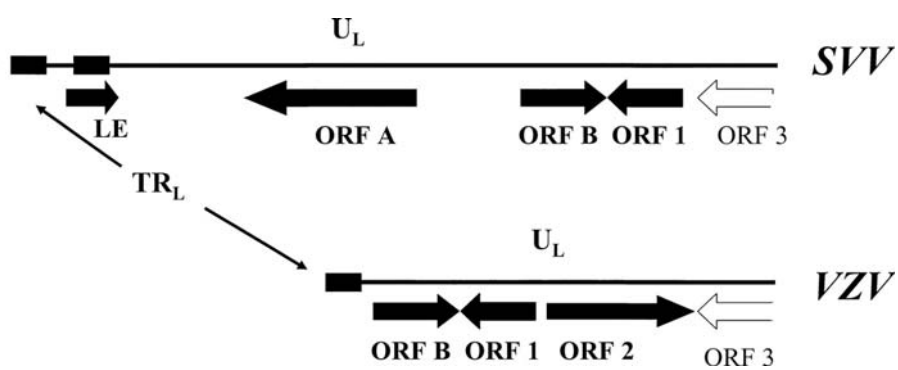

Fig. 58.4. Sequence organization at the leftward end of the SVV and VZV genomes. TR_L indicates the 64- and 80-bp of terminal repeat sequences located at the leftward end of the SVV and VZV genomes, respectively. U_L indicates the leftmost parts of the unique long regions of the virus genomes. SVV ORFs within the 3600-bp SVV EcoRI-I fragment and homologous to the VZV ORFs are shown. ORF B was assigned based on amino acid sequence similarity between SVV and VZV sequences upstream of ORF 1. ORFs LE and A are present in SVV but not in VZV, whereas ORF 2 is present only in VZV. (Reprinted with permission of *Virology.*)

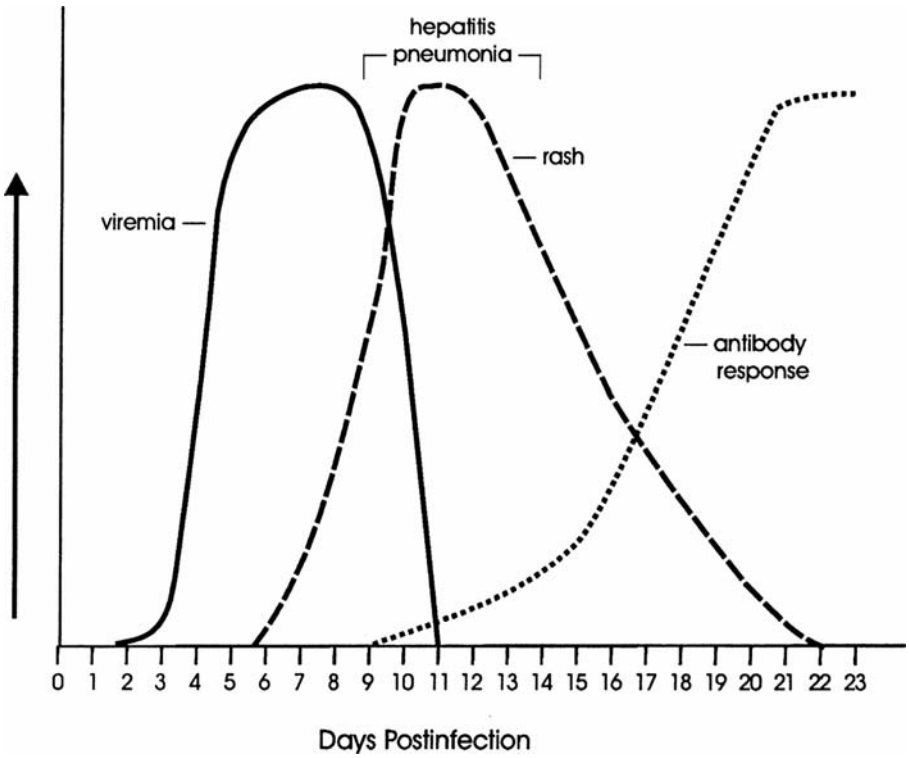

Fig. 58.5. Summary of the clinical course and pathogenesis of experimental SVV infection in monkeys. (Reprinted with permission of *J. Med. Primatol.*)

ganglia of monkeys sacrificed 6–7 days later (before rash). Intravenous inoculation produced more SVV DNA-positive ganglia (63%) than after intratracheal inoculation (13%), pointing to the role of hematogenous spread in ganglionic infection. Like other organs, monkey ganglia become infected with SVV before the appearance of rash (Mahalingam *et al.*, 2001). SVV-specific antigens and nucleic acids have been detected in liver, lung, spleen, adrenal gland, kidney, lymph node, bone marrow, and in ganglia at all levels of the neuraxis (Wenner *et al.*, 1977; Roberts *et al.*, 1984; Padovan and Cantrell, 1986; Dueland *et al.*, 1992; Gray *et al.*, 2002).

Further, experimental intratracheal inoculation of SVV in monkeys results in the persistence of virus DNA for months to years in several tissues, including ganglia, liver and blood MNCs (White *et al.*, 2002a). SVV DNA representing multiple regions of the viral genome has been detected in blood MNCs of SVV-infected monkeys at 7 days and 10 months p.i. (White *et al.*, 2002b), suggesting the presence of most if not all of the virus genome. SVV-infected monkeys that were sacrificed at 10 months p.i., had viremia during acute varicella and SVV may have persisted in blood MNCs. It is also possible that MNCs were being infected while trafficking through tissue where SVV DNA continued to be expressed. Multiple SVV-specific transcripts, including late transcripts, were detected in ganglia from these monkeys (Table 58.1), indicating viral DNA replication and possible assembly of infectious viral particles (White *et al.*, 2002a). Vero cells that were cocultivated with blood MNCs 14 months after intratracheal inoculation did not develop a cytopathic effect, and SVV DNA could not be detected after three subcultivations of Vero cells in tissue culture (White *et al.*, 2002b). It is not clear whether these results represent persistence of the SVV genome as a result of infection of MNCs during acute varicella, or an ongoing abortive infection of MNCs, but the latter appears more likely. In vitro attempts by several laboratories to infect MNCs with VZV have yielded mixed results, but suggest that these cells are only semipermissive for VZV (Arbeit *et al.*, 1982; Gilden *et al.*, 1987; Koropchak *et al.*, 1989; Soong *et al.*, 2000; Zerboni *et al.*, 2000). In all studies, VZV-specific DNA and proteins were detected in T and B cells, monocytes and macrophages, but infectious VZV was recovered primarily from T lymphocytes (Arbeit *et al.*, 1982; Koropchak *et al.*,

Table 58.1. Detection of SVV-specific transcripts in ganglia, lung or liver of virus-infected adult African green monkeys

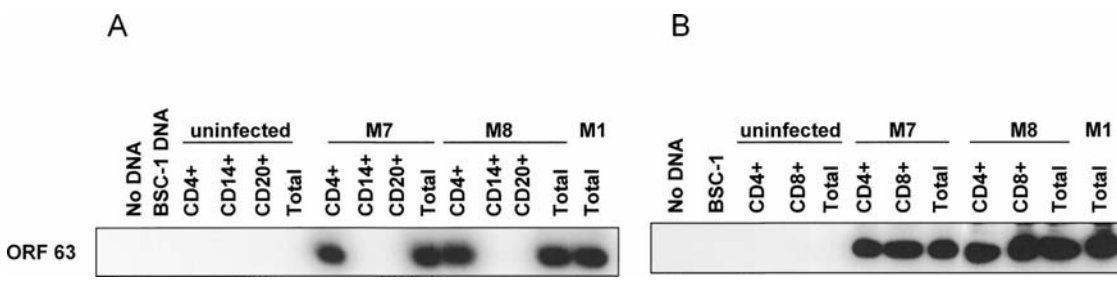

Fig. 58.6. Detection of SVV ORF 63-specific DNA in peripheral blood MNC subpopulations of SVV-infected adult African green monkeys. MNCs from an uninfected monkey and two SVV-infected monkeys (M7 and M8) at 14 months (a) and 23 months (b) after intratracheal inoculation with SVV were sorted by flow cytometry using (a) anti-CD4, anti-CD14 and anti-CD20 monoclonal antibodies and (b) anti-CD4 and anti-CD8 monoclonal antibodies. MNC DNA from the acutely infected monkey (M1) was used as a positive control. DNA extracted from the MNC populations was analyzed by nested PCR followed by Southern blot hybridization. SVV DNA was detected exclusively in $CD4^+$ and $CD8^+$ cells. (Modified and reprinted with permission of *Virology.*)

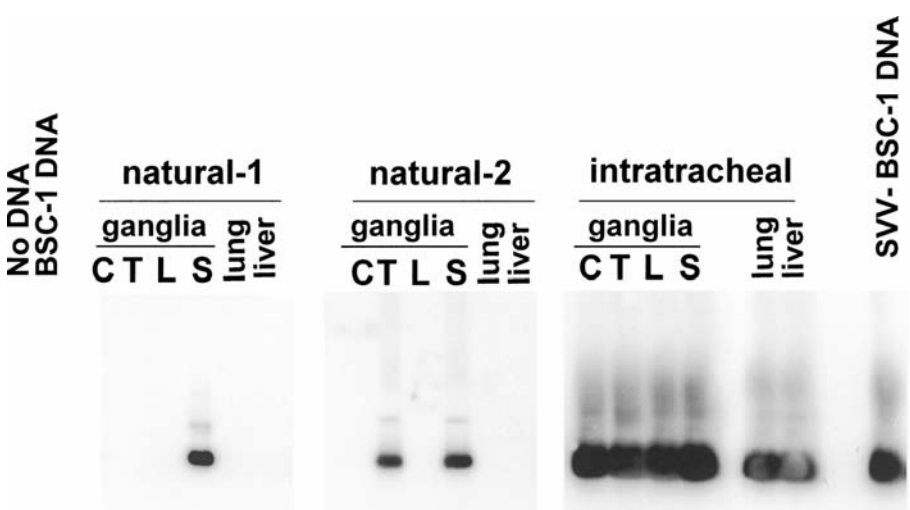

Fig. 58.7. Detection of SVV DNA in ganglia from monkeys naturally infected with SVV. DNA extracted from pooled cervical (C), thoracic (T), lumbar (L), and sacral (S) ganglia, lung and liver from two monkeys (natural-1 and -2) exposed to an intratracheally infected monkey (intratracheal) was analyzed by nested PCR using primers and probes specific for SVV ORF 63. DNA was omitted in one of the reactions (No DNA). DNA from uninfected (BSC-1 DNA) and SVV-infected BSC-1 cells in culture (SVV-BSC-1 DNA) was used as a negative and positive control, respectively. (Modified and reprinted with permission of *J. Virol.*)

1989; Soong *et al.*, 2000). At 14 months p.i., SVV-specific DNA was detected in CD4+ and CD8+ cells, but not in CD14+ or CD20+ cells (Fig. 58.6) (White *et al.*, 2002b). Detection of SVV DNA in blood MNCs likely reflects infection acquired while trafficking through tissue where SVV DNA persists.

The second model of SVV infection in African green monkeys is the simulated natural infection in which SVV-seronegative monkeys are exposed to monkeys previously inoculated intratracheally with SVV (Mahalingam *et al.*, 2002). As noted, monkeys given SVV by intra-tracheal inoculation develop a diffuse rash by 10–12 days after inoculation, and a mild rash also develops at 10–14 days in monkeys caged with the experimentally infected monkeys. SVV DNA is detectable in skin scrapings of the naturally infected monkeys, indicating that the disease is caused by SVV, although SVV DNA is detected only occasionally in the blood MNCs of these monkeys. Six to 8 weeks after the resolution of rash, SVV DNA is detected in multiple ganglia along the neuraxis but not in lung or liver (Fig. 58.7), indicating that latent infection is restricted to ganglia. This monkey model of SVV infection will, for the first time, allow analysis of the extent to which SVV is transcribed during latency and can also be used to dissect, at the molecular level, the cascade of cellular and immune factors in the reactivation process. This is important since VZV reactivation in elderly and immunocompromised individuals produces serious, often chronic and sometimes fatal neurological disease.

Primate betaherpesviruses

Peter A. Barry[1,2,3] and W. L. William Chang[1]

[1]Center for Comparative Medicine,
[2]Department of Pathology and Laboratory Medicine,
[3]California National Primate Research Center, University of California, Davis, CA, USA

The last few years have witnessed significant expansion of the simian cytomegalovirus (CMV) model of human CMV (HCMV) infection. Progress in the utilization of the simian CMV models has been highlighted by a better understanding of natural history, development of species-specific reagents and techniques, sequencing of several viral genomes, and generation of a bacterial artificial chromosome (BAC) containing a full-length CMV genome. This work has demonstrated that, not only is there strong conservation of genomic organization and coding content, but also that the simian CMV exhibit significant parallels to HCMV in the course of viral infection in both immunocompetent hosts and those without a fully functional immune system. A wide range of experimental approaches into the molecular biology of HCMV, mechanisms of HCMV persistence and pathogenesis, and the design of novel treatment and prevention strategies are now possible in different non-human primate (NHP) models.

Characterization of simian betaherpesviruses has been restricted almost exclusively to CMV. The single report that is consistent with the existence of human herpesvirus (HHV)-6/7-like viruses in non-human primates (NHP) is based on the amplification of a short DNA sequence with nucleic and amino acid homologies to DNA polymerase of HHV-6 and 7 (Lacoste *et al.*, 2000). In contrast, CMV has been isolated from multiple genera and species of old and new world NHP. Each simian species probably harbors its own variant of CMV that has co-evolved with its host during primate evolution. For this review, relevant examples are included from different NHP CMV to describe a monolithic simian CMV phenotype. However, comparative studies between different NHP CMV are extremely limited. There are likely to be important and, as yet, undiscovered variations between the different CMV isolates.

Natural history

Historical evidence of CMV in NHP

The earliest observations of CMV infection in NHP during the first part of the twentieth century were remarkable for their prescient descriptions of CMV–host relationships based entirely on microscopic characterization of the protozoan-like (cytomegalic) cells that had been previously noted in infant humans (Ribbert, 1904; Goodpasture and Talbot, 1921) and guinea pigs (Jackson, 1920). The first published report of NHP CMV occurred three years after Cole and Kuttner discovered that the salivary gland agent of guinea pigs was viral (filterable) in origin (Cole and Kuttner, 1926). In 1929, Stewart and Rhoads (Stewart and Rhoads, 1929) detected CMV cytopathology in tissues from the nasal passages of rhesus macaques (*Macaca mulatta*) acutely infected with poliomyelitis virus (PV). Although there was no PV-associated histopathology, they observed an "intracellular lesion [that] consisted of an acidophilic degeneration of the nuclear chromatin leading to the appearance strongly suggesting inclusion bodies." They also noted that "the lesion is not constant in all monkeys," but did recognize the lesion in the majority of monkeys examined. The lesions were frequently unaccompanied by any signs of a host inflammatory response. Covell extended these findings in 1931 by broadening the tissue distribution of the inclusion-bearing cells and articulating the low pathogenic potential of the probable virus. "I have encountered similar inclusions, not only in the situation mentioned by Stewart and Rhoads but, in addition, in the epithelial cells of the trachea, lungs and bile ducts. [That] such inclusions unaccompanied by symptoms in an animal like the monkey [are] caused by some virus of low virulence is a fair assumption." In 1935, Cowdry and

Scott made the seminal discovery that CMV could establish latency and reactivate from it. They observed that treatment of monkeys with irradiated ergosterol resulted in development of a large number of inclusions in the multiple tissues that were not seen in untreated animals. While it was concluded that ergosterol did not directly cause inclusion formation, the authors suggested that the treatment "may have activated or intensified a process already latent in the kidneys." Since the inclusions had the histological features of those described in humans and other species, they raised the "possibility of a virus being present in the kidney without any attention being called to it by any clinically recognizable symptoms of disease." The authors also concluded that "[the] association between persistence of inclusions and presence of active virus may be stressed."

Taken together, the earliest descriptions of the cytomegalic cells in NHP portrayed the probable virus as a ubiquitous infectious agent with low pathogenic potential that could establish persistent infections, reactivate from a latent state, and remain undetected in apparently healthy hosts. It was not until the first isolation of CMV from an African green monkey (AGM) (*Cercopithecine aethiops*) in 1962 (Black *et al.*, 1963), by one of the groups that had first isolated HCMV in 1956, that reagents became available to explore in detail the natural history and molecular biology of simian CMV.

Seroprevalence

Simian CMV has been described as "adventitious contaminants" during culture of primary simian cells (Smith *et al.*, 1969), a fact that is not surprising given the seroprevalence of CMV in colony-reared animals. Like HCMV, simian CMV is ubiquitous in NHP populations (Black *et al.*, 1963; Swack and Hsiung, 1982; Swack *et al.*, 1971; Andrade *et al.*, 2003; Eizuru *et al.*, 1989; Minamishima *et al.*, 1971; Kessler *et al.*, 1989; Blewett *et al.*, 2001, 2003). In breeding colonies of rhesus macaques, 50% of infants are seropositive by 6 months of age, and almost 100% are seropositive by 1 year of age (Vogel *et al.*, 1994). Similarly high rates of infection have been reported in NHP trapped in the wild, including AGM, rhesus and Japanese (*Macaca fuscata*) macaques, drill monkeys (*Mandrillus leucophaeus*), baboons (*Papio* sp.), and marmosets (*Callithrix jacchus*) (Eizuru *et al.*, 1989; Minamishima *et al.*, 1971; Blewett *et al.*, 2001, 2003; Nigida *et al.*, 1979; Ohtaki *et al.*, 1986; Jones-Engel *et al.*, 2006). The routes of transmission are not known. Virus is probably transmitted horizontally from mother to infant via breast milk and saliva, similar to identified modes in humans (Alford and Britt, 1993). Virus is also excreted in urine, adding another potential route of spread of the virus to naïve cohorts. There are no immunological or virological data indicating vertical transmission, although low rates cannot be excluded (Vogel *et al.*, 1994). Furthermore, there are no reports of spontaneously aborted monkey fetuses or neonates exhibiting histopathologic or clinical sequelae consistent with transplacental CMV infection. Rhesus macaques reach sexual maturity between 2.5 and 3 years, and virtually all breeding-age females are seropositive for rhesus CMV (RhCMV). Based on congenital HCMV infection rates in seropositive humans (Fowler *et al.*, 2003), transplacental transmission of CMV in NHP is likely to be rare ($\leq$1%).

The degree of CMV seroprevalence dramatically changes if animals are reared in smaller cohorts physically separated from seropositive animals. Efforts are underway at the National Primate Research Centers in the United States to develop breeding populations of macaques that are specific pathogen free (SPF) for herpes B virus (*Cercopithecine herpesvirus* 1), an alphaherpesvirus genetically related to herpes simplex virus (HSV) (Huff and Barry, 2003). SPF re-derivation involves separating the infant from the dam at birth, and hand rearing in a nursery. One offshoot of this program has been the recognition that the vast majority of infants are also seronegative for RhCMV and other endemic infectious agents. As long as the seronegative animals are segregated from CMV-infected monkeys, the animals remain CMV-free well past the age of sexual maturity (Minamishima *et al.*, 1971; Nigida *et al.*, 1979).

Multiple strains of CMV are present within each colony for each NHP species. Analyses of independent primary CMV isolates from naturally infected rhesus and Japanese macaques, AGM, and chimpanzee (*Pan troglodytes*) have shown that each isolate possesses distinct restriction fragment profiles (Eizuru *et al.*, 1989; Swinkels *et al.*, 1984; Alcendor *et al.*, 1993). Multiple strains have probably been introduced into each breeding facility by the importation of animals from different locations around the world and the occasional relocation of monkeys between breeding facilities.

Infection in immunocompetent hosts

Pathogenesis

Primary infection of healthy immunocompetent NHP, either by natural routes of exposure or experimental inoculation, does not result in overt clinical signs of disease. Since infection can naturally occur within the first months of life, simian CMV has low pathogenic potential, even in infants. Transient hematological changes, such as lymphocytosis, monocytosis, and, neutrophilia, are observed in

some rhesus macaques following intravenous inoculation, but not orally inoculated monkeys (Lockridge *et al.*, 1999). Mononucleosis is an uncommon but clinically important outcome of primary HCMV infection (Alford and Britt, 1993) that has not been associated with CMV infection in non-human primates. Recurrent infection is similarly unremarkable in terms of clinical outcomes. As noted above, the earliest postmortem descriptions of CMV in monkeys revealed that a large percentage of healthy animals had cytomegalic cells in the absence of overt disease (Stewart and Rhoads, 1929). The presence of the inclusion-bearing cells is now the exception. In recent years, inclusions have been rarely observed in tissues of immunocompetent monkeys. The reasons for this apparent change in frequency are not known, but may be related to improvements in colony management practices that may have reduced stresses in the animals. There is only a single description of recurrent CMV disease in NHP not associated with immunodeficiency or immunosuppression. Eight of 12 chimps euthanized in 1955 for a variety of clinical conditions were found to have characteristic CMV inclusions in the parotid and submaxillary glands (Vogel and Pinkerton, 1955). Three of the eight were further found to have CMV inclusions associated with focal to extensive areas of inflammation and necrosis in the adrenal cortex. One chimp also had a prominent myocarditis together with numerous cytomegalic cells. Although there was no evidence of immune suppression in these chimps, many were infected with *Mycobacterium tuberculosis* and enteric bacteria, which may have sapped their immune vigor, resulting in activation of CCMV.

Viral dynamics of primary infection

Since seroconversion begins long before the age of sexual maturity, primary infection most likely occurs via the oral mucosa following ingestion of virus-positive breast milk or saliva. The general course of primary infection involves rapid bloodstream dissemination from the site of infection to multiple tissues throughout the body. In monkeys naturally exposed to RhCMV, viral DNA can be PCR amplified from plasma coincident with the earliest detection of antiviral antibodies (these authors, unpublished). Although the time of exposure to virus can never be precisely defined in natural infections, the kinetics of CMV DNA in blood in relation to host immune responses suggest that spread of the virus through the blood is a normal component of early infection. This pattern of detection of viral DNA in plasma is recapitulated in experimental infections. Animals inoculated either intravenously (IV) or orally with RhCMV usually develop peak copy numbers of viral genomes in plasma at 7 days post inoculation, coincident with the development of anti-RhCMV IgM (Lockridge *et al.*, 1999). Monkeys inoculated IV with 10^5 to 10^6 plaque forming units (PFU) of RhCMV characteristically reach approximately 10^4 and 10^6 genome equivalents per milliliter of plasma within 5 and 7 days, respectively (Sequar *et al.*, 2002; Chang and Barry, 2003). Plasma CMV DNA levels decline after 7 days, although the rate of decline is variable between monkeys. Some become CMV DNA negative by 3 weeks post-inoculation, while others exhibit a more gradual decline with low copy numbers (1000/ml of plasma) present out to as long as 11 weeks. After its initial clearance, viral DNA is rarely detected in plasma. The presence of viral DNA or virus in the blood is not always observed with other forms of inoculation. Intraperitoneal injection of AGMCMV into rhesus macaques did not result in viremia, although the animals remained viuric for over two years (Swack and Hsiung, 1982). Similarly, subcutaneous inoculation of RhCMV efficiently results in systemic spread of virus, but RhCMV DNA is frequently undetectable in plasma (these authors, unpublished).

By the time CMV DNA is first amplified from plasma, the virus has probably disseminated throughout the body. RhCMV DNA can be detected in oral and genital swabs within two weeks of IV inoculation (these authors, unpublished) and in multiple tissues by 2 weeks (Lockridge *et al.*, 1999). Viral DNA is usually detectable in the spleen and frequently from axillary and inguinal lymph nodes, kidney, bone marrow, and liver (Lockridge *et al.*, 1999; Sequar *et al.*, 2002). In addition, the parotid and submandibular glands appear to be preferred sites after natural exposure to virus (unpublished). In acutely infected animals, lymphofollicular hyperplasia and neutrophilic splenitis are the most prominent histopathological changes observed in IV and orally inoculated animals (Lockridge *et al.*, 1999). Although no cytomegalic cells have been observed following experimental inoculation, cells expressing the viral immediate-early 1 (IE1) protein have been observed in the spleen of IV-inoculated monkeys (Lockridge *et al.*, 1999; Chang and Barry, 2003). The vast majority of antigen-positive cells following acute infection are localized to the perifollicular regions, with lower numbers of IE1-positive cells observed within the germinal centers or in the red pulp. The location of IE1-positive cells within the spleen changes over time such that, by 6 months, the majority of staining cells is within the red pulp.

Immunological parameters of primary infection

The development of viral-specific immune responses is rapid and increases in intensity as viral plasma DNA loads

decrease (Lockridge *et al.*, 1999). Antibodies to IgM become detectable 1 to 2 weeks post-inoculation (p.i.) and usually become undetectable by 4 to 8 weeks. Anti-CMV IgG develop 2 to 5 weeks p.i. and continue to increase for a period of 3 to 6 months. Neutralizing antibody titers follow the same kinetics as CMV-specific responses. Affinity maturation of antiviral IgG, measured as an increase in avidity, continues for a period of at least 6 months, even if antibody titers reached a plateau 3 months earlier. Antiviral antibodies are directed against multiple viral structural and non-structural antigens, although each monkey develops a distinct pattern of reactivity on western blots. Antibodies develop to glycoprotein B (gB) (Yue *et al.*, 2003) and the RhCMV equivalents of phosphoproteins (pp) 28, 65, and 150 (Yue *et al.*, 2006), as well as to other structural and non-structural proteins soon after infection (Vogel *et al.*, 1994). The region of RhCMV gB corresponding to the AD-1 region of HCMV gB is highly conserved and especially immunogenic (Kropff and Mach, 1997; Kravitz *et al.*, 1997), and can be neutralized by monoclonal antibodies specific to the AD-1 region of HCMV gB (Kropff and Mach, 1997). Analysis of gB-specific and neutralizing titers in rhesus macaques indicates that gB encodes a large proportion of neutralizing epitopes, but not all (Yue *et al.*, 2003). The NHP CMV encode all of the counterparts of the HCMV envelope glycoproteins (Davison *et al.*, 2003; Hansen *et al.*, 2003; Rivailler *et al.*, 2006), and some of these, such as gH and the gM/gN complex, may represent additional targets of neutralizing antibodies, similar to HCMV (Mach *et al.*, 2000; Urban *et al.*, 1996).

Cellular immune responses to total RhCMV antigens and to the IE 1 and 2, and pp65 proteins of RhCMV are detected as early as 2 weeks following experimental CMV infection in rhesus macaques and generally precede the onset of antibody responses (A. Kaur, unpublished data). The magnitude of the CMV-specific cellular immune responses increases with time and by 6 months to 1 year have reached levels comparable to those seen in naturally infected macaques. Cytolytic and cytokine-secreting $CD8^+$ T-lymphocytes specific to RhCMV IE1, IE2, and pp65 and the CMV-encoded interleukin-10 (cmvIL-10) are readily detected in long-term CMV-infected rhesus macaques (Kaur *et al.*, 2003; Pitcher *et al.*, 2002). A. Kaur, unpublished data). In addition, $CD8^+$ T lymphocyte-mediated cytolytic activity to an unidentified early protein presented by rhesus CMV-infected fibroblasts is detected in CMV-seropositive macaques (Kaur *et al.*, 1996). Although robust $CD4^+$ T lymphocyte responses to total RhCMV antigens are detected in the majority of CMV-seropositive macaques (Kaur *et al.*, 2002), the immunodominant target specificity of this response has not yet been determined.

Virological and immunological parameters of chronic infection

Two salient features characterize the persistent phase of infection: chronic viral shedding and stability of the antiviral immune responses. It has long been recognized that healthy, infected monkeys can remain viuric for many years following primary infection (Swack and Hsiung, 1982; Asher *et al.*, 1974). In a cross-sectional survey of three subspecies of colony-reared and wild-caught baboons, baboon CMV (BaCMV) was isolated from approximately 50% of the animals (Blewett *et al.*, 2001), a detection rate that is similar to colony-reared rhesus macaques (these authors, unpublished). For BaCMV, virus was isolated almost exclusively from saliva and throat swabs and only rarely from genital swabs or urine. Molecular techniques for the detection of RhCMV DNA have yielded similar results. In a longitudinal study involving repeated sampling, some monkeys had amplifiable RhCMV DNA in oral and/or genital fluids at multiple timepoints over a 30-day period (Huff *et al.*, 2003). A cross-sectional analysis of adult males indicated that approximately 50% were DNA-positive at any one time. In contrast to the clearance of CMV DNA from the blood within a few weeks, the presence of infectious virus and/or viral DNA in mucosal fluids demonstrates that there is active and ongoing virus replication at mucosal surfaces, probably for the life of the infected host.

Active viral gene expression at mucosal surfaces does not necessarily engender phenotypic changes or inflammatory responses at the site of infection. Antigen-positive cells can be detected occasionally by immunohistochemistry in tissues such as the spleen (Lockridge *et al.*, 1999) and salivary glands (these authors, unpublished data). What is especially noteworthy is that the tissues are frequently histologically normal, without any cellular infiltrate in response to viral antigen production. The level of viral replication is sufficient, presumably, to enable horizontal transmission to naïve cohorts, while at the same time minimizing tissue destruction and host immune responses. At the level of the infected host, therefore, it can be stated that CMV is a persistent virus because of the chronic, ongoing production of viral antigens and progeny virions. At the cellular level, however, CMV can clearly establish, maintain, and recrudesce from a quiescent state. Based on the high frequency of animals that shed virus and the social dynamics of NHP populations, seropositive animals should be regularly challenged with heterotypic strains of virus that may be immunologically distinct from the variant associated with primary infection. It is unknown whether prior immune responses restrict subsequent challenge following natural exposure. Seropositive monkeys can be reinfected

following experimental RhCMV inoculation with as little as 100 plaque forming units of a subsequent prolonged viuria of the challenge virus (L. Picker and J. Nelson, unpublished data).

The relatively constant exposure to CMV antigens (endogenous and exogenous) probably explains the pattern of antiviral immune responses observed in long-term infected monkeys. End-point IgG titers to total viral antigen preparations hover around the plateau level achieved at the end of the primary infection (Yue *et al.*, 2003; Baroncelli *et al.*, 1997). Although there can be a wide range of antiviral/neutralizing antibody titers and avidity indices observed amongst infected animals, only minor fluctuations occur over time within any one monkey. However, different results can be observed if antibody responses to individual viral antigens are assayed longitudinally. While antibody responses to gB usually parallel those to total RhCMV antigens, a minority of monkeys exhibit changes in gB reactivity while total antibody responses remain unchanged (Yue *et al.*, 2003). Cellular responses to RhCMV antigens also appear to be relatively stable over time. In one study, the frequency of $CD4^+$ T-cells secreting IFN-γ following stimulation with RhCMV antigens remained within a twofold range over a 6-month period (Kaur *et al.*, 2002). Similar to antibody titers, a wide range of CMV-specific $CD4^+$ responses occurs within a cohort of infected monkeys.

The stability of the virus-host relationship, exemplified by the absence of disease, places a relatively high immunological burden upon the infected host. One study of healthy, CMV-positive rhesus macaques observed that 0.16%–5.8% of total $CD4^+$ T-lymphocytes were CMV-specific (Kaur *et al.*, 2002). In a cross-sectional analysis of eight healthy CMV-seropositive macaques, 0.4% to 8% of peripheral $CD8^+$ T-lymphocytes were specific for CMV antigens (A. Kaur, unpublished data). Comparably high frequencies of CMV-specific memory T-cells have been observed in persistently HCMV-infected humans (Kern *et al.*, 2002; Gillespie *et al.*, 2000; Sylwester *et al.*, 2005). In contrast to humans, however, IE1 but not pp65, appears to be the dominant protein recognized by CMV-specific $CD8^+$ T-lymphocytes in rhesus macaques (A. Kaur, unpublished data).

Infection in non-immunocompetent hosts

Retroviral-induced immunodeficiency

The first published descriptions of fulminant CMV disease in NHP were in the context of rhesus macaques naturally coinfected with the immunosuppressive simian type D retrovirus (SRV). Beginning in the late 1960s and occurring through the early 1980s, periodic outbreaks of an acquired immunodeficiency disease were observed in macaque species housed at the California and New England Primate Centers (Henrickson *et al.*, 1984; London *et al.*, 1983; Henrickson *et al.*, 1983; Letvin *et al.*, 1983a,b; Osborn *et al.*, 1984; King *et al.*, 1983). The disease was characterized by persistent lymphadenopathy, severe wasting, chronic diarrhea, high morbidity and mortality, and multiple opportunistic infections, including activated CMV. Because of the strong immunological and pathological similarities between immunodeficient macaques and the emerging human AIDS, intense efforts were initiated to isolate the etiological agent of the so-called simian AIDS (SAIDS). The great majority of the SAIDS cases were due to the spread of SRV from healthy carriers that were unknowingly infected with this immunodeficiency-inducing virus. Subsequently, simian immunodeficiency virus (SIV) was isolated at the New England Primate Center from a few immunodeficient rhesus macaques that were free of SRV (Gardner *et al.*, 1994).

The presence of cytomegalic cells containing cytoplasmic and/or intranuclear inclusions in tissues from immunodeficient monkeys, often associated with tissue necrosis and neutrophilic infiltration, bore almost all of the hallmarks of CMV disease in human AIDS patients. The incidence of CMV disease in monkeys with SAIDS caused by SIV or SRV can be variable, but upwards of one-third to one-half of CMV seropositive animals exhibit evidence of CMV activation at necropsy (Kaur *et al.*, 2003; Osborn *et al.*, 1984; King *et al.*, 1983; Kuhn *et al.*, 1999; Baskin *et al.*, 1988). As with HCMV, simian CMV can produce end-organ disease in different tissues, including central and peripheral nervous system, lung, lymph nodes, liver, gastrointestinal tract, and arteries (Baskin, 1987). Depending on the thoroughness of sampling, CMV pathology can be detected within multiple tissues of an animal or may be limited to just a single site. To date, CMV retinitis has not been reported in a SAIDS monkey. A single published report describes the electron micrographic detection of herpesvirus-like particles within the eyes of two SIV-infected, RhCMV seropositive macaques (Conway *et al.*, 1990). The reasons for the absence of detectable CMV retinitis in monkeys are not known. They may be related to the relatively rapid onset of SAIDS (within 1–2 years of SIV or SRV inoculation) and the frequent early termination of experiments to spare the animals excess pain and suffering.

The activation of RhCMV infection during SAIDS pathogenesis is similar to that of HCMV during human AIDS and stands in marked contrast to the status of the virus

during persistent infection in immunocompetent hosts. In addition to the increased frequency of cytomegalic cells, other changes include an increased frequency of detectable viral DNA in blood, elevated genome copy numbers in tissues, and declining measures of anti-CMV immune functions, such as CTL activity, cytokine secretion, and neutralizing antibody titers (Sequar *et al.*, 2002; Kaur *et al.*, 2003). The magnitude and timing of the changes can be used to predict those animals most at-risk for developing RhCMV disease. The kinetics of these perturbations are variable, dependent, in part, on the relative timing of CMV and SIV infection.

If SIV infection occurs during the primary phase of RhCMV infection, the onset of RhCMV disease and SAIDS is both accelerated and more severe, compared to older monkeys that are persistently infected with RhCMV at the time of SIV infection (Sequar *et al.*, 2002). Five juvenile rhesus macaques inoculated with SIV two to four weeks after RhCMV infection (either experimental or natural exposure) died with SAIDS or with early lymphoid depletion within 10–25 weeks of SIV inoculation. Three of the monkeys required euthanasia between 10 to 15 weeks post-SIV and died with histological evidence of RhCMV disease in multiple tissues. Compared to controls infected with only RhCMV, all five coinfected animals had elevated RhCMV genome copy numbers in plasma and tissues at the time of necropsy. A different pattern of RhCMV infection emerges when the time interval between RhCMV and SIV infection is increased. When monkeys persistently infected with RhCMV are inoculated with SIV, the range in the time of death post-SIV is greatly extended (10 – >72 weeks) (Sequar *et al.*, 2002; Kaur *et al.*, 2003). One study observed that SIV-positive monkeys with histologically confirmed RhCMV disease have significantly shorter median time of death (17 weeks) than monkeys without RhCMV disease (57 weeks) (Kaur *et al.*, 2003). The same study also noted significant associations between the potential for RhCMV disease and changes in virological and immunological markers of RhCMV infection. Monkeys that had multi-organ disease due to reactivated RhCMV had large increases in RhCMV plasma DNAemia and lower neutralizing antibody titers at death, compared to the monkeys without histological evidence of RhCMV disease. In addition, there were significant reductions over time in RhCMV-specific $CD4^+$ and $CD8^+$ T lymphocytes in those animals with RhCMV sequelae. The declines in immune competence in these monkeys appear to have been specific to RhCMV. No significant correlations were observed between changes in anti-RhCMV antibodies and those specific to the rhesus rhadinovirus and lymphocryptovirus (related to the human herpesviruses, human herpesvirus 8 and Epstein–Barr virus -EBV, respectively) (Kaur *et al.*, 2003).

A second study has also observed that specific changes in parameters of RhCMV infection can be used to predict the occurrence of RhCMV disease in SIV-infected monkeys. Four of five animals with RhCMV sequelae exhibited at least two of the following characteristics prior to death: (a) either a failure to develop an increase in anti-RhCMV antibody avidity or a decline in avidity over time, (b) a progressive decline in anti-RhCMV antibody titers, and/or (c) prolonged detection of RhCMV DNA in plasma (Sequar *et al.*, 2002). Immunodeficient monkeys without RhCMV disease had no more than one of these characteristics.

Many papers published since the advent of HIV and AIDS have speculated on the role of HCMV in augmenting HIV pathogenesis (Drew *et al.*, 1985; Robain *et al.*, 2001; Peterman *et al.*, 1985; Webster, 1991). Studies of RhCMV and SIV coinfection are consistent with the notion that activated RhCMV can enhance progression to SAIDS (Sequar *et al.*, 2002; Kaur *et al.*, 2003). Rigorous experiments demonstrating a causal effect of RhCMV on SIV pathogenesis are still required. One study has noted a possible direct effect of CMV on HIV-1 infection in chimpanzees (Castro *et al.*, 1992). Two chimps seropositive for chimpanzee CMV (CCMV) were infected with HIV-1. PBMC cultures had been persistently negative for isolation of HIV over a 3–4-year period. After intrarectal and/or intravenous inoculation with CCMV-infected human fibroblasts, HIV was recovered from the PBMC from both chimps. One was positive for HIV isolation six times over a 12-month period, and HIV was recovered once from PBMC from the other chimp. Two chimps similarly treated with uninfected fibroblasts did not reactivate HIV.

Transplantation

The onset of CMV sequelae in NHP is not limited to immunodeficiency but can also be a factor in another clinically relevant parallel of HCMV pathobiology. CMV disease has been observed in immunosuppressed NHP receiving either allografts or xenografts, although the number of published descriptions is limited to date. The frequency of activated CMV appears to be related to the intensity of the immunosuppression regime. Xenograft recipients, such as either rhesus- or pig-to-baboon, that undergo treatments designed to prevent acute rejection (e.g., anti-thymocytic globulin – ATG) can develop CMV histopathology similar to HCMV disease in human allograft recipients, including pneumonitis and vasculopathies (Teranishi *et al.*, 2003; Mueller *et al.*, 2002; Ghanekar *et al.*,

2002). Prophylactic antiviral therapies common in human transplant recipients are not routinely employed in NHP studies. In the case of the pig-to-baboon xenograft, viral histopathology occurred only in the species-appropriate tissues; no cross-species disease was observed (Mueller *et al.*, 2002). The mechanisms of CMV reactivation in these studies are poorly defined, primarily because the studies were not designed initially to identify causal relationships to transplant-associated CMV disease. A potential association with recipient CMV serostatus was noted in one rhesus-to-rhesus renal allograft study (Pearson *et al.*, 2002). When monkeys were treated with antibodies to block the CD40/CD40 ligand signaling pathway, disseminated CMV disease was seen only in the CMV seronegative recipients ($n = 3$, seropositive donor), but not in 15 seropositive recipients.

Two early studies provide intriguing hints of potential stimuli for triggering reactivation of CMV. In the first study, CMV seropositive cynomolgus macaques were treated with a regimen of three immunosuppressive agents (ATG, cyclophosphamide, and cortisone acetate) given multiple times over 18 days (Ohtaki *et al.*, 1986). With this treatment protocol, 2 of 6 monkeys exhibited only a limited number of cytomegalic cells following necropsy 21 days after initiation of immunosuppression. If the animals were infected with varicella zoster virus (VZV) 3 days after the first immunosuppressive injection, 100% of the monkeys ($n = 11$) developed severe and systemic reactivation of CMV, similar in pathology to HCMV disease in human transplant recipients. CMV inclusions were observed in multiple tissues, and 50% of the animals developed pneumonia. Other tissues demonstrated evidence of CMV vasculitis, consistent with a critical role of the endothelium in simian CMV reactivation. None of the animals exhibited evidence of VZV disease. Similar rates of CMV reactivation were observed when immunosuppressed monkeys were injected with formalin-inactivated VZV, demonstrating that active VZV replication was not essential for the development of CMV lesions (Ohtaki *et al.*, 1988).

The utility of NHP as experimental models to study transplantation-associated CMV disease remains to be determined, based on the fact that the frequency of CMV disease in allograft and xenograft recipients is unknown. There are multiple examples in the literature of long-term studies of simian xenografts (>300 days post-transplant) occurring in the absence of clinical or histopathological evidence of reactivated CMV. Based on the transplant literature, it appears that the incidence of CMV disease in NHP is lower than in human allograft recipients. Whether this is due to sampling error or differences in reactivation potential following immunosuppression is unknown.

Immunosuppression associated with measles virus

CMV activation and disease can also be observed following viral, non-iatrogenic immunosuppression. Macaques are highly susceptible to infection by measles virus, a paramyxovirus that can induce temporary immunosuppression in non-SIV/SRV-infected monkeys (McChesney *et al.*, 1997; Willy *et al.*, 1999). Measles virus pathogenesis in NHP is similar to infection in humans, ranging from subclinical, to mild (skin rash), to fatal infection. Disseminated CMV infection (lung, lymph node, and stomach) has been detected in Japanese macaques that died of measles virus infection (Choi *et al.*, 1999).

Fetal Infection

RhCMV can cause a range of developmental and growth defects in rhesus macaque fetuses similar to those observed in human infants congenitally infected with HCMV. However, the published studies of CMV-induced fetal disease in rhesus macaques required direct inoculation of fetuses with virus in utero. Until transmission across the placenta can be demonstrated (either natural or experimental), fetal infection in NHP should be viewed as a model of intrauterine pathogenesis. Taking advantage of timed matings in NHP, it is possible to establish the time of conception to within two days (Tarantal, 1990; Tarantal and Hendrickx, 1988a,b). Using ultrasound guidance, needles can be directed through the abdominal wall of the dam to deliver virus to precise locations within the developing fetus at defined stages of gestation. Growth and developmental outcomes can be prospectively monitored by ultrasound, and fetal samples (blood, amniotic fluid, and tissue) can be obtained by needle biopsy (Tarantal, 1990; Tarantal and Hendrickx, 1988a,b).

Inoculation of rhesus macaque fetuses with RhCMV has been done via the intra-amniotic (IA), intracranial (IC), and IP routes from late in the first trimester through mid-gestation (Tarantal *et al.*, 1998; London *et al.*, 1986; Chang *et al.*, 2002). Severe developmental anomalies were observed in approximately 50% of inoculated fetuses, independent of the route of inoculation. Some fetuses, however, are developmentally normal even with inoculating titers as high as 10^6 PFU delivered in the late first trimester (Barry *et al.*, 2006). The developing CNS appears to be especially sensitive to CMV disease, with a spectrum of developmental abnormalities ranging from focal lesions to severe bilateral anomalies (Tarantal *et al.*, 1998; London *et al.*, 1986; Chang *et al.*, 2002). These include microcephaly, lissencephaly, ventricular dilatation, leptomeningitis, encephalitis, and periventricular calcifications, all

hallmarks of congenital HCMV infections. Some of the neuropathological changes, especially lissencephaly and microcephaly, are consistent with early insults to CNS development (Barkovich and Lindan, 1994; Hayward *et al.*, 1991; Twickler *et al.*, 1993). The periventricular zones and the choroid plexus are early targets for RhCMV infection following IC inoculation of RhCMV (Chang *et al.*, 2002). The systemic distribution of RhCMV-infected cells soon after IC inoculation supports the hypothesis that RhCMV readily crosses the blood–cerebrospinal fluid barrier to sites of susceptible neuronal stem cells and protoneurons. The cortical malformations observed in the inoculated fetuses may have resulted from an early cytopathic effect that initiated a cascade of defects in proliferation, migration, and organization.

Although RhCMV histopathology was limited to just the brain in one study (London *et al.*, 1986), other sequelae have usually been observed, including intrauterine growth retardation and systemic RhCMV disease (Tarantal *et al.*, 1998; Chang *et al.*, 2002; Barry *et al.*, 2006). Placental abnormalities (deciduitis, infarction, calcification, and lymphocytic infiltration) have been seen in some inoculated fetuses (London *et al.*, 1986).

Molecular biology

As more simian CMV sequences have become available on GenBank, it is now possible to extend the comparisons of their coding content and genetic organization with that of HCMV to include simian–simian analyses. In general, the strong parallels between the natural histories of the primate CMV are reciprocated at the structural and genomic levels, although important interspecies differences exist. An overarching issue in comparing CMV genomes is the consideration of what factors have driven adaptation of a CMV species to its particular host. Since viruses are obligate intracellular pathogens, CMV evolution is driven by virus–host interactions. Commonalities amongst and distinctions between primate CMV can be viewed as a reflection of the similarities and variations of selective pressures between the different but closely related primate hosts.

For any genetic element to be fixed within the population of any CMV species, it must have conferred a selective advantage during evolution from a progenitor CMV. This is equally applicable to both coding and non-coding portions of the genome. Regions of cross-species sequence identity, therefore, represent those domains where significant sequence divergence would produce a selective disadvantage. Conversely, highly divergent domains can be considered as focal points for evolutionary adaptation necessary to maintain optimal replication of the virus during host speciation. What might distinguish the macro- and microselective pressures between hosts is essentially unknown. Comparisons of CMV natural histories indicate that genetic changes have not come at the expense of altering the unifying concept of the CMV-host relationship. That is, CMV is a virus with low pathogenic potential that establishes a lifelong persistence in an immunocompetent host.

Virion structure

The basis for inclusion in the *Herpesviridae* family is the structural conservation of a linear double-stranded DNA genome packaged within an icosadeltahedral capsid (100 to 110 nm in diameter) composed of 162 capsomers. The nucleocapsid is surrounded in turn by a featureless tegument and a viral glycoprotein-studded envelope (Roizman and Pellet, 2001). By definition, the simian CMV adhere to this rule, and they exhibit little structural distinction from HCMV (Fig. 59.1). Mature virus particles and distinct capsid forms are observed by electron micrograph in infected cells. The variant capsid structures include the A (empty capsid, no DNA), B (scaffolding proteins but no DNA), and C (mature capsids containing DNA) forms characteristic of HCMV and HSV (Blewett *et al.*, 2001, 2003; Lee *et al.*, 1988). The RhCMV virion is identical in size to that of HCMV (220–230 nm), whereas those of BaCMV and drill CMV are slightly smaller (140–230 nm) (Blewett *et al.*, 2001, 2003). The range in sizes of these latter two simian CMV species is apparently due to variability in the size of the envelope. Similarly, the B-capsid form of AGMCMV is almost identical in size (inner radius = 49.5 nm) with that of HCMV (50 nm). Density mapping of the AGMCMV B-capsid demonstrates that the architecture (i.e., T = 16 triangulation geometry, capsomer shape, and intercapsomer triplexes) is strongly conserved with other herpesviruses (Trus *et al.*, 1999; Butcher *et al.*, 1998; Chen *et al.*, 1999). Some distinctions in structure have been observed between the cytoplasmic forms of the B capsid of AGMCMV and HCMV, although the differences may have resulted from the loss of some protein constituents during purification (Trus *et al.*, 1999; Chen *et al.*, 1999).

Genome coding content

The genomes of the RhCMV (Hansen *et al.*, 2003; Rivailler *et al.*, 2006) and CCMV (Davison *et al.*, 2003) genomes have been fully sequenced and described in the literature, as have selected regions of the AGMCMV genome. A partially completed sequence of BaCMV has been deposited on GenBank (AC090446), although there has been no published analysis of it, yet. There has been strong conservation of coding content, nucleotide and amino acid sequences,

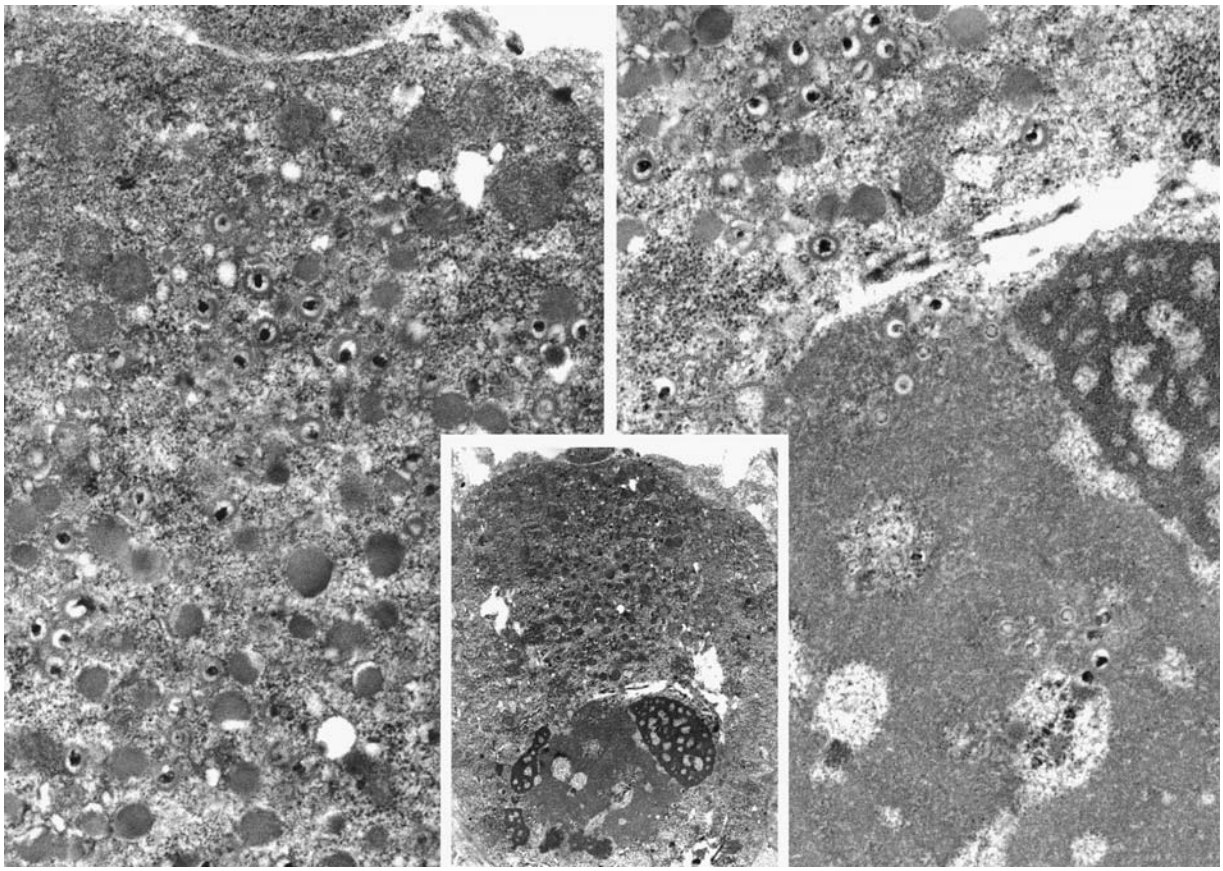

Fig. 59.1. Electron micrographs of RhCMV virions in a cochlear cell of a rhesus macaque fetus. A rhesus macaque fetus was inoculated intracranially with RhCMV strain 68–1, and the cochlea was removed and processed for electron microscopy 25 days later (S. Tinling, A. Tarantal, P. Barry, unpublished). A low magnification (center) and two high magnification (right and left) images of a cytomegalic cell of unknown type are presented illustrating nuclear and cytoplasmic forms of the RhCMV capsid and virion, respectively.

and linear genetic order amongst the primate CMV following the divergence and speciation of their hosts. Noted distinctions are observed, however, between the primate CMV. These include the selective addition (or loss) of genes within one CMV genome relative to the others, and the high rate of interspecific (but not necessarily intraspecific) sequence variation of some viral proteins that bind to highly conserved cellular proteins.

The coding content of HCMV is still open to debate 13 years after the original analysis of the AD169 sequence predicted 208 ORF (Chee *et al.*, 1990). One recent study compared potential ORF of HCMV and CCMV reasoning that legitimate coding regions would likely have been conserved between viruses isolated from the two most closely related primate hosts. This led to the recognition of 145 ORF in the tissue culture adapted AD169 strain of HCMV, 164–167 in wild-type HCMV, and 165 in a CCMV strain that was isolated from an adult chimp (Davison *et al.*, 2003). A subsequent study, using an algorithm that evaluates coding potential by looking for pattern relationships of HCMV amino acid sequences to the Swiss-Prot/TrEMBL database of proteins (Murphy *et al.*, 2003a), predicted that AD169 encodes 192 proteins. Finally, comparisons of clinical isolates of HCMV with each other and with tissue culture adapted strains have led to the conclusion that there are 252 ORF in clinical isolates, almost 30 of which have not been described before (Murphy *et al.*, 2003b).

The vast majority of ORF in HCMV have counterparts in the CCMV and RhCMV genomes. Two RhCMV genomes have been sequenced and annotated. One sequence (GenBank accession number AY186194) was derived from purified virion DNA of a low passage strain (68-1, available from ATCC) that had been cultured on primary rhesus fibroblasts (Hansen *et al.*, 2003). The other sequence (GenBank

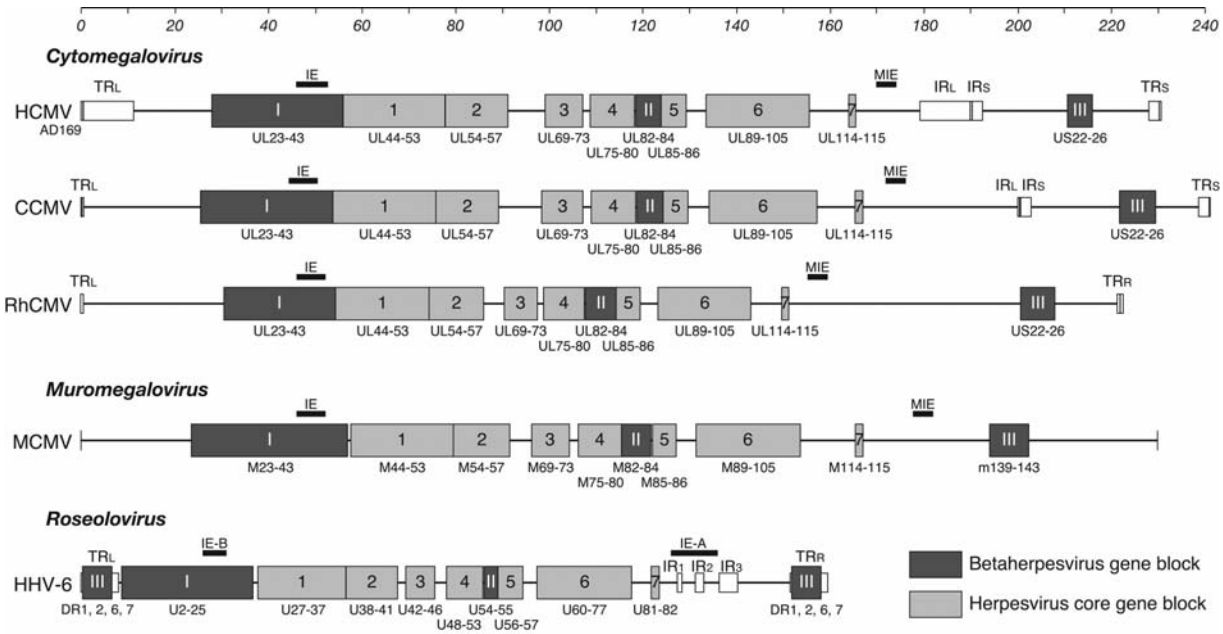

Fig. 59.2. Schematic illustration of the genome structure and gene arrangement of representative viruses comprising the Subfamily *Betaherpesvirinae* and two non-human primate CMV. The size scale at the top is shown in kbp. The horizontal lines represent unique regions of the viral genomes. Open rectangles represent reiterated sequences in the viral genomes. TRL, IRL, IRS, and TRS denote terminal or internal inverted repeats flanking the UL and US components, respectively. For RhCMV and HHV-6, TRL and TRR denote terminal direct repeats at the left and right termini of the viral genomes, respectively. Filled rectangles represent sequence blocks consisting of genes in similar orientation and/or encoding homologous amino acid sequences. The sequence blocks of conserved core genes among the herpesvirus family (block 1 though 7, shown as light grey rectangles) and conserved genes found only in betaherpesvirus subfamily (block I through III, shown as dark grey rectangles) are diagrammed. Corresponding ORF within each conserved gene block are listed. The locations of two complex IE loci within each viral genome are marked with black bars. Gene nomenclature and location are from the following references: HCMV AD169 (Davison *et al.*, 2003; Chee *et al.*, 1990), CCMV (Davison *et al.*, 2003), MCMV (Rawlinson *et al.*, 1996), and HHV-6 (Gompels *et al.*, 1995). The nomenclature for RhCMV genes (Hansen *et al.*, 2003) is based on the layout shown in Fig. 59.3(b).

accession number DQ120516) corresponds to a RhCMV (strain 180.92) isolated from an SIV-infected macaque that had been passaged six times in human fibroblasts and seven times on rhesus fibroblasts (Rivailler *et al.*, 2006).

The 68-1 strain, first isolated in 1968 (Asher *et al.*, 1974), contains a 221 459 bp genome that potentially encodes 230 ORF of 100 or more contiguous amino acids, each of which possesses a translation initiation codon (Hansen *et al.*, 2003). Some of the RhCMV ORF have no apparent equivalent in the HCMV and CCMV genomes, and it is not known whether they represent expressed genes. The total of 230 RhCMV genes should be considered provisional at this point in time and subject to reinterpretation with subsequent analysis. The 180.92 strain genome (215,678 bp) potentially encodes 258 ORF and includes 8 additional ORF not found in 68-1 and 34 ORF that were not listed in the characterization of 68-1 (Rivailler *et al.*, 2006). The 180.92 strain lacks 10 ORF that are present within the 68-1 genome. Expression analysis has not been performed to determine whether the potential ORF are, in fact, expressed. Whatever the final tally, it is evident that evolution of RhCMV in its rhesus host has resulted in coding capacity not found in either HCMV or CCMV (described below).

Importantly, the sequences of both the 68-1 and 180.92 genomes are consistent with the interpretation that there have been deletions and rearrangements during in vitro passage. Comparison of the 180.92 sequence with that of 68-1 (Rivailler *et al.*, 2006) led to the recognition that there is a discontinuity between the genomes within the portion of the genome corresponding to the ULb′ region of HCMV. ULb′ represents a labile region of the HCMV genome that is deleted and rearranged during tissue culture adaptation, such that the intact sequence is found in clinical isolates of HCMV and not in strains that have undergone extensive passage in vitro. The fact that there is the same lability within the corresponding region of the RhCMV genome

indicates that deletion and rearrangement can occur within a limited number of serial passages in tissue culture.

Genome structures

A hallmark of herpesvirus genomes is the conservation of its sequence organization. Based on the copy number, location, and orientation of repeat elements, herpesviral genomes can be grouped into six classes, designed A to F (Roizman and Pellet, 2001). Three types of genome structure have been identified in the members of *Betaherpesvirinae* (Fig. 59.2). HCMV and CCMV possess a complex type E genome, consisting of two unique components (UL and US), each flanked by inverted repeats RL and RS, respectively (Davison *et al.*, 2003). The size of CCMV repeat elements flanking the UL component (TRL and IRL) is considerably smaller than the AD169 and Towne strains of HCMV, but is similar to those of Toledo and low-passage clinical isolates (Prichard *et al.*, 2001). The RhCMV, AGMCMV, and BaCMV genomes each consist of one unique sequence with no internal repeat elements subdividing the genomes into two components (type F genome) (Chang and Barry, 2003; Hansen *et al.*, 2003; Hayward *et al.*, 1984; Rivailler *et al.*, 2006) (E. Blewett, unpublished data). The RhCMV genome contains a 750-bp sequence element from the left end of the genome variably repeated ($0 - \geq 4$) at the right end of the genome (predominantly one or two copies) (Chang and Barry, 2003), similar to the termini of the guinea pig CMV (GPCMV) genome (McVoy *et al.*, 1997). The RhCMV genome does not undergo genome inversion at the junction between the UL and US genes (Chang and Barry, 2003).

Gene arrangements

Based on the completely sequenced betaherpesvirus genomes (Davison *et al.*, 2003; Hansen *et al.*, 2003; Chee *et al.*, 1990; Nicholas, 1996; Cha *et al.*, 1996; Gompels *et al.*, 1995; Rawlinson *et al.*, 1996; Vink *et al.*, 2000), there are several fundamental principles of betaherpesvirus genetic architecture (Fig. 59.2). These relate to the extent of genetic conservation amongst the herpesvirus family members. Primate CMV genes can be grouped into those present (a) in all herpesviruses, (b) only in betaherpesviruses, and (c) only in primate CMV. Genes in CCMV have been named based on their sequence and positional homology with HCMV (Fig. 59.3(a)) (Davison *et al.*, 2003). Both murine and rat CMV (MCMV and RCMV, respectively) exhibit a simple genome structure (type F) with ORF colinear only to the UL region of HCMV genome (Fig. 59.2). The nomenclature for MCMV and RCMV ORF numbers them from the left to the right end of the genome (Rawlinson *et al.*, 1996; Vink *et al.*, 2000). The numbers of the homologous ORF are arranged to be congruent with the HCMV numbering system for the UL region. ORF with sequence homology to HCMV ORF are indicated by uppercase prefixes (M or R), whereas those not conserved in HCMV genome are designated with lowercase prefixes. As described by Hansen *et al.* (2003), RhCMV genes are sequentially numbered beginning at the first ORF at the left end of the genome. To emphasize the higher level of genomic colinearity between members of Genus *Cytomegalovirus* for this review, RhCMV ORF are designated according to their HCMV homologues (Fig. 59.2 and 59.3(b)). The original designations (Hansen *et al.*, 2003) are also presented in Fig. 59.3(b).

The core genes inherited from the herpesvirus family progenitor are located within seven core-gene blocks in the central region of the viral genome (Fig. 59.2) (Roizman and Pellet, 2001). Core genes include those encoding proteins involved in nucleic acid metabolism, DNA replication, and virion structure and maturation (Table 59.1). Sequence analysis of the 68-1 strain of RhCMV did not identify a full-length UL71 gene due to the presence of an apparent single base insertion (Hansen *et al.*, 2003). However, a highly conserved UL71 ORF is present within BaCMV (AC090446; E. Blewett, unpublished data) and the 180.92 RhCMV isolate (Rivailler *et al.*, 2006), although both predicted peptides are shorter than the UL71 of either HCMV or CCMV. The UL22-33 block of genes was originally considered to be betaherpesvirus-specific (Roizman and Pellet, 2001). Analysis of the HCMV and CCMV genomes has led to the recognition that the UL22 ORF does not represent a true gene (Davison *et al.*, 2003). With more betaherpesvirus sequences now available, betaherpesvirus-specific gene blocks (beta-blocks) can now be expanded to include UL23-43 (block I), UL82-84 (block II), and US22-26 (block III) (Fig. 59.2). These gene clusters are retained in the viral genomes across all three genera of *Betaherpesvirinae* with identical order and polarity along with the core-gene blocks, except that beta-block III is within the direct repeat regions of HHV6/7 and at the left end of the tupaia herpesvirus genome (Bahr and Darai, 2001). Included within these are three unique gene families (UL25, UL82, and US22) and one G-protein coupled receptor (UL33) that have no counterparts in the genomes of alpha- or gammaherpesviruses. In addition to the seven pan-herpesviral core gene blocks and three beta-blocks, two complex IE loci are positionally preserved within the betaherpesviral genomes with high similarity in both structures and splicing patterns (Davison *et al.*, 2003; Nicholas, 1996; Rawlinson *et al.*, 1996; Colberg-Poley *et al.*, 1992; Chang *et al.*, 1995; Barry *et al.*, 1996; Nicholas, 1994; McCormick *et al.*, 2003; Schiewe *et al.*, 1994) (Fig. 59.2).

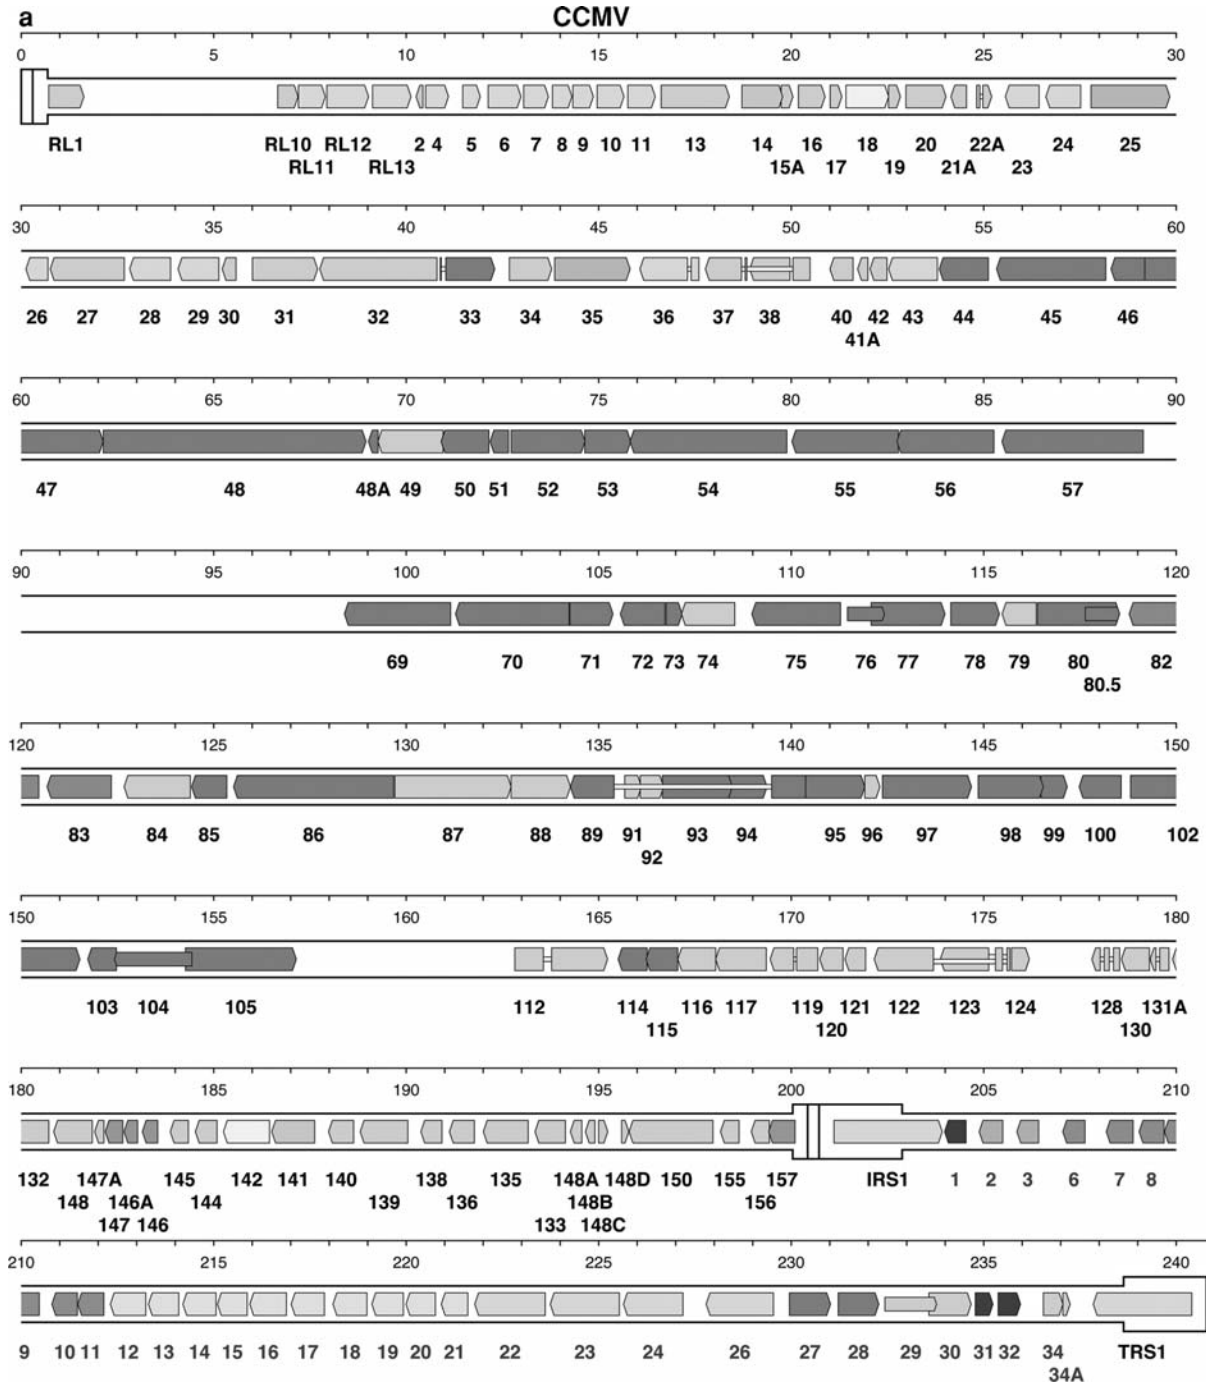

Fig. 59.3. Layout of the genes in the (a) CCMV and (b) RhCMV genomes. The size scales are in kbp. Reiterated sequences (TRL, IRL, IRS, and TRS of CCMV; TRL and TRR of RhCMV) are shown in a thicker format than the unique components of the viral genomes. Colored arrows with gene nomenclature listed below denote the order, orientation, and gene family (grouped according to the key) of predicted protein-coding regions within each viral genome. Narrow white bars represent introns connecting the coding exons. The prefixes of genes corresponding to those in HCMV UL region (shown in black text) and US (shown in blue text) have been omitted. Genes corresponding to those in HCMV AD169 RL and RS regions are given their full nomenclature. Colors differentiate between conserved core genes in the Family *Herpesviridae* with subsets of non-core genes, grouped into unique gene families, conserved in Subfamily *Betaherpesvirinae*, or Genus *Cytomegalovirus*. The nomenclature system for HCMV and CCMV genes is applied to the homologous genes within the RhCMV genome. The RhCMV ORF originally described in Hansen *et al.*, 2003 are listed within each colored arrow. RhCMV ORF with no apparent HCMV homologue are not listed in this figure and can be found in the original manuscript. [a]UL83−1 and UL83−2, respectively.

[b]UL18 and 111A homologues not present in RhCMV and CCMV, respectively.

Accession numbers for amino acid identities: BK000394 (HCMV AD169), AF480884 (CCMV), and AY186194 (RhCMV). Amino identities were determined using the GAP program (Scoring Matrix: Blosum62, Gap creation penalty: 8, Gap extension penalty: 2) of SeqWeb® (version 2, San Diego, CA).

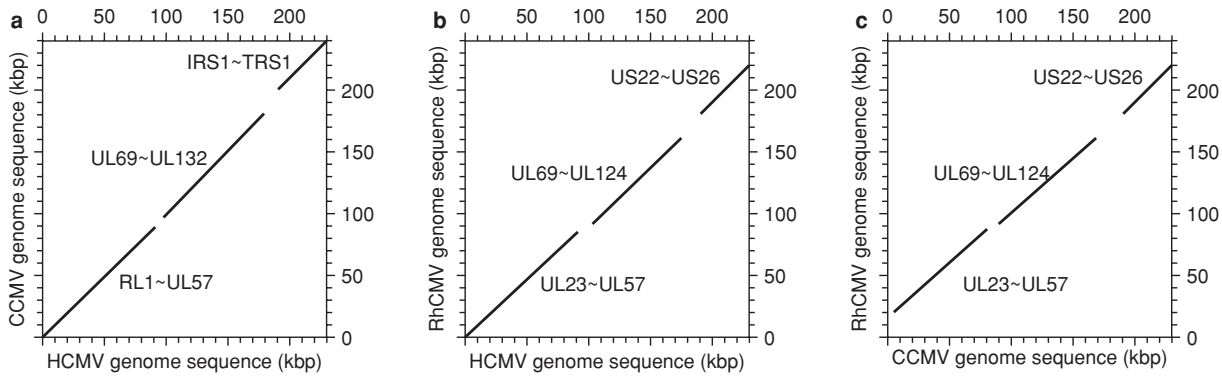

Fig. 59.4. Matrix plot demonstration of the sequence colinearity between (a) HCMV and CCMV, and (b) HCMV and RhCMV (Strain 68–1). The diagrams were computed and plotted using the Compare program (moving window: 30, stringency: 24) of SeqWeb® (version 2, San Diego, CA). The corresponding ORF within the colinear regions of each plot are indicated. The comparison of the HCMV and CCMV genomes using the same criteria has been published previously (Davison *et al.*, 2003). GenBank accession numbers of the genome sequences used for comparison are BK000394 (HCMV AD169), AF480884 (CCMV), and AY186194 (RhCMV).

The conserved gene blocks comprise more than 80% of the total genome content of HHV-6 and HHV-7. The other two betaherpesvirus subgroups are distinguished from HHV-6/7 by larger genome sizes resulting from the presence of highly divergent genes, including tandemly arrayed, genus-specific, gene families. The HCMV genome contains the RL11 family at the left end of the genome and the US2, US6, US12 families near the right end, all of which are present in CCMV and RhCMV (Fig 59.3(a) and 59.3(b)). These families are not present in rodent CMV.

Genomic DNA sequences

Phylogenetic analysis of mammalian and avian herpesviruses based on the sequences of several core-genes, including gB and DNA polymerase, demonstrate that CCMV is the closest known relative of HCMV (McGeoch *et al.*, 2000). Although RhCMV and AGMCMV branch away from the consensus sequence of HCMV and CCMV, these primate CMV cluster into a distinct sublineage among the betaherpesvirus subfamily, taxonomically equivalent to Genus *Cytomegalovirus* (van Regenmortel *et al.*, 2000). Co-speciation of virus and host has been a prominent feature in herpesvirus evolution (McGeoch *et al.*, 1995). The evolutionary branching points that separate the Old from New World primate CMV, and HCMV from CCMV are congruent with the dates of divergence of their hosts (23.3 million years or 5.5 million years ago, respectively) (McGeoch *et al.*, 2000). The DNA sequences of HCMV and CCMV are closely colinear throughout the entire viral genome except for three regions (Fig. 59.4(a)). Regions of divergence include the RL11 gene family locus (7–16 kbp in CCMV) and the origin of DNA replication (*ori*Lyt, 90–98 kbp in CCMV). The largest distinct difference of their sequence organization (180–200 kbp region of CCMV) corresponds to the 19 kbp region that is missing from the AD169 genome but is present in Toledo and clinical isolates (ULb′) (Davison *et al.*, 2003; Cha *et al.*, 1996). The genome sequence of RhCMV exhibits a greater level of sequence discontinuity from HCMV than does CCMV (Figs. 59.4(b)). The colinear relationship of RhCMV to both HCMV and CCMV is largely retained in the central portion of their genomes where the conserved seven core-gene blocks, two beta-gene blocks, and the major immediate-early (MIE) locus are located (Fig. 59.4(b) and 59.4(c)). Sequence discrepancies are found at the *ori*Lyt region (87–90 kbp in RhCMV), the ULb′ region, and the left terminus of the genome. The region of the AGMCMV genome encoding *ori*Lyt (Anders and Punturieri, 1991) is strongly conserved with *ori*Lyt of RhCMV. The sequence from 161 kbp to the right end of the RhCMV genome is no longer colinear to HCMV (Fig. 59.4(b)) or CCMV (Fig. 59.4(c)), except the third beta-gene block comprising the US22-26 ORF. The lack of colinearity in the matrix plots is probably the result of the different copy numbers of ORF belonging to US6, US14, and GCR gene families within this region of RhCMV (Fig. 59.3).

A common feature of the genome in all betaherpesviruses is the absence of any functional coding regions between UL105 and the UL111A ORF. The latter ORF is found only in primate CMV except CCMV (discussed below). As large a genome as CMV possesses, there are relatively few non-coding areas of the genome, outside of the region between UL57 and UL69, which contains *ori*Lyt. The presence of

a 3–4 kbp stretch without apparent coding function begs the question of what function it might serve in the CMV genome, as well as all betaherpesviral genomes. No site-directed mutational analyses have been reported for this portion of the genome, and the area is intact in tissue culture-adapted strains that have deleted other portions of the genome (Cha *et al.*, 1996). Preliminary evidence has been reported that this region of the HCMV genome may represent a stable intron of an unidentified viral transcript (Murphy *et al.*, 2003a, b).

Herpesvirus core proteins

As would be expected for proteins present in all herpesviruses, the core proteins constitute some of the most conserved ORF between HCMV and simian CMV (Table 59.1). Sequence identities of most core proteins are 60%–90% for CCMV/HCMV alignments and 50%–82% for RhCMV/HCMV alignments. The proteins involved in nucleic acid metabolism, DNA replication, and genome packaging are especially conserved when comparing either CCMV or RhCMV with HCMV. The functional importance of the high sequence identity in these proteins is emphasized by in vitro studies evaluating susceptibility to anti-HCMV drugs. RhCMV and HCMV are comparably inhibited by the currently approved compounds ganciclovir, foscarnet (Swanson *et al.*, 1998), and cidofovir, and to benzimidizole nucleosides (North *et al.*, 2004). These drugs are known to target the HCMV DNA polymerase (pUL54), phosphotransferase (pUL97), transport/capsid assembly protein (pUL56), and the DNA packaging protein (pUL89) (Krosky *et al.*, 1998; Underwood *et al.*, 1998; Emery, 2001).

Consistent with the conservation of capsid structure, there is strong sequence conservation of the proteins involved in capsid assembly, particularly for the minor (pUL85) and major (pUL86) capsid proteins mCP and MCP, respectively), and the mCP-binding protein (pUL46). The fourth capsid protein, the small capsid protein (pUL48A), is the most divergent of the group. pUL48A, which has been localized to the hexon tip (Chen *et al.*, 1999), is one of the rare exceptions to the rule that CCMV proteins are more conserved with their HCMV homologues than are those of RhCMV (Table 59.1). The two regions of pUL48A that are the most conserved in any comparison of HCMV, CCMV, and RhCMV (75% identity), corresponding to amino acids 13-31 and 43-75 of HCMV, are involved in binding to the major capsid protein (MCP) of HCMV (Lai and Britt, 2003).

There are five viral proteins, encoded by UL32, 80, 80.5, 82, and 99, that are known to be intimately associated with the capsid either during assembly or within the mature virion, three of which are encoded by core gene members. These include the assemblin maturational proteinase (pUL80) and the capsid assembly protein precursor (pAP) (pUL80.5), both of which are only transiently present within the immature capsid (Chan *et al.*, 2002; Wood *et al.*, 1997), and the tegument phosphoprotein pp28 (ppUL99) (Gibson, 1996). Whereas the proteinase domain of pUL80 is uniformly conserved, the pAP portion exhibits considerably more heterogeneity (Table 59.1). Extensive work with AGMCMV has mapped functional domains within these two proteins. Amino acids involved in the active site and proteolytic cleavage site of assemblin (Welch *et al.*, 1991), and the self-interaction of pAP and binding to MCP (Wood *et al.*, 1997) are the most conserved between simian CMV (AGMCMV, CCMV, and RhCMV) and HCMV. pp28 is the most divergent of all the core proteins with only 50 (CCMV/HCMV) and 33% (RhCMV/HCMV) amino acid identities (Table 59.1). There is only 18% identity between the pp28 proteins of CCMV and RhCMV (not shown). Conserved amino acids in pp28 are predominantly confined to the amino terminal one-third of the protein, suggesting that these may represent the domains that interact with capsid proteins.

Betaherpesvirus-specific proteins

The betaherpesvirus-specific proteins (beta-proteins) have diverged between species to a greater extent than have the core proteins. The CCMV betaherpesvirus proteins are 45%–85% identical with their HCMV equivalents (Table 59.1), which is less than the range of core protein identities (60%–90%). The same proteins of RhCMV have retained 27%–69% amino acid identities with the corresponding HCMV proteins, considerably lower than observed for the core proteins (50%–82%). Sequence variability appears to be limited to comparisons between species and is not a common theme for comparisons of an ORF between isolates of the same species. Some of the RhCMV ORF that are especially divergent from their HCMV counterparts, such as pUL37, ppUL83, and pUL123, are highly conserved between different RhCMV isolates. All three ORF exhibit >97% identity when comparing primary RhCMV isolates with strain 68-1 (these authors, unpublished data). The absence of intraspecies variation and the presence of profound interspecies divergence are consistent with the hypothesis that there were intense selective pressures on these proteins during adaptation to the host. One possible interpretation of the greater divergence of RhCMV beta-proteins versus those of CCMV is that this

group of proteins may interact with cellular proteins to a greater extent than the core proteins. According to this scenario, as the cellular proteins diverged in sequence following the ape/monkey split, there was a compensatory evolution of viral proteins to maintain the putative interactions.

Some of the monkey beta-proteins are almost unrecognizable from their HCMV counterparts. The UL40 protein of HCMV has been implicated in modulation of natural killer (NK) cell activity by virtue of a nine amino acid sequence in its leader peptide that is also found in the leader peptide of most HLA-C molecules (Cerboni *et al.*, 2001). The nonamer peptide of HLA-C is bound by the nonclassical, MHC class I protein, HLA-E, in a TAP-dependent fashion. This complex can activate inhibitory receptors on NK cells. Evidence has been presented that the HCMV-derived peptide of UL40 may function via a similar mechanism, although the issue is not resolved (Cerboni *et al.*, 2001). The RhCMV UL40 protein is only 29% identical to HCMV UL40, and BLASTP searches with it fail to identify its positional homologue within HCMV. However, RhCMV UL40 contains a nonamer sequence within the predicted leader peptide (VMAPRTLLL) that matches that found in the UL40 protein of the AD169 strain and clinical isolates of HCMV (VMAPRTLIL), and CCMV (TMAPKTLLI). One possible implication of the apparent conservation of the UL40 nonamer within the primate CMV UL40 is that dramatic sequence shifts within certain ORF during co-speciation of CMV with its host may not preclude strong functional homology.

Gene duplication events have helped shape the genomes of betaherpesviruses, in general, and CMV, in particular. There are three gene families (UL25, UL82, and US22) within all betaherpesviruses, and 11 unique gene families have been described for HCMV (Davison *et al.*, 2003; Hansen *et al.*, 2003; Chee *et al.*, 1990; Nicholas, 1996; Gompels *et al.*, 1995; Rawlinson *et al.*, 1996; Vink *et al.*, 2000). The HCMV gene families have been conserved both in number and genomic location in both RhCMV and CCMV with one notable exception. The UL82 family is within beta-block II and is comprised of the upper and lower matrix proteins, pp71 (ppUL82) and pp65 (ppUL83), and pUL84. Both RhCMV and BaCMV have a tandem duplication of the UL83 ORF, as opposed to the single UL83 locus found in HCMV and CCMV. This gene duplication produces in a small gap in the matrix plot of the two-dimensional comparison between the RhCMV and either HCMV or CCMV (Fig. 59.4(b) and 59.4(c), around 110–113 kbp in RhCMV). The two RhCMV UL83 ORF are 41% identical at the amino acid level. While the function of pUL83-1 has not been analyzed, pUL83-2 localizes to the nucleus (Yue *et al.*, 2006) and has slightly higher sequence identity to HCMV UL83 than does the RhCMV UL83-1 ORF (42 vs. 36%). In addition, pUL83-2 elicits stronger cellular responses than pUL83-1 (L. Picker, unpublished). The UL83 duplication in monkey CMV bears some resemblance to the situation in murine CMV (MCMV) in which both M83 and M84 loci have sequence homology with HCMV UL83. Although M83 is analogous in position and homologous in sequence to the UL83 gene of HCMV, it also has homology to HCMV pp71 (UL82) (Morello *et al.*, 1999; Cranmer *et al.*, 1996). While the M84 protein is not present within the virion, it, too, has homology with HCMV pUL84, a regulatory protein with incompletely defined functions (Lischka *et al.*, 2003). M84 is considered the MCMV homologue of HCMV pp65 (UL83).

The simian CMV contain two loci found in all other betaherpesviruses that are usually expressed with immediate-early (IE) kinetics, UL36 and 37, and the MIE region coding for IE1 and IE2 (UL123 and 122, respectively) (Fig. 59.3). UL36 and 37 of HCMV code for the viral inhibitor of caspase-8-induced apoptosis (vICA) and viral mitochondrial inhibitor of apoptosis (vMIA), respectively. Both functions are conserved in the RhCMV homologues, although vMIA of RhCMV and HCMV have retained only 32% amino acid identity (McCormick *et al.*, 2003). Interestingly, a naturally occurring RhCMV variant without vICA activity does not impair growth, persistence, or pathogenesis in vivo (Chang and Barry, 2003; Chang *et al.*, 2002; McCormick *et al.*, 2003). Unlike the UL36 and 37 genes in all other betaherpesviruses, which are expressed with IE kinetics, the RhCMV UL36 and 37 genes are transcribed with delayed-early kinetics (McCormick *et al.*, 2003).

The organization, splicing patterns, and strong transcriptional activity of the AGMCMV and RhCMV MIE region (Alcendor *et al.*, 1993; Chang *et al.*, 1990, 1995; Barry *et al.*, 1996; Jeang *et al.*, 1982, 1984, 1987) are similar to those found in HCMV (Stenberg *et al.*, 1989). While the overall structure of the MIE locus is conserved in the betaherpesviruses, there has been significant sequence divergence of the IE coding region in monkey CMV. The IE1 proteins of RhCMV and AGMCMV are only 27%–29% identical with HCMV IE1, the least of all beta-protein comparisons, and only 40% identical with each other (Chang *et al.*, 1995; Barry *et al.*, 1996). In contrast, the IE2 proteins of both monkey CMV are approximately 49% identical with HCMV IE2 and 65% identical to each other (Chang *et al.*, 1995; Barry *et al.*, 1996). The prominent divergence of monkey CMV IE1 is further emphasized by the strong conservation of the CCMV

IE1 and IE2 ORF with those of HCMV (71 and 72%, respectively), suggesting that the monkey CMV IE1 sequence was especially labile during adaptation to a monkey host.

Primate CMV-specific proteins

Primate CMV contain numerous ORF not found in other betaherpesviruses, some of which are restricted to a subset of the primate CMV members. These are largely clustered at either end of the UL portion of the viral chromosome and within the US region, with the exception of the CMV interleukin-10 (cmvIL-10) homologue encoded by UL111A. There are several notable features about these ORF besides their restriction to primate CMV. For the most part, those found within UL are some of the most variable in pairwise alignments between any two primate CMV. Sequence identities range between 25 and 65% for CCMV/HCMV and <29%–39% for RhCMV/HCMV. The left end of UL in RhCMV is so divergent that either the putative ORF within this region (Hansen *et al.*, 2003; Rivailler *et al.*, 2006) are unique to the monkey lineage of CMV and/or only have vestigial homology to their HCMV counterpart, similar to that proposed for UL40. Several of the RhCMV ORF in this region are present within BaCMV, and the DNA sequence of the left end of the RhCMV genome does not align with the corresponding regions of HCMV and CCMV (Fig. 59.4(b) and 59.4(c)).

The right end of UL also has sequence discontinuity between the primate CMV, especially when RhCMV is compared to either HCMV or CCMV. This appears to be the result of a variety of factors including high sequence diversity and the loss of gene colinearity. This same region (UL/b') has either been deleted or undergone rearrangement in tissue culture-adapted strains of HCMV (Cha *et al.*, 1996). The linear order of genes is distinct for each primate CMV (Fig. 59.3). A likely arrangement of ORF within ULb′ has been proposed for RhCMV (Rivailler *et al.*, 2006), and sequence homologues to HCMV UL128, 130, 131A, 132, 148 – 144, and 141 are present within either or both of RhCMV strains 68-1 and 180.92. There are no sequence homologues within RhCMV for HCMV UL140 – 157, although there is a large number of uncharacterized ORF within this region of the RhCMV genome that could possibly be functional homologues. For examples, there are some potential structural similarities between the rh174 ORF of RhCMV with the UL139 ORF of HCMV (these authors, unpublished data). The proposed arrangement of genes within RhCMV ULb′ has been confirmed by sequence amplification of the corresponding region of the RhCMV genome from RhCMV circulating in rhesus macaque populations, with one notable exception. PCR amplification of DNA purified from buccal swabs of naturally infected rhesus macaques has identified an additional 1.5 kb of ULb′ DNA present within wild-type RhCMV not present within either 68-1 or 180.92 (these authors, unpublished data). UL128. The lack of UL128 in RhCMV is intriguing since UL128 has been identified also in the closely related Colburn stain of AGMCMV, albeit with a premature stop codon within the first exon like that in CCMV (Davison *et al.*, 2003; Akter *et al.*, 2003). Some of the genes within the UL/b′ region of simian CMV, such as UL146, have radically diverged from their HCMV homologue to a point of barely detectable homology.

A RhCMV version of the HCMV pUL146 α-chemokine has been identified (accession number AY183378; M. Penfold, unpublished data) based on conservation of a short amino acid sequence (ELRCXC) that is both critical for neutrophil activation by cellular CXC chemokines and present in almost all clinical isolates of HCMV (Prichard *et al.*, 2001). Apart from this motif, however, the remainder of the protein has little identity with HCMV or CCMV pUL146 (30 and 25% amino acid identities, respectively). Notably, the sequence of pUL146 of HCMV is extremely variable (50% divergence) between different clinical isolates (Prichard *et al.*, 2001). UL146 is one of a few HCMV genes with a high degree of intra-species sequence polymorphism (20–50%). Others include UL73 (gN), UL74 (gO), UL144 (TNF receptor), UL4, and UL11 (Rasmussen *et al.*, 2003 and references therein). In contrast, primary isolates of RhCMV from the California National Primate Research Center exhibit 99% identity for pUL146 (these authors, unpublished data).

These ORF appear to be the exceptional sites for genetic heterogeneity between HCMV isolates since most other genes that have been analyzed are considerably more conserved. For example, the US9 and US28 coding regions in clinical isolates of HCMV are >96% identical with the sequences of AD169 (Rasmussen *et al.*, 2003. Therefore, the profound sequence divergence in most of the primate CMV-specific proteins must have occurred during co-speciation with the host following radiation of the primates. The US28 and UL111A ORF, which encode a viral β-chemokine receptor and cmvIL-10 (Lockridge *et al.*, 2000; Kotenko *et al.*, 2000), respectively, are illustrative for the extent of sequence divergence that can occur without loss of functional activity.

RhCMV, BaCMV, and AGMCMV (strain 9610, accession numbers AY340790–340794) (Sahagun-Ruiz *et al.*, 2004) each contain a tandem array of five genes that are homologous to HCMV US28 by position and sequence. The five

RhCMV US28 proteins have a range of identities with HCMV pUS28 (24–39%) that is comparable to the identities between HCMV pUS27 and pUS28 (31%) and between themselves (21%–41%). Of the five, only one (RhCMV US28-5) binds the membrane-bound chemokine, fractalkine (FKN), and multiple β-chemokines with similar binding affinities as HCMV pUS28 (Penfold *et al.*, 2003). Moreover, functional RhCMV US28-5 has been localized to the mature virion, like HCMV US28 (Penfold *et al.*, 2003). Based on the low homology between RhCMV pUS28-5 and HCMV pUS28 (39% identity), it is reasonable to speculate that evolution of the primate US28 coding regions has been driven by maintenance of a high affinity for the host's chemokines. However, it appears that the US28 chemokine receptors have diverged to a much greater extent than might be predicted by the rate of divergence of cellular ligands. The human and rhesus macaque FKN proteins are 93% identical, indicating that US28 evolution was not proportionate to the rate of change of this particular cellular ligand. The evolutionary pressures that have driven the rate of change of pUS28 sequences may be especially complicated since pUS28 binds to multiple cellular ligands (Penfold *et al.*, 2003).

Similarly, cmvIL-10 proteins encoded by RhCMV and HCMV are as divergent from each other (27% identical) as they are from their host species' cellular IL-10 (cIL-10) (Lockridge *et al.*, 2000). The divergence of cmvIL-10 is distinct from viral IL-10 encoded by EBV (ebvIL-10), which is 90% identical to cIL-10. The sequence of cmvIL-10 is stable amongst multiple clinical isolates of HCMV (Hector and Davison, 2003) and RhCMV (these authors, unpublished data), indicating that sequence variation occurs between species, not within species. cmvIL-10 functions through the IL-10 receptor (Kotenko *et al.*, 2000; Jones *et al.*, 2002; Spencer *et al.*, 2002), binding with an affinity almost identical to that of cIL-10 (Jones *et al.*, 2002). As with pUS28, it appears that the cmvIL-10 proteins have diverged to a much greater extent than might be predicted by the rate of divergence of cIL-10 receptors. Although there is no available monkey IL-10 receptor sequence to enable a rhesus/human comparison, rhesus dendritic cells (DC) respond as well as human DC to recombinant human cIL-10 (these authors, unpublished data), suggesting a strong conservation of the IL-10 receptor between humans and rhesus macaques. Transduction of cIL-10 by a progenitor primate CMV and subsequent genetic drift in sequence could impart new functions to the viral IL-10, although this presents something of a conundrum for the virus. On one hand, genetic drift in a transduced cellular gene can result in the acquisition of novel functions. On the other, this could result in the conversion of a non-immunogenic "self" protein into a highly immunogenic "non-self" protein. The crystal structure of the cmvIL-10 homodimer bound to the high affinity IL-10 receptor is similar to that of cIL-10 and the receptor (Jones *et al.*, 2002). Distinctions in quaternary structures between these two complexes suggest potential differences in downstream signaling pathways, although it has not yet been determined what functional phenotype separates cmvIL-10 from cIL-10 (Kotenko *et al.*, 2000; Jones *et al.*, 2002; Spencer *et al.*, 2002).

The UL111A locus of primate CMV is in a state of genetic flux. The structure of the cIL-10 gene consists of five exons/four introns. The monkey UL111A genes (RhCMV, AGMCMV, and BaCMV) have lost the intron between exons 4 and 5 (126), while the HCMV UL111A has further lost the intron between exons 3 and 4 (Lockridge *et al.*, 2000; Kotenko *et al.*, 2000). In contrast, the ebvIL-10 gene has no introns. CCMV has no UL111A ORF (Davison *et al.*, 2003), similar to the rodent CMV genomes. It may be that CCMV, like murine CMV, up-regulates expression of cellular IL-10 following infection of cells (Redpath *et al.*, 1999), obviating the need to both encode its own IL-10 function and maintain the integrity of the UL111A gene.

The absence of UL111A in CCMV (and rodent CMV) serves as an important reminder that while the primate CMV share an overwhelming repertoire of genes and similarities in natural history, each species has adapted to its niche in its own unique way, jettisoning, transducing, or modifying coding capacity and regulatory regions as selective pressures dictated. In some cases, this meant having to evolve independent mechanisms for similar virus/host scenarios, as may be the case for activation of IL-10 through expression in the context of either the viral or host genome. Another potential example of this is provided by the apparent importance of cyclooxygenase 2 (COX-2) in the CMV life cycle.

Infection of human fibroblasts with HCMV alters the level of more than 250 cellular genes prior to replication of the viral genome, including COX-2 (Zhu *et al.*, 1998). The function of elevated COX-2 remains to be determined, but the constellation of cellular genes whose expression levels are temporally changed along with COX-2 point to a need for the virus to regulate intracellular and extracellular inflammatory responses. Indeed, HCMV infection of fibroblasts is severely attenuated in the presence of COX-2 inhibitors (Zhu *et al.*, 2002). RhCMV does not increase cellular COX-2 levels (J. Nelson, unpublished data), but it may have come up with its own solution to the regulation of COX-2. RhCMV encodes a multiply spliced COX-2 homologue at the left end of UL that is approximately 75% identical with the cellular COX-2 protein (Hansen *et al.*, 2003).

Deletion of RhCMV COX-2 does not impair growth in fibroblasts but does inhibit replication in endothelial cells (J. Nelson, unpublished data). Assuming retention of function, transduction of cellular COX-2 by monkey CMV would appear to be an example of convergent evolution whereby the virus is better able to control its own destiny by modulating host inflammatory processes. Although the mechanism may differ from that employed by HCMV, the net effect is probably the same.

Summary

In sum, the simian CMV are an important primate complement to the other animal models of HCMV. Progress in characterizing them at the molecular and biological levels facilitates new avenues of inquiry into the mechanisms of HCMV persistence and pathogenesis. It is now possible to define the role of specific gene products in CMV natural history by applying the same DNA modification tools elegantly used for genetic engineering of bacterial artificial chromosomes containing the genomes for HCMV, MCMV, RCMV, and GPCMV. The full-length RhCMV genome has been cloned into a BAC (Chang *et al.*, 2003), enabling the efficient and accurate introduction of any site-directed mutation into the viral genome. In addition, novel vaccine and chemotherapeutic intervention strategies can be tested in primate hosts that closely approximate the human condition.

Acknowledgments

The authors would like to thank Meghan Eberhardt, Jennifer Huff, Glenn Jackson, Jennifer Johnson, Rachel Kravitz, Kristen Lockridge, Getachew Sequar, Yujuan Yue, and Shan Shan Zhou for their contributions. The authors would also like to thank Kristina Abel, James Carlson, Amitinder Kaur, Lisa Strelow, and Kate Wasson for their critical reading of the material, and Earl Blewett, Laurie Brignolo, Don Canfield, Amitinder Kaur, Andrew Lackner, Jay Nelson, Louis Picker, Mark Penfold, P. Rivailler, Meredith Simon, Abigail Spinner, Ross Tarara, Steve Tinling, and F. Wang for sharing unpublished data. P.A.B would also like to express his deepest appreciation to Pam, Amelia, and Watson for their support and patience.

Gammaherpesviruses of New World primates

Bernhard Fleckenstein and Armin Ensser

Institut für Klinische und Molekulare Virologie Erlangen, Germany

Introduction

Numerous Gamma-herpesviruses, a large subfamily of the herpes group, have limited pathogenic potential upon primary infection of their natural host. They are most relevant however as tumor viruses of the hematopoietic system and form an important chapter of viral oncology. The prototype of the genus lymphocryptovirus (γ1-herpesvirus), Epstein-Barr Virus (EBV), was the first clearly identified human herpesvirus. EBV causes lymphomas of B-cell origin and other lymphoproliferative syndromes, nasopharyngeal carcinomas and, possibly, gastric cancer. The second known genus of gamma-herpesviruses, rhadinoviruses or γ2-herpesviruses, is biologically and molecularly distinct. The prototypic members of this group, termed Herpesvirus (H.) saimiri (HVS) and H. ateles (HVA), were detected as T-lymphotropic tumor viruses in neotropical primates and raised primary interest from the fact that they cause fulminant T-cell lymphomas in numerous primates as well as in rabbits, although no exact correlates of these tumors exist in human pathology. This led to the identification of novel viral membrane-associated T-cell oncoproteins, termed Stp and Tip. These are small adaptor molecules that efficiently act on T-lymphocyte signaling. The viruses have been used as expression vectors in T-lymphocytes and allow to study mechanisms of episomal persistence in components of the T-cell system. Later on it became clear that certain strains of HVS can transform human T-lymphocytes to continuous growth in an antigen- and mitogen-independent fashion, providing for the first time a reliable means of human T-lymphocyte immortalization in cell culture. Additional interest in the γ2-herpesviruses arose when the Kaposi-sarcoma-associated Human Herpesvirus 8 (KSHV/HHV8) was identified as the first human pathogenic rhadinovirus. However, in view of the complex biology of Kaposi's Sarcoma or other neoplastic diseases such as body cavity-based B-cell lymphomas and multifocal Castleman's Disease, it is by far less clear which KSHV/HHV8 genes encode the relevant oncoproteins of KSHV/HHV-8. In this chapter, we wanted to focus mostly on the basic biology and gene expression profiles of HVS and HVA, on the viral mechanisms of oncogenic transformation, and possible applications of these viruses as T-cell vectors and in cell-based immunotherapy.

Herpesvirus saimiri

Natural occurrence and pathology

The rhadinovirus (γ2-herpesvirus) Herpesvirus saimiri (HVS) is regularly found in squirrel monkeys (*Saimiri sciureus*), whose natural habitat are South American rainforests. Squirrel monkeys are usually infected via saliva within the first two years of life. The virus does not cause disease or tumors and establishes lifelong persistence in the species (Melendez *et al.*, 1968). In other New World primate species such as tamarins (*Saguinus (S.) spp.*), common marmosets (*Callithrix (C.) jacchus*) or owl monkeys (*Aotus trivirgatus*), the infection with HVS causes acute peripheral T-cell lymphoma within less than two months after experimental infection (Melendez *et al.*, 1969; Wright *et al.*, 1976; for review see Fleckenstein and Desrosiers, 1982). The experimental infection is usually performed intramuscularly or intravenously. Intramuscular injection of purified virion DNA also causes disease in susceptible primates (Fleckenstein *et al.*, 1978b). HVS strains were classified into the three subgroups A, B and C depending on the pathogenic properties and on the sequence divergence in the left-terminal non-repetitive genomic

region (Desrosiers and Falk, 1982; Medveczky *et al.*, 1989; Medveczky *et al.*, 1984). The major representative strains are A11 (Falk *et al.*, 1972) for subgroup A, B-S295C (Melendez *et al.*, 1968) and B-SMHI (Daniel *et al.*, 1975) for subgroup B, and C488 (Biesinger *et al.*, 1990) and C484 (Medveczky *et al.*, 1984) for subgroup C. Viruses of subgroup B are considered to be less oncogenic, subgroup C strains have the strongest oncogenic properties. Tamarins are susceptible to viruses of all subgroups, while subgroup B viruses were reported as not being able to cause disease in adult common marmosets (reviewed in Fickenscher and Fleckenstein, 2002). The parental strain C488 as well as various viral deletion mutants cause acute peripheral T-cell lymphoma within only a few weeks in common marmosets or in cottontop tamarins (*S. oedipus*) (Duboise *et al.*, 1998a; Ensser *et al.*, 2001; Glykofrydes *et al.*, 2000; Duboise *et al.*, 1998b; Knappe *et al.*, 1998a,b). Remarkably, high intravenous doses of HVS strain C488 can induce a similar fulminant disease in Old World monkeys such as rhesus and cynomolgus monkeys (*Macaca (M.) mulatta, M. fascicularis*). The pathological findings in macaques were similar to those in New World primates, and the disease in cynomolgus monkeys was designated as a pleomorphic peripheral T-cell lymphoma or alternatively as a pleomorphic T-lymphoproliferative disorder (Alexander *et al.*, 1997; Knappe *et al.*, 2000a). Whereas HVS infection or pathogenicity has not been reported in rodents, a non-permissive infection and tumor induction was described in New Zealand white rabbits, although with variable efficiency (Ablashi *et al.*, 1985; Medveczky *et al.*, 1989). HVS can be isolated from peripheral blood cells of persistently infected squirrel monkeys, or from leukemic animals, presumably from infected T cells, by co-cultivation with permissive owl monkey kidney (OMK) cells (Falk *et al.*, 1972). HVS replicates productively and induces cell lysis of OMK cells (Daniel *et al.*, 1976). A series of transformed T-cell lines were derived from leukemias or tumors of virus-infected tamarins and could be cultivated continuously for several years (reviewed in Fleckenstein and Desrosiers, 1982). While virus particles were found initially in most cases, virus production was frequently lost after prolonged culture. The episomal DNA is heavily methylated in such cell lines (Desrosiers *et al.*, 1979), and some of these cell lines carried rearrangements or large deletions in the episomal HVS genomes (Kaschka-Dierich *et al.*, 1982). Marmoset and tamarin T-cells can be transformed by HVS to stable T-cell lines in vitro and are designated as semi-permissive, since virus particles are released, although to lower titers than from OMK cells (Desrosiers *et al.*, 1986; Kiyotaki *et al.*, 1986; Schirm *et al.*, 1984; Szomolanyi *et al.*, 1987).

Genome structure and replication

HVS is the prototype of the subfamily *rhadinovirus* (g2-herpesviruses) (Roizman *et al.*, 1992). The term "rhadino" viruses uses the ancient Greek word "ραδιυοσ" for fragile (Roizman *et al.*, 1992), because the genomic viral DNA splits upon isopyknic centrifugation into two classes of highly different density, the L-DNA containing the viral protein-coding genes (low density, low G+C content) and the terminal non-coding repetitive H-DNA (high density, high G+C content). The intact rhadinoviral so-called M-genome has intermediate density in CsCl gradients (M-DNA). Two strains of HVS, #A11 and the highly oncogenic subgroup C strain #C488 were sequenced (Albrecht *et al.*, 1992a; Ensser *et al.*, 2003). In the case of HVS A11, the H-DNA contains multiple tandem repeats of 1444 bp with 70.8% G+C, whereas the long unique L-DNA has 112 930 bp with 34.5% G+C (Albrecht *et al.*, 1992a; Fleckenstein and Desrosiers, 1982). The size of the total M-DNA genome is variable due to different numbers of H-DNA segments attached to both ends of the linear virion genome. In strain C488, the L-DNA comprises 113027 bp, and it is flanked by two distinct repeat units of 1318 and 1458 bp. The shorter unit is a subset of the longer repeat unit of which 140 bp are deleted. The size of the packaged C488 M-genome is approx. 155 kbp, ranging from 130–160 kbp due to variable numbers of terminal H-DNA segments (Ensser *et al.*, 2003). The HVS L-DNA genomes contain at least 76 to 77 open reading frames and 5 to 7 U-RNAs (Albrecht *et al.*, 1992a; Hör *et al.*, 2001; Ensser *et al.*, 2003). These are the gene blocks of typical herpesvirus genes which are highly conserved between herpesvirus families (Gompels *et al.*, 1988; Albrecht and Fleckenstein, 1990). Flanking or interspersed are genes which do not usually occur in other herpesviruses families, among these are transforming oncogenes and viral homologues of cellular genes which will be described below. While most genes are well conserved between different HVS strains, there is extensive sequence variation at the so-called left end of the HVS L-DNA and in the region of the R transactivator gene *orf50* and the glycoprotein gene *orf51* (Biesinger *et al.*, 1990; Thurau *et al.*, 2000; Hör *et al.*, 2001; Ensser *et al.*, 2003). The genome structures of HVS and KSHV/HHV-8 are compared in Fig. 60.1. Not much is known about the replication mechanisms of rhadinoviruses in general or of HVS in particular. The HVS A11 origin of lytic replication was mapped to the untranslated region upstream of the thymidylate synthase gene (Lang and Fleckenstein, 1990; Schofield, 1994). A putative origin in the left-terminal region of the L-DNA was described to mediate plasmid maintenance in strain C484 (Kung and Medveczky, 1996) that is neither conserved between

different HVS strains, nor is it required for viral replication or episomal persistence in strain C488 or C484 (Ensser *et al.*, 1999; Medveczky *et al.*, 1989). In transformed human T cells, HVS persists as stable non-integrated episomes at high copy number (Biesinger *et al.*, 1992). There are no indications yet for the genetic correlate of a plasmid-like origin of replication and of the viral factors involved. In contrast to herpes simplex virus, the infection of tissue culture cells by HVS is asynchronous (Randall *et al.*, 1985). Therefore, the classification of HVS genes to the immediate-early (IE) phase of infection has been difficult and was mostly based on experiments using cycloheximide to inhibit viral protein synthesis. The IE gene *ie57* codes for a nuclear phosphoprotein of 52 kDa (Nicholas *et al.*, 1988; Randall *et al.*, 1984) with structural and functional homology with ICP27/IE63 of herpes simplex virus and EBV BMLF1. Correspondingly, IE57 stimulates the expression of unspliced and represses the expression of spliced transcripts (Whitehouse *et al.*, 1998). IE57 further redistributes nuclear components of the splicing machinery (Cooper *et al.*, 1999) and is involved in nuclear RNA export (Goodwin *et al.*, 1999). Thus, the *ie57* post-transcriptional regulator appears to be the sole regulatory viral IE gene. A strong viral transactivator function was mapped to the delayed-early gene *orf50* (Nicholas *et al.*, 1991), the homologue to the R transactivator of EBV. Due to differential splicing and promoter usage, the gene codes for a larger protein ORF 50A and for a smaller C-terminal variant ORF 50B. The transactivation domain resides in the C-terminus of the ORF 50 proteins and binds to the TATA-binding protein in the basal transcription complex. Post-transcriptional inhibition of spliced *orf50A* transcripts by the IE57 can not have functional relevance in this context, suggesting that orf50 exerts the dominant function for regulation of replication, at least in HVS strain C488. While *ie57* is highly conserved between subgroup A and C, the genomic *orf50* region encoding this major viral transactivator was found to be strongly divergent (Thurau *et al.*, 2000; Ensser *et al.*, 2003). Neither HVS nor HVA encode a homologue to the bZip/Zta of EBV or KSHV (Sinclair, 2003). The HVS ORF73 protein of strain A11 and C488 localizes to the host cell nucleus, and like the latent nuclear antigen LANA of KSHV, it can associate with host cell chromosomal DNA (Hall *et al.*, 2000; Schäfer *et al.*, 2003). The A11 ORF73 is highly expressed in HVS-infected human epithelial cancer cell lines, it can associate with the cellular p32, thereby coactivating heterologous as well as its own promoter (Hall *et al.*, 2002). A11 ORF73 further binds to GSK-3ß, which is involved in *WNT*-signaling and possibly contributes to oncogenic transformation (Fujimuro and Hayward, 2003). Although not detectable by Northern blotting from C488-transformed human T-cells (Fickenscher *et al.*, 1996), transcripts of this gene are found by RT-PCR. The HVS C488 orf73 gene product can downregulate the orf50A and B promoters and prevents the ORF50 mediated activation of viral replication gene promoters, and it can block the initiation of the lytic replication cascade. This suggests that HVS ORF73 can control the transition between rhadinoviral latency and lytic replication (Schäfer *et al.*, 2003).

Rhadinoviruses like HVS and KSHV contain several intronless viral genes that are homologous to cellular genes; it might be speculated on a role for reverse transcription in this context. While a few of these likely captured cellular gene homologs are unique to specific viruses, some are common to several rhadinoviruses (Fig. 60.1) or to γ-herpesviruses including EBV. This may suggest that the uptake of cellular genes is a rather infrequent event during herpesvirus evolution. Most of these cellular homologues can be categorized into two major groups: (I) genes related to nucleotide metabolism or cellular growth control, and (II) genes that modulate innate or adaptive immune functions (discussed below). HVS homologues to enzymes of the nucleotide metabolism include a dihydrofolate reductase (*orf2*, DHFR) and a functional thymidylate synthase (*orf70*, TS). Both *orf3* and *orf75* encode large tegument proteins, which share local homology to formylglycineamide ribotide amidotransferase (FGARAT) (summarized in Ensser *et al.*, 2003). The functions of these enzymes may possibly augment the free nucleotide pool and could thus facilitate DNA synthesis and virus replication. *Orf2* and the adjacently located viral U-RNA genes are dispensable for virus replication and T-cell transformation (Ensser *et al.*, 1999). HVS *orf72* codes for a functional viral cyclin D that is expressed in semipermissive HVS-transformed marmoset T-cells and is resistant to cyclin-dependent kinase inhibitors $p16^{Ink4a}$, $p21^{Cip1}$ and $p27^{Kip1}$. This deregulation pushes the cell cycle towards the S phase, thereby supporting virus replication in permissive cells (Nicholas *et al.*, 1992; Jung *et al.*, 1994; Swanton *et al.*, 1997). Although enhanced replication might secondarily promote transformation or tumor induction, the viral cyclin seems to provide only auxiliary functions, since it is not required for replication, T-cell transformation and lymphomagenesis (Ensser *et al.*, 2001).

Immunomodulatory proteins

Rhadinoviruses target various host mechanisms involved in pathogen elimination, both in the innate and adaptive immune system. Two HVS genes are functional regulators of the complement system; the *orf4* codes for a complement control protein homologue (CCPH), which inhibits C3 convertase, an enzyme involved in the initiation of early steps in

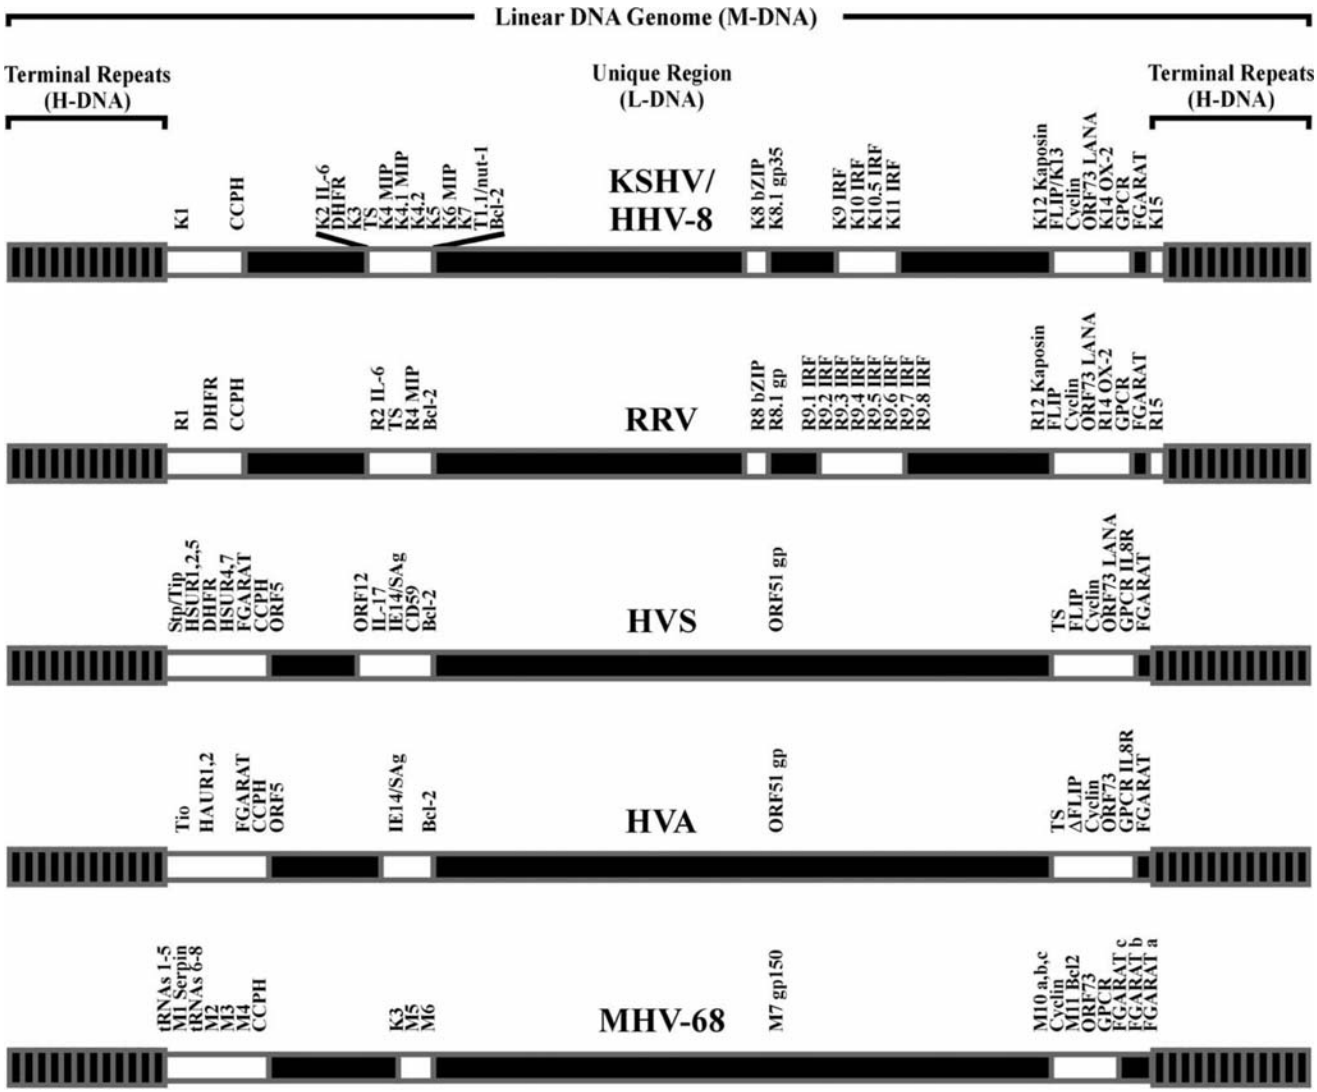

Fig. 60.1. Genome structure of selected rhadinoviruses. The genome structures of the rhadinoviruses KSHV/HHV-8 (Russo *et al.*, 1996; Neipel *et al.*, 1997), rhesus rhadinovirus (RRV; Alexander *et al.*, 2000; Searles *et al.*, 1999), herpesvirus saimiri (HVS; Albrecht *et al.*, 1992a; Ensser *et al.*, 2003), herpesvirus ateles (HVA; Albrecht, 2000), murine herpesvirus 68 (MHV-68; Virgin *et al.*, 1997) are shown with special respect to variable areas harboring non-conserved genes or genes with homology to cellular counterparts (white boxes). Conserved genomic regions of virus genes with typical herpesvirus functions are shown in black. Abbreviations are: bZIP, basic-leucine zipper protein. CCPH, complement control protein homologue. DHFR, dihydrofolate reductase. FGARAT, formylglycineamide ribotide amidotransferase. FLIP, FLICE inhibitory protein. gp, glycoprotein. GPCR, G-protein coupled receptor. HSUR or HAUR, HVS or HVA-encoded URNA. IRF, interferon regulatory factor. MIP, macrophage-inflammatory protein. SAg, superantigen homologue. Stp, saimiri transformation-associated protein. Tio, two-in-one-protein. Tip, tyrosine kinase-interacting protein. TS, thymidylate synthase.

complement activation (Albrecht and Fleckenstein, 1992; Fodor *et al.*, 1995). *Orf15* is a viral variant of CD59, which prevents the insertion of the membrane attack complex formed by C8 and C9, and thus blocks the terminal complement cascade (Albrecht *et al.*, 1992b; Rother *et al.*, 1994). T-cell stimulatory functions have been described for cellular CD59 via CD2 (Korty *et al.*, 1991; Deckert *et al.*, 1995), but functional data are not available for the viral CD59. The orf12 has homology to the K3 and K5 genes of KSHV (Coscoy and Ganem, 2000; Ishido *et al.*, 2000a,b; Means *et al.*, 2002), but is dispensable for replication and human T-cell transformation in vitro (Knappe *et al.*, 1998a).

Several rhadinoviral ORFs encode potent inhibitors of cell death or apoptosis, such as *orf16* and *orf71*. The ORF16 is a viral Bcl-2 homologue (Bellows *et al.*, 2000; Derfuss *et al.*, 1998; Nava *et al.*, 1997). Both Bcl-XL and viral Bcl-2 inhibit cell death induced by either cell-autonomous (independent of death receptors) or receptor-mediated mechanisms, depending on the cell type studied. The ORF71, a viral FLICE (FADD-like interleukin 1-converting enzyme (ICE)-like protease) inhibitory protein (vFLIP), interacts with cellular FADD (Fas-associated protein with death domains) and FLICE via homophilic interaction of their respective death-effector domains, therefore blocks formation of the death-signal-induced signaling complex, and consequently prevents caspase 8 (FLICE) activation. Although the vFLIP inhibited death-receptor-dependent apoptosis and partially protected permissive OMK cells from Fas-dependent apoptosis at a late stage of infection (Thome *et al.*, 1997), the vFLIP was dispensable for virus replication to high virus titers, T-cell transformation and lymphoma induction (Glykofrydes *et al.*, 2000).

The HVS gene *orf13* led to the discovery of its cellular homologue ctla-8 (Rouvier *et al.*, 1993) that codes for IL-17, a CD4+ T-cell specific cytokine. The viral IL-17 is functionally not distinguishable from its cellular counterpart that is capable of supporting T-cell proliferation (Yao *et al.*, 1995; Fossiez *et al.*, 1998). However, deletions of the HVS C488 *orf13*/*vIL-17* had no phenotype with regard to virus replication and oncogenicity (Knappe *et al.*, 1998a). In contrast to the vIL17 that is unique to HVS, G-protein coupled receptors (GPCR) are found in most rhadinoviruses. The HVS *orf74* encodes a viral IL-8 receptor (IL-8R) that is classified to the low-affinity B type of IL-8R (Ahuja and Murphy, 1993; Murphy, 1994; Nicholas *et al.*, 1992).

The viral immediate early gene *orf14*/*vSag* has local homology to the superantigen (Sag) of mouse mammary tumor virus (MMTV) and to murine *mls* superantigens (Thomson and Nicholas, 1991). Although recombinant viral IE14/vSag protein bound to MHC class II molecules and stimulated T-cell proliferation, there is no evidence of a selective advantage for specific Vb families that would be typical for superantigens, neither after stimulation of human T-cells with IE14/vSag in vitro (Yao *et al.*, 1996; Duboise *et al.*, 1998a), nor after infection and transformation with HVS (Knappe *et al.*, 1997). The HVS C488 ie14/vsag (Thomson and Nicholas, 1991) is dispensable for viral replication but its role in the transformation of human and simian T-cells in vitro or pathogenicity has remained controversial (Knappe *et al.*, 1997, 1998b; Duboise *et al.*, 1998a). Like other rhadinoviruses, HVS has acquired a series of cellular genes, but most if not all of these genes are dispensable for virus replication, T-cell transformation in culture, and pathogenesis in susceptible New World primates. Similar to KSHV infected B-cell lines, many of the cell-homologous viral genes are only expressed during lytic virus replication, but not in transformed human lymphocytes (Fickenscher *et al.*, 1996; Knappe *et al.*, 1997).

Oncogenesis

The major factors responsible for induction of T-cell leukemia and T-cell transformation in vitro reside in the variable region at the left end of the HVS L-DNA (Koomey *et al.*, 1984; Desrosiers *et al.*, 1985a; Desrosiers *et al.*, 1986; Murthy *et al.*, 1989; Chou *et al.*, 1995; Duboise *et al.*, 1998b). In subgroup A and B strains there is only one gene at this position, termed stpA or stpB (saimiri transformation associated protein of subgroup A or B strains) (Murthy *et al.*, 1989; Hör *et al.*, 2001). At the homologous location, the virus strains of subgroup C carry two open reading frames, that were later termed *stpC* (saimiri transformation-associated protein of subgroup C strains) and *tip* (tyrosine kinase interacting protein) (Biesinger *et al.*, 1990; Jung and Desrosiers, 1991; Biesinger *et al.*, 1995) (Fig. 60.2). The closely related HVA encodes the protein Tio at the homologous genomic position (Albrecht *et al.*, 1999). StpA and B share limited sequence homology with StpC, but are structurally unrelated to Tip (Fig. 60.2). While not required for viral replication, deletion of either *stpC* or *tip* abolishes the transformation by HVS in vitro and pathogenicity in vivo (Duboise *et al.*, 1996, 1998b; Knappe *et al.*, 1997; Medveczky *et al.*, 1993). Both *stpC* and *tip* genes are transcribed into a single bicistronic mRNA from a common promoter directed toward the left genomic end of the L-DNA, where *tip* is situated downstream of *stpC*. The transcription of *stpC*/*tip* is regulated similarly to cellular IE genes in human T-cells and no obvious viral factors seem to be involved. In C488-transformed human T-cells, *stpC* and *tip* are the only constitutively transcribed viral genes. (Biesinger *et al.*, 1995; Fickenscher *et al.*, 1996; Fickenscher *et al.*, 1997). The StpC protein is a 102 aa perinuclear membrane-associated phosphoprotein with a predicted molecular mass of approximately 10 kDa but migrates with an apparent molecular mass of 20 kDa. The N-terminus of StpC consists of 17 mostly charged amino acids. The C-terminus is a hydrophobic region, which probably serves as an anchor to perinuclear membranes. In between are 18 collagen tripeptide repeats (GPX)n, which may mediate multimerization of the protein (Fig. 60.2) (Biesinger *et al.*, 1990; Fickenscher *et al.*, 1997; Jung and Desrosiers, 1991, 1992, 1994). *stpA* of strain A11 and *stpC* of strain C488 transfected rodent fibroblasts formed foci in vitro and induced tumors in nude mice (Jung *et al.*,

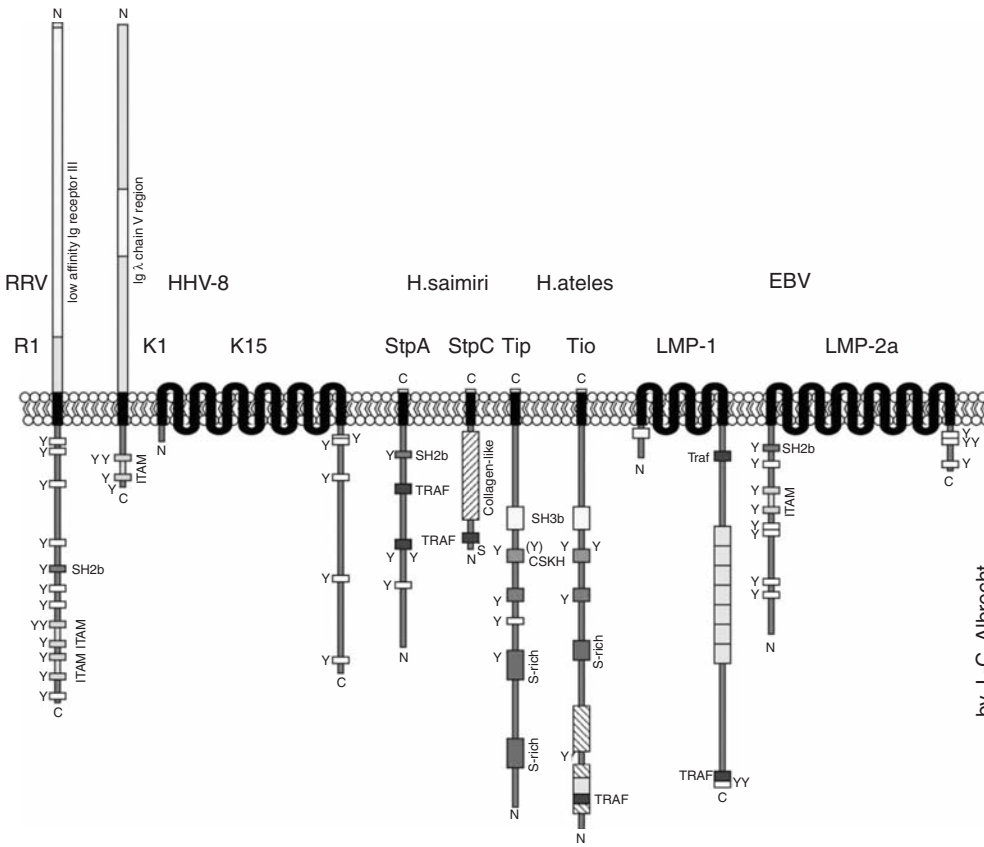

Fig. 60.2. Structural diversity of the major gammaherpesvirus signaling proteins. The HVS oncoproteins Stp, Tip, or HVA Tio, the KSHV K1 and K15, RRV R1 proteins are shown along with the EBV LMP1, LMP2a. CSKH, C-terminal Src kinase homology region. ITAM, immunoreceptor tyrosine-containing activation motif. SH3b, domain interacting with src-family kinase SH3 domain. SH2b, domain interacting with src-family kinase SH2 domain. S-rich, Serine rich motif. TRAF, potential binding site for TNF-R associated factors. Y and YY, tyrosine and double-tyrosine residues, putative signaling motifs. Black, Transmembrane domain. N or C, amino- or carboxyterminus of the protein, respectively.

1991). *stpA* transgenic mice developed polyclonal peripheral T-cell lymphoma, while an *stpC* transgene induced epithelial tumors (Kretschmer *et al.*, 1996; Murphy *et al.*, 1994). StpA was reported to bind to and to be phosphorylated by the non-receptor tyrosine kinase Src (Lee *et al.*, 1997). The non-transforming StpB also associates with Src (Choi *et al.*, 2000). StpC was shown to interact with the small G-protein Ras and stimulated mitogen activated protein (MAP) kinase activity (Jung and Desrosiers, 1995). Both proteins StpA and StpC interact with TNF-associated factors (TRAFs) leading to nuclear factor kappa B (NFkB) activation (Lee *et al.*, 1999; Sorokina *et al.*, 2004). Tip was first observed as a 40 kD phosphoprotein that coprecipitated with the T-cell-specific non-receptor tyrosine kinase $p56^{lck}$ in C488-transformed T-cells and was only detectable by a phosphotransferase assay. The protein was thus named tyrosine kinase interacting protein (Tip) and could be identified as the gene product of the leftmost C488 reading frame (Biesinger *et al.*, 1995). Tip of HVS strain C488 has 256 aa and a predicted molecular mass of 29 kD. Considerable interstrain variation of the *tip* genes has been observed (Greve *et al.*, 2001; Ensser *et al.*, 2003), but the common denominators are a N-terminal glutamate-rich region, which is duplicated in some strains, followed by one or two serine-rich regions, a bipartite kinase interacting domain, and a C-terminal hydrophobic domain which anchors the molecule at the inside of the plasma membrane. The kinase interacting domain consists of nine amino acids with homology to the C-terminal regulatory regions of various Src kinases (CSKH), and a proline-rich SH3-domain-binding sequence (SH3B); both motifs are required for the interaction with the kinase (Fig. 60.2) (Biesinger *et al.*,

1995; Jung *et al.*, 1995a; Heck *et al.*, 2006). Several tyrosine residues, three of which are conserved between all strains investigated, are a substrate for the tyrosine kinase Lck. The phosphorylated tyrosine residue 127 of Tip (pY127) was identified by biophysical binding analyses as a potential third Lck interaction site at the Lck-SH2 domain (Bauer *et al.*, 2004). Y127 is the major tyrosine phosphorylation site of Tip, but this does not enhance Lck binding in T cells. Recombinant virus expressing mutations in Tip show that the strong Lck binding mediated by cooperation of both SH3B and CSKH motifs is essential for transformation of human T cells by herpesvirus saimiri C488, whereas the Y127 of Tip was particularly required for transformation in the absence of exogenous interleukin-2, suggesting its involvement in cytokine signaling pathways (Heck *et al.*, 2006). Tip binding to Lck modulates the kinase activity: (Fickenscher *et al.*, 1997; Hartley *et al.*, 1999; Lund *et al.*, 1997a; Wiese *et al.*, 1996). When compared with their non-infected parental clones, HVS C488-transformed human T-cell clones had increased basal levels of tyrosine phosphorylation (Wiese *et al.*, 1996). Dependent on the presence of both the CSKH or SH3B motifs, Tip could activate Lck even when the regulatory tyrosines Y394 and Y505 of Lck had been mutated, suggesting a novel mechanism of Lck activation (Hartley *et al.*, 1999), which may result in an altered substrate specificity of the kinase contributing to the abrogation of ZAP70 phosphorylation (Cho *et al.*, 2004). This dysregulation may further link Tip-bound Lck to alternative downstream effectors. Since constitutively active Lck mutants have an oncogenic potential, stimulation of Lck signaling by Tip would contribute to the activated phenotype of HVS-transformed T-cells and to the transformation process, whereby Tip and StpC would act in synergy.

In addition to Lck, phosphorylated signal transducer and activator of transcription (STAT) factors 1 and 3 were immunoprecipitated with Lck and Tip-C484 (Lund *et al.*, 1997b). The implication of Y114 with constitutive active STATs, especially STAT3, and the role of STATs in growth regulation and oncogenesis in multiple cell types (Bowman *et al.*, 2000; Bromberg *et al.*, 2000) suggested a central role for Tip-induced STAT activity in viral T-cell transformation. However, recombinant herpesvirus saimiri C488 expressing Tip with a tyrosine-to-phenylalanine mutation at position 114 was able to transform primary human T-lymphocytes in the absence of STAT1 or STAT3 activation (Heck *et al.*, 2005). Thus, the essential function of Tip in lymphocyte transformation does not rely on Lck-mediated STAT1 or 3 phosphorylation. When Tip was highly expressed in stable *tip*-transfected Jurkat T-cells, low basal levels of tyrosine phosphorylation, impaired response to T-cell-receptor activation, and downregulation of CD3 and CD4 were observed. Tip further partially reversed the transformed phenotype of fibroblasts, which had lost contact inhibition after transfection with a constitutively active mutant of Lck. These effects were even more pronounced when Tip Tyrosine 114 was mutated in position 114 to Serine (Y114S) to enhance its binding to Lck (Guo *et al.*, 1997; Jung *et al.*, 1995b). Enhanced binding and activation of Lck by Tip carrying a Y114S might provide an explanation for the increased transformation efficiency, however, there were no differences in Lck binding for Tip Y114F (Heck *et al.*, 2006) and a Tip Y114 phosphopeptide exhibits no significant affinity for the SH2 domain of Lck (Bauer *et al.*, 2004).

The activation of Lck and the inhibition of T-cell signaling by Tip may be two different aspects of the same function, since the activation of Lck by Tip might trigger negative feedback mechanisms in stably transfected Jurkat cells expressing high levels of Tip, such as apoptosis (Hasham and Tsygankow, 2004). Another possible reason for this are the low expression levels of Tip in such HVS-transformed primary human and simian T-cells, while $p56^{lck}$ is abundantly expressed; any possible changes in the Lck enzymatic activity after binding of Tip may be masked by the excess free Lck. Tip function has evolved in the context of the natural infection of squirrel monkeys, where uncontrolled T-cell transformation seems not to occur. A better understanding of HVS biology in squirrel monkeys could help to elucidate this problem (Greve *et al.*, 2001).

A cellular Tip-associated protein of 65 kDa termed Tap could contribute to T-cell activation by Tip (Yoon *et al.*, 1997), although Tap is an RNA export factor that has no known T-cell-specific functions as yet (Grüter *et al.*, 1998). Coexpression of Tip and a recently identified lysosomal WD-repeat protein p80 at high levels in 293 and Jurkat cells induced enlarged endosomal vesicles and recruited Lck and TCR complex into these vesicles for trafficking or degradation. Since Tip is constitutively present in lipid rafts, it was also found that Tip can recruit p80 into lipid rafts; the C-terminus of Tip seems to interact with Lck to recruit TCR complex to lipid rafts, and TCR and Lck then may interact with p80 to initiate the aggregation and internalization of the lipid raft domain and thereby downregulate the TCR complex (Park *et al.*, 2002, 2003). The lipid raft association of Tip is essential for the TCR and CD4 downregulation but not for the inhibition of TCR signal transduction and the activation of STAT3 transcription factor (Cho *et al.*, 2006).

Growth transformation of human T-cells

Rapidly proliferating T-lymphoblastic tumor cell lines such as Jurkat (Schneider *et al.*, 1977) are frequently used as a cellular and biochemical model for primary human T-cells, although they display a strongly altered phenotype with respect to signal transduction, gene regulation and proliferation control. On the other hand, primary human T-cell culture is laborious and requires repeated stimulation with a mitogen or specific antigen in the presence of accessory cells expressing the appropriate MHC restriction elements. Since they are limited in their natural life span, it is rarely possible to grow primary T-lymphocytes to large numbers. A practical method of T-cell transformation became available through the observation that HVS strain C488 stimulated human T-lymphocytes to stable antigen-independent growth in culture (Biesinger *et al.*, 1992). These growth-transformed human T-cells retained many essential T-cell functions including the MHC-restricted antigen- specific reactivity of their parental T-cell clones (Bröker *et al.*, 1993; De Carli *et al.*, 1993; Weber *et al.*, 1993), they are not tumorigenic in nude or SCID mice, but could induce xenogenic graft-versus-host disiease similar as primary human T-cells (Huppes *et al.*, 1994). These observations have opened up a novel research direction which links T-cell biology, signal transduction pathways and transforming viral functions. Although HVS-transformed Old and New World monkey T-lymphocytes produce infectious viral particles in many cases, it was not possible to isolate virus from transformed human T-cell cultures (Biesinger *et al.*, 1992). Although the formal proof that the virus can never be reactivated from transformed human T-lymphocytes is difficult, neither treatment with phorbol esters or nucleoside analogues, nor other drugs that can cause reactivation of other viruses such as EBV or KSHV, nor specific or non-specific stimulation of the T-cells could induce virion production (Fickenscher *et al.*, 1996). StpC and Tip are the only viral proteins which have been regularly demonstrated in HVS-transformed human T-cells. The non-coding viral U-RNA genes (HSUR, HVS URNA) were abundantly expressed in a similar way to the EBER RNAs of EBV, but deletion of all HSUR did not influence virus replication or T-cell transformation (Ensser *et al.*, 1999). While the viral gene *stpC/tip* was strongly and inducibly transcribed into a bicistronic message (Fickenscher *et al.*, 1996; Medveczky *et al.*, 1993), other viral transcription was rarely detected. The gene *ie14/vsag* was abundantly transcribed for a few hours only after of stimulation of transformed human T-cells with phorbol ester, and the IE gene *ie57*, the early gene *orf50*, and the viral thymidylate synthase gene were found transcribed at extremely low abundance or only after additional T-cell stimulation (Knappe *et al.*, 1997; Thurau *et al.*, 2000). These findings argue for a strong block of virus replication in C488-transformed human T-cells that is downstream of the expression of the regulatory genes *orf50* and *ie57*.

The transformation procedure and the specific properties of HVS-transformed T-cells have been comprehensively reviewed (Fickenscher and Fleckenstein, 2001; Ensser *et al.*, 2002; Fickenscher and Fleckenstein, 2002; Ensser and Fleckenstein, 2004). Briefly, the infection of peripheral blood mononuclear cells, cord blood cells, thymocytes, or established T-cell clones by HVS C488 results in T-cell lines that continuously grow without restimulation with antigen or mitogen and do not require the presence of feeder or antigen presenting cells. The morphology of such lines resembles the irregular shape of T blasts, they carry non-integrated viral episomes in high copy number, and have a normal karyotype (Troidl *et al.*, 1994). The HVS strain C488 is commonly used for the targeted transformation of human T cells; other subgroup C virus strains were able to transform human T-cells, but to a varying extent (Fickenscher *et al.*, 1997). The surface phenotype of the transformed T-lymphocytes resembles mature, activated T cells, that are CD4+CD8− or CD4−CD8+ T cells and carry ab- or gd-type T-cell receptors; transformation of established T-cell clones demonstrated that the phenotype and HLA-restriction of the parental T-cells is conserved. If transformed by the same virus strain, ab and gd-clones were similar with respect to viral persistence, virus gene expression, proliferation and Th1-type cytokine production. The phenotype of HVS-transformed T-cells is remarkably stable for many months in culture, a significant technical advance over immortalization of human T-cells by the hybridoma technique or infection with HTLV-1 (Biesinger *et al.*, 1992; reviewed in Fickenscher and Fleckenstein, 2002). While many normal T-cell functions are preserved, a few specific cellular and biochemical features are changed in comparison with their parental cells. This relates to the hyper-responsiveness to CD2 ligation (Meuer *et al.*, 1984; Mittrücker *et al.*, 1992). Second, the protein tyrosine kinase $p53/56^{lyn}$ is expressed and enzymatically active in HVS transformed T-cells (Fickenscher *et al.*, 1997; Wiese *et al.*, 1996). Third, HVS-transformation shifts the range of cytokines secreted by stimulated T-cells towards a Th1 profile: IL-4 and IL-5 production is diminished and secretion of IL-2 and IFN-g is increased in comparison with parental cells. (Bröker *et al.*, 1993; De Carli *et al.*, 1993; Weber *et al.*, 1993). A novel IL-10-like cellular gene is specifically overexpressed in HVS-transformed T-cells, termed *ak155* or IL-26 (Knappe *et al.*,

2000b). Whereas IL-26 receptors have not been found on T-cells, this cytokine induces STAT activation in epithelial cells (Hör *et al.*, 2004). Thus, it is unlikely that IL-26 contributes to HVS-mediated T cell-transformation. However, this cytokine may be involved in the lymphocyte-epithelium interaction which is typical for various gamma herpesviruses.

T-cell transformation by HVS C488 was used to study T cells from primary human immunodeficiencies, and in many cases has been the only way to cultivate and amplify the patients' cells for further research. HVS transformed T-cell lines were established from patients with a variety of genetic T-cell defects (reviewed in Fickenscher and Fleckenstein 2001). HVS-transformed human CD4+ T-cells provide a productive system for T-lymphotropic viruses such as HHV-6 (F. Neipel and B. Fleckenstein, unpublished data) and human immunodeficiency virus (HIV) (Nick *et al.*, 1993).

Vectors for gene therapy

Both oncogenic and non-transforming HVS variants have been used as eukaryotic expression vectors. HVS vectors were used to define the transforming functions of the HTLV-1 X region and the *stpC* oncogene was successfully substituted by cellular *ras* (Guo *et al.*, 1998), by the K1 gene of KSHV/HHV-8 (Lee *et al.*, 1998), or by R1 of rhesus monkey rhadinovirus (RRV) (Fig. 60.2) (Damania *et al.*, 1999), in deletion mutants which still contained the *tip* gene. HVS has been used as a vector for growth hormone, for secreted alkaline phosphatase, anti-inflammatory cytokines and for green fluorescent protein (Desrosiers *et al.*, 1985b, 1996; Hoggard *et al.*, 2004; Stevenson *et al.*, 1999; Wieser *et al.*, 2005). A non-transforming replication-competent HVS vector expressing the bovine growth hormone in persistently infected simian T cells produced high amounts of the circulating bovine hormone in experimentally infected New World primates (Desrosiers *et al.*, 1985b, 1986). This suggested that episomally persisting, non-integrating HVS vectors could be used for therapy of hereditary genetic disorders, like cytokine receptor deficiencies (Altare *et al.*, 2001). HVS-vectors efficiently transduce human mesenchymal cells including bone marrow stromal cells (Frolova-Jones *et al.*, 2000) or haematopoietic precusors (Doody *et al.*, 2004); infection of human hematopoietic progenitor cells is somewhat less efficient and with a tendency towards partially differentiated cells (Stevenson *et al.*, 1999). Limited replication of HVS replication was observed in certain human cell types (Daniel *et al.*, 1975; Simmer *et al.*, 1991; Stevenson *et al.*, 1999). Although totipotent mouse embryonic stem (ES) cells were infected under drug selection with rather stable transgene expression (Stevenson *et al.*, 2000a), the infection of differentiated murine or rat cells is mostly inefficient.

The behavior of HVS C488 in various Old World monkey systems is of interest although macaque T-cell lines were shown to shed low amounts of virus particles in many cases (Alexander *et al.*, 1997; Knappe *et al.*, 2000a), reinfusion of autologous transformed T cells into the donor macaques did not induce disease, the infused T-cells persisted for extended periods, and the animals were protected against tumor induction by challenge with the HVS C488 virus (Knappe *et al.*, 2000a). Conversely an attempt to improve the biological safety of HVS vectors by inserting the prodrug activating thymidine kinase gene of herpes simplex virus looked promising in vitro (Hiller *et al.*, 2000b), but failed in vivo: the recombinant HVS-TK viruses not only showed no response to the administration of ganciclovir but induced tumors even more rapidly than the wild-type HVS control (Hiller *et al.*, 2000a). Nevertheless, since gene transfer into primary human T-cells by transfection or retroviral transduction methods remains difficult, the maintained functional phenotype of HVS-transformed T lymphocytes supports the use of HVS-vectors for human T-cells (reviewed in Fickenscher and Fleckenstein, 2002). Transformation-competent HVS-vectors might be valuable for the targeted amplification of functional human T-cells, or even for therapeutic redirection of human T-cell antigen specificity, as a tool for experimental cancer therapy applications.

Herpesvirus ateles

Natural occurrence and pathology

Herpesvirus ateles can be isolated at a high rate from spider monkeys (*Ateles (A.) spp.*) (for review see Fleckenstein and Desrosiers, 1982). Isolate #810 from *A. geoffroyii* (Melendez *et al.*, 1972) is officially classified as ateline herpesvirus type 2, whereas isolate #73 and related strains (#87, 93, 94) from *A. paniscus* were designated as ateline herpesvirus type 3 (Falk *et al.*, 1974). HVA replicates in OMK cells (Daniel *et al.*, 1976), but remains mostly cell-associated with syncytia formation. As a result, supernatants of such cultures have lower and unstable HVA titers. Like HVS, HVA is not pathogenic in its natural host, but causes acute T-cell lymphoma in various New World primate species including tamarins (*Saguinus oedipus*) and owl monkeys (*Aotus trivirgatus*) (Hunt *et al.*, 1972). The pathological changes are similar to those observed after HVS infection. In addition, HVA transforms T-cells of certain New World monkey species such as cotton-top tamarins in culture,

Table 60.1. Gammherpesviruses

Designation, Abbreviation	Host	Associated pathogenicity
Rhadinovirus species		
Kaposi's sarcoma associated herpesvirus, KSHV	Human	Kaposi's sarcoma, multicentric Castleman's disease, primary effusion lymphoma
Retroperitoneal fibromatosis-associated herpesvirus, RFHV, MnRhRV	Rhesus monkey	Retroperitoneal fibromatosis ?
Rhesus monkey rhadinovirus, RRV	Rhesus monkey	B-cell hyperplasia ?
Herpesvirus saimiri, HVS[a].	Squirrel monkey	T-cell lymphoma in other neotropical monkeys
Herpesvirus ateles, HVA	Spider monkey	T-cell lymphoma in other neotropical monkeys
Alcelaphine herpesvirus 1, AHV-1	Wildebeest	Malignant catarrhal fever in cattle
Alcelaphine herpesvirus 2, AHV-2	Hartebeest, Topi	
Ovine herpesvirus 2, OHV-2	Sheep	Malignant catarrhal fever in cattle and deer
Caprine herpesvirus 2	Goat	Chronic disease in deer ?
Bovine herpesvirus 4, BHV-4	Cattle	None reported
Equine herpesvirus 2 and 5, EHV-2, -5	Horse	Mononucleosis in horses?
Porcine lymphotropic herpesviruses, PLHV-1/2	Pig	None reported
Herpesvirus sylvilagus	Cottontail rabbit	Mononucleosis in rabbits ?
Murine gammaherpesvirus 68, MHV-68	Wood mouse, Bank vole	Mononucleosis in mice
Lymphocryptovirus Species		
Epstein–Barr Virus, EBV, HHV-4[a]	Human	B-cell lymphoma; NPC; Hodgkin's disease, other
Chimpanzee LCV, Herpesvirus pan	Chimpanzee	
Baboon LCV, Herpesvirus papio	Baboon	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
Rhesus LCV, Cercopethine HV 15	Rhesus Monkey, Macaca mulatta	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
cynomolgus LCVs (HVMF1, Cyno-EBV, Si-IIA-EBV)	Cynomolgus sp, Macaca fascicularis	Spontaneous B-cell lymphoma (and in immunosuppressed animals)
Marmoset LCV, CalHV3	Common marmoset	Spontaneous B-cell lymphoma
SmiLHV1	Gold-handed tamarin	Unknown
SscLHV1	Squirrel monkey	Unknown
PpiLHV1	White-faced saki	Unknown

[a]Type species

yielding cytotoxic T-cell lines (Falk *et al.*, 1978; reviewed in Fleckenstein and Desrosiers, 1982). Human T-cells have not been susceptible to transformation with various HVA strains.

Genome structure and replication

HVA strain #73 has a similar genome structure as HVS (Albrecht, 2000; Fleckenstein *et al.*, 1978a)(Fig. 60.1). The long unique L-DNA containing all the virus genes has 108 409 bp with 36.6% G+C, and the terminal repetitive H-DNA without coding capacity contains multiple tandem repeats of 1582 bp with 77.1% G+C. The HVA genome contains 73 ORFs and only two genes for U-RNA like transcripts (Albrecht, 2000; Albrecht *et al.*, 1999). While the viral SAG, Cyclin, GPCR homologues of HVS are conserved in HVA, it does not encode homologues to the ORF12, vIL17, vCD59 nor vFLIP (Fig. 60.1). The impression is rather convincing that HVA resembles an ancient variant of HVS which has either collected a smaller set of cell-homologous genes or has secondarily lost several genes.

Oncogenesis

In HVA strain #73, a spliced gene with two exons was detected in the left-terminal L- to H-DNA transition region. The derived viral protein shares local sequence homology with StpC and Tip of HVS and was therefore termed Tio ("two in one," Fig. 60.2). Tio is expressed in HVA-transformed simian T cells. After cotransfection, Tio

bound to and was phosphorylated by the Src kinases Lck or Src (Albrecht *et al.*, 1999). Human T-cells can be successfully transformed by recombinant HVS C488 in which the StpC and Tip genes were replaced by either the HVA #73 region containing the promoter and both exons of Tio, or a cDNA of Tio transcribed from a heterologous promoter; thus, Tio can substitute for both StpC and Tip in human T-cell transformation (Albrecht *et al.*, 2004). Tyrosine phosphorylation of Tio is required for transformation of human T-cells in the context of a recombinant HVS genome (Albrecht *et al.*, 2005), and it has been found that Tio induces NFkB signaling through direct interaction with TRAF6 (Heinemann *et al.*, 2006).

Lymphocryptoviruses of New World primates

Gammaherpesviruses that are closely related to EBV were recognized in several species of Old World primates from the mid-70s. Until recently the paradigm was that the lymphocryptoviruses (LCV) are restricted to Old World primates including humans (Wang *et al.*, 2001). However, a virus was isolated from common marmosets, both from healthy animals and animals with spontaneous B-cell lymphomas (Ramer *et al.*, 2000; Cho *et al.*, 2001); Related LCV have also been detected in several other New World primate species (de Thoisy *et al.*, 2003; Table 60.1). This marmoset LCV (CalHV3) clearly had a EBV-like genome structure, yet several Old World primate LCV specific genes (Rivailler *et al.*, 2002b) were absent in this isolate (Rivailler *et al.*, 2002a). Namely, strong divergences were found in the LMP1 and 2, and the EBNA-LP, -2, and -3, and the marmoset LCV does not have homologues to BCRF1/vIL10, BARF1/CSF-1R, BARF0, EBERs, and several other EBV genes of unknown function. Also, the organization of the putative marmoset LCV OriP-region is clearly distinct from the Old World primate LCV; the *family of repeats* are a succession of two different and diverged repeat subunits, and it lacks the *dyad symmetry* elements (Rivailler *et al.*, 2002a). In-vitro transformation of B-cells by human and simian OWP-LCV seems to be mostly restricted to the natural host or closely related species (Moghaddam *et al.*, 1998). However, experimental T-cell tumors can be induced in rabbits following infection by Cynomolgus (Cyno-EBV) and Baboon (HVP) -LCV (Hayashi *et al.*, 2001).

Conclusions

The γ-herpesvirus subgroups *Lymphocryptovirus* and *Rhadinovirus* occur in New World as well as Old World primates including humans. Several members of both virus subgroups are closely related to viral oncogenesis, though the simian viruses do not generally provide an uncomplicated model for multifaceted human diseases. Kaposi's sarcoma is a complex entity that may be caused by the direct transforming action of viral oncogenes as well as a chronic inflammatory reaction, which may be amended or modulated by KSHV-encoded or -induced cytokines and/or angiogenic factors. No comparable animal model could be based on the use of the KSHV-related primate γ2-herpesviruses. Although a comparable virus-associated acute peripheral pleomorphic T-cell lymphoma is not known yet in humans, Herpesvirus saimiri can serve as an experimental model for general tumor development in humans. The ability of certain HVS-strains to transform human T lymphocytes to provides a promising tool for laboratory studies in T-cell immunology, including inherited and acquired immunodeficiency. Stp, Tip and Tio represent new classes of membrane-bound viral oncoproteins, most likely as small adaptor polypeptides that proficiently dominate T-cell signaling. Recombinant rhadinoviruses can deliver foreign genes into primary human mesenchymal cells and T-lymphocytes; this may prepare the ground for future therapeutic applications of persisting rhadinoviral vectors in adoptive immunotherapy.

EBV and KSHV – related herpesviruses in non-human primates

Blossom Damania

Lineberger Comprehensive Cancer Center, Department of Microbiology and Immunology, University of North Carolina, NC, USA

Introduction

Herpesviruses can be found in primates throughout the animal kingdom.In the animal kingdom, the order of primates is classified into two suborders, the Prosimians and the Anthropoids (Fig. 61.1(a)). Prosimians are the earliest and most primitive of primates and are comprised of lemurs, lorises and tarsiers. Tarsiers share characteristics that are intermediate between the prosimians and the anthropoids, and hence are sometimes considered a third suborder. The Anthropoids are classified into platyrrhines (flat nosed) and catarrhines (downward pointing nose).

The platyrrhines are New World monkeys found exclusively in Mexico and Central and South America. This group includes tamarins, common marmosets, squirrel monkeys and spider monkeys. Evolution of the platyrrhines has been a subject of intense debate. Most believe that the origin and early diversification of platyrrhines occurred on the African continent. It is thought that the platyrrhines then crossed the Atlantic Ocean to the Americas at a time when sea levels were lower and the ocean ridges in the Atlantic were likely exposed as islands, creating pathways that were conducive to platyrrhine migration.

The catarrhines are sub-divided into Cercopithecoids or Old World monkeys (with tails) and Hominids (no tails) (Fig. 61.1(b)). Old World monkeys are found in both Africa and Asia. The rhesus monkey (*Macaca mulatta*) and the cynomolgus monkey (*Macaca fascicularis*) are examples of Old World primates found in Asia, while African green monkeys and baboons are Old World primates found exclusively in Africa. The Hominids include apes like chimpanzees, gibbons, gorillas, orangutans, and humans. Hominids are divided into three groups: the *pongidae* (orangutans) and the *hylabatidae* (gibbons) that live in Asia, and the *panidae,* including gorillas and chimpanzees, that live in Africa. The divergence of the platyrrhines and the catarrhines is thought to have occurred 35 million years ago and the divergence of the cercopithecoids from the hominoids is thought to have occurred about 25 million years ago. These estimates are based on paleontological fossil records, as well as sequence comparisons of mitochondrial genes (Schrago and Russo, 2003; Stewart and Disotell, 1998).

Nomenclature

A wide body of literature has identified the presence of the gammaherpesvirinae throughout the animal kingdom (Fig. 61.1). These viruses include members of both the lymphocryptovirus (LCV) and rhadinovirus sub-families of the gammaherpesvirinae. The name Lymphocrypto is derived from the Latin word *lympha* meaning "water" and the Greek word *kryptos* meaning "concealed," and the name Rhadino is derived from the Greek adjective *rhadinos*, meaning slender (ICTV website). Many of these non-human primate gammaherpesviruses are distinctly related to the human lymphocryptovirus, Epstein–Barr virus (EBV/HHV-4) and the human rhadinovirus, Kaposi's sarcoma-associated herpesvirus (KSHV/HHV-8).

The nomenclature used for the primate herpesviruses can be quite obscure. Names such as Herpesvirus papio and Herpesvirus pan are not specific since they do not clearly designate which herpesvirus is being identified. To clarify this, the International Committee on the Taxonomy of Viruses (ICTV) has suggested a defined nomenclature system which uses the family or sub-family of the natural host followed by the sequential number in order of discovery (ICTV website). Examples of this nomenclature system are *Cercopithecine herpesvirus* 17 which refers to the 17th herpesvirus found in rhesus macaques (also known as rhesus monkey rhadinovirus (RRV)), while *Cercopithecine herpesvirus* 15 refers to the 15th herpesvirus found in rhesus

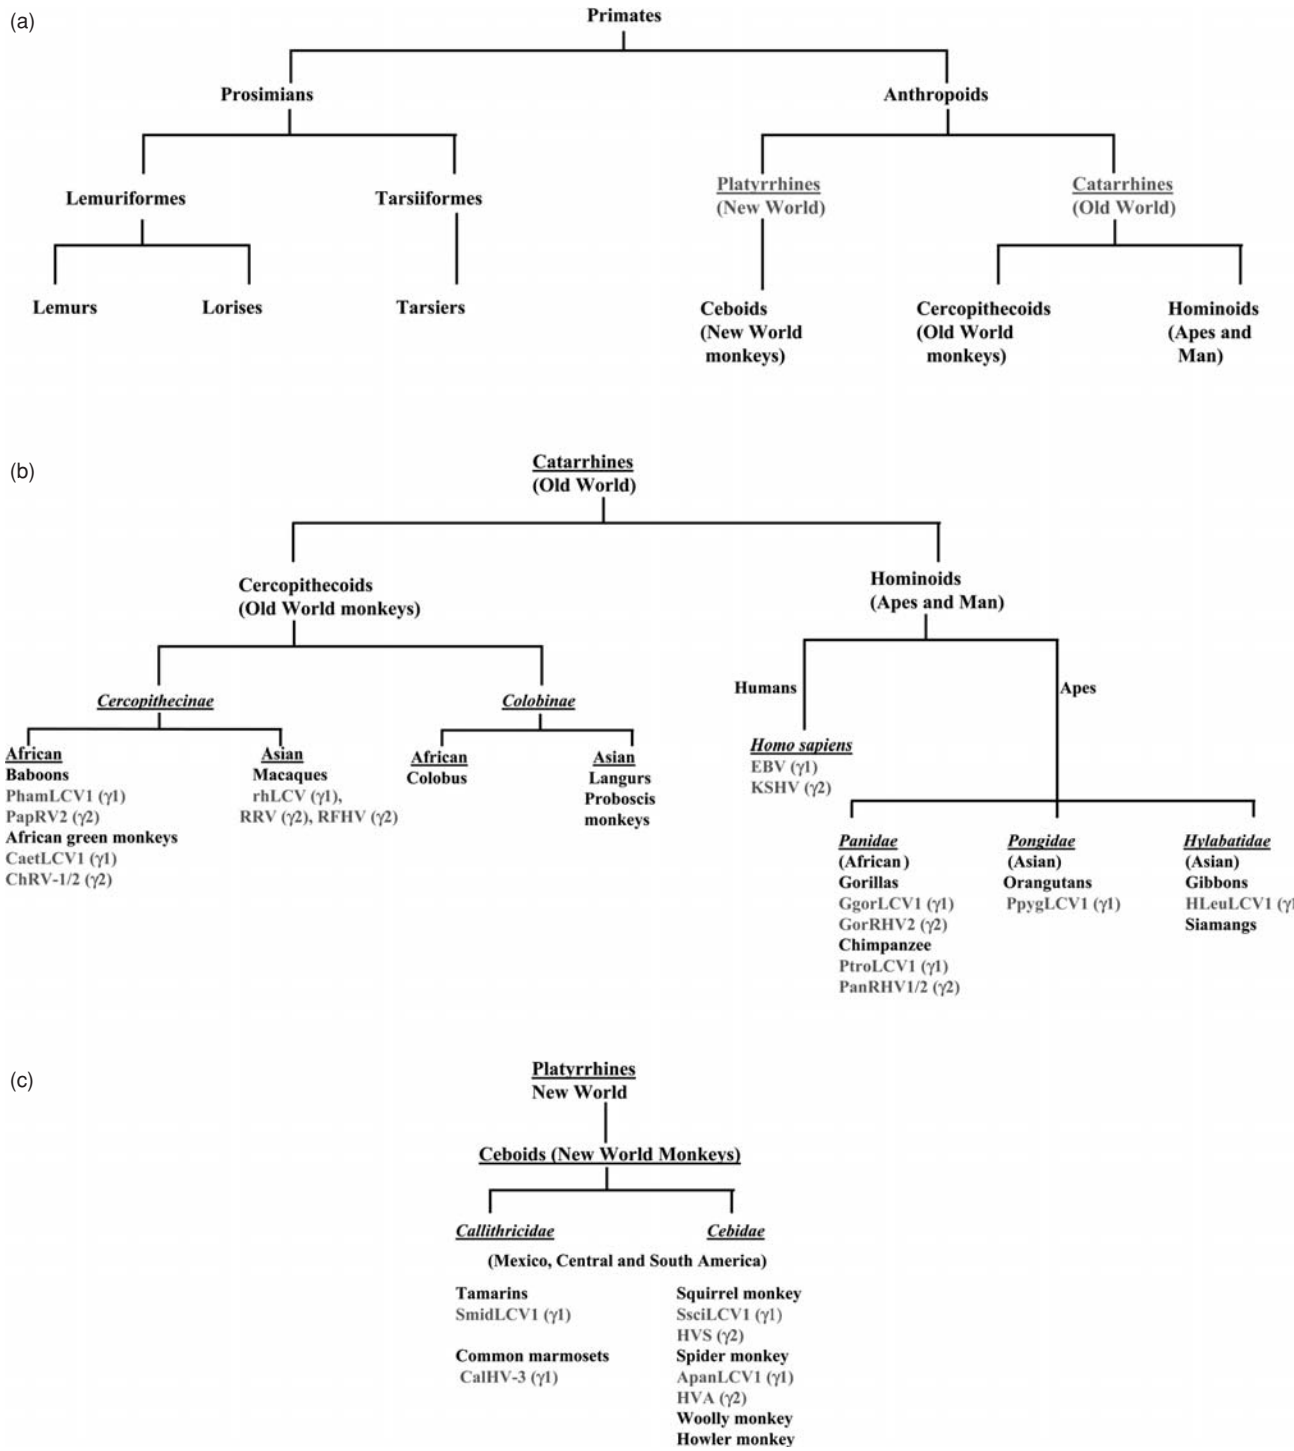

Fig. 61.1. Classification of primates and gammaherpesviruses in the Animal Kingdom. (a) Primates are classified into two groups; the Prosimians and the Anthropoids. (b) Classification of the Catarrhines or Old World Primates. The gammaherpesviruses found in the different primate species are shown in gray. (c) Classification of the Platyrrhines or New World Primates. The gammaherpesviruses found in the different primate species are shown in gray.

macaques also referred to as rhesus EBV. In order to facilitate recognition and easy usage, several investigators have combined the host species and virus for vernacular usage, e.g., baboon LCV. Further, due to the identification of multiple isolates of primate rhadinoviruses, some investigators have further chosen to numerically identify the lineage. For example, *Papio anubis* RV2 or PapRV2 is the alternate name for one of two rhadinoviruses found in baboons, whereas ChRV1 is the name of one of two rhadinoviruses found in African Green monkeys (Whitby *et al.*, 2003; Greensill *et al.*, 2000b) (Table 61.1).

Evolution of New and Old World Lymphocryptoviruses

The platyrrhines diverged from the catarrhines around 35 million years ago, and hence parallel the divergence of the New World and Old World lymphocryptoviruses. Thus, the rhesus LCV and human EBV genomes are more closely related to each other than the common marmoset LCV genome. However, it is clearly evident that both these viruses evolved from a common ancestral viral genome since many genes are conserved between these different lymphocryptoviruses. For example, several essential genes like EBV nuclear antigen 1 (EBNA-1), which is required for episome maintenance, and BZLF1 and BRLF1, which are required for viral replication, are conserved between the Old and New World lymphocryptoviruses and speak to the importance of their functions in the viral lifecycle (Tables 61.2 and 61.3). Other genes like the colony-stimulating factor 1 receptor (CF1R) homologue and the interleukin 10 (IL-10) homologue are present in only the Old World lymphocryptoviruses like EBV and rhesus LCV, but are absent from the New World lymphocryptovirus genome (Tables 61.2 and 61.3). This suggests that these two genes were captured by rhesus LCV or an ancestral virus after the divergence of the New and Old World LCV, and were selected for and retained by the human virus because they provide a biological advantage during the viral lifecycle.

Lymphocryptoviruses of Old World Monkeys

There are several lymphocryptoviruses that have been identified in both Old and New World monkeys (Table 61.1). Similar to their human counterpart, EBV, all these viruses are capable of immortalizing B cells in vitro. These viruses manifest both persistent infection and B-cell lymphomagenesis raising the speculation that a biological selection for these two characteristic properties of lymphocryptoviruses has existed throughout evolution. The first clue that Old World primates were indeed infected with EBV-related viruses came from studies demonstrating that the serum of several Old World primates exhibited antibody cross-reactivity against human EBV (Dunkel *et al.*, 1972; Kalter *et al.*, 1972; Naito *et al.*, 1971; Levy *et al.*, 1971; Landon and Malan, 1971). Lymphocryptoviruses were identified in baboons, common marmosets, gorillas and orangutans, and several LCV cell lines containing these viruses have been established in vitro (Rabin *et al.*, 1977a,b; Neubauer *et al.*, 1979; Rasheed *et al.*, 1977). Interestingly, viruses from these cell lines were shown to immortalize both autologous B cells, as well as B cells from closely related species (Falk *et al.*, 1977; Ishida and Yamamoto, 1987; Neubauer *et al.*, 1979; Rabin *et al.*, 1977a,b; Rangan *et al.*, 1986). Further, analysis of the restriction digestion patterns of the lymphocryptovirus herpesvirus papio (HVPapio) from baboons revealed that the viral genome was organized in a collinear fashion with human EBV and that the genomes shared 40% homology (Heller *et al.*, 1981; Heller and Kieff, 1981). To date, multiple lymphocryptoviruses have been identified from different Old World primates such as chimpanzees (Landon *et al.*, 1968), baboons (Vasiljeva *et al.*, 1974), African green monkeys (Bocker *et al.*, 1980), orangutans (Rasheed *et al.*, 1977) and gorillas (Neubauer *et al.*, 1979).

Other studies give credence to the close similarity between the simian and human lymphocryptoviruses. For example, rhesus macaques contain two rhesus lymphocryptoviruses (Type 1 and Type 2) similar to the situation in humans (Cho *et al.*, 1999). In the human population, there are two types of EBV isolates, EBV-1 and EBV-2 that can be distinguished by genetic polymorphisms in the EBNA genes (Dambaugh *et al.*, 1980, 1984, 1986; Zimber *et al.*, 1986; Rowe *et al.*,1989; Rowe and Clarke, 1989; Sample *et al.*, 1990). EBV-1 is more efficient in B cell immortalization than EBV-2 (Rickinson *et al.*, 1987; Cohen *et al.*, 1989). The two types of rhesus LCVs have similar genetic polymorphisms as seen in the human isolates, and share the same biological properties (Cho *et al.*, 1999). Thus, both the human and non-human primate lymphocryptoviruses share similar genomic organizations and biological properties, which suggests that they arose from the same ancestral lymphocryptovirus and that there exists a similar selection pressure for the evolution of two different LCVs in both humans and macaques.

The rhesus LCV genome

The complete rhesus LCV (type 1) genome has been cloned and sequenced (Rivailler *et al.*, 2002b). Rhesus LCV encodes

BZLF1	71.3	Transcription factor
BRLF1	76.3	Transcription factor
BALF5	94.8	DNA polymerase

eighty open reading frames (ORFs) and each ORF shares homology to a corresponding gene in human EBV. The average gene homology between EBV and rhesus LCV is 75.6% (Rivailler *et al.*, 2002b). Each ORF is located at an equivalent position in the viral genome (Rivailler *et al.*, 2002b). Many of the latent and lytic genes of rhesus LCV are conserved with those of human EBV. Latent genes include those of the EBV nuclear antigens, EBNA-1, 2, 3A, 3B, 3C, the EBV-encoded small RNAs (EBERs) and the latent membrane proteins LMP1, 2A and 2B (Rivailler *et al.*, 1999, 2002b; Blake *et al.*, 1999; Cho *et al.* 1999; Franken *et al.*, 1996; Jiang *et al.*, 2000; Peng *et al.*, 2000). Both the rhesus LCV and human EBV genomes have four homologues of cellular genes: CSF1R (BARF1), two bcl-2 homologues (BHRF1 and BALF1) and an IL-10 homologue (BCRF1) (Rivailler *et al.*, 2002b). Interestingly, although the bcl-2 homologues are conserved between the Old and New World lymphocryptoviruses (Tables 61.2 and 61.3), the IL-10 homologue and the colony-stimulating factor 1 receptor were recently acquired genes, and are not present in an LCV genome isolated from a

Table 61.3. A comparison of proteins encoded by the human and marmoset lymphocryptoviruses

Marmoset LCV	% aa similarity to EBV	Function	Positional homologue in EBV
C1	–	Unique gene (Transforming gene)	LMP-1
C2	–	Unique gene	BILF2
C3	–	Unique gene	EBNA-3
C4	–	Unique gene	BHLF1
C5	–	Unique gene	EBNA-2
C6	–	Unique gene	none
C7	–	Unique gene	LMP-2
ORF39 (EBNA-1)	36.0	Episomal maintenance	EBNA-1
ORF 64 (BHRF1)	20.5	Bcl-2 homologue	BHRF1
ORF 1 (BALF1)	27.6	Bcl-2 homologue	BALF1
ORF 43 (BZLF1)	29.0	Transcription factor	BZLF1
ORF 42 (BRLF1)	39.0	Transcription factor	BRLF1
ORF 5 (BALF5)	73.5	DNA polymerase	BALF5

common marmoset (Rivailler *et al.*, 2002b) (Tables 61.2 and 61.3). Table 61.2 shows a list of important genes encoded by rhesus LCV and their function.

Latency, immune-modulatory and transforming genes of rhesus LCV

Epstein–Barr virus nuclear antigen-1 (EBNA-1)

The latency gene, EBV EBNA-1 is a critical gene required for establishment and maintenance of the viral genome in the latent state. Both baboon LCV (*Cercopithecine herpesvirus 12* or herpesvirus papio) and rhesus LCV (*Cercopithecine herpesvirus 15*) encode homologues of EBV EBNA-1 that are highly conserved (Blake *et al.*, 1999; Yates *et al.*, 1996). The same is true for the EBNA-1 protein from a lymphocryptovirus infecting cynomolgus monkeys (Ohara *et al.*, 2000). Interestingly, these simian viral EBNA-1 proteins are slightly smaller than the human viral protein due to differences in the glycine-alanine (GAR) repeat domain. The baboon and rhesus LCV EBNA-1 proteins can both function to support EBV ori-P-dependent plasmid replication and maintenance, similar to EBV EBNA-1 (Marechal *et al.*, 1999; Ruf *et al.*, 1999). In addition, the molecular mechanisms governing latent gene expression such as the EBNA-1 and EBNA-2 transcripts are also conserved among the primate LCVs (Ruf *et al.*, 1999; Fuentes-Panana *et al.*, 1999).

However, one difference between these proteins is that, although the EBV EBNA-1 protein can inhibit antigen presentation to escape CTL surveillance (Levitskaya *et al.*, 1995), this immunomodulatory function is not conserved in the rhesus LCV EBNA-1 protein (Blake *et al.*, 1999) using in vitro assays. However, in naturally and experimentally infected rhesus macaques, the LCV EBNA-1 protein appeared to play a role in immune evasion in vivo (Fogg *et al.*, 2005).

Epstein–Barr virus nuclear antigen-2 (EBNA-2)

Despite the fact that the EBNA-2 protein in the rhesus and baboon LCVs show only limited homology to each other and to human EBV, their functional characteristics such as their interactions with the transcription factor RBP-Jk have been retained (Ling *et al.*, 1993; Ling and Hayward, 1995; Cho *et al.*, 1999; Peng *et al.*, 2000). The polyproline repeat in the rhesus and baboon EBNA-2 proteins is shorter than the EBV EBNA-2 protein (Peng *et al.*, 2000). However, since this region appears to be dispensable for transactivation and B cell immortalization (Yalamanchili *et al.*, 1994) the significance of this divergence may be minimal. As mentioned above, genetic polymorphisms in the EBNA-2 genes have suggested the presence of two types of LCVs in rhesus macaques, similar to the situation in humans.

Epstein–Barr virus nuclear antigen- 3A,3B,3C (EBNA-3A, 3B, 3C)

The rhesus LCV latency-associated genes, EBNA-3A, 3B and 3C, show loose homology to human EBV EBNA-3A, 3B and 3C genes. Again, despite the limited conservation in sequence among these proteins, the interaction with RBP-Jk has been retained (Dalbies-Tran *et al.*, 2001; Zhao *et al.*, 2003; Jiang *et al.*, 2000). Further, the transactivation function of EBNA-3C has also been conserved between the rhesus, baboon and human viral proteins, and all three

proteins can interact with the Spi proteins (Zhao *et al.*, 2003). Both non-human primate 3C proteins can support transcriptional activation mediated by the Spi proteins in the presence of EBNA-2 (Zhao *et al.*, 2003). Despite these similarities, gene replacement studies demonstrated that the rhesus LCV EBNA-3 genes were unable to functionally substitute for the EBV EBNA-3 genes in the EBV genome, for immortalization of human B-cells (Jiang *et al.*, 2000). However, the ability of this recombinant virus to immortalize rhesus B cells was not tested.

EBV latent membrane protein (LMP-1)

The EBV-encoded latent membrane protein 1 (LMP1) structurally and functionally resembles a constitutively active TNF family receptor. LMP1 aggregates in the plasma membrane and can activate a multitude of signaling pathways in the cell resulting in cell proliferation and transformation. Sequence analysis of the LMP-1 proteins from baboons (*Cercopithicine herpesvirus 12* or herpesvirus papio) and rhesus monkeys (*Cercopithicine herpesvirus 15*) showed that although the transmembrane domains of these proteins are conserved with that of EBV LMP-1, there is great divergence within the carboxy-terminal cytoplasmic domains of these proteins (Franken *et al.*, 1996). The C-terminal domain of EBV LMP1 has been shown to be essential for B-cell immortalization and interaction with members of the tumor necrosis factor receptor family. A comparative study of the simian LMP-1 proteins with EBV LMP-1 showed that the simian LCV LMP-1 proteins could induce NF-kB activity, bind tumor necrosis factor associated factor −3 (TRAF3) and induce ICAM1 expression (Franken *et al.*, 1996). This is likely through the multiple TRAF3 binding sites (PXQXT/S) that are contained within the simian LCV LMP1 C-terminal domain (Franken *et al.*, 1996). A similar study performed with an LCV LMP1 protein from cynomolgus monkeys (*Macaca fascicularis*) shows that this simian LMP1 protein also contains two PXQXT/S motifs and retains its ability to activate the NF-kB pathway (Faucher *et al.*, 2002). It has recently been reported that the transmembrane domain of EBV LMP1, specifically FWLY (amino acids 38–41), is critical for signal transduction which includes raft localization of the viral protein, TRAF3 interaction and NF-kB activation (Yasui *et al.*, 2004). Although the identical FWLY motif is not present in either the baboon or rhesus LCV LMP-1 proteins, the simian LMP-1 viral proteins may contain motifs that are functionally similar to FWLY, since they can activate NF-kB. Further, Eliopoulos and Young (1998) have reported that LMP1 homologues from the baboon and rhesus EBV are also capable of activating the c-Jun N-terminal kinase (JNK) pathway (Eliopoulos and Young, 1998). Thus, activation of the NF-kB and JNK pathways by the primate LMP1 proteins is an important function that has been conserved throughout evolution.

EBV latent membrane protein-2 (LMP-2)

The LMP2A homologues in the baboon and rhesus LCV genomes show homology to EBV LMP2 and contain an immunoreceptor tyrosine based activation motif (ITAM) (Franken *et al.*, 1996; Rivailler *et al.*, 1999). All three primate LCV LMP2A proteins contain 12 transmembrane domains, and although the amino acids in the cytoplasmic domain are quite different, the ITAM and proline-rich domains are well conserved. These conserved motifs/domains in EBV LMP2A have been shown to be required for interaction with protein tyrosine kinases (Portis *et al.*, 2002) and are essential for LMP2A function. Moreover, the rhesus LCV LMP2B gene is located at an equivalent genomic position as EBV LMP2B, and the EBNA-2 responsiveness and the bidirectional nature of the LMP1-LMP2B promoter is conserved between the rhesus and human lymphocryptoviruses (Rivailler *et al.*, 1999).

Rhesus LCV as an animal model system for EBV

Historically, several investigators attempted and failed to infect Old World primates such as baboons and rhesus macaques with human EBV (Frank *et al.*, 1976; Gerber *et al.*, 1969; Levine *et al.*, 1980). This failure to establish EBV infection in Old World primates may be due to the route of inoculation used in these studies, pre-existing antibody cross-reactivity due to natural LCV infection in the primates, or the utilization of non-transforming deletion mutants of EBV, namely P3HR1 (Levine *et al.*, 1980). It is also possible that there is a species restriction imposed on EBV infection of non-human primates, since LCVs tend to be competent for immortalization of B-cells from the same or closely related species, but immortalization potential varies for B-cells from a more divergent species. For example, Moghaddam *et al.* (1998) found that rhesus LCV did not immortalize human B cells, and human EBV could not immortalize rhesus monkey B cells (Moghaddam *et al.*, 1998). Further, since the rhesus LCV was able to infect human B cells, the species restriction was after virus penetration (Moghaddam *et al.*, 1998). Rhesus and baboon LCVs have been reported to be incapable of immortalizing human B-cells (Falk *et al.*, 1977), although other reports suggest that this is possible at a much lower frequency (Rabin *et al.*, 1977a; Gerber *et al.*, 1977). In a similar manner, EBV has been shown to immortalize B cells from chimpanzees, which are more closely

related to humans, and chimpanzee LCV can immortalize human B-cells (Gerber *et al.*, 1977; Ishida and Yamamoto, 1987). Likewise, baboon LCV can immortalize B-cells from gibbons, rhesus and cynomolgus macaques (Gerber *et al.*, 1977).

In light of the fact that human EBV fails to establish long-term infection in rhesus macaques, rhesus LCV serves as a valuable animal model to study EBV pathogenesis since successful experimental infection of naïve rhesus macaques with rhesus LCV has been previously reported (Moghaddam *et al.*, 1997). Naïve rhesus macaques were orally infected with rhesus LCV and this resulted in an acute and persistent LCV infection, which closely resembled that seen with primary EBV infection of humans. Initial viral load peaked between 4 to 21 days and declined to almost undetectable levels over a 3-month period (Rao *et al.*, 2000). Immune activation was evidenced three days after oral inoculation by the presence of T-cells expressing IL-2, IL-10 and gamma interferon. Activated CTL activity against LCV infected cells was observed in the first few weeks post-infection similar to what has been described for infectious mononucleosis patients in the human population (Wang, 2001). In addition, antibody responses against EBNA-2 and viral capsid antigens develop within 2 weeks post-inoculation (Moghaddam *et al.*, 1997; Mohle *et al.*, 1997; Rao *et al.*, 2000). Persistent viral infection could be detected in the oropharynx of infected animals by PCR (Cho *et al.*, 1999; Moghaddam *et al.*, 1997; Mohle *et al.*, 1997; Rao *et al.*, 2000) and in B-cells, and a percentage of these infected B cells were immortalized and could be grown in tissue culture (Moghaddam *et al.*, 1997; Mohle *et al.*, 1997). Persistent infection as measured by RT-PCR of the rhesus LCV EBER genes in peripheral blood mononuclear cells (PBMCs) was detected three years post-infection (Rao *et al.*, 2000). Thus, clinically speaking, primary, acute and persistent infection of macaques with rhesus LCV appears to closely mimic EBV infection of humans, further validating the use of rhesus LCV as an animal model system to study EBV pathogenesis.

The potential to use the rhesus LCV animal model system to study EBV-associated tumorigenesis is the subject of current and future investigation. Rivailler *et al.* reported that four immunosuppressed macaques infected orally with LCV failed to debelop lymphoproliferative disease. However, intravenous inoculation of autologous LCV immortalized B cells in four SHIV89.6P-infected animals resulted in one severely immunosuppressed animal developing an aggressive monoclonal LCV-positive lymphoma (Rivailler *et al.*, 2004). Feichtinger *et al.* (1992a,b) have shown that when cynomolgus monkeys naturally infected with LCV were infected with simian immunodeficiency virus (SIV), malignant B cell lymphomas containing DNA which cross-hybridized with human EBV were detected. In another study, squamous epithelial proliferative lesions in SIV-infected rhesus monkeys were also shown to contain EBV-like sequences by immunohistochemistry and *in situ* hybridization (Baskin *et al.*, 1995). A study on SIV-infected monkeys at the Tulane Primate Center showed that SIV-infected macaques have a higher rhesus LCV load in PBMCs than uninfected animals, but that the virus load varies widely among animals during disease progression (Habis *et al.*, 2000).

The current availability of the genomic sequence of rhesus LCV will facilitate the construction of recombinant LCVs that can be tested in rhesus macaques. Such studies will provide an understanding of the contribution of individual genes to the life cycle of these lymphocryptoviruses and serve to verify rhesus LCV as a tractable system to model EBV pathogenesis.

Other lymphocryptoviruses in Old World primates

A recent study by Ehlers *et al.* (2003) has identified the presence of novel lymphocryptoviruses in several species including baboons, chimpanzees, and gorillas (Table 61.1). Interestingly, this group found evidence for a second lymphocryptovirus in gorillas, baboons, mandrills and Japanese macaques (Fig. 61.2). Together these data raise the possibility that another yet to be discovered human lymphocryptovirus, different from the type 1 and 2 human EBV strains, may exist in the human population. This theme will be revisited when discussing the family of primate rhadinoviruses.

Lymphocryptoviruses of New World monkeys

Early serological studies had indicated that there was no evidence for the presence of lymphocryptoviruses in New World primates since there was no antibody cross-reactivity with human EBV from sera of New World monkeys (Frank *et al.*, 1976). However, Ramer *et al.* (2000) recently reported the identification of novel viral DNA sequences from common marmoset monkeys (*Callithrix jaccus)* afflicted with spontaneous B-cell lymphomas. These sequences were most closely related to EBV and suggested the presence of a novel lymphocryptovirus in New World primates. Subsequently, the first EBV-related herpesvirus in New World primates was cloned from common marmoset monkeys (Cho *et al.*, 2001; Jenson *et al.*, 2002). This virus was formally named Callitrichine herpesvirus

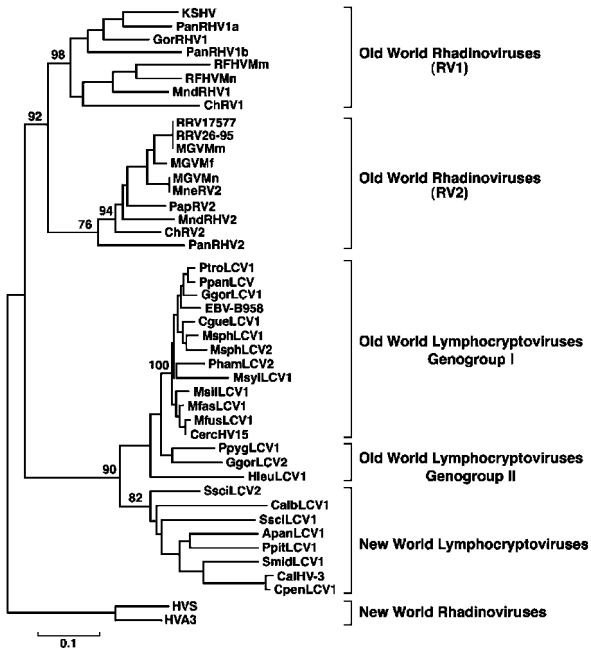

Fig. 61.2. Phylogenetic analysis of the gammaherpesviruses. Forty-four DNA polymerase nucleotide sequences (400bp) were aligned using the Clustal W matrix and edited in GeneDoc (v.2.6) to remove gaps. The tree was rooted using the New World Rhadinoviruses, HVS and HVA3 as the Outgroup. The Neighbor-Joining tree was constructed in Mega 2.1 from pairwise sequence distances calculated using the Kimura 2-parameter (K80) method. Bootstrap values were determined by 100 replica samplings. Sequences included in the phylogenetic analysis: KSHV (U75698); PanRHV1a (*Pan troglodytes*, AF250879); GorRHV1 (*Gorilla gorilla*, AF250886); PanRHV1b (*Pan troglodytes*, AF250882); RFHVMm (*Macaca mulatta*, AF005479); MndRHV1 (*Mandrillus sphinx*, AF282943); ChRV1 (*Chlorocebus aethiops*, AJ251573); RRV17577 (*Macaca mulatta*, AF083501); RRV26-95 (AF029302); MGVMm (*Macaca mulatta*, AF159033); MGVMf (*Macaca fascicularis*, AF159032); MGVMn (*Macaca nemestrina*, AF159031); MneRV2 (*Macaca nemestrina*, AF204167); PapRV2 (*Papio anubis*, AY270026); MndRHV2 (*Mandrillus sphinx*, AF282939); ChRV2 (*Chlorocebus aethiops*, AJ251574); PanRHV2 (*Pan troglodytes*, AF346490); PtroLCV1 (*Pan troglodytes*, AF534226); PpanLCV1 (*Pan paniscus*, AF534220); GgorLCV1 (*Gorilla gorilla*, AF534225); EBV-B95.8 (V01555); CgueLCV1 (*Colobus guereza*, AF534219); MsphLCV1 (*Mandrillus sphinx*, AF534227); MsphLCV2 (*Mandrillus sphinx*, AY174066); PhamLCV2 (*Papio hamadryas*, AF534229); MsylLCV1 (*Macaca sylvanus*, AY172956); MsilLCV1 (*Macaca silenus*, AF534222); MfasLCV1 (*Macaca fascicularis*, AF534221); MfusLCV1 (*Macaca fuscata*, AF534224); CercHV-15 (*Cercopithicine*, AY037858); PpygLCV1 (*Pongo pygamaeus*, AY129398); GgorLCV2 (*Gorilla gorilla*, AY129395); HleuLCV1 (*Hylobates leucogenys*, AY174068); SsciLCV2 (*Saimiri sciureus*, AY139024); CalbLCV1 (*Cebus albifrons*, AY139027); SsciLCV1 (*Saimiri sciureus*, AY172953); ApanLCV1 3 or CalHV3. A closely related virus to CalHV3 was also seen in squirrel monkeys (*Saimiri scireus*) (Cho *et al.*, 2001). Sequencing of the CalHV3 or marmoset LCV DNA revealed that the genomic organization was similar to that of EBV (Rivailler *et al.*, 2002a). Sequence analysis of the 73 open-reading frames (ORFs) revealed that although many genes showed high homology to genes in EBV, there were some striking differences between the two genomes as well.

The marmoset LCV (CalHV3) genome

The marmoset LCV genome is composed of approximately 160 000 nucleotides. Of the 73 ORFs found in the marmoset LCV genome, 59 of these share homology to genes found in all herpesviruses. Six additional genes encoded by ORFs 1,6,39,43,44 and 45 show homology to EBV BALF1, BILF1, EBNA-1, BZLF1, BZLF2 and gp350, respectively (Rivailler *et al.*, 2002a). The eight other marmoset ORFs show no sequence relatedness to either cellular or viral genes and were named C0 through C7 (Table 61.3). Based on their genomic position only, C0, C1,C2, C3,C4, C5 and C7 are in the equivalent genomic locations as EBV EBNA-LP, LMP1, BILF-2, EBNA-3, BHLF1, EBNA-2 and LMP2, respectively. In addition to encoding unique genes, there are also eleven EBV genes that are not present in marmoset LCV. These include the EBERs, BARF0, BCRF1, BARF1, and BDLF3 (Rivailler *et al.*, 2002a).

CalHV3 C1

C1 is a positional homologue of EBV LMP1. Although it shares no homology with LMP1 at the amino acid level and does not contain the PXQXT/S motifs that are contained in the C-terminus of the rhesus LCV and human EBV, C1 is a functional homologue of LMP1. It can transform rodent fibroblasts in vitro and can also induce NF-kB activity to similar levels as LMP1. Hence, C1 can interact with the TRAFs through an alternative TRAF binding motif (Wang *et al.*, 2001).

CalHV3 ORF39 (EBNA-1)

The CalHV3 EBNA-1 protein shows homology to EBV EBNA-1 in the C-terminal domain and the GR-rich

←

Fig. 61.2. (*cont.*) (*Ateles paniscus*, AY139028); PpitLCV1 (*Pithecia pithecia*, AY139025); SmidLCV1 (AY166693); CalHV-3 (*Cercopithicine*, AY049065); CpenLCV1 (*Callithrix penicillata*, AY139026); HVS (*Saimiri*, M31122); HVA3 (*Ateline*, AF083424). We thank R.K. Bagni and D. Whitby for help with the construction of the phylogenetic tree.

domains, which in EBV EBNA-1, are required for episomal maintenance (Wang *et al.*, 2001). However, the CalHV3 EBNA-1 homolog does not contain the Gly-Ala repeat region, which has previously been shown to be involved in immune-modulation (Levitskaya *et al.*, 1995).

CalHV3 C5

CalHV3 C5 is a positional homologue of EBNA-2 and shares no relatedness at the amino acid level. However like EBV EBNA-2, the C5 protein has a cluster of C-terminal acidic residues that may be important for transcriptional transactivation (Rivailler *et al.*, 2002a). Unlike the EBV and rhesus LCV EBNA-2, C5 is missing the polyproline repeat, which is present in EBV EBNA-2 (Yalamanchili *et al.*, 1996).

CalHV3 C7

C7 is a positional homologue of EBV LMP2. Similar to LMP2, it contains 12 transmembrane domains but a shorter N-terminus and a longer C-terminus (Rivailler *et al.*, 2002a). The latter contains five tyrosine residues, three of which may serve as part of Src-homology-2 (SH2) binding motifs (Rivailler *et al.*, 2002a).

New World primates as an animal model system for EBV

Historically, an extensive body of work has been published on using New World primates as an animal model system to study EBV (Shope *et al.*, 1973; Miller *et al.*, 1972, 1973). EBV readily infects and immortalizes B-cells from common marmosets (Desgranges *et al.*, 1976; Rabin *et al.*, 1977b). In fact one of the most widely used EBV-infected cell lines, B95-8, is a marmoset B-cell line infected with human EBV (Miller *et al.*, 1972). New World monkey species, including the cotton-top tamarin (*Sanguinus oedipus*), and owl monkey (*Aotus trivirgatus*) develop B-cell lymphomas upon infection with EBV (Cleary *et al.*, 1985; Johnson *et al.*, 1983; Epstein *et al.*, 1973a,b; Miller *et al.*, 1977; Werner *et al.*, 1975). Some publications suggest that common marmosets (*Callithrix jacchus*) also develop lymphoproliferative disease when infected with EBV DNA, and that lymphosarcomas in these animals contain EBV DNA (Falk *et al.*, 1976). Conversely, others have reported no substantial evidence of lymphoproliferative disease or lymphoma in EBV-infected common marmosets (de-The *et al.*, 1980; Ablashi *et al.*, 1978). Infection of common marmosets is thought to serve as a model for primary and persistent EBV infection (Wedderburn *et al.*, 1984).

Inconsistency in the induction of tumors by EBV in common marmosets, suggests that the cotton top tamarin is a more susceptible animal model for EBV oncogenesis. However, the cotton top tamarin was declared endangered in 1973 following the exportation of twenty to forty thousand tamarins from Colombia to the United States for use in biomedical research related to colonic adenocarcinoma (Hernandez-Camacho, 1976; Clapp *et al.*, 1982). Hence, their potential value as an animal model for EBV pathogenesis is limited due to their unavailability as well as the expense of the monkeys.

A comprehensive study on lymphocryptoviruses (LCV) that infect New and Old World primates has identified the presence of many lymphocryptoviruses from a multitude of primates (Ehlers *et al.*, 2003; de Thoisy *et al.*, 2003) (Table 61.1). These studies were done using degenerate PCR and revealed that some New and Old World monkeys are infected with two different lymphocryptoviruses, denoted as LCV1 and LCV2 (Table 61.1). In each primate species examined, one LCV virus was more closely related to human EBV and grouped in the same genogroup as EBV (Fig. 61.2), while the viruses that were less closely related to EBV all grouped together in a second lymphocryptovirus genogroup (Ehlers *et al.*, 2003) (Fig. 61.2).

Evolution of New and Old World rhadinoviruses

The Old World rhadinoviruses like RRV, RFHV and KSHV share more sequence relatedness amongst each other than with the New World rhadinovirus, HVS (see chapter on *Herpesvirus saimiri*), exemplifying the split of the platyrrhines and catarrhines 35 million years ago. Similar to the situation for the divergence of the lymphocryptoviruses, the rhadinoviral genomes of Old and New World primates both retain key viral genes such as Orf73 or Latency associated nuclear antigen (LANA), which is required for episomal maintenance of the viral genome, and Orf50/Rta which is required for viral replication. However, other proteins like viral interleukin 6 (vIL-6), macrophage inflammatory proteins (MIPs I, II and III), and the viral interferon regulatory factors (vIRFs) are only encoded by the Old World rhadinoviral genomes, RRV and KSHV, but are not present in the HVS genome, suggesting that these genes are more recent acquisitions in the rhadinovirus family, occurring after the split of the Old and New World primates. These proteins likely play key roles in the escape from immune surveillance and survival of the rhadinoviruses in their host species, and thus have been retained by KSHV, the most recent addition to the rhadinovirus evolutionary tree.

Rhadinoviruses of Old World primates

A wide body of literature supports the prevailing view that rhadinoviruses can be found throughout the animal kingdom in both Old and New World primates (Fig. 61.1). Rhadinoviruses that infect New World monkeys include herpesvirus saimiri (HVS) whose natural host is the squirrel monkey and herpesvirus ateles (HVA), which infects spider monkeys (Table 61.1) (Melendez *et al.*, 1969, 1972). Rhadinoviruses that infect Old World monkeys include rhesus monkey rhadinovirus (RRV) and retroperitoneal fibromatosis herpesvirus (RFHV) (Rose *et al.*, 1997; Desrosiers *et al.*, 1997).

Phylogenetic analysis

Among Old World primates, rhesus monkey rhadinovirus (RRV) and closely related viruses like RFHV, are gamma-2 herpesviruses of the macaque genus (Rose *et al.*, 1997; Desrosiers *et al.*, 1997). The similarity between the genomes of RRV and KSHV is high and all of the open reading frames (ORFs) in RRV have at least one homologue in KSHV (Alexander *et al.*, 2000; Searles *et al.*, 1999). RRV replicates lytically in cell culture and multiple isolates have been obtained independently by different laboratories (Desrosiers *et al.*, 1997; Searles *et al.*, 1999). The genomes of these isolates have been fully sequenced (Alexander *et al.*, 2000; Searles *et al.*, 1999). Rhadinoviruses closely related to RRV have been cultured from other macaque species, specifically *Macaca nemestrina* and *Macaca fascicularis* (Auerbach *et al.*, 2000; Mansfield *et al.*, 1999).

Short stretches of related but phylogenetically distinct sequences have also been amplified from *Macaca mulatta* and *Macaca nemestrina* (Bosch *et al.*, 1999; Strand *et al.*, 2000; Schultz *et al.*, 2000). The putative viruses represented by these sequences, named retroperitoneal fibromatosis herpesvirus *macaca mulatta* and *macaca nemestrina* (RFHVMm and RFHVMn, respectively), have been difficult to culture and lack information on genomic organization and sequence relatedness of the complete viral genome. Short stretches of related sequence have also been amplified from African green monkeys (*Chlorocebus aethiops*). In one particular study on rates of infection, 6 of 68 monkeys were found to be infected with *Chlorocebus aethiops* rhadinovirus 1 (ChRV1) while 22 of 68 monkeys were positive for *Chlorocebus aethiops* rhadinovirus 2 (ChRV2) (Greensill *et al.*, 2000b). Thus, the putative viruses represented by these sequences fall into two distinct phylogenetic groupings RV1 and RV2 (Fig. 61.2), neither of which have yet been successfully cultured in vitro (Greensill *et al.*, 2000b). In these studies, PCR products of the DNA polymerase genes from ChRV1, ChRV2, RFHVMm, and RFHVMn were amplified (Rose *et al.*, 1997; Bosch *et al.*, 1999; Strand *et al.*, 2000; Schultz *et al.*, 2000).

The above phylogenetic studies suggested the presence of at least two distinct lineages of KSHV-like rhadinoviruses in primates. One lineage contains KSHV, RFHVMm, RFHVMn, and ChRV1, and the other contains RRV, ChRV2 and *Macaca nemestrina* rhadinovirus type 2 (MneRV2). Short stretches of rhadinovirus sequences have since been amplified from chimpanzees, gorillas and mandrills (Lacoste *et al.*, 2000a,b; 2001; Greensill *et al.*, 2002a). Similar to the two distinct rhadinoviruses found in rhesus macaques and African green monkeys, both mandrills and chimpanzees also contain two gamma-2 herpesviruses, MndRHV1 and MndRHV2 for mandrills and PtRV-1 or PanRHV1a/1b and PanRHV2 for chimpanzees (Greensill *et al.*, 2000a; Lacoste *et al.*, 2000a,b) (Table 61.1, Fig. 61.2).

Retroperitoneal fibromatosis herpesviruses: RFHVMm and RFHVMn

Sequence from the RFHVMm and RFHVMn viruses were amplified from macaques (*Macaca mulatta* and *Macaca nemestrina*) affected with retroperitoneal fibromatosis (RF) (Rose *et al.*, 1997). RF is a vascular fibroproliferative disease that resembles Kaposi's sarcoma (KS) morphologically and histologically (Rose *et al.*, 1997). Nine of 40 *Macaca nemestrina* monkeys with retroperitoneal fibromatosis were positive for RFHvMn by PCR, while two out of two *Macaca mulatta* monkeys with RF were positive for RFHvMm. Two of two unaffected *Macaca nemestrina* monkeys were negative for RFHvMn by PCR (Rose *et al.*, 1997). As described above, phylogenetic analysis demonstrated that these two viruses clustered with KSHV in the RV1 genogroup, while RRV and MneRV2 cluster in a RV2 genogroup. This classification was originally based on the sequence of the viral DNA polymerase gene. To date, only a 7.7 kb fragment of the RFHVMm genomic sequence has been cloned (Rose *et al.*, 2003). This segment of the viral genome codes for glycoprotein B (gB), ORF 9, ORF10, vIL6, vDHFR, K3 and viral thymidylate synthase (TS). These genes are organized in a similar linear fashion as the corresponding homologs in KSHV. However, RFHVMm and RFHVMn are missing ORF11. Analysis of the amino acid similarity between the RFHVMm/RFHVMn and KSHV proteins indicated that RFHVMm and RFHVMn are most closely related to KSHV than any other virus, thus supporting their grouping in the RV1 lineage (Rose *et al.*, 2003). Further comparisons and evolutionary

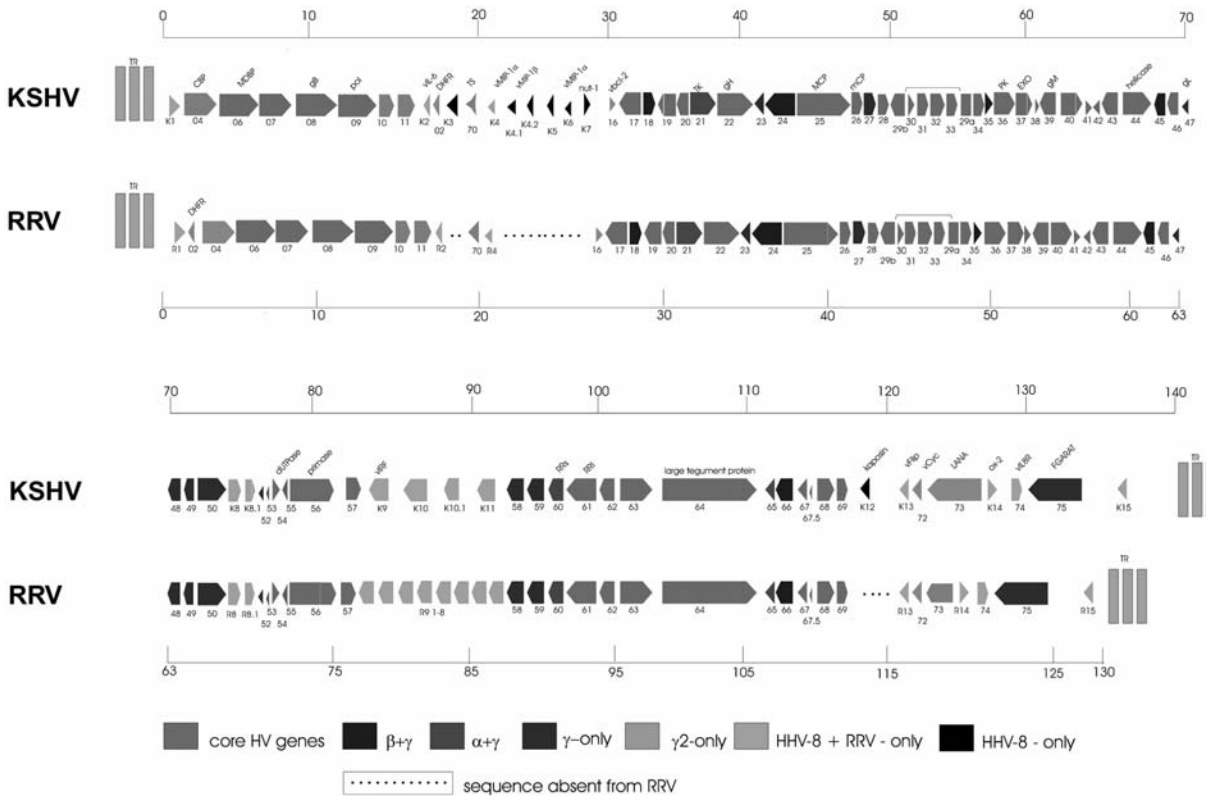

Fig. 61.3. Alignment of the KSHV and RRV genomes. The different colors signify ORFs contained in KSHV and RRV 26–95 that are conserved in the indicated herpesvirus subfamilies or subgroups. The square side of the symbol signifies the 5′ end and the pointed side of the symbol signifies the 3′ end of the depicted ORFs. The ORFs are not drawn to scale. (Taken from Alexander *et al.*, 2000, with permission from the *Journal of Virology*.) (See color plate section.)

analyses await sequencing of the complete RFHVMm and RFHVMn genomes. The RFHVs are currently being amplified from paraffin-embedded or frozen retroperitoneal fibromatosis tumor samples, and are not widely prevalent in the macaque populations housed in most US primate centers.

Rhesus monkey rhadinovirus (RRV)

Greater than 90% of adult macaques at the New England Regional Primate Center (NERPRC) are seropositive for RRV (Mansfield *et al.*, 1999; Desrosiers *et al.*, 1997). A similar frequency of infected macaques was also found at the Oregon Regional Primate Research Center (Wong *et al.*, 1999). Thus, RRV appears to be a natural infectious agent of macaques. However, newborn macaques can be raised free of RRV by hand-rearing (Mansfield *et al.*, 1999). RRV isolated from one species can readily infect macaques of another species upon experimental inoculation (Mansfield *et al.*, 1999). Although gB sequences of RRV isolates from three different macaque species, *Macaca mulatta, Macaca nemestrina* and *Macaca fascicularis* were all closely related, they clustered according to species of origin (Auerbach *et al.*, 2000). A limited study of R1 sequences of RRV from three different species did not reveal a clustering according to species of origin (Damania *et al.*, 1999).

Genomic organization of RRV

Two complete RRV genomes have been sequenced at the Oregon Regional Primate Research Center (ORPRC) and the NERPRC. RRV strain 26–95 from NERPRC and RRV strain 17577 from ORPRC are very similar both in sequence

Table 61.4. A comparison of proteins encoded by the human and macaque rhadinoviruses

RRV (strain 26–95)	% aa similarity to KSHV	Function	Positional homologue in KSHV
R1	33.0%	Unique gene (Transforming gene)	K1
R2/ vIL-6	30.6%	IL-6 homologue	vIL-6
R4/vMIP	42.4%	MIP homologue	vMIP I,II,III
Orf16	58.0%	Bcl-2 homologue	vBcl-2
Orf50/Rta	55.0%	Transcription factor	Orf50/Rta
R8	53.0%	Replication protein	K8/bZip
R8.1	43.0%	Glycoprotein	K8.1
R9.1	60.6%	IRF homologue	vIRF
R13	40.1%	FLIP homologue	vFLIP/Orf71
Orf72	50.2%	Cyclin homologue	vCyclin/Orf72
Orf73	24.9%	Episome maintenance	LANA/Orf73
Orf74	54.7%	G-protein coupled receptor	vGPCR/Orf74
R14	37.6%	N-CAM Ox-2 homologue	K14

and genomic organization (Searles *et al.*, 1999; Alexander *et al.*, 2000). Only four of the 84 ORFs exhibited less than 95% sequence identity at the amino acid level (Alexander, 2000). The primary sequence of the long unique region (LUR) of RRV2695 consists of 130 733 base pairs that contain 84 open reading frames (Fig. 61.3). The overall organization of the RRV genome was found to be very similar to that of human KSHV (Alexander *et al.*, 2000). BLAST search analysis revealed that in almost all cases, RRV coding sequences have greater degrees of similarity to corresponding KSHV sequences than to any other herpesvirus (Table 61.4). All of the ORFs present in KSHV have at least one homologue in RRV except KSHV K3 and K5, K7 (nut-1), and K12 (Kaposin). RRV contains one macrophage inflammatory gene (MIP-1) and eight interferon regulatory factor (vIRF) homologues compared to three MIP-1/vCCLs and four vIRF genes in KSHV. All homologues are correspondingly located in KSHV and RRV with the exception of DHFR. The location of the DHFR gene in KSHV is different from that in RRV and HVS, suggesting that KSHV may have rearranged or reacquired the DHFR gene during the course of evolution from an Old World rhadinovirus to the human rhadinovirus or that RRV acquired the DHFR gene after divergence from KSHV (Fig. 61.3). Only four of the corresponding ORFs between RRV strain 26–95 and RRV strain 17577 exhibit less than 95% sequence identity: these include the glycoproteins H and L genes, uracil DNA glycosidase, and a tegument protein (ORF 67). Analysis of the two genomes indicate that RRV26–95 and RRV17577 are clearly independent isolates of the same virus species and both are closely related in structural organization and overall sequence to KSHV (Searles *et al.*, 1999; Alexander *et al.*, 2000). In addition to homology between the KSHV and RRV ORFs, there is also similarity with respect to the splicing patterns of viral genes. For example, the RRV Orf50, R8 and R8.1 polycistronic transcript is spliced in the same manner as the transcript encoding the corresponding genes in KSHV, (DeWire *et al.*, 2002; Lin *et al.*, 2002) and the LANA, vCyclin, vFLIP transcripts are likewise spliced in a similar fashion (DeWire *et al.*, 2002).

RRV R1

The first open reading frame of RRV encodes for a gene named R1, which is located at an equivalent position in the genome as the K1 gene of KSHV (Damania *et al.*, 1999). Analogous to KSHV K1, R1 is also a transforming gene (Damania *et al.*, 1999). R1 can transform rodent fibroblasts and functionally substitute for STP-C of HVS in immortalizing common marmoset PBMCs to IL-2 independent growth in vitro (Damania *et al.*, 1999). Injection of R1-expressing rodent fibroblasts into nude mice resulted in the formation of multifocal and disseminated tumors in these mice (Damania *et al.*, 1999). Although R1 shows limited sequence homology to K1, the amino-terminal extracellular domains of both K1 and R1 closely resemble members of the immunoglobulin receptor superfamily and exhibit 40% similarity to each other at the amino acid level (Damania *et al.*, 1999; Lee *et al.*, 1998). However, the cytoplasmic tail of R1 is significantly longer than that of K1 and contains several potential SH2 binding motifs, which function as ITAMs to elicit B-cell activation (Damania *et al.*, 2000).

RRV vIL6

KSHV, RRV and RFHV are the only herpesviruses that encode for a viral interleukin 6 homologue (vIL6). RRV vIL-6 has been shown to functionally stimulate the IL-6

receptor/gp130 pathway (Kaleeba *et al.*, 1999). The IL-6R-binding residues in the KSHV and RRV vIL-6 proteins are conserved suggesting that RRV vIL-6 may also bind gp130 in the absence of IL-6R, similar to KSHV vIL-6 (Kaleeba *et al.*, 1999).

RRV vGPCR

KSHV and RRV contain genes for a viral G-protein coupled receptors (vGPCR) that shows homology to the cellular GPCR, IL-8 receptor. Like KSHV vGPCR (for review see Moore and Chang, 2003), RRV vGPCR can transform NIH3T3 fibroblasts in vitro, and stimulate an increased secretion of vascular endothelial growth factor from these cells. RRV vGPCR has been shown to activate the ERK1/2 (p44/42) mitogen-activated protein kinase signaling pathway (Estep *et al.*, 2003). These results suggest that RRV vGPCR, like KSHV vGPCR, may play a role in viral pathogenesis in vivo. The RRV vGPCR transcript is bicistronically expressed with RRV R 15 (Pratt *et al.*, 2005). RRV R15 encodes a viral CD200 protein which shares homology with human and KSHV CD200 proteins (Langlais *et al.*, 2006).

RRV Orf50/Rta and RRV R8

The KSHV Orf50/Rta transactivator is encoded by a polycistronic transcript, which also contains the multiply spliced KSHV K8 and K8.1 genes. Analogous to the situation with KSHV, the homologous genes in RRV, Orf50/Rta, R8 and R8.1, respectively, are also encoded by a polycistronic, spliced transcript (DeWire *et al.*, 2002; Lin *et al.*, 2002). The KSHV Orf50 mRNA has a small 5′ exon, followed by a larger second exon encoding the remainder of the Orf50 sequence (Zhu *et al.*, 1999). Similarly in RRV, the Orf50 mRNA has a small upstream exon followed by a larger second exon (DeWire *et al.*, 2002; Lin *et al.*, 2002). In contrast, the gamma-1 herpesvirus, EBV, encodes an Orf50 homolog, BRLF1, whose cDNA is identical to the genomic ORF (Manet *et al.*, 1989). The RRV Orf50 protein is localized to the nucleus and functions as a transcriptional activator (DeWire *et al.*, 2002). A striking observation is that the KSHV Orf50 protein can activate certain RRV promoters, while the RRV Orf50 protein can also activate a subset of KSHV promoters, suggesting that there is a conservation in protein function of the Orf50/Rta transactivators of these rhadinoviruses (DeWire *et al.*, 2002; Damania, 2004).

Unrecognizable from the RRV genomic sequence alone, two other spliced genes of RRV include the R8 and R8.1 genes. The R8 protein is localized in the nucleus and shows 39% identity and 53% similarity at the amino acid level to the K8/bZip protein of KSHV. The R8.1 protein is localized in the cytoplasm and shows 26% identity and 43 % similarity at the amino acid level. The R8.1 protein has two potential glycosylation sites (NXS/T) (DeWire *et al.*, 2002).

RRV LANA

RRV also encodes a latency-associated nuclear antigen (R-LANA). Similar to KSHV LANA, R-LANA exhibits a nuclear speckled localization and possesses the ability to homodimerize. R-LANA can inhibit viral lytic replication by repressing the transactivation function of RRV Orf50/Rta. The mechanism for this repression involves the recruitment of histone deacetylase complexes since R-LANA′s ability to repress RRV Orf50 transactivation was reversed by the addition of the HDAC inhibitor trichostatin A (TSA) and TSA could significantly reactivate RRV from latently infected cells (Dewire and Damania, 2005).

RRV transcription program

The overall transcription profile of the RRV lytic cycle is very similar to that of KSHV. The immediate early genes expressed during the RRV lifecycle are Orf50 and Orf57, similar to the case seen with KSHV reactivation. Consistent with the KSHV transcriptome, early genes transcribed by RRV include vIL6, DNA polymerase, and R1 (DeWire *et al.*, 2002; Dittmer *et al.*, 2005). An exception to this pattern is the cluster of genes classically defined as latent in KSHV, i.e., Orf73 (LANA), vCyclin, and vFLIP, which are expressed as delayed early genes during the RRV lytic cycle (DeWire *et al.*, 2002). Late transcripts include those of RRV vIRF-1, Orf62, Orf65, and gB genes (DeWire *et al.*, 2002; Dittmer *et al.*, 2005).

RRV capsid structure

As with other herpesviruses, RRV lytic infection of rhesus fibroblasts leads to the synthesis of three distinct intranuclear capsid species. A and B capsids do not contain viral genomes, while C capsids do contain the viral genome at their center and are considered infectious. There are multiple similarities in capsid structure and assembly between KSHV and RRV. Both viruses make all three types of intranuclear capsids (A, B and C) during lytic infection, and the three RRV capsid species are similar in structure to KSHV as measured by transmission electron microscopy (TEM) (O'Connor *et al.*, 2003). In addition, both the RRV and KSHV virions assemble with similar slow kinetics and the capsids possess a highly conserved protein composition (O'Connor *et al.*, 2003). Both the RRV and KSHV capsid proteins include the major capsid protein (MCP) encoded by ORF25,

components of the triplex, TRI-1 and TRI-2, encoded by RRV ORFs 62 and 26 respectively, RRV SCIP encoded by ORF65, and RRV SCAF encoded by ORF 17.5 (O'Connor *et al.*, 2003). All five RRV capsid proteins demonstrate similarity to their KSHV homologues at the amino acid level (O'Connor *et al.*, 2003; Alexander *et al.*, 2000; Searles *et al.*, 1999). However, one difference between these viruses is the efficiency of capsid assembly. As opposed to the inefficiency of KSHV maturation following reactivation from latently infected B-cell lines (Nealon *et al.*, 2001), de novo RRV infection results in the release of much higher levels of infectious virions with genome-containing C capsids at their center and a lower amount of the incomplete A and B capsids which do not contain viral genomes (O'Connor *et al.*, 2003). This discrepancy may explain the reason why RRV can be grown to high titers ($\sim 10^6$ pfu/ml) (DeWire *et al.*, 2003) in vitro relative to KSHV, since only virions containing intact viral genomes (i.e. C capsids) are infectious (O'Connor *et al.*, 2003). Three-dimensional structure comparisons of the RRV capsid structure by electron cryomicroscopy have shown that the A capsid is empty and its penton channels are open, the B-capsid contains a scaffolding core and its penton channels are closed, and the C-capsid contains a DNA genome closely packed as regularly spaced density shells (25 Å apart), and its penton channels are open (Yu *et al.*, 2003). The RRV A capsid reconstruction was achieved at 15-Å resolution (Fig. 61.4), which is the best, achieved for any gammaherpesvirus to date. The best resolution for the KSHV capsid was achieved at 24-Å and both capsids appeared almost identical (Yu *et al.*, 2003; Wu *et al.*, 2000). Further, although the RRV capsid showed overall structural similarities to alpha and betaherpesvirus capsids, there were prominent differences in the Ta triplex and SCIP structures suggesting that SCIP and triplex, together with tegument and envelope proteins, confer structural, and potentially functional, specificity to alpha-, beta- and gamma-herpesviruses (Yu *et al.*, 2003) (Fig. 61.4). Thus, this study validates the use of RRV as a model system for the study of KSHV and other gammaherpesviruses, since the latter appear significantly different from the alpha and beta herpesviruses, despite the fact that the individual structural proteins of all three groups of herpesviruses share a high degree of homology.

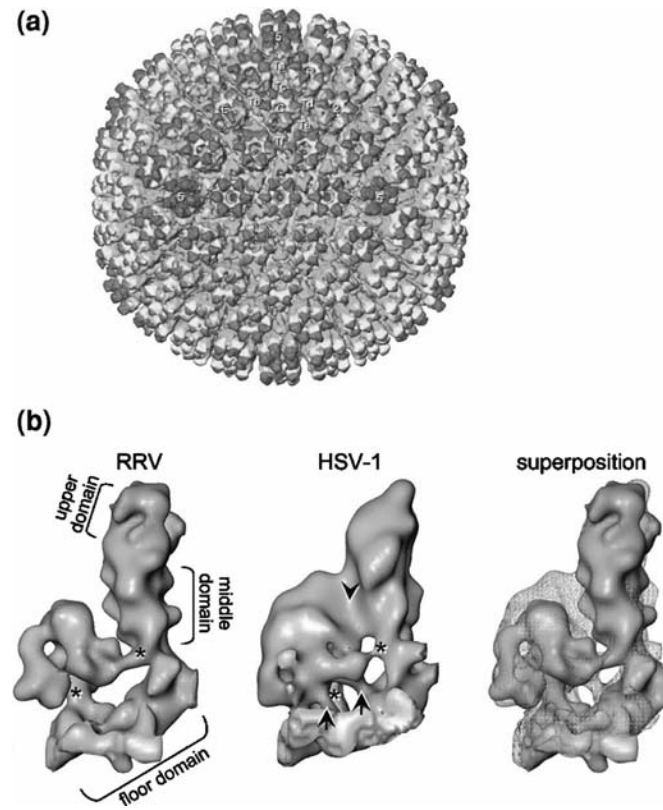

Fig. 61.4. Structural similarity between the KSHV and RRV capsids. (a) The RRV A capsid structure at 15 Angstrom resolution. (b) Structural difference between the gammaherpesvirus RRV and alphaherpesvirus HSV-1 capsids. The figure represents one penton sub-unit and one triplex (Ta) that was computationally extracted from the RRV A capsid taken at 15 Angstroms shown in panel A, and an HSV-1 capsid map filtered to the same resolution. The RRV and HSV-1 Ta triplex interacts with MCP through the leg connected to the MCP floor domain, as well as through a small link to the MCP middle domain (indicated by asterisks). The differences between the RRV and HSV-1 capsids are indicated by an arrowhead and arrows, and represent interactions that are present in HSV-1 but missing in RRV.

RRV pathogenesis

Wong *et al.* (1999) at the ORPRC experimentally inoculated rhesus macaques with RRV (strain 17577) with and without SIVmac239 co-infection to determine whether RRV played a role in the development of lymphoproliferative disease. In contrast to two control animals inoculated with SIVmac239 or RRV alone, two of two animals coinfected with SIVmac239 and RRV17577 developed hyperplastic lymphoproliferative disease resembling the multicentric plasma cell variant of Castleman's disease, characterized by persistent angiofollicular lymphadenopathy, hepatomegaly, splenomegaly and hypergammaglobulinemia. Hypergammaglobulinemia was associated with severe immune-mediated hemolytic anemia in one RRV17577/SIV-infected macaque. Thus, experimental RRV17577 infection of

SIV-infected rhesus macaques was associated with the hyperplastic B cell lymphoproliferative manifestations analogous to those seen in individuals infected with KSHV. Mansfield *et al.* (1999) at the NERPRC have also performed co-infections using RRV (strain 26–95) and SIV mac239. Experimental infection of macaques was associated with a lymphadenopathy that was characterized by paracortical hyperplasia and vascular hypertrophy/hyperplasia that subsequently was replaced by marked follicular hyperplasia. In the most severe cases, this follicular hyperplasia destroyed the medullary sinuses and completely effaced the normal lymph node architecture. Similar changes have been found in KSHV infected, HIV-negative human patients with histologic features of angioimmunoblastic lymphadenopathy and reactive lympadenopathy. B-cell proliferation is a feature common to multicentric Castleman's disease and angioimmunoblastic lymphadenopathy (Mansfield *et al.*, 1999). However, 12 weeks post-RRV infection, these pathologies appeared to be resolved. Thus, the immune system in these macaques was able to halt the progression of the hyperplasia. In addition, Mansfield *et al.* (1999) observed that three of four monkeys co-infected with RRV and SIV developed an arteriopathy. This arteriopathy was similar to the vascular endothelial lesion seen in patients with KS and to the large vessel arteritis in MHV68 infected mice. Despite some drawbacks to the RRV model system, a large number of critical questions can still be addressed using this system of experimental infection.

RRV as an animal model system for KSHV

Since its discovery in 1994, studies to identify a KSHV lytic culture system have been intense. Although lytic systems for KSHV have been developed in several laboratories using reactivated B-cells, 293 cells and *de novo* infection of endothelial cell lines (Renne *et al.*, 1998; Lagunoff *et al.*, 2002; Poole *et al.*, 2002; Cannon *et al.*, 2000, Sun *et al.*, 1998; Moses *et al.*, 1999; Foreman *et al.*, 1997), these systems yield low quantities of virus resulting in limited replication and serial transmission. The lack of a traditional permissive system for KSHV limits the ability to study the temporal order of events of the full virus life cycle. There have been two KSHV bacterial artificial chromosomes (BAC) constructed to date (Zhou *et al.*, 2002; Delecluse *et al.*, 2001). However, methods to analyze properties of recombinant KSHVs are limited. In contrast, RRV can be grown to high titers ($\sim$1x10^6 pfu/ml) in rhesus fibroblasts (RhFs) (DeWire *et al.*, 2003) and both plaque assays and real-time PCR assays to measure RRV replication have been devised (DeWire *et al.*, 2003). In addition, RRV can be used as a genetic system to create recombinant RRVs as exemplified by the construction of a recombinant RRV virus expressing green fluorescent protein (RRV-GFP)(DeWire *et al.*, 2003). An infectious RRV model system has been developed such that naïve RRV-negative rhesus macaques inoculated with RRV demonstrate persistent viral infection (Mansfield *et al.*, 1999). Use of the rhesus virus can help address a large number of critical questions. These include the ability to define the relative importance and contribution of individual genes to the establishment of primary infection, dissemination, persistence, tropism, pathologic manifestations and immune avoidance strategies.

At the present time, RRV is the closest simian KSHV homologue that can be grown lytically and has a genetic system to analyze viral gene function. The transcription program of RRV resembles that of KSHV (DeWire *et al.*, 2002), the capsid structure and assembly of RRV and KSHV virions are very homologous (O'Connor *et al.*, 2003; Yu *et al.*, 2003) and a method to generate RRV recombinant viruses has been established (DeWire *et al.*, 2003). Thus, the biological properties of RRV, the ability to construct recombinant RRVs and the ability to generate persistent RRV infection in naïve rhesus macaques experimentally infected with RRV, makes RRV a tractable model to study the KSHV lifecycle in vitro and in vivo.

Conclusions

The presence of gammaherpesviruses in most primates tested to date alludes to the fact that these viruses evolved with their host species. They share similarity in genomic sequence, organization and biological properties. Current evidence indicates that there are two distinct lineages of primate rhadinoviruses and lymphocryptoviruses, both of which are evolutionarily related to KSHV. This suggests that the gammaherpesviruses have diversified from a common ancestor in a manner mediating co-speciation of herpesviruses with their host species. As this theme is conserved for all gammaherpesviruses of Old World Primates including the great apes, it raises the possibility that viruses belonging to a second major phylogenetic grouping of lymphocryptoviruses and rhadinoviruses may be found in humans. The evidence suggests the possible existence of a novel genogroup 2 human lymphocryptovirus which include viruses like GgorLCV2 and PpygLCV1 (Ehlers *et al.*, 2003), and a novel human rhadinovirus belonging to the RV2 genogroup, which include viruses like RRV and PanRHV2 (Lacoste *et al.*, 2000a, 2001).

The non-human primate viruses provide a means to model human infection in an experimental setting that

would not be possible in humans. While use of the simian viruses as animal models for human EBV and KSHV are still in the early developmental stage, they will likely prove useful for studying the pathogenesis, prevention, and treatment of gammaherpesvirus infections.

The multiple layers of the human immune response present a challenge to viruses, which must survive and multiply within a host for a sufficient period of time to allow successful transmission to susceptible individuals. Given the large proteomes and comparatively low polymerase error rate of human herpesviruses, antiviral immunity at first glance appear to have the upper hand. Nonetheless, herpesviruses manage prolonged incubation periods following initial infection, with systemic dissemination and prolonged secretion, often from multiple sites. In contrast to the similarly large poxviruses, the ability to subsequently establish persistent infection is a hallmark of the human herpesviruses. To enable this lifestyle, the herpesviruses devote a significant proportion of their genome coding capacity to the expression of immuno-evasins, a collection of molecules that disrupt normal immune physiology. Each human herpesvirus studied has evolved elegant cell biological solutions to problems posed by the immune response.

Innate immunity, an evolutionarily conserved and relatively non-specific system of pattern recognition molecules hardwired in the genome, cytokines such as interferons, phagocytes and natural killer (NK) cells, represents the first line deployed against microbial invaders, including herpesviruses (Janeway and Medzhitov, 2002). The clonal expansion of B- and T- lymphocytes that bear antigen-specific receptors for viral epitopes underlies the adaptive antiviral immune response, laying the groundwork for a highly pathogen-specific defense. Such specificity comes at a price – lymphocyte proliferation requires time to unfold, and innate immunity, in particular NK-cell activity, limits the initial herpesvirus spread. Indeed, NK cell immune deficiencies result in dramatic infection by several herpesviruses (McClain *et al.*, 1988; Biron *et al.*, 1989). There is significant cross-talk between the innate and adaptive systems, and preliminary pathogen recognition by the innate immune system directly contributes to the development of adaptive immunity. Further, the eventual adaptive response utilizes branches of the innate system for crucial effector function (Medzhitov and Janeway, 1999).

Innate and adaptive immunity act in concert to allow recovery from acute herpesvirus infection. Adaptive immunity then allows for lifelong immunological memory, affording both control of persistent herpesvirus infection and protection against reinfection. Once present, virus-specific CD4+ T-lymphocytes then coordinate the adaptive antiviral response, directing the production of virus-specific immunoglobulin by B-lymphocytes, the antiviral activity of CD8+ T-lymphocytes and NK cells, and further stimulating the activity of phagocytic cells.

Through millennia of coevolution, herpesviruses have largely reached a state of equilibrium with their human hosts. At the cost of a large proportion of their coding capacity, herpesviruses perturb adaptive immunity to achieve persistent infection, in general with remarkably little collateral damage to their hosts. However, lapses in T-cell immunity, such as by immunosuppressive agents or by coinfection with other pathogens such as Human Immunodeficiency Virus, can lead to significant herpesvirus-associated pathology.

Human herpesvirus genome size and polymerase fidelity place constraints on epitope mutation, and generally do not allow for antigenic variation as a means to avoid T-cell immunity. Herpesviruses therefore, have devised a range of mechanisms to subvert adaptive immunity. Generalized T-cell immuno-evasion strategies shared by herpesviruses include latency, restriction of viral gene expression to immunoprivileged sites such as the CNS, interference with complement, cytokines, NK-cell function, and apoptosis,

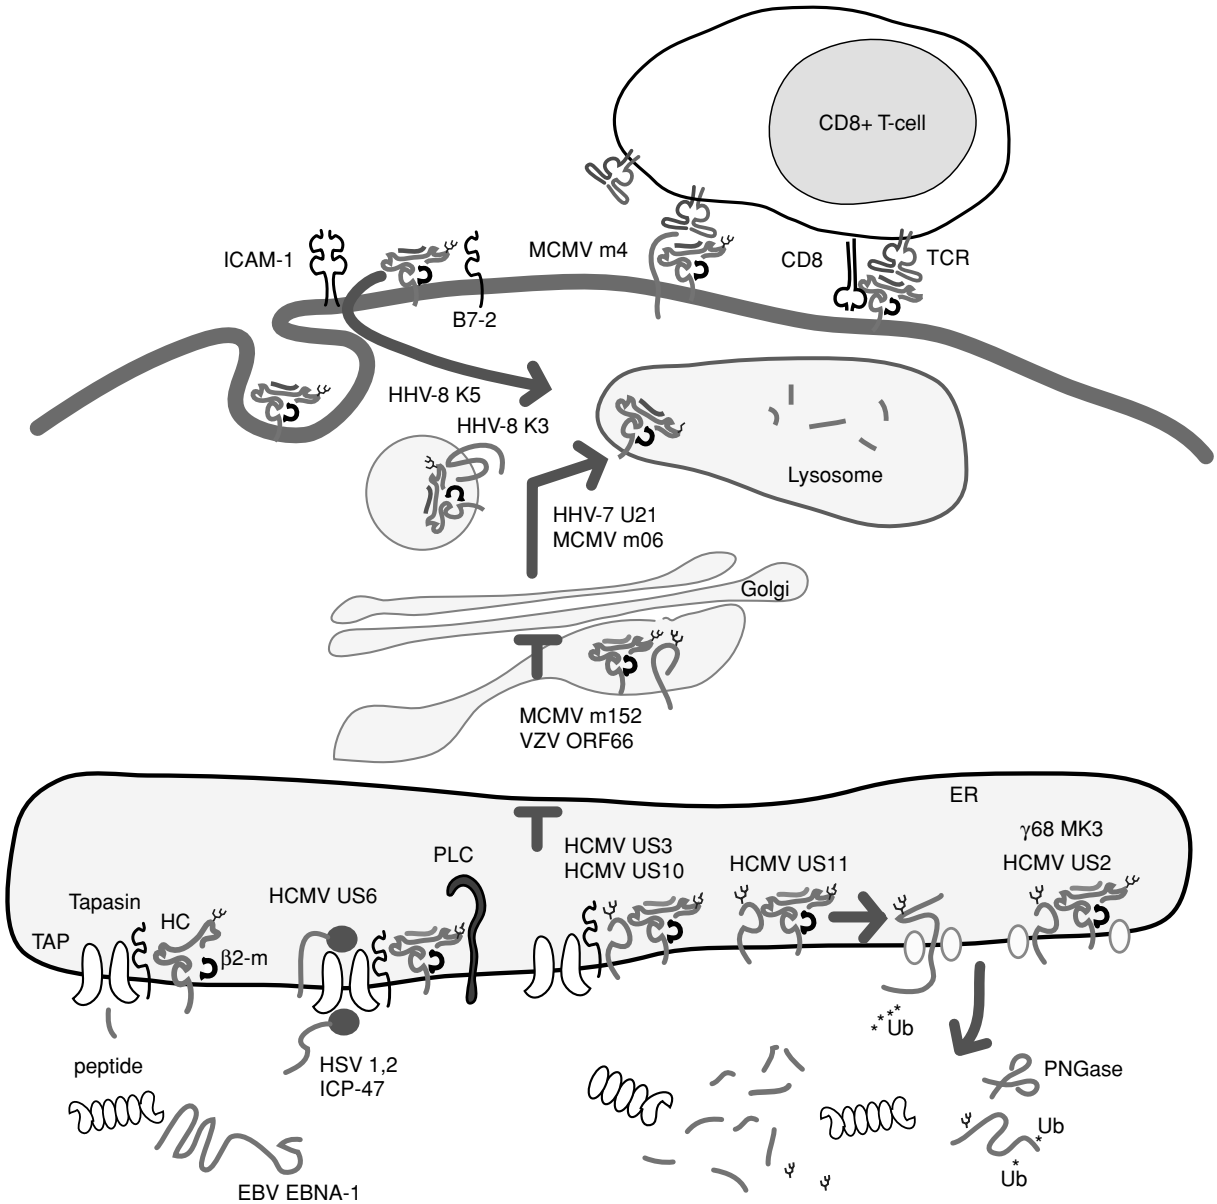

Fig. 62.1. Herpesvirus immunoevasins that directly interfere with class I MHC molecule biosynthesis. Class I MHC molecules are assembled from free HC and β-2 microglobulin within the ER, along with antigenic peptide. Peptides are produces by cytosolic proteasome degradation. The EBV EBNA-1 GAr domain interferes with proteasomal degradation in-*cis*. Tapasin and the PLC facilitate loading of peptide cargo onto empty class I MHC molecules. HSV-1,2 ICP47 and HCMV US6 block TAP peptide transport, while HCMV US3 inhibits tapasin and retains class I complexes in the ER. Following receipt of peptide, the loaded class I MHC molecules travel through the secretory pathway to the cell surface. HCMV US10 delays transport of class II molecules from the ER, while VZV ORF66 and MCMV m152 retain class I MHC in the Golgi complex. HCMV US2, US11 and MHV-68 MK3 dislocate class I molecules via an unidentified ER membrane pore to the cytosol. The dislocated class I MHC heavy chains are ubiquitinated (Ub) and deglycosylated by cellular PNGase prior to proteasomal cleavage. HHV-7 U21, MCMV m6 and HHV-8 K3 redirect class I molecules from the secretory to the endolysosomal pathway for degradation. HHV-8 K5 likewise targets class I MHC, B7-2 and ICAM-1 molecules to the endolysosomal pathway for destruction. MCMV m4 disrupts recognition of cell surface-disposed class I MHC molecules by CD8+ T-cells. (See color plate section.)

all of which are reviewed in detail in other chapters. This section will highlight the cell biology that underlies herpesvirus evasion of T-cell immunity.

Disruption of class I MHC antigen presentation

Presentation of virus-derived antigenic peptides by major histocompatibility (MHC) class I molecules plays a key role in the clearance of many viruses from the body. Viral proteins expressed in the cytosol may be targeted for degradation and presented by class I MHC, alerting CD8+ T-cells to the presence of an intracellular viral pathogen. CD8+ lymphocytes bear the T-cell receptor (TCR), which recognizes peptides in an MHC-restricted fashion. Recognition of peptide cargo derived from foreign proteins alerts the CD8+ T-cell, and in the proper context stimulates cytotoxic T-cell (CTL) mediated lysis of the infected target cell. Though sacrificing the host cell, lysis ultimately limits the spread of the viral pathogen (Heemels and Ploegh, 1995). Interference with the class I pathway appears to be a central mechanism of immuno-evasion of persistent viruses, herpesviruses in particular (Tortorella *et al.*, 2000). All human herpesviruses examined thus far employ strategies to perturb class I MHC antigen presentation to CD8+ T-cells (Fig. 62.1, Table 62.1).

Class I MHC molecules are heterotrimeric complexes that consist of a heavy chain, light chain and antigenic peptide (Heemels and Ploegh, 1995). The class I MHC heavy chain is a 43-kDa polymorphic type I membrane glycoprotein that binds antigenic peptide cargo, generally of 8–10 residues in length. The heavy chain α1 and α2 domains form the peptide-binding groove, consisting of two antiparallel α-helices and an eight-stranded β-sheet (Bjorkman *et al.*, 1987). The class I MHC light chain, or β-2 microglobulin, is an invariant 12-kDa protein of the immunoglobulin (Ig) fold family.

Class I MHC peptide ligands are primarily generated in the cytosol by the 26S proteasome, a barrel-shaped multicatalytic threonine protease complex whose 20S core is composed of α and β subunits. The β subunits, x, y and z, contain the protease active sites with tryptic, chymotryptic and caspase-like protease activities, respectively (Voges *et al.*, 1999). Upon Interferon-γ (IFN-γ) stimulation, LMP-2, LMP-7 and MECL-1 replace the x, y, and z subunits, respectively, giving rise to the immunoproteasome. IFN-γ also induces expression of the 11S proteasome regulator PA28αβ. The mammalian MHC complex encodes the LMP2 and LMP7 subunits (Brown *et al.*, 1991). While the proteasome and immunoproteasome have substrate specificity, the immunoproteasome may generate peptides with motifs suitable for class I MHC presentation at higher frequency (Nazif and Bogyo, 2001).

Interference with proteasomal proteolysis

Both human CMV (HCMV) and murine CMV (MCMV) can disrupt immunoproteasome formation (Khan *et al.*, 2004). MCMV appears to achieve this phenotype via its M27 gene-product. M27 targets STAT2, a key molecule in the IFN-γ signal transduction pathway, for degradation by the ubiquitin-proteasome pathway. Deletion of M27 restores fibroblast immunoproteasome formation and enhances sensitivity to IFN-γ in cell culture (Khan *et al.*, 2004). MCMV mutants that lack functional M27 activity are attenuated in growth and virulence (Abenes *et al*, 2001), a phenotype that is partially restored in IFN-γ receptor knockout mice (Zimmermann, 2005). M27 is conserved in all γ-herpsevirinae; the homologous HCMV UL27 remains poorly characterized, though HCMV UL27 deletion mutants likewise display attenuated growth in culture and *in vivo* (Prichard *et al.*, 2006).

EBV and CMV encode factors that disrupt proteasomal proteolysis of specific substrates. Vigorous CD8+ T-cell responses can be detected against all EBV nuclear antigens, except EBNA-1, which eludes T-cell recognition (Khanna *et al.*, 1995). EBNA-1 is essential for viral genome persistence during cell division and is a major protein expressed during latency (Lee *et al.*, 2004). Although EBNA-1 specific CD8+ T-cells can be isolated from peripheral blood of EBV-infected individuals, they are less abundant than T-cells specific for other EBV nuclear antigens. Further, EBNA-1-specific T-cells generally fail to be activated during EBV infection (Khanna *et al.*, 1995; Blake *et al.*, 1997). This stealth behavior has been attributed to the unusually long EBNA-1 half-life, enabled by the presence of its internal Gly–Ala repeat domain (GAr). The GAr domain is reported to act as a *cis*-inibitor of ubiquitin-proteasomal proteolosis in B cells, and thereby prevents the introduction of EBNA peptides into the class I pathway. The GAr domain is both necessary and sufficient for altering protein half-life, and cytosolic fusion proteins that harbor GAr motifs gain resistance to proteasomal proteolysis (Dantuma *et al.*, 2002). For instance, fusion of a 200-residue or even 17-residue Gly–Ala repeat to EBNA-4 confers resistance to proteasome degradation and results in reduced antigen presentation of EBNA-4 epitopes (Dantuma *et al.* 2002). Several mechanisms have been proposed to explain the inhibitory function of the GAr domain, for instance the formation of tightly-folded beta-sheet structures that resist disassembly and/or interactions with the ubiquitin-proteasomal pathway. GAr also reduce the rate of EBNA-1

Table 62.1. Human herpesvirus immuno-evasins of adaptive T-cell immunity discussed in the chapter

Virus	Immuno-evasin	Putative mechanism
HSV 1/2		
	ICP47	Blocks TAP peptide transport
	Unknown	CD83 internalization and inhibition of DC function.
	Unknown	Inhibition of DC cell maturation
	US1	Kinase activity inhibits CD4+ T-cell activation by B cells
	US3	Kinase activity inactivates (stuns) CTLs in *trans*
	Unknown	Intracellular redistribution of class II MHC molecules
VZV		
	?ORF66	Retains class I in the Golgi complex
	Unknown	Inhibition of DC function, down-regulation of multiple surface proteins
	Unknown	Reduction of cell surface ICAM-1 (CD54)
	Unknown	Inhibition of Jak/STAT expression, disruption of IFN-γ signaling
EBV		
	EBNA-1	Gly-Ala repeat domain blocks proteasomes in *cis*
	BCRF1	IL-10 homologue, down-regulates class I expression
	General	Anchor residue mutations prevent epitope presentation by subset of class I alleles (epitope loss)
	Gp25-gp42-gp85	Inhibits DC maturation
	Unknown	Inhibition of monocyte phagocytic function
	LMP-2A	Activates env superantigen, may dysregulate CD4+ T cell responses
	gp42	Inhibits class II MHC recognition by $CD4^+$ T-cells
CMV		
	Pp65 (UL83	Kinase activity blocks proteasomal proteolysis of IE-1
	US2	Targets folded class I and class II molecules for proteasome degradation
	US3	Inhibits tapasin, retains folded class I and class II molecules in the ER
	US6	Blocks TAP peptide transport
	US8	Binds free class I heavy chains, function unknown
	US10	Delays egress of folded class I molecules from ER
	US11	Targets class I heavy chains for proteasome degradation via a Derlin-1 pathway
	UL18	class II homologue, binds to LIR-1 (ILT-2) inhibitory receptor on APCs, lymphocytes
	UL111A	IL-10 homologue, downregulates class I expression
	UL111.5A	IL-10 homologue, expressed during latency
	M27, ?UL27	Targets STAT2 for degradation, impairs immunoprotasome formation
	Unknown	Interference with DC activity and expression of multiple DC surface proteins, including CD83
	UL20	TCR-γ chain homologue, function unknown
	Unknown	Targets Jak1 for proteasomal degradation, disrupts IFN-γ upregulation of class II MHC expression
	Unknown	Alters trafficking of class II MHC molecules
HHV-6		
	Unknown	Down-regulation of TCR/CD3 expression
HHV-7		
	U21	Targets class I for lysosomal degradation
HHV-8		
	K3/MIR1	Induces rapid internalization of cell surface class I
	K5/MIR2	Induces rapid internalization of cell surface class I, ICAM-1, and B7-2, and PE-CAM

translation (Dantuma *et al.*, 2002). Nonetheless, EBNA-1 peptides can circumvent GAr blockade at a low level via defective ribosomal products (DriPs), misfolded polypeptides that result from errors in translation or folding. DriPs are rapidly degraded and may contribute a significant percentage of all peptides to the class II pathway. Thus, DriPs that do not contain functional GAr sequences should be susceptible to proteasomal degradation, and CD8+ T-cell recognition of EBNA-1 derived peptides have now been described (Lee *et al.*, 2004; Tellam *et al.*, 2004; Voo *et al.*, 2004).

The HCMV matrix phosphoprotein 65 (pp65) can disrupt antigen presentation of epitopes derived from immediate-early protein 1 (IE1) in *trans*. The pp65 kinase can

phosphorylate IE1, and through an unknown mechanism, prevent the proteasomal degradation of IE1 (Gilbert *et al.*, 1996).

Interference with peptide transport

Empty class I MHC molecules receive their peptide cargo shortly after assembly in the endoplasmic reticulum (ER). Empty class I molecules are generally short-lived, and are either retained within the ER or dissociate (Heemels and Ploegh, 1995). Thus, antigenic peptides must be pumped across the ER membrane to reach nascent class I complexes, and this process represents a key control point in the class I MHC biosynthetic pathway. Peptide transport is accomplished by a dedicated MHC-encoded ATP-binding cassette (ABC) family member, the transporter associated with antigen presentation (TAP) (Neefjes *et al.*, 1993). TAP molecules are heterodimers formed by the association of TAP-1 and TAP-2 subunits, which together comprise the peptide-binding site. Peptide substrates, optimally 8–12 residues in length, interact with TAP in two distinct phases: ATP-independent binding; subsequent ATP-dependent peptide transport versus rapid dissociation from TAP (Heemels and Ploegh, 1995).

Several human herpesviruses have convergently evolved polypeptides that inhibit TAP peptide transport. HSV-1 and HSV-2 encode a cytosolic 9-kDa (88 residues HSV-1; 86 residues HSV-2) immediate early gene product, called infected-cell protein 47 (ICP47) (York *et al.*, 1994; Hill *et al.*, 1995). The HSV-1 and HSV-2 ICP47 molecules demonstrate 47% amino acid sequence identity and appear to utilize the same mechanism. ICP47 of both HSVs binds to TAP with high affinity (KD = 50 nM) at a site that overlaps the peptide binding site of both TAP subunits, and functions as a competitive inhibitor of TAP-peptide interactions (Ahn *et al.*, 1997; Tomazin *et al.*, 1998; Pfander *et al.*, 1999). 100- to 1000-fold molar excess of peptide is required to overcome ICP47 inhibition of TAP peptide-transport (Tomazin *et al.*, 1998). ICP47 functions in a species-specific fashion and inhibits human, but not murine, TAP. Residues 3–34 of ICP47 are sufficient to inhibit TAP transport, even when a synthetic 32-mer is added to permeablized cells (Galocha *et al.*, 1997; Neumann *et al.*, 1997; Tomazin *et al.*, 1998).

Preliminary nuclear magnetic resonance structural characterization suggests that ICP47 undergoes a conformational change from an unstructured state in solution to the formation of a helix-turn-helix motif in the presence of a lipid environment (Pfander *et al.*, 1999). The lipid environment greatly increases binding affinity of ICP47 with TAP, where ICP47's amino-terminal helix serves as a membrane anchor (Aisenbray, 2006). How ICP47 itself avoids transport and ATP-induced dissociation remains unclear, but it may rely on interactions outside the TAP peptide binding site to stabilize its cytosolic localization (Galocha *et al.*, 1997). Further understanding of ICP47 function requires structural analysis of the TAP-ICP47 complex.

Apparently despite 100-fold lower affinity for murine TAP, ICP47 deletion mutants nonetheless exhibit reduced neurovirulence in a murine infection model, a phenotype that required the presence of CD8+ T-cells (Goldsmith *et al.*, 1998). Akin to its use by HSV, ICP47 may also at some point be used in clinical applications. Indeed, several groups have explored ICP47 immuno-evasion in applications ranging from gene therapy to xenotransplantation (Berger *et al.*, 2000; Crew and Phanavanh, 2003; Radosevich *et al.*, 2003).

HCMV likewise disrupts TAP transport, though by a distinct approach. The HCMV US genome region encodes a cluster of immuno-evasins that comprise the US2, US6 and US11 glycoprotein families (the US2–US11 gene products) (Britt and Mach, 1996). At least six of these ten gene-products are now known to interact with the class I MHC biosynthetic pathway. HCMV US6 is a 21-kD ER-resident type I integral membrane glycoprotein that is expressed during the late phase of viral infection. US6 interferes with TAP by binding with micromolar affinity to the ER-lumenal face of the transporter. The ER-lumen domain of US6 is necessary and necessary for TAP inhibition (Ahn *et al.*, 1997; Kyritsis *et al.*, 2001). US6 does not appear to function as a competitive inhibitor of TAP peptide transport, and US6 neither influences the amount of peptides that bind to TAP nor the TAP-peptide affinity (Kyritsis *et al.*, 2001). Rather, US6 reduces TAP1 affinity for ATP and may thereby cut off the energy source for peptide transport (Hewitt *et al.*, 2001).

How do interactions with the ER lumen between US6 and TAP influence the cytosolic nucleotide-binding domain? Though presently awaiting experimental confirmation, US6 likely induces a conformational rearrangement that is transmitted to the TAP cytoplasmic ATP-binding site (Hewitt *et al.*, 2001; Kyritsis *et al.*, 2001). Indeed, US6 affects the conformational stability of TAP. In the presence of either US6 or ATP, TAP remains stable at 37 °C, whereas the isolated heterodimer would normally dissociate (Hewitt *et al.*, 2001). Taken together, US6 appears to either lock TAP in a conformational intermediate of its catalytic cycle, or may induce an aberrant conformation. Similarly, recombinant HSV engineered to express other class I MHC immunoevasins cause increased viral burden in the CNS (Orr, 1995). Additional herpesvirinae-encoded TAP inhibitors have recently been discovered, including Epstein–Barr BNLF2a (Ressing, 2005 and Wiertz, E.J., personal communication).

Herpesviruses encode multiple cytokines (virokines) that alter antiviral immunity (reviewed in other chapters). Both EBV and CMV encode homologues of interleukin-10 (IL-10) that retain some, but not all IL-10 functions. Both EBV and CMV IL-10 suppress class I surface levels *in vitro*, including via downmodulation of TAP1 expression and therefore ER peptide transport (Zeidler *et al.*, 1997; Spencer *et al.*, 2002; Jenkins *et al.*, 2004).

Interference with ER chaperones required for class I biosynthesis

Class I MHC molecules are assembled in a multistep process. ER chaperones, including the lectins calreticulin and calnexin, and the thioreductase ERp57 facilitate folding of nascent class I molecules (Cresswell, 2000). The heavy chain/β-2 microglobulin heterodimer is then recruited to the peptide loading complex (PLC), a multiprotein assembly that that includes TAP and facilitates peptide loading (Cresswell, 2000). The ER-resident molecule tapasin is uniquely dedicated to class I molecule assembly. Tapasin tethers empty class I molecules to TAP and also possesses peptide exchange activity, optimizing the class I peptide repertoire by selecting for high affinity class I-peptide complexes (Momburg and Tan, 2002).

The human cytomegalovirus has evolved a mechanism to subvert the interaction between tapasin and empty class I molecules that await peptide cargo. US3, expressed during the immediate-early period of HCMV infection, is 23-kDa type I integral membrane capable of oligomerization (Jones *et al.*, 1996; Misaghi *et al.*, 2004). US3 binds directly to both class I molecules and tapasin, and causes ER-retention of class I via two mechanisms. First, the US3 ER lumenal domain contains a retention sequence that is distinct from the canonical KDEL or KKXX ER-retention motifs. The US3 residues Ser-58, Glu-63, and Lys-64 are required for ER-retention and may interact with an ER-resident protein, such as tapasin (Lee *et al.*, 2003; Misaghi *et al.*, 2004). US3 may retain class I molecules in the ER via direct association, in effect physically preventing class I molecules from traveling along the secretory pathway to the cell surface (Lee *et al.*, 2003; Misaghi, *et al.*, 2004). Interestingly, both the US3 ER-lumenal and transmembrane domains are required to bind class I molecules, and the affinity of class II binding appears to correlate with the extent of ER retention for certain alleles (Lee *et al.*, 2000; Park *et al.*, 2004). NMR structural analysis and comparison with the homologous CMV US2 gene-product (see below) suggests that the US3 ER-lumenal domain forms an Ig-like fold. Though Ig-like folds underlie many protein–protein interactions, even when present at high concentrations, the US3 ER-lumenal domain by itself does not appear to interact with class I with any measurable affinity in vitro or in vivo (Lee *et al.*, 2000; Misaghi *et al.*, 2004). Thus, the transmembrane domain does not appear to simply increase US3 local concentration by confining it to the plane of the ER membrane. Although the structural mechanism by which both the soluble and transmembrane domains are required for class I binding remains unclear, interactions within the lipid bilayer underlie the activity of several herpesvirus class I immuno-evasins.

US3 has a short half-life and associates with class I molecules only transiently. Perhaps the dominant mechanism of US3 function instead results from its direct inhibition of tapasin-dependent peptide loading (Park *et al.*, 2004). Reminiscent of US6 activity, US3 may induce a conformational change in tapasin and thereby alter tapasin-induced peptide loading and exchange activity. A subset of class I alleles do not require tapasin for peptide loading and surface expression, and these class II molecules largely escape US3-mediated ER retention (Park *et al.*, 2004). An alternatively spliced form of US3 lacking the transmembrane domain can associate with tapasin, but not class I MHC molecules, and acts as an endogenous dominant negative inhibitor of US3 function (Shin, 2006). The truncated US3 isoform may modulate US3 function across different cell types or different stages of infection, though the role of truncated US3 isoforms during infection awaits further characterization.

Perhaps US3 evolved dual mechanisms for class I retention to cope with the extensive heavy chain sequence and structural polymorphism present in a given outbred human population. Though no other human herpesviruses are known to inhibit ER chaperones, the murine herpesvirus γ-68 K3 gene product and adenovirus E19 likewise exploit tapasin to interfere with class I molecule assembly (Bennett *et al.*, 1999; Lybarger *et al.*, 2003).

Destruction of class I molecules via proteasomal proteolysis

Herpesviruses appear to have studied cellular pathways that control protein turnover and craftily manipulate multiple such pathways to reduce the abundance of the class I MHC molecule on the cell surface. One such pathway, utilized by HCMV and murine γ-herpesvirus-68, requires proteasomal proteolysis itself to break down newly synthesized class II molecules.

During the early period of HCMV infection, the ER-resident US2 and US11 gene-products are expressed with β, or delayed early kinetics. US2 and US11 independently bind to class I molecules undergoing assembly and rapidly target their ER dislocation, the rapid transfer from the ER to the cytosol. Once in the cytosol, class I heavy chains

are deglycosylated by a cellular N-glycanase and then degraded. Via emerging pathways that resemble cellular quality control pathways, US2 and US11 trick the cell into recognizing nascent class I molecules as misfolded proteins and selectively accelerate the rate constant of the dislocation reaction (Wiertz *et al.*, 1996a,b).

US2 is a 199-residue type I integral membrane protein, with an amino-terminal ER-lumenal domain comprised of an Ig-like fold, a single transmembrane domain, and a short carboxyterminal cytoplasmic tail (Gewurz *et al.*, 2001a). Although it targets a population of newly synthesized ER-resident class all I molecules for degradation, US2 recognizes a class I surface that apparently arises late in the biosynthesis and assembly of class I molecules in the ER (Gewurz *et al.*, 2001a). SiRNA-mediated knockdown of β2-microglobulin light chain expression blocks US2 association with and the dislocation of class I MHC molecules (Blom *et al.*, 2004). Recombinant US2 likewise associates with the folded class I, and not with the free class I heavy chains in vitro (Gewurz *et al.*, 2001b). Interactions between the US2 and class I ER-lumenal domains are required for subsequent removal of class I molecules from the ER: mutation of a single class I residue at the US2-binding site abrogates dislocation (Gewurz *et al.*, 2001a).

US2 associates with the class I MHC heavy chain at the junction between the peptide-binding cleft and the α3 domain. The class I binding surface recognized by US2 has several important properties. US2 chooses a relatively conserved surface on the highly polymorphic class I molecule, allowing it to interact with many class I alleles (Gewurz *et al.*, 2001a, b). The sequence of class I peptide cargo does not influence US2 binding, and US2 likely also binds with empty class I molecules awaiting receipt of peptide, as would be the case when US2 and US6 are coexpressed (Gewurz *et al.*, 2001a, b). Further, the proposed binding surface for the peptide-loading complex maps to a face of the class I MHC molecule opposite that of the US2 binding site. Thus, US2 should have access to class I even when associated with the multisubunit PLC, and so diminishes the probability of class I molecule escape from the ER.

NK-cells scan for the loss of class I surface expression, providing an important back-up function, as cells without class I MHC are no longer recognized by CD8+ T-cells. Upon recognition of cells that have lost surface expression of class I molecules, in particular the HLA-C, -E and -G locus products, NK cytotoxic activity is stimulated (Lanier, 2003). In contrast, NK cell inhibitory receptors specific for these class I loci restrain NK-cell activity against host cells with surface disposed class I MHC molecules. Interestingly, the US2 ER-lumenal domain dictates binding to class I molecules in a locus-specific fashion (Gewurz *et al.*, 2001b). US2, and perhaps by a similar mechanism US11, downregulates HLA-A and HLA-B, but not HLA-C, HLA-E molecules (Schust *et al.*, 1998; Furman *et al.*, 2000; Barel *et al.*, 2003). Such locus specificity may allow HCMV to selectively diminish antigen presentation to CD8+ T-cells, which rely heavily on HLA-A and HLA-B products, whereas NK-cell inhibitory receptors predominantly recognize HLA-C, HLA-E and HLA-G molecules. Further highlighting this dichotomy, the signal peptide of HCMV UL40 supplies a peptide ligand for HLA-E in a TAP-independent fashion, assuring that loaded HLA-E complexes can travel to the cell surface even during the expression of US2, US6 or US11 (Tomasec *et al.*, 2000).

US2 association does not significantly alter the conformation of the class I molecule (Gewurz, *et al.*, 2001a). How then does US2 initiate the dislocation of class I molecules from the ER? Though important molecular details of the US2 pathway remain to be elucidated, it appears likely that US2 recruits cellular factors following association with class I MHC. The US2 Ig-like fold has multiple additional binding surfaces that could associate with additional ER-resident proteins, for example the loops between its beta-strands that by analogy mediate immunoglobulin and TCR binding to antigens (CDR loops) (Gewurz *et al.*, 2001a). Alternatively, the US2 cytoplasmic tail is required for dislocation and may also interact with cytosolic or membrane proteins (Furman *et al.*, 2002). The intramembrane-cleaving protease, signal peptide peptidase associates with US2 and is required for dislocation of the class I MHC complex from the ER (Loureiro, 2006).

US2 triggers the mono-, di- and triubiquitination of folded molecules (Furman *et al.*, 2003). However, removal of all lysine residues from the class I cytoplasmic tail does not prevent dislocation (ubiquitination is not thought to occur in the oxidizing environment of the ER) (Furman *et al.*, 2003). A ubiquitin-independent step must therefore initiate dislocation, with ubiquitin attachment occurring either on the class I cytoplasmic tail, or on an ER-lumenal lysine residue following dislocation. Alternatively, ubiquitination of cellular machinery involved in assembly of the dislocation complex may be required to initiate class I MHC removal from the ER. Recombinant class I MHC molecules that lack lysine residues continue to be dislocated by US11, but not US2, even though CMV immuno-evasins require the activity of cellular E1 ubiquitin activating enzymes for US2-mediated dislocation (Hassink, 2006). Once in the cytosol, class I molecules are deglycosylated by cellular enzyme peptide: *N*-glycanase (PNGase or PNG1) (Blom *et al.*, 2004). *N*-glycanase cleaves the β-aspartyl-glucosamine bond of glycans attached to Asn residues. The products of the *N*-glycanase reaction

are a free oligosaccharide and a peptide containing an Asp residue at the site of hydrolysis (formerly an Asn). The class I heavy chain is then rapidly degraded by the proteasome. Deglycosylation precedes proteasomal degradation, as siRNA-mediated knock-down of PNGase expression in US2+ cells results in the accumulation of glycosylated class I heavy chains in the cytosol (Blom *et al.*, 2004).

US2 binds to the folded class I complex with micromolar affinity, and the recombinant US2-HLA-A2 complex is sufficiently stable to survive consecutive size exclusion and ion exchange chromatography steps. The stability of the complex raises the question of whether it must be disassembled prior to exit from the ER (Gewurz *et al.*, 2001a, b). If so, dissociation would require ER machinery that has yet to be identified. Rather, experimental evidence increasingly suggests that US2 dislocates intact class I MHC molecules. Chimeric class I MHC molecules bearing an ER-lumenal green fluorescence protein (GFP) undergo US2- and US11-mediated ER dislocation (as evidenced by the Asn-to-Asp sequence conversion that accompanies PNGase-mediated removal of the N-linked glycan, previously attached in the ER) (Fiebiger *et al.*, 2002). Fluorescent, deglycosylated intermediates can be recovered from the cytosol and imply that the GFP moiety traversed the membrane in a folded state. Likewise, chimeric class I MHC molecules with an appended ER-lumenal dihydrofolate reductase (DHFR) domain, a tightly folded moiety of considerable size, undergo dislocation by US2 and US11. Again, deglycosylated class I heavy chains with a folded DHFR can be retrieved from the cytosol (Tirosh *et al.*, 2003).

Which ER membrane pore might accommodate a complex of folded molecules? Preliminary experiments implicated the Sec61 pore in ER dislocation, a membrane complex that allows insertion of secretory and membrane proteins into the ER during their biosynthesis (Wiertz *et al.*, 1996a,b). However, it has been difficult to identify a complex between Sec61 and proteins undergoing dislocation. Importantly, the glycosylated US2–class I complex would not likely be accommodated by the Sec61 translocon, given the strict upper limit of the pore diameter suggested by the structure of the analogous archea SecY complex. Physiological measurements of the Sec61 translocon itself also suggest that a folded US2-class I complex would not be allowed through (Hamman *et al.*, 1997; Van den Berg *et al.*, 2004). By analogy with the US11 pathway (see below), an unidentified pore most likely accommodates the US2–class II MHC complex.

US11 is a 215-residue ER-resident glycoprotein that is homologous with US2. US11 likewise directs the degradation of class I MHC heavy chains within minutes of their synthesis (Wiertz *et al.*, 1996a,b). US11 induces the expression of X-box binding protein 1 (XBP-1), a key transcription factor that regulates the unfolded protein response (UPR) pathway. XBP-1 expression coincides with that of US11 in human cytomegalovirus infected foreskin fibroblasts, and the UPR appears to facilitate US11-medicated degradation of class I MHC (Tirosh, 2005). In the presence of US11, polyubiquitinated conjugates are affixed to class II heavy chains, in a fashion that appears to be independent of their tertiary structure. Whereas US2 causes addition of 1–3 ubiquitin moieties only to folded class II molecules, US11 attacks unfolded class I heavy chains and folded class I molecules alike. Ubiquitination is required for the US11 ER dislocation reaction (Kikkert *et al.*, 2001; Shamu *et al.*, 2001; Furman *et al.*, 2003). Cells that express both US11 and a temperature-sensitive mutant of the E1 ubiquitin-activating enzyme demonstrate normal US11-mediated degradation of class I molecules at permissive temperatures. However, upon shift to non-permissive temperatures, the class I heavy chains remain within the ER (Kikkert *et al.*, 2001). Isopeptide linkage between the ε-amino group of target proteins and ubiquitin residue 48 slates multiple proteins for proteasomal destruction, and likewise appears required for extraction of the class I heavy chain from the ER membrane in the US11 pathway (Flierman *et al.*, 2003; Varadan *et al.*, 2004). US11 may direct the ubiquitin-conjugating enzyme E2-25K, perhaps along with the E3 ligases MARCHVII/axotrophin or gp78, to attach polyubiquitin conjugates to class I MHC (Flierman, 2006).

Whereas the US11 cytoplasmic tail is dispensable for its function, the US11 transmembrane domain plays an active role in dislocation (Furman *et al.*, 2002; Lilley *et al.*, 2003). US11 Gln-192 is required for interactions with host proteins within the plane of the membrane, in particular Derlin-1 (Lilley and Ploegh, 2004). Derlin-1 is a recently identified homologue of yeast Der1p, an ER membrane protein that is required for the degradation of a subset of misfolded yeast ER proteins (Knop *et al.*, 1996). A Derlin-1 dominant-negative mutant prevents US11-, but not US2-mediated class I dislocation (Lilley and Ploegh, 2004). The integral membrane protein VIMP associates with Derlin-1 and recruits a complex of cytosolic proteins, the cytosolic p97 ATPase (also known as VCP, or CDC48 in yeast) and its cofactor complex Ufd1-Npl4 (Ye *et al.*, 2001, 2004). A complex containing US11, ubiquitinated class I heavy chain, Derlin-1, VIMP, and p97 has been detected (Ye *et al.*, 2004; Lilley, 2005). Further, p97 activity is required for US11-mediated heavy chain retro-translocation (Ye *et al.*, 2001, 2004). The P97–Ufd1–Npl4 complex recognizes proteins undergoing ER retro-translocation and provides the driving force for protein movement into the cytosol (Ye *et al.*, 2001). Thus, P97 captures MHC heavy chains marked by US11 for

disposal, and following poly-ubiquitination, extracts them from the ER membrane. The multiple membrane spanning Derlin-1 interacts with class I heavy chains both before and immediately after dislocation to the cytosol. Perhaps in concert with accessory proteins, Derlin-1 may comprise the exit channel utilized by the US11 pathway (Lilley and Ploegh, 2004; Ye *et al.*, 2004). A dominant negative Derlin-1 mutant blocks US11-, but not US2-dependent degradation of class I molecules (Lilley and Ploegh, 2004).

The apparent redundancy of US2 and US11 appears to contradict the general parsimony of viral genomes brought about by selective pressure. Yet, US2 and US11 are present in the genomes of multiple clinical HCMV isolates (Erica Mayer, Rebecca Tirabassi and Hidde Ploegh, data unpublished). Retention of both US2 and US11 may benefit CMV in several fashions. The two immuno-evasins utilize distinct dislocation pathways, and perhaps maximize the number of complexes that can be extruded during a given time. Since US2 and US11 recognize distinct intermediates in class I assembly, perhaps US2 serves an editing function and catches proteins missed by US11 (it is known whether for example US11 can bind to class I molecules occupied by PLC). Alternatively, either pathway may be preferred in a given cell type, a notion that is supported by experimental data from HCMV infection of human dendritic cells and from analogous MCMV inhibitors of class I (Hengel *et al.*, 2000; Rehm *et al.*, 2002). Finally, the distinct US2 and US11 binding sites on class I allow US2 and US11 to target distinct subsets of class I alleles and thereby counter class I polymorphism (Machold *et al.*, 1997; Gewurz *et al.*, 2001a,b; Barel *et al.*, 2003). The MCMV immuno-evasins likewise bind class I molecules in an allele-specific fashion and cooperatively prevent antigen presentation to a variety of CTL clones (Kavanagh *et al.*, 2001a,b).

The murine γ-herpesvirus-68 evolved a distinct pathway for proteasomal proteolysis of ER-resident class I molecules. The MK3 locus encodes an E3 ubiquitin ligase that directs the ubiquitination of the class I MHC cytosolic tail. MK3 forms a multiprotein complex with class I molecules, tapasin and TAP, and targets properly folded class II molecules during the peptide loading stage (Lybarger *et al.*, 2003). Association with tapasin/TAP appears to determine the class I allele-specificity (Wang *et al.*, 2004). Although initially characterized as a member of the plant homeodomain/leukemia-associated protein (PHD/LAP) family, a recent solution structure of the MK3 cytosolic domain reveals it to be a variant member of the RING domain family (Dodd *et al.*, 2004). RING motifs are 8 kDa zinc-binding domains that serve as adaptors for E2 ligases. RING domains do not generally possess their own enzymatic function, but instead provide substrate selectivity by directing E2 ubiquitin ligase activity (Freemont, 2000). The MK3 ring domain associates with cellular ubiquitin-conjugating enzymes UBCH5A-C and UBCH13, which have previously been shown to function in concert with cellular RING domain proteins. MK3 ubiquitination of the class I MHC molecule stimulates its removal from the ER (Bartee *et al.*, 2004). Akin to US11, MK3 requires the cellular proteins Derlin-1 and AAA-ATPase p97 for dislocation (Wang, 2006).

Disruption of the class I secretory pathway

Following receipt of peptide cargo, stable class II complexes exit the ER and traverse the Golgi *en route* to the cell surface. Herpesviruses once again a specific step in class I molecule biosynthesis, interfering with export of class I molecules. The HCMV US10 gene-product encodes a type I integral membrane glycoprotein that associates with class I molecules and delays egress of the class I MHC molecules from the ER (Furman *et al.*, 2002). The mechanism of US10 action remains uncertain. While US10 expression does not appear to alter the kinetics of class II MHC molecule degradation by US2 or US11, perhaps US10 serves to retard class I molecule egress from the ER and thereby minimize the probability that class I molecules escape US2/11 mediated degradation. For instance, at the onset of the early period of viral infection, US2 and US11 likely encounter a large population of class I molecules retained by US3 during the IE period.

HCMV US8 encodes a 26-kDa type I membrane glycoprotein that partially co-localizes with markers of the endolysosomal pathway. Although US8 associates with free class I MHC heavy chains within the ER, the significance of US8 association has not been fully elucidated: US8 expression does not appear to alter the maturation of class I products in cellular transfectants (Tirabassi and Ploegh, 2002). It remains possible that US8 exerts its effect on class II trafficking in concert with other CMV immuno-evasins. Indeed, such cooperative activity has been observed with the MCMV class II inhibitors m4 and m152 (Kavanagh *et al.*, 2001a,b). The MCMV m152 gene-product (gp40) blocks the export of class I from an ER-Golgi intermediate compartment (ERGIC) (Ziegler *et al.*, 2000). Although the mechanism remains to be fully defined, m152-mediated class I molecule retention does not require the m152 cytoplasmic tail or transmembrane domains. Further, class I molecules continue to be retained in the secretory pathway after the complex dissociates (Ziegler *et al.*, 2000). The m4 gene-product forms biochemically distinct complexes with differential stabilities with class I molecules in the presence and absence of m152 (Kavanagh *et al.*, 2001a,b).

Cell surface expression of class I molecules is reduced upon VZV infection, an effect that has been observed in both human T-cells in the SCID-hu thymus/liver mouse model and in skin biopsy specimens (Abendroth *et al.*, 2001a,b; Nikkels *et al.*, 2004). Microscopic and biochemical experiments demonstrate the accumulation of class I MHC molecules in the Golgi compartment in VZV-infected cells (Abendroth *et al.*, 2001a,b). The ORF66 gene-product is expressed during the early period of virus infection and serves to retain class I molecules in the Golgi complex. Cellular transfectants that express ORF66 demonstrate reduced cell surface expression of class I MHC (Abendroth *et al.*, 2001a,b). The molecular mechanism by which VZV halts class I in the Golgi has yet to be fully elucidated. The UL49.5 gene-product of several varicelloviruses including bovine herpesvirus I, pseudorabies virus, and equine herpesvirus 1, though not of varicella zoster, blocks the TAP peptide transporter through conformational arrest and subsequent proteasomal degradation (Koopers-Lalic, 2005).

Rerouting of class I molecules from the Golgi to the endolysosomal pathway

The human herpesvirus 7 (HHV-7) interferes with the class I MHC antigen presentation via the U21 gene product. U21 is a 55-kDa integral membrane glycoprotein that associates tightly with folded class I molecules within the ER, shortly after class I molecule biosynthesis (Hudson *et al.*, 2001). Although the molecular affinity remains unknown, U21 association with multiple class I alleles appears strong and survives treatment with .01% SDS in cellular extracts (Hudson *et al.*, 2001). The complex travels at least as far as the trans-Golgi network, where U21 diverts class I to the endolysosomal pathway. class I molecules are then degraded by lysosomal proteases.

MCMV employs a similar strategy via its m6 gene product. M6 is a type I ER-resident integral membrane glycoprotein that likewise associates with class I molecules within the ER and redirects them for lysosomal destruction. M6 utilizes a dileucine sorting signal within its cytoplasmic tail to achieve relocalization to lysosomes (Reusch *et al.*, 1999). Surprisingly, although the U21 cytoplasmic tail can likewise utilize a dileucine-like sorting motif to mediate its own intracellular sequestration, U21's cytoplasmic domain is dispensable for its function. U21 truncation mutants that lack cytoplasmic tails continue to target class I MHC molecules to lysosomes (Hudson *et al.*, 2003). Perhaps the U21 cytoplasmic tail is required for other U21 functions, for instance retrieval of surface-disposed class I molecules?

Akin to most herpesvirus immuno-evasins of the class I pathway, U21 demonstrates no significant homology with cellular proteins. Even HHV-6 U21, with its 50% amino acid similarity to HHV-7 U21, does not appear to interact with class I MHC molecules (Hudson *et al.*, 2001). The function of HHV-6 U21 remains to be determined.

Retrieval of cell surface class I molecules

HHV-8 relies upon two type III integral membrane proteins to perturb the class I MHC pathway during the early lytic cycle of viral replication, K3 and K5 (also called MIR-1 and MIR-2, for modulator of immune recognition) (Coscoy and Ganem, 2003). K3 and K5 function independently and utilize interactions within the lipid bilayer to recognize their targets, highlighting the skilled manipulation of cell biology co-opted by herpesviruses to subvert class I (Ishido *et al.*, 2000; Sanchez *et al.*, 2002). Additional cellular cofactors may be involved K3/5 recognition of class I MHC.

K3 and K5 share approximately 40% amino acid identity and are predicted to have cytoplasmic amino- and carboxy-terminal domains, two transmembrane domains, and a short ER lumenal domain (Coscoy and Ganem, 2003). Though initially characterized as a PHD/LAP domain, it appears likely that K3/K5 instead contain a variant RING domain (Scheel and Hofmann, 2003; Bartee *et al.*, 2004; Dodd *et al.*, 2004). Surprisingly, although they are homologous to the γ-herpesvirus 68 MK3 gene product that targets class I for ER dislocation, K3/5 instead re-route mature class I molecules to the endolysosomal pathway. Inhibition of lysosomal acidification by chloroquin or bafilomycin prevents class II molecule degradation (Fruh *et al.*, 2002). Covalent attachment of short-ubiquitin chains can mediate multiple intracellular trafficking processes, such as endocytosis and sorting to multi-vesicular bodies (MVB). Thus, K3 and K5 appear to function as E3 ligases and thereby initiate internalization of cell surface-disposed (or perhaps recycling) class I molecules to MVBs (Coscoy and Ganem, 2003). The K5 RING domain promotes ubiquitin transfer in an ATP- and E2-dependent reaction in vitro (Coscoy *et al.*, 2001). Disruption of the K3 RING domain prevents class I molecule internalization, even though association with class I still takes place (Hewitt *et al.*, 2002).

The majority of K3 and K5 molecules localize to the ER. Nonetheless, class II molecules exit the ER apparently unscathed and reach the plasma membrane with normal kinetics in the presence of K3 and K5 (Coscoy and Ganem, 2003). Perhaps ubiquitination of class I cytoplasmic tails might occur while the molecules are still in the ER and thereby mark them for eventual plasma membrane internalization. Alternatively, the minority of K3 and K5 that travels along the secretory pathway may be the active population. The available experimental evidence favors the latter model (Hewitt *et al.*, 2002; Coscoy and Ganem, 2003).

Ubiquitination of the conserved class I MHC cytoplasmic tail Lys-340 residue provides an internalization signal (Hewitt *et al.*, 2002). Interestingly, in an apparently novel enzymatic reaction, K3 can catalyze ubiquitination of cysteine residues via thiolester bond formation. class I MHC molecules that lack lysine residues in their cytoplasmic tails undergo cysteine-ubiquitination, which is sufficient to target class I for endocytosis and degradation (Cadwell, 2005). Sorting of ubiquitinated surface membrane proteins to MVB requires the activity of multiple cellular proteins, including dynamin and tumor susceptibility gene-101 (TSG101) (Hewitt *et al.*, 2002; Coscoy and Ganem, 2003). SiRNA-mediated knockdown of TSG101 expression prevents K3- and K5-mediated endocytosis of class I MHC molecules.

K3 subsequently directs the internalized class I molecules to lysosomes, perhaps via the concerted action of two distinct sorting motifs: a YXXϕ motif (where Y represents tyrosine; X signifies any residue; ϕ signifies a hydrophobic residue) and a diacidic cluster region. YXXϕ motifs are recognized by the adaptor protein (AP) complexes AP-1, AP-2 and AP-3, and direct trafficking into clathrin coated vesicles (Owen and Evans, 1998). The K3 Y_{152}AAV motif directs class I molecules to the *trans*-Golgi network via AP-1. The K3 diacidic cluster motif subsequently targets class I to the lysosomal compartment (Means *et al.*, 2002). Acid cluster dileucine motifs sort proteins from the trans-Golgi network to lysosomes via cargo proteins, including the so called Golgi-localized, γ-ear-containing, ARF-binding proteins (GGAs) (Takatsu *et al.*, 2001).

Proteasome activity also plays a key role in K3-mediated sorting of class II to the endocytic compartment, and small molecule proteasome inhibitors prevent K3-mediated delivery of class I MHC molecules to the dense endosomal compartment (Lorenzo *et al.*, 2002). Proteasome inhibition does not appear to increase cell surface expression of class I, however. Thus, the specific mechanistic role of the proteasome in the K3 pathway remains to be determined. Once within the endosomal compartment, cysteine protease activity removes the class I cytoplasmic tail, and an aspartyl protease subsequently cleaves class I within the plane of the membrane, liberating a soluble class I MHC molecule (Lorenzo *et al.*, 2002).

Poxviruses and several other herpesviruses also encode an immuno-evasin of the K3 family that likewise target class I molecules, suggesting a common evolutionary origin. These unrelated viruses appear to have acquired K3 and K5 from the mammalian MARCH family, a group of 9 subcellular integral membrane proteins that target glycoproteins for lysosomal destruction (Bartee *et al.*, 2004). Like K3 and K5, MARCH IV and MARCH IX possess ubiquitin-ligase activity against the class I cytoplasmic tail and stimulate endocytosis (Bartee *et al.*, 2004). MARCH proteins may participate in the regulation of endogenous class I surface expression, perhaps in a fashion analogous to regulation of growth factor receptors endocytosis by E3 ligases (Hicke, 2001). Interestingly, the extreme constraints on the retroviral genome may have forced HIV-1 to convergently evolve a unique approach for class I MHC inhibition via its Nef gene-product, which has no homology to MARCH proteins. Nef is a cytosolic protein that appears to promote endocytosis of class I molecules by a distinct pathway that involves cellular phosphofurin acidic cluster sorting protein-1 (PACS-1) (Piguet *et al.*, 2000).

K3 and K5 are adjacent in the HHV-8 genome and likely arose via gene duplication. Once again, why does a herpesvirus retain homologous factors with apparently overlapping function and kinetics? As with HCMV, K3 and K5 may counteract allelic variation (albeit less prevalent among class I cytoplasmic tails) and may function to varying degrees among various cell types. Indeed, K5 significantly downmodulates HLA-A and HLA-B locus products, whereas K3 downregulates HLA-A, -B, -C and -E molecules (Ishido *et al.*, 2000). Further, K5 targets additional proteins for endocytosis, and additional K3 targets may likewise exist. Studies of the MARCH family reveal an analogous an functional division: several MARCH proteins have a spectrum similar to K3, while a second subset more closely resemble K5 target specificity (Bartee, *et al.*, 2004). Indeed, the RING domain of K3 can be replaced with the corresponding domain of a cellular MARCH homologue without altering K3 function (Goto *et al.*, 2003).

Interference with class I molecules at the cell surface

The cell surface itself represents the final compartment for the inhibition of class I MHC display of antigenic peptides. Though no examples of physical interference with TCR recognition of class I/peptide complex are yet known among the human herpesviruses, MCMV m4 appears to do so. The m4 gene-product encodes a 34-kDa type I integral membrane glycoprotein (gp34) that initially associates with folded class II molecules within the ER. The m4-class II complex is then exported to the cell surface. Where M4 may sterically hinder TCR association the class I MHC–peptide complex. m4 thereby blocks antigen presentation at the cell surface to $K^{(b)}$-restricted clones (Kavanagh *et al.*, 2001a,b). Cell tropism has been observed for m4 function, with greater inhibitory function present in macrophages than in fibroblasts (LoPiccolo *et al.*, 2003), and macrophage infection with MCMV deletion mutants suggest synergistic function between its three class I immuno-evasins (LoPiccolo *et al.*, 2003).

Interference with the immunological synapse

T-cells form stable associations with antigen presenting cells (APCs) known as the immunological synapse to facilitate cell signaling. Intracellular adhesion molecule-1 (ICAM-1, or CD54) is a member of the Ig-superfamily and plays a key role in stable synapse formation, binding tightly to its T cell counter-receptor, LFA-1. ICAM-1 represents another cellular target of K5 and, like class I, is re-routed for lysosomal degradation, apparently by the same pathway (Ishido *et al.*, 2000; Coscoy *et al.*, 2001). Reduction of ICAM-1 cell surface expression has been observed on infected keratinocytes from skin biopsy specimen of VZV-infected patients (Nikkels *et al.*, 2004). HHV-8 infection also leads to the downregulation of PE-CAM (CD31) surface expression, and may even occur during the latent stage of infection (Tomescu *et al.*, 2003).

Interference with costimulation

Interactions between numerous cell surface receptors tightly regulate the context of T-cell activation to restrain the production of T-cell toxins. Along with recognition of an MHC–peptide complex, initial T-cell activation requires simultaneous, costimulatory signals from the APC. Interactions between costimulatory molecules and their counter-receptors present an additional step in T-cell activation that herpesviruses disrupt.

Professional APCs express the costimulatory molecules B7-1 and B7-2, which independently can provide an important second signal for T-cell activation. HHV-8 K5 and murine-γ68 MK3 perturb this control point of adaptive immunity. Both K5 and MK3 target B7-2 molecules for degradation, apparently by the same pathways utilized for class I degradation (Ishido *et al.*, 2000; Coscoy *et al.*, 2001; Wang *et al.*, 2004). Although B7-1 and B7-2 are both functionally and structurally similar, B7-1 lacks cytoplasmic tail lysines and escapes both K5 and MK3. Introduction of lysines into the B7-1 cytoplasmic tail confers susceptibility to K5-mediated degradation (Coscoy *et al.*, 2001). Why should two herpesviruses destroy B7-2 and not B7-1? Perhaps such selectivity helps the virus to strike a balance with the host. For example, mice deficient in both B7 molecules have a more profound immunodeficiency than those lacking B7-2 alone (Borriello *et al.*, 1997). Inhibition of just B7-2 may enable the establishment of persistent infection but limit damage to its host. Indeed, MCMV encodes a class I-like molecule that likewise may function to reduce host damage. The m157 gene-product encodes a class I-like NK-cell ligand that allows control of MCMV acute infection. Strains whose NK cells fail to recognize this CMV-encoded ligand do not survive acute infection, whereas persistent infection is established only in strains whose NK cells control acute viremia (Arase *et al.*, 2002; Bubic *et al.*, 2004).

Though at first glance downmodulation of B7-2 appears unique to gamma-herpesviruses, the targeting of B7 molecules was most likely usurped from the mammalian genome. Several MARCH proteins, including MARCH I, MARCH II and MARCH VIII (c-MIR) likewise target B7-2, apparently by the same pathway (Goto *et al.*, 2003; Bartee *et al.*, 2004). Further, a subset of MARCH proteins (IV and IX) target class II, whereas others (I and VIII) target both B7-2 and class II, reminiscent of K3 and K5, respectively (Bartee *et al.*, 2004). The K5 gene-product targets PE-CAM for lysosomal degradation, apparently via the same pathway described previously for disposal of class I MHC molecules by K5 (Mansouri, 2006).

Interference with APC function

Dendritic cells (DCs) are professional antigen-presenting cells that play a crucial role in stimulation of adaptive T-cell responses. Multiple members of the human herpesvirus family decrease the capacity of DC to stimulate T-cells.

HCMV infects a subset of DCs and disrupts their activity. HCMV-infected DCs demonstrate reduced capability to stimulate T cell proliferation and cytotoxicity, a phenotype that has been attributed to pleiotropic effects on the DC. These include reduced surface expression of multiple proteins (including class I MHC and II, B7-1 and B7-2 and CD40) as well as reduced capacity to secrete stimulatory cytokines and a functional unresponsiveness to maturation stimuli (Hertel *et al.*, 2003). Monocyte-derived DCs infected with HCMV do not migrate toward several lymphoid chemokines, potentially delaying the kinetics of primary CD8+ T-cell activation (Moutaftsi *et al.*, 2004). Functional paralysis of multiple DC functions has likewise been observed following MCMV infection of DCs (Andrews *et al.*, 2001). Further, VZV infection of mature dendritic cells causes downregulation of a similar subset of cell surface molecules (Morrow *et al.*, 2003). Infection of DCs can even facilitate VZV dissemination and support infection of T-cells themselves (Abendroth *et al.*, 2001). VZV-infected T-lymphocytes play an important role in supporting persistent viremia.

HSV-1 can infect immature DCs and inhibit their maturation (Kobelt *et al.*, 2003). EBV infection of monocytes can similarly prevent their development into dendritic cells, an activity that is observed even with UV-inactivated virion. The trimolecular gp25-gp42-gp85 complex appears to exert

this inhibitory activity via interactions with class II MHC at the monocyte membrane (Li *et al.*, 2002). EBV-infected monocytes also demonstrate significantly reduced phagocytic activity, though the mechanism remains incompletely understood (Savard *et al.*, 2000).

HSV also interferes with DC function by perturbing CD83, a 45-kD cell surface adhesion molecule important for DC interaction with T-cells. Within hours after HSV infection, CD83 cell surface expression is significantly reduced, a phenotype that has been attributed to re-routing of CD83 molecules to the endolysosomal pathway. The molecular mechanism, including the responsible HSV factor(s), remains to be determined (Kruse *et al.*, 2000). However, a similar reduction in DC CD83 surface disposition during CMV infection has been attributed to TGF-β expression by HCMV-infected fibroblasts (Arrode *et al.*, 2002).

HSV-1 infection of B cells strongly inhibits their ability to stimulate CD4+ T-cells (Barcy and Corey, 2001). The immediate-early HSV US1 gene-product ICP22 is both necessary and sufficient for this phenotype, by an unknown mechanism.

Stunning of Cytotoxic T-cell activity

HSV-1 infection of target cells appears to exert an inhibitory effect *in trans* on CTLs. Inactivated, or stunned, CTL are transiently incapable of cytokine synthesis or cytotoxic granule release in response to TCR ligation (Sloan *et al.*, 2003). The phenomenon requires close cell–cell contact between CTL and the HSV-infected target cell (Sloan *et al.*, 2003), and HSV penetration into T-cells.

Though no *de novo* viral transcription or translation is required, the TCR signal transduction cascade is inhibited at the level of the linker for activation of T cells (LAT). Through an uncharacterized mechanism, HSV infection reduces LAT phosphoryation (Sloan, 2006).

CTL escape mutants

EBV, like other herpesviruses, is a genetically stable virus. Nonetheless, mutations occur at low frequency, and may allow EBV to adapt to populations where a particular class I MHC allele or haplotype prevails. For example, mutations that affect class I binding (anchor residues) are regularly detected in HLA-A11 epitopes of South East Asia EBV isolates, where greater than 50% of the population expresses HLA-A11. In contrast, HLA-A11 epitope loss is much less common in central African isolates, where HLA-A11 is absent (de Campos-Lima *et al.*, 1993).

Ligation of inhibitory receptors

HCMV and MCMV each encode a viral class I MHC molecule homologue. The HCMV UL18 molecule forms a complex with β2-microglobulin and peptide, and is exported to the cell surface. Interestingly, UL18 is resistant to the activity of the HCMV class I immuno-evasins (Park *et al.*, 2002). Rather than presenting antigenic peptide to CD8+ T-cells, UL18 binds tightly to LIR-1 (ILT2, or CD85), an inhibitory receptor expressed on monocytes, dendritic cells and lymphocytes (Willcox *et al.*, 2003). UL18 binds to LIR1 with >1000-fold higher affinity than the association between class I MHC and LIR1 (Willcox *et al.*, 2003). Though it is not yet clear to what extent UL18 modifies lymphocyte function, the widespread expression pattern of LIR-1 suggests that UL18 may potentially alter multiple steps in T-cell activation.

Inhibition of T-cell receptor signaling

Several herpesviruses alter the interaction between APC and T-cells from within T-lymphocytes. The lymphotropic HHV-6A has been reported to reduce expression of the TCR/CD3 complex on the transcriptional level, with transcriptional downregulation of multiple components of the T-cell receptor signaling apparatus. An HHV-6 factor expressed during the late stage of virus infection has been implicated (Lusso *et al.*,1991). HCMV UL20 encodes a protein with amino acid sequence similarity to both the constant and variable regions of the T-cell receptor γ chain (Beck and Barrell, 1991). Further studies are required to elucidate the role of the putative HCMV TCR γ homologue.

Though not yet observed among the lymphotropic human herpesviruses, the Herpesvirus saimiri (HVS) interferes with downstream components of the TCR signal transduction pathway. The HVS Tip (tyrosine kinase–interacting protein) gene-product interferes with early signaling events of the TCR signal transduction pathway (Cho *et al.*, 2004). Tip constitutively localizes to lipid rafts, where it binds to the SH3 domain of Lck, a member of the Src tyrosine kinase family. Tip interacts also with endosomal protein 80 and induces endosomal vesicle formation, thus sequestering Lck. Tip may also interfere with T-cell signaling by promoting the internalization of lipid rafts (Cho *et al.*, 2004b).

Erroneous T-cell activation

EBV infection transactivates the env gene, a superantigen encoded by the human endogenous retrovirus HERV-K18. LMP-2 activity is sufficient for env induction at the

transcriptional level (Sutkowski *et al.*, 2001). Env preferentially activates the TCR Vβ13 subset of CD4+ T-cells (Sutkowski *et al.*, 2001). While it remains to be determined if env transactivation supports EBV immuno-evasion or is incidental, it is noteworthy that superantigen activity can deregulate the establishment of specific immunity. In a more direct fashion, MCMV primes the development of CD8+ T-cells specific for virus epitopes that are not presented in relevant tissues, where they are hidden by immuno-evasin activity (Holtappels *et al.*, 2004).

Disruption of class II MHC antigen presentation

The class II MHC antigen presentation pathway presents antigenic peptides derived from the extracellular compartment to CD4+ T-cells. Whereas class II MHC molecules are expressed by most nucleated cells, class II expression is largely restricted to APC, such as DC, monocyte/macrophages, and B-cells, though immune cytokines can induce class II expression on a variety of other cell types. APC deliver pathogens (or material derived from pathogens) via phagocytosis or receptor-medicated endocytosis into the endolysosomal pathway for destruction (Denzin and Cresswell, 1995).

Class II MHC molecules are heterotrimeric complexes that contain the class II α and β chains, and an antigenic peptide. There are three class II loci: DP, DQ and DR. The class II αβ heterodimer undergoes folding within the ER and associates with an accessory protein called the invariant chain (Ii). Ii prevents class II peptide loading within the ER, and by virtue of a dileucine motif within its cytoplasmic tail, shuttles the nascent class II molecules through the TGN to the lysosomal compartments (Wubbolts and Neefjes, 1999). Ii is degraded within the lysosomal compartment, where the class II molecules encounter peptide-fragments produced by lysosomal proteolysis of internalized material. The MHC-encoded HLA-DM molecule then catalyzes exchange of the class II-bound Ii peptide called CLIP with higher affinity, lysosomally-derived peptide ligands. Peptide-loaded class II molecules are exported to the cell surface for antigen presentation to CD4+ T-cells. Not surprisingly, herpesviruses manipulate antigen presentation by the class II MHC pathway as well.

Interference with class II expression

The expression of class II MHC molecules is under the control of both constitutive and inducible elements (Boss 1997). Class II is constitutively expressed on APCs, activated T-cells, and thymic epithelial cells, whereas a subset of cells upregulate class II MHC expression in an IFN-γ dependent fashion. In response to IFN-γ, the Jak/STAT signaling pathway is activated and translates the IFN-γ signal into transcriptional responses. Stat1α activity upregulates expression of the class II transcriptional activator CIITA, which in turn drives the expression of class II molecules (Boss, 1997). Fibroblasts, endothelial and epithelial cells all upregulate CIITA in response to IFN-γ (Boss, 1997).

HCMV interferes with the IFN-γ pathway of class II upregulation by several distinct mechanisms. During the immediate-early and early phases of virus infection, an HCMV factor targets JAK1 to the proteasome (Miller *et al.*, 1998). MCMV also interferes with IFN-γ upregulation of class II transcription, though apparently does not involve STAT1α perturbation (Heise *et al.*, 1998). Also, as mentioned earlier, MCMV M27 targets STAT2 for protosomal degradation. VZV also interferes with Jak/STAT signaling, apparently by the inhibition of Jak/STAT2 protein synthesis (Abendroth and Arvin, 2001).

Manipulation of class II molecules

The HLA-DR-α and HLA-DM-α molecules are targeted for proteasomal degradation in cells that are engineered to overexpress HCMV US2 (Tomazin, *et al.*, 1999). US3 has also been shown to interact with class II molecules and to retain them in the ER (Chevalier and Johnson, 2003). The observation that HLA-DRα and HLA-DMα are targeted for degradation by US2 is not readily explained by the structural data from the US2-HLA-A2 complex, as the class I binding surface recognized by US2 is not conserved on class II molecules (Gewurz *et al.*, 2001). Thus, it appears likely that a different US2 binding site is required for the downmodulation of class II MHC molecules. Likewise, though tapasin plays a key role in US3 interactions with class I molecules, tapasin is not known to interact with class II MHC complexes. Perhaps US3 might interact with the invariant chain in an analogous fashion in its class II pathway? Alternatively, US3 may also use a different mechanism altogether to retain class II molecules in the ER. In any case, it will be interesting to determine whether US2 and US3 alter the class II pathway in HCMV-infected cells.

HCMV has also been reported to alter trafficking of class II molecules within infected cells, causing the retention of vesicles bearing class II molecules in an aberrant perinuclear distribution (Cebulla *et al.*, 2002). A similar effect of HCMV has been observed in latently infected cells, where a block in protein trafficking causes the accumulation of class II molecules in intracellular vesicles. The responsible HCMV factor(s) have not been identified, but do not involve the US2–11 gene products (Slobedman *et al.*, 2002). Murine infection models demonstrate HSV-mediated

intracellular redistribution of class II MHC molecules within the CNS (Lewandowski *et al.*, 1993). Further studies are required to better define the biology underlying this observation.

The EBV BZLF2 gene-product (gp42) is a 42-kDA type II integral membrane glycoprotein that binds to class II MHC molecules. BZLF2 has been reported to interfere with CD4+ T-cell activation (Spriggs *et al.*, 1996). Gp42 is known to associate with class II MHC molecules to facilitate EBV entry into B cells. The molecular structure of the gp42–class II MHC complex has been determined, and gp42 belongs to the C-type lectin family and has homology with a family of human NK-cell receptors that bind to class II MHC (Mullen *et al.*, 2002).

gp42 occurs in two forms, including a soluble form generated by proteolytic cleavage within the ER. Soluble gp42 is secreted, and may inhibit cell surface class II MHC recognition by CD4+ T-cells. Secreted gp42 was detected during EBV lytic replication (Ressing, 2005).

Conclusions

Selective pressure exerted by adaptive immunity has led herpesviruses to convergently evolve a surprising number of immuno-evasins that specifically dysregulate T-cell responses. Even so, numerous herpesvirus gene-products have yet to be ascribed functions, in particular factors required for growth in vivo but dispensable for growth in cell culture. Further mechanisms of T-cell evasion by herpesviruses are sure to be discovered. Multiple herpesvirus-encoded micro-RNAs have been discovered, and may well serve as immunoevasins, as has been described for other viruses (Sullivan, 2005). With the set of immuno-evasins better defined, an ongoing challenge will be to define the specific role of T-cell immuno-evasins during the various stages of the herpesvirus lifecycle. An enhanced understanding of how herpesviruses solve the immunological puzzles faced during primary infection, dissemination, establishment of latency, reactivation, and sporadic shedding will be a challenging, though important endeavor. Such knowledge should directly lead to the development of novel antiviral agents, vaccines, gene therapy, and permit the application of immuno-evasins themselves to immunological disease states outside of viral biology.

Subversion of innate and adaptive immunity: immune evasion from antibody and complement

Lauren M. Hook and Harvey M. Friedman

Department of Medicine, University of Pennsylvania School of Medicine, PA, USA

Many herpesviruses encode immune evasion molecules that interfere with activities mediated by antibody and complement, suggesting the importance of antibody and complement in host defense against herpes infections. How does this observation reconcile with the clinical findings that severe infections develop mostly in subjects with T-cell deficiencies, such as transplant recipients or those with advanced HIV infection? An explanation that we favor is that T-cells assume a pivotal role in host defense partly because herpesviruses are very effective at limiting the activities of antibody and complement. Support for this hypothesis comes from experimental studies using mutant HSV-1 strains defective in antibody and complement immune evasion that demonstrate a marked increased in effectiveness of antibody and complement in host defense against the mutant viruses (Lubinski *et al.*, 2002).

Newborns lack mature T-cell repertoires and generally have low serum complement levels; therefore, observations in human newborns provide opportunities to assess the contributions of antibodies independent of T-cells and perhaps complement in host defense against herpesviruses. The severity of HSV and CMV infection in the fetus and newborn are greatly reduced when the infection in the mother is recurrent rather than primary. In recurrent infection, antibodies pass transplacentally to the fetus and protect against the infection. Passive transfer of VZV antibodies from mother to fetus protects the newborn from severe chickenpox when exposed days to weeks after delivery. Similarly, treating newborns with varicella zoster immune globulin greatly reduces the severity of infection in infants born too soon after onset of chickenpox in their mothers to benefit from passive transfer of maternal antibodies. Therefore, lacking mature T-cells, newborns rely on passive transfer of maternal IgG antibodies to modify disease severity, suggesting that antibodies are partially effective against herpesviruses. The immune evasion strategies of herpesviruses target the IgG Fc domain, but do not inhibit neutralizing activities mediated by the IgG Fab domain, which likely accounts for the partial protection provided by antibodies.

Role of the herpesvirus IgG Fc receptor in immune evasion

Introduction

Herpesviruses encode glycoproteins that bind the Fc domain of IgG, referred to as viral IgG Fc receptors (vFcγR). Table 63.1 lists the human herpesviruses that encode vFcγRs and the genes involved. Non-human herpesviruses, pseudorabies virus (PRV) and murine cytomegalovirus (MCMV), also express vFcγRs, suggesting that vFcγRs fulfill important roles in pathogenesis (Favoreel *et al.*, 1997; Thale *et al.*, 1994). FcγRs are detected on many microorganisms, including staphylococci (protein A), streptococci (protein G), schistosomes, trypanosomes, hepatitis C virus (core protein), and coronaviruses (S peplomer protein). FcγRs are also detected on mammalian cells (cFcγRs) and regulate B-cell activation, phagocytosis (engulfing particles $\geq$1 μM), endocytosis, antibody-dependent cellular cytotoxicity (ADCC), and release of inflammatory mediators (Raghavan and Bjorkman, 1996). Below, we discuss the structure and function of vFcγRs and consider similarities with cFcγRs.

The IgG Fc domain mediates important antibody effector activities, including C1q binding, interacting with cFcγR on NK cells to trigger ADCC, phagocytosis and release of cytokines and proinflammatory molecules from

Table 63.1. IgG Fc receptors encoded by human herpes viruses

Virus	Gene	Protein	Comments
HSV-1, HSV-2	U_S8	gE	Low affinity FcγR; homology with domain 2 of human FcγRII (Dubin *et al.*, 1994)
HSV-1, HSV-2	U_S8, Us7	gE-gI complex	gE-gI forms a higher affinity FcγR than gE alone (Dubin *et al.*, 1990).
CMV	U_L118, U_L119	gp68	Homology with domain 3 of FcγR1 (Atalay *et al.*, 2002)
CMV	TRL11, IRL11	gp34	Homology with FcγRII/III domain 2 (Atalay *et al.*, 2002)
VZV	ORF68	gE	VZV gE amino acids 328–500 shares homology with HSV-1 gE 211–381 (region involved in Fc binding) (Litwin *et al.*, 1992)

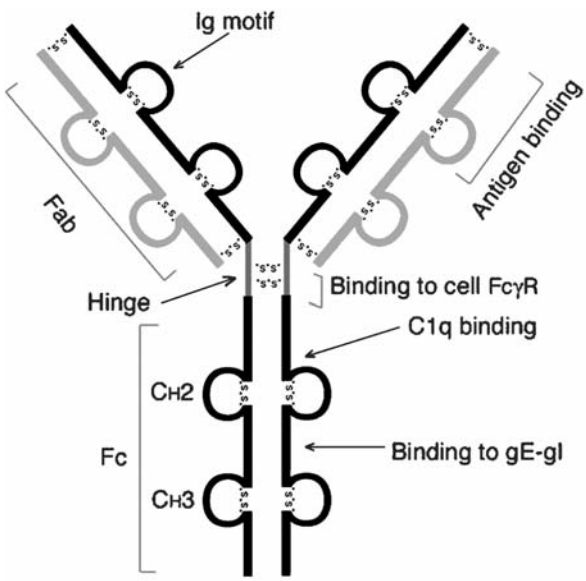

Fig. 63.1. Schematic drawing of the IgG molecule. Four immunoglobulin motifs are shown on the IgG heavy chains (black) and two on the IgG light chains (grey). Sites of interaction are shown between the IgG Fc domain and FcγRs on mammalian cells, C1q and HSV-1 gE-gI.

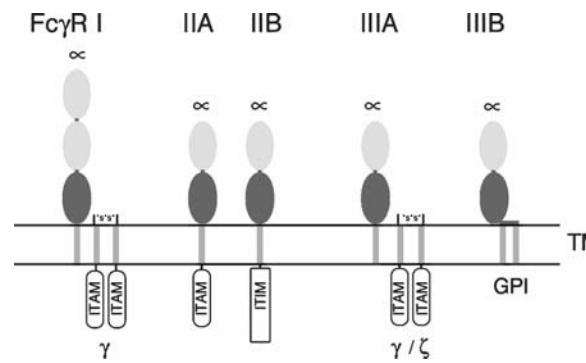

Fig. 63.2. Schematic drawing of cellular FcγRs. The FcγRs contain an α chain that has two or three Ig superfamily motifs (shown as ovals). The motif closest to the cell membrane (dark grey) functions as the IgG Fc binding domain. FcγR1 has two γ chains that contain ITAM (immunoreceptor tyrosine-based activation motif) sequences. FcγRII has two isoforms, IIA and IIB. IIA has an ITAM, while IIB has an ITIM (immunoreceptor tyrosine-based inhibitory motif) that inhibits activation signals. FcγRIII has two isoforms, IIIA that has ITAMs and IIIB that has glycophosphatidyl inositol (GPI) linkage.

granulocytes and macrophages. Figure 63.1 depicts an IgG molecule with its Fc domain showing the regions involved in C1q binding and interaction with cFcγRs or the HSV-1 vFcγR (gE-gI).

IgG Fc receptors on mammalian cells

Specific cellular Fc receptors interact with each of the immunoglobulin classes, IgA, IgD, IgE, IgG and IgM. However, only IgG Fc receptors have been detected on human herpesviruses; therefore, the discussion below focuses on cFcγRs.

Three classes of cFcγRs are present on mammalian cells, including FcγRI (CD64), FcγRII (CD32) and FcγRIII (CD16) (Fig. 63.2) (Raghavan and Bjorkman, 1996). FcγRI is detected on granulocytes (neutrophils, eosinophils and mast cells), monocytes and macrophages, and is a heterodimer consisting of one α-chain and two γ-chains. The α-chain contains three extracellular Ig-like domains. The membrane proximal domain is the region primarily involved in Fc binding activity. The γ-chains are linked by a disulfide bond and are necessary for cell signaling events and for expression of the α chain at the cell surface. The γ-chains contain amino acid sequences, referred to as ITAMs (immunoreceptor tyrosine-based activation motifs) that become phosphorylated at tyrosine positions upon cross-linking of the FcγR. The ITAMs trigger intracellular signaling events that are initiated by src family protein tyrosine kinases and that induce phagocytosis and endocytosis. FcγRI binds single IgG molecules (monomeric IgG)

with high affinity ($2 \times 10^9 - 5 \times 10^9$ M^{-1}). IgG complexes are required for efficient triggering of FcγRII and FcγRIII since these receptors bind monomeric IgG with low affinity ($\sim 10^6$ M^{-1}).

FcγRII has two human isoforms, IIA and IIB. Both contain a single α-chain with two Ig-like extracellular domains. The membrane proximal domain is involved in Fc binding activity. The cytoplasmic domain of FcγRIIA contains an ITAM motif, while IIB has an ITIM motif (immunoreceptor tyrosine-based inhibitory motif) that inhibits cell activation. Receptors with ITIMs are found on neutrophils, macrophages, mast cells and B cells and contain sequences that are phosphorylated at a tyrosine position upon receptor cross-linking leading to inhibition of activation signals (Ravetch and Bolland, 2001).

FcγRIII in involved in ADCC (NK cell-mediated), phagocytosis and endocytosis. This receptor has two isoforms, IIIA with a polypeptide chain anchor, and IIIB with a glycophosphatidyly inositol (GPI) linkage. FcγRIIIA contains an α chain with two Ig-like extracellular domains, and a γ- or ζ-chain that contains ITAMs. FcγRIIIB has only an α-chain with two extracellular Ig-like motifs. IgG Fc interacts with the membrane proximal Ig-like domains of both FcγRIII isotypes. FcγRIIIA is found on macrophages, mast cells and as the only FcγR on NK cells, where it mediates ADCC, while IIIB is detected on neutrophils.

Herpes simplex virus FcγR

Both HSV-1 and HSV-2 encode vFcγRs, although considerably more is known about the structure and functions of the HSV-1 FcγR, which is discussed below.

gE and gI structure

Glycoproteins gE and gI form a heterodimeric complex that contains one molecule each of gE and gI and that functions as an FcγR (Chapman *et al.*, 1999; Johnson *et al.*, 1988). HSV-1 gE strain 17 has a molecular mass of ~80 kDa and is a 550 amino acid type 1 transmembrane glycoprotein, although strain NS, used extensively in the authors' laboratory, encodes two additional amino acids, glycine and glutamine, at positions 186 and 187 respectively (Lin *et al.*, 2004). The NS strain gE ectodomain includes 421 amino acids with a predicted signal sequence from amino acids 1–23, two N-linked glycosylation sites, a transmembrane domain (422–446), and a large cytoplasmic tail (447–552) that undergoes serine phosphorylation (Edson *et al.*, 1987).

HSV-1 strain 17 gI has a molecular mass of ~70 kD and contains 390 amino acids. Sequences of strains KOS and NS differ from strain 17 in that a 7-amino acid repeat at position 225–231 in strain 17 is absent in KOS and NS (H. M. Friedman, unpublished observations). HSV-1 strain NS gI has a predicted signal sequence from amino acid 1–20, three N-linked glycosylation sites, a transmembrane domain (267–287), and a large cytoplasmic tail (288–383).

Glycoprotein gE binds Fc in the absence of gI, while gI cannot bind Fc without gE. The gE-gI complex binds Fc with higher affinity than gE alone (Bell *et al.*, 1990; Dubin *et al.*, 1990). IgG monomers bind to the gE–gI complex with an affinity of $0.4 \times 10^7 - 2 \times 10^7$ M^{-1}, while gE binds IgG aggregates, but not IgG monomers (Chapman *et al.*, 1999; Dubin *et al.*, 1990). Approximately 4×10^6 vFcγR binding sites are present on HSV-1 infected cells in vitro, which exceeds the number of cFcγR detected on human leukocytes by ~100-fold (Johansson and Blomberg, 1990). The HSV-1 FcγR binds human IgG4 with higher affinity than IgG1 or IgG2, while IgG3 fails to bind (Johansson *et al.*, 1984). A substitution of arginine for histidine at IgG4 Fc amino acid 435 abolishes Fc binding to gE-gI, which is consistent with the observation that most human IgG3 allotypes contain an arginine at Fc position 435 (Chapman *et al.*, 1999). IgG subclass concentrations in serum are age dependent, but in general, IgG1 is most abundant, followed by IgG2, with considerably lower concentrations of IgG3 and IgG4. IgG1 and IgG3 are potent activators of complement, while IgG2 is slightly less so, and IgG1 binds to FcγRIIIA on NK cells to mediate ADCC (Ghirlando *et al.*, 1995). Therefore, by interacting with IgG1 and IgG2, the vFcγR is binding the two most abundant IgG subclasses and potentially interfering with complement activation and ADCC mediated by these subclasses.

Mapping studies have determined that gE amino acids 24–211 are required to form a complex with gI, while gI amino acids 43–192 interact with gE (Basu *et al.*, 1995; Rizvi and Raghavan, 2001). Two approaches were used to define regions on gE involved in Fc binding. Fragments of gE DNA were fused to HSV-1 gD DNA and expressed in mammalian cells. The smallest gE fragment to retain FcγR activity included gE amino acids 183–402 (sequences based on strain 17) (Dubin *et al.*, 1994). Linker insertion mutagenesis was used as a second approach to evaluate gE domains involved in FcγR activity. Four amino acid inserts at each of ten positions between gE amino acids 235–380 eliminated IgG Fc binding. Therefore, the results of the two approaches were complementary, establishing the gE domain between amino acids 183 and 402 as sufficient for Fc binding, while mutations between amino acids 235 and 380 resulted in loss of function. The crystal structure has been solved for

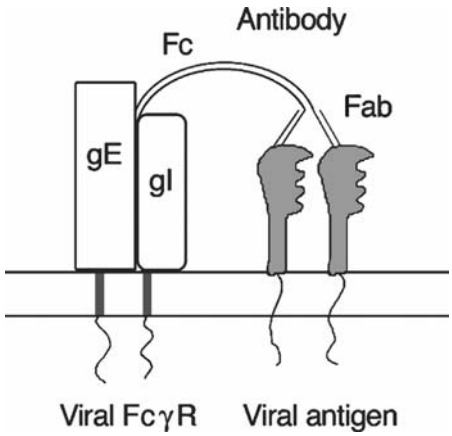

Fig. 63.3. Schematic drawing of antibody bipolar bridging. The IgG Fab domains bind to the viral antigen and the Fc domain of the same antibody molecule binds to the vFcγR (gE-gI).

the interaction of the IgG Fc fragment with a soluble form of cFcγRIII (Sondermann *et al.*, 2000). Five contact sites were identified on the cFcγR over a linear range of 73 amino acids, suggesting that the much broader linear range of gE mutations that resulted in loss of function likely reflect changes in conformation and contact sites. This conclusion is supported by a low-resolution crystal structure of the gE–gI/Fc complex that was solved at 5 Å (Sprague *et al.*, 2006). The crystal structure was verified by a theoretical prediction model of gE–Fc interaction that was based on the crystal structure of the gE C-terminal ectodomain (CgE amino acids 213–390) solved at 1.78 Å. The gE–gI/Fc crystal structure demonstrates that two gE-gI molecules interact with one Fc dimer and predicts that Fc interfaces with gE amino acids 225, 245–247, 249–250, 256, 258, 311, 316, 318–322, 324 and 338–342. Loss of Fc binding when gE is mutated at other sites likely occurs because of changes in gE conformation.

The HSV-1 FcγR and immune evasion

An IgG antibody molecule that is directed against HSV-1 can bind by its Fab domain to viral antigens on the virion or infected cell while the Fc domain of the same antibody molecule binds to the vFcγR (Fig. 63.3) (Frank and Friedman, 1989). Antibody bipolar bridging is used to describe this form of antibody binding, which requires considerable flexibility of the IgG molecule at the hinge region. Studies of the dynamic conformations of IgG in solution and bound to receptors confirm IgG has the flexibility to mediate bridging (Zheng *et al.*, 1992). The crystal structure of the gE–gI/Fc complex is also compatible with antibody bipolar bridging (Sprague *et al.*, 2006). Antibody bridging is postulated to be an important immune evasion strategy, since the vFcγR binds the Fc domain of antibody molecules that are targeting the virus. The affinity of the HSV-1 FcγR for Fc is ~100-fold lower than that of cFcγR1; therefore, binding of monomeric, non-immune IgG is limited. The IgG Fab domain binds with high affinity to the target antigen, which anchors the IgG Fc domain onto the virion or infected cell surface. The vFcγR is then able to bind the IgG Fc domain to block its activities.

Figure 63.1 shows the regions on Fc that interact with host and viral proteins. The region on IgG that binds to cFcγRs is located at the lower portion of the hinge region and the upper margin of the C_H2 domain (Sondermann *et al.*, 2000). The IgG Fc C_H2 domain interacts with C1q to initiate complement activation, while the C_H2–C_H3 interface of the Fc domain binds to gE–gI, which is similar to the site of interaction between protein A and Fc (Johansson *et al.*, 1989; Miletic and Frank, 1995). Despite the distance between domains on Fc involved in binding to gE–gI, C1q and cFcγRs, the HSV-1 FcγR is effective at blocking functions mediated by these regions of the Fc molecule (Dubin *et al.*, 1991).

Studies were performed to assess the role of the vFcγR in pathogenesis. A mutant HSV-1 strain was produced by introducing 4 amino acids at gE position 339 (based on the sequence of strain 17). The mutant virus expressed gE and gI at the infected cell surface, but failed to bind IgG Fc measured by rosetting assays using IgG-coated erythrocytes and by flow cytometry using biotin-labeled non-immune human IgG (Nagashunmugam *et al.*, 1998). Wild-type, gE mutant and gE-restored viruses were injected into the murine flank to assess the contribution of the vFcγR to virulence. The Fc domain of murine IgG does not bind to the HSV-1 FcγR; therefore, the three virus strains were expected to cause similar disease in mice, which was the observed result (Johansson *et al.*, 1985; Nagashunmugam *et al.*, 1998). Human IgG does bind to the HSV-1 FcγR; therefore, passive transfer of HSV antibodies was predicted to be more active against the vFcγR defective strain than against wild-type or restored virus. When infection was performed one day following passive transfer of HSV IgG antibodies, approximately 100-fold higher titers of gE mutant virus were required to cause the same level of disease as wild-type or restored virus. Passive transfer of non-immune human IgG or murine HSV IgG antibodies showed no differences among the various strains. Therefore, these in vivo studies define a contribution of the vFcγR to pathogenesis that depends upon the ability of the virus to block activities mediated by the IgG Fc domain. Synergy between gC and gE in mediating immune evasion was demonstrated

in vitro and in vivo using an HSV-1 mutant virus defective in C3b and IgG Fc binding (Lubinski *et al.*, 2002). Glycoproteins gC and gE interfere with complement activation at different steps in the cascade, which likely contributes to the synergy.

Additional mechanisms have been proposed for vFcγR-mediated immune evasion. The vFcγR promotes capping of viral antigens on the surface of infected cells in response to human HSV antibodies (Rizvi and Raghavan, 2003). The antibodies promote virus spread cell-to-cell when gE is expressed on the cell surface, which suggests that when antibodies are present, gE enables the virus to remain intracellular to avoid neutralization. In separate studies, the binding of Fc to gE-gI was noted to be pH dependent (Sprague *et al.*, 2004). Binding of Fc occurs at an affinity of $2 \times 10^7 - 3 \times 10^7$ M^{-1} at pH 7.4, which is the pH at the cell surface. In contrast, no binding occurred at pH 6.0. Based on antibody internalization studies described below, the results suggest that the vFcγR may internalize IgG and then dissociate within acidic intracellular compartments promoting degradation of antibodies. The crystal structure of the gE–gI/Fc interaction predicts that histidines at gE position 247 and Fc positions 310 and 435 are likely involved in Fc dissociation from gE at acidic pH (Sprague *et al.*, 2006).

Human CMV FcγR

Cells infected with human CMV (HCMV) express $\sim 10^6$IgG Fc receptors per cell that have an association constant of 2×10^8 M^{-1} (Antonsson and Johansson, 2001). Two HCMV vFcγRs have been reported (Atalay *et al.*, 2002; Lilley *et al.*, 2001). The first is a 234-amino acid type 1 transmembrane glycoprotein that migrates with an apparent molecular mass of 34 kDa (gp34) and has three potential N-linked glycosylation sites in the ectodomain (Lilley *et al.*, 2001). The glycoprotein is encoded by TRL11 and IRL11, which are identical copies of a gene found in the terminal and internal repeats of the HCMV DNA long fragment. The cytoplasmic tail of gp34 has 31 amino acids and contains a conserved dileucine motif that is postulated to participate in IgG endocytosis. Sequence similarities were detected between gp34 and domain 2 of cFcγRII and III (Atalay *et al.*, 2002). The other HCMV FcγR is encoded by the UL119–118 open reading frame that produces a 347 amino acid type 1 transmembrane glycoprotein with a molecular mass of 68 kDa (gp68) (Atalay *et al.*, 2002). The glycoprotein has 12 potential N-linked sites and an immunoglobulin supergene family-like variable domain that shares sequence homology with cFcγRI domain 3 (Atalay *et al.*, 2002). The cytoplasmic tail has a possible modified ITIM-like motif (WSYKRL) that may be involved in cell signaling events. The lack of laboratory animal models for HCMV has hampered attempts to define the role of the HCMV FcγRs in pathogenesis.

Varicella zoster FcγR

The VZV US8 gene encodes gE, which functions as an FcγR on infected human cells (Litwin *et al.*, 1992). Glycoprotein gE is a 623-amino acid type 1 transmembrane glycoprotein that has a signal sequence of 24 amino acids, a 544-amino acid extracellular domain with three predicted N-linked glycosylation sites, a 17-amino acid transmembrane domain and a 62 amino acid cytoplasmic tail. Binding of IgG Fc to gE initiates endocytosis, unloading the IgG cargo in lysosomal vesicles and subsequent recycling of gE to the cell surface (Olson and Grose, 1997). Endocytosis requires the gE cytoplasmic tail, and is mediated by tyrosine phosphorylation of a YAGL endocytosis motif (Olson and Grose, 1997). VZV gE shares sequence similarities with HSV gE, but not with cFcγRs (Litwin *et al.*, 1992). Similar to HCMV, the in vivo relevance of the VZV FcγR in immune evasion has not been determined because of the lack of animal models.

vFcγRs on non-human mammalian herpesviruses

Murine CMV

The m138 (fcr-1) gene of MCMV encodes a vFcγR that has a molecular mass of 88 kDa and is a 569 amino acid type 1 transmembrane glycoprotein. The protein has a predicted signal sequence of 17 amino acids, a transmembrane domain from amino acids 535–552, 10 potential N-linked glycosylation sites, and a 17 amino acid cytoplasmic tail (Thale *et al.*, 1994). Studies were performed to assess the function of the vFcγR in its natural host by preparing a mutant virus deficient in the fcr-1 gene and a revertant strain (Crnkovic-Mertens *et al.*, 1998). The fcr-1 deficient strain showed normal replication kinetics in vitro, but significantly reduced replication in vivo. To determine if the reduced replication in vivo was caused by increased susceptibility to antibody, mutant and revertant strains were injected into B cell deficient mice. The expectation was that the two strains would have similar replication patterns in antibody deficient mice; however, this did not occur, suggesting that the vFcR had little or no role in pathogenesis. While this conclusion is potentially correct, other explanations are also possible. For example, to demonstrate a

role for the HSV-1 FcγR in pathogenesis, small deletions were made in gE to abolish Fc binding without interfering with virus spread, another activity mediated by gE (Nagashunmugam *et al.*, 1998). A similar approach may be required to assess the potential role of the MCMV vFcγR in pathogenesis.

Pseudorabies virus

PRV gE and gI form a molecular complex that functions as a vFcγR (Favoreel *et al.*, 1997). PRV US8 encodes gE, a 62 kD type 1 transmembrane glycoprotein containing 577 amino acids, including an extracellular domain of 428 amino acids, a transmembrane domain of 26 amino acids, and a cytoplasmic tail of 123 amino acids (Klupp *et al.*, 2004). PRV US7 encodes gI, which is a type 1 transmembrane glycoprotein containing 366 amino acids, including an extracellular domain of 285 amino acids, a transmembrane domain from amino acid 286–308, and a cytoplasmic tail of 58 amino acids (Klupp *et al.*, 2004).

Studies performed in swine kidney cells demonstrate that PRV-specific antibodies induce capping of viral glycoproteins followed by their extrusion from the cell surface (Favoreel *et al.*, 1997). Phosphorylation of two tyrosine motifs in the gE cytoplasmic tail are required for glycoprotein capping (Favoreel *et al.*, 1999). Studies of PRV in swine monocytes, which are infected by PRV during natural infection, demonstrate that antibodies induce endocytosis of viral glycoproteins with co-internalization of MHC class I proteins (Favoreel *et al.*, 2003). Endocytosis removes viral glycoproteins from the cell surface and reduces the effectiveness of antibody dependent complement lysis of infected cells. Endocytosis is not uniquely mediated by gE-gI, but the vFcγR contributes to this activity (Van de Walle *et al.*, 2003).

Summary of vFcγR studies

Activities mediated by the vFcγRs of human and non-human herpesviruses can be summarized as follows. First, antibody bipolar bridging is an important mechanism used by vFcγRs to protect the virus and infected cell against activities mediated by the IgG Fc domain, including complement activation and ADCC. Second, some vFcγRs mediate antibody capping, while others promote antibody internalization. In acidic intracellular compartments, antibodies may dissociate from the vFcγR and degrade, while the vFcγR recycles to the cell surface. Third, potential ITIM motifs have been noted on some vFcγRs that may regulate responses to antibody. Fourth, the HSV-1 FcγR is a virulence factor, reducing the effectiveness of antibodies in vivo.

Role of the herpesvirus complement receptors in immune evasion

Introduction

The complement system plays an important role in both the innate and adaptive immune responses to viral infection. Activation of complement early following viral infection relies on the presence of highly specific recognition proteins, which have evolved to recognize and bind pathogen associated molecular patterns (PAMPs). These pattern recognition proteins include natural antibodies (IgM), C1q, C-reactive protein, mannan-binding lectin, and ficolins H and L. IgG and IgM antibodies are able to trigger the activation of complement following induction of specific humoral immune responses.

Complement is activated by one of three different pathways: classical, mannan-binding lectin (MBL), or alternative (Fig. 63.4). The classical complement pathway was the first pathway to be identified, and is normally considered to be antibody-dependent. Activation of the classical pathway occurs when the first component of the pathway, C1, binds the Fc region of either natural antibody or specific IgG antibody in complex with viral antigen. The classical pathway is also triggered in an antibody-independent manner when C1 binds directly to virions or infected cells.

Activation of the MBL pathway is antibody-independent and occurs when one of the C-type lectins, MBL, ficolin H, or ficolin L recognizes carbohydrate structures on the surface of pathogens. The alternative complement pathway was originally described as the antibody-independent pathway (the MBL pathway was identified much later). Activation of the alternative pathway is spontaneous as a continued low-level release of the internal thioester bond of C3 allows it to bind to a wide range of "foreign" sites. The diversity of serum recognition proteins able to recognize and activate complement allows the complement system to protect against a wide variety of microbial pathogens.

Recently a fourth pathway for complement activation was described that involves SIGN-R1, a C-type lectin detected on marginal-zone macrophages in the spleen. The unique feature of this pathway is that SIGN-R1 binds C1q and activates the classical complement pathway in the absence of immunoglobulins. SIGN-R1 also binds the capsular polysaccharide of *S. pneumoniae*, and perhaps carbohydrates on other microbial pathogens, leading to C3 deposition on the organism and enhanced innate resistance to infection (Kang *et al.*, 2006).

Activation of the complement cascade leads to numerous effector functions that result in neutralization and elimination of virus, thereby limiting spread, infection and disease. These include neturalization of viral particles, phagocytosis of complement-opsonized virus and virus-infected cells, direct lysis of virus and infected cells by the formation of pores known as the membrane attack complex, induction of inflammation, and enhancement of the adaptive immune response.

Regulation of complement

Given the complexity of the complement system, with over 30 complement proteins involved in activating the three divergent complement pathways, proper control is imperative. Regulation of the complement systems is necessary to prevent inappropriate activation and injury to bystander cells. Therefore, complement is tightly regulated by proteins present in serum and expressed on the surface of cells. These complement regulatory proteins include C1 inhibitor, CD59, and a class of proteins referred to as regulators of complement activation (RCA). RCA proteins include secreted plasma factor H, C4-binding protein and membrane bound complement regulatory proteins 1, 2, 3 (CR1, CR2, CR3), membrane cofactor protein (MCP) and decay accelerating factor (DAF) (Carroll, 2000; Da Costa *et al.*, 1999; Spear *et al.*, 1995; Spiller *et al.*, 1997). Both CR2 and DAF are GPI-linked.

RCA proteins are homologous in structure, characterized by the presence of motifs known as short consensus repeats (SCRs). SCR motifs contain approximately 58 to 66 amino acids, with four conserved cysteine residues disulfide linked (cys 1 to 3, and cys 2 to 4) and several hydrophobic residues. SCR motifs are highly conserved, sharing 30%–40% amino acid identity. However, the number of SCRs contained within RCA proteins is highly variable, for example, both MCP and DAF contain four SCRs, while CR1 contains 30.

As the complement system plays an important role in host defense against viral infection, not surprisingly, viruses have evolved numerous mechanisms to control complement. Strategies employed by viruses fall into three categories: (1) viral proteins which are homologous to mammalian complement regulatory proteins; (2) viral proteins which have no sequence homology, but which share functional characteristics with complement regulatory proteins; and (3) viruses that incorporate host complement regulatory proteins into their envelope during viral maturation and egress.

Strategies employed by human herpesviruses to evade complement immunity

Viral proteins homologous to human complement regulatory proteins: Kaposi's sarcoma associated herpesvirus complement control protein

Sequencing of the Kaposi's sarcoma associated herpesvirus (KSHV) genome indicated that one gene, KSHV open reading frame 4 (ORF4), encoded a protein displaying a high degree of homology to many complement regulatory proteins, including RCA proteins DAF and MCP (Neipel *et al.*, 1997; Russo *et al.*, 1996). The KSHV ORF4 was predicted to encode a protein of 550 amino acids residues, with the first 270 amino acids forming four SCRs sharing 24.7% identity with DAF (Spiller *et al.*, 2003b).

Characterization of transcripts produced by KSHV ORF4 indicated that three transcripts were produced, one full length, and two smaller, alternatively spliced forms (Spiller *et al.*, 2003b). All three protein isoforms contained the four amino-terminal SCRs and transmembrane regions, not a GPI anchor present in DAF, and collectively, are referred to as KSHV complement control protein (KCP) or kaposica (Mullick *et al.*, 2003; Spiller *et al.*, 2003b).

Functional studies indicated that all three forms prevented C3 deposition on cell surfaces (Spiller *et al.*, 2003b). Addition of a soluble form of each KCP isoform accelerated the decay of the classical pathway C3-convertase (Spiller *et al.*, 2003a). All three forms of soluble KCP also accelerated the decay of the alternative pathway C3-convertase; however, they were 1000-fold less efficient than DAF, indicating that KCP mainly affects the classical pathway C3-convertase.

KCP acts as a cofactor for factor I (fI) mediated cleavage and inactivation of C3b and C4b (Mullick *et al.*, 2003; Spiller *et al.*, 2003a). KCP results in fI mediated cleavage of C4b to C4d, when both soluble and cell bound. KCP also acts as a cofactor for fI mediated cleavage of C3b to iC3b, and induces cleavage of iC3b to C3d, the only viral protein shown to date to do so. Binding affinity of KCP is higher for C4b than C3b, which may explain differences in the ability of KCP to degrade the classical and alternative pathway C3-convertases.

Viral proteins with no sequence homology, yet functional similarities with human complement regulatory proteins

HSV-1 and HSV-2 glycoprotein gC

HSV-1 and HSV-2 encode gC, a viral complement control protein that inhibits complement activation by

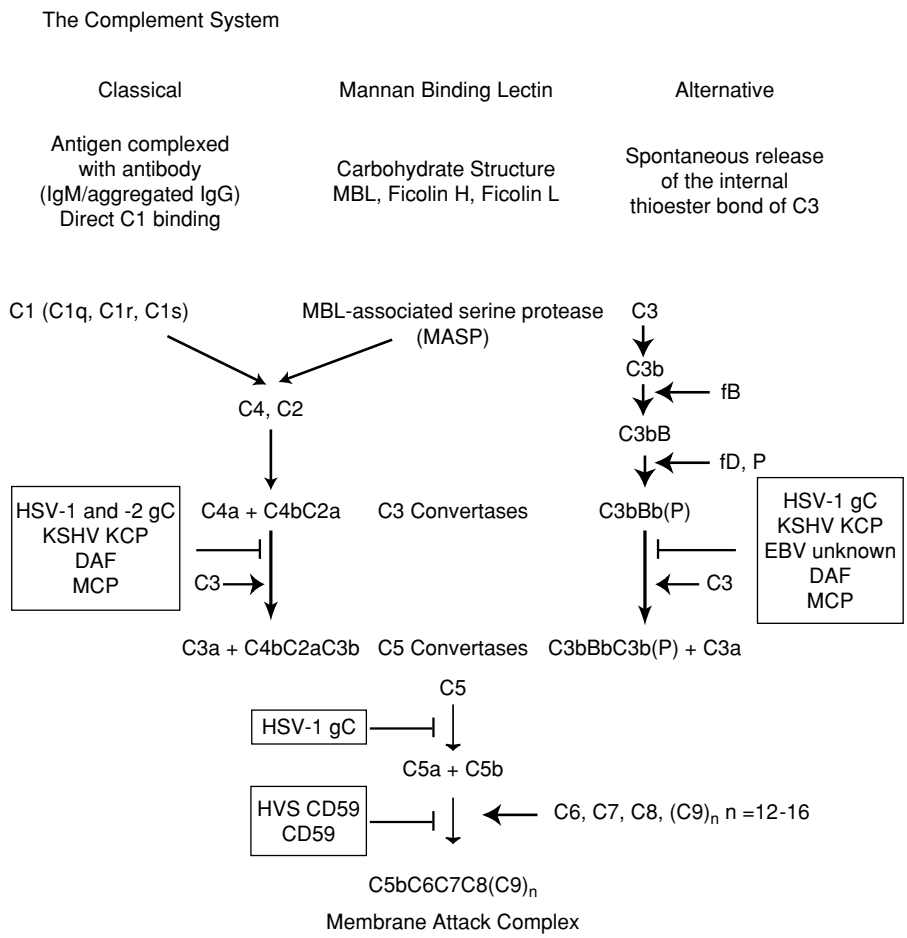

Fig. 63.4. Sites of interaction between herpesviruses and the complement cascade. The boxed type identifies the sites in the complement cascade inhibited by viral proteins or by host-derived cellular proteins captured by viruses.

binding C3b (Friedman *et al.*, 1984; Kostavasili *et al.*, 1997). gC of HSV-1 (gC-1) was the first complement control protein identified, and has been extensively characterized. Both gC-1 and gC-2 are rarely absent from clinical isolates, underscoring their importance *in vivo*. Moreover, gC is well conserved among members of the alpha-herpesvirus family, with homologues present in VZV, PRV, bovine herpesvirus 1 (BHV-1), and equine herpesviruses 1 and 4 (EHV-1, EHV-4). Despite this high degree of sequence conservation among alphaherpesviruses, gC displays little sequence homology with known complement regulatory proteins.

gC-1 and gC-2 are encoded by the UL44 gene and are type I membrane glycoproteins of 511 and 480 amino acids respectively, which are expressed on virions and infected cells. Both are highly glycosylated with 9 and 7 N-linked glycosylation sites respectively (Rux *et al.*, 1996). gC-1 also contains several O-linked glycosylation sites, localized to the amino terminus of the protein; gC-2, however, is not O-linked glycosylated. gC-1 and gC-2 share eight highly conserved cysteines, the disulfide bonding pattern of which has been determined for gC-1, and is likely similar for gC-2 and the gC homologues from other herpesviruses (Rux *et al.*, 1996).

gC of both HSV-1 and HSV-2 binds C3b in a purified form and when expressed on the surface of transfected cells (Eisenberg *et al.*, 1987; Tal-Singer *et al.*, 1991). However, only HSV-1 infected cells express gC that is able to bind C3b (Friedman *et al.*, 1984). Cells infected with HSV-2 display no C3b receptor activity (Friedman, 1986; Friedman *et al.*, 1984). Lack of binding to C3b appears unrelated to affinity of gC-2 for C3b, as optical biosensor technology indicates that gC-2 has a tenfold higher affinity for C3b compared with gC-1 (Rux *et al.*, 2002). One possible explanation may be that other host cell membrane components or viral glycoproteins expressed on the HSV-2 infected cell surface may interfere with the ability of gC-2 to bind C3b.

Both gC-1 and gC-2 bind C3 and its activation products C3b, iC3b and C3c (Kostavasili *et al.*, 1997; Tal-Singer *et al.*, 1991). This binding is mediated by C3b regions, which are well conserved in both glycoproteins. Four regions in gC-1 and three in gC-2 were identified by site-directed and linker insertion mutagenesis, with binding phenotypes confirmed in rosetting assays using C3b-coated sheep erythrocytes (Hung *et al.*, 1992; Seidel-Dugan *et al.*, 1990).

Functional studies indicate that gC-1 prevents complement-mediated neutralization of HSV-1 by binding C3b, thereby inhibiting activation of the classical complement pathway (Friedman *et al.*, 1996; Harris *et al.*, 1990). Evidence suggests that gC-2 may function in a similar manner (Gerber *et al.*, 1995). Neutralization of HSV-1 in the absence of gC-1 is mediated by a C5 dependent mechanism that does not require viral lysis, aggregation, or prevention of viral attachment (Friedman *et al.*, 2000). Complement likely interferes with HSV infection at a stage following viral attachment, for example, during virus entry or uncoating (Friedman *et al.*, 2000).

gC-1 also prevents complement-mediated cell lysis of HSV-1 infected cells by accelerating the decay of the alternative pathway C3 convertase, C3bBb (Fries *et al.*, 1986; Harris *et al.*, 1990). The half-life of the C3bBb complex is extended three- to four-fold by the binding of properdin to C3b in the convertase. gC-1 contains a properdin interacting domain, localized to the amino-terminus, which interferes with the binding of properdin to C3b, destabilizing the C3 convertase (Hung *et al.*, 1994; Kostavasili *et al.*, 1997). By interfering with properdin's ability to bind C3b, gC-1 prevents activation of the alternative complement pathway. This prevents lysis of HSV-1 infected cells.

gC-1 also contains a C5 interacting domain which prevents C5 from binding C3b (Fries *et al.*, 1986). gC-1 thus interferes with activation of both the classical and alternative complement pathways, limiting neutralization of both virus and lysis of virus-infected cells. While both gC of HSV-1 and HSV-2 prevent complement-mediated neutralization of HSV virions, differences do exist. Only gC-1 is able to disrupt the activation of alternative pathway C3 convertase (Fries *et al.*, 1986; Kostavasili *et al.*, 1997). Moreover, the region of gC-1 important in blocking the binding of C5 and properdin to C3b is absent in gC-2.

Studies comparing the importance of both complement interacting domains of gC-1 were evaluated both in vitro and in an in vivo model of HSV pathogenesis (Lubinski *et al.*, 1999). Complement neutralization experiments performed with a low passage clinical isolate that had been mutated within the C3 binding domain, the C5 and properdin blocking domain, or both, indicated that while both domains were important, elimination of the C3 binding domains significantly diminished the ability of gC to modulate complement (Lubinski *et al.*, 1999). Similar results were seen in vivo in a murine model of HSV pathogenesis. HSV-1 was mutated in the C5 and properdin blocking, the C3 binding, or both domains (double mutant). Each mutant virus was significantly more attenuated than the wild type HSV-1 virus (Lubinski *et al.*, 1999). That the C3 binding domain mutant was as attenuated as the gC double mutant indicated that the C3 domain is more important than the C5 and properdin in modulating complement activity.

EBV complement regulatory activity: unidentified protein

In addition to gC of HSV-1 and HSV-2, evidence suggests that Epstein–Barr virus (EBV) encodes a complement regulatory protein displaying no sequence homology with known human complement regulatory proteins. EBV virions derived from either marmoset or human B lymphoblastoid cells maintains complement regulatory activities (Mold *et al.*, 1988). Incubation of purified EBV with immune human serum resulted in the cleavage of C3 into the inactive C3c. In addition, EBV functions as a cofactor for the Factor I mediated cleavage of C3b and iC3b and C4b and iC4b. No degradation occurred in the absence of Factor I. EBV accelerates the decay of the alternative, but not the classical C3 convertase. The EBV envelope protein responsible for this complement regulatory activity remains unknown. No virally encoded proteins with homology to known complement regulatory proteins have been identified; therefore, cellular proteins incorporated into the virion are possibly mediating this effect.

Viruses that incorporate human complement regulatory proteins into their envelope during viral maturation and egress: human CMV

HCMV-infected cells remain susceptible to antibody-mediated complement cytolysis for only a brief time following acute infection, suggesting that the cells are protected from complement lysis. Analyses of the complete genomic sequence of HCMV revealed no homologues of known complement regulatory proteins, and HCMV does not appear to encode a C3 binding protein (Smiley and Friedman, 1985). It was hypothesized that HCMV may alter the expression of host-encoded complement regulatory proteins in order to interfere with complement (Spiller *et al.*, 1996). Candidates included DAF, MCP, and CD59, since each are expressed on uninfected cells that are permissive to infection by HCMV.

Studies examining the cell surface expression of both DAF and MCP by HCMV infected human foreskin fibroblasts indicated that levels were enhanced at 24, 48,

and 72 hours post infection compared with mock-infected controls. Maximal expression was seen 72 hours post infection with a 3.4-fold and 8-fold increase in MCP and DAF respectfully. Expression of CD59, however, remained relatively stable (Spiller *et al.*, 1996).

Incubation of HCMV virions with complement alone consumed complement activity and resulted in C3 deposition on the surface of the virion, yet resulted in negligible amounts of C9 deposition and no loss of viral infectivity (Spiller *et al.*, 1997). These data suggest that HCMV is able to regulate complement and accomplishes this by interfering with the complement system upstream of C9 activation. Studies examining the expression of MCP, DAF, and CD59 on HCMV virions produced in human foreskin fibroblasts indicated that the three complement regulators were captured by the virion during egress and maturation (Spear *et al.*, 1995; Spiller *et al.*, 1997).

The mechanism by which MCP, DAF, and CD59 become incorporated within the HCMV virion remains unknown. Incorporation could represent a passive capture of upregulated plasma membrane proteins, as levels of both DAF and CD59 are increased during HCMV infection and are readily incorporated into foreign membranes (Spiller *et al.*, 1996). Moreover, the distribution of both DAF and CD59 expressed on the surface of the virion correlates roughly with levels of each detected on the surface of the host derived cells, indicating that virions may obtain the host cell derived complement regulatory proteins in a passive manner (Spear *et al.*, 1995). Incorporation, however, could be an immune evasion strategy adopted by HCMV, in order to protect virions and virus infected cells from complement-mediated neutralization. Treatment of HCMV virus with an anti-DAF antibody, not anti-CD59, reduced HCMV infectious titer in the presence of complement, indicating that DAF interferes with complement-mediated neutralization of HCMV virus (Spear *et al.*, 1995).

Strategies employed by non-human mammalian herpesviruses to evade complement immunity

Viral proteins homologous to mammalian complement regulatory proteins

Murine Gammaherpesvirus 68: MHV-68 RCA

Murine Gammaherpesvirus 68 (γHV68) gene 4 product is a complement regulatory protein, with significant homology to both virally encoded and cellular proteins, including the herpesvirus saimiri complement control protein homologue (CCPH), DAF, and MCP (Virgin *et al.*, 1997). γHV68 ORF 4 includes four regions with homology to SCRs of RCA complement regulatory proteins. γHV68 gene 4, named γHV68 RCA, produces a 5.2 kb bicistronic mRNA of the late kinetic class, encoding multiple γHV68 RCA proteins, including both plasma membrane bound and soluble forms (Kapadia *et al.*, 1999).

Functional studies indicate that γHV68 RCA interferes with both murine and human complement activation, resulting in a decrease in C3b deposition (Kapadia *et al.*, 1999). γHV68 RCA was found to prevent activation of both the classical and alternative complement pathways (Kapadia *et al.*, 1999).

The γHV68 RCA contributes to virulence in mice, as γHV68 virus mutated within the RCA protein was more attenuated during both acute and persistent γHV68 infection when compared with wild type or marker rescued virus (Kapadia *et al.*, 2002). γHV68 RCA accomplishes this by interfering with the complement system, as the virulent phenotype of the γHV68 RCA protein mutant virus was restored in mice lacking C3. Interestingly, γHV68 RCA was not involved in evading C3 mediated innate immunity during latent infection.

Herpesvirus saimiri (HVS): complement control protein homologue (CCPH)

While determining the nucleotide sequence of genes within the vicinity of STP-A and STP-C (saimiri transformation associated protein of subgroup A and C), a gene was detected that encodes a protein displaying a significant degree of homology to the RCA protein family (Albrecht and Fleckenstein, 1992; Albrecht *et al.*, 1992a). This protein, named complement control protein homologue (CCPH), is encoded by HVS 04, and contains four SCRs within its N-terminal domain (amino acids 21–265), seven potential amino-linked glycosylation sites, and a transmembrane domain.

HVS 04 was found to encode two transcripts, one full length, and one smaller, alternatively spliced form. The unspliced transcript encodes a membrane-bound glycoprotein (mCCPH) of 65–75 kD, similar to the membrane-bound RCAs MCP, DAF, CR1, and CR2. Splicing produced a secreted glycoprotein (sCCPH) of 47–53 kD, like the soluble complement inhibitors C4-binding protein and Factor H. Functional studies indicated a role for CCPH in complement regulation. Cells stably transfected with mCCPH were approximately two times more resistant to complement mediated cell lysis, with levels similar when compared with DAF as a control (Fodor *et al.*, 1995).

HVS: CD59

In addition to HVS CCPH, sequence analyses of the HVS genome indicated the presence of a second gene, HVS 15

that encodes a protein sharing significant homology with the complement regulatory protein CD59 (Albrecht *et al.*, 1992b). The HVS 15 ORF consists of 363 nucleotides, sharing 64% sequence identity with human CD59 cDNA and was predicted to encode a protein of 121 amino acids with 48% identity to human CD59. Both HVSCD59 and CD59 have hydrophobic carboxyl-terminal sequences, which for CD59, is replaced by a GPI anchor. Additional studies confirmed that HVS 15 protein product was also a GPI linked membrane glycoprotein (Rother *et al.*, 1994). The overall structure of both HVS 15 and CD59 were expected to be very similar as the proteins shared amino acid identities and a single N-linked glycosylation site, and all cysteines were highly conserved.

Expression of either HVSCD59 or squirrel monkey CD59 (SMCD59), the natural host of HVS, on the surface of Balb/3T3 cells rendered the cells resistant to complement-mediated cell lysis by human serum (Rother *et al.*, 1994). However, only HVSCD59 expressing cells were protected from challenge with rat serum, indicating that HVSCD59 is less species specific than either human or SMCD59. Protection occurred following C3b deposition, suggesting that HVSCD59 prevents complete formation and function of the membrane attack complex (Rother *et al.*, 1994). It was hypothesized that the location of the N-linked glycosylation site was responsible for the less species restrictive phenotype of HVSCD59, as the N-linked glycosylation of human CD59 appears necessary for its function.

Viral proteins with no sequence homology, yet functional similarities with mammalian complement regulatory proteins, and that incorporate host complement regulatory proteins: PRV gC and unknown host cell derived complement regulatory protein(s)

Pseudorabies virus (PRV) is protected from complement-mediated innate immunity by the presence of at least two proteins able to interfere with complement, gC and one or more host cell derived complement regulatory proteins. PRV gC shares homology with gC from other members of the alpha-herpesvirus family, and like HSV-1 gC, mediates viral attachment and facilitates immune evasion by binding C3. Neutralization experiments comparing PRV-CPK, a virus containing both gC and host cell derived complement regulatory proteins, and PRV-ΔgC-CPK which expresses the host cell derived complement regulatory proteins, yet lacks gC were performed (Maeda *et al.*, 2002). The PRV virus lacking gC was more readily neutralized by swine serum than the wild type virus, suggesting that gC protects PRV from complement-mediated neutralization.

Pseudorabies virus (PRV) in which gC was deleted was propagated on either swine kidney derived CPK or rabbit kidney derived RK13 cells and then tested for susceptibility to complement-mediated virus neutralization using either swine or rabbit serum as the source of complement (Maeda *et al.*, 2002). Results indicated that the gC deletion mutant grown in the CPK porcine cells was protected from neutralization mediated by swine serum. However, PRV derived from the RK13 rabbit cells was susceptible, suggesting that in the absence of gC, PRV was protected by at least one additional complement regulatory protein. No known homologues of complement regulatory proteins exist within the PRV genome; therefore, a host cell derived complement regulatory protein likely confers protection. Additional studies indicated that while the greatest level of protection was obtained when both gC and the cell derived factor(s) were coexpressed, the cell derived factor(s) afforded the most protection.

Summary of viral complement regulatory proteins

The complement system is an early innate defense able to thwart viral infection. Viruses have evolved numerous mechanisms to interfere with complement that are summarized in Fig. 63.4. Strategies reflect those used by the host to regulate and control complement activation and include encoding complement regulatory proteins that can be secreted or expressed on the surface of virions and infected cells or up-regulating and incorporating the host's own complement regulatory proteins on infected cells and within virions. Expression of complement control proteins by viruses can impart the capacity for increased infection and spread, resulting in greater virulence.

Part VI

Antiviral therapy

Edited by Ann Arvin and Richard Whitley

64

Antiviral therapy of HSV-1 and -2

David W. Kimberlin and Richard J. Whitley

Department of Pediatrics, University of Alabama at Birmingham, AL, USA

Introduction

The discovery of effective antiviral agents has been facilitated by advances in the fields of molecular biology and virology. In the pre-antiviral era, the widely held belief was that any therapeutically meaningful interference with viral replication would destroy the host cell upon which viral replication was dependent. A growing understanding of host cell–virus interactions and viral replication, however, has led to the development of safe and effective antivirals. These agents act by impeding entry of viruses into host cells; interfering with viral assembly, release, or deaggregation; inhibiting transcription or replication of the viral genome; or interrupting viral protein synthesis.

Antiviral agents can be used to treat disease (a therapeutic strategy), to prevent infection (a prophylactic strategy), or to prevent disease (a preemptive strategy). Prophylaxis refers to the administration of an agent to patients at risk of contracting infection (e.g., acyclovir given to HSV-seropositive renal transplant recipients). Pre-emptive treatment refers to the administration of a drug after there is evidence of infection, but before there is evidence of disease (e.g., ganciclovir given to bone marrow transplant recipients with positive CMV culture, but no symptoms of infection).

The effectiveness of antiviral therapy sometimes is limited by the development of antiviral resistance. Antiviral drug resistance has increased in parallel with the expanded use of, and indications for, antiviral therapy. Resistance most commonly occurs in patients with chronic and/or progressive infections who have been exposed to prolonged or repeated courses of therapy. An impaired host immune system which cannot fully contribute to suppressing viral replication, thus leaving to antiviral agent(s) as the sole defense against ongoing viral disease, also predisposes to the development of antiviral resistance, as does administration of the antiviral agent at doses which produce subtherapeutic drug concentrations relative to that needed for virocidal or virostatic activity. In general, antiviral resistance should be suspected if the clinical response to therapy is less than that anticipated on the basis of prior experience (Kimberlin *et al.*, 1995b).

There are a number of antiviral medications with activity against HSV-1 and HSV-2. With the exception of foscarnet and cidofovir, all are nucleoside analogues. While three of these medications (acyclovir, famciclovir, and valaciclovir) are used to treat the overwhelming majority of cases of HSV-1 and HSV-2, the other medications reviewed in this chapter (cidofovir, foscarnet, ganciclovir, and valganciclovir) also have activity against the alpha herpesviruses and are indicated in certain circumstances, such as the treatment of some acyclovir-resistant HSV isolates. Discussion in this chapter of the efficacies of these first-line and second-line drugs will be limited to their use as second-line agents for HSV-1 and HSV-2 infections. Antiviral treatment of VZV and CMV can be found in Chapters 70 and 71, respectively.

First-line antiviral agents for HSV-1 and HSV-2 infections

Acyclovir

Acyclovir is in many regards the prototypic antiviral agent. The notable safety profile of acyclovir relates to its initial activation by the viral-induced enzyme thymidine kinase. Acyclovir is most active against HSV; activity against VZV also is substantial but approximately ten-fold less. Epstein Barr virus (EBV) is only moderately susceptible to acyclovir

because EBV has minimal thymidine kinase activity. Activity against CMV is poor because CMV does not have a unique thymidine kinase, and CMV DNA polymerase is poorly inhibited by acyclovir triphosphate. Acyclovir is the most frequently prescribed antiviral agent. It has been available for clinical use for over two decades and has demonstrated remarkable safety and efficacy against mild to severe infections caused by HSV and VZV in both normal and immunocompromised patients.

Mechanism of action and pharmacokinetics

Acyclovir is a deoxyguanosine analogue with an acyclic side chain that lacks the 3′-hydoxyl group of natural nucleosides (Wagstaff *et al.*, 1994). Following preferential uptake by infected cells, acyclovir is monophosphorylated by virus-encoded thymidine kinase; host cell thymidine kinase is approximately 1 millionfold less capable of converting acyclovir to its monophosphate derivative. Subsequent diphosphorylation and triphosphorylation are catalyzed by host cell enzymes, resulting in acyclovir triphosphate concentrations that are 40 to 100 times higher in HSV-infected cells than in uninfected cells (Elion, 1982). Acyclovir triphosphate prevents viral DNA synthesis by inhibiting the viral DNA polymerase. In vitro, acyclovir triphosphate competes with deoxyguanosine triphosphate as a substrate for viral DNA polymerase. Because acyclovir triphosphate lacks the 3'-hydroxyl group required to elongate the DNA chain, the growing chain of DNA is terminated. In the presence of the deoxynucleoside triphosphate complementary to the next template position, the viral DNA polymerase is functionally inactivated (Reardon and Spector, 1989). In addition, acyclovir triphosphate is a much better substrate for the viral polymerase than for cellular DNA polymerase α, resulting in little incorporation of acyclovir into cellular DNA.

The oral bioavailability of acyclovir is poor, with only 15%–30% of the oral formulations being absorbed. Following a 200 mg dose, a peak concentration of about 0.5 μg/ml is attained at approximately 1.5 to 2.5 hours (Wagstaff *et al.*, 1994). Higher doses of acyclovir result in higher serum concentrations. Food does not substantially alter extent of absorption. After intravenous doses of 2.5 to 15 mg/kg, steady-state concentrations of acyclovir range from 6.7 to 20.6 μg/ml. Acyclovir is widely distributed; high concentrations are attained in kidneys, lung, liver, heart, and skin vesicles; concentrations in the cerebrospinal fluid (CSF) are about 50% of those in the plasma (Wagstaff *et al.*, 1994). Acyclovir crosses the placenta and accumulates in breast milk. Protein binding ranges from 9% to 33% and less than 20% of drug is metabolized to biologically inactive metabolites.

In the absence of compromised renal function, the half-life of acyclovir is 2 to 3 hours in older children and adults and 2.5 to 5 hours in neonates with normal creatinine clearance. More than 60% of administered drug is excreted in the urine (Wagstaff *et al.*, 1994). Elimination is prolonged in patients with renal dysfunction; the half-life is approximately 20 hours in persons with end-stage renal disease, necessitating dose modifications for those with creatinine clearance less than 50 ml/min per 1.73 m^2 (Laskin *et al.*, 1982). Acyclovir is effectively removed by hemodialysis but not by continuous ambulatory peritoneal dialysis (Krasny *et al.*, 1982).

Antiviral therapy

Clinical efficacy in HSV-1 and HSV-2 infections

Genital herpes

For the treatment of first episode genital herpes, the dose of oral acyclovir is 200 mg orally five times per day, or 400 mg orally three times per day (Table 64.1). Neither higher doses of oral acyclovir nor the addition of topical acyclovir provide added benefit (Wald *et al.*, 1994). Duration of therapy in first episode disease is 7–10 days (Anonymous, 2002). Acyclovir therapy for the treatment of first episode genital herpes reduces the duration of viral shedding by about a week, time to healing of lesions by approximately four days, and time to complete resolution of signs and symptoms by approximately two days (Bryson *et al.*, 1983; Mertz *et al.*, 1984) (Table 64.2).

For the episodic treatment of recurrent genital herpes, dosing options for acyclovir include 200 mg orally five times per day, or 800 mg orally two times per day, administered for 5 days (Anonymous, 2002) (Table 64.1). Topical acyclovir provides no clinical benefit in the episodic management of recurrences and is not recommended (Corey *et al.*, 1982; Luby *et al.*, 1984). A recent study indicates that 2 days of oral acyclovir therapy (800 mg three times per day) is also efficacious in the episodic treatment of genital HSV recurrences (Wald *et al.*, 2002). When started within 24 hours of the onset of a genital herpes recurrence, oral acyclovir reduces the duration of viral shedding by approximately two days, time to healing by just over a day, and time to complete resolution of signs and symptoms by approximately a day (Tyring *et al.*, 1998) (Table 64.2). Episodic treatment does not reduce the length of time to subsequent recurrence (Nilsen *et al.*, 1982; Reichman *et al.*, 1984; Ruhnek-Forsbeck *et al.*, 1985).

In addition to the treatment of an active genital herpes infection, acyclovir has been effectively used to prevent recurrences of genital herpes. The most frequent indication for suppressive acyclovir therapy is in patients with frequently recurrent genital infections, in whom chronic

Table 64.1. Therapeutic management of genital herpes[a]

	First clinical episode (treat orally for 7–10 days 6[b])	Episodic recurrent infection[e] (treat orally for 5 days)	Oral suppressive therapy	Episodic recurrent infection in HIV-infected persons (treat orally for 5–10 days)	Oral suppressive therapy in HIV-infected persons	Advantages	Disadvantages[f]
Acyclovir	200 mg 5×/day *or* 400 mg 3×/day	200 mg 5×/day *or* 800 mg 2×/day	400 mg 2×/day	200 mg 5×/day *or* 400 mg 3×/day	400–800 mg 2×/day *or* 3×/day	Less expensive Smaller tablets Liquid formulation available	Less convenient dosing regimens

[a] Modified from Reference (Anonymous, 2002).

[b] The range of duration of therapy relates to differences in treatment durations in the original clinical studies. If the shorter course of therapy is initially prescribed, the patient should be reevaluated toward the end of treatment and therapy should be continued if new lesions continue to form, if complications develop, or if systemic signs and symptoms have not abated.

[c] Three-day course of therapy also acceptable

[d] For patients with ≤9 recurrences/year

[e] When started within 24 hours of the recurrence

[f] Allergic and other adverse reactions to acyclovir, valaciclovir, and famciclovir are rare.

Table 64.2. Efficacies of acyclovir, valaciclovir, and famciclovir in the treatment of genital HSV disease

	First episode genital herpes	Episodic treatment of genital herpes recurrences	Suppressive therapy for genital herpes
Acyclovir	2-day decrease in time to complete resolution of signs and symptoms (vs. placebo) (Mertz *et al.*, 1984)	1.1-day decrease in time to complete resolution of signs and symptoms (vs. placebo) (Tyring *et al.*, 1998)	After 1 year of therapy, 44% of acyclovir recipients were recurrence-free, vs. 2% of placebo recipients (Mertz *et al.*, 1988b)
	4-day decrease in time to healing of lesions (vs. placebo) (Mertz *et al.*, 1984)	1.2-day decrease in time to healing of lesions (vs. placebo) (Tyring *et al.*, 1998)	After 4 months (120 days) of therapy, 71% of acyclovir recipients were recurrence-free, vs. 6% of placebo recipients (Douglas *et al.*, 1984)
	7-day decrease in duration of viral shedding (vs. placebo) (Mertz *et al.*, 1984)	2.0-day decrease in duration of viral shedding (vs. placebo) (Tyring *et al.*, 1998)	80–94% reduction in days with subclinical shedding (vs. placebo) (Wald *et al.*, 1997; Wald *et al.*, 1996)
Valaciclovir	Compared with acyclovir, no difference in time to healing of lesions, duration of symptoms, and duration of viral shedding (Fife *et al.*, 1997)	1.9-day decrease in time to complete resolution of signs and symptoms (vs. placebo) (Spruance *et al.*, 1996) 1.9-day decrease in time to healing of lesions (vs. placebo) (Spruance *et al.*, 1996) 2.0-day decrease in duration of viral shedding (vs. placebo) (Spruance *et al.*, 1996) Compared with acyclovir, no difference in time to healing of lesions, duration of symptoms, and duration of viral shedding (Bodsworth *et al.*, 1997; Tyring *et al.*, 1998)	After 16 weeks (112 days) of therapy, 69% of valaciclovir recipients were recurrence-free, vs. 9.5% of placebo recipients (Patel *et al.*, 1997) Compared with acyclovir, no difference in effectiveness (Reitano *et al.*, 1998) 81% reduction in days with subclinical shedding (vs. placebo) (Wald *et al.*, 1998) Compared with acyclovir, no difference in reduction of subclinical shedding (Wald *et al.*, 1998)
Famciclovir	Compared with acyclovir, no difference in time to healing of lesions, duration of symptoms, and duration of viral shedding (Loveless *et al.*, 1995)	0.5-day decrease in duration of signs and symptoms (vs. placebo) (Sacks *et al.*, 1996a) 1.0-day decrease in time to healing of lesions (vs. placebo) (Sacks *et al.*, 1996a) 1.6-day decrease in duration of viral shedding (vs. placebo) (Sacks *et al.*, 1996a) Compared with acyclovir, no difference in time to healing of lesions, duration of symptoms, and duration of viral shedding (Chosidow *et al.*, 2001)	After 4 months (120 days) of therapy, 78% of famciclovir recipients were recurrence-free, vs. 42% of placebo recipients (Mertz *et al.*, 1997b) 87% reduction in days with subclinical shedding (vs. placebo) (Sacks *et al.*, 1997)

suppressive acyclovir therapy reduces the frequency of recurrences by approximately 75% (Douglas *et al.*, 1984; Mertz *et al.*, 1988a; Mertz *et al.*, 1988b; Mindel *et al.*, 1988; Straus *et al.*, 1984) (Table 64.2). One quarter to one-third of patients on suppressive therapy experience no further recurrences while taking acyclovir. Daily administration of acyclovir maintains a high degree of efficacy and little toxicity, even after more than 5 years of continuous suppressive therapy (Goldberg *et al.*, 1993). Suppressive therapy reduces the frequency of asymptomatic shedding of HSV in the genital tract by more than 80% (Wald *et al.*, 1997; Wald *et al.*, 1996) (Table 64.2). The acyclovir dose when used as suppressive therapy is 400 mg administered twice daily (Table 64.1).

The historic rationale for episodic treatment of genital herpes was that, in many patients, the frequency and/or

severity of clinical recurrences made treatment of the recurrences desirable, but they were not sufficiently frequent or annoying to warrant daily suppressive therapy. Advances in recent years in our understanding of asymptomatic viral shedding have begun to shift our therapeutic management away from episodic treatment and toward suppressive therapy (Kimberlin and Rouse, 2004). The current rationale for suppressive treatment is as follows: (1) most persons with first episode genital herpes are at risk of frequent recurrences over the next few years (Benedetti *et al.*, 1994); (2) 70%–80% of patients receiving suppressive therapy remain recurrence-free at 4 months (Table 64.2), vs. 5%–10% of persons receiving placebo (Douglas *et al.*, 1984; Mertz *et al.*, 1988b; Mertz *et al.*, 1997b; Patel *et al.*, 1997; Reitano *et al.*, 1998); (3) days with subclinical (asymptomatic) shedding are reduced by 80%–95% compared with placebo (Table 64.2) (Sacks *et al.*, 1997; Wald *et al.*, 1997; Wald *et al.*, 1998; Wald *et al.*, 1996); (4) suppressive therapy reduces the risk of HSV transmission to uninfected partners (Corey *et al.*, 2004); (5) quality of life often is improved in patients with frequent recurrences who receive suppressive compared with episodic treatment (Alexander and Naisbett, 2002); and (6) suppressive therapy is safe (Douglas *et al.*, 1984; Mertz *et al.*, 1997b; Patel *et al.*, 1997; Reitano *et al.*, 1998).

HSV gingivostomatitis and recurrent herpes labialis

Treatment of primary gingivostomatitis in pediatric patients using oral acyclovir decreases time to cessation of symptoms by 30%–50%, and time to lesion healing by 20%–25% (Aoki *et al.*, 1993). Compared with patients receiving placebo, subjects treated with oral acyclovir at 600 mg/m^2 per dose administered four times per day for 10 days experienced cessation of drooling in 4 days (vs. 8 days in placebo recipients) and resolution of gum swelling in 5 days (vs. 7 days in placebo recipients). Intraoral lesions in acyclovir recipients healed at 6 days (vs. 8 days in placebo recipients), and extraoral lesions healed in 7 days (vs. 9 days in placebo recipients) (Aoki *et al.*, 1993).

Oral acyclovir has a more modest effect in the treatment of recurrent herpes labialis (Raborn *et al.*, 1988; Raborn *et al.*, 1987), and treatment of these patients should be individualized (Kimberlin and Prober, 2003). In general, therapeutic benefit is enhanced if treatment is initiated as soon as possible after onset of symptoms, preferably within 24 to 48 hours of onset of the recurrence. Among patients who start treatment in the prodrome or erythema lesion stage, acyclovir therapy (400 mg five times a day for 5 days) reduces the duration of pain by approximately one-third, and the healing time to loss of crust by approximately one-fourth (Spruance *et al.*, 1990). Topical acyclovir cream may also modestly decrease the duration of a clinical recurrence of herpes labialis by approximately half a day (approximately $4\frac{1}{2}$ days for topical acyclovir recipients, compared with approximately 5 days for placebo recipients) (Spruance *et al.*, 2002), although benefit of topical acyclovir is not conferred by acyclovir ointment, which has a polyethylene glycol base (Shaw *et al.*, 1985; Spruance *et al.*, 1984).

Prophylactic acyclovir also has been used to prevent reactivation of herpes labialis following exposure to ultraviolet radiation, facial surgery, or exposure to sun and wind while skiing (Gold and Corey, 1987; Spruance *et al.*, 1991; Spruance *et al.*, 1988). Topical acyclovir cream also is effective in preventing recurrent herpes labialis in skiers (Raborn *et al.*, 1997) and in persons with a history of frequent recurrences of herpes labialis (Gibson *et al.*, 1986). Long-term suppressive therapy reduces the number of recurrences of oral infection in those with histories of frequent recurrences (Rooney *et al.*, 1993). In one study of 400 mg of oral acyclovir administered twice daily for 4 months, clinical recurrences were reduced by more than half, and culture-confirmed recurrences were reduced by more than two-thirds (Rooney *et al.*, 1993).

Herpes simplex encephalitis (HSE)

For herpes simplex encephalitis, intravenous acyclovir should be administered at 30 mg/kg per day for 14–21 days for the treatment of HSE (Whitley *et al.*, 1986). Some experts recommend higher dosages of intravenous acyclovir be considered (45–60 mg/kg per day), although neurotoxicity can be a limiting factor in increasing the dose in larger children and adults. In untreated patients, mortality from HSE exceeds 70%, and only 2.5% of survivors return to normal neurologic function. Even with appropriate administration of antiviral therapy, substantial mortality and morbidity from HSE remain (Skoldenberg *et al.*, 1984), with 19% of patients dying and 62% of survivors having residual neurologic sequelae (Whitley *et al.*, 1986). Patients with a Glasgow coma score of less than 6, those older than 30 years, and those with encephalitis for longer than 4 days have a poorer outcome (Whitley *et al.*, 1986).

Neonatal HSV

For neonatal HSV disease, intravenous acyclovir at 60 mg/kg per day delivered in three divided daily doses is currently recommended (American Academy of Pediatrics, 2003; Kimberlin *et al.*, 2001a). The dosing interval of intravenous acyclovir may need to be increased in premature infants, based upon their creatinine clearance (Englund *et al.*, 1991). Duration of therapy is 21 days for patients with disseminated or CNS neonatal HSV disease, and 14 days for patients with HSV infection limited to the SEM (American Academy of Pediatrics, 2003). The primary apparent

Table 64.3. Mortality and morbidity outcomes among 295 infants with neonatal HSV infection, evaluated by the National Institutes of Allergy and Infectious Diseases' Collaborative Antiviral Study Group between 1974 and 1997[a]

	Treatment

[a] Adapted from Kimberlin (2001).

toxicity associated with the use of this dose of intravenous acyclovir is neutropenia, with approximately one-fifth of patients with localized HSV disease (CNS or SEM) developing an absolute neutrophil count (ANC) of $\leq$1000/μl (Kimberlin *et al.*, 2001a). Although the neutropenia resolves either during continuation of intravenous acyclovir or following its cessation, it is prudent to monitor neutrophil counts at least twice weekly throughout the course of intravenous acyclovir therapy, with consideration being given to decreasing the dose of acyclovir or administering granulocyte colony stimulating factor (GCSF) if the ANC remains below 500/μL for a prolonged period of time (Kimberlin *et al.*, 2001a). All patients with CNS HSV involvement should have a repeat lumbar puncture at the end of intravenous acyclovir therapy to determine that the specimen is PCR-negative in a reliable laboratory, and to document the end-of-therapy CSF indices (Kimberlin *et al.*, 2001b). Those persons who remain PCR-positive should continue to receive intravenous antiviral therapy until PCR-negativity is achieved (Kimberlin *et al.*, 1996b; Kimberlin *et al.*, 2001b).

In the pre-antiviral era, 85% of patients with disseminated neonatal HSV disease died by one year of age, as did 50% of patients with CNS neonatal HSV disease (Whitley *et al.*, 1980a) (Table 64.3). Evaluations of two different doses of vidarabine and of a lower dose of acyclovir (30 mg/kg/day for 10 days) documented that both of these antiviral drugs reduce mortality to comparable degrees (Whitley *et al.*, 1991a; Whitley *et al.*, 1980a; Whitley *et al.*, 1983), with mortality rates at 1 year from disseminated disease decreasing to 54% and from CNS disease decreasing to 14% (Whitley *et al.*, 1991a) (Table 64.3). Despite its lack of therapeutic superiority, the lower dose of acyclovir quickly supplanted vidarabine as the treatment of choice for neonatal HSV disease due to its favorable safety profile and its ease of administration. Unlike acyclovir, vidarabine had to be administered over prolonged infusion times and in large volumes of fluid.

With utilization of a higher dose of acyclovir (60 mg/kg per day for 21 days), 12 month mortality is further reduced to 29% for disseminated neonatal HSV disease and to 4% for CNS HSV disease (Kimberlin *et al.*, 2001a) (Figs. 64.1 and

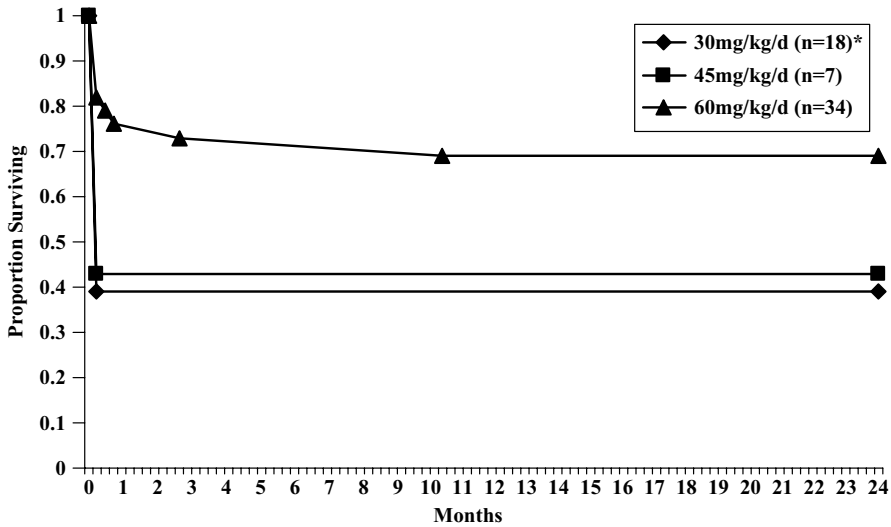

Fig. 64.1. Mortality in patients with disseminated neonatal HSV disease. (From Kimberlin *et al.*, 2001a.)

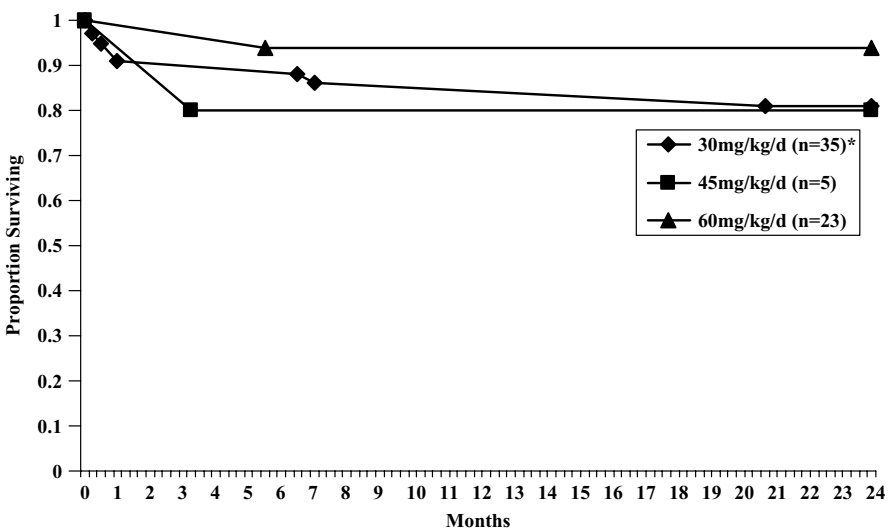

Fig. 64.2. Mortality in patients with CNS neonatal HSV disease. (From Kimberlin *et al.*, 2001a.)

64.2). Differences in mortality at 24 months among patients treated with the higher dose of acyclovir and the lower dose of acyclovir are statistically significant after stratification for disease category (CNS vs. disseminated) (Kimberlin *et al.*, 2001a). Lethargy and severe hepatitis are associated with mortality among patients with disseminated disease, as are prematurity and seizures in patients with CNS disease (Kimberlin *et al.*, 2001b).

Improvements in morbidity rates with antiviral therapies have not been as dramatic as with mortality. In the pre-antiviral era, 50% of survivors of disseminated neonatal HSV infections were developing normally at 12 months of age (Whitley *et al.*, 1980a) (Table 64.3). With utilization of the higher dose of acyclovir for 21 days, this percentage has increased to 83% (Kimberlin *et al.*, 2001a) (Fig. 64.3). In the case of CNS neonatal HSV disease, 33% of patients in the pre-antiviral era were developing normally at 12 months of age (Whitley *et al.*, 1980a) (Table 64.3), while 31% of higher dose acyclovir recipients develop normally at 12 months today (Kimberlin *et al.*, 2001a) (Fig. 64.3). While

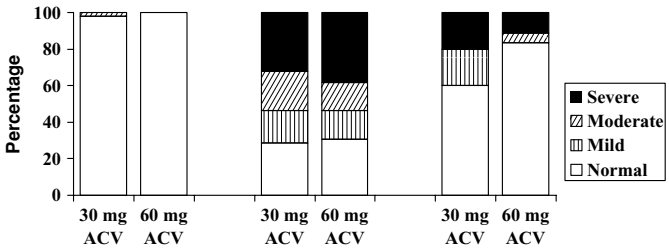

Fig. 64.3. Morbidity among patients with known outcomes after 12 months of life. (From Kimberlin *et al.*, 2001a.)

these differences are not dramatic, it is important to note that as more neonates survive neonatal HSV disease based upon the mortality data presented above, the total numbers of patients who subsequently develop normally is higher today even while the percentages of survivors with normal development are not dramatically different. Seizures at or before the time of initiation of antiviral therapy are associated with increased risk of morbidity both in patients with CNS disease and in patients with disseminated infection (Kimberlin *et al.*, 2001b).

Unlike disseminated or CNS neonatal HSV disease, morbidity following SEM disease has dramatically improved during the antiviral era. Prior to utilization of antiviral therapies, 38% of SEM patients experienced developmental difficulties at 12 months of age (Whitley *et al.*, 1980a) (Table 64.3). With vidarabine and lower dose acyclovir, these percentages were reduced to 12% and 2%, respectively (Whitley *et al.*, 1991a). In the high-dose acyclovir study, no SEM patients developed neurologic sequelae at 12 months of life (Kimberlin *et al.*, 2001a) (Fig. 64.3).

In the pre-antiviral era, 70% of neonates with disease initially limited to skin vesicles experienced progression of disease to involvement of the CNS or visceral organs (Whitley *et al.*, 1980b). It is likely that the initial reduction in morbidity among patients with SEM disease from 38% (Whitley *et al.*, 1980a) to 2–12% (Whitley *et al.*, 1991a) resulted from antiviral therapy impeding this progression to CNS or disseminated disease categories, each of which carries a higher risk of neurologic sequelae (Whitley *et al.*, 1988). The continued reduction in morbidity among patients with SEM disease seen in the recently completed high-dose acyclovir study might relate to a redefinition of what constitutes SEM vs. CNS involvement. Prior to the application of PCR technology to neonatal HSV disease, patients were classified as having SEM disease if they had no overt laboratory or clinical evidence of viral dissemination to the viscera and/or CNS. The lack of CNS involvement was manifest by no CNS symptomatology (seizures, abnormal neuroimaging studies, abnormal electroencephalograms, etc.) and normal CSF indices. As discussed above, however, PCR analysis of CSF specimens from neonates classified by these criteria as having SEM disease revealed that approximately one-quarter (7 of 29, or 24%) of these infants actually had HSV DNA present in their CSF during the acute disease course (Kimberlin *et al.*, 1996b). One of these seven patients subsequently developed significant neurologic impairment by age 12 months. Thus, it is possible that at least some of the SEM patients in the earlier studies who subsequently developed neurologic impairment actually had subclinical CNS disease, which could only be detected by means of the powerful investigative tool provided by PCR beginning in the 1990s. These data have resulted in a revised classification of CNS disease, such that a positive CSF PCR result is now sufficient to classify a patient as having CNS HSV infection.

Another possible explanation for the neurologic impairment previously experienced by some infants with SEM disease could be that, while low level viremia from the cutaneous lesions results in seeding of the CNS, initial damage to brain tissue during the acute illness does not occur either due to a host response to infection or due to antiviral therapy. Subclinical reactivation of virus within the CNS, with or without a clinical cutaneous recurrence, might then produce neurologic impairment, as has been suggested (Kimberlin, 2001; Whitley *et al.*, 1991b). Supporting this hypothesis, HSV DNA has been detected in the CSF of an SEM infant at the time of a cutaneous recurrence (Kimberlin *et al.*, 1996a). Randomized, controlled studies of long-term suppressive oral acyclovir therapy following the acute neonatal disease are currently being conducted by the NIAID Collaborative Antiviral Study Group to evaluate this hypothesis. At the current time, however, no evidence exists to suggest that suppressive oral acyclovir therapy is beneficial in preventing neurologic complications. Furthermore, almost half of infants receiving oral acyclovir in an open-label phase I/II investigation developed neutropenia while on therapy (Kimberlin *et al.*, 1996a), raising substantial questions about the safety of such a therapeutic approach outside of the strictly monitored confines of a clinical investigation.

HSV disease in the immunocompromised host

Acyclovir also is indicated for the treatment of disseminated HSV infections in otherwise normal hosts, including pregnant women, and mucocutaneous HSV infections in immunocompromised hosts (Kimberlin and Prober, 2003). Similarly, HSV infections of the lip, mouth, skin, perianal area, or genitals may be much more severe in immunocompromised patients than in normal hosts, with HSV lesions tending to be more invasive, slower to heal, and

associated with prolonged viral shedding. Intravenous acyclovir therapy is very beneficial in such patients (Wade *et al.*, 1982). Immunocompromised patients receiving acyclovir have a shorter duration of viral shedding and more rapid healing of lesions than patients receiving placebo (Meyers *et al.*, 1982). Oral acyclovir therapy is also very effective in immunocompromised patients (Shepp *et al.*, 1985).

Acyclovir prophylaxis of HSV infections is of clinical value in severely immunocompromised patients, especially those undergoing induction chemotherapy or transplantation. Intravenous or oral administration of acyclovir reduces the incidence of symptomatic HSV infection from about 70% to 5%–20% (Saral *et al.*, 1981). A sequential regimen of intravenous acyclovir followed by oral acyclovir for 3 to 6 months can virtually eliminate symptomatic HSV infections in organ transplant recipients. A variety of oral dosing regimens, ranging from 200 mg 3 times daily to 800 mg twice daily, have been used successfully. Among bone marrow transplant recipients and patients with AIDS, acyclovir-resistant HSV isolates have been identified more frequently after therapeutic acyclovir administration than during prophylaxis (Wade *et al.*, 1983).

HSV keratitis or keratoconjunctivitis

Topical therapy with acyclovir for HSV ocular infections is effective, but probably not superior to trifluridine (Hovding, 1989). Long-term suppressive therapy reduces the number of recurrences of ocular infection in those with histories of frequent recurrences (Herpetic Eye Disease Study Group, 1998, 2000).

Challenges for achieving clinical benefit, including adverse drug effects

Perhaps the most prominent challenge impacting clinical benefit of acyclovir therapy relates to the timing of drug initiation following onset of disease symptoms. In the case of life-threatening HSV disease, consideration of HSV as a possible cause of the illness is needed in order to then initiate acyclovir therapy. In the case of less severe but still consequential infections, such as primary genital herpes, the patient must present to medical attention, be correctly diagnosed, and then started on antiviral therapy as quickly as possible to achieve maximal benefit.

Acyclovir is a safe drug which is generally very well tolerated. Oral acyclovir sometimes causes mild gastrointestinal upset, rash, and headache. If it extravasates, intravenous acyclovir can cause severe inflammation, phlebitis, and sometimes a vesicular eruption leading to cutaneous necrosis at the injection site. If given by rapid intravenous infusion or to poorly hydrated patients or those with preexisting renal compromise, intravenous acyclovir can cause reversible nephrotoxicity due to the formation of acyclovir crystals precipitating in renal tubules and causing an obstructive nephropathy. Administration of acyclovir by the intravenous route occasionally is associated with rash, sweating, nausea, headache, hematuria, and hypotension. High doses of intravenous acyclovir (60 mg/kg per day) in neonates and prolonged use of oral acyclovir following neonatal disease have been associated with neutropenia (Kimberlin *et al.*, 1996a,2001b).

The most serious side effect of acyclovir is neurotoxicity, which usually occurs in subjects with compromised renal function who attain high serum concentrations of drug (Revankar *et al.*, 1995). Neurotoxicity is manifest as lethargy, confusion, hallucinations, tremors, myoclonus, seizures, extrapyramidal signs, and changes in state of consciousness, developing within the first few days of initiating therapy. These signs and symptoms usually resolve spontaneously within several days of discontinuing acyclovir.

Although acyclovir is mutagenic at high concentrations in some in vitro assays, it is not teratogenic in animals. Limited human data suggest that acyclovir use in pregnant women is not associated with congenital defects or other adverse pregnancy outcomes (Reiff-Eldridge *et al.*, 2000).

The likelihood of renal toxicity of acyclovir is increased when administered with nephrotoxic drugs such as cyclosporine or amphotericin B. Somnolence and lethargy may occur in subjects being treated with both zidovudine and acyclovir. Concomitant administration of probenicid prolongs acyclovir's half-life, whereas acyclovir can decrease the clearance and prolong the half-life of drugs such as methotrexate that are eliminated by active renal secretion.

Clinical indications

Acyclovir is licensed in the United States for the treatment of initial episodes and management of recurrent episodes of genital herpes, for the treatment of chickenpox, and for the treatment of acute herpes zoster infections. It is also indicated for the treatment of neonatal HSV disease, herpes simplex encephalitis, mucocutaneous and viscerally disseminated herpes infections in immunocompromised hosts, and the treatment of chickenpox in the normal host.

Antiviral resistance

Resistance of HSV to acyclovir has become an important clinical problem, especially among immunocompromised patients exposed to long-term therapy (Englund *et al.*, 1990). Viral resistance to acyclovir usually results from mutations in the viral TK gene although mutations in

the viral DNA polymerase gene also occur rarely. Resistant isolates can cause severe, progressive, debilitating mucosal disease and, rarely, visceral dissemination (Field and Biron, 1994; Lyall *et al.*, 1994). Isolates of HSV resistant to acyclovir also have been reported in normal hosts, most commonly in patients with frequently recurrent genital infection who have been treated with chronic acyclovir (Morfin and Thouvenot, 2003).

Famciclovir/penciclovir

Famciclovir is the inactive diacetyl ester prodrug of penciclovir, an acyclic nucleoside analogue. Following oral ingestion and systemic absorption, famciclovir is rapidly deacetylated and oxidized to form the active parent drug penciclovir.

Mechanism of action and pharmacokinetics

In cells which are infected with HSV, the viral thymidine kinase (TK) phosphorylates penciclovir to its monophosphate derivative, which in turn is converted to the active penciclovir triphosphate by cellular kinases. Penciclovir triphosphate inhibits viral DNA polymerase by competing with deoxyguanosine triphosphate for incorporation into the growing DNA strand. While penciclovir triphosphate is neither an obligate DNA chain terminator nor an inactivator of the DNA polymerase, once incorporated penciclovir triphosphate does retard the rate of subsequent nucleotide incorporation. Penciclovir is approximately 100-fold less potent than acyclovir in inhibiting herpesvirus DNA polymerase activity. By virtue of its high intracellular concentrations and long intracellular half-life (7 to 20 hours), though, it remains an effective antiviral agent.

The bioavailability of penciclovir following oral administration of famciclovir is about 70%. Peak concentrations of drug after intravenous administration of 10 mg/kg are approximately six-fold higher than those attained after oral doses of 250 mg. Food delays absorption but does not affect the final plasma drug concentration. Following oral administration, little or no famciclovir is detected in plasma or urine. The plasma half-life of penciclovir is about 2.5 hours, and almost three-quarters is recovered unchanged in the urine. Measurable penciclovir concentrations are not detectable in plasma or urine following topical administration of penciclovir cream. A 12-hour dosing interval is recommended for those with creatinine clearances between 30 and 50 ml/min per 1.73 m^2, and a 24-hour interval for those with creatinine clearances less than 30 ml/min per 1.73 m^2 (Boike *et al.*, 1994).

Antiviral therapy

Penciclovir's (and thus famciclovir's) spectrum of activity against herpesviruses is similar to that of acyclovir. In addition to HSV, penciclovir has demonstrable *in vitro* activity against VZV, EBV, and hepatitis B virus (HBV).

Clinical efficacy in HSV-1 and HSV-2 infections

Genital herpes

In the episodic treatment of genital herpes, famciclovir reduces time to healing, time to cessation of viral shedding, and durations of lesion edema, vesicles, ulcers, and crusts when compared with placebo (Sacks *et al.*, 1996b). Times to cessation of all symptoms and of moderate to severe lesion tenderness, pain, and burning are also reduced (Sacks *et al.*, 1996b). For suppression of genital HSV recurrences, famciclovir delays the time to the first recurrence of genital herpes when compared with placebo (Diaz-Mitoma *et al.*, 1998; Mertz *et al.*, 1997a). Dosing and anticipated benefits of treatment of primary and recurrent genital herpes, and of suppressive therapy, are shown in Tables 64.1 and 64.2, respectively.

Recurrent herpes labialis

Topical penciclovir (Denavir) for the treatment of recurrent herpes labialis reduces time to healing and duration of pain by about half a day (Boon *et al.*, 2000). Topical penciclovir cream decreases the time to lesion healing by approximately 1 to 2 days when compared with placebo (Boon *et al.*, 2000; Spruance *et al.*, 1997), and is equally effective as topical acyclovir cream (Lin *et al.*, 2002). Additional benefit is noted in a reduction in lesion area; faster loss of lesion-associated symptoms; and reductions in daily assessments of pain, itching, burning, and tenderness (Boon *et al.*, 2000). Faster healing and pain resolution occurs both among patients who first apply penciclovir cream in the prodrome and erythema stages and among those who start treatment in the papule and vesicle lesion stages (Spruance *et al.*, 1997). Application of medicine should begin as early as possible, preferably during the prodromal phase, and should be continued every 2 hours during waking hours for 4 days. (Diaz-Mitoma *et al.*, 1998; Mertz *et al.*, 1997a)

Challenges for achieving clinical benefit, including adverse drug effects

Famciclovir is as well tolerated as acyclovir. Complaints of nausea, diarrhea, and headache occurred in clinical trials, but at frequencies similar to those reported by placebo recipients. No clinically significant drug interactions have been reported to date, although concentrations of famciclovir among volunteers increase by about 20% in

patients receiving concomitant cimetidine or theophylline administration.

Clinical indications

Famciclovir was approved by the FDA for the treatment of acute herpes zoster in 1994, and subsequently was approved for the treatment and suppression of genital HSV disease in immunocompetent patients. Famciclovir is also approved for the treatment of recurrent mucocutaneous HSV disease in HIV-infected patients. Topical penciclovir is approved for the treatment of recurrent herpes labialis in adults.

Dosage regimens

For the episodic treatment of recurrent genital HSV disease, the dosage of famciclovir is 125 mg twice daily, administered for 5 days (Table 64.1). The recommended dose for suppression of genital HSV is 250 mg twice daily for up to 1 year (Table 64.1). Note that the lack of harmonization of treatment regimens resulted from different doses of famciclovir being studied in the clinical trials; this produced the unusual dosage recommendation of decreasing the suppression dose to treat a genital HSV recurrence. The safety and efficacy of famciclovir therapy beyond 1 year of treatment have not been established. For recurrent orolabial or genital HSV infection in HIV-infected patients, the recommended dose is 500 mg twice daily for 7 days.

Application of topical penciclovir to recurrent herpes labialis lesions should begin as early as possible, preferably during the prodromal phase, and should be continued every 2 hours during waking hours for 4 days.

Dose reduction of famciclovir is recommended for patients with compromised renal function. A 12-hour dosing interval is recommended for persons with creatinine clearances between 30 and 50 ml/min per 1.73 m^2, and a 24-hour interval for those with creatinine clearances less than 30 ml/min per 1.73 m^2 (Boike *et al.*, 1994).

The safety and efficacy of famciclovir and topical penciclovir in children have not been established. No liquid or suspension formulation exists currently.

Antiviral resistance

Because penciclovir, like acyclovir, must be activated by the viral encoded TK enzyme, TK-deficient viral strains are resistant to both acyclovir and penciclovir. Strains of HSV whose resistance to acyclovir is conferred by alteration of the TK enzyme or by DNA polymerase mutations may remain sensitive to penciclovir (Kimberlin *et al.*, 1995a).

Valaciclovir

Valaciclovir is the L-valyl ester of acyclovir that is rapidly converted to acyclovir after oral administration by first-pass metabolism in the liver (Jacobson, 1993). Licensed in 1995, it has a safety and efficacy profile similar to which of acyclovir but offers potential pharmacokinetic advantages.

Mechanism of action and pharmacokinetics

As a prodrug of acyclovir, valaciclovir has the same mechanism of action, antiviral spectrum, and resistance profiles as those of its parent drug, acyclovir. Following oral administration of valaciclovir, rapid and complete conversion to acyclovir occurs with first-pass intestinal and hepatic metabolism. The bioavailability of valaciclovir exceeds 50%, which is three to five times greater than that of acyclovir (Soul-Lawton *et al.*, 1995). Peak serum concentrations, attained about 1.5 hours after a dose, are proportional to the amount of drug administered; they range from 0.8 to 8.5 μg/ml for doses of 100 to 2000 mg (Weller *et al.*, 1993). The area under the drug concentration time curve approximates that seen after intravenous acyclovir. All other pharmacokinetic characteristics are similar to those of acyclovir (Nadal *et al.*, 2002).

Antiviral therapy

Acyclovir is most active in vitro against HSV, with activity against VZV being about tenfold less. Although EBV has only minimal thymidine kinase activity, EBV DNA polymerase is susceptible to inhibition by acyclovir triphosphate and thus EBV is moderately susceptible to acyclovir in vitro. Activity against CMV is limited by CMV's lack of a gene for thymidine kinase; furthermore, CMV DNA polymerase is poorly inhibited by acyclovir triphosphate.

Clinical efficacy in HSV-1 and HSV-2 infections

Genital herpes

Valaciclovir treatment of first-episode genital HSV is as effective as acyclovir therapy, while at the same time providing a more favorable dosing schedule compared with acyclovir (Fife *et al.*, 1997) (Tables 64.1 and 64.2). In the treatment of recurrent genital HSV, valaciclovir decreases the duration of lesions, the duration of pain, and the duration of viral shedding when compared to placebo (Spruance *et al.*, 1996). Valaciclovir also is as effective as acyclovir for the episodic treatment of recurrent genital HSV, again providing a more favorable dosing schedule compared with acyclovir (Tyring *et al.*, 1998) (Tables 64.1 and 64.2). It should be

administered for 3 to 5 days when administered as episodic treatment (Anonymous, 2002; Leone *et al.*, 2002). Valaciclovir is also effective in suppressing recurrences of genital HSV when administered as once-daily suppressive therapy (Reitano *et al.*, 1998). Valaciclovir has recently demonstrated efficacy in the suppression of recurrent herpes labialis with 500 mg once-daily (Baker *et al.*, 2000).

Recurrent herpes labialis

Valaciclovir administered at high doses for short periods of time (2 grams orally twice a day for 1 day) reduces the time to lesion healing and time to cessation of pain and/or discomfort compared to placebo, with the overall duration of the episode being decreased by approximately one day (Spruance *et al.*, 2003). However, early valaciclovir treatment does not appear to increase the likelihood that a clinical recurrence will be aborted prior to cold sore lesion development (Chosidow *et al.*, 2003; Spruance *et al.*, 2003).

Valaciclovir administered as a 500 mg dose once daily is effective in suppressing recurrences of herpes labialis, with almost two-thirds of treated patients remaining recurrence-free during four months of suppressive therapy compared with approximately one-third of placebo recipients (Baker and Eisen, 2003; Baker *et al.*, 2000).

Herpes simplex encephalitis

Herpes simplex encephalitis is managed acutely with intravenous acyclovir, as discussed above. A randomized, controlled trial of long-term suppressive oral valaciclovir therapy following the treatment of the acute HSE disease is currently being conducted by the NIAID Collaborative Antiviral Study Group. This study will determine whether subclinical reactivation of HSV within the brain contributes to the neurologic impairment experienced by many HSE survivors. At the current time, however, no evidence exists to suggest that suppressive oral valaciclovir therapy is beneficial in preventing neurologic complications.

Challenges for achieving clinical benefit, including adverse drug effects

The profiles of adverse effects and potential drug interactions observed with valaciclovir therapy are the same as those observed with acyclovir treatment. Neurotoxicity has not been reported in humans to date, although it has been observed in animal models (Jacobson, 1993). Manifestations resembling thrombotic microangiopathy have been described in patients with advanced HIV disease receiving very high doses of valaciclovir (8 grams per day), but the multitude of other medications being administered to such patients makes the establishment of a causal relationship to valaciclovir difficult (Bell *et al.*, 1997). Although causation has not been established, use of valaciclovir at such high doses should involve evaluation of potential risks and benefits.

A limited number of adverse drug interactions with acyclovir have been reported. Subjects being treated with both zidovudine and acyclovir can develop severe somnolence and lethargy. The likelihood of renal toxicity is increased when acyclovir is administered with nephrotoxic drugs such as cyclosporine and amphotericin B. Concomitant administration of probenicid decreases renal clearance of acyclovir and prolongs its half-life; conversely, acyclovir can decrease the clearance of drugs such as methotrexate that are eliminated by active renal secretion.

Clinical indications

Valaciclovir is indicated for the treatment of herpes zoster, and for the treatment or suppression of genital herpes. Although data from controlled clinical trials are limited, because of greater bioavailability, valaciclovir may be advantageous in treating infections caused by viruses relatively less sensitive to acyclovir than HSV (e.g., VZV and CMV).

Dosage regimens

Adult treatment doses for HSV-1 and HSV-2 infections are: 1) 1 gram orally twice daily for 7–10 days for first episode genital herpes (Table 64.1, 64.2) 500 mg orally twice daily for 3–5 days for episodic treatment of recurrent genital HSV disease (Table 64.1); and 64.3) 1 gram orally once daily for suppression of recurrent genital HSV (Table 64.1). Suppression of recurrent oral herpes infections has been accomplished with single daily doses of 500 mg.

Valaciclovir dosages in children are not yet established. A valaciclovir oral suspension has recently been formulated and is undergoing Phase I evaluation in infants and children.

With decreasing creatinine clearance, the dosing interval should be spread. With significant renal impairment, the dose should also be reduced in half. Acyclovir is removed during hemodialysis, and therefore an extra dose of valaciclovir should be administered following completion of hemodialysis. Supplemental doses of valaciclovir are not required following chronic ambulatory peritoneal dialysis (CAPD) and continuous arteriovenous hemofiltration/dialysis (CAVHD).

Antiviral resistance

HSV resistance to acyclovir can result from mutations in either the viral TK gene or the viral DNA polymerase gene. Although these acyclovir-resistant isolates exhibit

diminished virulence in animal models, among HIV-infected patients they can cause severe, progressive, debilitating mucosal disease and (rarely) visceral dissemination (Gateley *et al.*, 1990). Acyclovir-resistant strains of HSV also have been recovered from cancer chemotherapy patients, bone marrow and solid organ transplant recipients, children with congenital immunodeficiency syndromes, and neonates (Kimberlin *et al.*, 1996a). Although it is uncommon, genital herpes caused by acyclovir-resistant isolates has also been reported in immunocompetent hosts who usually have received chronic acyclovir therapy (Kost *et al.*, 1993).

Second-line antiviral agents for HSV-1 and HSV-2 infections cidofovir

Cidofovir was first approved for use in the United States for the therapy of AIDS-associated retinitis caused by CMV, and this remains the main indication for this antiviral agent. With a mechanism of action independent of viral TK activity, however, cidofovir can have a role in the management of HSV-1 and HSV-2 infections which are acyclovir resistant, as described below.

Mechanism of action and pharmacokinetics

Cidofovir is a novel acyclic phosphonate nucleotide analogue. In its native form, cidofovir already has a single phosphate group attached, and thus viral enzymes are not required for initial phosphorylation of drug. In this regard, it is dissimilar to the nucleoside analogues such as acyclovir and ganciclovir. Cellular kinases sequentially attach two additional phosphate groups, converting cidofovir to its active diphosphate form.

Cidofovir has a mechanism of action which is similar to other nucleoside analogues. The active cidofovir diphosphate serves as a competitive inhibitor of DNA polymerase (Ho *et al.*, 1992). While cidofovir is taken up by both virally infected and uninfected cells, the active form of the drug exhibits a 25- to 50-fold greater affinity for the viral DNA polymerase as compared to the cellular DNA polymerase, thereby selectively inhibiting viral replication (Ho *et al.*, 1992). Incorporation of cidofovir into the growing viral DNA chain results in reductions in the rate of viral DNA synthesis.

Only 2%–26% of cidofovir is absorbed after oral administration, requiring that cidofovir be administered intravenously in the clinical management of patients. The plasma half-life of cidofovir is 2.6 hours, but active intracellular metabolites of cidofovir have half-lives of 17 to 48 hours (Cundy *et al.*, 1995). Ninety percent of the drug is excreted in the urine, primarily by renal tubular secretion (Lalezari *et al.*, 1995).

Antiviral therapy

While primarily a CMV drug, cidofovir has demonstrable activity against HSV as well. Due to its unique phosphorylation requirements for activation, the drug usually maintains activity against acyclovir- and foscarnet-resistant HSV isolates (Safrin *et al.*, 1999). Although cidofovir is less potent in vitro against HSV than is acyclovir, its favorable pharmacokinetic profile increases its anti-HSV activity. Cidofovir also has demonstrated in vitro activity against varicella-zoster virus, Epstein–Barr virus, human herpesvirus-6, human herpesvirus-8, polyomaviruses, adenovirus, and human papillomavirus (HPV).

Clinical efficacy in HSV-1 and HSV-2 infections

The primary use for cidofovir at the current time is for the management of CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS) (Lalezari *et al.*, 1997; Studies of Ocular Complications of AIDS Research Group in collaboration with the AIDS Clinical Trials Group, 1997). However, cidofovir has been utilized successfully in the management of disease caused by acyclovir-resistant HSV isolates (Lalezari *et al.*, 1994). Due in part to its toxicity profile (described below), cidofovir does not have a role in antiviral prophylaxis of herpesvirus infections.

The safety and efficacy of cidofovir in children have not been studied. Due to the risk of long-term carcinogenicity and reproductive toxicity, the use of cidofovir in children warrants caution.

Challenges for achieving clinical benefit, including adverse drug effects

The principle adverse event associated with systemic administration of cidofovir is nephrotoxicity. Cidofovir concentrates in renal cells in amounts 100 times greater than is seen in other tissues, producing severe proximal convoluted tubule nephrotoxicity when concomitant hydration and administration of probenicid are not employed (Cundy *et al.*, 1995; Lalezari *et al.*, 1995). When present, renal toxicity manifests as proteinuria and glycosuria. In order to decrease the potential for nephrotoxicity, aggressive intravenous prehydration and coadministration of probenecid are required with each cidofovir dose. Within 48 hours prior to delivery of each dose of cidofovir, serum creatinine and urine protein must be determined, with adjustment in dose as indicated. Due to its potential for nephrotoxicity, cidofovir should not be administered

concomitantly with other potentially nephrotoxic agents (e.g., intravenous aminoglycosides (e.g., tobramycin, gentamicin, and amikacin), amphotericin B, foscarnet, intravenous pentamidine, vancomycin, and non-steroidal anti-inflammatory agents).

Cidofovir's potential for nephrotoxicity, neutropenia, ocular hypotony, and metabolic acidosis are judged significant enough to warrant warning statements from the FDA in the package insert. Cidofovir is carcinogenic, teratogenic, and causes hypospermia in animal studies.

Clinical indications

Cidofovir is licensed for the treatment of CMV retinitis in AIDS patients. The safety and efficacy of cidofovir for the treatment of other CMV infections, including those in non-HIV-infected individuals, or of resistant HSV infections has not been established.

Dosage regimens

Due to poor oral bioavailability (2%–26%), cidofovir can only be administered intravenously or topically. The recommended induction dose of cidofovir for patients with a serum creatinine of $\leq$1.5 mg/dl, a calculated creatinine clearance $>$55 ml/min, and a urine protein $<$100 mg/dl (equivalent to $<$2 + proteinuria) is 5 mg/kg body weight administered once weekly for two consecutive weeks. The recommended maintenance dose of cidofovir is 5 mg/kg body weight administered once every 2 weeks. Aggressive intravenous prehydration and coadministration of probenecid are required with each cidofovir dose. Cidofovir must not be administered intraocularly due to the potential for ocular hypotony.

Cidofovir is contraindicated in patients with serum creatinine $>$1.5 mg/dL, calculated creatinine clearance $\leq$55 ml/min, or urine protein $\geq$100 mg/dl (equivalent to $\geq$2+ proteinuria). The maintenance dose of cidofovir must be reduced from 5 mg/kg to 3 mg/kg for an increase in serum creatinine of 0.3–0.4 mg/dl above baseline. Cidofovir therapy must be discontinued if serum creatinine increases $\geq$0.5 mg/dl above baseline.

Foscarnet

Foscarnet is an organic analogue of inorganic pyrophosphate, with the chemical name of phosphonoformic acid (PFA). As such, it is the only antiherpes drug that is not a nucleoside or nucleotide analogue. It has the potential to chelate divalent metal ions, such as calcium and magnesium, to form stable coordination compounds. It is not a first-line drug but is useful for the treatment of infections caused by resistant herpes viruses.

Mechanism of action and pharmacokinetics

Foscarnet directly inhibits DNA polymerase by blocking the pyrophosphate binding site and preventing cleavage of pyrophosphate from deoxynucleotide triphosphates (Wagstaff and Bryson, 1994). It is a non-competitive inhibitor of viral DNA polymerases or HIV reverse transcriptase, and is not incorporated into the growing viral DNA chain. It is approximately 100-fold more active against viral enzymes than host cellular enzymes.

Foscarnet is poorly absorbed after oral administration, with a bioavailability of only about 20%, thereby limiting foscarnet's delivery to the intravenous route. Maximum serum concentration attained after a dose of 60 mg/kg is approximately 500 μmol/l (Wagstaff and Bryson, 1994). Data are limited regarding tissue distribution, but CSF concentrations are about two-thirds of those in serum. Eighty percent of an administered dose of foscarnet is eliminated unchanged in the urine; half-life is 48 hours, and dosage adjustments are necessary even in the presence of minimal degrees of renal dysfunction. Hemodialysis efficiently eliminates foscarnet and therefore an extra dose of drug is recommended after a 3-hour dialysis run (MacGregor *et al.*, 1991). There are no pharmacokinetic data for foscarnet in neonates.

Antiviral therapy

Foscarnet inhibits all known human herpesviruses, including acyclovir-resistant HSV and VZV strains and most ganciclovir-resistant CMV isolates. It also is active against HIV. While the drug concentrations required for inhibition of viral replication vary markedly, they generally range from 10 to 130 μM for HSV, 100 to 300 μM for CMV, and 10 to 25 μM for HIV.

Clinical efficacy in HSV-1 and HSV-2 infections

While primarily a CMV drug, foscarnet has demonstrable activity against HSV as well, and infections caused by acyclovir-resistant strains of HSV have been successfully controlled with foscarnet (Safrin *et al.*, 1991a; Safrin *et al.*, 1991b).

The safety and efficacy of foscarnet in the pediatric population has not been established. Potential exists for deposition of foscarnet in the developing teeth and bone of children. Therefore, administration of foscarnet to pediatric patients should be undertaken only after careful evaluation

and only if the potential benefits for treatment outweigh the potential risks.

Challenges for achieving clinical benefit, including adverse drug effects

The most common adverse effects of foscarnet are nephrotoxicity and metabolic derangements. Evidence of nephrotoxicity includes azotemia, proteinuria, acute tubular necrosis, crystalluria, and interstitial nephritis (Studies of Ocular Complications of AIDS Research Group in collaboration with the AIDS Clinical Trials Group, 1992). Serum creatinine concentrations increase in up to 50% of patients, usually during the second week of therapy. Fortunately, renal function returns to normal within two to four weeks of discontinuing therapy in most affected patients. Preexisting renal disease, concurrent use of other nephrotoxic drugs, dehydration, rapid injection of large doses, or continuous intravenous infusion of drug are risk factors for developing renal dysfunction (Deray *et al.*, 1989).

Metabolic disturbances associated with foscarnet therapy include symptomatic hypo- and hypercalcemia and hypo- and hyperphosphatemia (Markham and Faulds, 1994). Hypocalcemia is due to direct chelation of ionized calcium by the drug, and patients can have such symptoms as paresthesias, tetany, seizures, and arrythmias. Metabolic disturbances can be minimized if foscarnet is administered by slow infusion, with rates not exceeding 1 mg/kg per min. Common central nervous system (CNS) symptoms associated with foscarnet therapy are headache, tremor, irritability, seizures, and hallucinations. Fever, nausea, vomiting, abnormal serum hepatic enzymes, anemia, granulocytopenia, and genital ulcerations also have been reported. The genital ulcerations appear to be associated with high urinary concentrations of drug.

Concomitant use of amphotericin B, cyclosporine, gentamicin, and other nephrotoxic drugs increases the likelihood of renal dysfunction associated with foscarnet therapy. Co-administration of pentamidine increases the risk of hypocalcemia. Anemia and neutropenia are more common when patients also are receiving zidovudine. No drug–drug interactions are known to exist with the concomitant use of foscarnet and ganciclovir.

Foscarnet's major toxicity of renal impairment is judged significant enough to warrant warning statements from the FDA in the package insert. Serum creatinine should be monitored frequently, and adequate hydration with foscarnet administration is imperative. Elevations in serum creatinine are usually, but not always, reversible following discontinuation or dose adjustment of foscarnet. Patients receiving foscarnet must also be monitored for development of mineral and electrolyte abnormalities that might result in seizures, including hypocalcemia, hypophosphatemia, hyperphosphatemia, hypomagnesemia, and hypokalemia.

Clinical indications

Foscarnet is indicated for the treatment of acyclovir-resistant mucocutaneous HSV infections in immunocompromised patients, and is the drug of choice for both HSV and VZV infections caused by acyclovir-resistant strains. Foscarnet also is indicated for the treatment of CMV retinitis in patients with AIDS.

Dosage regimens

When used for the treatment of acyclovir-resistant strains of HSV, foscarnet should be administered at 120 mg/kg per day in three divided doses. In patients with AIDS, foscarnet therapy should be initiated within 7 to 10 days of suspicion of infection caused by acyclovir-resistant HSV or VZV. Therapy should be continued until lesions have resolved.

The degree of dose reduction is proportional to reduction in creatinine clearance; when creatinine clearance is 50% of normal, the dose should be reduced by about 50%. Detailed tables of dosage adjustments are available in the foscarnet package insert.

Antiviral resistance

Foscarnet does not require activation by viral kinases, including thymidine kinase, and therefore is active *in vitro* against HSV TK-deficient mutants. Resistance occurs as a result of DNA polymerase mutations (Kimberlin *et al.*, 1995a). Strains of CMV, HSV, and VZV with three- to fivefold reduced sensitivity to foscarnet have been reported (Kimberlin *et al.*, 1995b; Safrin *et al.*, 1994; Snoeck *et al.*, 1994). These isolates may respond to therapy with acyclovir (Safrin *et al.*, 1994) or cidofovir (Snoeck *et al.*, 1994). Conversely, infections caused by acyclovir-resistant strains of HSV and VZV have been successfully controlled with foscarnet (Safrin *et al.*, 1991a; Safrin *et al.*, 1991b).

Ganciclovir

Ganciclovir is a nucleoside analogue that differs from acyclovir by having an extra hydroxymethyl group on the acyclic side chain.

Mechanism of action and pharmacokinetics

As with acyclovir and penciclovir, the first step in ganciclovir phosphorylation is carried out by a virus-encoded

enzyme, and the final steps by cellular enzymes. Ganciclovir triphosphate is a competitive inhibitor of herpesviral DNA polymerases, resulting in cessation of DNA chain elongation (Markham and Faulds, 1994). Ganciclovir triphosphate also has some activity against cellular DNA polymerases, and this potential for incorporation into cellular DNA accounts for ganciclovir's significant toxicities. Ganciclovir has similar activity to acyclovir against HSV-1, HSV-2, and VZV but, in contrast with acyclovir, its greatest activity is against CMV.

Peak serum concentrations of ganciclovir after 5 mg/kg of intravenously-administered drug range from 8 to 11 μg/ml. Concentrations of ganciclovir in the central nervous system range from 24% to 70% of those in the plasma, with brain concentrations of approximately 38% of plasma levels (Fletcher *et al.*, 1986). Most of an administered dose of ganciclovir is eliminated unchanged in the urine, with an elimination half-life of 2 to 3 hours. Intracellular ganciclovir triphosphate has a half-life of more than 24 hours.

Oral bioavailability of ganciclovir is poor, with less than 10% of drug being absorbed following oral administration (Frenkel *et al.*, 2000; Jacobson *et al.*, 1987; Markham and Faulds, 1994). Despite this, an oral dose of 1000 mg of ganciclovir produces a peak plasma concentration of 1 μg/ml. Intravitreal drug concentrations achieved during intravenous induction therapy also average 1 μg/ml, while subretinal concentrations are comparable to those achieved in plasma (Kuppermann *et al.*, 1993).

The pharmacokinetic of intravenous ganciclovir in the neonatal population are similar to those of adults (Trang *et al.*, 1993). Following intravenous administration of 6 mg/kg of ganciclovir, peak concentrations of 7.0 μg/ml are achieved. The mean elimination half-life is 2.4 hours.

Dose reduction, proportional to the degree of reduction in creatinine clearance, is necessary for persons with impaired renal function. A supplemental dose is recommended after dialysis because it is efficiently removed by hemodialysis (Swan *et al.*, 1991).

Antiviral therapy

Ganciclovir's greatest in vitro activity is against CMV, although it is also as active as acyclovir against HSV-1 and HSV-2 and almost as active against VZV.

Challenges for achieving clinical benefit, including adverse drug effects

Myelosuppression is the most common adverse effect of ganciclovir; dose-related neutropenia (less than 1000 WBC/μl) is the most consistent hematologic disturbance, with an incidence of about 40% of ganciclovir-treated patients (Markham and Faulds, 1994). Neutropenia is dose limiting in about 15% of subjects, and is reversible upon cessation of drug. Neutropenia is less frequent following oral administration of ganciclovir (Drew *et al.*, 1995). Hematopoietic growth factors may be useful in preventing or managing neutropenia. Thrombocytopenia (less than 50 000 platelets/μl) occurs in approximately 20% of treated patients, while anemia in about 2% of ganciclovir recipients. Due to its marrow suppressive effects, ganciclovir should not be administered if the absolute neutrophil count is less than 500 cells/μl or if the platelet count is less than 25 000 cells/μL.

Two to 5% of ganciclovir recipients experience headache, confusion, altered mental status, hallucinations, nightmares, anxiety, ataxia, tremors, seizures, fever, rash, and abnormal levels of serum hepatic enzymes, either singly or in some combination (Markham and Faulds, 1994). Intraocular injection of ganciclovir can cause transient increases in intraocular pressure with associated intense pain and amaurosis lasting up to 30 minutes.

Since both zidovudine and ganciclovir have the potential to cause neutropenia and anemia, some patients may not tolerate concomitant therapy with these drugs at full dosage. Renal clearance of ganciclovir decreases in the presence of probenicid. Generalized seizures have been reported in patients who received ganciclovir and imipenem-cilastatin, and these drugs should not be used concomitantly unless the potential benefits outweigh the risks.

In preclinical test systems, ganciclovir is mutagenic, carcinogenic, and teratogenic. Additionally, it causes irreversible reproductive toxicity in animal models. The use of ganciclovir in the pediatric population warrants extreme caution due to this potential for long-term carcinogenicity and reproductive toxicity. Administration of ganciclovir to pediatric patients should be undertaken only after careful evaluation and only if the potential benefits of treatment outweigh the potential risks.

Clinical indications

Ganciclovir is indicated for the treatment and prevention of CMV infections in immunocompromised patients. Its role in the treatment of HSV-1 or HSV-2 infections is limited to unique situations in which coverage of these viruses in addition to CMV is desirable.

Dosage regimens

The usual therapeutic and prophylactic dose of ganciclovir is 10 mg/kg per day, given by intravenous infusion twice a day for 2 to 3 weeks. For continued suppressive therapy to prevent relapse of infection or for long-term prophylaxis,

either of the following may be used: (1) 5 mg/kg as a single daily dose each day of the week; or (2) 6 mg/kg administered 5 days a week. Despite the absence of data, utilization of intravenous ganciclovir is largely being supplanted by oral valganciclovir in clinical practice.

Dose reduction, roughly proportional to the degree of reduction in creatinine clearance, is necessary in persons with impaired renal function (Spector *et al.*, 1995; Swan *et al.*, 1991). When creatinine clearance is between 50 and 79 ml/min per 1.73 m^2, half of the usual dose should be given every 12 hours. This same dose should be given every 24 hours if creatinine clearance is between 25 and 49 ml/min per 1.73 m^2. Twenty-five percent of the usual dose should be given every 24 hours if creatinine clearance is less than 25 ml/min per 1.73 m^2. Because ganciclovir is efficiently removed by hemodialysis, a supplemental dose is recommended after dialysis (Swan *et al.*, 1991).

Antiviral resistance

Strains of HSV that are resistant to acyclovir because of TK deficiency also are much less sensitive to ganciclovir. DNA polymerase HSV mutants that are ganciclovir-resistant have been generated in vitro but are not yet a clinical problem.

Valganciclovir

Valganciclovir was approved by the FDA in March, 2001. Because it is well absorbed after oral administration, it may represent a favorable option to intravenously-administered ganciclovir for the treatment and suppression of CMV infections in immunocompromised hosts.

Mechanism of action and pharmacokinetics

Valganciclovir is an L-valine ester prodrug of ganciclovir and as such has the same mechanism of action, antiviral spectrum, and potential for development of resistance as ganciclovir (Cocohoba and McNicholl, 2002). Valganciclovir is rapidly converted to ganciclovir, with a mean plasma half-life of about 30 minutes (Jung and Dorr, 1999). The absolute bioavailability of valganciclovir exceeds 60% and actually is enhanced by about 30% with concomitant administration of food (Brown *et al.*, 1999). The area under the curve of ganciclovir after oral administration of valganciclovir is one-third to one-half of that attained after intravenous administration of ganciclovir. Patients with impaired renal function require dosage reduction that is roughly proportional to their reduction in creatinine clearance (Cocohoba and McNicholl, 2002).

Antiviral therapy

Valganciclovir provides a more tolerable means by which ganciclovir can be delivered to the body than does intravenous ganciclovir. Studies of this drug to date have not included investigations of use for HSV infections.

Challenges for achieving clinical benefit, including adverse drug effects

Based upon data from 370 subjects participating in clinical trials, the most common side effects associated with valganciclovir therapy include diarrhea (41%), nausea (30%), neutropenia (27%), anemia (26%), and headache (22%) (Cocohoba and McNicholl, 2002).

Clinical indications

Valganciclovir has similar indications to ganciclovir. However, based upon limited controlled trials published to date, it currently is approved for the induction and maintenance therapy of CMV retinitis (Martin *et al.*, 2002).

Dosage regimens

The recommended dose of valganciclovir for induction therapy is 900 mg twice daily for 2 weeks. The recommended dose for maintenance therapy is 900 mg once daily.

Antiviral resistance

Resistance mechanisms are identical between ganciclovir and valganciclovir. Since selective pressure resulting from exposure to lower concentrations of drug appears to increase the likelihood of resistance developing among CMV isolates (Drew *et al.*, 1999), it is likely that the higher serum and tissue concentrations of ganciclovir achieved with administration of valganciclovir will produce less emergence of resistance when compared to oral ganciclovir. Whether or not this is seen in the clinical setting requires completion of Phase IV trials.

Antiviral therapy of varicella-zoster virus infections

John W. Gnann, Jr.

Departments of Medicine, Pediatrics and Microbiology, Division of Infectious Diseases, University of Alabama at Birmingham and the Birmingham VA Medical Center Birmingham, AL, USA

Introduction

Primary infection caused by varicella-zoster virus (VZV) is manifest by varicella (chickenpox), while reactivation of latent virus causes herpes zoster (shingles). In immunocompetent children, varicella is usually not a serious disease, but can cause severe morbidity and mortality in adults and in immunocompromised individuals. Similarly, herpes zoster is associated with much greater morbidity in patients with impaired cell-mediated immune responses. In addition, herpes zoster can cause prolonged pain (postherpetic neuralgia) that can be very difficult to manage, particularly in older individuals. The outcomes of varicella and herpes zoster, especially in immunocompromised patients, have been dramatically improved by the development of safe and effective antiviral drugs with potent activity against VZV. Early drugs with modest efficacy and substantial toxicity (e.g., interferon, vidarabine, etc.) have been replaced by antiviral agents with enhanced *in vitro* activity, improved pharmacokinetic properties, and excellent safety profiles.

Diagnosis

Most experienced physicians will be able to make an accurate clinical diagnosis of chickenpox based on the distinctive appearance of the skin lesions (Fig. 65.1(a)). The clinical syndrome of a child with mild constitutional symptoms, the typical diffuse vesicular rash, and no prior history of chickenpox is strongly suggestive of the diagnosis, especially if there has been exposure to VZV within the previous two weeks. However, in countries where the incidence of varicella is dramatically declining (such as the United States), younger physicians will have fewer opportunities to see patients with chickenpox and may feel less confident with the clinical diagnosis. In addition, a variety of atypical presentations may occur in immunocompromised patients that will require laboratory confirmation. The classical dermatomal presentation of herpes zoster is also highly distinctive and readily lends itself to clinical diagnosis, although the diagnosis may be obscure initially in patients who present with dermatomal neuralgic pain prior to the onset of skin lesions (Fig. 65.1(b)).

Culture for VZV is performed by inoculating vesicular fluid onto monolayers of human fetal diploid kidney or lung cells. Unlike HSV, VZV is labile and every effort should be made to minimize the time spent in specimen transport and storage. Ideally, fluid should be aspirated from clear vesicles using a tuberculin syringe containing 0.2 ml of viral transport medium, inoculated directly into tissue culture at the bedside (or taken immediately to the laboratory), and then incubated at 36 °C in 5% CO_2 atmosphere. If no vesicles or pustules are available for aspiration, the clinician should carefully remove overlying debris or crusts from the freshest lesions available, swab the underlying ulcers, and place the swab directly into viral transport medium for rapid delivery on ice to the laboratory. Characteristic cytopathic effects are usually evident in tissue culture in 3–7 days, although cultures should be held for 14 days before they are declared negative. The culture process can be accelerated by using centrifugation cultures in shell vials. Identification of the viral isolate is confirmed by staining the monolayer with VZV-specific monoclonal antibodies. In general, viral culture for VZV is highly specific but slow, insensitive, and expensive.

Since VZV is not shed asymptomatically, demonstration of VZV virions, antigens, or nucleic acids in body fluids or tissues (other than sensory ganglia) is diagnostic of active infection. Visualization of multinucleated giant cells or herpesvirus virions in tissues by histopathology or electron microscopy does not distinguish between VZV

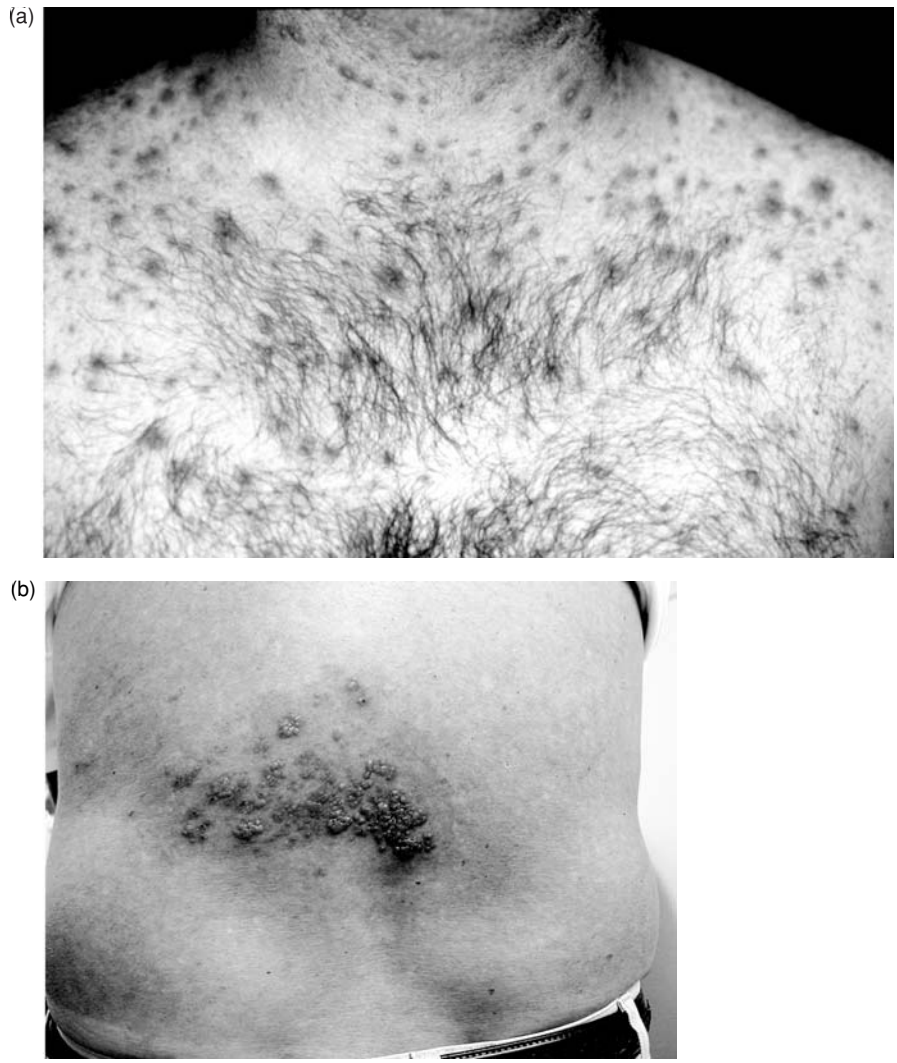

Fig. 65.1. Clinical appearance of varicella and herpes zoster. (a) Typical generalized vesicular rash of chickenpox in an adult. (b) Typical dermatomal papulo-vesicular rash of shingles in an adult. (See color plate section.)

and herpes simplex virus (HSV). Immunohistochemical staining of viral antigens can provide a more specific diagnosis. Direct fluorescent antigen (DFA) staining using fluorescein-conjugated monoclonal antibodies to detect VZV glycoproteins in infected epithelial cells is especially helpful for making a rapid diagnosis when the clinical presentation is atypical. To perform the DFA assay, epithelial cells are scraped from the base of a vesicle or ulcer with a scalpel blade, smeared on a glass slide, fixed with cold acetone, stained with fluoroescein-conjugated monoclonal antibodies, and then examined using a fluorescence microscope. By using virus-specific monoclonal antibodies, HSV can be readily distinguished from VZV, making DFA staining a much more powerful technique then a simple Tzanck preparation. DFA is also more sensitive than virus culture, especially in later stages of VZV infection when virus isolation becomes more difficult. In a population of 92 HIV-infected adults with suspected herpes zoster, DFA and viral culture were positive in 85 of 92 (92%) and 60 of 92 (65%) patients, respectively (Dahl *et al.*, 1997).

Using the polymerase chain reaction (PCR) to detect VZV nucleic acids in clinical specimens is an important diagnostic method (Stranska *et al.*, 2004). PCR overcomes the difficulties inherent in culturing labile VZV and has been used successfully to detect viral DNA in cerebrospinal fluid (CSF) from patients with VZV encephalitis

and in ocular fluids and tissues from cases of VZV retinitis. Diagnosing VZV infection of the central nervous system (CNS) can be difficult, especially when there are no concomitant cutaneous lesions. Examination of the CSF usually reveals a moderate lymphocytic pleocytosis, normal to moderately elevated protein, and normal glucose. The PCR for VZV DNA in CSF should be positive in more than 75% of cases. In one series of 34 HIV-infected patients with VZV neurologic complications, the mean CSF white blood cell count was 126/mm^3, the mean protein concentration was 230 mg/dl, and the PCR was positive for VZV in all cases (De La Blanchardiere *et al.*, 2000).

Serologic techniques can be used to determine susceptibility to VZV infection and to document rising antibody titers following varicella. Serum IgG becomes detectable several days after the onset of varicella and titers peak after 2 to 3 weeks, so routine serologic testing provides only a retrospective diagnosis. Acute infection can be confirmed by VZV-specific serum IgM titers, but antigen detection techniques are usually faster and more reliable. Patients with herpes zoster are VZV-seropositive at the time of disease onset, but most show a significant rise in antibody titer during the convalescent phase. A variety of methods have been used to detect VZV antibodies, but many laboratories have adopted an enzyme-linked immunosorbent assay (ELISA) or a latex agglutination (LA) assay for VZV serodiagnosis. The ELISA is capable of detecting IgG or IgM responses, is a reliable indicator of immune status following natural infection, and is readily automated. However, the ELISA may not be sufficiently sensitive to detect vaccine-induced immunity. The LA assay is rapid, simple, inexpensive and highly sensitive, but cannot be automated or used to detect IgM.

Drugs with activity against VZV

Acyclovir and valacyclovir

Acyclovir, an acyclic analogue of guanosine, is a selective inhibitor of VZV and HSV replication (Whitley and Gnann, 1992). The drug is converted to acyclovir monophosphate by virus-encoded thymidine kinase (TK), a reaction that does not occur to any significant extent in uninfected cells. Cellular enzymes catalyze the subsequent diphosphorylation and triphosphorylation steps which yield high concentrations of acyclovir triphosphate in VZV-infected cells. Acyclovir triphosphate inhibits viral DNA synthesis by competing with deoxyguanosine triphosphate as a substrate for viral DNA polymerase. Incorporation of acyclovir triphosphate into viral DNA results in obligate chain termination since the molecule lacks the 3-hydroxyl group required for further DNA chain elongation. Viral DNA polymerase is tightly associated with the terminated DNA chain and is functionally inactivated. Viral DNA polymerase has a much higher affinity for acyclovir triphosphate than does cellular DNA polymerase, resulting in little incorporation of acyclovir triphosphate into cellular DNA. The median inhibitory concentration of acyclovir necessary to reduce VZV plaque counts by 50% (IC50) is approximately 3 μg/ml.

After oral administration, acyclovir is slowly and incompletely absorbed with bioavailability of about 15–30%. Following oral administration of multiple doses of 200 mg or 800 mg of acyclovir, mean plasma peak concentrations at steady state are approximately 0.6 and 1.6 μg/ml, respectively. Plasma protein binding is less than 20%. Acyclovir penetrates well into most tissues, including the CNS. About 85% of an administered acyclovir dose is excreted unchanged in the urine via glomerular filtration and tubular secretion. The terminal plasma half-life of acyclovir is 2–3 hours in adults and 3–4 hours in neonates with normal renal function, but is extended to about 20 hours in anuric patients.

Valacyclovir is an orally administered prodrug of acyclovir that overcomes the problem of poor oral bioavailability and exhibits improved pharmacokinetic properties (Acosta and Fletcher, 1997). Valacyclovir, the L-valine ester of acyclovir, is well absorbed from the gastrointestinal tract via a stereospecific transporter and undergoes essentially complete first pass conversion in the gut and liver to yield acyclovir and L-valine. Using this prodrug formulation, the bioavailability of acyclovir is increased to about 54%, yielding peak plasma acyclovir concentrations that are three- to fivefold higher than those achieved with oral administration of the parent compound. Oral valacyclovir doses of 500 mg or 1000 mg produce peak plasma acyclovir concentrations of 3–4 and 5–6 μg/ml, respectively. Following administration of valacyclovir at a dose of 2 g orally four times daily, plasma acyclovir area-under-the-curve (AUC) values approximate those produced by acyclovir given intravenously at a dose of 10 mg/kg every 8 hours. Acyclovir AUC values after oral valacyclovir dosing are slightly higher in elderly individuals when compared with younger control groups, presumably due to declines in creatinine clearance associated with aging.

Acyclovir is cleared primarily by renal mechanisms so dosage modification for both acyclovir and valacyclovir are required for patients with significant renal dysfunction. The mean elimination half-life of acyclovir after a single 1 gram dose of valacyclovir is about 14 hours in patients with end-stage renal disease. Acyclovir is readily removed by hemodialysis, but not by peritoneal dialysis. No specific dosage modification for these drugs is required for

patients with hepatic insufficiency. Acyclovir and valacyclovir are not approved for use in pregnancy, but have been widely use to treat serious HSV and VZV infections in pregnant women without evidence of maternal or fetal toxicity (Reiff-Eldridge *et al.*, 2000).

Acyclovir is an extremely safe and well-tolerated drug. Local inflammation and phlebitis may occur following extravasion of intravenous acyclovir. Renal dysfunction resulting from accumulation of acyclovir crystals in the kidney has been observed following rapid intravenous infusion of large doses of acyclovir, but is uncommon and usually reversible. Acyclovir-related neurotoxicity (including agitation, hallucinations, disorientation, tremors, and mild clonous) has been reported, most often in elderly patients with underlying CNS abnormalities and renal insufficiency (Hellden *et al.*, 2003). Oral acyclovir therapy is rarely associated with either neurotoxicity or nephrotoxocity. Studies of patients receiving long-term acyclovir for chronic suppression of genital herpes have revealed no cumulative toxicity (Tyring *et al.*, 2002).

At standard doses, valacyclovir is also a very safe and well-tolerated drug (Acosta and Fletcher 1997). A syndrome of thrombotic microangiopathy (characterized by fever, microangiopathic hemolytic anemia, thrombocytopenia, and renal dysfunction) was observed in AIDS patients receiving high dose valacyclovir (8 grams per day) in a clinical trial. However, this syndrome has not been observed in immunocompetent patients receiving valacyclovir at standard doses (up to 3 grams per day). There is no contraindication to using valacyclovir at approved doses in HIV-infected patients. Clinically significant interactions between acyclovir or valacyclovir and other drugs are extremely uncommon.

Acyclovir is available in topical, oral, and intravenous formulations. The dermatologic preparation consists of 5% acyclovir in a cream or polyethylene glycol ointment base. Topical acyclovir is intended for treatment of minor mucocutaneous HSV infections and plays no role in treatment of VZV. Oral acyclovir preparations include a 200 mg capsule, 400 and 800 mg tablets, and a liquid suspension (200 mg per 5 ml). Acyclovir sodium for intravenous infusion is supplied as a sterile water-soluble powder that must be reconstituted and diluted to a concentration of 50 mg/ml. The approved dose of oral acyclovir for chickenpox is 200 mg/kg (up to a maximum of 800 mg) 4–5 times daily for 5 days. Adults with herpes zoster can be treated with oral acyclovir at a dose of 800 mg five times daily. The recommended dose of intravenous acyclovir for VZV infections is 10 mg/kg every 8 hours, although higher doses (12–15 mg/kg) are sometimes used for life-threatening infections, especially in immunocompromised patients. Dosage reduction is required in patients with renal insufficiency. Valacyclovir is available as 500 mg and 1000 mg tablets. The recommended dose for immunocompetent adults with varicella or herpes zoster is 1000 mg three times daily for 7 days. Because a suspension formulation of valacyclovir is not available, clinical experience with this drug in children with chickenpox is limited.

Penciclovir and famciclovir

Penciclovir is an acyclic guanine derivative that resembles acyclovir in chemical structure, mechanism of action, and spectrum of antiviral activity (Perry and Wagstaff, 1995). Like acyclovir, penciclovir is first monophosphorylated by viral TK, then further modified to the triphosphate form by cellular enzymes. Penciclovir triphosphate blocks viral DNA synthesis through competitive inhibition of viral DNA polymerase. Unlike acyclovir triphosphate, penciclovir triphosphate is not an obligate chain terminator and can be incorporated into the extending DNA chain. Intracellular concentrations of penciclovir triphosphate are higher then those seen with acyclovir triphosphate. In VZV infected cells, the half-life values for penciclovir triphosphate and acyclovir triphosphate are 7 hours and 1 hour, respectively. However, this potential advantage is offset by the lower affinity of penciclovir triphosphate for viral DNA polymerase. The median IC50 of penciclovir for VZV in MRC-5 cells is 4.0 μg/ml. Because penciclovir is very poorly absorbed, famciclovir (the diacetyl ester of 6-deoxy-penciclovir) was developed as the oral formulation. The first acetyl side chain of famciclovir is cleaved by esterases found in the intestinal wall and the second acetyl group is removed on first pass through the liver. Oxidation catalyzed by aldehyde oxidase occurs at the six position, yielding penciclovir.

When administered as the famciclovir prodrug, the bioavailability of penciclovir is about 77%. Following a single oral dose of 250 mg or 500 mg of famciclovir, peak plasma penciclovir concentrations of 1.9 and 3.5 μg/ml are achieved at 1 hour. The pharmacokinetics of penciclovir are linear and dose dependent over a famciclovir dosing range of 125–750 mg. Penciclovir is not metabolized, but is eliminated unchanged in urine, with an elimination half-life of about 2 hours after intravenous administration. Penciclovir for intravenous administration has not been commercially marketed. Famciclovir is available as 125 mg, 250 mg, and 500 mg tablets. In the United States, the recommended dose of famciclovir for uncomplicated herpes zoster is 500 mg three times daily. Famciclovir doses of 250 mg three times daily and 750 mg once daily are approved for treatment of shingles in some countries and appear to be comparable with respect to cutaneous healing of herpes

zoster (Shafran *et al.*, 2004). Adjustment of the famciclovir dose is required in patients with creatinine clearance of <60 ml/min. The adverse effects most frequently reported by patients participating in clinical trials of famciclovir were headache and nausea, although these symptoms did not differ significantly between famciclovir and placebo recipients.

Other drugs

Brivudin

Brivudin (bromovinyl deoxyuridine) is a highly potent thymidine nucleoside analogue with selective activity against HSV-1 and VZV (Keam *et al.*, 2004). The mechanism of action of brivudin appears to be inhibition of the viral DNA polymerase. The drug is well-absorbed after oral administration and has a favorable pharmacokinetic profile which permits once-daily dosing. Brivudin is generally well-tolerated; nausea is the most frequently reported adverse event. Because of concerns about the safety profile of the drug, commercial development of brivudin was halted in the United States. The drug is available in several countries as a 125 mg tablet and as a 0.1% ointment for ophthalmologic use.

Foscarnet

Foscarnet (phosphonoformic acid) is a pyrophosphate analogue that functions as an inhibitor of viral DNA polymerase by blocking the pyrophosphate binding site (Wagstaff and Bryson, 1994). Unlike the nucleoside analogues discussed above, foscarnet does not require intracellular activation by TK, therefore, TK-deficient HSV and VZV isolates that are resistant to acyclovir and related drugs remain susceptible to foscarnet. Foscarnet is administered only by the intravenous route and 80%–90% of an administrated dose is excreted unchanged in the urine. The appropriate dose of foscarnet for treatment of acyclovir-resistant VZV infections has not been assessed systematically, but doses ranging from 40 mg/kg every 8 hours to 100 mg/kg every 12 hours have been used successfully. The most important adverse effect associated with foscarnet therapy is nephrotoxicity. Dose limiting renal toxicity was noted in 15%–20% of patients treated with foscarnet for CMV retinitis. Loading the patient with intravenous saline prior to foscarnet infusion can help reduce the risk of nephrotoxicity. Foscarnet can also induce a variety of electrolyte and metabolic abnormalities, most notably hypocalcemia. Foscarnet-induced electrolyte disturbances can predispose the patient to cardiac arrhythmias, tetany, altered mental status, or seizures. To avoid serious adverse effects that can result from bolus infusion, foscarnet must be administered with an infusion pump over a duration of at least one hour. Serum creatinine levels should be checked at least three times weekly in patients receiving foscarnet and the dosage adjusted according to the manufacturer's guidelines.

Vidarabine

Vidarabine (adenine arabinoside) was the first intravenous antiviral drug accepted for widespread clinical use and was shown to be effective for VZV infections in immunocompromised patients. Vidarabine has now been replaced by more effective and less toxic antiviral drugs.

Interferon

Administration of alpha-interferon to immunocompromised patients with herpes zoster reduces the risk of viral dissemination, but has little impact on dermatomal rash healing or pain. Interferon therapy was associated with significant adverse events and has been supplanted by more specific antiviral drugs.

Clinical indications for therapy

Varicella

Children

In healthy children, varicella is associated with low rates of morbidity and mortality. For most children, supportive care alone is sufficient. Astringent soaks, antipruritics, and antipyretics (preferably acetaminophen) improve comfort. Trimming the fingernails closely helps prevent bacterial superinfections caused by scratching. If bacterial cellulitis (especially caused by group A streptococcus) develops, antibiotics may be required.

Oral acyclovir has been evaluated for treatment of uncomplicated varicella in immunocompetent children (Balfour *et al.*, 1990; Dunkle *et al.*, 1991). Acyclovir therapy, initiated within 24 hours of the onset of rash, resulted in shorter duration of fever, fewer skin lesions, and accelerated lesion healing. Overall, oral acyclovir was well tolerated and reduced the duration of symptomatic illness by about 24 hours. The populations studied in these clinical trials were not significantly large to assess the impact of acyclovir therapy on the incidence of varicella complications. Unlike acyclovir, valacyclovir and famciclovir are not available as suspension formulations and have not been evaluated extensively for treatment of varicella in small children. Some pediatricians still view antiviral therapy as optional for otherwise healthy children with chickenpox. Since the introduction of the varicella vaccine in the United

Table 65.1. Antiviral therapy for VZV infections

	Drug	Dose[a]	Major toxicities
Immunocompetent patients			
Varicella	Acyclovir	20 mg/kg (800 mg max.) po 5 times daily × 5 d. In adults, famciclovir and valacyclovir will also likely be effective.	None; minor nausea or headache
Herpes zoster	Acyclovir	800 mg po 5 times daily × 7–10 d	As above
	Valacyclovir	1000 mg po every 8 h × 7 d	None; minor nausea or headache
	Famciclovir	500 mg po every 8 h × 7 d	None; minor nausea or headache
	Brivudin[b]	125 mg po once daily × 7 d	Potentially lethal interaction with fluoropyrimidines (e.g., 5-fluorouracil)
Immunocompromised patients			
Varicella	Acyclovir	10–15 mg/kg (or 500 mg /m^2) intravenously every 8 h for ≥7 d	Nephrotoxicity (rare); CNS disturbances (rare)
Herpes zoster	Acyclovir	IV therapy (as above). Mild to moderately immunocompromised patients (including most AIDS patients) can be treated with oral therapy.	As above
Disseminated VZV syndromes (e.g., encephalitis, pneumonitis)	Acyclovir	IV therapy (as above)	As above
Infection caused by acyclovir-resistant VZV	Foscarnet	60–90 mg/kg intravenously every 12 h until healed (≥10 d)	Nephrotoxicity (common): electrolyte disturbances (common), seizures, arrhythmias, anemia, genital ulcers

[a] Doses given are for adults with normal renal function.
[b] Not licensed in the United States.

States in 1995, the incidence of chickenpox has declined dramatically, reducing the need for antiviral options in this population.

Adults

Immunocompetent adolescents and adults with varicella can be seriously ill, with high fever, hundreds of cutaneous lesions, incapacitating constitutional symptoms, and a higher risk of complications (especially pneumonitis). Since they are likely to miss at least seven days of school or work, interventions that will reduce the duration of the acute illness are warranted. In a placebo-controlled trial of therapy for 148 adults with varicella, acyclovir (800 mg orally five times daily) was shown to reduce the duration of new lesion formation, reduce the maximum number of lesions, accelerate cutaneous healing, and shorten the duration of fever (Wallace *et al.*, 1992). Similarly, a study of acyclovir treatment in otherwise healthy adolescents demonstrated shorter duration of new lesion formation and of constitutional symptoms, including fever (Balfour *et al.*, 1992). In these studies, the benefit of acyclovir therapy was minimal when treatment was initiated later than 24 hours after rash onset. Overall, acyclovir reduced the duration of illness by about two days. Valacyclovir and famciclovir are also likely to be effective in this setting, but data from controlled clinical trials are lacking. While antiviral therapy is considered optional for healthy children with varicella, the higher potential for morbidity clearly favors treatment in adolescents and adults (Table 65.1). Available data are insufficient to determine whether acyclovir therapy reduces the risk of complications such as pneumonitis or encephalitis.

In immunocompetent patients, visceral dissemination of varicella most often involves the CNS (presenting as cerebellar ataxia, encephalitis, transverse myelitis, or stroke syndromes) or the lungs (viral pneumonitis) (Gnann, 2002). No controlled studies of antiviral therapy for these complications of varicella have been performed. However, information derived from clinical experience and case reports suggests that intravenous acyclovir (10–15 mg/kg every 8 hours) may be beneficial (Haake *et al.*, 1990; Wilkins *et al.*, 1998) (Table 65.1).

The decision whether to initiate antiviral therapy in a patient with chickenpox will hinge on the patients age, underlying medical conditions, and the risk of complications (Arvin, 2002). In general, young children (under age

12 years) are at lower risk for complications than are adolescents or adults. An exception may be secondary pediatric cases in a household, who tend to have more severe disease than the index case. Benefits of antiviral therapy are minimal for healthy children presenting with greater than 24 hours of illness. Because of the greater risk of complications, antiviral therapy is appropriate for adolescents and adults with chickenpox, probably even for those presenting 48–72 hours into the course of illness. Immunocompromised patients with varicella are at significant risk for viral dissemination and visceral involvement and should always receive antiviral therapy.

Pregnant women

Although based more on case reports than on prospectively acquired data, the evidence that varicella in pregnancy is associated with enhanced morbidity is compelling (Nathwani *et al.*, 1998). Women who contract varicella while pregnant have an estimated 10% risk for developing severe VZV pneumonitis. Aggressive antiviral therapy is recommended for a pregnant woman with varicella who develops any evidence of pulmonary involvement, including cough, shortness of breath, or abnormal chest radiograph. Data from clinical trials are lacking, but several case series have reported clinical improvement in pregnant women with varicella pneumonia who were treated with intravenous acyclovir. Although acyclovir is not approved for use during pregnancy for any indication, no fetal toxicity attributable to acyclovir has been demonstrated and the risk-benefit ratio clearly supports the use of acyclovir in the setting of maternal varicella pneumonia (Reiff-Eldridge *et al.*, 2000). Many experts favor antiviral therapy (with acyclovir or valacyclovir) for all pregnant women with chickenpox in an effort to reduce maternal morbidity. No data are available to indicate whether treating the mother will alter the risk of the rare fetal varicella syndrome (Harger *et al.*, 2002).

Immunocompromised patients

The availability of safe and effective antiviral drugs has greatly reduced the high mortality rate previously associated with varicella in immunocompromised patients. Populations at high risk include organ transplant recipients, patients with cancer (especially hematologic malignancies), and other patients receiving immunosuppressive medications (including corticosteroids). Because of the high frequency of visceral involvement in immunocompromised children (or adults) with chickenpox, antiviral therapy is mandatory (Nyerges *et al.*, 1988). A small placebo-controlled trial of intravenous acyclovir in immunocompromised children with varicella demonstrated a dramatic reduction in the frequency of VZV pneumonitis from 27% to 0% (Prober *et al.*, 1982). Therapy with intravenous acyclovir (10 mg/kg or 500 mg/m^2 every 8 hours for 7–10 days) should be initiated at the first sign of infection. A switch to oral antiviral therapy (acyclovir, valacyclovir, or famciclovir) can be considered when the patient is afebrile and new lesion formation has ceased. When feasible, the dosage of immunosuppressive medications should be temporarily reduced in immunosuppressed patients with varicella. Despite the lack of data from large-scale controlled trials, the safety and efficacy of intravenous acyclovir have led to its acceptance as the drug of choice for varicella in severely immunocompromised patients (Table 65.1). Oral antiviral therapy may be efficacious in modestly immunocompromised patients (e.g., those with solid tumor malignancies or a low-dose corticosteroids), but prospectively acquired data are limited. In a retrospective review of 14 pediatric heart transplant recipients with varicella, half received intravenous acyclovir and half received oral valacyclovir; all patients recovered without serious complications (Dodd *et al.*, 2001).

Patients with HIV infection

Varicella does not appear to be unusually severe in most HIV-seropositive children, although some investigators have reported a longer duration of new lesion formation and higher median lesion counts. A variety of varicella complications in HIV-infected children have been reported (including DIC, pneumonitis, hepatitis, and encephalitis), although reliable incidence figures are not available. Deaths attributable to chickenpox in children with HIV infection are rare and are usually due to pneumonitis. No controlled prospective studies of antiviral therapy for chickenpox in HIV-infected children have been reported, so recommendations must be derived from anecdotal experience. Most clinicians prescribe oral antiviral therapy, reserving intravenous acyclovir for patients with unusually severe or complicated infections (Gershon *et al.*, 1997).

Herpes zoster

Immunocompetent adults

The goals of therapy for herpes zoster in immunocompetent adults are to accelerate the events of cutaneous healing, reduce the severity of acute neuritis, and most importantly, to reduce the incidence, severity, and duration of chronic pain (Gnann and Whitley, 2002). Even without antiviral therapy, the cutaneous lesions of herpes zoster almost always resolve within a month. However, chronic pain (postherpetic neuralgia) can persist for months or even years and is the most significant manifestation of herpes zoster in the normal host (Johnson, 2002). Three oral

antiviral drugs are currently approved in the United States for treatment of herpes zoster. Acyclovir, valacyclovir, and famciclovir have been demonstrated to reduce the duration of viral shedding, promote resolution of skin lesions, and limit the duration of pain when antiviral therapy is initiated within 72 hours of lesion onset (Table 65.1).

In placebo-controlled trials, oral acyclovir (800 mg five times daily for 7 days) was shown to accelerate cutaneous healing and to reduce the severity of acute neuritis in immunocompetent adults with herpes zoster (McKendrick *et al.*, 1986; Huff *et al.*, 1988; Wood *et al.*, 1988; Morton and Thomson, 1989). Overall, acyclovir therapy reduced the duration of new vesicle formation by about 1.5 days and the time to 50% lesion healing by about 2.5 days. These clinical trials with acyclovir showed variable benefit for reduction of the frequency and duration of postherpetic neuralgia (PHN), partially due to limitations in study design and population size. Data from these studies were reexamined in another analysis which demonstrated that acyclovir was significantly superior to placebo for reducing the duration of "zoster associated pain," defined as the continuum of pain measured from initial onset until final resolution (Wood *et al.*, 1996). Among patients ≥50 years of age, the median time to resolution of pain was 41 days and 101 days and the proportion with persistent pain at 6 months was 15% and 35% in the acyclovir and placebo treatment groups, respectively. Intravenous acyclovir is also effective in this setting, but is impractical for outpatient management of most patients with shingles. Extending oral acyclovir therapy beyond 7 days does not produce any additional benefit (Wood *et al.*, 1994).

Valacyclovir (1000 mg three times daily for 7 days) was compared with oral acyclovir in a study of 1141 immunocompromised patients over 50 years of age with herpes zoster (Beutner *et al.*, 1995). When initiated within 72 hours of lesion onset, the two drugs were equivalent for accelerating the events of cutaneous healing, but valacyclovir was superior to acyclovir in shortening the median time to resolution of zoster associated pain (38 days vs. 51 days; $P = 0.001$). The proportion of patients still experiencing pain at six months was 25.7% in the acyclovir treatment group and 19.3% in the valacyclovir groups ($P = 0.02$). Extending valacyclovir therapy to 14 days did not result in any additional benefit.

In a controlled trial conducted in 419 immunocompetent patients presenting within 24 hours of lesion onset, famciclovir (500 mg three times daily) was significantly superior to placebo in reducing the duration of viral shedding, limiting the duration of lesion formation, and accelerating the events of cutaenous healing (Tyring *et al.*, 1995). In a subset of shingles patients ≥50 years of age who had persistent pain after skin healing ($n = 170$), the median duration of PHN was reduced from 163 days to 63 days ($P = 0.004$) in the placebo and famciclovir treatment Groups, respectively. In a study comparing famciclovir and acyclovir, the two drugs were shown to have similar efficacy for herpes zoster (Degreef and the Famciclovir Herpes Zoster Study Group, 1994).

Valacyclovir and famciclovir were compared for treatment of herpes zoster in immunocompetent patients in a randomized clinical trial. In this population of 597 patients ≥50 years of age enrolled within 72 hours of rash onset, the two drugs were shown to be therapeutically equivalent, both in terms of cutaneous healing and pain resolution (Tyring *et al.*, 2000). At six months after onset of shingles, 19% of patients in each treatment group still reported pain. Acyclovir, valacyclovir, and famciclovir are all well tolerated and appear to be approximately comparable in clinical efficacy for managing herpes zoster in the immunocompetent host. Because their improved pharmacokinetic properties allow simpler dosing regimens, valacyclovir and famciclovir are preferred over acyclovir for this indication. Comparative drug cost is also a legitimate variable in selecting an antiviral drug for treatment of herpes zoster.

Brivudin (125 mg once daily × 7 days) was compared with acyclovir (800 mg 5 times daily × 7 days) in a study of 1227 immunocompetent adults with herpes zoster. Brivudin was judged to be superior to acyclovir for reducing the time to cessation of new vesicle formation and equivalent to acyclovir in terms of cutaneous healing and acute pain alleviation (Wassilew and Wutzler, 2003a,b). In a follow-up survey of subjects ≥50 years old, the incidence of PHN was lower in brivudin recipients (32.7%) than in acyclovir recipients (43.5%) (Wassilew and Wutzler, 2003a,b). Brivudin is commercially available in several European Union countries, but has not been approved in the United Kingdom or the United States because of concerns about potential drug-related toxicities (Gross *et al.*, 2003).

Certain characteristics have been defined which identify immunocompetent patients at highest risk for complications of shingles and thus most likely to benefit from antiviral therapy. Careful studies have clearly showed that older age, greater skin surface area involved with herpes zoster, and severity of pain at time of clinical presentation are all predictors of more severe and long lasting pain (Wood *et al.*, 1996; Dworkin *et al.*, 1998; Harrison *et al.*, 1999; Whitley *et al.*, 1999; Nagasako *et al.*, 2002). Patients meeting these criteria should be targeted for therapy with antiviral drugs and potent analgesics. Conversely, patients under 50 years of age are at lower risk for severe or prolonged pain and an argument could be made that antiviral therapy in

this group is optional. Available efficacy data from published studies relate to patients who present within 72 hours of lesion onset, although patients frequently present for medical care beyond that window (Wood *et al.*, 1998). The presence of new vesicles correlates with recent viral replication and may be a marker for patients who would benefit from antiviral therapy, even beyond 72 hours. In addition, patients presenting with the high-risk characteristics cited above should be considered for antiviral treatment, even when presenting beyond 72 hours after lesion onset. However, patients whose lesions that have all begun to crust are unlikely to derive benefit from antiviral therapy.

Adding corticosteroids to antiviral therapy in patients with acute herpes zoster has been suggested as a way to reduce pain. A study conducted in the United Kingdom compared acyclovir with and without prednisolone in 400 immunocompetent patients over 18 years of age (Wood *et al.*, 1994). Another clinical trial, conducted in the United States, enrolled 208 patients over 50 years of age into a four-armed study (acyclovir plus placebo, prednisone plus placebo, acyclovir plus prednisone, placebo plus placebo) (Whitley *et al.*, 1996). Both studies targeted patients within 72 hours of the appearance of lesions. Both of these studies demonstrated that corticosteroid therapy led to a reduction of pain during the acute phase of herpes zoster, but neither showed any reduction in the risk of postherpetic neuralgia (Wood *et al.*, 1994; Whitley *et al.*, 1996). Addition of corticosteroids to antiviral therapy for treatment of herpes zoster in selected older adults may result in improvements in quality of life measurements such as reduction in time to uninterrupted sleep, reduction in time to return to usual activities, and reduction in analgesic use (Whitley *et al.*, 1996). In the American trial cited above, prednisone was given for three weeks (60 mg daily for 7 days, 30 mg daily for 7 days, and 15 mg daily for 7 days), although it is possible that shorter courses of prednisone are also effective. Corticosteroid therapy can have significant adverse effects and should not be used in patients at risk for steroid toxicity (e.g., patients with diabetes mellitus, gastritis, etc.). Although only the combination of corticosteroids plus acyclovir has been studied, combination therapy using valacyclovir or famciclovir is assumed to be equally effective. Use of corticosteroids for herpes zoster without concomitant antiviral therapy is not recommended. Furthermore, use of corticosteroids in immunocompromised patients with herpes zoster has not been evaluated and is not recommended.

Symptomatic measures should be suggested to keep the patient with herpes zoster more comfortable. Patients should keep the cutaneous lesions clean and dry to reduce the risk of bacterial superinfection. Patients may wash the skin lesions with soap and water in the shower and then carefully pat the skin dry with a clean towel. Some patients find warm or cool astringent soaks (e.g., Domeboro® solution) to be soothing. A sterile non-occlusive, non-adherent dressing placed over the involved skin will protect the lesions from contact with clothing, which may be especially helpful for patients with increased skin sensitivity (i.e., allodynia). There is no role for topical creams or ointments (including topical acyclovir or penciclovir) in management of herpes zoster. The acute pain of shingles can be very severe and should not be underestimated by the clinician. The pain may be disproportionate to the rash; that is, patients with limited skin involvement can still have severe neuralgic pain. Pain is the most important symptom of herpes zoster and should be aggressively managed. In patients with severe neuralgic pain, sympathetic nerve blocks can provide rapid, but temporary relief (Opstelten *et al.*, 2004). Short-acting narcotic analgesics given on a scheduled (rather than as-needed) basis should be prescribed. Some models used to explain the pathogenesis of PHN suggests that early attenuation of acute pain will reduce the degree of nociceptive input that reaches the spinal cord neurons and prevent the initiation of central mechanisms of chronic pain, thereby reducing the risk of PHN (Dworkin *et al.*, 2000).

Medical management of established PHN is complex and often requires a multifaceted approach (Dworkin and Schmader, 2003; Johnson and Dworkin, 2003). Opioid analgesics are the mainstay of therapy during the acute phases of neuralgic pain (Table 65.2). A clinical trial with controlled-release oxycodone for patients with PHN demonstrated a significant level of pain reduction (67% of those receiving oxycodone versus 11% receiving placebo) as measured by visual analogue scale (Watson and Babul, 1998). Long-acting opioid preparations (oral or transdermal) are preferable to short-acting analgesics for management of chronic PHN. Several randomized, controlled clinical trials have shown tricyclic antidepressants (including amitriptyline, nortriptyline and desipramine) to be effective in reducing the pain of PHN, either as a single agent or in combination with other drugs (Raja *et al.*, 2002; Bowsher, 2003). Because tricyclic antidepressants are frequently associated with sedation and anticholinergic side effects, treatment should begin with a relatively low dose at bedtime, with a gradual increase in dosage as required and tolerated. Nortriptyline is as efficacious as amitriptyline for PHN, but nortriptyline is associated with fewer adverse effects in elderly patients (Watson *et al.*, 1998). In two clinical trial, the anticonvulsant gabapentin was shown to significantly reduce established PHN when

Table 65.2. Management of postherpetic neuralgia

Drug	Dosing	Comments	Adverse effects
Opioid analgesics	Varies with drug	Begin with short-acting drug at morphine oral equianalgesic dose of 5–15 mg every 4 hr. After 2 wk, convert to equianalgesic does of long-acting drug[a]	Sedation, nausea, constipation, dizziness, dependence, abuse, overdose
Gabapentin[b]	Begin with 100 mg po every 8 hr	Titrate dose up by 300 mg/d (in divided doses) to target dose of 1800–3600 mg/d, as tolerated	Somnolence, dizziness, ataxia, peripheral edema
Tricyclic antidepressants	Nortriptyline 25 mg po at bedtime	Titrate dose up to 75–150 mg/d, as necessary. Amitriptyline also effective but may cause more adverse effects in elderly patients. Desipramine is option if nortriptyline causes excess sedation	Sedation, confusion, anticholinergic effects (dry mouth, blurred vision, constipation, urinary retention)
Lidocaine (5%) patch	Apply to painful area; up to 3 patches can be used at a time for a maximum of 12 hr daily	Apply only to healed, intact skin. Patches may be cut to size. Especially helpful for allodynia. Benefit apparent within 2 weeks.	Localized skin irritation only. Systemic toxicity from cutaneous absorption of lidocaine is very rare.

[a] Options for long-acting opioid analgesics include: controlled-release morphine, controlled-release oxycodone, transdermal fentanyl, levorphanol, methadone.
[b] Pregabalin is available as an alternative to gabapentin.
(Modified with permission from Gnann and Whitley, *N. Engl. J. Med.*, 2002.)

used alone or in combination with other modalities (Rowbotham *et al.*, 1998; Rice and Maton, 2001). For treatment of PHN, physicians should initiate gabapentin at a low dose of 100 mg three times daily and escalate (in increments of 100 mg t.i.d.) as required, watching for adverse effects such as somnolence, dizziness, and ataxia. Total daily doses of 1800–3600 mg may be required (Stacey and Glanzman, 2003). Pregabalin has also been shown to be effective and well-tolerated in studies of patients with PHN and is likely to replace gabapentin for this indication (Dworkin *et al.*, 2003; Sabatowski *et al.*, 2004). The adverse effects of these medications can be additive (such as sedation due to opioid analgesics, tricyclic antidepressants, and gabapentin), especially in elderly patients (Schmader, 2001). Local transdermal administration of lidocaine via patches has been shown to significantly reduce PHN in two controlled trials (Davies and Galer, 2004). Topical treatments should only be used on intact healed skin. Topical application of capsaicin cream can provide relief of PHN for some patients, but the local stinging and burning associated with capsaicin may be intolerable for many individuals. In a controlled clinical trial of 277 patients with intractable PHN, intrathecal injection of 60 mg of methylprednisolone acetate once weekly for 4 weeks resulted in significant pain reduction, but these results require confirmation (Kotani *et al.*, 2000). There is no evidence that prolonged administration of antiviral drugs has any benefit for treatment of established PHN (Acosta and Balfour, 2001).

Herpes zoster ophthalmicus

Special emphasis should be given to patients presenting with herpes zoster involving the first division of the trigeminal nerve because of the potential for sight-threatening ocular complications. The ophthalmic division of the trigeminal nerve is the cranial nerve most frequently affected by herpes zoster. Without antiviral therapy, 50% of patients with herpes zoster ophthalmicus (HZO) will develop significant ocular complications (which can include neurotrophic keratopathy, episcleritis, iritis, epithelial or stromal keratitis, etc.) (Liesegang, 1999). Controlled prospective clinical trials clearly demonstrated that oral acyclovir therapy reduced the frequency of serious late ocular inflammatory complications of HZO from about 50%–60% to 20%–30% (Cobo *et al.*, 1986; Harding and Porter, 1991; Herbort *et al.*, 1991; Hoang-Xuan *et al.*, 1992; Beutner *et al.*, 1995). A clinical trial comparing the efficacy of valacyclovir and acyclovir for HZO demonstrated the two drugs to be comparable (Colin *et al.*, 2000). Similarly, a controlled study comparing acyclovir and famciclovir in 454 patients with HZO found that the prevalence of severe and non-severe ocular manifestations (58%) was the

same for both treatment groups (Tyring *et al.*, 2001a,b). Some experts favor intravenous acyclovir as initial therapy for patients (especially immunocompromised patients) with severe HZO. Systemic antiviral therapy has largely replaced topical antiviral preparations for treatment of the ocular complications of HZO. Systemic or topical corticosteroids may be indicated for some of the ocular inflammatory phenomena that accompany HZO (e.g., uveitis), but should only be administered under the supervision of an experienced ophthalmologist (Liesegang, 1999). Available data strongly support the routine and early use of systemic antiviral therapy in all patients with HZO in an effort to reduce the risk of ocular complications (Severson *et al.*, 2003; Zaal *et al.*, 2003).

Immunocompromised patients

Patients with disorders of cell-mediated immunity are at increased risk for development of herpes zoster. In this population, those patients with the greatest degree of immunosuppression (such as hematopoietic stem-cell transplant (HSCT) recipients or patients with lymphoproliferative malignancies) are at highest risk for VZV dissemination and visceral organ involvement. Clinical trials with intravenous acyclovir for localized or disseminated herpes zoster in immunocompromised patients clearly demonstrated that treatment resulted in more rapid virus clearance and halted disease progression (Serota *et al.*, 1982; Balfour *et al.*, 1983). Subsequent studies in HSCT recipients have demonstrated that acyclovir, in addition to promoting faster disease resolution, is highly effective at preventing VZV dissemination (Meyers *et al.*, 1984; Shepp *et al.*, 1986). Because most VZV-related fatalities result from disseminated infection, the ability to prevent dissemination has markedly reduced the herpes zoster mortality rate in immunocompromised patients. In addition, intravenous acyclovir is considered the drug of choice for treating dissemination when it occurs, although efficacy data from prospective studies are limited (Balfour *et al.*, 1983; Whitley *et al.*, 1992). The recommended dose of intravenous acyclovir for herpes zoster in severely immunocompromised patients is 10–15 mg/kg (or 500 mg/m^2) every 8 hours (Table 65.1). When the infection is under control, therapy can be switched from intravenous acyclovir to an oral antiviral drug for the remainder of the course of treatment. Patients should be treated until healing is complete or for a minimum of 10–14 days (whichever is longer) to reduce the risk of relapsing disease.

Treating shingles in immunocompromised patients on an outpatient basis with oral antiviral drugs is an attractive approach, although supporting data are limited. One small study randomized 27 allogenic HSCT recipients with herpes zoster to either oral or intravenous acyclovir. No VZV dissemination occurred in either group, and no differences in healing or clinical outcome were apparent (Ljungman *et al.*, 1989). Published data from clinical trials with famciclovir and valacyclovir for herpes zoster in immunocompromised patients remain limited, but a growing body of clinical experience suggests that these drugs are safe and effective in this setting (Tyring *et al.*, 2001a,b). For less severely immunosuppressed patients, oral therapy with acyclovir (800 mg five times daily), valacyclovir (1000 mg three times daily), or famciclovir (500 mg three times daily), coupled with close clinical observation, is a reasonable option. Because of the risk of ocular involvement, intravenous acyclovir plus evaluation by an ophthalmologist are recommended for highly immunocompromised patients who present with HZO.

HIV-seropositive patients

The incidence of herpes zoster is about 15-fold higher in HIV-seropositive men than in age-matched controls. Shingles in this population is associated with higher rates of CNS complications, necrotizing retinitis, and recurrent episodes. Prospectively acquired data to guide clinicians when selecting antiviral therapy for herpes zoster in HIV-seropositive patients are currently limited. Nearly 300 HIV-infected patients with shingles were enrolled in controlled studies comparing orally administered acyclovir with the investigational antiviral drug sorivudine. Overall, the time to cessation of new vesicle formation, total crusting, and resolution of zoster-associated pain were 3–4 days, 7–8 days, and about 60 days, respectively (Bodsworth *et al.*, 1997; Gnann *et al.*, 1998). These studies confirm the efficacy and safety of oral antiviral therapy for herpes zoster in patients with HIV infection. Valacyclovir and famciclovir have not been systematically evaluated as treatments for herpes zoster in HIV-infected patients, although anecdotal clinical experience suggests therapeutic benefit. Long term administration of antiherpes virus drugs to prevent recurrences of herpes zoster in patients with AIDS is not routinely recommended. Because of the documented risk of relapsing infection, VZV disease in HIV-seropositive patients should be treated until all lesions are completely resolved, which is often longer than the standard 7–10-day course. What impact anti-VZV therapy may have on the risk of subsequent complications such as CNS infection or retinitis is unknown. Adjunctive therapy of herpes zoster with corticosteroids has not been evaluated in HIV-infected patients and is not currently recommended.

On the basis of clinical experience, most physicians select intravenous acyclovir as the drug of choice to treat severe or complicated herpes zoster in HIV-infected patients. The literature contains numerous case reports documenting

successful therapy of neurologic complications with intravenous acyclovir (Poscher, 1994; Lionnet *et al.*, 1996). Some experts have recommended intravenous acyclovir for initial therapy of HZO in HIV-infected patients, although oral therapy appears adequate in most cases.

A syndrome of herpetic retinal necrosis can occur as a late complication of herpes zoster in either immunocompetent or immunocompromised patients, but is seen with the greatest frequency in patients with AIDS. Responses to intravenous acyclovir or ganciclovir have been inconsistent and disappointing. Several case reports have documented preservation of vision in patients treated with a combination of intravenous ganciclovir plus foscarnet, with or without intravitreal ganciclovir (Galindez *et al.*, 1996). The optimal duration of induction therapy and options for long-term maintenance therapy for acute retinal necrosis in HIV-seropositive patients have not been established (Ormerod *et al.*, 1998). When VZV retinitis occurs in immunocompetent patients, the clinical outcome is clearly improved by acyclovir therapy and the prognosis is better. In this population, a suggested treatment regimen based on clinical experience is intravenous acyclovir (10–15 mg/kg every 8 hours) for 10–14 days, followed by oral valacyclovir 1 gram po three times a day for 4–6 weeks (Palay *et al.*, 1991).

Clinical indications for prophylaxis

Varicella

Immunocompetent patients

Administration of varicella vaccine within the first few days after exposure to VZV will produce a protective (or partially protective) immune response in VZV seronegative individuals (Watson *et al.*, 2000). About half of patients receiving post-exposure immunization may still develop some signs and symptoms of chickenpox, but the disease manifestations are usually very mild. Postexposure vaccination appears to be more effective and less expensive than pre-emptive therapy with antiviral drugs. This approach may be useful for managing VZV exposures that occur in a family, in the workplace, or in a medical care setting.

Pregnant women

Advisory committees have recommended administration of varicella-zoster immune globulin (VZIG) to VZV-susceptible pregnant women who have been exposed to varicella (Centers for Disease Control and Prevention, 1996). For maximal efficacy, VZIG must be administered as soon as possible after exposure (within 96 hours). VZIG (as available in the United States) is administered by deep intramuscular injection at a dose of 125 units/10 kg of body weight, to a maximum of 625 units. Intravenous immunoglobulin also contains substantial titers of VZV-specific IgG and may be substituted if VZIG is not available. Unfortunately, in this time-critical scenario, the true VZV serologic status of a pregnant woman with a negative history of varicella is often not known. The clinician may be faced with a decision to initiate passive immunoprophylaxis empirically or to wait for the results of serologic testing. The ideal time to determine VZV serologic status is before pregnancy, when vaccination can be offered to women who are confirmed to be seronegative (Glantz and Mushlin, 1998). Varicella vaccination of pregnant women is not currently recommended because of the theoretical risk of the live virus vaccine for both the fetus and the mother. Prophylactic (or pre-emptive) therapy with acyclovir for a pregnant woman after VZV exposure may be effective, but is an unproven approach.

Immunocompromised (including HIV-seropositive) patients

VZV-seronegative immunocompromised patients with a defined close exposure to either chickenpox or herpes zoster should receive VZIG to provide passive immunity (Zaia *et al.*, 1983). In most cases, VZIG administration will not prevent infection in the susceptible host, but it will significantly reduce the severity of the resultant illness. Placebo-controlled trials in immunocompromised children have demonstrated that VZIG ameliorates the severity of chickenpox and that it significantly reduces the risk of disseminated infection. A single treatment reduces the risk of disseminated infection by about 75% and provides four weeks of passive immunity. VZIG must be administered within 96 hours of exposure at the dose described above. VZIG is not useful for the treatment of established varicella or herpes zoster. The efficacy of VZIG prophylaxis in HIV-seropositive children or adults has not been evaluated prospectively.

Prophylactic administration of acyclovir following VZV exposure has been studied to a limited extent in susceptible immunocompetent patients, but not in immunocompromised individuals. In studies of healthy children conducted in Japan, varicella developed in 16% of the children prophylactically treated with acyclovir and in 100% of children in the control group (Asano *et al.*, 1993) About 80% of children prophylactically treated with acyclovir subsequently seroconverted, indicating VZV infection without significant disease (Suga *et al.*, 1993). However, additional data are required before this approach of preemptive antiviral chemotherapy can be routinely recommended

in either immunocompetent or immunocompromised populations. A suggested (but unvalidated) regimen is acyclovir 200 mg orally four or five times daily for 21 days beginning five days after VZV exposure.

Concerns about the use of the live, attenuated VZV_{oka} vaccine in immunocompromised patients have focused on the potential for the vaccine virus to cause disease and on the possibility that immunocompromised patients will fail to mount a protective immune response. Limited experience with the vaccine in leukemic children and renal transplant recipients have demonstrated that it can be used safely in highly selected populations (Arbeter *et al.*, 1990; Furth and Fivush, 2002).

Herpes zoster

Immunocompetent patients

There are no circumstances that warrant antiviral chemotherapy to try to prevent herpes zoster in immunocompetent individuals. A live-virus vaccine has proven to be effective for preventing herpes zoster and reducing PHN (Oxman *et al.*, 2005). A randomized, double-blind, placebo-controlled clinical trial enrolling 38,546 adults (age 60 and over) was conducted to evaluate the live attenuated Oka/Merck VZV vaccine. The primary endpoint was "herpes zoster burden of illness," a composite score capturing zoster incidence, duration, and severity of total pain and discomfort. Compared with placebo, the vaccine reduced the zoster burden of illness by 61.1%, reduced the incidence of herpes zoster by 51.3%, and reduced the incidence of PHN by 66.5% ($P < 0.001$ for all comparisons). The vaccine was associated with mild reactogenicity (local erythema or tenderness) in 48.3% of recipients, but was otherwise well tolerated. The herpes zoster vaccine was approved for use in the United States in 2006 for immunocompetent adults 60 years of age and over.

Immunocompromised patients

Drug regimens designed to prevent HSV recurrences in immunocompromised patients undergoing cancer chemotherapy or organ transplantation will also effectively prevent herpes zoster (Ljungman, 2001). Combined results from two placebo-controlled trials of long-term (6 months) acyclovir prophylaxis in HSCT recipients demonstrated herpes zoster in 11 (18%) of 62 placebo recipients and in none of the 62 acyclovir treated patients (Lundgren *et al.*, 1985; Perren *et al.*, 1988). Interestingly, the incidence of zoster increased dramatically after the discontinuation of prophylaxis such that, 12 months after transplantation, the cumulative number of herpes zoster cases was virtually identical between the acyclovir and placebo groups. Nonetheless, acyclovir prophylaxis effectively prevents herpes zoster during the early post-transplant period when patients are most severely immunosuppressed and thus have the highest risk for VZV-related complications. Although transplant specialists almost universally recommend 3–6 months of acyclovir prophylaxis, no consensus currently exists regarding the relative merits of longer term prophylaxis. Development of a heat-inactivated VZV vaccine for use in immunocompromised patients is an area of active investigation (Hata *et al.*, 2002).

HIV-seropositive patients

Antiviral chemoprophylaxis for prevention of herpes zoster in patients with AIDS is not routinely recommended. A significant number of HIV-seropositive patients take suppressive antiviral drugs to prevent genital HSV reactivations, which may also prevent herpes zoster. In patients with multiple recurrent episodes of herpes zoster, chemoprophylaxis could be considered (e.g., valacyclovir 1 gram orally twice a day or famciclovir 500 mg orally twice a day), although this approach is unvalidated.

Drug-resistant varicella-zoster virus

Since first reported in 1988, multiple isolates of acyclovir-resistant VZV have been recovered from immunocompromised patients, usually HIV-infected individuals with very low CD4+ T-lymphocyte counts. The mechanism of resistance is based on the deletion or truncation of the gene expressing thymidine kinase. Most isolates resistant to acyclovir are also resistant to valacyclovir, famciclovir, penciclovir, and ganciclovir, all of which depend on viral TK for activation. A strong association exists between acyclovir-resistant VZV and the presence of atypical skin lesions (Boivin *et al.*, 1994; Levin *et al.*, 2003a,b). One report described four HIV-seropositive adults undergoing chronic suppressive acyclovir therapy who developed disseminated hyperkeratotic papules that failed to respond to acyclovir (Jacobson *et al.*, 1990). In vitro susceptibility testing confirmed that the VZV isolates were acyclovir-resistant with a mean IC50 for acyclovir of 20 μg/ml, compared with 0.75 μg/ml for the reference strain (VZV_{oka}). Although the mechanisms that lead to the development of acyclovir resistance are incompletely understood, clinical data indicate that many cases are associated with inadequate dosing of acyclovir for either acute therapy or long-term suppression, possibly allowing for selection of TK-deficient mutants. Clinicians using acyclovir or related drugs for treatment of varicella or herpes zoster in AIDS patients should

utilize the full therapeutic dose and continue therapy until all VZV lesions have completely resolved (Jacobson *et al.*, 1990).

The drug of choice for treatment of acyclovir-resistant VZV disease is foscarnet, an inhibitor of viral DNA polymerase that is not dependent on TK for activation (Breton *et al.*, 1998) (Table 65.1). In a series of 13 patients with AIDS and acyclovir-resistant VZV infections treated with intravenous foscarnet, 10 patients (77%) had complete lesion healing after a mean of 17.8 days of therapy (Breton *et al.*, 1998). Most cases of disease caused by acyclovir-resistant VZV have been limited to cutaneous involvement, although a few instances of visceral infection caused by acyclovir-resistant VZV have been reported, including cases of retinal necrosis and meningoradiculitis.

Fortunately, VZV isolates resistant to both acyclovir and foscarnet have been encountered infrequently. The molecular biology of these duly-resistant isolates has not been fully explored, but a mutation in the viral DNA polymerase can account for both acyclovir and foscarnet resistance. Cidofovir would likely retain activity against these isolates and would become the drug of choice for patients with disease caused by dually-resistant VZV.

Antiviral therapy for human cytomegalovirus

Paul D. Griffiths[1] and Michael Boeckh[2]

[1]Royal Free and University College Medical School, London, UK
[2]Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Introduction

The remit of this chapter is to summarize what is known about licensed antiviral drugs for CMV. In summary, we do not possess a single anti-CMV drug, which is potent and safe enough to be given to all individuals infected with this virus. What follows therefore, is the evidence-base for prescribing the existing compounds with the objective of maximizing therapeutic efficacy and cost-effectiveness while minimizing toxicity.

Licensed drugs and mechanism of action

Nucleosides

Ganciclovir (GCV) and acyclovir (ACV) are related nucleosides (see Fig. 66.1) which are anabolized by a common cellular pathway. After activation, they are competitive inhibitors of CMV encoded DNA polymerase. In cells infected with CMV, the first stage of phosphorylation is achieved by the UL97 protein kinase. Once GCV is monophosphorylated within the virus-infected cell, it is charged and so unable to diffuse out of the cell. A concentration gradient is thereby formed across the plasma membrane, aiding diffusion of more GCV into the infected cell. Cellular enzymes convert GCV monophosphate to the triphosphate. GCV triphosphate is a potent inhibitor of CMV DNA polymerase and has a long intracellular half-life. Selectivity for virus-infected cells is achieved both by UL97 activation and because GCV triphosphate is a better inhibitor of CMV-encoded DNA polymerase than cellular DNA polymerase.

Ganciclovir possesses a free hydroxyl at a position equivalent to the 3' of the open sugar ring and so can allow DNA elongation. This means that it is not an obligate chain terminator, although chain termination usually occurs after incorporation of one or more molecules. The ability to allow chain elongation is theoretically undesirable because it might occur in uninfected cells leading to a mutagenic event in cellular DNA; GCV in particular is oncogenic at low dosages in rodents due to this incorporation into cellular DNA.

ACV can also be activated by UL97 (Talarico *et al.*, 1999) and acyclovir triphosphate is a potent inhibitor of CMV DNA polymerase (Mar *et al.*, 1985) so that this compound can also inhibit CMV. Acyclovir triphosphate is an obligate chain terminator and also a suicide inhibitor of herpesvirus DNA polymerase (Furman *et al.*, 1984). In combination, these characteristics potently inhibit CMV replication. However, the intracellular half-life of ACV-triphosphate is significantly shorter than that of GCV-triphosphate so that high drug levels and frequent dosing are needed for ACV to control CMV replication in vivo (Lowance *et al.*, 1999). Selectivity for virus-infected cells is achieved by UL97 activation and because ACV triphosphate is a better inhibitor of CMV-encoded DNA polymerase than cellular DNA polymerase.

The oral absorption of GCV is poor while that of ACV is better but also variable between individuals. Oral bioavailability of these compounds has been improved via esters which are absorbed and then cleaved in the intestinal wall and/or liver to release free compound. Valganciclovir is the valine ester of GCV. Valaciclovir is the valine ester of ACV.

Nucleotides

Cidofovir (CDV) is a nucleotide. These compounds are phosphonates, structurally equivalent to the nucleoside monophosphate but without the charge which would prevent the molecule crossing the plasma membrane. Cidofovir bypasses the UL97 step and is converted to the diphosphate (equivalent to the nucleoside triphosphate; see

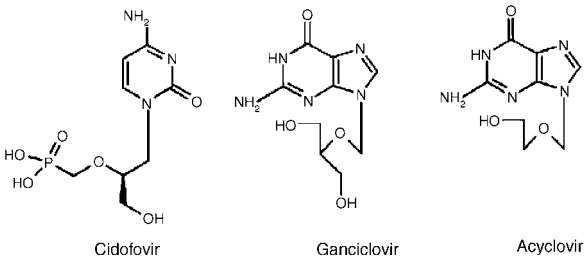

Fig. 66.1. Chemical structures of licensed antiviral drugs with activity against CMV in vivo.

Fig. 66.2) by cellular enzymes. The selectivity of CDV resides in the preferential inhibition of CMV DNA polymerase rather than cellular DNA polymerase by CDV diphosphate.

Foscarnet

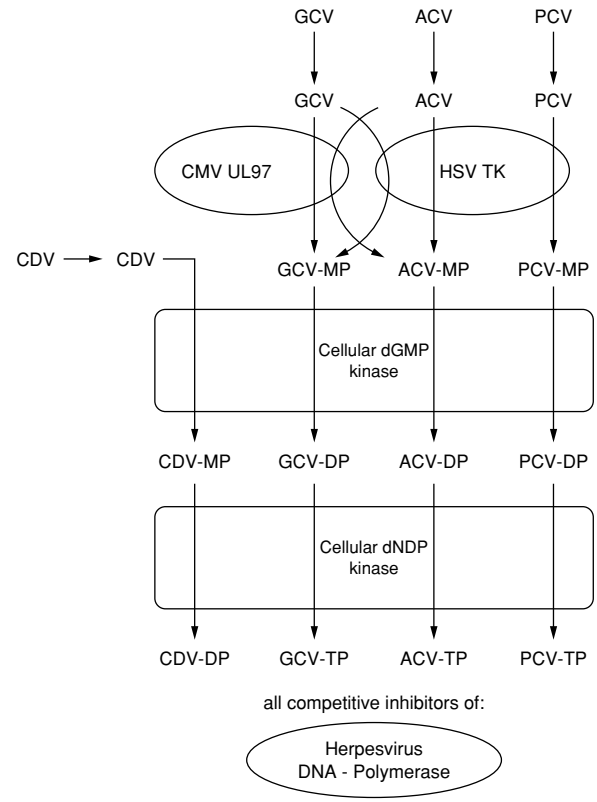
Pyrophosphate is eliminated when a phosphodiester bond is formed as a natural nucleoside triphosphate and is incorporated into a growing DNA chain. Foscarnet is structurally analogous to pyrophosphate and inhibits CMV DNA polymerase by binding to the enzymic site for pyrophosphate. Since pyrophosphate is one of the products of DNA enzyme activity, foscarnet is a product inhibitor, not a substrate inhibitor, and so does not compete with the natural nucleotides.

Fomivirsen

Molecules complementary (antisense) to mRNA bind mRNA to prevent expression of the encoded gene. For CMV, the antisense molecule fomivirsen binds to the major immediate-early transactivator gene. The half-life of this compound is long because it contains modified nucleosides such as phosphorothioates (substitution of sulfur into the phosphodiester background) and/or modified sugar residues, which are not readily degraded by host cell enzymes. In contrast to the other compounds mentioned above, fomvirsen is administered intravitreally only to the end-organ involved with CMV retinitis and so does not affect systemic CMV.

Clinical efficacy; challenges for achieving clinical benefit

Opportunistic infection with CMV occurs when a patient is immunocompromised because the immune system is immature (fetus/neonate), dysregulated (engrafting hematopoietic stem cell transplant), suppressed pharmacologically (solid organ transplant recipient) or suppressed by HIV infection (AIDS). The clinical benefits of treatment must therefore be seen in the context of these complex medical cases and require a detailed understanding of disease pathogenesis in each of the patient groups. Specifically, there is evidence (Rubin, 1991) that CMV has "direct effects" (where the virus can be seen histologically in the affected end-organ) and "indirect effects" where the virus is statistically associated with and may trigger conditions such as graft rejection, accelerated atherosclerosis, an immunosuppressive syndrome and death (not attributable to CMV end-organ disease). Antiviral treatment has the potential of inhibiting both direct and indirect effects but



Enzymes encoded by herpesviruses are shown as ovals.
Enzymes encoded by mammalian cells are shown as rectangles.

ACV = acyclovir
GCV = ganciclovir
PCV = penciclovir
MP = monophosphate
DP = diphosphate
TP = triphosphate
CDV = cidofovir
TK = thymidine kinase
UL97 = 97th gene in unique long region

Indirect effects			
Immunosuppression	+	+	
Rejection/GvHD	+	?	
Atherosclerosis	+		
Death		+	+

carefully controlled clinical trials are required to prove this definitively.

All seropositive individuals should be assumed to possess latent CMV capable of reactivation. Thus, if they become immunocompromised, CMV frequently reactivates from latency and may cause disease (reactivation infection). In addition, organs harvested from a seropositive individual may transmit virus (Grundy *et al.*, 1988), irrespective of whether the recipient is seronegative (primary infection) or seropositive (reinfection).

Table 66.2. Implications of the CMV viral load results from 1975

CMV is a systemic infection
Sampling of urine can provide a paradigm of CMV replication in inaccessible target organs
There may be a threshold value of viral load above which disease becomes common
Antiviral therapy may have clinical benefits even if it cannot completely stop virus replication
A short duration of therapy may provide clinical benefit, even though virus excretion continues for years

Pathogenesis

Viremia and viral load

Most CMV end-organ disease in the immunocompromized is caused by viremic spread to multiple organs (Table 66.1). The risk of CMV disease correlates strongly with high CMV viral loads as first described in 1975 by Stagno and colleagues (Stagno *et al.*, 1975). They compared viruria in neonates with symptomatic congenital, asymptomatic congenital, or perinatal infection. The group with CMV disease had, on average, one log higher viruria than those with asymptomatic congenital infection, who in turn had an average one log higher viruria than those with perinatal infection (see Fig. 66.3). This observation has a series of implications for understanding pathogenesis and for focussing antiviral therapy (see Table 66.2). For example, the results suggested that there might be a threshold viral load above which CMV disease became common. This possibility has been investigated using

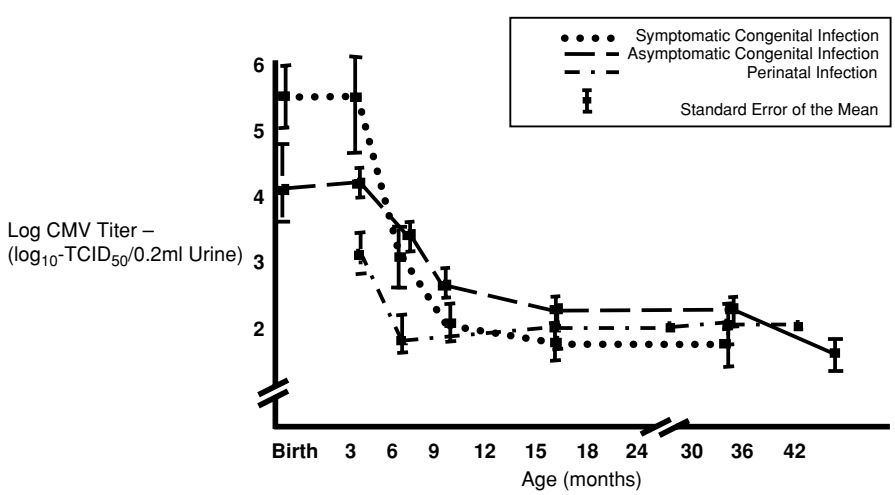

Fig. 66.3. CMV load From Stagno *et al.*, 1975.

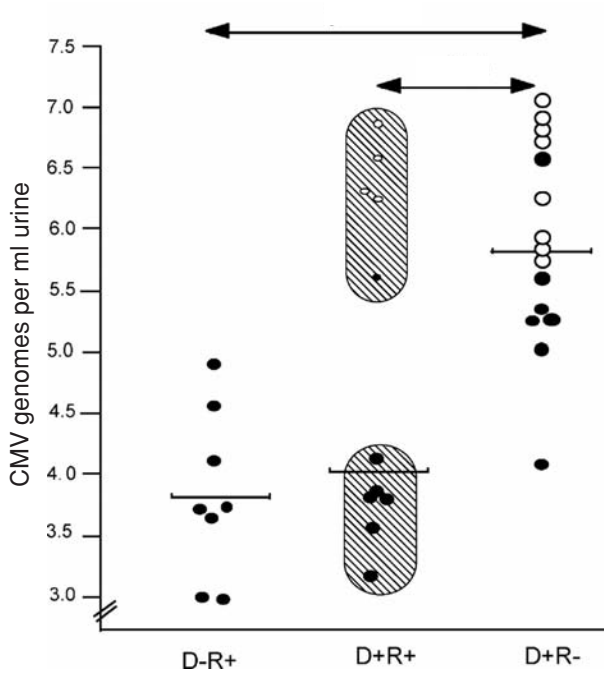

Fig. 66.4. Inter-relationships between peak CMV viral load, donor recipient serostatus and CMV disease in 35 patients with active CMV infection after renal transplantation. (Reprinted with permission from Cope, 1997b)

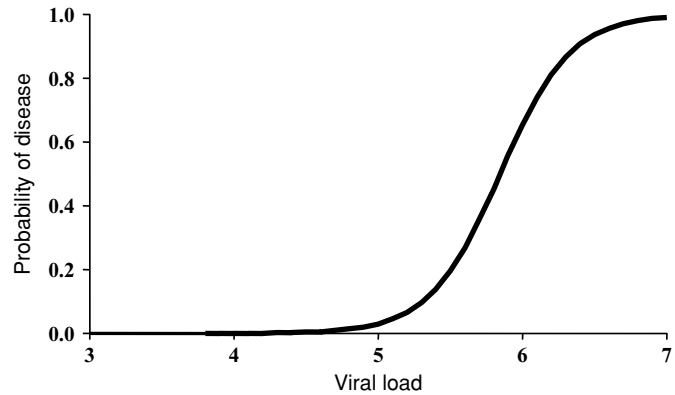

Fig. 66.5. The threshold concept From Cope, 1997b

quantitative-competitive PCR (QCPCR), which showed that, after renal transplant, a significant correlation is apparent (Cope *et al.*, 1997b) between the median values of maximum viruria post-transplant and the presence of CMV disease (see Fig. 66.4). The same is true when viral load is measured in blood (Hassan-Walker *et al.*, 1999) from renal transplant, liver transplant, and stem cell transplant patients, with CMV viral loads in the blood significantly greater in patients with CMV disease in each case (Cope *et al.*, 1997a,b; Gor *et al.*, 1998).

Donor/recipient serostatus at the time of transplant also identifies (Betts *et al.*, 1977) patients at risk of CMV disease (e.g. see Fig. 66.4). For recipients of solid organs, highest risk groups are D+R− (ie donor seropositive, recipient seronegative), followed by D+R+, then D−R+. These groups represent primary infection, reinfection plus reactivation and reactivation infections, respectively. For stem cell transplant recipients, the highest risk is D−R+, followed by D+R+, then D+R−. These groups correspond to reactivation, reactivation in the presence of marrow from immune donors and possible transmission of virus from donor marrow, respectively. In addition, multiple studies in all transplant patient groups identified viremia as a risk factor for CMV disease (Meyers *et al.*, 1990). Multivariate statistical analyses showed that for all patient populations, high viral load remained a risk factor for CMV disease after viremia and donor/recipient serostatus had been controlled statistically. In contrast, donor/recipient serostatus and viremia were no longer statistically significant once viral load had been controlled (Cope *et al.*, 1997a,b; Gor *et al.*, 1998) . Thus, high viral load is the major determinant of CMV disease and the classically defined risk factors of donor/recipient serostatus and viremia are markers of CMV disease because of their association with high viral load. In addition, the relationship between increasing viral load and disease is non-linear, with a threshold value above which CMV disease is much more common (Cope *et al.*, 1997a,b) (Fig. 66.5). This finding implies (Table 66.2) that potent prevention of disease could be achieved if drugs were deployed to prevent viral load exceeding critical values.

Serial measurements of viremia in several groups of immunocompromized patients demonstrated that CMV replicates with rapid dynamics, approximating to a doubling time (viral load increasing) or half-life (viral load decreasing) of one day (Emery *et al.*, 1999). The half-life is even shorter among patients experiencing primary infection (Emery *et al.*, 2002). This means that its reputation as a "slowly growing" virus is undeserved and that drugs of high potency are required to interfere with its replication. Thus, viral load measurements explain much of the pathogenesis of CMV disease and are important for understanding disease processes, for targeting the deployment of antiviral drugs, for measuring the success of antiviral therapy and for predicting the development of resistance (see later).

Disease processes within infected organs

Direct effects

Much of the end-organ disease caused by CMV can be attributed to *lysis*, i.e., destruction of cells as a direct result of virus replication. This can literally be seen clearly in the special case of the retinal cells destroyed by CMV (i.e. retinitis) but similar processes probably account for hearing loss, hepatitis, adrenalitis, gastrointestinal tract ulceration, encephalitis, and polyradiculopathy. In all of these cases, CMV can be seen histopathologically in biopsies, can be cultured from biopsies (showing productive replication) and responds to antiviral therapy. In contrast, some other diseases associated with CMV may be triggered by the virus, but may be caused by immune responses.

CMV pneumonitis appears typically in the second month post stem cell transplant after patients have had CMV viremia and asymptomatic CMV lung infection as shown by bronchial lavage at day 35 (Schmidt *et al.*, 1991). Thus, marrow engraftment, often associated with GvHD, represents a risk factor for CMV pneumonitis, implying that an aberrant immune response may contribute to disease (for review, see Grundy *et al.*, 1987). However, CMV can also occur before engraftment. Once established, CMV pneumonitis responds very poorly to ganciclovir alone, but the addition of immunoglobulin may give an improved response rate (Ljungman *et al.*, 1992). A cytokine-driven disease caused by abnormal cell-mediated effectors is suspected and, if correct, could explain why CMV pneumonitis is uncommon in AIDS patients with low CD4 counts. An alternative hypothesis is that the pulmonary toxicity of chemotherapy and/or irradiation causes damage which predisposes to viral pneumonia when viral replication occurs in the lung following transplantation (Schmidt *et al.*, 1991). A corollary to the former hypothesis (Grundy *et al.*, 1987) was that restoration of the immune deficit in AIDS patients with anti-retroviral medication, might trigger CMV pneumonitis. Although we are unaware of any such cases of CMV pneumonitis in AIDS patients given HAART, an inflammatory response to CMV is commonly seen in the *eye*, with corresponding increased levels of patient morbidity (Karavellas *et al.*, 1999).

Indirect effects

CMV is associated with an increased incidence of acute graft rejection. The presumed pathogenesis involves CMV infection of the transplanted organ acting like a transplantation antigen, marking the organ for immune attack. Evidence for CMV playing this pathogenic role includes statistical association (Grattan *et al.*, 1989), detection of CMV in organs undergoing rejection, apparent response of late rejection to ganciclovir therapy in an uncontrolled study (Reinke *et al.*, 1994), and a significant reduction in biopsy-proven acute graft rejection among patients randomized to high-dose valaciclovir in a placebo-controlled trial of prophylaxis after renal transplant (Lowance *et al.*, 1999).

CMV is also associated with accelerated atherosclerosis after heart transplantation (Grattan *et al.*, 1989). CMV persists in monocytes/macrophages that could be attracted to sites of graft atheroma, either bringing CMV to that site or facilitating the formation of foam cells laden with oxidized lipids (Guetta *et al.*, 1997). CMV major immediate-early protein binds p53 in arterial smooth muscle cells (Speir *et al.*, 1994) suggesting that CMV could reduce apoptosis leading to proliferation of such cells. The US28 gene of CMV encodes a chemokine receptor which, once transferred experimentally to smooth muscle cells, confers the ability to migrate towards a source of chemokines. Thus, CMV infection might stimulate chemotactic mobility of these cells towards a site of inflammation (Streblow *et al.*, 1999). Finally, CMV stimulates the formation of reactive oxidized intermediates and could contribute further to the progression of atherosclerosis (Speir *et al.*, 1996). Irrespective of the mechanism(s), follow-up of heart allograft patients who took part in a placebo-controlled trial of GCV reported reduced accelerated atherosclerosis among those allocated the drug (Valantine *et al.*, 1999), so replicating in humans what had previously been shown with rat CMV in rats (Lemstrom *et al.*, 1997).

CMV infection is associated with an increased incidence of bacterial or fungal superinfection (Falagas *et al.*, 1996; Nichols *et al.*, 2002) follow-up of the heart allograft patients mentioned above demonstrated reduced fungal infection in those randomized to receive GCV (Wagner *et al.*, 1995). This implies that CMV is functionally immunosuppressive and possible mechanisms have been reviewed recently (Boeckh and Nichols, 2003). If CMV does contribute to the net level of immuosuppression, this could explain why it is associated with EBV-induced lymphoproliferative disease. It could also explain why AIDS patients with first episode CMV retinitis have a significantly higher mortality rate if their CMV viral load in blood is above the median of the whole group of patients (Bowen *et al.*, 1996) and why the death rate (in the pre-HAART era) was associated more strongly with CMV viral load than with HIV viral load (Spector *et al.*, 1999). Recent results show that this same effect is still present in the era of HAART (Deayton *et al.*, 2004).

Clinical manifestations of CMV end-organ disease

The major clinical manifestations of CMV disease in different groups of immunocompromised patients are summarized in Table 66.1. These should be defined with

reference to the criteria laid down at the International CMV Workshop (Ljungman *et al.*, 2002) which include: compatible clinical features plus signs of end-organ dysfunction plus demonstration of CMV in the affected organ (exception retina). In particular, diseases should be described in terms of the body system affected and the term "CMV syndrome" should be avoided.

Fever/leukopenia

CMV viremia is often associated with prolonged spiking fever (e.g. $>38\,^{\circ}C$ on two consecutive days), with or without leukopenia. These constitutional symptoms may resolve spontaneously or may lead to end-organ disease. Other causes of fever (e.g., bacteremia) and leukopenia (e.g., doses of immunosuppressive drugs) must be excluded. CMV-related marrow graft failure has been described as a rare complication after stem cell transplant.

Hepatitis

Transaminases may be raised (e.g., $>2.5\times$ upper limit of normal), with or without alkaline phosphatase representing an obstructive component. Hyperbilirubinemia may be present but frank jaundice is uncommon. Hepatitis usually resolves spontaneously but may herald other end-organ disease. It is predominantly seen in solid organ transplant recipients, with a predeliction to liver transplantation.

Gastrointestinal disease

CMV may involve the gastrointestinal tract anywhere from the mouth to the anus. The presentation is usually with pain, often accompanied by fever. Esophagitis, odynophagia and abdominal pain mimicking perforation indicate involvement of the esophagus/colon, respectively. Endoscopy reveals mucosal ulcerations, with or without *Candida* superinfection. The ulcers respond slowly to anti-CMV treatment and may perforate and/or hemorrhage.

Retinitis

This can occur in any immunocompromised patient but is most common in AIDS. Symptoms, if present, include "floaters," flashing lights, and/or loss of central vision. Small peripheral lesions may be unnoticed by the patient; lesions involving the macula may be imminently sight-threatening and demand immediate treatment. Involvement of a large proportion of the retina interrupts retinal/scleral attachment and represents a risk factor for retinal detachment. Before the availability of HAART, most patients had progression of retinitis and the goal of treatment was to preserve vision (for review, see Jacobson, 1997). Treatment with HAART may be followed by vitritis (see Pathogenesis section), with paradoxical impaired vision despite better control of retinitis. Retinitis is also seen in the neonates born with symptomatic congenital CMV infection and rarely in transplant recipients (Crippa *et al.*, 2001).

Encephalitis

In AIDS patients, CMV reaches the brain by one of two routes; extension of a neighboring endotheliitis or via the choroid plexus. In the former case, the encephalitis follows a subacute course, difficult to distinguish from HIV dementia. In the latter, necrotizing ventricular encephalitis produces cranial nerve defects, nystagmus and ventriculomegaly (reviewed in Griffiths and McLaughlin, 1997). In both cases, response to treatment is poor. Encephalitis is a rare complication in stem cell transplant recipients.

Polyradiculopathy

An AIDS patient with a very low CD4 count presents with subacute weakness of the lower limbs, with or without bladder paralysis. Lumbar puncture reveals abundant polymorphonuclear leukocytes in the CSF. Immediate treatment is indicated but the clinical response is poor.

Pneumonitis

Most cases occur after stem cell transplantation with or without concurrent graft versus host disease (see Pathogenesis section). There is rapid onset of dyspnea plus hypoxia. Chest X-ray may be relatively clear initially but progresses to show interstitial infiltrates. Co-infection with aspergillus is common in stem cell transplant recipients. There is a high mortality, with poor response to treatment (Ljungman *et al.*, 1992).

Hearing loss

This may be apparent at birth in neonates born with symptomatic congenital CMV infection. It is also clear that hearing may be normal at birth but may deteriorate months or years later, irrespective of whether symptoms were present at birth. The hearing loss may be bilateral or unilateral.

Laboratory diagnosis

Detection of viremia

This can be performed by any published method which has been shown to provide a good positive predictive value for CMV disease, e.g. 50%–60% for the patient population to

Table 66.3. Strategies for chemotherapy of CMV

Term used	When drug given	Risk of disease	Acceptable toxicity	Treatment decision prompted by:
True prophylaxis	Before active infection	Low	None	Clinician
Delayed prophylaxis	Before active infection but after rejection	Medium	Low	Clinician
Suppression	After peripheral detection of virus	Medium	Low	Laboratory
Pre-emptive therapy	After systemic detection of virus	High	Medium	Laboratory
Treatment	Once disease apparent	Established	High	Both

be followed. Thus, the rapid diagnostic techniques using cell culture amplification testing of virus (termed DEAFF testing in Europe (Griffiths *et al.*, 1984) and shell-vial in the USA (Gleaves *et al.*, 1984) are no longer sufficiently sensitive and should be replaced with newer methods. Examples include PCR in whole blood (Kidd *et al.*, 1993), PCR in plasma (Spector *et al.*, 1992), ultrasensitive quantitative plasma PCR assays (Boeckh *et al.*, 1996) and antigenemia (The *et al.*, 1990). Recent results demonstrate that PCR from whole blood is superior to either PCR in plasma or peripheral blood leukocytes (Razonable *et al.*, 2002) and has the advantage of not requiring separation of blood specimens with the attendant risks of contamination and mis-labeling. A randomized trial has shown PCR to be superior to conventional cell culture for deciding when to initiate pre-emptive therapy (Einsele *et al.*, 1995). Laboratory protocols differ and it is important that all aspects of each method are followed in detail including sample processing and virus detection. These have been optimized to avoid the detection of latent virus while providing good sensitivity for predicting disease **not** necessarily the highest sensitivity for detecting asymptomatic infection (see Fig. 66.5). Thus, it is not possible to "mix and match" different aspects of PCR protocols.

CNS involvement

PCR of CSF is the method of choice for diagnosing CMV CNS infection (Shinkai *et al.*, 1995).

DEAFF/Shell vial

This method is still sufficiently sensitive and robust to diagnose CMV lung infection using bronchoalveolar lavage fluid. Cells from this fluid can also be cytocentrifuged and stained with monoclonal antibodies but this approach, while more rapid, lacks sensitivity compared to DEAFF/shell vial amplification. The assay is also very well suited to detect CMV in biopsy specimens (e.g., lung, gastrointestinal tissue).

Histopathology

This is performed on tissue biopsies to detect classic Cowdry type A intranuclear "Owl's eye" inclusion bodies. It is insensitive and so has a high specificity for disease (Mattes *et al.*, 2000).

Cell culture

This is performed on tissue biopsies after tissue is minced and inoculated directly on to cells. It is slow but sensitive.

Serology

Many enzyme immunoassays are commercially available for the detection of CMV IgG antibodies pre-transplant in both donor and recipient. Serologic testing has no role to play post-transplant.

Clinical indications for antiviral prophylaxis and dosage regimens

Management

The principles of managing CMV infection and disease in the immunocompromised host are to anticipate their development, to define policies for monitoring patients routinely for the presence of viremia according to their baseline risk of CMV disease, and to enhance surveillance if patients develop a condition likely to increase their risk of CMV disease. Using the principles of evidence-based medicine, the patient will then be offered prophylaxis or pre-emptive therapy based upon an assessment of their individualized risk of disease, together with data from controlled clinical trials in the same patient group supporting the efficacy and safety of possible antiviral interventions.

Strategies for deploying antiviral agents

Different strategies have been devised for controlling CMV disease based on the efficacies and toxicities of the drugs available at present (summarized in Table 66.3).

True prophylaxis

This strategy should be followed where baseline risk of disease is high, the chance of severe disease is also high and where at least one double-blind, randomized, placebo-controlled trial supports the efficacy and safety of prophylaxis in the target population. The drug is given from the time of transplant onwards (or from the time of engraftment in the case of GCV in stem cell transplants) and continued for the duration studied in the controlled clinical trial which provided evidence for its use. This is termed "true prophylaxis" because, from a virologic perspective, it administers the drug before there is active virus replication. By giving the drug early, prophylaxis may provide clinical benefits even if the drug has relatively low antiviral potency.

Delayed prophylaxis

At baseline, a decision was made that true prophylaxis was not indicated. However, the patient's situation has changed eg because augmented immunosuppression is required to control an episode of graft rejection and so it is decided to start prophylaxis now (Hibberd *et al.*, 1995). This is still termed "prophylaxis" because the drug is given before there is active virus replication and a drug with relatively low potency may be used.

Suppression

Some laboratories monitor weekly samples of urine and/or saliva from transplant patients and process them by a method shown to provide a moderate positive predictive value for CMV disease, e.g., 30% (Kidd *et al.*, 1993). If CMV is detected, an antiviral drug is given with the intention of suppressing virus replication below the level needed to cause viremia. A drug with moderate potency is required to keep CMV suppressed.

Pre-emptive therapy

This term describes intervention when the results of laboratory tests indicate that a patient is at imminent risk of CMV disease (Rubin, 1991). Nowadays it refers to detection of viremia in any immunocompromised patient but in the past was also used when asymptomatic lung infection was detected after stem cell transplantation (Schmidt *et al.*, 1991). In the first example, the patient should be monitored by collecting weekly samples of blood processed by laboratory methods known to provide a high positive predictive value for CMV disease, e.g., 50%–60% (Kidd *et al.*, 1993). The objective is to give an antiviral drug with the intention of halting CMV viremia before it reaches the high viral loads required to cause disease. A drug with high potency is therefore required.

Decision-points for starting pre-emptive therapy must be based upon the results of clinicopathologic studies with the assay under evaluation. Examples include qualitative detection of viremia by PCR or antigenemia where the assay level of detection has been shown to be associated with a high risk of disease, or two consecutive samples PCR-positive. Alternatively, if samples are processed by real-time quantitative PCR, then any value above a pre-determined cut-off should trigger antiviral intervention. The results of viral dynamic assessments can also be applied to this problem; patients at risk of disease can be identified by the absolute value of viral load found in the first PCR-positive sample, coupled with an assessment of individual viral dynamics by calculating the rate of increase from the last PCR-negative sample (Emery *et al.*, 2000). All of these approaches work well in clinical practice and comparative studies are required to determine if any one of them is superior to the others.

The treatment of neonates born with symptomatic congenital CMV infection also fits into this category because the objective is to prevent new end-organ damage.

Treatment of established disease

When a patient meets the case definition of CMV disease because he/she has compatible symptoms and signs, together with detection of CMV in the affected organ, a highly potent drug is required which will penetrate the affected organ and resolve the disease, including any immunopathologic components.

Results of double-blind, randomized, placebo-controlled trials

Results of published trials of licensed drugs defined according to these criteria are given in Table 66.4. It will be seen that the most potent drug *in vitro*, ganciclovir, has been subjected to several such clinical trials while foscarnet and cidofovir have not. Other agents such as interferon-alpha, acyclovir, valaciclovir and immunoglobulin, have also been evaluated although they were traditionally not thought to have useful anti-CMV activity.

For the endpoint of CMV infection, Table 66.4 shows that, in addition to ganciclovir (Balfour *et al.*, 1989; Cheeseman *et al.*, 1979; Lui *et al.*, 1992), interferon alpha (Cheeseman *et al.*, 1979; Lui *et al.*, 1992; Ljungman *et al.*, 1992) and acyclovir (Lowance *et al.*, 1999; Balfour *et al.*, 1989; Prentice *et al.*, 1994) have activity against CMV in vivo. The only two studies not to show an effect were the two studies of

immunoglobulin (Metselaar *et al.*, 1989; Snydman *et al.*, 1993). This implies that, if immunoglobulin has a role in the prophylaxis of CMV disease, it may not work by inhibiting CMV replication.

For the endpoint of CMV disease, Table 66.4 shows that ganciclovir failed to demonstrate a significantly better resolution of established CMV disease than placebo (Reed *et al.*, 1990). Part of this disappointing outcome may be attributed to the low dose (2.5 mg/kg t.i.d.) and/or short duration used (14 days) to treat gastrointestinal disease in stem cell transplant patients (Reed *et al.*, 1990). Nevertheless, it illustrates the difficulty of treating established CMV disease and so argues that the other strategies, which aim to prevent CMV disease, should always be pursued in preference to waiting for disease to present. Ganciclovir did reduce CMV disease when used in the suppressive mode for stem cell transplant patients (Goodrich *et al.*, 1991). It also had a significant benefit when used in one (Goodrich *et al.*, 1993) of two trials of prophylaxis after stem cell transplant; the second study (Winston *et al.*, 1993) showed a strong trend in favor of GCV which just failed to reach conventional statistical significance. Ganciclovir also significantly reduced CMV disease following prophylaxis given orally to liver transplant patients (Gane *et al.*, 1997) and intravenously to heart transplant patients (Macdonald *et al.*, 1995; Merigan *et al.*, 1992). However, benefit after heart transplant was evident only in the low risk group, with no effect in the D+R− group of one study (Merigan *et al.*, 1992), whereas the opposite outcome was seen in a second (Macdonald *et al.*, 1995). This difference might result from the longer treatment course in the latter study, together with a design difference such that patients experiencing rejection were given additional doses of GCV. Prophylactic ACV significantly reduced CMV disease after renal transplant (Balfour *et al.*, 1989), as did prophylactic valaciclovir (Lowance *et al.*, 1999). In a prophylaxis trial after stem cell transplantation, acyclovir significantly decreased CMV viremia and showed a non-significant trend towards reduced CMV disease (Prentice *et al.*, 1994). A trial of immunoglobulin prophylaxis showed reduced "CMV syndrome" in liver transplant recipients despite having no significant effect on CMV infection (Snydman *et al.*, 1993). Sub-group analysis showed an effect on CMV-associated fungal superinfection (part of the pre-defined "CMV syndrome") so it remains possible that the immunoglobulin predominantly reduces fungal rather than CMV infection. CMV-specific immune globulin and a gH monoclonal antibody were ineffective in stem cell tranplant recipients (Boeckh *et al.*, 2001; Bowden *et al.*, 1991).

Table 66.4 also summarizes the impact of these drugs on the indirect effects of CMV infection. The number of deaths in the solid organ transplant populations is too low to provide the statistical power to address this endpoint. After stem cell transplant, GCV significantly improved survival when used suppressively (Goodrich *et al.*, 1991). However, when used prophylactically, no effect was seen (Goodrich *et al.*, 1993; Winston *et al.*, 1993). This was not a problem of small sample size and neither study demonstrated even a trend in favor of ganciclovir. The most likely explanations are that (i) some patients with viremia still received preemptive therapy (Goodrich *et al.*, 1993) so reducing CMV-induced mortality in both arms (ii) neutropenia induced by prophylactic GCV predisposed patients to succumb to bacterial or fungal superinfections, so mitigating the potential benefits of this drug. Overall, these studies indicate that GCV is too toxic a compound to be used for prophylaxis after stem cell transplant, although it is literally life-saving

when used in a suppressive mode (Goodrich *et al.*, 1991). This illustrates that, in prophylaxis, all patients are exposed to side-effects and that suppression or preemptive therapy, by limiting the number of patients exposed to the drug, can produce an enhanced therapeutic ratio. In contrast, ACV prophylaxis after stem cell transplant produced a survival benefit (Prentice *et al.*, 1994), presumably because its more modest efficacy was not offset by serious toxicity. After renal transplant, VACV produced a marked reduction in biopsy-proven acute graft rejection corresponding to a 50% decrease in incidence among seronegative recipients at risk of primary infection (Lowance *et al.*, 1999). The effects in seropositive recipients were smaller, implying that CMV (rather than another herpesvirus susceptible to the drug) is responsible for this indirect effect and that most CMV-induced graft rejection occurs in the subset of patients with primary infection. Following heart transplantation, GCV significantly reduced fungal infections (Wagner *et al.*, 1995) and accelerated atherosclerosis (Valantine *et al.*, 1999).

Table 66.5 summarizes randomized studies which compared two anti-CMV strategies. Boeckh *et al.* (1996) compared antigenemia-guided preemptive therapy with ganciclovir prophylaxis at engraftment and found a higher CMV disease rate at day 100 with pre-emptive therapy; however, there was no statistically significant difference at day 400 between the two groups. Invasive bacterial and fungal infections were more common with GCV prophylaxis, resulting in similar mortality rates at day 400 (Boeckh *et al.*, 1996). Humar *et al.* compared GCV based on a surveillance BAL at day 35 with antigenemia-guided preemptive therapy and found these two strategies equivalent in a small randomized trial (Humar *et al.*, 2001). Reusser *et al.* compared foscarnet with GCV for preemptive therapy in stem cell transplant recipients (Reusser *et al.*, 2002). Survival without CMV disease was similar between the groups, however, GCV caused more neutropenia. Foscarnet was associated with more electrolyte imbalances but renal insufficiency was no different between the two groups. One trial by Winston *et al.* compared valacyclovir with ganciclovir prophylaxis in stem cell transplant recipients. The incidence of CMV disease was similar in both groups, however, the trial was not large enough to make meaningful conclusions (Winston *et al.*, 2003). Another small trial by Winston *et al.* compared sequential intravenous and oral ganciclovir with intravenous ganciclovir for 3 months in D+/R− liver transplant recipients (Winston and Busuttil, 2004). The incidence of CMV disease was not statistically different between the groups.

In liver transplant patients, prophylaxis with GCV is superior to prophylaxis with ACV (Winston *et al.*, 1995).

Prophylaxis	V-GCV				

A large randomized double-blind trial of valganciclovir versus oral GCV in D+/R− solid organ transplant recipients showed similar rates of CMV disease with the two compounds (Paya *et al.*, 2004). Neutropenia was observed more frequently with valganciclovir. In another randomized trial in AIDS patients with CMV retinitis valganciclovir showed similar activity to intravenous ganciclovir for treatment of retinitis (Martin *et al.*, 2002).

Additional randomized trials compared different methods of detecting CMV in blood for preemptive therapy and found equivalence between antigenemia and pp67 mRNA (Gerna *et al.*, 2003a,b) and IE mRNA (Gerna *et al.*, 2003a,b). An earlier randomized trial by Einsele *et al.* established that PCR-based detection by CMV viremia is superior to culture-based detection of viremia for initiation of preemptive therapy (Einsele *et al.*, 1995). A comparison of ganciclovir plus foscarnet (each at half dose) compared to full dose ganciclovir showed that these two drugs are not synergistic in humans when used for pre-emptive therapy (Mattes, 2004).

Aspects of CMV management in HIV-infected individuals

The introduction of highly active antiretroviral therapy (HAART) for HIV has dramatically changed the

Table 66.6. Relative merits of prophylaxis vs. pre-emptive therapy

Proposed advantages of prophylaxis
Proven benefit controlled clinical trials
• *CMV disease*
• *indirect effects*
Avoids complicated logistical problems
• *real-time laboratory assays*
• *organization of sample collection*
• *geographical location*
Protects against HSV, VZV
Overall, may be more cost-effective
• *costs of laboratory tests*
• *indirect effects CMV*
• *other herpesviruses*
Proposed advantages of pre-emptive therapy
Target resources on patients most at need (financial, skill)
Treat when viral load lower
• *shorter treatment*
• *reduced recurrences*
• *reduced resistance?*
Allows low level stimulation of immunity
• *reduces late-onset disease?*
Protects patients non-compliant with prophylaxis
It is possible that PET may also reduce indirect effects

From Snydman, 2006, Singh, 2006.

significance of CMV in HIV-infected individuals. There is now good evidence that in patients with CMV retinitis who have a sustained response to HAART, CMV viremia disappears promptly (Deayton *et al.*, 1999) and maintenance treatment can be discontinued without relapse of retinitis. Several groups have reported HAART-naïve patients with good CD4 (>150/μl) and HIV virologic responses (Lin *et al.*, 2002) to therapy who have been able to stop anti-CMV maintenance medications completely without disease progression (Whitcup *et al.*, 1999). Thus, intravenous or oral therapy (i.e., Valganciclovir (Martin *et al.*, 2002) can be used until the anticipated return of the patient's CMV-specific immunity. CMV disease can still occur within 4 months of HAART initiation despite adequate suppression of HIV replication (Jacobson *et al.*, 1997). Some patients also develop immune recovery vitritis when HAART is initiated at the time of CMV retinitis (Karavellas *et al.*, 1999; Whitcup *et al.*, 1999). Alternatives to intravenous and oral antivirals for the treatment of CMV retinitis are available. In the current era, intraocular implants are used primarily in salvage regimens (disease progression with first-line agents) or in patients for whom immunologic recovery with HAART is not anticipated.

Conclusions

1. Decisions about which drugs to recommend for particular treatment strategies must draw upon evidence-based medicine provided by the results of controlled clinical trials. Decisions must consider toxicity as well as efficacy.
2. For stem cell transplant patients, prophylaxis with ACV (Prentice *et al.*, 1994) or VACV (Lowance *et al.*, 1999) is recommended; however, virologic monitoring and pre-emptive therapy are still required to allow GCV to be administered (Goodrich *et al.*, 1991). Since the latter study showed that, of the samples of urine, saliva, and blood processed, only blood provided prognostic value, this conclusion probably applies to pre-emptive therapy as well.
3. The toxicity problems of GCV apply specifically to the stem cell transplant population where GCV and VACV have been shown to be equally potent in practice (Winston *et al.*, 2003). A head-to-head comparison of low dose GCV versus ACV for prophylaxis after liver transplant shows that GCV is superior (Winston *et al.*, 1995).
4. Prophylaxis and pre-emptive therapy are both effective strategies for preventing CMV disease. Their relative merits are hotly debated (see Table 66.6).
5. Similar data from AIDS patients cannot be presented because, remarkably, no trials have been designed based on these virologic criteria. Two trials (Feinberg *et al.*, 1998; Spector *et al.*, 1996) have been conducted of clinical prophylaxis but these are not the same as true prophylaxis because, at the time of randomization, although no patients had CMV disease, some of them would be expected to have asymptomatic infection. Indeed, the subsequent virologic studies show that oral GCV had its greatest effect when given to the subset receiving true prophylaxis and had little effect in the subset receiving pre-emptive therapy (Spector *et al.*, 1998). In contrast, the virologic studies of VACV demonstrated that this drug had its greatest effect when given for pre-emptive therapy (Griffiths *et al.*, 1998). This might be thought to imply that VACV is more potent in vivo than oral GCV but a randomized head-to-head comparison would be needed to test this possibility. Such a trial is unlikely to be conducted because the high dose of VACV chosen (2 g q.i.d.) was poorly tolerated by the AIDS patients (Feinberg *et al.*, 1998), although the same dose was safe when studied in renal transplant patients

(Lowance *et al.*, 1999). Furthermore, the incidence of CMV disease in the current era of HIV management has declined due to immune reconstitution following initiation of HAART.

6. The ACV and VACV studies do show that potent inhibition of CMV DNA polymerase by ACV-TP triphosphate can have clinical utility under some circumstances. In the renal transplant study, the authors provide evidence that plasma levels of ACV were higher than expected because of poor renal clearance, but were still lower than would be required to inhibit CMV based on in vitro data (Fletcher *et al.*, 1991), which demonstrates clearly that the IC50 levels produced by fibroblast cell cultures are misleadingly high.
7. Although the incidence of CMV end-organ disease has been dramatically reduced in both transplant and HIV patients, the indirect effects of CMV remain important. Recent data in unrelated donor or T-cell depleted stem cell transplant recipients demonstrate that preemptive therapy alone, although quite effective in reducing the risk of CMV disease, has not eliminated the survival disadvantage associated with CMV seropositivity (Boeckh and Nichols, 2004). In AIDS patients, CMV viremia remains an important factor for poor outcome in the era of highly-active antiretroviral therapy (Deayton *et al.*, 2004). Indeed, once CMV viremia was accounted for in multivariable models, HIV viral load was no longer associated significantly with death (Deayton *et al.*, 2004).
8. In the case of neonates born with symptomatic CMV infection with CNS involvement, a study by Kimberlin *et al.* (2003) shows that the proportion who develop progressive hearing loss can be decreased by a six week course of GCV at 6 mg/kg i.v. bid. Although this study was not placebo-controlled (due to the ethical problems of administering an intravenous placebo to neonates), the results of this seminal study are included here because they are clinically important and entirely consistent with the pathogenetic implications of neonatal viral load (see Fig. 66.3 and Table 66.2).

Resistance

Resistance to GCV maps to two genetic loci, UL97 and DNA polymerase. In general, changes in UL97 are common and confer low level resistance while changes in DNA polymerase are rare but some of them confer cross-resistance to other antiviral drugs.

Methods used to define resistance

It is important to note that both UL97 and DNA polymerase are large genes in which spontaneous polymorphisms exist. It is not therefore possible to sequence the gene from a patient, find a genetic change compared to the standard laboratory strain, AD169, and then conclude that resistance has developed. A mutation identified in a patient sample must be examined by marker transfer (site-directed mutagenesis) before it can be concluded that the mutation is responsible for conferring resistance. In the process of marker transfer, the genetic sequence is altered in a laboratory-adapted strain and it is proven that this change confers resistance to the antiviral drug by analyzing the phenotype in plaque reduction tests. To demonstrate that no additional changes have been introduced by mistake, the resistant strain should then be back-mutated to the wild type and it should be proven that sensitivity to the antiviral drug has returned. Given the slow evolution of cytopathic effect in vitro, these experiments are time-consuming, inefficient and expensive. In addition, the requirement for selection by means of ganciclovir is undesireable because it offers the potential of introducing additional changes at the in vitro passage level. However, recent technical changes have made ganciclovir selection now no longer necessary so it should become easier in the future for marker transfer experiments to be performed. These technical advantages include a particular strain that has been developed with a novel restriction enzyme site, the ability to use cosmid clones of the genome to reconstitute infectious viruses and the recent cloning of CMV as a bacterial artificial chromosome (Adler *et al.*, 2003; Chou *et al.*, 2002). All of the mutations described in the sections which follow have been identified in clinical samples and proven by marker transfer experiments to confer resistance.

Gene UL 97

Gene UL97 produces a serine/threonine kinase enzyme which is essential for virus replication. Through studies with a gene deleted virus, and with an experimental drug (maribavir) which inhibits gene UL97, it was shown that UL97 is important for nuclear egress (Krosky *et al.*, 2003). It has also recently been shown that UL97 phosphorylates elongation factor 1 delta at codon serine 133. This is exactly the biochemical change made by the cellular CDC2 plus cyclin B when they prepare the nuclear envelope for dissolution just prior to mitosis. It is therefore tempting to suggest that UL97 mimics this cellular pathway to prepare the cell to release into the cytoplasm virions synthesized in the nucleus (Kawaguchi and Kato, 2003).

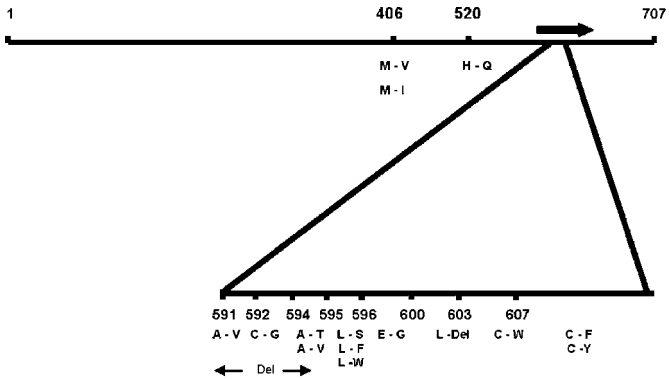

Fig. 66.6. UL97 mutations conferring GCV resistance. (From Chen, 2002.)

Figure 66.6 shows the mutations which confer ganciclovir resistance in gene UL97. Many of these individual mutations have been transferred to recombinant vaccinia viruses and shown to significantly reduce phosphorylation of ganciclovir compared to wild-type. However, the reductions in phosphorylation are rather low (e.g., 10% reduction for the deletion of 590–593). If CMV replication continues in the presence of ganciclovir then additional mutations can occur in UL97 which do not themselves confer resistance but act to partially restore the efficiency of the enzyme. For example, by transferring the individual mutations into recombinant vaccinia viruses, Chou and colleagues were able to show that D605E compensates for an A594P mutation (Chou *et al.*, 2000).

When these UL97 mutants are propagated in vitro they appear to have identical replication kinetics in one step growth curves (Chou *et al.*, 2002). This makes it very difficult to identify the true significance of these mutations in vivo and represents one of many deficiencies of studying this virus in fibroblasts (for review, see Griffiths, 2002). Fortunately, the high rate of replication demonstrated in patients explains how CMV variants resistant to GCV can evolve, and provides a basis for calculating their relative fitness compared to wild type (Emery *et al.*, 1999). These mathematical modelling techniques can also be used to explain and predict the circumstances under which resistant strains become prominent (Emery and Griffiths, 2000). In summary, short courses of GCV are unlikely to select resistant strains, but long or repeated courses, especially with oral GCV, provide ideal opportunities for resistant strains to flourish. They also demonstrate why resistant strains are cultured infrequently in practice; the process of incubating mixed populations of strains for 3–4 weeks in cell cultures lacking GCV allows the wild-type virus to out-compete the mutant strain, leading to the incorrect conclusion that resistance is not present in vivo.

Gene UL54 (DNA polymerase)

Fig. 66.7 shows a schematic representation of the DNA polymerase gene showing the important catalytic sites and areas where resistance to ganciclovir or foscarnet or cidofovir have been mapped. In contrast to the finding with UL97 mutants, changes in UL54 often confer a growth disadvantage upon virus replication in vitro (Chou *et al.*, 2003) which may help explain the infrequency of their detection in patients.

Although the three-dimensional structure of CMV DNA polymerase is not known, important insights into its mechanism of action can be gleaned by comparison with the known structures of related enzymes (Chou *et al.*, 2003). Changes at the exonuclase site (Fig. 66.7) probably facilitate pyrophosphorolysis (i.e., the reverse reaction of DNA polymerization) which results in the excision of an incorporated drug moiety. Changes in region V interfere with the normal function of "thumb" (GCV/CDV cross-resistance) and "fingers" pyrophosphate exchange and acceptance of the incoming nucleotide (GCV/Foscarnet cross-resistance). Changes at other regions of the enzyme may reflect subtle conformational effects on these or other functions of the enzyme. At least one such change can confer hypersensitivity to foscarnet, a phenomenon which was first described for HSV but which is now frequently encountered in HIV.

Patterns of cross-resistance

Given the structural similarity of, GCV and ACV (Fig. 66.1), it would be expected that virus resistant to one compound exhibits cross-resistance to the other. This is difficult to prove because fibroblast cell cultures do not demonstrate the sensitivity of CMV to ACV, let alone its resistance. In practice, GCV has been used so widely that the small number of resistant strains available for study have been selected through the use of this drug and all of these viruses should be assumed to exhibit cross-resistance to ACV.

If strains of CMV resistant to GCV due to mutations in UL97 are encountered in clinical practice and alternative treatment is required then foscarnet is the first choice. Cidofovir is an alternative which, by bypassing UL97, has the advantage of avoiding the genetic change commonly selected for under GCV pressure (Safrin *et al.*, 1997).

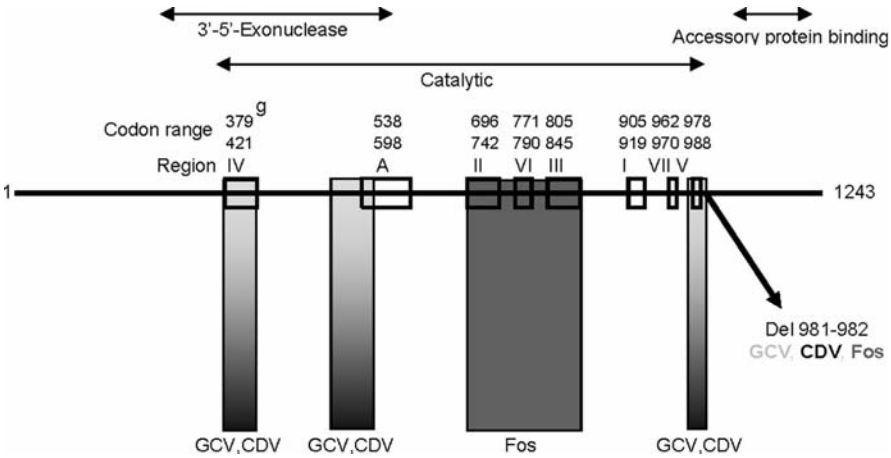

Fig. 66.7. Mutations in CMV DNA polymerase which confer antiviral resistance. (From Chou, 2002, 2003.)

If resistance to GCV has been acquired through mutations in UL54 then precise details of the genetic changes are required. Many of the changes confer cross-resistance to cidofovir (see Fig. 66.7) so this drug is not usually indicated. Foscarnet remains the drug of choice for UL54 mutants; although one particular mutant exhibits low-level cross-resistance to ganciclovir, cidofovir and foscarnet.

Recognition of resistance in clinical practice

The early studies of CMV in AIDS patients receiving chronic GCV therapy were important because they provided laboratory strains to allow a definition of biochemical resistance in vitro (Drew *et al.*, 1991; Erice *et al.*, 1989). However, they underestimated the incidence of resistance because viruses from samples of urine or blood were propagated in cell cultures in vitro. Most such clinical samples contain mixed populations of wild-type and resistant strains of CMV. As explained earlier, the UL97 mutants have decreased fitness in the absence of GCV (Emery *et al.*, 1999). As a result, they are readily out-competed by wild strains in the laboratory, especially given the requirement for serial passage in vitro in order to provide high titer inocula for the plaque reduction test. This problem can be bypassed by either collecting samples from patients with CMV end-organ disease, which are less likely to contain mixed populations of virus, or by using molecular techniques to detect genetic markers of resistance directly in the patient samples without passage in vitro.

Bowen *et al.* used a point mutation assay and sequencing to identify GCV resistance in 10/45 (22%) AIDS patients with CMV retinitis (Bowen *et al.*, 1998). Limaye and colleagues (Limaye *et al.*, 2000) examined blood isolates from 25 cases of CMV disease in recipients of solid organ transplants and found GCV resistance in 5 (20%). Liu *et al.* (2000) showed that virtually all CMV DNA extracts from the eyes of untreated AIDS patients had wild type UL97 sequences, consistent with the concept that UL97 mutants have impaired fitness in the absence of GCV. Hu *et al.* (2002) identified 13 (15%) UL97 mutations in vitreus samples from 87 AIDS patients and found the same mutations in the blood of 11 of these patients, showing that changes in

Table 66.7. Management algorithm for suspected resistant CMV

When to suspect drug resistance

1. Drug-naïve patient:
   - If viremia fails to disappear with preemptive therapy
     - culture-positive > 3 weeks
     - increasing antigenemia levels > 2 weeks
     - increasing PCR levels > 2 week
   - If viremia appears during prophylaxis
     - Any culture positivity
     - Increasing level for > 2 weeks

Diagnostic

Obtain blood PCR or DNA from site and sequence UL97 (UL54)

Drug therapy:
- *Check compliance/dose/schedule*
- *swap to alternative antiviral agent*

General
- Reduction of immunosuppression if feasible (in severe cases or resistant CMV disease "sacrificing" the transplanted organ may be considered or necessary)

If toxicity appears:
- *GCV/foscarnet each at half-dose*
- Novel compounds needed

blood strains frequently mirror those in the eye. Boivan et al used restriction fragment length polymorphisms and direct sequencing of UL97 to detect resistant strains in approximately 12% of AIDS patients receiving valganciclovir and showed that UL97 sequencing directly from the blood correlated well with disease progression (Boivin *et al.*, 2001). They also showed UL97 sequence discordance when the same samples were passed in cell culture, consistent with the concept that cell cultures preferentially select wild type isolates during passage in vitro (Gilbert and Boivin, 2003).

It should now be clear that resistance to GCV has been underestimated in the past. New drugs targeted at different CMV genes are required (see Chapter 68) and randomized controlled trials are essential to define their efficacy.

The basic principles to help avoid the development of resistance are to reduce CMV replication in the presence of drug (i.e., treat with potent compounds and adequate doses for a short time and then stop therapy) and to treat promptly at an early stage (when the virus load is low) (Table 66.7). Serially monitored patients with increasing viral loads over several weeks are at high risk of having drug resistance, especially after prolonged prior exposure to the drug. Ideally, treated patients should be followed with serial quantitative measures of CMV viral load to demonstrate when CMV replication has been controlled and so optimize when treatment can be stopped (or an alternative antiviral drug used). Randomized controlled clinical trials are required to determine whether such individualization of therapy duration confers advantages over prescription of a course of standard length.

New approaches to antiviral drug discovery (genomics/proteomics)

Mark N. Prichard

Department of Pediatrics, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Discovery of antiviral drugs has always been an opportunistic endeavor. Small molecules in general and nucleoside analogues in particular have led investigators to discover uncharacterized viral gene products that could be exploited for the purpose of antiviral chemotherapy. Great strides have also been made in understanding fundamental events in the viral replication cycle including the binding of viral glycoproteins to cellular receptors, viral regulatory proteins that control expression of viral and cellular gene expression, viral genes that affect the synthesis and packaging of the viral genome, and viral factors that subvert the host immune response (Whitley and Roizman, 2001). Many of the viral genes that contribute to these processes are known and for some of them, the precise function is understood at the molecular level. For these targets it is comparatively simple to reduce the essential function to a biochemical assay, such as a polymerase or protease assay for use in a high throughput screen in order to identify small molecule inhibitors of enzyme function (Liu and Roizman, 1993). This approach has facilitated the proactive and rational search for specific enzyme inhibitors and has led to the development of effective antiviral therapies. Although this approach is effective, it requires well-characterized targets with a defined biochemical function, and can be applied only to a very small proportion of the essential viral gene products. At present, the best targets for antiviral chemotherapy likely remain undescribed and unutilized.

The development of new classes of antiviral drugs is limited by our understanding of biology. More often than not, it is unclear which viral gene products contribute to essential functions. Less clear still is the precise function or functions that the constituent proteins perform such that the biochemical activity can not be modeled in vitro. Thus, the challenge and rate-limiting step in this process is to identify the functions of gene products that are required for viral replication and to define precisely the molecular mechanisms involved with these processes.

Advances in genomics and associated technologies are offering new opportunities to investigators to answer such questions. This endeavor is driving technological developments in bioinformatics, genetics and laboratory automation and promises to generate a host of new resources that can be brought to bear on all fields of biology (Collins *et al.*, 2003). Advances in molecular virology will help drive this effort and will also benefit tremendously as virus–host interactions are defined in more detail and on a grander scale. Genomics, proteomics and related technologies can also be applied specifically to the discovery and development of antiviral therapies. Techniques and approaches that are particularly suited to this task are discussed and early experiments in this arena will be described.

Development of bioinformatics and computational tools

The emerging and evolving fields of genomics and proteomics are changing the way that biological research is conducted and technologies associated with these efforts can be applied effectively to the study of viral biology. The development of these fields is driven in part by the technological advances that produce genomic sequences more efficiently every year (Venter *et al.*, 2003). Significant technological advances in chemistry, biotechnology, and bioinformatics are also major drivers in this field and each of these efforts has produced tremendous new resources and even greater quantities of raw data. Perhaps the most

defining characteristic of these emerging fields of research is the tremendous size and complexity of the data sets they generate. Significant computational resources are required to manage the volumes of data, manipulate it, and parse it into databases that can be queried by researchers. This process requires training in computer science and mathematics. Investigators who specialize in these fields will contribute greatly to any future drug discovery projects using these new technologies. Bioinformatics resources are also required to analyze the data, identify patterns and display the patterns in a way that can be interpreted by investigators in the field. Data that is processed in this manner is designed to help investigators understand the problem at hand and can help them make hypotheses. Inferences drawn from these efforts need to be tested and confirmed in the laboratory, but the process helps to focus valuable research time on prioritized compounds or genes.

The application of computational methods to the study of herpesviruses biology is particularly intriguing. Large DNA viruses present a unique set of well characterized genomes that are comparatively well studied and characterized (Davison *et al.*, 2002). New tools developed by scientists in bioinformatics can be applied to these genomes to test their ability to predict the organization of viral genes, their global coding capacity and the function of viral proteins (Novotny *et al.*, 2001; Rigoutsos *et al.*, 2003). Laboratory confirmation of transcriptional patterns and gene expression and gene function is essential to this process, particularly early on when the bioinformatics algorithms are being tested on these genomes. The genetic tractability of herpesviruses and availability of genome wide methods to test these hypotheses make this an ideal system to validate new approaches to study biological processes (Stingley *et al.*, 2000). Communication and cooperation between the specialists in bioinformatics and bench level virologists is essential and will facilitate the incremental improvement of algorithms predictive of biological structure and function. The iterative process of algorithm refinement and biological confirmation will lead to computational approaches that are increasingly predictive of viral biology.

Studying new methods in bioinformatics in herpesviruses presents certain virus specific problems. Even within the alphaherpesviruses, the variation in G + C content will present a codon bias that must be taken into consideration. The genomic organization of 3′ coterminal transcription units as well as readthrough of certain stop codons will complicate the computational analysis as well as laboratory characterization of gene expression. Indeed, this is true in other viruses, such as SV40 where algorithms trained on mammalian genomes fail in many cased because of conservative assumptions about splicing sites and polyadenylation signals. Nevertheless, the genomics studies at the level of herpesviruses will be particularly instructive and will guide efforts to define and interpret sequences from more complex genomes, such as the human genome.

Data relevant to the discovery of new drugs tend to be concentrated at the intersection of large data sets. Databases that contain information related to biological function, chemical structure, and the biologic activity of small molecules all can contribute to the search for new lead compounds. The nature of this problem is inherently complex and databases will be required to handle the volumes of data. In the near term, computational methods can suggest aspects of viral replication that might be targeted specifically by small molecule inhibitors. Similarly, these methods may identify small molecules with well described biological effects that could be used to probe cellular functions that may be required by the virus. In the long term, computational approaches have the potential to link databases containing information on chemical structure, protein structure, biochemical activity, and biologic activity of small molecules. It may eventually be possible to mine existing data in a meaningful way to suggest chemical classes that might be used to inhibit known biochemical activities.

Impact of genomics and related fields on herpesvirus research

The scientific landscape has changed dramatically in the last 15 years with the completion of the DNA sequence for the genomes of all eight known human herpesviruses (Baer *et al.*, 1984; Chee *et al.*, 1990; Davison and Scott, 1986; Dolan *et al.*, 1998; Gompels *et al.*, 1995; McGeoch *et al.*, 1988, 1991; Pfeiffer *et al.*, 1995; Russo *et al.*, 1996). This is a very significant step in the path towards understanding the biology of herpesvirus infections. These and other resources in the publicly available databases are tremendously valuable to scientists studying herpesvirus infections and provide a map and common reference points to help scientists describe precisely viral transcripts and open reading frames (ORFs). Genomic sequences can also be used to compare genomic organization among all the herpesviruses, and represents a starting point in the path towards the identifying evolutionary relationships in this virus family. Importantly, the nucleotide sequences in the databases are not static. Sequence data are inherently noisy and most genomic sequences in GenBank have mistakes that need to be corrected when they are identified, especially in information-dense viral genomes. Annotations of

viral genomes are conducted with the best tools available at the time of submission, but they become outdated as gene prediction algorithms improve and as experiments in the laboratory identify new genes (Cha *et al.*, 1996). Since the annotation process is evolving, scientists should expect to find inconsistencies among the annotations of different genomes, as the terminology used to describe gene function is continually evolving (Ashburner *et al.*, 2000). Thus, prototype viral genomes will need to be updated and reannotated in an iterative process, particularly as new strains and viruses are sequenced (Davison *et al.*, 2003). Versioning of genomes and annotations is becoming more important when comparing sequences and annotations due to the continual annotation process, analogous to the versioning of software and human genome release versions in NCBI.

Genomics studies in herpesviruses initially focused on defining the structure and coding capacity of each of the viral genomes and comparing them with annotated sequences of related viruses. The DNA sequence and structure of the genomes is comparatively simple to define, yet even for these simple organisms it is not possible to predict with any certainty which, if any genes will be expressed in the context of an infection. Depending on the algorithms used, different numbers of ORFs will identified and laboratory experimentation is required to confirm which ORFs are actually expressed in the context of a viral infection (Davison *et al.*, 2003; Rigoutsos *et al.*, 2003). As synthesized microarrays become less expensive, oligonucleotide probes which hybridize to putative exons and splice junctions can be used for confirming the expression of predicted transcripts and splice variants in a bulk fashion (Shoemaker *et al.*, 2001). Continued experimentation and consistent reannotation among the submitted sequences will help define how these viruses, and indeed their human host use DNA to regulate and code for all the required functions. As this knowledge base expands, relationships among all the herpesviruses will crystallize and molecular evolutionary patterns will start to emerge.

The viral proteome represents all of the proteins expressed by the virus and reflects both the processing of RNA transcripts as well as the post-translational processing that occurs. Proteomics methods have the potential to be particularly powerful because it can distinguish the modification of viral gene products during the course of viral infection and can help characterize how proteolysis, glycosylation and phosphorylation impact viral replication. At one level, mass spectrometry and protein microsequencing can be used to identify sets of viral proteins involved in a particular biologic process (Greco *et al.*, 2001). Genome wide searches using algorithms to predict protein structure or identify conserved motifs can also be used to generate hypotheses regarding protein function (Oien *et al.*, 2002). Yeast two-hybrid studies provide an experimental approach for the study protein-protein interactions among viral and cellular proteins and will help to provide information about functional complexes in an infected cell. Efforts underway to construct protein-protein interaction maps have the potential to help understand which gene products cooperate in biological processes.

The emerging field of chemical genetics will also likely impact the discovery of antiviral therapies and could be one of the most useful tools (Strausberg and Schreiber, 2003). Genes can be classified in orthologous groups (Tatusov *et al.*, 1997) and small molecules can be classified into families based on the chemical structure. Genetics can be used to characterize the phenotype associated with a particular gene, and in an analogous manner the biological effect of a drug, or chemotype, can be associated with small molecules. Relating chemotypes and genotypes can help identify the molecular targets and pathways affected by groups of compounds. This information can be used to infer the mechanism of action of candidate molecules by comparing the chemotype with existing phenotypes associated with viruses containing mutations in different pathways. This process might also be particularly useful in identifying cellular response patterns associated with drug toxicity that could be used to eliminate lead compounds early in the discovery process (Waring *et al.*, 2002).

New resources for use in drug discovery

Genomics and proteomics are promising new fields with lofty goals, but can they provide immediate utility to efforts currently underway to identify new classes of antiviral drugs? At present, the impact of these fields is most apparent in the widespread use of data and tools provided by the publicly available databases. The GenBank, EMBL, and DDBJ nucleotide databases provided freely on the web are a tremendous resource to everyone and most researchers use the databases or related tools on a regular basis. The National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov/) and the European Bioinformatics Institute (http://www.ebi.ac.uk/services/index.html) websites in particular provide access, to basic tools and services that are used in laboratories every day. These tools include nucleotide and protein database searching tools, genome maps, structural databases and pattern recognition tools. The STDGEN database provided by Los Alamos National Laboratories (http://www.stdgen.lanl.gov/) is a wonderful resource that provides specific genomic and proteomic information on

herpesviruses and contains BLAST search results with links to other viral orthologues and conserved orthologous groups. Tools provided by these organizations are continually upgraded and new tools appear on a regular basis. Thus, a review of the available tools will be quickly outdated and can not substitute for a trip to the web sites listed in this text.

A number of new material resources have also been created through the automation of laboratory procedures. Microarrays of several different types are commercially available for characterizing changing transcription patterns in infected cells (Browne *et al.*, 2001). Herpesvirus specific microarrays have also been constructed and can rapidly assess viral transcript changes in response to stimuli (Stingley *et al.*, 2000). Expression clone libraries have been produced in efforts designed to assay gene function and virus knockout libraries have been assembled by a number of investigators. Each of the resources described here has the potential to be used in a genome wide search to identify viral genes that are important in the replication process.

Application of new technologies to cell-based antiviral assays

New tools and resources described herein, have the potential to be extremely useful in the drug discovery process and some strategies are currently in use. Many of the new strategies are unproven, and as such, are high risk activities that are used sparingly in the industrial setting. Nevertheless, high risk–high reward strategies have their place in the discovery process, particularly in the search for new classes of antivirals. The specific application of new technologies and resources to conventional screening and development activities has the potential to make an immediate and positive impact on the drug discovery process.

Cell-based screens for small molecules with antiviral activity have been utilized for all of the herpesviruses. Historically, most approved therapies for herpesvirus infections resulted from this approach to antiviral discovery, but continued screening of the same libraries with very similar assays is not likely to identify new lead compounds. It is possible to change the assays to bias the hit compounds away from molecules already identified in previous screens and towards molecules with different mechanisms of action. For example, screening recombinant viruses that lack the thymidine kinase (in herpes simplex virus (HSV)), or recombinant viruses lacking the *UL97* kinase (in cytomegalovirus (CMV)) will identify small molecules and nucleosides that do not require phosphorylation to be active. Lead compounds identified in these particular screens would also be candidates for the treatment of drug resistant infections. Genetically sensitized viruses, like the recombinants described above, might react more strongly to weakly active compounds and could unmask these molecules in existing chemical libraries. Candidate molecules with unusual mechanisms of action or good pharmacologic properties could then be selected for chemical modification to improve the antiviral activity.

As an alternative to the conventional endpoint of cytopathic effect inhibition, the affect of small molecules on viral transcriptional patterns could be monitored to reveal molecules with unusual mechanisms of action. Microarray technologies would be particularly useful in this regard, but it limits the number of compounds that could be examined in detail. In essence, this approach has already been validated through the characterization of gamma or late viral transcripts by treatment with phosphonoacetic acid (Stingley *et al.*, 2000). The cellular transcriptional response to small molecules could also be monitored simultaneously to measure changes in the host response to infection induced by the small molecules (Browne *et al.*, 2001; Fruh *et al.*, 2001). Microarrays can also help identify the mechanisms of transformation in infected cells and could potentially lead to better therapies for virus induced malignancies (Moses *et al.*, 2002). Potential toxicities could also be identified at an early stage by monitoring the induction of cellular genes associated with the response to toxic compounds (Waring *et al.*, 2002). Data generated by such an approach could also be queried at a later date using chemical genetics techniques to classify and cluster the chemotypes of molecules in the library.

Application of new technologies to biochemical assays

Biochemical screening assays will likely derive the greatest benefit from genomics and proteomics technologies. The increased characterization of viral gene products will likely identify additional biochemical activities that can be converted rapidly into small molecule screens. Homology searching algorithms also play a major role because of their ability to extend knowledge from one herpesvirus to related viruses. BLAST searches with a known gene can identify orthologues in other herpesviruses and related genes (paralogues) within the same virus in an effort to identify viral proteins with a similar biochemical activity (Davison *et al.*, 2002). For example, an orthologue of the HSV protease was identified in CMV and a similar biochemical assay could be used for both to screen for inhibitors of this biochemical activity (Jarvest *et al.*, 1999; Pinto *et al.*, 1999).

Many viral gene products have no known function, yet possess characteristic motifs that could potentially be used in biochemical screens (Rigoutsos *et al.*, 2003). Hypotheses generated by searches such as these could be tested in the laboratory and if confirmed could be used in a biochemical screen. For instance, nucleotide binding motifs in poorly characterized genes could be used to identify nucleosides that bind to these sites with high affinity. Similarly, a structural search revealed that *UL57* in CMV appears to be related at a structural level to some endonucleases (Novotny *et al.*, 2001). If this activity were confirmed in the laboratory, a biochemical screen could be used to identify specific inhibitors of this activity and might be effective in inhibiting viral replication given that this gene is known to be essential for viral replication.

Biochemical assays based on protein-protein interactions are capable of identifying molecules with antiviral activity. Information garnered from proteomics methods or yeast-two hybrids could be used to devise a rapid assay for protein–protein interactions that are presumed to be important for viral replication. Screening of small molecule libraries or peptide libraries could identify specific inhibitors that also possess antiviral activity (Liuzzi *et al.*, 1994). This same strategy could be employed to identify inhibitors that disrupt the interaction of viral and cellular proteins that appear to be important viral replication. If fact, it may be possible to perform the high throughput screen directly in yeast if the interaction was originally defined in this system.

The best characterized molecular targets have had their crystal structures determined. Given these data, it is possible to recrystallize these molecules with known inhibitors to identify protein binding sites or to dock small molecules *in silico* to identify molecules in improved binding affinities to the active site (Stoll *et al.*, 2003). This approach is particularly useful in lead optimization and medicinal chemistry efforts to increase potency. For any of the technologies discussed here, their greatest utility is generating testable hypotheses that could identify new and unexploited targets for antiviral therapy.

Application of new technologies to functional assays

Genetic approaches can identify gene products that are essential for viral replication, but without a biochemical assay, it is not possible to screen for inhibitors of these molecules. Functional genomics approaches can be employed to try to identify surrogate phenotypes for interesting genes. With these sorts of assays, the surrogate assays do not necessarily measure the relevant functional aspect of the gene in question. Any inhibitors identified from screens based on surrogate assays need to be validated in secondary assays (Tugendreich *et al.*, 2001). Although surrogate approaches are high risk high reward propositions, they are particularly useful for screening ion channels or other molecules that require an intact membrane for activity (Hahnberger *et al.*, 1996).

Application of new technologies to characterize mechanism of action and spectrum of activity

New technological developments also impact how researchers conduct preclinical studies on compounds with antiviral activity. Mechanism of action studies still involve the isolation of drug resistant viruses, but genomic sequencing of drug resistant viruses can be faster than conducting conventional marker transfer studies to identify the molecular targets of investigational drugs (S.W. Chou, pers. commun.). Direct sequencing is also cost effective in identifying resistance mutations in clinical isolates where the mechanisms of drug resistance are well characterized (Lurain *et al.*, 2001).

Genomics approaches can also be used to help predict the spectrum of activity of a compound if the mechanism of action is known. Homology searches can be used to identify gene families common to a wide variety of organisms and are called clusters of orthologous groups (COGs) (Tatusov *et al.*, 1997). This process was also conducted for all sequenced herpesviruses and a set of viral COGs was assembled (Montague and Hutchison, 2000). In addition to helping define orthologues in this group of viruses, the COGs can also be used to construct genome-wide phylogenetic trees, that closely match trees constructed using the highly conserved core genes (Davison *et al.*, 2002). COGs can also be clustered based on the viruses in which they appear, and can help to define a theoretical spectrum of activity for antiviral drugs based on the conservation of the molecular targets. A comparison of the predicted drug efficacy (shaded area) is compared with antiviral activity reported in the literature (+ or −) in Table 67.1. A number of interesting disparities are immediately apparent. Penciclovir did not appear to be active against EBV, and neither acyclovir nor penciclovir exhibited significant antiviral activity against HHV8, despite the fact that they possess relatively well conserved thymidine kinases. These results are explained in part by apparent low activity of the HHV8 thymidine kinase and narrow substrate specificity (Gustafson *et al.*, 2000). The activity of ganciclovir in viruses without TK orthologues can be explained

Table 67.1. Predicted spectrum of activity based on molecular target conservation

Drug	Molecular target	COG #(43) (Identity)	HSV1	HSV2	VZV	EBV	HHV8	CMV	HHV6A	HHV6B
Acyclovir	Thymidine kinase[a] (15, 23)	COG97 (18.9%)	+ (23)	+ (23)	+ (4)	+ (12)	− (31)	− (29)	− (37)	− (37)
Penciclovir	Thymidine kinase[a] (22)	COG97 (18.9%)	+ (6)	+ (6)	+ (6)	− (37)	− (37)	− (6)	− (37)	− (37)
Ganciclovir	Thymidine kinase[a] (15, 23)	COG97[a] (18.9%)	+ (39)	+ (39)	+ (14)	+ (39)	+ (31, 42)	+ (39)	+ (37)	+ (37)
	Protein kinase[a] (34, 55)	COG60[a] (17.2%)								
Foscarnet	DNA polymerase (10)	COG51 (27.6%)	+ (62)	+ (32)	+ (2)	+ (16)	+ (37)	+ (37, 62)	+ (37)	+ (37)
Cidofovir	DNA polymerase (20)	COG51 (27.6%)	+ (20)	+ (20)	+ (20)	+ (20)	+ (37)	+ (20)	+ (37)	+ (37)
4-oxo-dihydro-quinolines	DNA polymerase (46)	COG51 (27.1)	+ (57)	+ (57)	+ (57)	+ (57)	+ (57)	+ (57)	− (57)	− (57)
BDCRB	Terminase (UL89) (60)	COG59 (22.8%)	− (58)	− (58)	− (65)	− (58)	− (65)	+ (58)	− (65)	− (65)
	Terminase (UL56) (33)	COG93 (20.5%)								
maribavir	UL97 (5)	COG60 (17.2%)	− (65, 66)	− (65, 66)	− (65)	+ (66)	− (65)	+ (66)	− (65)	− (65)

[a] The molecular target is the polymerase (COG51), but the compounds derive most of their selectivity at the level of phosphorylation by the COGs shown.

by the alternative phosphorylation by *UL97* protein kinase in cytomegalovirus and related orthologues in the other β herpesviruses (Littler *et al.*, 1992; Sullivan *et al.*, 1992). The high degree of conservation among the herpesviruses in the DNA polymerase is very predictive for broad efficacy of foscarnet, cidofovir, and the 4-oxoquinoline derivatives. The exception is the reduced susceptibility of HHV6A,B, that can be explained by an unusual V823A polymorphism in the active site of these viruses. Of interest, both of the benzimidazole analogs (maribavir and BDCRB) exhibit a very limited spectrum of activity, which is not predicted given the well conserved molecular target, particularly with BDCRB. Like other computational methods described herein, their greatest utility of this approach is generating a hypothesis to be tested in the laboratory. Future mechanism of action studies for this series of compounds will be needed to explain the limited spectrum of activity for this series of compounds.

Conclusions

As genomics and related technologies develop, they will be applied to the study of herpesvirus biology and to the discovery of new antiviral drugs to treat these infections. Initial reports have provided indications that these strategies may be particularly useful in this family of viruses. These approaches hold promise and will likely make substantial contributions to the field as the technologies mature.

Acknowledgment

I thank David Shivak for his helpful comments and his critical reading of the manuscript.

Candidate anti-herpesviral drugs; mechanisms of action and resistance

Karen K. Biron

Clinical Virology, GlaxoSmithKline, Research Triangle Park, NC, USA

Research into the molecular biology of herpes replication in recent years has revealed novel targets for drug development (Fig. 68.1). The characterization and functional assay of these targets have been facilitated by advancements in gene expression, protein purification, proteonomics, bioinformatics, and efficient robotic screening technologies. The pipeline for new herpes drugs has been expanding as drug candidates have evolved more rapidly due to improvements in chemical synthesis (i.e., combinatorial and parallel synthesis methods), and with aids for drug design (X-ray crystallography, in silico computer modeling tools, as well as chemoinformatics). Many new herpes inhibitors have been reported, and most of these possess novel modes of actions. Several have entered clinical evaluation, with some later discontinued because of safety issues. This chapter will describe promising drug candidates in early development that appear to act at individual steps of the viral replication cycle, and focus on those that have the most potential for success (Table 68.1).

The chemotherapy of herpes infections was markedly advanced by the discovery of the first, highly selective antiherpetic agent, acyclovir (ACV, Zovirax®; [9-(2-hydroxyethoxymethyl)guanine]) (Elion *et al.*, 1977). Since the introduction of this agent, there has been only incremental progress in new drug approvals for the myriad of diseases caused by this family of diverse pathogens. The drugs approved since the introduction of ACV include valacyclovir (VACV, Valtrex®, the L-valine ester prodrug of ACV, penciclovir (PCV; [9-(4-hydroxy-3-hydroxymethylbutyl-1-yl) guanine]), a related nucleoside analogue with a similar basis for drug action against HSV and VZV, and its prodrug, famciclovir (FCV, Famvir®). More efficacious treatment of CMV disease was achieved with yet another guanosine analogue ganciclovir (GCV, Cymevene®, Cytovene®; 9-(1,3-dihydroxy- 2-propoxymethyl)guanine), and its recently approved prodrug, valganciclovir (Valcyte®; L-Valine, 2-[(2-amino-1,6-dihydro-6- oxo-9H-purin-9-yl)methoxy]-3-hydroxypropyl ester, monohydrochloride),. The treatment of ocular CMV infections was advanced by the antisense agent ISIS 2922 (formivirsen, Vitravene®). Broad-spectrum antiherpetics include the pyrophosphate analogue foscarnet (PFA, Foscavir®; trisodium phosphonoformate, phosphonoformic acid) and the nucleotide analogue cidofovir (CDV, HPMPC, Vistide®; (S)-1-(3-hydroxy-2-phosphonylmethoxypropyl)cytosine).

Although these agents have proven efficacious in the prophylaxis and treatment of herpes infections, there remains a need for drugs with higher potency, more rapid and durable antiviral action, more convenient dosing regimens, and importantly, fewer and less severe side effects. Because these systemic drugs ultimately target the viral DNA polymerase, and the nucleoside analogs are viral TK-dependent, cross-resistance can occur (Erice, 1999). New drugs with novel mechanisms of actions would provide valuable alternatives. Ideally, the new drug would eliminate the latent reservoir; a challenging goal since the herpesviruses have evolved complex strategies to persist under the reach of host defense mechanisms.

The drug development process: an overview

The scientific literature abounds with reports of the in vitro anti-herpetic activities of diverse organic molecules and biological products, and in many cases, the selectivity index (SI; the ratio of cellular toxicity to antiviral potency in vitro) appears promising (Snoeck *et al.*, 2002). However, the demonstration of in vitro activity is only the first step in the long and arduous journey from the laboratory bench into the clinic (Scolnick *et al.*, 2001). Other considerations, particularly absorption, distribution, metabolism and excretion (ADME) parameters are

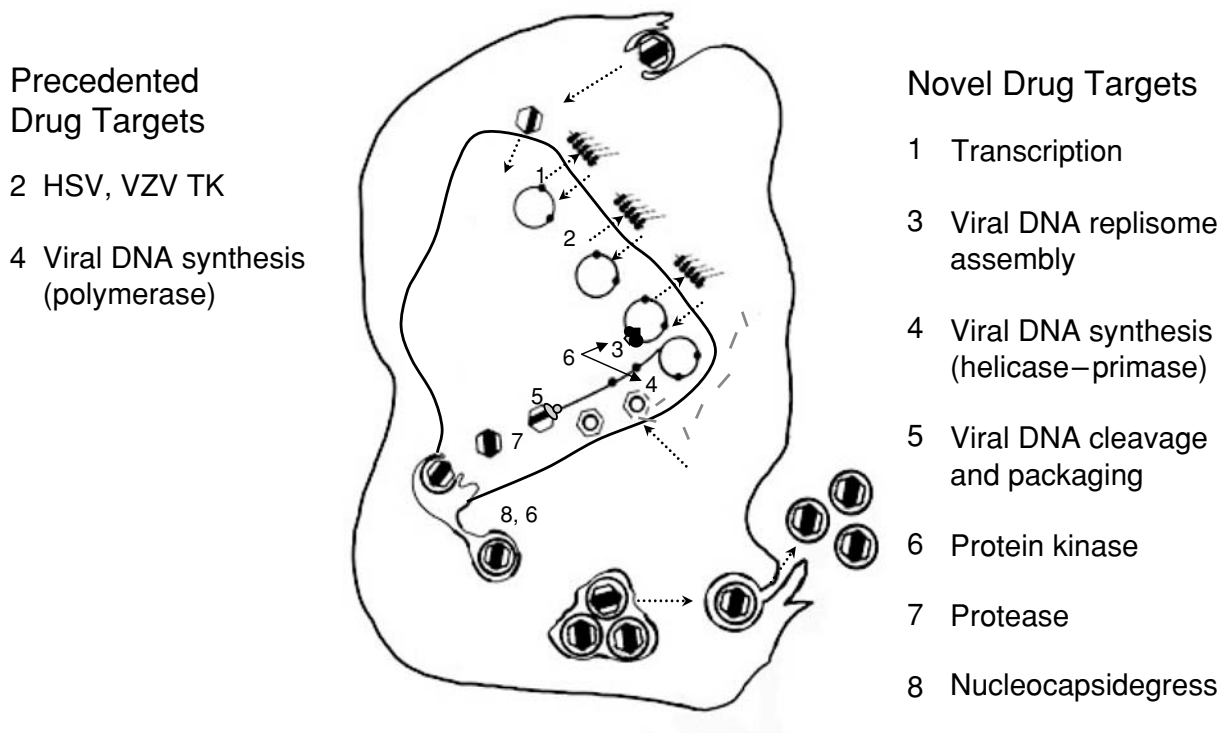

Fig. 68.1. Herpesvirus replication cycle illustrating precedented and novel drug targets (numbered) and their general stage of function in the viral replication cycle. (Adapted from Roizman *et al.*, 1993.)

key to success. Lipinski's rule-of-five analysis (Lipinski *et al.*, 2001) which established guidelines regarding structural properties most often associated with viable drug candidates has been embraced by the pharmaceutical industry.

The discovery and development process is slow and costly. The industry average to bring a new drug to market was estimated at over $500 million dollars for drugs introduced in 1990 and is undoubtedly higher today (Boston Consulting; Pharmaceutical R&D Costs, 1993). The time from synthesis of a new drug to regulatory approval has grown to over 14 years from an average of 8 years in the 1960s, according to analyses by the Tufts Center for the Study of Drug Development. Figure 68.2 provides a schematic review of some of the major preclinical development activities generally required to advance a drug to approval.

Historically, anti-infectives have been discovered through the screening of compound libraries directly against the replicating organism. This classic approach was used in the discovery of all the currently approved systemic antiherpetics. ACV, which was originally synthesized to potentiate the anticancer activity of the nucleoside analogue, cytosine arabinoside (Ara C), by inhibition of adenosine deaminase (the enzyme responsible for its metabolic breakdown), emerged as a potent antiherpetic during random screening in herpes simplex virus (HSV)-infected cells (Elion *et al.*, 1977).

Screening of diverse chemical libraries in virally-infected cell cultures, although less efficient than individual enzyme or target-based screens (discussed below), provides the opportunity to identify new viral targets. Active inhibitors can then serve as laboratory tools to probe the biology of viral replicative events. The mechanisms of novel action are defined by identifying changes in the phenotype of infected, treated cells, often aided by time of inhibitor addition and withdrawal experiments. Antiviral selectivity is indicated by the ability of the virus to develop resistance to escape drug inhibition, and genetic mapping of resistance mutations identifies the viral target(s).

A second approach to the discovery of new inhibitors consists of direct screening of compounds against a catalytic enzyme or other biological function. Often screening and inhibitor optimization may be directed by structural

Table 68.1. New anti-herpes inhibitors in the discovery and development pipeline

Drug/ compound class/ chemical structure	Virus/ antiviral activity per status (early 2004)	Mechanism of action (MOA)/target gene(s)	Key reference(s)
Inhibitors of early replication events			
PD146626 (benzothiophene) 	• HSV-1, IC_{50} 0 ~ 0.1 μM • Cytotoxicity ≥1.0 μM (HFF) • early preclinical	• MOA unknown; MOI-dependent in vitro activity • blocks IE (VP16 and ICPO) gene expression • cell target likely no resistant virus	Boulware *et al.*, 2001 Hamilton *et al.*, 2002
CMV423 (tetrahydroindolizine derivative) 	• CMV, HHV-6, HHV-7 • IC_{50} range CMV:0.005–0.05 μM (at low MOI) • IC_{50} range HHV-6: 0.1–0.3 μM • activity cell-type dependent for HHV-6 • Preclinical	• MOA unknown;MOI-dependent in vitro activity • cell target likely: no resistant virus • host tyrosine kinase may be involved • blocks early event prior to viral DNA synthesis	Snoeck *et al.*, 2002 DeBolle *et al.*, 2004 Cirone *et al.*, 1996
828, 951, and 1028 non-nucleoside pyrrolo[2,3-*d*]pyrimidines  **951**	• CMV • all three compounds comparable to GCV (IC_{50} 0.4–1.0 μM) • early preclinical	• MOA unknown; MOI-dependent in vitro activity • blocks early event prior to viral DNA synthesis	Jacobson *et al.*, 1999
Inhibitors of herpes DNA polymerase			
Lobucavir (LBV) (cyclobutyl guanosine analogue) 	• VZV, CMV, HBV • clinical anti-CMV activity demonstrated in HIV-infected subjects • development terminated 2002.	• phosphorylated by cellular enzymes • triphosphate a potent inhibitor of CMV DNA polymerase (limits chain extension) • target gene: pol	Tenney *et al.*, 1997 Dunkle, 1996 *Lalezari et al., 1997*
Omaciclovir (H2G) Carbocyclic guanosine analogue Prodrug MIV-606  H2G	• VZV, HSV-1 and 2, EBV • More potent vs VZV than ACV • efficacy demonstrated in simian VZV infection in African green monkeys • resistance profile similar to ACV for TK- mutants • phase II clinical studies	• MOA similar to ACV: – substrate for VZV & HSV 1 & 2 TK – competitive inhibitor of viral DNA polymerase • MOA differences from ACV: – not an obligate chain terminator, but limits chain extension – substrate for mitochondrial TK – longer intracellular $t_{1/2}$ of H2G-TP • resistance mutations: – VZV TK frameshift mutations: – dels A76, G805, or A806 produce truncated polypeptide – cross resistant to ACV	Abele *et al.*, 1991 Soike *et al.*, 1993 Lowe *et al.*, 1995 Ng *et al.*, 2001

(*cont.*)

Table 68.1. (*cont.*)

Drug/ compound class/ chemical structure	Virus/ antiviral activity per status (early 2004)	Mechanism of action (MOA)/target gene(s)	Key reference(s)
Alkoxyalky ester of CDV (nucleotide analogue) 	• broad spectrum antiviral • herpes activity $IC_{.50.}$ range 0.5–30.0 μM • potential therapeutic for smallpox, rescue of herpes-resistant infections in immunocompromised • accelerated development through Phase I for smallpox	• nucleotide monophosphate, further phosphorylated by cell enzymes • competitive inhibitor of viral DNA synthesis • single point mutations in pol confer CDV-resistance	Ciesla *et al.*, 2003 De Clercq, 2002 Safrin *et al.*, 1997 Neyts *et al.*, 2004 Aldeon *et al.*, 2003 Painter and Hostetier, 2004 Kern *et al.*, 2004a
A-5021 Guanosine analogue 	• HSV-1 & 2; $IC_{.50.}$ range 0.013–0.15ug/ml • VZV IC50 ~ 0.77 ug/ml • more potent vs HSV-1 than ACV in vitro and in animal models	• MOA similar to ACV: – substrate for VZV & HSV 1 & 2 TK – competitive inhibitor of viral DNA polymerase – longer intracellular $t_{1/2.}$ of A-5021-TP vs ACV-TP – not a chain terminator, but limits chain extension • resistance profile similar to ACV for TK mutants	Ono *et al.*, 1998 Iwayama *et al.*, 1998 Iwayama *et al.*, 1999
BCNAs bicyclic pyrimidine nucleoside analogues 	• VZV • highly potent at sub-nanomolar concentrations IC50 1nM10–μM	• MOA not fully elucidated: – substrate for VZV TK – TK- deficient VZV also resistant to BCNAs – no triphosphate detected in VZV-infected cells	Balzarini and McGuigan, 2002 DeClercq, 2003a,b McGuigan *et al.*, 2003 Sienaert *et al.*, 2002 Balzanini *et al.*, 2002
PNU-183792 non-nucleoside (4-oxo-DHQs) naphthalene carboxamide 	• VZV, HSV, CMV, HHV8, EBV • CMV $IC_{.50.}$ ~ 0.95 μM; comparable to GCV • HSV-1 & 2,VZV, HHV8 IC50 ~3.5 μM • EBV IC_{50} 0.17 μM • no detectable cross-resistance with approved antivirals	• inhibitor of viral DNA polymerase • competitive inhibition with the binding of natural substrate (dTTP) to the polymerase enzyme, with a low level affinity for the enzyme substrate complex that was not defined	Vaillancourt *et al.*, 2000 Oien *et al.*, 2002 Thomsen *et al.*, 2003 Wathen, 2002
Inhibitors of herpes helicase-primase			
T157602 2-aminothiazole 	• HSV • $IC_{.90.}$ = 3 μM	• Inhibits viral DNA synthesis • stabilizes the helicase-primase complex trapping the enzyme on the DNA substrate, and blocking all activities of the complex.	Spector *et al.*, 1998

(*cont.*)

Table 68.1. (*cont.*)

Drug/ compound class/ chemical structure	Virus/ antiviral activity per status (early 2004)	Mechanism of action (MOA)/target gene(s)	Key reference(s)
BILS 179 BS thiazolylphenyl containing compounds 	• HSV • 10-15 times more active than ACV in vitro ($EC._{50s.}$ 27nM- 100nM) • Efficacy studies in animals demonstrated comparable &/or superior efficacy to ACV	• stabilizes the helicase-primase complex and DNA substrate, imposing a physical constraint both to enzyme progression (DNA-unwinding reaction), and primase catalytic activity • Resistance mutations in UL5 • Rapid selection of stable, pathogenic phenotype	Crute *et al.*, 2002 Kleyman *et al.*, 2003a,b Liuzzi *et al.*, 2004
BAY 57-1293 triazole urea compounds 	• HSV $IC._{50.}$ 20 nM • ~100-fold more sensitive that ACV against HSV	• inhibits viral DNA synthesis • novel mode of action inhibits the ATPase activity of the viral helicase-primase complex in a dose-dependent manner ($IC._{50.}$ of 30 nM). • Resistance mutations in UL5, UL52	Kleymann *et al.*, 2002 Kleymann, 2003a Betz *et al.*, 2002
Compound 9 	• CMV IC50 0.039 μM • Range of analogs 0.4⇒10 μM • Leads comparable to CDV, GCV in potency	• Inhibits viral DNA synthesis • Target; UL70 component of helicase-primase complex, based on co-IP. • Irreversible covalent binding proposed; no viral resistance genetics confirmation yet reported	Cushing *et al.*, 2006
Inhibitors of the portal protein of HSV/ viral DNA packaging			
WAY 150138 benzamide thiourea compounds 	• alpha herpes viruses	• inhibitor of viral DNA cleavage & packaging • target gene: HSV UL6 • resistance mutations UL6 – Glu121Asp, Ala618Val, Gln621Arg	van Zeijl *et al.*, 2000, Visalli and van Zeijl, 2003 Newcomb and Brown, 2002
Comp I N-methylbenzyl-N'-arylthiourea analogues 	• VZV ($IC._{50s.}$ 0.1 to 0.6 μM)	• VZV DNA cleavage and packaging is restricted via inhibition of the ORF54 gene • ORF54 resistance in 2 isolates due to changes in codons 324 & 408 in 1 isolate and codon Gly407Asp in another isolate	Visalli *et al.*, 2003 van Zeijl *et al.*, 2000 Akanitapichat and Bastow, 2002)
Hydroxyacridone derivative(s)  5-chloro-1,3-dihydroxyacridone	• HSV $IC._{50.}$ ~10 μM • hCMV $IC._{50.}$ <10 μM (multiple derivatives) • early preclinical	• MOA unknown, selectivity questionable • diverse phenotype in treated, HSV-infected cells; reduction in: – viral DNA packaging – production of B capsids – infectious virions	Akanitapichat and Bastow, 2002 Lowden and Bastow, 2003

(*cont.*)

Table 68.1. (*cont.*)

Drug/ compound class/ chemical structure	Virus/ antiviral activity per status (early 2004)	Mechanism of action (MOA)/target gene(s)	Key reference(s)
Inhibitors of the CMV terminase complex			
BAY 38-4766 	• CMV • IC $_{50}$ ~1 μM • Anti CMV activity comparable to GCV in hollow fiber mouse model	• novel, late-stage inhibition of UL89 and UL56 gene products (2 subunits of the CMV terminase) • reduction in viral DNA packaging • resistance mutations in UL89, UL56	Buerger *et al.*, 2001 Reefschlaeger *et al.*, 2001 McSharry *et al.*, 2001a,b
TCRB & BDCRB benzimidazole ribosides 	• CMV • IC$_{50}$ < 3 μM	• inhibits viral DNA cleavage and packaging • target genes: UL89, UL56 • resistance mutations: – pUL89: Asp344Glu, Ala355Thr – pUL56: Gln204Arg	Townsend *et al.*, 1995 Underwood *et al.*, 1998 Krosky *et al.*, 1998
GW275175X B-D-ribopyranosyl derivative of BDCRB 	• hCMV; IC$_{50}$ range 0.16-2.03 μM • antiviral activity similar to GCV in vitro • not active vs animal CMV; SCID hu efficacy model tested • Phase I single-dose study completed	• inhibits viral DNA cleavage and packaging • target genes UL89, UL56 • mutations conferring cross resistance: – UL89: Asp344Glu, Ala 355Thr UL56: Gln204Arg	Underwood *et al.*, 2003 Williams *et al.*, 2003 Krosky *et al.*, 1998
Inhibitors of the CMV UL97 protein kinase			
Indole carbazoles 	• hCMV; IC$_{50}$ range 0.009–0.4 μM	• inhibits pUL97autophosphorylation and pUL97-dependent GCV phosphorylation • target gene UL97	Zimmermann *et al.*, 2000 Marschall *et al.*, 2001 Slater *et al.*, 1999
Maribavir, 1263W94 	• CMV, IC$_{50}$ values are assay, cell-type dependent, and range from 0.08–26 μM • generally 3–10-fold more potent than GCV • EBV; IC$_{50}$ values for lytic viral DNA synthesis reduction 0.2–17 μM	• inhibits viral DNA synthesis and nucleocapsid maturation/egress • target genes/resistance mutations – UL97: Leu397Arg (AD169) – UL27 gene: Leu335Pro (Towne), Arg233Ser (AD169), Ala406Val, Cys415 stop (AD169), Trp362Arg (AD169)	Biron *et al.*, 2002 Komazin *et al.*, 2003 Chou *et al.*, 2004 Lalezari *et al.*, 2002 Williams *et al.*, 2003 Ma *et al.*, 2006

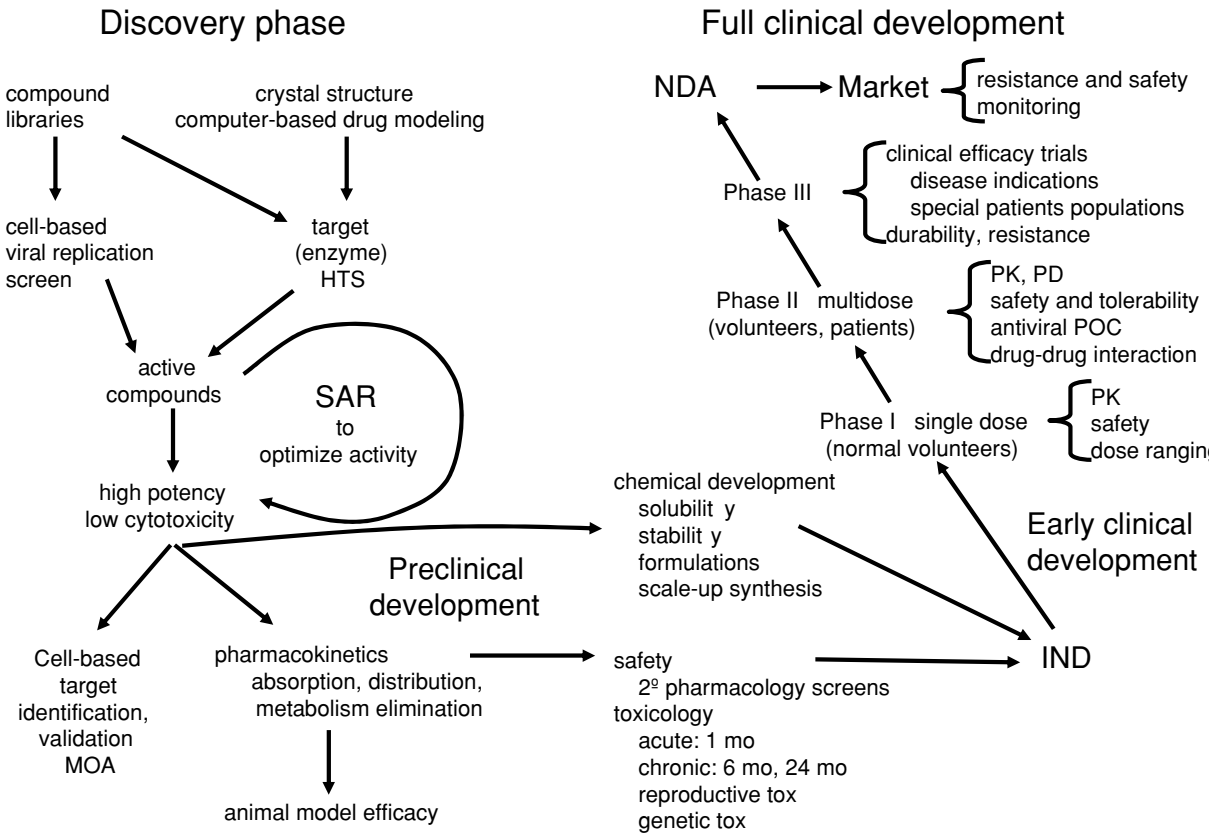

Fig. 68.2. Schematic overview of drug development process.

modeling. This approach is highly efficient, and has been particularly successful in the human immunodeficiency virus (HIV) arena, producing candidates or approved drugs targeting HIV entry, fusion, genetic integration, protease, and the HIV reverse transcriptase. Significant efforts to identify herpes protease inhibitors have not been successful to date, but direct screening of herpes DNA polymerases and the helicase-primases have produced exciting drug candidates with strong development potential.

A few principles emerge from the collective experiences in the field of antiviral drug discovery. The ideal target will be unique to the virus, or sufficiently distinct from the host cell counterparts to allow preferential inhibition, and will be essential for viral replication (in vitro for assay purposes) and for disease pathogenesis in the host. The genetic barrier to resistance will be high, and drug-resistant variants will pay a penalty in replication competence or tissue tropism. In the case of the alpha herpesviruses, drug-resistant variants will lack the ability to reactivate from latency.

An active antiviral compound must have other attributes in order to progress successfully through the drug development process. The chemical and pharmaceutical development criteria of cost-effective manufacturing, product stability, good solubility, oral bioavailability, and acceptable protein binding preclude development of high molecular weight compounds, or complex biological products, except as topical or injectable formulations. For the well-defined catalytic sites of many target enzymes, small molecule inhibitors ($\leq$600 Da MW) can provide the ideal "fit." However, for the less well-defined catalytic sites of some enzymes, or the broad surfaces of protein–protein interactions (Tsai *et al.*, 1997), larger MW inhibitors, such as protein mimetics, may be required. Protein-protein interactions comprise many opportunities for antiviral intervention, but from a pharmaceutical perspective, these remain challenging targets (Arkim and Wells, 2004).

Host cell targets as an approach to virus inhibition

Drugs that target host cellular functions have been considered as potential antiviral agents (Shugar, 1999) and the herpes virus literature documents the antiherpes activity

of a variety of host cell kinase inhibitors, such as roscovitin and inhibitors of p38 and cdk-E (Schang, 2002; Schang *et al.*, 2002; Chang, 2003). Investigators have looked at the effects of various antimetabolites on the ability of host cells to support viral replication. Although these are useful probes for discerning the contributions of host functions to viral growth, none have yet been shown to have clinical development potential as systemic therapies for the herpes diseases.

Reveratrol, a natural plant phytoalexin, was recently shown to inhibit HSV 1 and 2 replication early in the infection cycle by inhibition of ICP-4 (Docherty *et al.*, 1999). The mechanism may not directly involve a virus target, but could have application as a topical agent similar to the anti-inflammatory effect of n-docosanol 10% cream (Abreva®). One category of host targets which may be fruitful for the development of novel therapeutics that deserves mention here are immune response modulators. The herpes viruses have developed multiple ways to evade the host's innate immunity and to block antigen presentation required for the adaptive immune responses. Thus, agents which protect or augment host defense mechanisms by interfering with viral immune evasion functions may provide additional tools in disease management. Such agents could complement antiviral drugs and may potentiate vaccine efficacy (Miller *et al.*, 2002). For example, Imiquimod, an immune response modifier approved for the topical treatment of external genital and perianal warts, has recently been shown to be an agonist to the toll-like receptor 7 (TLR-7) (Hemmi *et al.*, 2002). The related analog, resiquimod, has also been shown to have immunomodulatory properties and efficacy as a topical therapeutic agent in genital HSV-2 infections models (Bernstein *et al.*, 2001; Miller *et al.*, 2002). TRL-7 may be involved in the induction of cytokines, especially alpha interferon, and other antiviral effector molecules which may enhance cell mediated immunity (Wang *et al.*, 2005). Moreover, Imiquimod has also been shown to have potent adjuvant/priming properties in several vaccine models (Rechtsteiner *et al.*, 2005; Thomsen *et al.*, 2004). Several candidate TLR agonists, plus other immunomodulatory agents are in development for various viral diseases, but will not be discussed further.

Antiviral targets in early replication events

In principle, an inhibitor that blocks the very earliest steps in the invasion of a cell by a virus should effectively restrict the spread of infection and could also serve as a prophylactic agent. However, inhibition of herpes viral attachment and uncoating may not be feasible, since there are no unique, restrictive mechanisms for herpes entry that could be exhaustively (and presumably safely) disabled. This is in contrast to the prospects for the antagonist of the CCR5 host receptor element required for HIV infection (Baba *et al.*, 1999), the recently approved HIV fusion inhibitor (LaBranchea *et al.*, 2001) in HIV infection, and the rhinovirus uncoating blocker (Diana *et al.*, 1987).

Immediate early gene (IE) expression or the transactivation functions of their products could after the earliest replication events for intervention, and their inhibition should effectively restrict productive viral infections and potentially decrease reactivation from latency. However, since the transcription of viral genes and the viral-mediated transactivation intimately involve host transcriptional machinery and factors, selectively would be difficult to attain.

Three or four series of compounds with designated early modes of action have emerged from cell-based screening programs. Time-of-addition studies or quantitation of viral transcription and translation indicated that these classes of compounds acted after the adsorption phase of HSV or CMV infection but before viral DNA synthesis. Two striking features of their mechanism of action (MOA) were common to these agents: their in vitro potency was compromised by increased multiplicity of infection (MOI), and the investigators were unable to select resistant viruses, despite repeated attempts to passage virus in the presence of the inhibitors. These features, particularly the latter, are consistent with inhibition of a cellular target. In the case of CMV423 (see below), the inhibition of a host protein kinase is demonstrated. Although the in vitro SIs for these agents indicate at least a preferential inhibition of viral growth, drug development potential of these compounds is doubtful. They will be briefly described.

PD146626

The activity of the benzothiophene class was identified in a random compound screening program. The lead compound, PD146626 (9-(methyloxy)-3,4-dihydro[1]benzothieno[2,3-f][1,4]thiazepin-5(2H)-one), was shown to inhibit HSV type 1 (HSV-1) replication by blocking immediate early viral gene expression, specifically VP16 and ICPO expression. However, viruses deleted for the VP16 and ICPO loci ("knock-out" viruses) lacked resistance to PD146626, and the compound showed apparent anti-viral activity against CMV, which lacks VP16 and ICP0 homologues. Moreover, PD146626 could exert this inhibitory effect in cells pretreated before viral infection, or in cells treated with only short exposures (up to 2 hours) during viral infection. Thus, PD146626 apparently targets a cellular function critical for the expression of HSV-1 immediate early genes (Boulware *et al.*, 2001). Extensive SAR studies that focused on stereospecific substitution on the diazepine ring and optimal nitrogen substitution achieved striking improvements as evidenced by a 2-log

enhancement in potency and a 3-log improvement in therapeutic index. However, in vivo efficacy could not be determined due to metabolic issues, and thus the safety consequences of this inhibitory mechanism remains to be determined (Hamilton *et al.*, 2002).

Non-nucleoside pyrrolopyrimidines 828, 951, and 1028
Three structurally distinct analogues in a series of non-nucleoside pyrrolo[2,3-d]pyrimidines emerged from a cell-based screening program (Jacobson *et al.*, 1999). At low MOIs compounds 828, 951, and 1028 all showed potency comparable to that of GCV. One of these compounds, 828, was tested for toxicity and shown to be less toxic against human bone marrow progenitor cells than GCV, a key improvement.

CMV423
Perhaps the best-studied agent with activity early in the herpes life cycle is CMV423, 2-chloro-3-pyridin-3-yl-5,6,7,8- tetrahydroindolizine-1-carboxamide. This tetrahydroindolizine derivative is active against CMV, HHV-6, and HHV-7 at low concentrations, but shows only modest activity against HSV-1 and -2 and none against varicella-zoster virus (VZV) (Snoeck *et al.*, 2002; De Bolle, 2004). The synergistic activity against CMV observed when CMV423 was combined with GCV, PFA, or CDV suggested that CMV423 was inhibiting a different step in viral replication, most likely an earlier one, than these DNA polymerase inhibitors. A series of studies aimed at defining the point of inhibition, using the low multiplicity of infection (MOI) multi-cycle format and probing for the expression of the IE (immediate early) and E (early) antigens showed transient reductions in the levels of IE antigen detectable on days 1 and again on days 4 and 5, in concert with first- and second- round of viral replication. Interestingly, CMV423 was able to block substantial expression of IE antigen at the viral input of 0.1 PFU/cell, an MOI at which antiviral activity is lost, indicating that low IE expression is sufficient to overcome the block to replication. This result suggests that any drug directed against the CMV IE gene would have to be almost 100% effective to produce the desired virus suppression.

Further work on the mechanism of inhibition of human herpesvirus (HHV)-6 replication again pointed to a cell target, as inhibition occurred in a cell-line dependent fashion (De Bolle *et al.*, 2004). The molecular target in HHV-6 is most likely a different early event, occurring before viral DNA synthesis but after IE antigen production. Based on the similarity of the action of herbimycin, which is known to inhibit cellular tyrosine kinase activity through binding to heat shock protein (Cirone *et al.*, 1996) and to block infection of human T lymphoid cells by HHV-6, the antiviral action of CMV423 is likely to be mediated through inhibition of a host cell tyrosine kinase. Preclinical safety and pharmacokinetic studies on this interesting inhibitor continue (Aventis, data on file; Bournique *et al.*, 2001). The clinical relevance of the MOI-dependence, and the safety margin with host inhibitory mechanisms, remain to be determined.

ISIS 13312
One very specific and clinically validated inhibitor of CMV IE gene expression is the approved anti-sense agent formivirsen (ISIS 2922, Vitravene®). Its utility is greatly limited due to the need for monthly intravitreal injections, and the occurrence of adverse ocular reactions. ISIS 13312, an analogue of ISIS 2922, has been shown to have a longer half-life than ISIS 2922 (approximately 2 months in monkey retina) and could provide the advantage of less frequent dosing (Henry *et al.*, 2001). However, ISIS 13312 is not currently in clinical development.

Antiviral targets in the herpesvirus DNA replication complex

The six or seven essential proteins that comprise the herpes viral DNA replication machinery offer several attractive enzyme targets for drug development, as well as some of the more challenging protein-protein interactions (Matthews *et al.*, 1993; Anders and McCue, 1996; Loregian and Coen, 2006). These components of the HSV replication machinery include the single-stranded DNA binding protein (ICP8, pUL29), the polymerase accessory factor (pUL42), the helicase-primase complex (pUL5, pUL8, pUL 52) and the viral DNA polymerase (pUL30). HSV requires an origin-binding protein specifically (pUL9). These proteins work in concert, are co-localized within specific intranuclear structures, and are found in association with other viral and host proteins involved in the replication cycle events. In principle, points of antiviral intervention could include those that affect protein recruitment and transport (post-translational modification), the sequentially–ordered protein–protein binding events in replisome assembly, and the individual catalytic functions of the enzymes involved in the DNA synthetic process.

The direct inhibition of the DNA polymerase function through nucleoside/nucleotide substrate analogues or pyrophosphate mimics, such as seen with the ACV, GCV, and PFA, is a clinically-validated approach. Discovery efforts continue to exploit this well-validated target, usually in concert with the viral encoded nucleoside kinase for added selectivity in the monophosphorylation step (or also including thymidylate kinase activity). Successful

inhibition of the HIV RT through non-catalytic mechanisms (non-nucleotide reverse transcriptase inhibitors such as nevarapine and efaverenz) have prompted the search for similar agents in herpes discovery screening programs. Representatives in both these categories are in advanced preclinical or early clinical testing. Also in the pipeline are agents that interfere with the function of the helicase primase complex (Fig. 68.3).

Herpesvirus DNA polymerase inhibitors

The herpes virus DNA polymerase is a multifunctional enzyme that possesses both a deoxynucleotide polymerizing activity and a 3′–5′ exonuclease proofreading function, and the structure of the herpes virus replicating complex has been modeled (Franklin *et al.*, 2001). The polymerase polypeptide shares regions of sequence similarity with the catalytic subunits of other alpha – like DNA polymerases of eukaryotes (Braithwaite and Ito, 1991). The conserved regions involved in substrate recognition within the polymerase have been determined by comparative modeling with the Klenow polymerase, and by genetic analysis of mutants resistant to nucleoside/nucleotide analogs (Gibbs *et al.*, 1998; Larder *et al.*, 1987). These regions (I, II, III, V, VII and the delta *region C) are non-contiguous, indicating the broad areas of contact across the polymerase polypeptide during the catalytic polymerization process. The ability of an inhibitor to interfere with correct folding through binding outside of the catalytic sites could impair enzyme function, although mutational escape may be more feasible, based on precedence in the HIV NNRTI series (Spence *et al.*, 1995).

Nucleoside/nucleotide analogue inhibitors

The apparent tolerance of the herpes DNA polymerases for modified acyclic and carbocyclic sugar moieties, exemplified by ACV, GCV, and PCV, drove additional exploration in the purine nucleoside series during the late 1980s and the early 1990s. The discovery of oxetanocins with the structural characteristic of two hydroxymethyl groups located on a rigid 4-membered ring led to the synthesis and antiviral evaluation of a number of related compounds and investigation of their antiviral properties (Sakuma *et al.*, 1991; Sekiyama *et al.*, 1998). Compounds in the oxytanocin series of base analogues, characterized by a carbocyclic sugar moiety, were investigated and showed broad-spectrum activity against the herpesviruses.

Lobucavir

Lobucavir, (R)-9-[4-hydroxy-2-(hydroxymethyl)butyl] guanine], (LBV, cygalovir, BMS 180194), a cyclobutyl analogue of guanine arose from the oxytanocin series and was advanced through early clinical evaluations (Yang *et al.*, 1996a, b). The ultimate outcome serves to illustrate the risks associated with the discovery and development process.

LBV has antiviral activity against HIV, hepatitis B virus, and most herpesviruses, and the triphosphate of LBV is a potent inhibitor of hCMV DNA polymerase in vitro. However, Tenney *et al.* (1997) showed that this nucleoside analogue is phosphorylated intracellularly to its triphosphate form in both infected and uninfected cells, with phosphorylated metabolite levels only two- to three-fold higher in CMV-infected cells compared to uninfected cells. The lack of selective anabolism in virally infected cells (a factor contributing to the broad antiviral activity) provides the potential for substrate utilization by host cell DNA polymerases with corresponding safety risks.

LBV was advanced to the clinic. Preliminary human data showed a dose-related anti-CMV effect (Dunkle, 1996). A clinical study in HIV- and CMV-co-infected patients demonstrated a 50% reduction in CMV viruria and a greater than 1 log reduction in HIV viral load from semen at the highest dose. Side effects were dose-related, and included mild to moderate diarrhea and nausea in 10%–20%, and 7%–12% of recipients respectively (Lalezari *et al.*, 1997).

Despite promising early clinical results, an international Phase III study of LBV as therapy for hepatitis B was suspended in February 1999 due to safety concerns. Toxicologic studies in rodents had suggested increased incidence of stomach, vaginal and cervical cancers with long-term exposure.

Omaciclovir H2G and its pro-drug

Another carbocyclic guanosine analogue, H2G, (*R*)-9-[4-hydroxy-2-(hydroxymethyl)butyl]guanine (omaciclovir), was shown to be a potent broad-spectrum antiherpes agent especially active against VZV (Abele *et al.*, 1991). The MOA is similar to that of ACV, with less selectivity as a substrate for TK. Resistance mechanisms at the TK locus overlap with those of ACV (Ng *et al.*, 2001). H2G is not an obligate chain terminator, although once incorporated, H2G-MP will only support limited chain elongation (Lowe *et al.*, 1995). The triphosphate of H2G has a considerably longer intracellular half-life in infected cells than does ACV-triphosphate (Lowe *et al.*, 1995), a feature that could provide dosing advantages over VACV if clinically validated. Preclinical efficacy studies in the simian varicella model indicated superior potency over ACV (Soike *et al.*, 1993). However, species-specific differences in metabolism of ACV make such comparisons misleading. ACV oral bioavailability is lower in monkeys than in humans, and

the higher aldehyde oxidase levels in monkeys result in faster metabolic clearance in monkeys than in humans, dogs, and rodents (de Miranda and Burnette 1994; de Miranda and Good, 1992).

MIV-606

(ABT-606; [L-valine-(2-hydroxy-4-hydroxymethyl-butylyl) guanine]) is a prodrug of H2G that significantly enhances its oral bioavailability. MIV-606 is quickly converted to H2G, with undetectable concentration of parent prodrug MIV-606 (Medivir AB, Huddinge Sweden, unpublished data). – Three phase I studies with a total of more than 100 volunteers, including subjects 65 years of age and older, demonstrated that MIV-606 was safe and well tolerated after multiple dosing up to total daily doses of 1500 mg.

A phase II study comparing 250, 500, and 750 mg twice daily of MIV-606 with 800 mg five times a day of ACV in zoster patients has also been completed. Trial results suggested equivalent or superior efficacy of MIV-606, compared to ACV, at significantly lower doses. If this claim can translate into an improved therapeutic effect of MIV-606 at a more convenient dose, it could provide enough improvement over current therapies to justify further development. Availability of MIV-606 could potentially lead to much wider treatment of zoster, and the broad spectrum of action could benefit patients with compromised immune function, such as transplant recipients, cancer patients, and AIDS patients (Medivir AB, Huddinge Sweden, unpublished data).

Alkoxyalkyl esters of cidofovir (CDV)

CDV is a nucleotide (monophosphate) analog with broad spectrum anti-herpes activity that is licensed for the intravenous treatment of CMV retinitis in HIV-infected patients. CDV is phosphorylated by cellular enzymes, and the CDV-diphosphate (DP) is a competitive inhibitor of viral DNA polymerase (Safrin *et al.*, 1997). Mechanistically, CDV-DP inhibits many viral DNA polymerases, and recent studies document activity against pox viral infections (Neyts *et al.*, 2004; De Clercq, 2002). In CMV, resistance to CDV can arise from single point mutations in the polymerase locus, usually mapping to the exonuclease functional domains (Chou *et al.*, 2003).

CDV exhibits a number of drawbacks that greatly limit its utility as an anti-herpetic agent. Oral bioavailability is low (<5%) requiring IV administration, usually on a weekly or semi-weekly basis, and dose-dependent nephrology may require pre-hydration, dose reduction and/or co-treatment with probenecid. Other safety liabilities were documented in preclinical toxicology studies Vistide® [package insert], Gilead Sciences, 1999.

Prodrug strategies, accelerated by the threats of bioterrorism, have been employed to increase oral bioavailability and improve the safety profile of CDV (Huggins *et al.*, 2002). The basic prodrug design exploited a natural fatty acid (lysophosphatidylcholine) molecule as carrier to facilitate drug absorption in the gastrointestinal tract. The lipid ester conjugates were much more active in vitro (EC_{50} values at least 100-fold lower) than CDV or cyclic CDV against a range of herpes viruses, including strains of HSV, VZV, CMV, EBV, HHV-6, and HHV-8. SAR of the ether lipid ester analogs defined a 20 atom optimum for alkyl chain length, and explored the nature of the linker group (Williams-Aziz *et al.*, 2005). Consistent with the observed increase in antiviral potency of the 1-O-hexadecyloxypropyl conjugate of CDV in cell culture, studies with radiolabelled compound confirmed increased cell penetration (10–20 fold) and higher intracellular levels (100-fold) of the active antiviral form CDV-DP than those measured in cells treated with CDV parent drug (Aldern *et al.*, 2003).

These lipid carrier prodrugs showed significant advantages over CDV in several in vivo models of murine and human CMV (Bidanset *et al.*, 2004; Kern *et al.*, 2004a; Wan *et al.*, 2005; Kern *et al.*, 2004b). Higher levels of protection were also achieved with the CDV oral prodrugs in a lethal cowpox challenge model (Huggins, 2002). Studies evaluating the oral bioavailability and tissue distribution of ^{14}C-labeled hexadecyloxypropyl-cidofovir (HDP-CDV), octadecyloxyethyl-cidofovir (ODP-CDV), and oleyloxypropyl-cidofovir (OLP-CDV) in female NIH Swiss mice demonstrated that these alkoxyalkyl esters are highly orally bioavailable (88–97%) and do not concentrate in the kidney (Ciesla *et al.*, 2003). Thus these compounds may avoid the dose-limiting toxicity of CDV, if these results translate into the clinic.

The lead compound, CMX001, will be progressed through phase I safety and pharmacokinetic studies in humans for potential use as a smallpox treatment or vaccine rescue (Painter and Hostetler, 2004). Such a therapeutic could also provide a safer salvage therapy for ACV or GCV resistant viruses in immunocompromised patients with life-threatening herpes infections.

This prodrug strategy was successfully applied to another nucleotide phosphonate 9-(S)-(3-Hydroxy-2-phosphonomethoxypropyl)adenine [(S)-HPMPA] with a similar enhancement of in vitro antiviral potency (Beadle *et al.*, 2006).

A-5021

Armed with structure activity relationship (SAR) clues from the crystal structure of the HSV-1 TK complexed with GCV (Brown *et al.*, 1995), and substrate potency

comparisons with ACV, PCV, H2G and the oxytanocins, the scientists at Ajinomoto set out to design a novel series of nucleoside analogues. Extensive exploration of the side chain conformation and enantiomeric specificity in the oxytanocin series lead to the identification of potent activity in a compound with a cyclopropyl sugar (Sekiyama *et al.*, 1998). The lead molecule in this series, **A-5021**, (1′S,2′R)-9-{[1′,2′-bis(hydroxymethyl)cycloprop-1′-yl]methyl}guanine, showed superior in vitro potency over the gold standards ACV or PCV against HSV-1 and VZV in vitro; however, the difference for HSV-2 was only marginal (Iwayama *et al.*, 1998). The compound was also active against EBV and HHV-6, but not HHV-8 (Neyts *et al.*, 2001). Since HSV-2 infection remains the most prevalent disease worldwide, A-5021 must show other development advantages over ACV, VACV and FCV to warrant the time and development investment for the genital herpes indications.

The mechanism of action of A-5021 was investigated (Ono *et al.*, 1998) and found to be qualitatively similar to that of ACV and PCV. A-5021 is anabolized to the monophosphate by the herpes TK enzymes and to the diphosphate by GMP kinase, as is ACV-MP. Levels of A-5021 triphosphate accumulating in HSV-1 or VZV-infected cells were higher than those for ACV-TP, but were roughly comparable to PCV-TP levels. The intracellular half life of A-5021-TP was longer than that of ACV-TP, but somewhat shorter than that of PCV-TP. However, ACV-TP had the most potency at the level of HSV DNA polymerase inhibition, with A-5021-TP intermediate in potency. Incorporation studies showed A-5201-MP could be incorporated into a growing DNA chain, although subsequent chain elongation was inefficient. The anti-HSV-1 and -2 activities were shown to be potentiated in vitro by the immunosuppressive agent mycophenolate mofetil, a finding consistent with the mechanism of competitive inhibition of GTP incorporation, since this agent is known to cause a reduction in cell dGTP pools (Neyts and De Clercq, 2001). A disadvantage of A-5021 is the likely cross-resistance with the most prevalent phenotype of ACV-resistant HSV, the TK-deficient phenotype.

A series of in vitro and in vivo studies suggested potential advantages of A-5021 over ACV for infections mediated by HSV-1. A-5021 exhibited more prolonged antiviral action than did ACV after short exposure of infected cells in vitro. This superior potency and durability carried over into several animal models of HSV-1 infection (Iwayama *et al.*, 1999). In a comparison using once-a-day oral administration with equivalent 25 mg doses, A-5021 demonstrated advantages over ACV in reducing the severity in HSV-1 cutaneous lesions. While the oral bioavailability and AUC of A-5021 is approximately half that of ACV, the superior in vitro potency and the prolonged effect contributed to better efficacy in this cutaneous HSV-1 murine infection model. When initiation of therapy by the intravenous route (100 mg/kg) was delayed to day 4 postinfection, A-5021 again was more effective in diminishing disease spread than ACV or PCV.

A-5021 treatment also resulted in a complete survival of mice infected intracerebrally with HSV-1 after IV dosing with 25 mg/kg A-5021 TID, compared to only 50% survival at 100 mg/kg IV ACV TID dosing (Iwayama *et al.*, 1999). The levels of A-5021 in the brain were not presented. Higher uptake of antiviral agent into the infected organ could be a major factor in the superior efficacy of A-5021 in this model, and a clear advantage of A-5021 over ACV, which has limited ability to penetrate the blood-brain barrier (de Miranda and Good, 1982).

In another variation of time of addition and withdrawal treatments in the animal model, high dose intrapertioneal (ip) infection of SCID mice was followed by once daily subcutaneous treatment (50 mg/kg). After 4 days of treatment, initiated at 1 hour, or 1 or 2 days post-infection, the delay in mortality and ultimate number of survivors was far greater in the A-5021 treated groups than in the ACV-treated groups (Neyts *et al.*, 2001). No pharmacokinetic information was provided to allow comparisons of actual systemic exposures.

In contrast to the superior performance of A-5021 against the gold standard of ACV in all the HSV-1 infection models, the efficacy of A-5021 was not distinguished from that of PCV in a model of systemic infection with HSV-2 (Iwayama *et al.*, 1999).

A-5021 has entered clinical development. It remains to be seen if the advantages in potency and duration of antiviral effects seen in cell culture and animal models will translate into superior efficacy in the various HSV and VZV disease indications. The ophthalmic use for herpetic keratitis is under development. Another proposed clinical application would be its use in gene therapy approaches to cancer, utilizing the HSV-1 TK vectors, since A-5021 is less cytotoxic than GCV, which is currently used (Hasegawa *et al.*, 2000).

BCNA compounds

A new structural class of bicyclic furo pyrimidines (BCNAs) have recently been discovered that demonstrate both highly specific and selective anti-VZV in vitro activity (Balzarini and McGuigan, 2002; McGuigan *et al.*, 2003; De Clercq, 2003a,b). The starting point for these compounds was BVDU, ((E)-5-(2-bromovinyl)-2′-deoxyuridine), which was established in the early 1980s as having good antivi-

ral activity but low selectivity. The BCNAs are characterized by a long alkyl or alkylaryl side-chain at the base moiety that may be responsible for both their antiviral properties and their lipophilic properties. The compounds are highly potent at sub-nanomolar concentrations, and cytotoxicity has not been observed at high micromolar concentrations.

The MOA has not been fully elucidated, but the compounds lose their antiviral activity against TK-deficient VZV strains, demonstrating that phosphorylation by the VZV-encoded TK is essential. Kinetic studies with purified enzymes revealed that the compounds were indeed a substrate for VZV TK, which is able to phosphorylate the BCNA compounds to both their corresponding 5′-mono and -diphosphate derivatives; a factor in their anti-VZV selectivity. Another indication of the unusual selectivity of this class of nucleoside analogs was the lack of substrate recognition by cellular kinases which contribute to the anabolism of other pyrimidine analogs; the cytosolic or mitochondrial TKs, cyrosolic dTMP kinase, and most striking, nucleoside diphosphate kinase, the host enzyme which converts BVDU-DP to the active triphosphate form. Consistent with this observation, no 5-triphosphate of BCNA could be detected in VZV-infected cells (Sienaert *et al.*, 2002). Information on the inhibitory effects of BCNA anabolites on the VZV DNA polymerase is not yet available.

There is no clear cut correlation between their affinity for VZV TK and the antiviral potency of the compounds, indicating that an additional SAR is likely (Balzarini and McGuigan, 2002). The closely related Simian varicella virus (SVV) is not sensitive to BCNA although in vitro studies indicate that SVV TK is able to phosphorylate BCNAs. Unfortunately this precludes the utility of the SVV animal model in the therapeutic development of BCNAs (Sienaert *et al.*, 2004).

The BCNAs are highly stable and not liable to breakdown by nucleoside/nucleobase catabolic enzymes (Balzarini *et al.*, 2002). The fact that they are not susceptible to degradation by thymidine phosphorylase and that they do not inhibit dihydropyrimidine dehydrogenase are key improvements over BVDU. Further clinical development is anticipated.

Non-nucleotide inhibitors

PNU-26730

In an effort to identify non-substrate inhibitors of the herpes polymerase with broad-spectrum activity, Pharmacia researchers set up herpes polymerase-based screens and tested 80 000 representatives of different compound diversity. Selectivity was achieved by secondary evaluation of hits against the mammalian DNA polymerases alpha, gamma and delta. The systematic discovery program identified the activity of the naphthalene carboxamide series, exemplified by the initial active compound, PNU-26730 (Vaillancourt *et al.*, 2000). Further optimization in this series led to a quinolone ring substitution and the 4-hydroxyquinoline-3-carboxamides series. Increased potency against the CMV, HSV-1 and VZV DNA polymerases was achieved by adding substitutions at the 6 position on the quinolone ring yielding the 4-oxo-dihydroquinolines (4-oxo-DHQs) series of compounds. These compounds, represented by PNU-182171 and PNU-183792, were also more active than the initial lead and the gold standard ACV against VZV and CMV, but showed no enhanced activity against HSV-1 or 2. These 4-oxo-DHQs were not active against other RNA and DNA virus tested: vaccinia, SV-40, adenovirus, HBV, influenza A, coxsackie B or VSV. (Brideau *et al.*, 2002; Knechtel *et al.*, 2002; Wathen, 2002).

PNU-183792

One of the 4-oxo-DHQ compounds, PNU-183792 (*N*-(4-cholorobenzyl)-1-methyl-6-(4-morpholinylmethyl)-4-oxo-1,4 dihydro-3-quinolinecarboxamide) was selected for additional investigations. Efficacy studies in a murine model of lethal MCMV infection showed antiviral activity similar to GCV when treatment was initiated up to 24 hours post infection, but was less efficacious at comparable doses given 48 hours postinfection (Brideau *et al.*, 2002). Other properties required for a drug candidate were demonstrated: for example, PNU-183792 was orally bioavailable in dogs and rodents, achieving concentrations above the IC_{50}, with reasonable rates of clearance and a half life of 3 hours in dogs. The important measure of available drug levels is at the intracellular site of action, and although this information was not published for PNU-183792, it is likely to be similar to the actual plasma concentrations. Nucleoside and nucleotide analogues may have an advantage over non-nucleoside inhibitors of DNA polymerase in this regard, as the $t_{1/2}$ of the triphosphate active form anabolized within the cell compartment can exceed plasma levels of unchanged drug.

The strong correlation between polymerase inhibition and viral replication inhibition in the analogue series supports inhibition of viral DNA polymerase as the MOA (Fig. 68.3). Further mechanistic studies into the nature of the polymerase inhibition showed competition with the binding of natural substrate (dTTP) to the polymerase enzyme, with a low-level affinity for the enzyme substrate complex that was not defined. Points of drug interaction with target protein were characterized by resistant virus

bearing point mutation(s) in the DNA polymerase gene (Oien *et al.*, 2002; Thomsen *et al.*, 2003).

This promising class of compounds will be active against the drug-resistant TK variants of HSV and VZV, and the current in vitro profile shows activity against clinically relevant HSV and CMV polymerase mutants (Thomsen *et al.*, 2003). This profile is consistent with this class of compounds interacting at a different molecular site in the polymerase polypeptide.

Information on the current development status is limited since Pharmacia was purchased by Pfizer. The selectivity screens have reduced the likelihood of mechanism-based toxicity within the series leads; and the safety profile will be defined by full in vivo toxiologic studies. Other key questions with this type of molecule and the nature of the MOA will be potency compared to valacyclovir or famciclovir, durability of action (related to frequency of dosing), and the ease of viral escape (resistance).

Herpes helicase-primase inhibitors

Efforts to identify drugs targeting other components of the DNA replication complex have focused on another enzyme, the helicase-primase (Hall and Matson, 1999). In the herpesviruses, the helicase-primase complex consists of 3 proteins that associate as a trimeric complex to carry out the essential tasks of unwinding the dsDNA in the 5′ to 3′ direction, RNA polymerase activity and ssDNA-stimulated ATPase activities (Crute and Lehman, 1991; Parry *et al.*, 1993). In HSV, these are the gene products of UL5, UL8, and UL52 ORFs. The drug candidates recently identified from screens targeting helicase-primase represent the next generation, and an exciting new class of antiviral agents. The major unknowns with this MOA include the ease of emergence of resistance in the clinic, and the pathogenicity (including reactivation) and transmission of potential of resistant virus.

T157602

The scientists at Tularik Inc. screened a library of >190,000 samples consisting of small organic molecules and natural products, using a novel filtration assay for the detection of the helicase DNA unwinding activity (Sivaraja *et al.*, 1998). The most active selective compound was a 2-aminothiazole compound, T157602 (Spector *et al.*, 1998). Preliminary MOA studies suggested that T157602 stabilized the helicase-primase complex, effectively trapping the enzyme on the DNA substrate and blocking all 3 activities of the complex (Fig. 68.3). The compound was a reversible inhibitor ($IC_{50} = 5\ \mu M$), of the helicase activity of the HSV UL5/8/52 complex, but was less active against other helicases, and could also interfere with primase activity at higher concentrations ($IC_{50} = 20\ \mu M$).

Strains of HSV-1 and HSV-2 resistant to T157602 that were selected in the laboratory carried individual point mutations in the UL5 viral gene that resulted in amino acid substitutions in the corresponding UL5 protein. Marker transfer studies confirmed the role of these genetic changes in the resistance phenotype, both at the level of the UL5 enzyme subunit and of mutant virus. Animal-model efficacy studies were not reported for this series.

In vitro cytotoxic studies revealed no apparent cellular toxicities at concentrations exceeding 100 μM, indicating a therapeutic window greater than 30-fold. However, as of 2003, the 2-aminothiazole compounds are no longer included in the Tularik development pipeline, suggesting safety deficiencies arose during the phase I/II clinical studies.

BILS 179 BS

Related compounds with more potent helicase-primase activity emerged from enzyme-based screens at Boehringer Ingelheim (Crute *et al.*, 2002) and cell-based viral replication screens at Bayer AG (Kleymann *et al.*, 2002). The thiazolylphenyl-containing compounds represented by BILS 179 BS inhibited all three enzyme activities of the HSV helicase-primase complex at 100 nM or lower concentrations. The antiviral activity was specific for HSV, with no activity against VZV, and human or murine CMV. Preliminary data suggest that the mechanism of inhibition involves a stabilization of the interaction between the enzyme complex and the DNA substrate, most likely by imposing a physical constraint both to enzyme progression through the DNA-unwinding reaction and to primase catalytic activity (Fig. 68.3).

Resistant viruses were selected by serial passage in BILS 179 BS for more definitive MOA studies. Helicase-primase purified from cells infected with these resistant viruses demonstrated decreased inhibition in an in vitro DNA-dependent ATPase assay that corresponded with antiviral activity. Single base pair mutations clustered in the N-terminus of the UL5 gene that resulted in single amino acid changes in the UL5 protein were identified by marker transfer and DNA sequence analysis. These results were consistent with helicase-primase inhibitor activity mediated through specific interaction with the UL5 protein (Liuzzi *et al.*, 2004).

BILS 179 BS was 10–15 times more active than ACV in vitro (EC_{50}s 27 nM–100 nM). Cytotoxicity effects were somewhat dependent on cell type, and additional experiments are needed to better clarify the cytotoxicity profile of these compounds. Efficacy studies were conducted

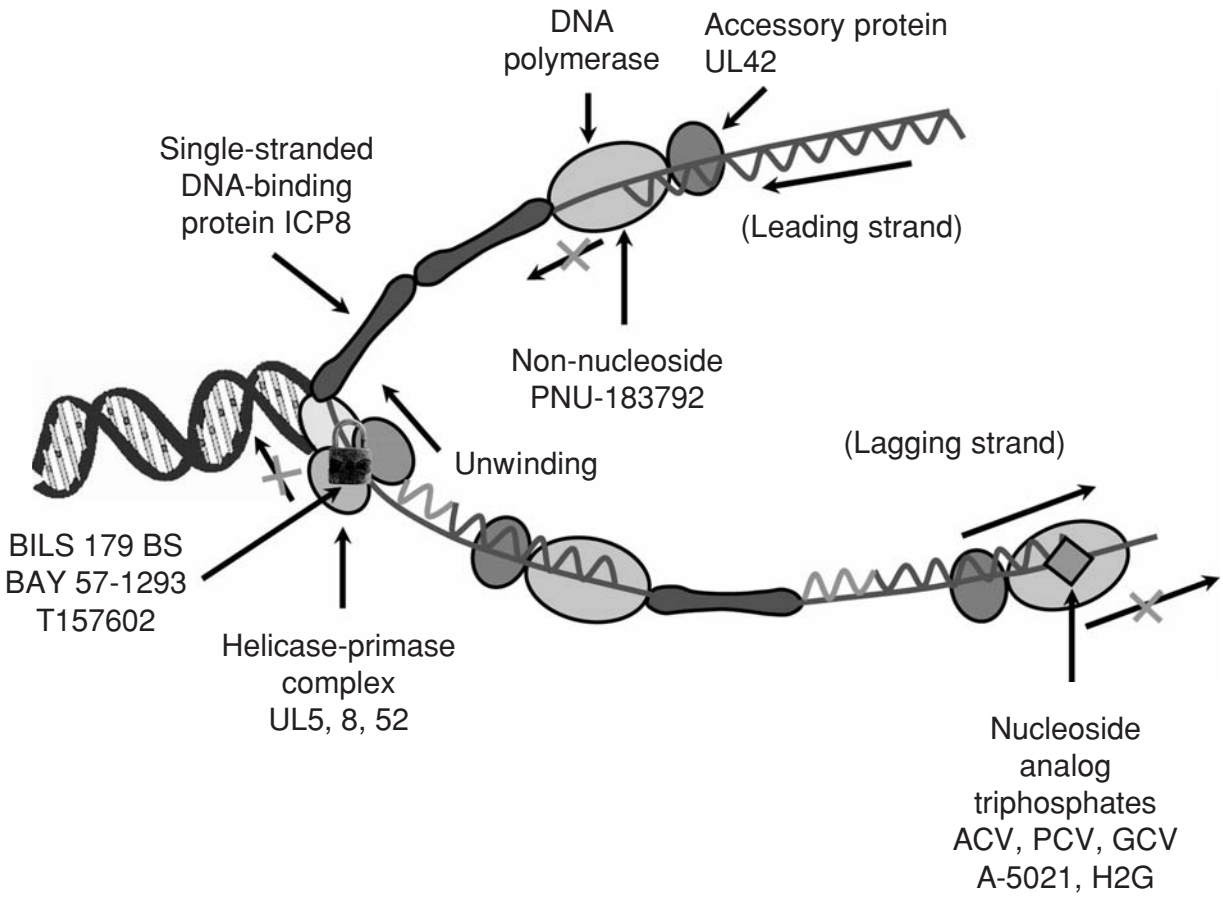

Fig. 68.3. HSV DNA replication targets. (Adapted from Crumpacker and Schaffer, 2002.)

in murine models of primary cutaneous and genital disease, using ACV as the treatment comparator (Crute *et al.*, 2002). In the cutaneous model of progressive zosteriform disease (hairless SKH-1 mouse infected with HSV-1 strain KOS), BILS 179 BS demonstrated comparable efficacy to ACV when treatment was initiated 3 hours post infection (1 × or 4 × daily). However, BILS 179 BS was superior to ACV when treatment frequency was reduced, or when initial treatment was delayed by 65 hours.

Comparable results were evident in the genital disease model (Swiss Webster mice vaginally infected with HSV-2 strain HG-52). Efficacy was based on a composite disease severity scoring system that included mortality. Again, BILS 179 BS had similar efficacy to ACV when treatment was initiated at 3 hours (1 × or 4 × daily), and superior efficacy when treatment frequency was reduced or when initial treatment was delayed by 65 hours. Actual drug exposures were not reported for these studies; however, BILS 179 BS was reportedly bioavailable, and on a weight-dosing basis, BILS 179 BS showed superior activity to ACV. Disappointing findings from a drug development perspective included the identification of pre-existing resistant variants within the wild type virus population, and rapid selection of highly resistant growth-competent viruses in vitro that maintained a stable drug-resistant phenotype in the absence of drug. Of more clinical relevance was the demonstration that two resistant strains studied were fully competent for disease pathogenesis (by cutaneous or intracerebral routes in mice), and for reactivation from latency in an ocular infection model (Liuzzi *et al.*, 2004). By contrast, ACV-resistant strains of HSV were generally less virulent in various infection models. This safety feature is based on the biology of HSV, and the mechanism of action of the drug ((Elion *et al.*, 1977). ACV resistant clinical isolates are generally TK-deficient, and as a consequence less pathogenic in the immune competent population and less competent for reactivation from latency (recurrences are ACV-susceptible). The potential for transmission of drug-resistant strains into the general population is a public health consideration and requires

careful monitoring (Shin *et al.*, 2001; Bacon *et al.*, 2003). The clinical development timetable for this compound is unknown at this time (mid 2006).

BAY 57-1293

The Bayer discovery program used a fluorometric high-throughput screening assay that identified inhibition in any target essential for viral replication in cell culture. Over 400,000 compounds were tested at 10 μM, and several compound classes with activity were identified (Kleymann, 2003 a,b). The triazole urea class of analogues was selected for additional study. Profiling and modeling techniques were employed, and optimization to improve the solubility led to the 2-pyridyl substituent in the para position of the phenyl ring in the lead compound to create BAY 57-1293 (*N*-[5-(aminosulfonyl)-4-methyl-1,3-thiazol-2-yl]-N-methyl-2-[4-(2-pyridinyl)phenyl]acetamide). BAY 57-1293 inhibited the replication of HSV type 1 and 2 in Vero cells (IC_{50} of 20nM) with a selectivity index of 2,500; ACV had an IC_{50} of 1 μM and a selectivity index of 250 under comparable conditions. There was no appreciable activity against VZV or CMV. BAY 57-1293 was equally active against ACV-resistant TK or polymerase mutants, and the activity was irrespective of cell type (Kleymann *et al.*, 2002). The in vitro replication block was reversible upon drug removal, and significant activity was still demonstrated when added late post infection.

Researchers selected virus resistant to each of the three analogues in the series. Resistance resulted from point mutations in UL5 (present in all six resistant strains), or in one case, a UL5 mutation together with a point mutation in UL52. These mutations in UL5 were clustered between nucleotides 1045 to 1077, a region that corresponds to the amino acids from 349 to 359 involved in the alpha helicase region that is most homologous across the herpesviridae (Kleymann *et al.*, 2002). BAY 57-1293 inhibits the ATPase activity of the viral helicase-primase complex in a dose-dependent manner (IC_{50} of 30 nM).

The treatment potential of BAY57-1293 was investigated in several cutaneous and systemic animal models of disease (Betz *et al.*, 2002). The activities of orally administered BAY 57-1293 for the treatment of acute HSV-1 and HSV-2 infections were assessed in a widely-used murine lethal challenge model of disseminated herpes. Mice were infected intranasally and treated, starting 6 hours later for 5 consecutive days, three times a day. BAY 57-1293 and comparator drugs (ACV, GCV, VACV, FCV, Brivudin) were tested in escalating doses, and ED50 (dose at which 50% of the infected animals survive) values calculated. With an ED_{50} of 0.5 mg/kg of body weight TID against HSV-1 and HSV-2, BAY 57-1293 was the most potent compound tested. Comparable values for ACV were 22 and 16 mg/kg of body weight. No toxic side effects of BAY 57-1293 treatment were apparent in the mice upon gross inspection, and the highest dose tested (60 mg/kg TID) appeared to be well tolerated. Comparable results were shown in a rat lethal challenge model.

In the cutaneous zosterform model, oral treatment of HSV-2 established by dermal scarification was delayed until establishment of disease (day 3) and then animals were treated for 5 days TID with 15 and 60 mg of BAY 57-1293 per kg and 60 and 240 mg of VACV per kg. The lower dose of BAY 57-1293 was statistically more efficacious than the highest dose of VACV used ($P < 0.011$), based on a compiled disease severity score.

In the guinea pig vaginal model of HSV-2 genital herpes, delayed treatment with BAY 57-1293 (20 mg/kg 2 × daily orally; days 4–14 post infection) rapidly shut down disease progression. VACV at 7.5 × higher dose levels produced only a weak response. Benefit in terms of time to healing was clearly superior in the BAY 57-1293 treatment group. Perhaps the most promising results observed in the animal studies were the observation that acute treatment in this model could reduce the number of subsequent recurrences. This latter outcome may reflect the more potent and rapid shut down of the virus feeding the latency reservoir, and illustrates the importance of rapid diagnosis and treatment of the primary infection.

In these studies, the actual drug exposures (PK parameters) for BAY 57-1293 and comparators were not reported (Betz *et al.*, 2002) making it difficult to compare potencies. However, the PK for single 1 mg/kg dose in female BALB/C mice indicated high oral bioavailiability C_{max} 4.4 μM after 1 hour, and relatively slow elimination from the plasma ($T_{max} = 1$ hr; $t\frac{1}{2}$ 6 hours). Oral bioavailability >60% and an elimination half-life of >6 hours has also been observed in rats and dogs. Plasma concentrations with these properties would exceed 0.025 μM at 24 hours post dose. Under the conditions used in the cutaneous efficacy model studies with 15 and 60 mg doses administered 3 times daily, one would expect significant accumulations of drug levels above IC_{90} over the 5-day course of treatment; providing extended antiviral cover in the post-dosing period (Kleymann *et al.*, 2002). BAY 57-1293 shows the potential for once daily dosing, a convenience important for chronic suppression. From a pharmaceutical manufacturing perspective, such potency has advantages in smaller pill size and burden (number of pills per dose), resulting in economic savings in the amount of drug substance.

The long duration of drug exposure can offer advantages in terms of efficiency in reduced frequency of dosing, but must be balanced by an excellent safety profile

to avoid undesired consequences of toxic build up. Early toxicology studies indicated that once-daily dosing of dogs with 30, 100, and 300 mg/kg of BAY57-1293 for 28 days was well tolerated. The identical dosing protocol in rats, however, resulted in a dose-dependent transitional hyperplasia of the urinary bladder epithelium (Kleymann *et al.*, 2002). Based on a structural similarity to the diuretic drug, Diamox® (acetylzolamide), the Bayer toxicologists hypothesized that inhibition of the carbonic anhydrase enzymes led to bladder hyperplasia. Sulfonamides with broad inhibitory activity against the carbonic anhydrases of rats, dogs, and humans, only cause this bladder hyperplasia in the rodents. The in vitro inhibition of a carbonic anhydrase standard assay by BAY57-1293 occurs at 2 μM; 100-fold above the viral inhibitory concentration. Extended toxicologic evaluations will be required to further clarify this observation. The overall preclinical profile of this compound would support clinical development, and the evidence of superior potency and more rapid onset of action, and durability compared to the gold standard therapy, make it one of the most promising agents in the development pipeline (2004).

A novel series of inhibitors of the CMV helicase primase function was identified in a cell-based viral replication (single cycle) assay (Cushing *et al.,* 2006). The imidazolylpyrimidine core scaffold was substituted extensively at the 2-, 4-, 5-, and 6 positions to produce an active series of analogs with in vitro potencies ranging from 0.04–0.30 μM. The SAR revealed the importance of the imidazole/nitro group dyad, and the nature of the substituents at the 4 position. The chemical features were consistent with a mechanism of action involving a covalent binding to a target protein. Irreversible binding to the UL70 component of the CMV helicase primase complex (UL102, UL105, UL70) was demonstrated by co-immunoprecipitation of UL70 bound to radiolabeled inhibitor (Cushing *et al.*, 2006). Resistance selection is not yet reported for these new inhibitors. Two compounds provide excellent starting points for the further optimization for the necessary properties of a viable drug candidate.

Inhibitors of DNA processing and packaging

After herpesvirus DNA replication, the concatemeric product is packaged into preformed capsids and cut into unit-length genomes by site-specific cleavage. At least seven HSV proteins have been identified as participants in this process; pUL6, pUL15, pUL17, pUL25, pUL28, pUL32 and pUL33 (Beard *et al.*, 2002) and many of these have been confirmed as essential for viral replication. By analogy with DNA bacteriophage packaging and processing, a terminase complex binds to the capsid portal, trims the concatemeric DNA at a specific sequence with unique structural features (Adelman *et al.*, 2004), translocates the DNA into the capsid and finally cleaves the DNA at a repeat of the specific sequence. The HSV pUL6 protein has been shown to form the capsid portal (Newcomb *et al.*, 2001, 2003). A variety of evidence indicates that the pUL15 and pUL28 proteins form the terminase complex that cleaves the HSV DNA at the sequence before and after packaging (Beard *et al.*, 2002; White *et al.*, 2003; Przech *et al.*, 2003). The packaging genes are well-conserved among the herpesviruses; for example at least six of the seven HSV genes have close homologues in CMV. Of the terminase components CMV pUL89, pUL56 and pUL104 are the homologues of HSV pUL15, pUL28 and UL6 (Fig. 68.4). Biochemical and structural studies of the hCMV pUL89 and pUL56 suggest that the pUL56 binds to the viral DNA, while pUL89 mediates DNA cleavage via an ATP-dependent-nuclease activity (Bogner *et al.*, 1998; Scheffczik *et al.*, 2002; Scholg *et al.*, 2003). Since the processing and packaging of concatemeric DNA has no exact counterpart in the human cell this target presents the possibility of discovering very selective antiviral agents.

Inhibitors of the portal protein of HSV

WAY 150138

Activity of the thiourea class of compounds emerged from cell-based replication screens, revealing a striking degree of specificity within the alpha herpesviruses, but no activity across other human herpesviruses (Visalli and van Zeijl, 2003). Minor structural changes in the main scaffold resulted in >10-fold shifts in activity between HSV and VZV, and the lead HSV compound, WAY 150138, (benzamide, N-[3-chloro-4-[[[(5-chloro-2,4-dimethoxyphenyl)amino]thioxomethyl] amino]phenyl]-2-fluoro-). Identification of the portal protein as the molecular target was made by the generation and mapping of laboratory-derived resistant mutants (van Zeijl *et al.*, 2000; Visalli and van Zeijl, 2003). The portal proteins of HSV-1 and HSV-2 share 86% amino acid identity or similarity, while VZV (pUL54) and human CMV (pUL104) portal proteins share only 44% and 27% identity/similarity, respectively. Although these homologues share a high degree of functional homology, and strong overall amino acid identity in conserved domains, no broad spectrum inhibitors have yet been identified.

The individual mutations identified in the HSV-1 strains resistant to WAY-150138 suggested points of interaction with the compound resulted from the folding of the UL6 protein in its active 3- dimensional conformation. A

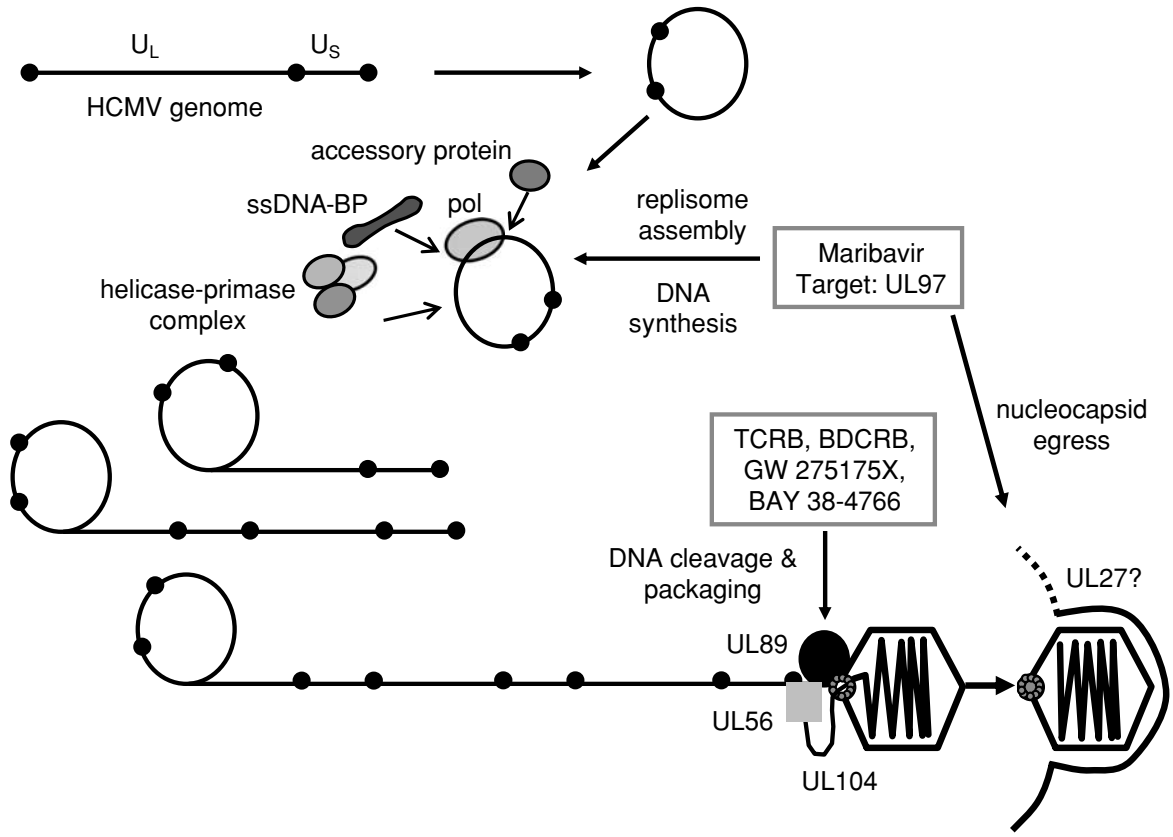

Fig. 68.4. Inhibitors of CMV DNA replisome, packaging, and nucleocapsid egress.

crystal structural model for the portal protein to aid in understanding the mechanism of UL6 binding and in further drug design was not available. Research on this class of portal protein inhibitors continues. No information is currently published on the other preclinical properties of these compounds that would indicate their potential as herpes simplex therapeutics.

Comp I

Subsequent screening of related compounds in the thiourea series revealed that a small chemical modification (addition of a spacer, -HC(CH3)-, between the aryl ring and the thiourea nitrogen) yielded compounds active against VZV, but with loss of activity against HSV. Three *N*-methylbenzyl-*N′*-arylthiourea analogues (Comp I, Comp II, and Comp III) were selected for further study.

A number of MOA studies were conducted confirming that VZV DNA cleavage and packaging is inhibited by these thiourea compounds via inhibition of the ORF54 gene (Visalli *et al.*, 2003). Resistant viral isolates were found to possess mutations in the VZV ORF54 gene, the homologue of HSV UL6, similar to the mechanism of WAY-150138 (van Zeijl *et al.*, 2000; Newcomb and Brown, 2002). As expected, treatment of wild-type virus with the inhibitor resulted in the absence of DNA-containing capsids, and restriction in the spread of infectious VZV to adjacent uninfected cells.

Current marketed VZV antivirals all target the DNA polymerase, and virus resistant to these new thiourea compounds are not cross-resistant to the approved drugs. Thus, targeted inhibition of the VZV ORF54 protein may prove to be a productive approach in identifying new agents to complement existing antivirals in the treatment of VZV infections.

Dihydroxyacridone series

The dihydroxyacridone series was investigated in order to target a MOA other than viral DNA polymerase (Akanitapichat *et al.*, 2000). Initial attempts focused on analogues with functional groups at the 5, 6, or 8 positions. The 5-Cl congener (5-chloro-1,3-dihydroxyacridone) was determined to be the most selective inhibitor of HSV and was selected for additional study. Mechanistic studies suggested that HSV replication was blocked after DNA and late protein synthesis. Further studies (Akanitapichat and

Bastow, 2002) indicated that maturation of replicating DNA and late virion production were inhibited in the same dose-dependent manner, resulting in a two- to three-fold reduction in the production of B capsids. Of interest was the inability to isolate resistant virus, although these attempts were limited, attempts to isolate resistant virus were unsuccessful.

Additional chemical elaboration and parallel synthesis of compounds in this series (Lowden and Bastow, 2003) identified compounds that were active against CMV (ED_{50} value of 1.4 μM at low MOI) and some that were active against both CMV and HSV. At least one compound in this series inhibited cell replication (mean CC_{50}s = 33 μM), but did not have antiviral activity. Preliminary mechanistic studies indicated the likelihood of diverse MOAs. While this has some appeal, more extensive work may be needed to determine the real selectivity and safety of this series of compounds.

Inhibitors of the CMV terminase complex

TCRB and BDCRB

The first selective inhibitors of the hCMV terminase complex, TCRB (2,5,6-trichloro-1-ß-D-ribofuranosyl benzimidazole) and its analogue BDCRB (1-(ß-D-ribofuranosyl)-2-bromo-5,6-dichlorobenzimidazole) arose serendipitously from a chemistry effort to modify the broad spectrum transcriptional inhibitor DRB into an anti-tumor agent (Townsend and Revenkar, 1970). The antiviral activity was uncovered during subsequent screening for antiviral activity in the series (Townsend *et al.*, 1995). In contrast to the action of GCV, viral DNA synthesis was unaffected in a single round of replication. The phenotype of infected, treated cells was consistent with a block in the viral DNA cleavage and packaging (Fig. 68.4).

Genetic mapping studies of the BDCRB and TCRB-resistant mutants of Towne and AD169 strains confirmed the interaction of these inhibitors with two subunits of the terminase complex (Krosky *et al.*, 1998; Underwood *et al.*, 1998). Specific point mutations were identified in the UL89 gene, which encodes the small subunit required for the nuclease cleavage of the precursor viral DNA into unit genome lengths (Bogner, 2002). A mutation was also selected in the UL56 gene, which encodes the large subunit responsible for sequence-specific DNA binding to the pac motifs, and ATP-dependent translocation of the viral DNA into the preformed capsids for final cleavage and packaging.

Precisely how two unrelated compound series, the β-D-ribosyl benzimidazoles and the sulfonamides, block DNA processing and packaging is not currently understood. The exact binding sites for BDCRB and BAY 38-4766 on the terminase subunits are apparently different, based on lack of cross-resistance (Evers *et al.*, 2004). Their binding could disrupt protein-protein interaction via allosteric mechanisms, or could directly interfere with enzymatic activity. The genome maturation process is complex, and occurs at the viral replication center sites, where viral and cellular transcriptional and DNA replication machinery also assemble (Dittmer *et al.*, 2005; McVoy and Nixon, 2005; Thoma *et al.*, 2006). BDCRB treatment of CMV-infected cells resulted in a major block to correct unit genome cleavage, and also allowed a minor level of monomer plus larger than unit product genomes resulting from skipped cleavages (McVoy and Nixon, 2005). This inhibitor also may directly interfere with the interaction of the pUL56 and the portal protein pUL104, as evidenced by the ability of BDCRB to block their co-immunoprecipitation from CMV-infected cells (Dittmer *et al.*, 2005). Consistent with a direct interaction of the pUL56 terminase subunit with the portal protein, resistance modifications in UL89 and UL56 to BDCRB, TCRB and BAY 38-4766 were accompanied by a compensatory change in UL104, which alone did not confer resistance (Buerger *et al.*, 2001; Reefschlaeger *et al.*, 2001; Komazin *et al.*, 2004). These interesting inhibitors continue to help elucidate the genome maturation events.

These two lead benzimidazole ribosides showed potent, selective activity for human CMV. However, pharmacokinetic studies indicated metabolic lability of the glycosidic bond between the base and the sugar moieties (Good *et al.*, 1994). Recently, the identification of two cellular enzymes that catalyze the cleavage of the glycosidic bonds of BDCRB and TCRB were reported (Lorenzi *et al.*, 2006). An active chemical program was undertaken to stabilize this linkage (Townsend *et al.*, 1999; Chulay *et al.*, 1999). The results of this effort were fruitful; yielding two clinical candidates, GW275175X, an inhibitor of the hCMV DNA terminase process packaging, and BW1263W94 (maribavir), an inhibitor of the pUL97 protein kinase (information as of 2003). The application of amino acid esters as pro drugs of BDCRB has also been successful, identifying L-Asp-BDCRB as a potential candidate for further development (Lorenzi *et al.*, 2005).

GW275175X

A benzimidazole with a pyranosyl sugar moiety selected for further development was **GW275175X** (2-bromo-5,6-dichloro-1-ß-D-ribopyranosyl-1-H-benzimidazole), a compound whose antiviral activity is specific for hCMV; there was no in vitro inhibition of HSV-types 1 or 2, VZV, or other DNA and RNA viruses tested (Williams *et al.*, 2003; Underwood *et al.*, 2004). MOA studies (Underwood *et al.*, 2004) supported inhibition of viral cleavage and packaging, consistent with the mechanism of BRCRB. As expected, virus with the BDCRB- and TCRB-resistant mutations in

UL89 were cross resistant to GW275175X. One notable aspect of the MOA is the rapid reversibility of the BDCRB or GW275175X block in infected cell culture, with resumption of viral DNA concatamer processing and restoration of the rate of viral yield production occurring within 8–10 hours following drug washout (Underwood *et al.*, 2004).

A battery of preclinical toxicology testing sufficient to support initial Phase I studies in humans (GSK, data on file) was completed for GW275175X. No significant adverse activity in in vivo assays designed to predict effects on metabolic parameters were exhibited. Other in vitro assessments of GW275175X were encouraging; pharmacology screens, and in vitro and in vivo mutagenecity tests were clean, and liver enzyme studies were clean. GW275175X was evaluated for toxicity in rodents (28-day acute, 6-month chronic) and primates (28-day acute). Systemic exposures at the various doses ranged from 60- to100-fold the in vitro IC_{50} for CMV inhibition. Importantly, penetration into the CNS and vitreous humor in primates was good, ranging from approximately 2 $\times$ the IC_{50} at 50 mg/kg/day to 8X the IC_{50} at 200 mg/kg per day. These characteristics would be important for treatment of congenital and ocular CMV disease.

Based on the overall preclinical properties and safety profile, GW275175X was progressed into Phase I single-escalating dose (100–1600 mg) studies. No drug-related or clinically significant changes from baseline were seen in vital signs, ECG, or clinical laboratory values, and all adverse events were considered mild. The pharmacokinetic profile indicated several advantages of this benzimidazole ribose over the parent BDCRB and the analogue, maribavir, including better CNS penetration, longer plasma half-life, and reduced serum protein binding.

While the overall preclinical and initial phase I data encouraged further clinical development, this compound was not advanced due to the sponsor's decision to progress the other anti-CMV agent from the benzimidazole riboside series (1263W94, maribavir) instead.

BAY 38–4766

The non-nucleosidic BAY 38–4766, 3-hydroxy-2,2-dimethyl-*N*-[4([[5-(dimethylamino)-1-naphthyl]sulfonyl] amino)-phenyl]propanamide compound emerged from a cell-based discovery program as the lead highly selective inhibitor of human, monkey and rodent CMV. Resistance to this drug was genetically mapped to the UL89 and the UL56 ORFs, indicating that this class of compound also targeted the hCMV terminase complex (Reefschlaeger *et al.*, 2001; Buerger *et al.*, 2001). The drug susceptibilities of 36 hCMV clinical isolates to the BAY 38–4766 and GCV were evaluated in two different phenotypic assays. All isolates including those resistant to GCV were inhibited by at least 50% at a concentration of approximately 1 μM of BAY-38–4776 (McSharry *et al.*, 2001a,b). Antiviral activity comparable to GCV was demonstrated in a hollow-fiber model where hCMV-infected human cells entrapped in hollow fibers were transplanted into immunodeficient mice (Weber *et al.*, 2001). Viruses resistant to BAY 38–4766 are not cross resistant to current marketed CMV drugs GCV, CDV or PFA.

A favorable pharmacokinetic profile has been demonstrated in humans for the initial lead compound in this series. A phase I study in healthy male subjects after single oral doses of BAY 38–4776 (100 to 2000 mg) indicated that the drug was well tolerated with no adverse events or changes in vital signs or lab parameters. The C_{max}s ranged from 0.33 mg/l (100 mg dose) to 4.2 mg/l (2000 mg/l dose) and occurred within 0.5 to 5 hours. After C_{max} concentrations were reached, drug was eliminated from plasma, with a $t_{1/2}$ of 3 to 5 hours reaching a terminal half life of 12–16 hours. The increases in AUC and C_{max} were dose dependent (Nagelschmitz *et al.*, 1999).

As of 2004, work continued to advance a compound from this interesting series into full clinical development.

Protease inhibitors

Impressive success in the development of protease inhibitors (PIs) in the treatment of HIV infection has not been paralleled in the herpesviruses. The PIs for HIV infection were introduced in 1996 and quickly set a new standard of care, dramatically extending the life of patients with HIV infection. Success in the design of therapeutic agents targeting the HIV protease is partly attributed to the well-defined structural features of the catalytic site in this aspartyl protease (Supuran *et al.*, 2003). In contrast, the herpes proteases belong to the serine protease family, and are characterized by a distinctive catalytic triad of his, his, ser within the less tractable active site. The cleavage sites are unique and highly conserved across the herpesviruses. The herpes proteases comprise the N-terminal sequence of the capsid scaffold protein. After completion of capsid assembly, auto cleavage by the protease releases the scaffold, permitting DNA packaging (Gibson *et al.*, 1994).

The herpes protease is essential for the production of infectious virus, and therefore represents a valid target. The quest for inhibitors of these proteases was facilitated by the development of efficient enzyme-based screens and wide-ranging X-ray crystallographic structure and catalytic site features that became available in the mid-1990s (Borthwick *et al.*, 1998; Holwerda, 1997; Qiu and Abdelmeguid, 1999; Waxman and Darke, 2000). Figure 68.5 illustrates the appli-

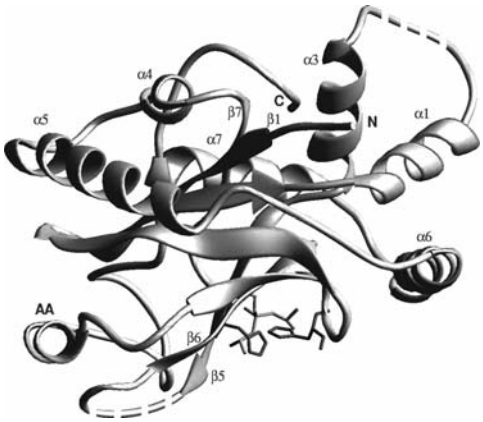

Fig. 68.5. The HSV-2 protease monomer. Two disordered surface loops are shown as dashed lines (N-terminal residues 1–16 are disordered). The two histidines in the active site are shown in red, one on the β6 and the other on the hairpin turn between β2 and β3, while the inhibitor diisopropyl phosphate covalently bound to the catalytic serine is in green on β5. (Reprinted with permission from Hoog *et al.*, 1997.)

cation of X-ray crystallographic structural information to the design and optimization of enzyme inhibitors (Hoog *et al.*, 1997), a tool used successfully in the HIV aspartyl PI discovery programs (Erickson *et al.*, 1990).

Several major pharmaceutical companies took up this quest, and several mechanism-based peptide and heterocyclic inhibitors of either the reversible or irreversible type were identified (Borthwick, 2005). However, these were not always active in virally-infected cells, and none have been progressed into clinical development to date. Any inhibitor would have to be capable of uptake not only into cells, but also into the capsid structure within the nucleus of the infected cells. This nucleocapsid barrier may contribute to the poor antiviral activity reported for compounds that are potent inhibitors of the enzyme assay in vitro (Borthwick, 2005). The protease as a target remains to be successfully exploited.

Inhibitors of the CMV UL97 encoded protein kinase

The CMV-encoded UL97 protein kinase has several features that make it highly attractive as a chemotherapeutic target. It belongs to a family of serine-threonine protein kinases highly conserved across all mammalian herpesviruses, suggesting its potential as a broad spectrum target (Chee *et al.*, 1989; Smith and Smith, 1989). The pUL97 shares structural features with aminoglycoside phosphotransferases; bacterial enzymes known to phosphorylate sugar-containing moieties, which may account for its fortuitous ability to monophosphorylate GCV and ACV (Littler *et al.*, 1992; Sullivan *et al.*, 1992; Talarico *et al.*, 1999; Zimmerman *et al.*, 1997; Michel and Mertens, 2004). This nucleoside phosphotransferase (ACV, GCV) activity has also been reported for the EBV homologue BGLF4 (Zacny *et al.*, 1999), but not for the alphaherpes virus kinase homologues. Importantly, the pUL97 differs from a prototypic serine-threonine protein kinase biochemically (high pH and NaCl optima) and substrate motif specificity (He *et al.*, 1997; Baek *et al.*, 2002).

The study of the replication functions of these herpes protein kinases is complicated by the fact that they are not absolutely essential for growth in cultured cells. Null mutants of the protein kinases of HSV-1, VZV, and CMV have shown variable phenotypes in different cell types, under different culture conditions, complicating MOA studies and predictably, quantitative drug inhibition studies (Moffat *et al.*, 1998; Chou *et al.*, 2006). Studies into the function of the HSV-1 pUL13 and the VZV gene 47 homologues indicate multiple activities throughout the virus replication cycle. These include regulatory roles in early gene expression, indirect effects on host gene expression, late protein post-translational modifications associated with virion maturation, and contributions to tissue-specific pathogenesis. (Purves *et al.*, 1993; Kato *et al.*, 2001; Kenyon *et al.*, 2001; Coulter *et al.*, 1993; Overton *et al.*, 1994; Ng *et al.*, 1994; Michel *et al.*, 1999; Kawaguchi *et al.*, 1999; Moffat *et al.*, 1998; Pritchard *et al.*, 1999; Wolf *et al.*, 2001; Krosky *et al.*, 2003b; Marschall *et al.*, 2005; Hu and Cohen, 2005).

Therefore, inhibition of such a target could cumulatively penalize viral replication. These proteins undoubtedly play essential roles in disease pathogenesis (Moffat *et al.*, 1998). In the case of the human CMV pUL97, the high degree of interstrain sequence conservation (Lurain *et al.*, 2001) coupled with the observations that there are no null mutants of the CMV pUL97 in clinical strains would argue that this is an ideal target. Two series of unrelated compounds are potent inhibitors of the CMV pUL97, and their MOA studies have extended our current knowledge of pUL97 function. Proof of concept for one of these has been achieved in the clinic.

Indolocarbazoles

Indolocarbazoles have been investigated as potential antiviral agents based on the fact that they are competitive inhibitors of the ATP binding sites of kinases in the protein kinase C family (Zimmerman *et al.*, 2000; Marschall *et al.*, 2001). A series of indolocarbazoles was recently analyzed and three (Go6976, K252a, K352c) were established to be highly effective inhibitors (IC_{50}s ranging from 0.009 to 0.4 μM) of both GCV-sensitive and -resistant hCMV,

with little effect against HSV. Cytotoxicity assays in proliferating cells reportedly indicated that the effective antiviral concentration of these compounds was significantly lower than those affecting cellular functioning. However, attempts to select resistant virus under the selective pressure of increasing concentrations of drug indicated that resistance was lost or restricted to low-level replication at higher drug concentrations, hinting that cellular functions may be involved (Kawaguchi and Kato, 2003). Alternative explanations include the possibility that resistance to Go6976 results in severe growth impairment, which could be established by the replication competence of a virus strain with deleted target. Growth impairment (1–2 logs titer reduction) has been reported for the deleted UL97 hCMV (Prichard *et al.*, 1999; Wolf *et al.*, 2001). Efforts to elucidate the exact MOA of the indolcarbazoles have focused on the hCMV pUL97 protein kinase. Indolcarbazoles with anti-CMV activity inhibited pUL97 protein kinase autophosphorylation in vitro, and mutant virus encoding a non-functional pUL97 (catalytic site mutant) deletion was completely insensitive to the indocarbazoles (Marschall *et al.*, 2001).

A series of symmetrical indolocarbazoles were independently synthesized to investigate SARs against a range of herpesviruses (Slater *et al.*, 1999). Several novel and potent inhibitors of hCMV were identified, although none were progressed to clinical development. Many of these had reasonable SIs in the normal diploid fibroblasts used for CMV activity, yet they were extremely toxic to human marrow stem cell differentiation. The development potential of this indolocarbazole class of compounds is unknown based on currently available information, which does not address pharmacokinetics and safety properties.

Recently a series of quinazolines with anti-CMV activity was shown to act through inhibition of the pUL97 (Herget *et al.*, 2004). Limited testing against cell protein Kinases indicated viral PK selectivity, although they also block host EGFR. The series appears promising, based on available data.

Maribavir

BW1263W94 1-(β-L-ribofuranosyl)-2-isopropylamino-5,6-dichlorobenzimidazole (maribavir), was derivatized from the original benzimidazole BDCRB and TCRB (Townsend *et al.*, 1995) as part of efforts to stabilize their metabolically labile glycosidic linkage and improve oral bioavailiability (Chulay *et al.*, 1999; Townsend *et al.*, 1995, 1999). The precedence of flipping the sugar conformation to the L or unnatural biologic form had been established in the nucleoside analog inhibitors of HIV RT as a way of reducing mechanism-based toxicity and rapid metabolic clearance. The potency of the β-L-BDCRB was amplified by various substitutions for the halogen in the 2-position of the benzimidazole base. The resulting development candidate BW1263W94 showed potent activity for CMV and EBV, but no other viruses, including the various animal CMV strains tested (Kern *et al.*, 2004). An unexpected finding was the change in the MOA: maribavir no longer exerted significant inhibition of viral DNA processing and packaging. Instead, maribavir strongly reduced viral DNA synthesis in the quiescent MRC-5 lung fibroblasts used in this study. The mechanism was not mediated through a substrate analog inhibition of the CMV DNA polymerase. Maribavir was not phosphorylated in infected cells, nor did the compound itself or any of its synthetic phosphorylated derivatives inhibit the CMV DNA polymerase (Biron *et al.*, 2002).

The discovery that maribavir was a selective inhibitor of the pUL97 came simultaneously from 2 independent approaches: selection and genetic mapping of a resistant virus strain, and fortuitously, from a broad protein kinase-inhibitor screening effort (Biron *et al.*, 2002). Resistant virus selected with a related analog in the series encoded a Leu397Arg amino acid substitution in pUL97, which conferred a 20- to 200-fold less sensitive phenotype to maribavir. This resistant virus remained susceptible to BDCRB and other approved anti-CMV drugs, including GCV, and was fully competent for in vitro growth. Supporting evidence for the pUL97 as the target was provided by studies with the pUL97 enzyme: the wild type pUL97-catalyzed phosphorylation of histone 2b was inhibited by maribavir (IC50 = 2 nM) while pUL97 with the Leu397Arg mutation was not (IC50 > 1000 nM). A second resistance mutation in the UL97 ORF was selected in the laboratory in the context of a clinical strain following serial passage in increasing concentrations of drug. The resulting point mutation encoded a Thr409Met change, which is also located close to the ATP-binding domain, and far upstream of the GCV resistance mutations which map to the substrate binding domain (Chou, 2006; Chou *et al.*, 2002). The resulting resistance phenotype was intermediate relative to that of the Leu397Arg mutation in AD169, conferring 80-fold vs. 200-fold increase (Biron *et al.*, 2002; Chou, 2006). Maribavir maintains activity against all GCV resistant UL97 mutants identified to date, indicating that the interactions of these two drugs with the protein kinase are distinct (McSharry *et al.*, 2001; Biron *et al.*, 2002).

Reduction in viral DNA synthesis by maribavir may be a consequence of inadequate or improper phosphorylation of pUL44 by the pUL97 kinase. The pUL97 carries a NLS, and locates to the nucleus during the replication cycle (Michel *et al.*, 1996). A direct interaction with, and phosphorylation by, pUL97 of the pUL44, the DNA processivity

factor, has been reported (Krosky *et al.*, 2003; Marshall *et al.*, 2003). This interaction was linked to the co-localization of pUL44 and pUL97 in the replication complexes (Marshall *et al.*, 2003).

The pUL97 has been shown to exert its major effects late in CMV replication (Wolf *et al.*, 2001; Krosky *et al.*, 2003a) based on studies with the RC∆97 (Prichard *et al.*, 1999). Consistent with studies of UL97 null virus, maribavir treatment of CMV-infected foreskin fibroblasts (HFF) also resulted in an increase of type A empty capsids (Wolf *et al.*, 2001) or type C DNA filled capsids (Krosky *et al.*, 2003a). These empty and precursor capsids accumulated in the nucleus of infected HFF cells at late times in the replication cycle, after infection with RC∆97, or in wild-type infected cells treated with maribavir. "Studies with HSV (Kato *et al.*, 2006; Simpson-Holley *et al.*, 2004) and with the CMV UL97 deficient virus (Wolf *et al.*, 2001; Krosky *et al.*, 2003a) have suggested a role for these viral protein kinases in nucleocapsid egress. The large nucleocapsids cannot exit through the nuclear membrane, which is composed of a tight structural matrix of proteins called lamins, without disassembly of lamin subunits in order to relax and open the junctions. Cellular p32 protein is reported to recruit pUL97 to the lamin B receptor, where it is hypothesized that pUL97 phosphorylates specific lamin components , resulting in their redistribution (Marschall *et al.*, 2005). Thus the viral protein kinase regulates a host protein substrate during virion maturation. The block of the CMV UL97 kinase activity by maribavir results in nuclear retention and accumulation of nucleocapsids (Wolf *et al.*, 2001; Krosky *et al.*, 2003a).

A second genotype has been associated with maribavir resistance following laboratory passage of both laboratory and clinical strains of CMV (Chou *et al.*, 2004; Komazin *et al.*, 2003; Chou, 2006). Mutations in the UL27 ORF, encoding changes of Arg233Ser, Ala269Thr, Leu335Phe, Leu335Pro, Trp362Arg, or Ala406Val-415stop, are reported to confer only a modest level of maribavir resistance (two-fold–5-fold increase in IC50s). Little is known about the function of pUL27 at this time. However, the UL27 homolog of mCMV, known as M27, was shown by mutagenesis studies to be non-essential for growth in culture, but was required for virulence and mortality in vivo (Abenes *et al.*, 2001). The CMV UL27 (1824 bp ORF, 608 amino acids) is transcribed as an early-late gene (Stamminger *et al.*, May 2002; Chou *et al.*, 2004), and has been shown to be nonessential for growth in vitro. The pUL27 encodes a nuclear localization signal (NLS); deletional mutagenesis resulted in cytoplasmic retention and a one-half log reduction in viral titers (Chou *et al.*, 2004).

Viral encapsidation and nuclear egress involve the action of a number of viral gene products (Mettenleiter, 2002), and the pUL97 clearly plays a role in the process. Data are accumulating which point to a role of the UL97 protein kinase action in CMV virion morphogenesis, perhaps by directing the normal intranuclear and intracytoplasmic distribution of viral proteins required for virion assembly and intracellular movement during the sequential steps of primary envelopment, tegumentation , translocation and final particle maturation (Azzeh *et al.*, 2006; Chou *et al.*, 2004; Prichard *et al.*, 2005). The pp65 antigen, product of the UL83 ORF, is phosphorylated by the pUL97 in transiently co-transfected cells, and its phosphorylation in cells infected with wild-type AD169 is blocked by maribavir , but pp65 phosphorylation is not blocked in cell infected with the maribavir-resistant strain Leu397Arg (Sethna, GSK data on file). Consistent with these findings, the intranuclear distribution of pp65 is altered in cells infected with the UL97 deficient strain, or in cells infected with wild type virus and treated with maribavir (Pritchard *et al.*, 2005). The pUL27 contains several proposed pUL97 substrate motifs (Baek *et al.*, 2002; Chou *et al.*, 2004). The elucidation of the role of pUL27 in the maribavir-resistant phenotype awaits further investigation on its function.

As maribavir progresses in clinical development, it will be important to understand the basis for drug resistance and its correlation with clinical outcome. The UL27 genetic changes that conferred resistance to maribavir resulted in only a low-grade resistance (three- to four-fold elevated IC50s) compared to the highly resistant phenotype of the L397RpUL97 strain. The gene sequence in 16 clinical isolates was 96% conserved, with no changes at the locations of the four UL27 maribavir resistance mutations noted. From a clinical perspective, the UL27 gene appears more tolerant of mutations than the UL97 gene (98% gene conservation; Lurain *et al.*, 2001), and the resulting levels of maribavir resistance may not preclude drug efficacy. It remains to be seen whether the prolonged drug selection pressure of prophylactic or suppressive regimens results in the accumulation of additional and multiple mutations in the UL27 and UL97 target genes, and potentially in as yet unidentified maribavir targets or UL97 substrates.

Preclinical toxicology testing of maribavir has been comprehensive, with overall results establishing a good safety profile (Koszalka *et al.*, 2002). These results contrast favorably with results of preclinical testing of GCV and CDV, both of which have a litany of toxicologic and tolerability concerns.

The pharmacokinetic profile of maribavir in rodents and primates demonstrated excellent oral bioavailability, although drug levels in the brain, cerebrospinal fluid, and vitreous humor of cynomologus monkeys were low. Maribavir is highly bound to human plasma proteins, principally

the albumin fraction; however, the binding is reversible in vitro. The impact of this property on efficacious dosing regimens remains to be determined.

Maribavir has successfully completed a series of Phase I–II clinical trials (Wang *et al.*, 2003; Lu and Thomas, 2004). In Phase I studies in healthy volunteers and HIV-infected subjects, single oral doses of 50 to 1600 mg produced similar dose-proportional pharmacokinetics. Maribavir was rapidly absorbed following oral administration with Cmaxs occurring within 1 to 3 hours. Absorption was at least 30% to 40%, and drug was eliminated from plasma with a t1/2 of 3 to 5 hours. The plasma and urinary excretion profiles indicated that the drug was extensively metabolized, with the major metabolite identified as the N-dealkylated analogue, which did not show anti-viral activity in vitro.

A pilot study was conducted in HIV patients ($n = 8$) with CMV retinitis, in order to measure the steady state pharmacokinetics in ocular tissues following 8 days of oral dosing. Antiviral drug levels were achieved in ocular tissues, although substantially lower than those found in plasma. This result indicates a potential for drug efficacy in CNS infections in congenital disease. As expected, blood CMV DNA levels in those viremic retinitis patients responded with a viral load drop. Additional Phase 1 studies included the important drug–drug interaction study using the drug cocktail approach to identify liver cytochrome P-450 enzymes capable of metabolizing maribavir, or being inhibited by maribavir (Ma *et al.*, 2006)

No safety concerns of note were observed in these studies; however, mild to moderate taste disturbance and headache were reported in 80% and 53% of the subjects, respectively (Wang *et al.*, 2003; Lu and Thomas, 2004). The taste disturbance was presumed to be due to secretion of drug or its principal metabolite metabolite into the salivary glands after systematic absorption and while not a safety concern, could have implications for adherence.

A subsequent phase I/II clinical trial was conducted to further determine the pharmacokinetics of maribavir and to monitor asymptomatic CMV shedding in semen in HIV-infected men (Lalezari *et al.*, 2002). Six dosage regimens (100, 200, or 400 mg three times a day, or 600, 900, or 1200 mg twice a day) or a placebo were evaluated for 28 days. In that proof of concept study, potent anti-CMV activity (2.9 to 3.7 $\log_{10}$ reductions in PFU/ml in semen) was established at all doses. The reductions in CMV titers for all regimens compared well with results reported for the approved doses of CDV (5 mg/kg) in a comparable trial (Lalezari *et al.*, 1995). Maribavir was reasonably well tolerated and safe with taste disturbance again the most frequently reported adverse event. Other adverse events reported by a higher percentage of subjects receiving maribavir than placebo included diarrhea, nausea, rash, pruritus, and fever.

Maribavir has recently demonstrated prophylactic efficacy in a Phase II randomized, double-blind, placebo-controlled trial in allogenic stem cell transplant patients (N = 111). Doses of 100 mg BID, 400 mg QD, and 400 mg BID for 12 weeks all reduced the rate of CMV reactivation; preemptive therapy was required for 15%, 30%, and 15% of the respective maribavir doses, relative to 57% for placebo recipients (ViroPharma Inc. press release March 29, 2006). The overall safety profile of maribavir in the 12 week study recapitulates earlier clinical results. The durability of the anti-viral effects and incidence of resistance is under study.

Maribavir is clearly the most advanced new anti herpes drug in the clinical development pipeline. Based on urgent medical need and the favorable development characteristics of maribavir, the FDA has granted Fast Track Status for the prevention of CMV infections in allogenic bone marrow and solid organ transplant patients (ViroPharma Inc. press release Feb. 7, 2005).

Antivirals with activity against EBV, HHV-6, HHV-7, and HHV-8

While anti-viral drug development efforts continue for HSV_1 VZV, and CMV utilizing both old and new targets, lack of progress against EBV virus is notable. There are several reasons for this. Primary EBV infection is generally subclinical in immunocompetent individuals. However, it may cause infectious mononucleosis (generally a benign and self-limiting disease) but the window of opportunity for antiviral treatment during the clinical course is short. The lytic EBV manifestation of oral hairy leukoplakia in immunocompromised patients responds to therapy with ACV. EBV-associated lymphoproliferative diseases, Burkitt's lymphoma and nasopharyngeal carcinoma, all of which may develop without obvious preceding immunodeficiency, remains a major unmet medical need. Latent EBV infection is considered either the etiologic agent for these conditions or a major contributing factor. (Thorley-Lawson and Gross, 2004).

From a drug development perspective; it is not yet clear what EBV or (host) functions to target; and the value of a viral replication inhibitor is unknown (Okano, 2003). The L-benzimidazole riboside, maribavir, which is in clinical developments for CMV disease, also shows activity against EBV in vitro, apparently by blocking both the appearance of linear forms of newly synthesized EBV DNA and the accumulation of the early antigen EA-D (Zacny *et al.*, 1999).

While the exact mechanism is unclear, it may be involve the EBV protein kinase, BGLF4, a close homolog of the hCMV UL97. This viral protein autophosphorylates, and has also been reported to phosphorylate the analogous DNA polymerase processivity factor, EA-D (Chen *et al.*, 2000). In lytically infected Akata cells, the level of hyperphosphorylated EA-D was reduced by maribavir treatment, similar to the impact of maribavir treatment on the hCMV pUL44. However, direct inhibition of the phosphorylation of EA-D has not been demonstrated, and maribavir did not block the phosphorylation of EA-D by EBV protein kinase in transient co-expression assays with these two viral genes (Gershburg and Pagano, 2002). Therefore the phenotype of maribavir-treated Alcata cells is consistent with inhibition of BGLF4 function; thus mechanism studies must be addressed within the context of the infected cell. While much remains to be determined regarding maribavir's mechanism of action against EBV, it should be considered a viable candidate for further study.

Information on the incidence of EBV-associated lymphomas in transplant patients treated prophylatically for CMV infections with maribavir may yield insights into the relationship of lytic replication to the post transplant lymphoproliferative diseases (Razonable *et al.*, 2005).

Research targeted at developing antivirals against human herpesvirus type 6 (HHV-6), type 7 (HHV-7) and type 8 (HHV-8) has been limited. A new series of arylsulfone derivatives have been shown to have in vitro activity against HHV-6 and HHV-7, as well as CMV. While work with this series of compounds is preliminary, a new MOA of indirect inhibition of viral DNA synthesis may be involved (Naesens *et al.*, 2006; Razonable *et al.*, 2005). Both HHV-6 and HHV-7 have an extremely high prevalence rate of about 95% in the US, but in the vast majority of cases their presence is associated with mild self-limiting symptoms, usually fever and rash, where treatment isn warranted. Infection with HHV-8 is more serious since reactivation is in the form of Kaposi's sarcoma (Ablashi, 2002). Immune preservation or reconstitution in AIDS patients by highly active anti-retroviral therapy (HAART) has reduced the incidence of Kaposis, indicting the protective effects of the functional immune system in this infection.

A systematic approach to identifying antivirals against HHV-6, HHV-7 and HHV-8 has been completed (de Clercq *et al.*, 2001b). Approved antivirals (ACV, VACV, PCV, FCV, GCV, PFA, CDV, and brivudin) and investigational compounds (Lobucavir, H2G, A-5021, D/L-cyclohexenyl G and S2242) with demonstrated activity against herpesviruses were evaluated in appropriate in vitro systems. The most potent compounds with the highest antiviral selectivity index were: (i) for HHV-6; PFA, S2242, A-5021 and CDV; (ii) for HHV-7; S2242, CDV and PFA; and (iii) for HHV-8; S2242, CDV and GCV.

Conclusions

The pipeline is indeed rich with new antiherpes agents. Many of these act by novel, and as yet unvalidated mechanisms of action from a therapeutic viewpoint. Their successful performance in the clinic will increase our understanding of the role of these new targets in viral disease.

For the two HSV helicase-primase inhibitors, a critical development milestone will be the human safety data for the thiazole class of compounds, the ease of viral escape (resistance), and the pathogenecity and transmissibility of mutant virus. The hCMV terminase inhibitor candidates start with the advantage of a highly selective and clearly essential target. However, it remains to be seen whether there are unanticipated (non-mechanism-based) toxicities in human studies with the two chemical series of inhibitors. Positive efficacy results in the Phase III clinical studies of the candidate CMV drug, maribavir, would provide target validation for the first inhibitor of a viral protein kinase.

As these drug candidates achieve regulatory approval, and with their expanded clinical use, the impact of drug potency and MOA on the emergence of resistance in the population will become the focus of studies. Resistance to the currently licensed antivirals (ACV, PCV, and their prodrugs) is low at <1.07 based on HSV isolates, a figure that has remained relatively constant since these drugs have been on the market, in spite of their widespread use (Bacon *et al.*, 2003). The vast majority of ACV-resistant HSV (TK-deficient) viruses are not capable of reactivating after latency, losing the transmission opportunity, and thus the presence of ACV-resistant virus in the overall population is acceptable. In an immunocompromised patient, the risk of developing resistance is much greater than in an immunocompetent individual, and clinical outcome becomes the critical issue. The availability of rescue therapies with novel MOAs will help fill this medical need.

Herpes simplex vaccines

George Kemble and Richard Spaete

MedImmune Vaccines, Inc., Mountain View, CA, USA

Introduction

Genital herpes, caused by both herpes simplex virus (HSV) types 1 and 2, can result in painful vesicular and ulcerative lesions on the genitalia and the genital tract, and may cause both urologic and neurologic problems. Following primary infection, HSV establishes a latent infection in the local ganglia and can reactivate on multiple occasions with manifestations ranging from asymptomatic viral shedding to painful recurrences of genital or orofacial lesions (Whitley, 2001). HSV-2 is the predominant etiologic agent of genital herpes and data from the second and third National Health and Nutrition Examination Surveys, spanning 1976 to 1994, demonstrated that the prevalence of HSV-2 infection increased by 30% since the late 1970's with the highest rates in teenagers and young adults (Fleming *et al.*, 1997). It is estimated that more than 1.6 million individuals are infected annually with HSV-2 in the USA (Armstrong *et al.*, 2001). From the perspective of vaccine development, however, genital herpes caused by HSV-1 cannot be overlooked. Although genital herpes caused by HSV-1 is generally less severe than HSV-2, HSV-1 is ubiquitous, infects a larger portion of the population than HSV-2, and the percentage of HSV-1 positive cultures isolated from individuals presenting with genital herpes appears to be increasing (Ribes *et al.*, 2001).

In addition to the pain and potential complications (e.g. psychological distress), that genital herpes causes in the infected individual, it is also responsible for increasing the risk of sexual transmission of HIV (Holmberg *et al.*, 1988). Shedding infectious virus during birth may infect the newborn and cause neonatal herpes (Wald *et al.*, 1995). Neonatal herpes caused by either HSV-1 or HSV-2, although relatively rare, can result in disseminated and/or central nervous system infections resulting in death or significant developmental impairments (Kimberlin *et al.*, 2001). The risk of neonatal herpes can be significantly reduced by Cesarean delivery when active lesions are detected immediately prior to birth; however in contrast to HIV transmission, subclinical shedding of infectious virus from the mother's genital tract during birth can cause neonatal herpes (Brown *et al.*, 2003). Despite the advances made in antiviral therapy over the past 20 years, genital herpes and neonatal herpes remain significant public health problems. Antiviral drugs can reduce the frequency of viral shedding and severity of symptoms associated with genital herpes and when given promptly can reduce some of the poor outcomes of neonatal herpes (Stanberry *et al.*, 1999; Kimberlin *et al.*, 2001). However, like many antiviral therapies, the effectiveness of the drug is limited by the development of viral resistance as well as delays in initiating treatment. Unfortunately, the awareness of neonatal herpes for acutely ill infants is low and the characteristic skin vesicles pathogenomonic for neonatal herpes do not occur in more than 30% of patients; both of these factors have contributed to the lack of progress in shortening the critical interval between diagnosis and treatment (Kimberlin *et al.*, 2001).

Cesarean delivery in high risk situations and antiviral treatment can reduce the total number of neonatal herpes cases; however, the frequency of inapparent genital lesions during delivery and the inability to quickly and specifically deliver antiviral therapy to many infected newborns combine to create an unacceptable burden of neonatal herpes cases (Stratton *et al.*, 2000). Moreover, infected women who do not have a history of genital lesions would not be targeted for antiviral prophylaxis, yet may excrete the virus. A vaccine approach that aims at reducing the overall burden of genital herpes and reducing the likelihood of viral transmission during birth should provide the largest public health benefit.

The feasibility of a vaccine approach is predicated on evidence that an immune response can positively modify the resulting disease. Specifically for neonatal herpes, maternal serostatus and the timing of infection relative to delivery has an impact on the frequency of neonatal herpes infections. Neonatal herpes occurred at a lower rate in neonates born to women who seroconverted prior to delivery than in neonates whose mothers did not seroconvert, demonstrating that the maternal immune status could impact the resulting disease (Brown *et al.*, 1997; Brown *et al.*, 2003). The mechanism of immune protection of the child remains unclear but transplacental transfer of maternal antibodies to HSV is likely to be important. In addition, serologic status also appears to have an impact on acquisition and/or outcome of infection with the heterologous virus type. Several studies have indicated that preexisting immunity to HSV-1, which is generally acquired early in life, can influence the outcome of HSV-2 infection at a later age (reviewed in Whitley, 2001). Individuals who were HSV-1 seropositive were not protected from acquiring HSV-2, but were approximately three times less likely to report a history of genital herpes than those who were HSV-1 seronegative (Langenberg *et al.*, 1999; Xu *et al.*, 2002). These data indicated that immunity elicited by prior infection with HSV-1 modified the disease due to the ensuing HSV-2 infection. Limited data suggests that the immune response elicited by HSV-2 infection may be even more robust than that elicited by a HSV-1 infection. Pregnant women with antibodies to HSV-2 were not infected with HSV-1 in contrast to women with no prior immunity (Stanberry *et al.*, 2002). Many of the vaccines in this review are derived from the antigens of HSV-2. These vaccines are expected to induce type specific immunity to the etiologic agent that is presumed to cause more significant disease as well as provide cross-protective immunity to HSV-1. Specific vaccines to prevent HSV-1 orofacial lesions have not been targets of significant development activity.

Notwithstanding widespread agreement that a vaccine will be the most cost effective way to reduce the morbidity associated with HSV infections (Arvin and Prober, 1997), no licensed vaccine is currently available to address the problems presented by these viruses. Development of herpesvirus vaccines present special hurdles associated with the complex replication cycles and propensity of these viruses to establish lifelong infections. Since much of the HSV disease burden is due to recurrent infection, a therapeutic as well as a prophylactic vaccine is needed. In addition, this family of viruses has also evolved mechanisms to counteract the immune response of the host. These cautions, however, are mitigated by the successful introduction of effective herpes vaccines such as Varivax® for the prevention of chicken pox and veterinary vaccines for Aujeszky's disease and Marek's disease, caused by alphaherpesviruses of pigs and chickens, respectively. This chapter will attempt to summarize the key steps and the more recent milestones in developing an effective vaccine for the prevention of disease caused by HSV-1 and -2.

History of HSV vaccine development

The history of HSV vaccine trials in humans is fast approaching the century mark with the ultimate goal of an efficacious vaccine still elusive. In the early to middle decades of the twentieth century, experimentalists used infectious wild-type viruses isolated from active lesions or passaged through animals to immunize individuals with the hope of having an impact on recurrent herpes. These approaches were later displaced by vaccine strategies using inactivated virus or glyocoprotein extracts. An excellent status report of previous vaccine development efforts that surveys the foundation of HSV vaccine strategies and that informs present day efforts is provided in a comprehensive review of a decade ago (Burke, 1993). For a variety of reasons including cost of clinical trials and difficulties in measuring clinical endpoints, many of these HSV vaccine candidates were not evaluated in rigorous placebo controlled, blinded, studies. Much more recently, Chiron Corporation and GlaxoSmithKline have sponsored double blind placebo controlled trials of two subunit vaccines that have put earlier basic and preclinical research vaccine concepts to the ultimate test. Other vaccine concepts need to be tested with similar rigor in clinical trials.

Development of live, attenuated vaccines

Live attenuated vaccines have many clear advantages as vaccine strategies. In principle, they can present the full range of all viral antigens to the immune system of the host, stimulating both the humoral and cell-mediated adaptive immune responses as well as innate immunity. This is an important consideration in rationalizing approaches to a vaccine because laboratory-based correlates of immune protection are not yet defined for the herpes simplex viruses. Generally, live vaccines evoke a longer-lived immune response than that elicited by other vaccine strategies. Additionally, powerful molecular tools exist for engineering recombinant vaccine viruses that can be employed to incorporate particular features designed to achieve the appropriate balance between attenuation and immunogenicity.

Developing a live, attenuated vaccine for HSV presents various challenges. HSV has evolved several mechanisms

to evade the host immune response, including functions that interfere with the production of interferon and products that inhibit the presentation of viral antigens to the host immune system (Johnson and Hill, 1998; Barcy and Corey, 2001; Lorenzo *et al.*, 2001; Leib, 2002; Hegde *et al.*, 2003). The advantage of removing these immune response modifiers has yet to be addressed in clinical trials. Removal could potentially increase the immunogenicity of the vaccine but it could also possibly create a scenario where superinfection or revaccination leads to significant reactogenicity. Another challenge to live vaccine approaches for HSV prevention is neurotropism. HSV establishes latent infections in sensory ganglia and can on rare occasion invade the central nervous system to cause encephalitis (Whitley, 2001). The optimal properties for a live, attenuated HSV vaccine candidate would remove the pathogenic signatures from the virus such that vaccination would not elicit any of the pain or ulcerative lesions typical of natural infection yet enable sufficient levels of replication in the host to elicit a vigorous immune response. In addition, the neurovirulence of the vaccine would need to be eliminated, although its propensity to establish a latent infection might be left intact. The ability of the vaccine to establish a latent infection could be viewed as a positive characteristic, since subclinical reactivation could restimulate the immune system, creating a more durable and effective immune response. However, delivering a vaccine that will establish a latent infection carries with it the concern that reactivation could result in transmission or disease at a time when the individual has become immunosuppressed due to infection or chemotherapy. In addition to these biological traits, any live HSV vaccine must be genetically stable and be able to be produced at sufficient quantities for effective administration.

Among the first live, attenuated HSV vaccines that were specifically manipulated to attempt to meet the above criteria were made by recombinant techniques. One of the viruses R7020 was constructed by replacing an approximately 14.5 kbp deletion extending from the α27 gene (UL54) in the unique long segment of the genome across the internal inverted repeats of HSV-1 with a fragment of HSV-2 encoding at least the gG glycoprotein (Meignier *et al.*, 1988). This construct was significantly attenuated in small animal models as well as in an exquisitely HSV sensitive nonhuman primate model (*Aotus trivirgatus*), and the neuroattenuation was genetically stable following serial passage through mouse brains (Meignier *et al.*, 1988, 1990). R7020 had a reduced propensity for establishing a latent infection and provided protection from direct challenge in animals. R7020 was evaluated in Phase 1 human trials. This construct was favored over a related *tk* negative construct (denoted R7017), since R7020 retained the *tk* gene and, therefore, retained sensitivity to available antiviral drugs such as acyclovir. Unfortunately, despite the promising immunogenicity results from the animal studies, the vaccine was poorly immunogenic in humans even given two doses of 10^5 PFU each and it was concluded that this vaccine was overly attenuated (Cadoz *et al.*, 1992). Although further development of these constructs as vaccines for immunocompetent individuals was aborted, they are still being evaluated as potential oncolytic agents for various cancer indications (for review see Varghese and Rabkin, 2002).

The next iteration of live attenuated HSV vaccines were developed based on the identification of a neurovirulence determinant identified as the $\gamma_1$34.5 gene. Removal of this gene, which is present in two copies in the genome of HSV, attenuated the neurovirulence of HSV-1 to a much greater extent than deletions of other specific genes that had been previously tested and did not significantly reduce the ability to replicate in cells that could be considered for vaccine production (Chou *et al.*, 1990; Whitley *et al.*, 1993). Experiments in small animal models demonstrated that this construct abolished the ability of the virus to migrate to and replicate in the central nervous system of mice and guinea pigs. An HSV-2 derivative of this construct denoted RAV 9395 was generated in which both copies of the $\gamma_1$34.5 gene were deleted as well as the ORFs antisense to the $\gamma_1$34.5 gene and the adjacent UL55 and UL56 ORFs. Since RAV 9395 was constructed from HSV-2, it was expected to elicit a more relevant immune response than the corresponding HSV-1 construct. RAV 9395 was tested in the guinea pig model of genital herpes and was shown to be attenuated and immunogenic. Following challenge of animals with the wild-type HSV-2 strain, animals previously vaccinated with 10^4–10^5 PFU of RAV 9395 were significantly protected from clinical disease compared to controls, and recurring lesions caused by the wild-type strain were reduced. Whether this was due to an inability to establish a latent infection in the dorsal root ganglia or a diminished ability to reactivate from this site is unclear (Spector *et al.*, 1998). The $\gamma_1$34.5 mutants were also characterized by their inability to grow in certain cell types *in vitro*, particularly those derived from nervous tissue. This characteristic, however, was not genetically stable in the HSV-1 background and could be reverted upon serial passage in these cells types (Mohr *et al.*, 2001). Further development of this or any recombinant based on deletion of the $\gamma_1$34.5 genes will require an analysis of the potential consequences of this instability, such as identifying compensatory mutations after serial passage and their effect(s) on attenuation. Recently, a vaccine candidate lacking both copies of γ134.5 as well as UL55, UL56 and the US10-12 region of HSV-2 (G) was shown to be genetically stable; this vaccine candidate remained highly attenuated following 9 serial passages in the CNS of mice. This highly

attenuated candidate protected guinea pigs from disease following challenge with the wild type virus (Prichard *et al.*, 2005).

Another set of approaches for making live, attenuated vaccines are based upon deletions or modifications to the viral genome that limit the replication of the virus except in specialized cell lines and have been denoted DISC, for disabled infectious single cycle mutants. In principle, a gene required for replication of HSV DNA or to produce infectious virus is removed from the genome and infectious virus is recovered on a cell line that provides the function *in trans*. Blocking different points in the replication cycle can alter the quantity and types of viral proteins expressed in a non-permissive infected cells (Farrell *et al.*, 1994; Da Costa *et al.*, 1997). Vaccine candidates with deletions of the gH, ICP8, ICP27 and ICP10 encoded functions have been constructed and tested. Recombinant HSV-2 viruses lacking the PK domain of ICP10 (the ribonucleotide reductase) have been tested in guinea pigs with favorable results. Exploration of the immune response in mice clearly demonstrated a Th1 type response characterized by development of both CD4+ Th1 and CD8+ CTLs with antiviral activity (Gyotoku *et al.*, 2002). Newer forms of DISC vaccines have been constructed in which two genes have been deleted and have been tested in mice. These modified vaccine elicited an immune response yet had significantly reduced quantities of latent viral DNA in the murine host (Da Costa *et al.*, 1999).

Preclinical evaluations of HSV-1 and -2 constructs lacking gH were tested in the guinea pig model and protected the animals in both prophylactic and therapeutic settings (McLean *et al.*, 1994; Boursnell *et al.*, 1997). A gH deleted HSV-2 strain HG52 was tested in a Phase 1 clinical trial to evaluate safety in HSV-2 seropositive and seronegative volunteers under the sponsorship of Cantab Pharmaceuticals. On the basis of acceptable safety and immunogenicity data reported for the prophylactic vaccine candidate, 485 patients were enrolled and vaccinated in a double-blind, placebo controlled Phase 2 trial of the DISC vaccine for the treatment of recurrent genital herpes. The results of this study have not yet been reported. The development of the prophylactic vaccine appears to have been discontinued.

Several of the DISC strategies are being exploited in the field of vectored vaccines. Nef antigens of simian immunodeficiency virus (SIV) were introduced into an HSV-1 mutant lacking ICP27. This replication incompetent vector elicited both cellular and humoral immune responses to HSV and SIV in rhesus monkeys and protected the animals following challenge 5 months post-vaccination (Murphy *et al.*, 2000). Many of the DISC viruses are being considered as potential vectors for use in gene therapy as well (reviewed in Rees *et al.*, 2002).

Subunit vaccines

Inactivated virus, glycoprotein extracts and recombinant subunit vaccines do not have several of the concerns associated with the development of live, attenuated vaccines such as neurotropism, transmission, or reactivation at a later time. Along with fewer safety concerns, a strength of these approaches is the ability to generate a well-defined biological product that can preserve conformational epitopes vital to eliciting an authentic immune response. A major consideration when choosing a subunit approach is the inclusion of an approvable adjuvant/antigen delivery system capable of eliciting both an antibody and a CTL response in humans.

Among the limitations of the subunit approach are the relatively narrow range of epitopes to which the immune system is exposed and the manner in which they elicit an immune response. Immunity generated to a specific target antigen may differ depending on how it is presented to the immune system and can also be affected by the HLA repertoire of the vaccinated individual. Strain variation coupled with HLA variability in an outbred population might influence the efficacy of the subunit protein vaccine in different subpopulations. The route of antigen presentation is another factor that must be considered, since an antigen introduced parenterally may elicit a different immune response than one that is expressed from a virally infected cell.

Many different inactivated HSV or glycoprotein preparations have been tested over the past several decades. Claims of positive benefit have resulted in use on a relatively large scale in some countries. Most of these claims, however, have not been substantiated by data from prospective, double-blind, placebo controlled clinical trials to establish safety and efficacy. Two recombinant subunit vaccine candidates, developed independently by Chiron and GlaxoSmithKline, are notable exceptions to this criticism. Both of these vaccines have been evaluated in relatively large, double-blind, placebo controlled trials to evaluate their impact on the occurrence of genital herpes disease or the prevention of new HSV-2 infection. The results of these studies will be described in more detail.

The Chiron subunit vaccine was made by expressing recombinant forms of two major surface glycoproteins of HSV-2, gB_2 and gD_2 lacking the carboxy-terminal regions, in Chinese hamster ovary (CHO) cells. The choice of

Table 69.1. Evaluation of recombinant subunit vaccine studies

	Dose (μg)	Regimen	Population	N	Vaccine effect reductions[a]	Comments
gB_2/gD_2/MF59						
	10	4 × 1 wk	guinea pig	15	Incidence, severity and mortality	Recurrence of challenge not reported
	30	0,1,6 mo	HSV-2^- Monogamous	531	No reduction in acquisition or severity	Transient reduction of acquisition in females only for the first 150 days of the trial
			HSV-2^- STD clinic	1862		
gD_2/ASO4						
	5	0,1,3 mo	guinea pig	15	Viral shedding, disease severity and recurrence	Incidence not reduced Mortality decreased
	20	0,1,6 mo	HSV-1^- / HSV-2^-	847	Genital herpes disease in HSV-1^-/HSV-2^- females only	Efficacy against genital herpes disease was not demonstrated in whole population or other subpopulations. Evidence of a trend toward prevention of infection in HSV-1^-/HSV2$^-$ females
			HSV-$1^{\pm}$ / HSV-2^-	1867		

[a] Observations with reported statistical significance.

these particular subunits relied on much basic research developed over the years that identified these glycoproteins as important stimulators of potent humoral and cellular responses (reviewed in Spear, 1985). These purified subunits were combined with the adjuvant MF59, a 5% squalene oil-in-water emulsion, to make the vaccine. The gD_2 subunit combined with MF59 was evaluated in the guinea pig model for its ability to protect the animals from a challenge with HSV-2. Animals that received 4 weekly doses of the vaccine developed significant serum IgG, as well as salivary, vaginal, and nasal IgA responses against HSV. Following intravaginal challenge with a lethal dose of HSV-2, vaccinated animals were significantly protected as measured by an decrease in disease incidence, severity and mortality (O'Hagan *et al.*, 1999).

A large clinical trial of the combination gB_2 and gD_2 subunit vaccine was conducted that evaluated the ability of this vaccine to prevent HSV-2 infection. The vaccine contained 30μg each of gB_2 and gD_2 combined with MF59 and given intramuscularly at 0, 1 and 6 months to adults who where seronegative for HSV-2 and were either attending an STD clinic or had a monogamous partner who was infected with HSV-2. The participants were followed for one year and acquisition of HSV-2 was measured by isolation of the virus in culture or seroconversion to HSV-2 proteins other than gB_2 or gD_2 (Corey *et al.*, 1999). Despite high titer HSV antibody responses, this vaccine had no impact on the overall frequency of acquisition of infection and did not modify the disease. The only difference between vaccine and placebo groups was a transient reduction in HSV acquisition in female subjects during the initial 150 days of the trial. The lack of impact on disease severity contrasted to an earlier study of this vaccine for a therapeutic indication. In the prior study, 212 adults with recurrent genital herpes were enrolled in a double-blind study and monitored for the number and frequency of recurrences as well as the duration and severity of each episode. As in the prophylactic trial, the number or frequency of recurrences was unchanged, however, the severity and duration of the first confirmed recurrence post vaccination was reduced significantly. (Straus *et al.*, 1997). The reason for these differences between the prophylactic and therapeutic trials is not clear but may relate to the difference between the natural history of a recurrent lesion that occurs when the host has immunity and a primary lesion in an individual who is immunologically naïve.

Another HSV subunit vaccine is under development by GlaxoSmithKline in which a purified carboxy-terminal truncated gD_2 expressed in CHO cells was formulated with the ASO4 adjuvant, containing aluminum hydroxide and 3-*O*-deacylated monophosphoryl lipid A (3-MPL). This vaccine was also evaluated in the guinea pig model. The vaccine was formulated by adding 5μg of gD2 to ASO4 and injected subcutaneously into the animals at 0, 1 and 3 months followed by an intravaginal challenge with HSV-2

two weeks later. Vaccination did not alter the incidence of infection, but it did reduce the titer of shed virus as well as the severity of the lesions and mortality. Recurrent lesions due to the challenge virus were also reduced when the number of episodes of recurrence was compared to controls (Bourne *et al.*, 2003).

This HSV vaccine was tested in a large double-blind randomized clinical trial to assess its ability to reduce the occurrence of genital herpes disease. Adults who were seronegative for HSV-2 were enrolled, vaccinated with 20 μg of gD_2 combined with alum and 3-MPL at 0, 1 and 3 months and monitored for the acquisition of genital herpes disease. The primary analyses did not show a vaccine effect. There was no reduction in the acquisition of genital herpes disease in HSV-2 seronegative adults who had received vaccine. However, post hoc analyses demonstrated that the vaccine significantly protected HSV-1 seronegative / HSV-2 seronegative women from acquiring genital herpes caused by HSV-2 (Stanberry *et al.*, 2002). In addition, although it did not reach statistical significance, there was a trend toward a reduction in HSV-2 infection in this same group.

Many of the differences between the results of the gD2/gB2/MF59 and gD2/ASO4 vaccine trials are enigmatic. Both vaccines protected guinea pigs from direct challenge with a high titered inoculum of HSV-2 indicating that these subunit compositions evoked similar immune responses in this animal model. Immunization of human subjects with gD2/gB2/MF59 resulted in the production of neutralizing antibodies as well as memory CD4+ T cells specific for the antigens in the vaccine (Langenberg *et al.*, 1995). However recent studies suggest that this vaccine may have induced only low levels of antibodies that mediate antibody-dependent cellular cytotoxicity in humans (Kohl *et al.*, 2000). The gD2/ASO4 vaccine also elicited high levels of neutralizing antibodies in humans as well as gD specific lymphoproliferation and interferon γ (Stanberry *et al.*, 2002). These adaptive immune responses, however, were not different between the groups protected from acquisition of genital herpes and those that were not. The reason for the efficacy of this vaccine in women and not men as well as the lack of effect in females who were HSV-1 seropositive will require additional studies; there is no obvious explanation for these differences. The positive results in HSV-1 seronegative/HSV-2 seronegative women in this trial have prompted GlaxoSmithKline Biologicals in conjunction with the National Institute of Allergy and Infectious Diseases to initiate a pivotal Phase 3 efficacy trial in 7,550 women who are seronegative to both HSV 1 and HSV 2.

Other approaches to vaccination

Many options for the development of prophylactic HSV vaccines are currently being explored in preclinical studies and several have progressed to immunogenicity studies in the guinea pig model of HSV. DNA vaccines that expressed either a full length or secreted, carboxy-terminal truncated form of gD2 reduced the lesion severity and number of recurrent lesions following challenge (Strasser *et al.*, 2000). Other more novel approaches such as ISCOMS (immunostimulating complex particles) made from detergent extracted preparations of virions have been tested in guinea pigs (Simms *et al.*, 2000), and attenuated Salmonella vaccines harboring a gD plasmid have been evaluated in rodents and shown to protect the animals following challenge (Flo *et al.*, 2001). Peptide vaccines are being evaluated based on the identification of immunologically dominant epitopes, but to date most have not developed past studies in the mouse model (Gierynska *et al.*, 2002; BenMohamed *et al.*, 2003). Approaches using chimeric DNA vaccines combining viral glycoprotein epitopes, protein fusions of viral glycoproteins with bacterial open reading frames, or with chemokines are being tested in mice. Alternative adjuvants such as CpG molecules are being added to formulations of peptide and DNA vaccines. Vectored approaches using other viruses offer other vaccine strategies. For example, VZV has been used as a vector to express HSV gD, and has been shown to protect against experimental HSV challenge in a guinea pig model (Heineman *et al.*, 1995). Further development of these new approaches as well as new ideas should continue to be advanced with time.

Conclusions

The goal of a safe, efficacious HSV vaccine has several components. Clearly the most easily measured benefit is to reduce the rate of acquistition of genital herpes disease. Reduction of the incidence of this disease or reduction of viral shedding from infected individuals should have a direct impact on the number of neonatal herpes cases every year as well as on the sexual transmission of HIV. The two most recent large clinical trials of subunit vaccine candidates have highlighted some of the issues that may need to be addressed during the development of a successful HSV vaccine. Gender differences influenced the vaccine efficacy as did the preexisting HSV-1 serological status. The mechanisms of these interactions are not understood at this point and the influence of these differences on other vaccine

strategies cannot be predicted. Further studies to understand how these factors affect vaccine efficacy should be done. In addition, genital herpes caused by HSV-1 appears to be increasing and HSV-1 can also cause severe neonatal herpes. A successful vaccine should confer immunity to both etiologic agents. Ultimately, the role of gender, preexisting immunity, and effectiveness for preventing both HSV-1 and HSV-2 disease and the impact on public health will be needed to evaluate HSV vaccine candidates.

Animal studies and serological assays as measures of the immune response may not be sufficient to completely predict the functional behavior and immunogenicity of a vaccine in humans. The immunogenicity of R7020, was poor in humans and the gD2/gB2/MF59 vaccine, while stimulating robust neutralizing antibodies was unable to protect individuals from acquisition of HSV-2 despite the promising immunogenicity and protection in mice and guinea pigs. These results highlight the need to further explore the mechanisms of functional immunity in humans at a fundamental and detailed level in order to define informative surrogate markers for the clinical development of an HSV vaccine candidate. In addition, the efficacy trials of the subunit vaccines confirmed that prevention of infection is a difficult endpoint to achieve and may misdirect the effort away from relieving the burden of disease associated with genital herpes. The potential for transmission of herpes during birth as a consequence of asymptomatic viral shedding despite vaccine induced immunity will have to be considered to predict the impact of candidate vaccines on neonatal herpes.

Although a specific vaccine and immunization strategy have not yet been identified for HSV, the overall progress made by the field has brought an increased understanding of the complexity of HSV-1 and HSV-2 disease and elucidated many issues that can now be addressed. A vaccine for human papilloma virus (HPV), another sexually transmitted disease, has recently been shown to have positive results in Phase 2 clinical trials (Koutsky *et al.*, 2002; Galloway, 2003). These virus-like particle vaccines have provided significant immunity to prevent establishment of a persistent infection. Adding an HSV vaccine to an armamentarium of STD vaccines would provide a major positive impact on public health throughout the world.

Varicella-zoster vaccine

Anne A. Gershon

Department of Pediatrics, Columbia University College of Physicians and Surgeons, New York, NY, USA

Varicella vaccines: background

A live attenuated varicella vaccine, the Oka strain, was developed by Takahashi and his colleagues in Japan the early 1970s (Takahashi *et al.*, 1974). This vaccine is now being adminstered to varicella-susceptible healthy children and adults in many countries; it is produced by at least 3 manufacturers worldwide (Merck and Co., Glaxo SmithKline, and Biken Institute/Aventis Pasteur). Although the vaccine was developed in Japan, the largest experience with it comes from the United States, where the Merck formulation was licensed for routine use in healthy susceptible individuals over the age of 1 year in 1995 (Centers for Disease Control, 1996). In both pre- and postlicensure studies (Gershon *et al.*, 1984a, b; White, 1997; Sharrar *et al.*, 2000) the vaccine was demonstrated to be extremely safe. Adverse effects in healthy persons are few and quite transient: a sore arm after the injection in 20%–25%, and a very minor rash resembling mild varicella in about 5%, usually appearing a month after immunization (White, 1997). A small proportion of vaccinees (15%) may also experience mild fever. It takes about a week to demonstrate antibodies to varicella-zoster virus (VZV) after immunization, but protection often results even after an exposure has occurred. As a result of widespread immunization of children, the epidemiology of varicella has begun to change in the United States, with a reported marked decline in incidence in sentinel areas, where active surveillance for the disease is being carried out (Seward *et al.*, 2002). Vaccination is now being explored for the possibility of its preventing or modifying zoster. In a very real sense, the development of live varicella vaccine paved the way for the development of other vaccines against herpesviruses.

A number of possible misconceptions concerning varicella and varicella vaccine are listed in Table 70.1. This manuscript will discuss these misconceptions in the framework of the history of development of the live vaccine and its record regarding safety and efficacy of prevention, with regard to varicella as well as zoster.

History of development of the live attenuated vaccine

In 1974, when the first publication concerning the Oka varicella vaccine appeared, there was considerable controversy concerning whether use of a vaccine against a herpesvirus was likely to be safe and could possibly be effective. In Japan, the strategy used was first to vaccinate healthy children and then to gradually try to immunize safely immunocompromised children, progressing from the mildly to the severely immunocompromised. This possibly protective approach was taken because at that time, many young children were surviving cancer only to die of varicella. In studies in Japan, involving less than 200 healthy and immunocompromised children, it was found that the Oka strain appeared to be safe, although more needed to be learned about its efficacy. Because immunocompromised children in the Untied States were similarly faced with the possibility of surviving malignancy but not surviving chickenpox, interest in the Oka strain began to increase during the decade of the 1970s. While vaccine use remained controversial in the United States, most experts in the field believed that the risk-benefit ratio had become, by the late 1970s, appropriate to explore the safety and efficacy of varicella vaccine in children with underlying acute lymphoblastic leukemia in remission, because they had a 7% mortality from varicella (Feldman *et al.*, 1975). Studies showed that the vaccine could be used safely in these high-risk children, although some developed fairly extensive vaccine-associated rashes that required treatment with antiviral drugs (Gershon, 1995). Importantly, the vaccine

Table 70.1. Misconceptions concerning varicella vaccine and its use

Varicella and zoster are invariably mild diseases.
The vaccine is not very efficacious.
Zoster will become epidemic with widespread vaccination.
Varicella will cause more disease in older age groups if vaccine is given routinely to children.
The vaccine is too expensive to use.
The vaccine is not safe.

proved to be highly protective against varicella, despite the weakened immune systems of these children. Because of the high-risk nature of varicella in children with malignancies, it was not possible to conduct a controlled efficacy study. Vaccine efficacy, however, could be tested because of the high clinical attack rate of varicella in susceptible children following a household exposure to VZV(Gershon *et al.*, 1984a,b). As data regarding the clinical efficacy of the vaccine began to emerge, significant interest developed in determining if the vaccine would prove safe and effective in healthy children, thus eventually eliminating much of the necessity to immunize immunocompromised children.

Virology of the attenuated Oka strain of VZV

The original virus was isolated from a 3-year-old, otherwise healthy Japanese boy with varicella. To prepare the seed lot, the virus was passaged 11 times at 34 °C in human embryonic fibroblasts, 12 times at 37 °C in guinea pig fibroblasts, and 5 times in human diploid fibroblasts (WI-38 and MRC-5 cells) at 37 °C. (Takahashi *et al.*, 1974) Additional passages were carried out by the manufacturers to prepare the vaccine to be marketed. Because VZV is so strongly cell-associated, the final product had to be sonicated and clarified by centrifugation to produce live cell-free virus.

Fortunately, it was possible soon after the vaccine was developed, to be able to distinguish between the wild type virus and the Oka strain, which made possible the reliable analysis of clinical information following vaccination. Initially it was necessary to propagate VZV from a rash or other body tissue or fluid in order to identify whether the vaccine type virus was implicated when a complication of vaccination was suspected (Gelb, *et al.*, 1987). Eventually, however, it became possible to distinguish between vaccine and wild type VZV using polymerase chain reaction (PCR) without having to resort to virus isolation. (LaRussa *et al.*, 1992; Gomi *et al.*, 2000, 2001; Loparev *et al.*, 2000a, b) A number of mutations have been found to be present in the Oka vaccine strain that are not present in the parental Oka virus (Gomi *et al.*, 2000, 2001; Loparev, *et al.*, 2000a, b). Although it is known that most of the mutations in the vaccine strain are in open reading frame (ORF) 62, exactly which mutations are associated with attenuation have not yet been identified. The Oka strain replicates less efficiently in human skin than does wild type VZV, as studied in the SCID-hu mouse model (Moffat *et al.*, 1998).

Based on the vast quantity of clinical experience with the live VZV vaccine, there is overwhelming clinical evidence that the vaccine virus is attenuated. Both the incidence and severity of rash following vaccination compared to natural infection are decreased by a factor of about 20, whether vaccination is given by injection or inhalation (Bogger-Goren *et al.*, 1982; Gershon, 2001). Transmission of the Oka strain from healthy vaccinees with rash to other susceptibles is extremely rare and has been reported only on 4 occasions (LaRussa *et al.*, 1997; Salzman *et al.*, 1997; Sharrar *et al.*, 2000). This is in marked contrast to the extraordinarily high degree of contagion of the wild type virus in which roughly 90% of susceptibles develop clinical varicella after family exposures (Ross *et al.*, 1962). Finally contact cases of Oka varicella, which occur with some frequency after vaccinating leukemic children as well as rarely from healthy populations, are extremely mild or subclinical (Tsolia *et al.*, 1990; Sharrar *et al.*, 2000). Transmission has only occurred when the vaccinee has manifested a rash due to the Oka strain, and there has been no clinical evidence of reversion of the vaccine strain to virulence.

Safety of the varicella vaccine for healthy individuals

With any preventive medical intervention that is to be used widely on a routine basis, particularly in children, safety is the major concern. Live varicella vaccine has proven to be extremely safe when given to susceptible children, as indicated by extensive pre- and postmarketing studies in the United States. Prior to licensure over 9000 healthy children and 2000 adults were safely immunized in clinical trials (Gershon, 1995; White, 1997). Adverse effects were minor and transient.

A post-marketing safety study of the vaccine was begun at its licensure in 1995, by investigators at Merck and Company and at Columbia University (Sharrar *et al.*, 2000). Medical providers and consumers were asked on a voluntary basis, to submit information on possible adverse reactions

to the vaccine they observed. In addition to clinical information, samples of rashes and other possibly involved fluids and tissues were submitted to analyze first for VZV by PCR, and then to distinguish between the two types of virus if VZV was identified (LaRussa *et al.*, 1992). Although these data were collected passively, and the information therefore is necessarily incomplete, important data emerged from the study. It was crucial to be able to distinguish between vaccine and wild-type viruses because the temporal relationship of vaccination and development of rash and other symptoms would seem to implicate the vaccine virus without laboratory identification. Had it not been possible to distinguish between the two viruses, many adverse events would have erroneously been attributed to the vaccine type virus.

In the first 4 years after licensure, over 16 million doses of varicella vaccine were distributed in the United States. In the postmarketing study covering this period, rash was the most frequently reported adverse event, and almost all rashes consisting of more than 50 skin lesions were found to be caused by the wild type virus. There were fewer than five patients with more than 200 skin lesions shown to be caused by the Oka strain; this is below the average number seen in children experiencing natural varicella. There were 19 reports of encephalitis and 24 reports of ataxia during the year following vaccination, but the Oka strain of virus was not implicated in any of these illnesses. Wild-type VZV was, however, implicated in one patient with ataxia and one with encephalitis. Although there have been many reported fatalities due to wild type VZV, there have been no reports of fatal VZV infection caused by the Oka strain (Sharrar *et al.*, 2000).

A handful of serious disseminated infections have been reported in children who were thought to be immunologically normal when vaccinated, but were eventually identified as immunodeficient. The varicella vaccine virus remains sensitive to acyclovir and other antiviral drugs. All of these children received antiviral therapy and recovered from the VZV infection. These include one child each with human immunodeficiency virus (HIV) infection and essentially no CD4 lymphocytes (Kramer *et al.*, 2001), asthma and high dose steroids (Sharrar *et al.*, 2000), adenosine deaminase (ADA) deficiency with immunodeficiency (Ghaffar *et al.*, 2000), neuroblastoma diagnosed and treated right after vaccination (Levin, 2003), and a deficiency in natural killer cells (Levy *et al.*, 2003).

Zoster has been reported after vaccination but infrequently. In the first 4 years after licensure, the Oka strain was identified in 22 patients and wild type VZV in 10 with zoster (Sharrar *et al.*, 2000). To date, after distribution of over 40 million doses in the United States, there have been less than 50 reported cases of zoster shown to be due to the Oka strain (Galea *et al.*, 2002).

Immunogenicity of varicella vaccine in healthy children and adolescents

In prelicensure studies, children under 12 years of age had a seroconversion rate of 97% after one dose of vaccine, as determined by the exquisitely sensitive glycoprotein immunosorbent assay (ELISA) 6 weeks after immunization. This test is not available on a commercial basis. Adolescents and adults had a seroconversion rate of 82% after one dose of vaccine, which rose to 99% after 2 doses (Provost *et al.*, 1991; Gershon, 1995). A seroconversion rate of 91.5% was noted after one dose of vaccine, using an immune adherence antibody assay (IAHA), in 2565 Japanese children immunized between 1987–1993 (Asano, 1996). Unfortunately, commercially available ELISAs are neither sensitive nor specific enough to detect reliably antibodies after VZV immunization (Saiman, *et al.*, 2001). There were a number of reports of failure to seroconvert (using a commercial ELISA test) in healthy children and adults in the Merck-Columbia post-licensure study (Sharrar *et al.*, 2000). Most of these probably represent a failure of the test used rather than of the vaccine itself. The most sensitive and reliable method to measure antibodies to VZV, the fluorescent antibody to membrane antigen test (FAMA), is not amenable to performance on a large scale, and therefore remains a research tool (Williams *et al.*, 1974; Gershon, 1995). In studies in leukemic children, this assay indicated a seroconversion rate of 82% after one dose of vaccine and 95% after two doses (Gershon *et al.*, 1996). A convenient test that is sensitive and specific to reliably measure VZV antibody titers on a large scale basis continues to be sorely needed.

Efficacy and post-licensure effectiveness of varicella vaccine

Early studies in vaccinated leukemic children who were in remission from their illness and usually received two doses of varicella vaccine indicated not only that the vaccine was safe but also that it was highly protective against varicella (Gershon *et al.*, 1984a,b). About 85% of vaccinated leukemic children were completely protected against varicella after household exposure and those who developed breakthrough infection had mild disease requiring no antiviral therapy. In contrast, one would expect that, in varicella-susceptibles, about 90% would become obviously

infected following a household exposure to the virus (Ross *et al.*, 1962). Early studies in healthy children indicated a similar degree of protection against household exposure, following 1 dose of vaccine, with breakthrough disease in about 15% (White, 1996).

Two double blind placebo-controlled studies of varicella vaccine in healthy children were performed, involving a total of about 1500 children. Both indicated that the vaccine provided protection of about 90% (Weibel *et al.*, 1984; 1985; Varis and Vesikari, 1996). In these studies, higher doses of vaccine (10 000–17 000 plaque forming units-pfu) were associated with better protection than lower doses (1000 pfu). Many different doses of varicella vaccine have been studied in various clinical trials. The currently licensed Merck vaccine contains about 3000 pfu per dose, and the Glaxo SmithKline (GSK) vaccine contains about 10 000 pfu at the time of release, which prior to expiration date falls to about 3000 pfu. The Merck vaccine is lyophilized and frozen, while the GSK product is lyophilized and stored in the refrigerator (Gershon *et al.*, 2002). No direct comparison of efficacy of these vaccines has been performed, and therefore it is assumed that they are similar in efficacy. Clearly both are highly efficacious.

A postlicensure case-control effectiveness study involving PCR-proven cases of varicella in otherwise healthy children examined the performance of varicella vaccine in clinical practice in New Haven, CT. This study indicated that the vaccine in the US is about 85% effective in preventing all varicella, and virtually 100% protective against severe varicella in otherwise healthy children (Vazquez *et al.*, 2001). There were 202 children with varicella and 389 matched controls. Of these, 23% with varicella and 61% of controls had been vaccinated (vaccine effectiveness 85%). Of 56 vaccinated children with varicella, 86% had only mild disease; in contrast 48% of the 187 unvaccinated children had mild varicella. Studying the vaccine as it is used in clinical practice is especially significant because the vaccine itself is labile and loses potency if it is not stored properly, as indicated in the package insert, lyophilized and frozen.

Perhaps the best indication of the effectiveness of varicella vaccine, however, is the reported dramatic decline in the disease since 1995. This has been observed in sentinel areas of the USA (Seward *et al.*, 2002). Varicella is often mild and uncomplicated in otherwise healthy children, but it may unpredictably be associated with significant morbidity and even mortality. In the United States, in the prevaccine era, there were about 100 annual deaths from varicella and and 11 000 hospitalizations. Most reported deaths from varicella occurred in otherwise healthy individuals. Beginning in 1995, active surveillance of varicella in three sentinel counties in Texas, California, and Pennsylvania, was carried out by investigators at the Centers for Disease Control (CDC). Vaccination coverage in the year 2000 in the sentinel counties in children aged 19 to 35 years of age ranged from 73.6% to 83.8%. For the period of study, the number of cases of varicella and hospitalizations decreased sharply, with a reduction ranging between 71%–84% in the 3 counties. Hospitalizations for varicella per 100 000 persons decreased from 2.7–4.2 in 1995–1998 to 0.6 in 1999 and 1.5 in 2000. The long-standing recognized seasonality of varicella with increases in incidence of disease in winter and early spring also disappeared after 2000. The decrease in varicella occurred in individuals of all age groups including infants too young to be immunized and also adults, who were less likely to be immunized than children, indicating that herd immunity had developed (Seward *et al.*, 2002) (see figure in Seward chapter).

A prospective study of the incidence of varicella in 11 day-care centers in North Carolina between 1995–1999, indicated a similar decrease in the incidence of varicella due to vaccination. A case control analysis of this population indicated vaccine effectiveness of 83% (Clements *et al.*, 1999). In a further analysis of this population, the rate of varicella vaccine coverage increased from 4.4% in 1995 to 63.1% in 1999. The incidence of varicella per 1000 person–months fell from 16.74 in July 1996 to 1.53 cases in December 1999. Because the decrease in varicella disease exceeded the increase in vaccination rate over the period studied, the investigators proposed that herd immunity had occurred (Clements, *et al.*, 2001).

Considerations of vaccine use

In the United States, contraindications to varicella vaccine include pregnancy, allergy to vaccine components, and immunodeficiency. It is recommended that children receiving doses of steroids of over 2 mg/kg per day of prednisone or its equivalent NOT be immunized unless this medication can be discontinued for at least 3 months before vaccination. There are currently no programs for immunization of children with underlying leukemia because of potential safety concerns. On the other hand, studies of children with infection with human immunodeficiency virus (HIV) have indicated that it is safe to immunize them as long as their CD4 lymphocytes exceed 25% of their total lymphocytes in their peripheral blood. Two doses of vaccine are given to HIV-infected children, 4–8 weeks apart (Levin *et al.*, 2001). The CDC has supported this recommendation (Centers for Disease Control 1999). Children undergoing renal transplantation have been safely immunized in French studies. These children have had protection

against varicella and also have had a decreased incidence of zoster, compared to similar children who experienced natural varicella (Broyer and Boudailliez, 1985a, b; Broyer *et al.*, 1997).

Because transmission of the vaccine virus to others is rare, healthy persons who have close contact with susceptible individuals who are at high risk to develop severe varicella are recommended to be immunized. This includes, for example, healthy children whose pregnant mothers are susceptible to varicella, and children whose varicella-susceptible siblings have malignant diseases for which they are being treated.

While the major thrust of vaccine use in the United States is in young children who have not been exposed to the virus, the vaccine often provides protection to susceptibles who have already been exposed. That post-exposure vaccination can be successful was best demonstrated in studies in Japan in the 1970s and 1980s (Asano *et al.*, 1977, 1982). In these studies, family members who were exposed to varicella were immunized within 3 days and the disease was largely prevented. Vaccination was also used successfully to control an outbreak of varicella in a shelter for homeless families that was experiencing an epidemic of chickenpox (Watson *et al.*, 2000).

The vaccine has been shown to be cost effective in a number of studies in the United States and abroad (Lieu *et al.*, 1994; Beutels *et al.*, 1996; Burnham *et al.*, 1998; Coudeville *et al.*, 1999; Diez Domingo *et al.*, 1999; Brisson and Edmunds, 2002). In general this is a vaccine that is geared for use in developed countries, where it is not uncommon for children to be cared for out of the home as both parents are employed, or in single parent households where there is only one breadwinner.

Persistent questions regarding varicella vaccine

While ideally a vaccine should induce protection of close to 100% against a given disease, breakthrough cases of chickenpox have consistently been reported despite the administration of varicella vaccine, an observation first made in the early clinical trials involving leukemic children (Gershon *et al.*, 1984a, b). The rate at which breakthrough varicella has occurred has varied from study to study. There are a myriad of possible explanations for the phenomenon. One obvious one is that not even natural varicella induces total immunity in every individual. Second cases of natural varicella are well recognized to occur (Gershon *et al.*, 1984a, b; Junker *et al.*, 1989, 1991). It is unrealistic to expect a viral vaccine to provide better protection than the natural illness itself. Another indication that complete immunity to VZV may never be quite achievable is the existence of zoster, which is due to reactivation of latent VZV in persons with partial immunity. Unless a vaccine that does not induce latent infection is developed and widely used, herd immunity will be required to control diseases due to VZV in addition to personal immunity from the vaccine itself.

There is now general agreement that varicella vaccine is both safe and effective. A number of important questions about the vaccine have been raised recently. None of these uncertainties preclude the use of varicella vaccine, but all need further exploration. The remainder of this chapter will address these issues.

Does immunity to varicella wane with time after immunization?

There are two types of vaccine failure, which have been termed primary and secondary. Primary vaccine failure, commonly called a "no take," is said to occur when there is no measurable immune response to a vaccine that was administered and the person remains susceptible to the immunizing product. Persons who received varicella vaccine and developed full blown infections which are severe have probably experienced this phenomenon. In the Merck-Columbia postmarketing study, there were 11 reports of severe varicella despite immunization (Sharrar *et al.*, 2000). How often primary vaccine failure occurs is unknown, but it should be recalled that even with the very sensitive gp ELISA antibody test, the seroconversion rate in healthy children was 97%, not 100%. Considering that about 4 million children are immunized annually in the United States, there would be expected to be over 100 000 children annually who might have primary vaccine failure. This might be true for other vaccines as well and underscores the need for strong herd immunity in protection against infections after vaccination.

Secondary vaccine failure is said to occur when an immune response brought about by vaccination decreases with time, leaving the vaccinee with varying degrees of susceptibility to the disease. At present, there is little evidence for secondary vaccine failure due to waning of immunity to VZV after immunization of healthy children, but subtle degrees of waning immunity may be difficult to identify. An extremely high degree of persistence of antibodies and cellular immunity to VZV have been reported for as long as 20 years after vaccination, in Japanese and American studies (Asano *et al.*, 1994; Arvin and Gershon, 1996; Ampofo *et al.*, 2002). Moreover, studies in over 400 vaccinated adults indicate that there is no increase in the incidence or severity of breakthrough varicella with time, with up to 20 years of

follow-up (Ampofo *et al.*, 2002). Were immunity to be waning, one would expect that breakthrough disease would become more frequent and more severe with time after vaccination, but this has not been observed.

Nevertheless there are hints that the current vaccine strategy in the U.S. may need some adjustment to provide better protection, especially to young children. It is disquieting that about 10% of children may develop a modified form of varicella despite vaccination, and in some studies the rate has been even higher. In four studies, the breakthrough rate of varicella in children followed for up to 10 years after immunization, ranged between 18%–34% (Clements *et al.*, 1995, 1999; Johnson *et al.*, 1997; Takayama *et al.*, 1997). This breakthrough varicella may occur months to years after immunization, and it is caused by wild type VZV (LaRussa *et al.*, 2000). It may be so mild that it is misdiagnosed clinically as insect bites or hives. It occurs mainly in individuals who have low VZV antibody levels following immunization.

A number of outbreaks of varicella in vaccinated young children have been reported in the United States (Dworkin *et al.*, 2002; Galil *et al.*, 2002a, b; Gershon, 2002). Some of these cases may have resulted from secondary vaccine failure. In addition, there are other possibilities to explain these outbreaks. The vaccine is labile, and improper storage may account for primary vaccine failure in some children. Children with asthma may have less ability to mount a protective immune response, possibly related to medications such as steroids (Izurieta *et al.*, 1997; Shapiro and LaRussa, 1997). Currently, a CDC study to examine the seroconversion rate to VZV in vaccinated asthmatic children, as determined by FAMA, is underway in the United States, which should provide an answer to this question. In two reports, children vaccinated when they were less than 15 months old had higher rates of breakthrough varicella than those immunized when they were older (Dworkin *et al.*, 2002; Galil *et al.*, 2002a, b). When varicella vaccine is administered with an interval of less than one month after another live vaccine has been given, the incidence of breakthrough varicella increases (Centers for Disease Control, 2001) (Table 70.2).

One report of an outbreak of chickenpox in a day-care center in New Hampshire, in which the rate of vaccination in attendees was high is especially compelling with regard to the possibility of secondary vaccine failure (Galil *et al.*, 2002a, b). In this outbreak, the effectiveness of the vaccine was only 44%, much lower than in any previous report. In this study, 25/88 (28.4%) of children developed varicella in a 6-week period. It seems likely that the index case, whose varicella was quite extensive, had experienced primary vaccine failure. In the other involved children, the only factor that was associated with vaccine failure was an interval of greater than 3 years since vaccination. However, the children involved were very young, and it may be that the age at vaccination combined with the interval of time after immunization also played a role in predisposing them to breakthrough varicella. Continued investigations will be necessary to further understand whether waning immunity is a significant factor in breakthrough disease and how frequently it might occur, but it seems to be a real possibility. A follow up of the study conducted in private practices in New Haven has indicated that vaccine efficacy decreases with time, from 97% in year 1 to 72% in year 6 (Vazquez *et al.*, 2003), which confirms and extends the above observations of Galil *et al.* (2002a, b).

Table 70.2. Factors associated with vaccine failure/breakthrough disease

Improper storage of vaccine
<14 months old when immunized
Asthma
<30 days between MMR and varicella vaccine
>30 months since immunization
Low vaccine dosage

Table 70.3. Factors associated with successful vaccination

High vaccine dosage (over 10 000 pfu)
Two doses of vaccine, which provide higher antibody titers which in turn correlate with better protection

It may be that a second dose of varicella vaccine given routinely will alleviate potential problems of primary and secondary vaccine failure (Gershon, 2002). (Table 70.3) One possible way in which this could be accomplished in a practical manner is to administer routinely two doses of vaccine as measles, mumps, rubella, varicella (MMRV). Developing an immunogenic formulation of the varicella component of MMRV has proven to be a difficult task. Even a formulation of very high titered VZV (40 000 pfu) did not produce significantly higher titers of VZV antibodies, although it appeared to be safe (Shinefield, *et al.*, 2002). However, MMR and varicella vaccine may be administered safely together, and many children receive the two vaccine formulations at the same time although in separate syringes at different body sites (White, 1996).

It should be emphasized that breakthrough varicella is almost always a mild infection. Reports of varicella of normal severity in vaccines are few and probably represent mostly episodes of primary vaccine failure (Sharrar *et al.*,

Table 70.4. A comparison of the reported percentage of immunocompromised patients developing zoster who were vaccinated and those who experienced natural infection

Underlying diagnosis	Interval of observation in years	Vaccinees N (%)	Natural varicella N (%)	Reference
Leukemia	6	(6)	(19)	Takahashi *et al.*, 1990
Leukemia	6	34 (0)	73 (21)	Brunell *et al.*, 1986
Leukemia	10	96 (4)	96 (16)	Hardy *et al.* 1991
Renal transplantation	10	212 (7)	415 (13)	Broyer *et al.*, 1997

2000). Zoster may be more of a concern although it appears that zoster is more common after natural than vaccine infection (see below). If skin lesions of varicella predispose to latency, as has been suggested by experimental evidence (Chen *et al.*, 2003), then it would be important to try to prevent breakthrough infection in order to minimize the chance of developing zoster.

Varicella-susceptible adults may be safely immunized against varicella. Two doses are utilized, 4–8 weeks apart. Adults manifest lower seroconversion rates after one dose of vaccine than children, and therefore two doses are routinely administered. As in children, adverse effects are minimal and protection is high (Gershon, *et al.*, 1988; 1990; Ampofo *et al.*, 2002).

Serologic testing following immunization is usually discouraged because VZV antibody tests are both insensitive and results may be non-specific. Whether adults with no history of varicella should have serologic testing prior to immunization or simply be given two doses of vaccine if they have no history of past varicella remains moot. Inadvertent administration of vaccine to persons with immunity to varicella is not harmful (Gershon *et al.*, 2002).

Zoster: effects and potential effects on its incidence in the vaccine era

Although use of varicella vaccine is now contraindicated in immunocompromised individuals, early vaccine studies often involved these children because they were at high risk of developing severe varicella. (Table 70.4) In these vaccinees, the incidence of zoster was shown to be lower than after natural infection (Hardy *et al.*, 1991; Arvin and Gershon, 1996). Thus, there is every reason to predict that vaccination would also be protective against zoster in healthy children. Although the data are of necessity not controlled, the existing information since 1995 to the present strongly suggests that this is the case. Although healthy vaccinees have developed zoster, less than 50 known cases have been reported after distribution of over 40 million doses of vaccine between 1995 and 2002 (White, 1996; Sharrar *et al.*, 2000; Galea *et al.*, 2002). The rate of zoster after vaccination is roughly 20 times less the expected rate for that age group (Gershon *et al.*, 2002).

Recently several studies have addressed the question of whether exposure to varicella is protective against zoster, because it is known that zoster is associated with a low cell-mediated immune response to VZV. It was found that in vaccinated leukemic children, both household exposure and additional doses of varicella vaccine correlated with greater protection against zoster than a single dose of vaccine alone (Gershon *et al.*, 1996a, b). A case-control study has shown that following natural varicella, there is a lower incidence of zoster in individuals who have exposures to children with VZV infections in comparison to those who do not (Thomas *et al.*, 2002). Based on such data, using computer modeling, a theoretical calculation of the incidence of zoster in a highly vaccinated population has been made. This model predicts an epidemic of zoster with accompanying significant mortality in countries where varicella vaccination is routine (Brisson *et al.*, 2002). These observations, even though theoretical, have led to reluctance to use varicella vaccine routinely in some countries. It is therefore important to put the possibility into perspective.

The reported incidence of zoster in healthy individuals aged 40–50 in developed countries ranges between 2–4 cases per 1000 person–years of observation (Hope-Simpson, 1965; Donahue *et al.*, 1995). It was calculated that the rate of zoster would double in countries where routine vaccination is being carried out (Brisson *et al.*, 2002). This would lead to an incidence of 4–8 cases per 1000 person–years of observation in this age group. The incidence of zoster per 1000 person–years of observation in other high risk groups has been reported to be as follows: vaccinated leukemics 8, unvaccinated leukemics 25, adults with AIDS 50, children with AIDS 300 (Gershon *et al.*, 1996a, b). Thus the projected increase in the incidence of zoster based on computer modeling might double but even this is unlikely to represent an epidemic. Moreover, the mortality of zoster appears to be less than that from

varicella, the primary infection, and thus the validity of an increasing incidence of zoster leading to significantly increased mortality must be questioned (Feldman *et al.*, 1973; 1975; Whitley *et al.* 1982a,b; Shepp *et al.*, 1988). Finally, as yet, no actual increase in the incidence of zoster has been observed in the United States although the CDC is collecting epidemiologic data on the issue. Should an increase in zoster be recognized, however, it can logically be approached by immunization to prevent zoster, as described below.

Vaccination to prevent zoster in the elderly

It is estimated that about 20% of individuals who have had natural varicella will develop zoster during their lifetime, usually if they become immunocompromised or elderly. After age 50, the incidence of zoster climbs steadily with each advancing decade. While mortality from zoster is rare, morbidity from this infection remains a significant medical problem. The risk of developing the severe and painful complication of post-herpetic neuralgia (PHN) also increases with increasing age. It has been recognized for years that zoster occurs when the cell-mediated immune (CMI) response falls to below a critical level, and with advancing age, fewer and fewer people maintain a positive CMI response to VZV, although their antibody titers remain intact or may even increase (Arvin *et al.*, 1978; Berger *et al.*, 1981; Gershon and Steinberg, 1981; Burke *et al.*, 1982; Hardy *et al.*, 1991).

In attempts to explore whether vaccination may be used to boost immunity to VZV and possibly be used to prevent zoster, at least 8 clinical trials have been performed by investigators in the United States and Europe. These trials have determined that it is possible to boost CMI responses safely in many, although not all, elderly subjects. Varying doses of vaccine from roughly 1000 to 12 000 pfu have been employed. Some of these studies employed controls and others did not; in each, the subjects and medical personnel was aware of whom had received which vaccine. While no firm conclusions can be made from these studies, it appeared that vaccination seemed to modify zoster. All observed cases of zoster were mild in these otherwise healthy adults (Levin, 2001).

Based on these apparently successful open label studies, a large double blind placebo controlled study of immunization of healthy individuals over the age of 60 is currently being carried out. This study has now enrolled approximately 30 000 subjects and the observational period is still in progress. After a 3-year follow-up interval, the code will be broken and the data will be analyzed. At present, no results from this study are available, but there should be some published information by 2005. The vaccine employed is the live attenuated product, at a dose of about 20 000 pfu, which is roughly ten times the dose that is administered to healthy children (Levin, 2001) (see update below).

Use of inactivated varicella vaccine in patients at high risk to develop zoster

As in the studies described above to try to prevent zoster in elderly individuals, these studies were undertaken to try to boost the CMI response to VZV in highly immunocompromised patients who are at even greater risk to develop zoster than elderly patients. Because of the possibility of inducing another serious VZV infection with the live vaccine itself, however, an inactivated formulation of the vaccine was utilized. In an early controlled study, three doses of heat-inactivated vaccine were administered to a heterogeneous group of 75 patients; the incidence of zoster remained unchanged but the illness appeared to have been modified (Redman *et al.*, 1997). In a second, more successful clinical trial, 4 doses were employed, including one given a month before transplantation, and the subject population was more homogeneous and included only patients with lymphoma who had undergone autologous stem cell transplantation (Hata *et al.*, 2002). A dose of 6115 pfu of heat-inactivated VZV was administered, which was well tolerated although induration, erythema, or pain occurred after 10% of the doses. The rate of zoster was significantly decreased in vaccines compared to controls. Zoster occurred in 17/56 (30%) of the evaluable unvaccinated control patients and in only 7/53 (13%) vaccinees. Protection correlated with reconstitution of CD4 T-cell immunity to VZV. Because all the patients who developed zoster received antiviral therapy for their illness, it was not possible to compare the severity of zoster in the vaccines and controls. While this vaccine remains experimental, it holds promise for eventual prevention of zoster in immunocompromised patients. It also suggests an approach that might successfully prevent infections with other herpesviruses in the immunocompromised (Hata *et al.*, 2002).

Recent developments

There are two recent changes in policy with regard to recommendations for VZV vaccine use in the United States. They involve a CDC mandated second dose of varicella vaccine for all children, and the use of the newly licensed

by the FDA of combined measles-mumps-rubella-varicella (MMRV) vaccine. An additional development concerns vaccination of healthy older adults against zoster. Recently it was demonstrated that zoster can be prevented by immunization of healthy individuals over the age of 60 years with a different formulation of the Oka vaccine VZV strain that contains over 10 times the dose of virus as the monovalent varicella vaccine.

As has been mentioned, by 2002, numerous outbreaks of varicella were being observed in immunized children in day care facilities and schools in the United States. Vaccine efficacy rates were calculated to vary from 85% to as low as 44%.(Galil *et al.*, 2002b) One study showed that it appeared that the vaccine failure rate after 1 dose of vaccine might be as high as 20%, which alone could account for apparent breakthrough disease. In 2006, a study of the seroconversion against VZV of 16 month old children vaccinated in a practice setting at Vanderbilt University in 2004, indicated a seroconversion rate of 76% (FAMA $\geq$ 1:4) 16 weeks after 1 dose of Varivax (Michalek, Gershon *et al.*, personal communication). As part of a study conducted by Merck study (Kuter *et al.*, 2004), roughly 1000 children received a second dose of varicella vaccine 3 months after the first dose. A similar number of children were followed for the same interval but received only 1 dose of vaccine. In these children who received 2 doses, the seroconversion rate 6 weeks after the second dose increased to 99.5%, and the geometric mean titer (GMT) to 141.5, indicating a marked booster response after the second dose. In this study, the gp ELISA assay was used to assess humoral immunity. In October, 2006, the FDA approved the use of the combined vaccine MMRV for use in the United States. Marked boosting of humoral immunity following a second dose of MMRV was also observed (Shinefield *et al.*, 2005a,b). Boosting against VZV was about 10 times greater than boosting against the MMR components, in which it was only about 2 times greater. Importantly, as part of the Merck study (Kuter *et al.*, 2004), protection against varicella over 10 years of follow up was significantly higher after 2 doses of vaccine than 1 dose, 94% vs 98% respectively.

Due to the costs, inconvenience, and transmission of wild-type VZV associated with the numerous outbreaks of varicella, as well as the consistently observed boosting of both humoral and cell mediated immunity after a second dose of vaccine, the ACIP mandated a second routine dose of varicella vaccine for infants and children, with catch up programs, in June 2006. For harmonization with MMR vaccine, MMRV will usually be given at 12–15 months of age with a second dose at 4–6 years of age. Details concerning this recommendation should become available on the CDC website in the near future. As yet this information is unpublished.

Without a second dose of vaccine it was predicted that there would be an accumulation of vaccinated children destined to become varicella-susceptible young adults, potentially at high risk to develop severe varicella. This would especially be liable to occur in the setting of less opportunity for boosting of immunity due to less exposure to cases of varicella. In addition, it had been found by the CDC that outbreak control with a second dose was expensive and almost impossible to implement. While it is uncertain that there will be complete protection against varicella after 2 routine doses of varicella vaccine, it is projected that the numbers of breakthrough cases will decrease significantly, with a subsequent decrease in transmission of the virus, and a decrease in outbreaks.

Monovalent varicella vaccine contains a dose of about 1350 plaque forming units (pfu) of virus, but MMRV contains about ten times this amount. The increased dose of varicella vaccine in MMRV was required in order to reach an acceptable seroconversion against VZV. It is hypothesized that the measles component in MMRV may suppress the immune response to VZV. This dose of virus in MMRV is similar to the dose of vaccine used to prevent zoster.

In 2005, it was shown in a double-blind placebo-controlled study that vaccination of healthy adults over age 60 years resulted in significant protection against zoster and that in preventing zoster, postherpetic neuralgia was also prevented (Oxman *et al.*, 2005). In vaccinees aged 60–69 years, the vaccine was 64% effective in protection against zoster. Although the vaccine was less effective in preventing zoster in vaccinees aged 70–79 years (41%), it was 55% protective against PHN in this age group. Many questions about the use of this vaccine remain, such as the duration of immunity, but thus far the vaccine appears to be safe and effective when used in this manner. Currently the decisions are being made as to exactly how this vaccine should be used in the elderly population; the outcome should be known in the fall of 2006 (see CDC website for further information).

Conclusions

Despite the controversial introduction, varicella vaccines represent the first truly successful preventive measure against VZV. Although the approach of routine vaccine regimens for children may require some adjustment, the vaccine safely prevents most cases of clinical varicella, which saves lives, hospitalizations, and resources. Recipients of live vaccine are also at decreased risk to develop zoster. The

promise of prevention of zoster in individuals who already have latent infection with the wild type virus due to past natural infection with VZV is a potential goal that is likely to be accomplished with either live or inactivated vaccine or both. A new era in herpesvirus virology is well underway.

Human cytomegalovirus vaccines

Thomas C. Heineman

Division of Infectious Diseases and Immunology
Saint Louis University School of Medicine, Missouri, USA

Efforts to develop a human cytomegalovirus (HCMV) vaccine began more than 30 years ago in response to then recent reports that HCMV was capable of causing severe congenital disease. During the intervening years, our understanding of HCMV biology and immunology has increased dramatically. That knowledge, coupled with the introduction of several new vaccine methodologies, opened the door to an impressive expansion of HCMV vaccine research, particularly during the past decade. This chapter focuses on the principles underlying HCMV vaccine development and on the vaccine approaches that are currently under investigation.

Cytomegalovirus and human disease

The manifestations of HCMV infection vary with the age and immunocompetence of the host. In both adults and children, HCMV infection is usually asymptomatic. On rare occasions, otherwise healthy adults with primary HCMV infection will experience an infectious mononucleosis-like syndrome, with prolonged fever and mild hepatitis (Cohen and Corey, 1985). However, HCMV can cause serious morbidity and mortality when the host is unable to mount an adequate immune response or when infection is acquired in utero.

Congenital HCMV infection occurs in about 1% of children born in the USA, resulting in approximately 40 000 new infections each year (Pass and Burke, 2002; Plotkin, 1999). More than 90% of infected infants are asymptomatic at birth, and most will escape serious consequences of HCMV infection. However, even among initially asymptomatic children, 5%–15% will eventually develop sequelae of infection including hearing loss, mental retardation, chorioretinitis or cerebral palsy (Fowler *et al.*, 1992; Revello and Gerna, 2002; Pass and Burke, 2002; Stagno *et al.*, 1982, 1986). Children born with symptomatic HCMV disease have a substantially worse prognosis. Approximately 10% will die, and most of the survivors will display profound deficits as the result of central nervous system damage (Istas *et al.*, 1995; Pass and Burke, 2002). All together, 4000 to 8000 children in the USA develop HCMV-related neurological disease each year, making HCMV the leading infectious cause of congenital mental retardation and deafness (Fowler *et al.*, 1992; Plotkin, 1999).

Despite the availability of antiviral therapy, HCMV disease also remains a feared complication in persons undergoing immunosuppressive therapy for malignancies or organ transplantation, and in persons with AIDS. In these individuals, who have severely impaired cellular immunity, HCMV can affect almost any organ system, and it commonly causes pneumonia, retinitis, hepatitis and ulcerative lesions of the gastrointestinal tract (Pass, 2001). For example, HCMV causes symptomatic illness in 35%, and death in 2% of all renal transplant recipients (Adler, 1996). In hematopoietic stem cell transplant (HSCT) recipients, the most common disease manifestation of HCMV infection is interstitial pneumonia (Leather and Wingard, 2001). Historically, this disease typically occurs during the first 100 days following transplantation. However, late-onset HCMV pneumonia is becoming more common due to the use of HCMV antiviral prophylaxis or pre-emptive therapy during the first 3 months following HSCT (Boeckh *et al.*, 1996; Leather and Wingard, 2001).

The case for a cytomegalovirus vaccine

Recognition of HCMV disease as a major public health problem has grown in the medical and scientific communities, if not among the general public. HCMV infection causes more CNS disease than did either *Hemophilus*

influenzae b or congenital rubella prior to their near eradication in the USA through vaccination (Pass and Burke, 2002). Moreover, it has been observed that HCMV infection now causes as many cases of mental retardation as the common genetic syndromes, trisomy 21 and fragile X chromosome (Plotkin, 1999). The disease burden associated with cytomegalovirus infection is estimated to cost the US healthcare system at least 4 billion dollars annually, with the majority of the cost attributable to long-term sequelae experienced by individuals who acquire congenital HCMV disease. These data placed HCMV in the highest priority grouping of vaccine targets in a recent Institute of Medicine report (Stratton *et al.*, 2000).

One alternative to vaccination, prevention of HCMV infection through public health measures, is complicated by the high prevalence of HCMV, its persistence following primary infection, its many avenues of transmission (including blood, urine, saliva, semen, breast milk, donated organs) and its propensity to be shed for long periods of time following primary infection, especially by children (Pass, 2001). Of particular relevance, non-pregnant women evaluated in a randomized, controlled trial who were given explicit instructions on methods to avoid HCMV infection nonetheless acquired HCMV infection at rates equivalent to women who received no counseling (Adler *et al.*, 1996).

The successful prevention and treatment of HCMV disease in immunocompromised patients has greatly improved in recent years due to continuing refinements in prophylactic and preemptive therapy for high risk individuals as well as an expanding arsenal of antiviral agents. Despite this, as many as 50% of solid organ transplant recipients develop symptomatic HCMV disease resulting in significant morbidity (Fishman and Rubin, 1998; Patel and Paya, 1997; Sia and Patel, 2000; Simon and Levin, 2003), and even with optimal therapy, mortality from HCMV pneumonia in hematopoietic stem cell transplant recipients may exceed 40% (Leather and Wingard, 2001). Recent data also suggest that antiviral therapy offers some benefit to newborns with HCMV disease (Michaels *et al.*, 2003; Kimberlin *et al.*, 2003). However, treatment alone will undoubtedly benefit only a minority of infants with congenital HCMV disease. Indeed, most infants who ultimately develop sequelae of HCMV infection are asymptomatic at birth and, thus, would not be considered for treatment (Griffiths, 2002). Also, treatment requires long-term antiviral therapy, which carries a substantial risk of complications, and treatment after birth is unlikely to repair organ damage, especially to the central nervous system, that occurred in utero (Kimberlin *et al.*, 2003; Michaels *et al.*, 2003). For all these reasons, then, a vaccine that prevents infection with HCMV, or at least mitigates its effects in vulnerable persons, is essential for eradicating the often devastating disease caused by HCMV.

Natural immunity confers protection

When considering the feasibility and design of an HCMV vaccine, it is important to first establish that natural immunity prevents disease. This issue is complicated for HCMV because virus capable of causing disease may arrive through three distinct avenues: primary infection, reactivation of virus already residing within the host, or reinfection of a previously infected individual with a different strain of HCMV. Data directly addressing the protective efficacy of pre-existing immunity in healthy adults is sparse. However, compelling evidence that previous infection prevents reinfection comes from a study of mothers of children shedding HCMV (Adler *et al.*, 1995). During the course of this study, 9 of 19 (47%) seronegative women developed primary infection, whereas only 3 of 42 (7%) seropositive women showed evidence of new HCMV infection, indicating 85% protection attributable to prior immunity (Plotkin, 2002). In addition, healthy adults with pre-existing immunity to HCMV were significantly protected from HCMV disease compared to seronegative individuals when challenged with the non-attenuated Toledo strain of HCMV (Plotkin *et al.*, 1989; Quinnan *et al.*, 1984). In this case, seropositive persons were also protected from HCMV infection, albeit to a lesser degree.

Since the primary goal of HCMV vaccination is to prevent congenital HCMV disease, the protection offered by preconceptual maternal immunity should predict the potential value of vaccination in this setting. Preconceptual immunity could protect newborns by preventing transmission of the virus to the fetus or by mitigating the effects of infection. Data indicate that maternal immunity to HCMV prior to conception provides both of these elements of protection. Primary infection during pregnancy results in transmission of HCMV to the fetus 15%–40% of the time, whereas women with preexisting immunity transmit HCMV only about 1%–2% of the time (Stagno *et al.*, 1982; Plotkin, 2002). In accordance with these data, a recent study showed that women who have naturally acquired immunity to HCMV prior to conception are 69% less likely to give birth to an infant with congenital HCMV infection than women who are initially seronegative (Fowler *et al.*, 2003). Moreover, congenital HCMV infections in infants born to women with HCMV immunity at the time of conception are considerably less likely to cause symptomatic disease at birth (Fowler *et al.*, 1992; Stagno *et al.*,

1982, 1997). In general, these children also have both fewer and less severe sequelae of HCMV infection, even when considering that adverse outcomes, such as hearing loss and mental retardation, may become apparent only months or years later (Fowler *et al.*, 1992). Maternal immunity prior to conception, however, does not confer complete protection against HCMV transmission to the fetus. Of note, a recent report concluded that while the severity of hearing loss in HCMV congenitally infected children was less if their mothers had preexisting immunity, the incidence of hearing loss was unaffected by maternal serostatus (Ross *et al.*, 2006). Indeed, in populations with high rates of HCMV seropositivity the majority of HCMV infections may occur in infants born to seropositive mothers even given the relatively low risk of transmission (Demmler, 1991; Pass and Burke, 2002; Stagno *et al.*, 1977; Schopfer *et al.*, 1978; Plotkin, 2002; Boppana *et al.*, 2001). Many of these infections presumably occur through the transmission of reactivated maternal virus, although a significant proportion undoubtedly arise from reinfection of the mother with a different strain of HCMV followed by transmission of the new virus to the fetus (Marshall and Plotkin, 1993; Boeckh *et al.*, 1996; Stagno *et al.*, 1982; Boppana *et al.*, 2001). In addition, symptomatic HCMV disease has been well documented in children born to mothers with preconceptual immunity to HCMV (Boppana *et al.*, 1999, 2001; Schopfer *et al.*, 1978; Ahlfors *et al.*, 1999; Morris *et al.*, 1994).

In conclusion, prior immunity to HCMV provides substantial protection against HCMV infection and disease, with the degree of protection estimated to be between 70% and 90% (Adler *et al.*, 1995; Fowler *et al.*, 2003; Plotkin, 2002). This conclusion engenders optimism that vaccination of seronegative girls prior to pregnancy may prevent a substantial proportion of cases of congenital HCMV disease and the attendant early and late sequelae. Moreover, vaccination may ultimately reduce asymptomatic infection and shedding by young children, which would lessen the reservoir of virus available to infect the fetuses of other mothers (Adler, 1988; Pass *et al.*, 1986). Indeed, it has been calculated that a vaccine that is only 60% effective against primary infection would be sufficient to eradicate HCMV from a given community within a developed country (Griffiths *et al.*, 2001).

Immunology of HCMV protection

Both neutralizing antibodies and cell-mediated immunity contribute to protection against HCMV disease (Table 71.1; for review see Gonczol and Plotkin, 2001; Plotkin, 2002; Pass and Burke, 2002). The importance of antibodies in preventing HCMV disease was first suggested by the observation that serious HCMV disease in newborn blood transfusion recipients was less frequent in infants born to seropositive mothers (Yeager *et al.*, 1981). This protection was presumably due to antibodies that had been transferred from the mother to the infant prior to birth. The protective benefit of HCMV antibodies in neonates was reinforced by subsequent data showing that passively administered antibodies, in the form of HCMV immune globulin, protected premature infants from HCMV disease (Snydman *et al.*, 1995). In addition, a nonrandomized study suggested that administration of HCMV-specific hyperimmune globulin to pregnant women may be effective in the treatment and prevention of congenital HCMV infection (Nigro *et al.*, 2005). HCMV immune globulin also appears to offer renal, liver, heart and bone marrow transplant recipients some protection from the most severe effects of HCMV disease (Snydman, 1993; Falagas *et al.*, 1997; Valantine, 1995; Bowden *et al.*, 1986; Glowacki and Smaill, 1994; Messori *et al.*, 1994). Protective levels of antibodies have not been established, but some evidence suggests that higher levels of neutralizing antibodies correlate with a lower risk for reinfection (Adler *et al.*, 1995). Regardless of the clinical setting, however, antibodies alone offer only partial protection and appear to be more effective in mitigating serious HCMV disease than in preventing infection.

Analysis of the HCMV genomic sequence suggests that is capable of encoding in excess of 60 glycoproteins, although how many are actually expressed is unknown (Chee *et al.*,

Table 71.1. Known targets of human immune responses to HCMV

HCMV gene product	Immune response
Glycoproteins	
gB	Major target of neutralizing antibodies; target of CTLs[a]
gH	Important target of neutralizing antibodies; target of CTLs
gM-gN	Target of antibody responses
US2, US3, US6, UL18	Targets of CTLs
Non-structural proteins	
pp65	Major target of CTLs; target of antibody responses
IE1	Important target of CTLs; target of antibody responses
pp150, pp28	Target of CTLs and antibody responses
pp50	Target of CTLs
pp71, pp52	Targets of antibody responses

[a] Cytotoxic T-lymphocytes.

1990; Cha *et al.*, 1996; Davison *et al.*, 2003). Most HCMV neutralizing antibodies, however, appear to recognize a tiny subset of these proteins, namely, glycoprotein B (gB), glycoprotein H (gH) and the glycoprotein M-N (gM-gN) complex (Britt *et al.*, 1990; Kari and Gehrz, 1990; Mach *et al.*, 2000; Marshall *et al.*, 1992, 1994; Rasmussen *et al.*, 1991; Urban *et al.*, 1996).

Glycoprotein B is the most abundant membrane protein in the HCMV envelope (Britt and Mach, 1996). It is highly conserved among all mammalian herpesviruses, and participates in several facets of the virus life cycle including entry and cell–cell spread (Bolds *et al.*, 1996; Compton *et al.*, 1993; Navarro *et al.*, 1993). Recently, it was shown that HCMV entry into cells is mediated by gB binding to the cellular epidermal growth factor receptor (Wang *et al.*, 2003). HCMV gB, like the gB homologues in other herpesviruses, is a large type I membrane protein (for review see Britt and Mach, 1996; Spaete, 1994). It is cleaved by a host cell protease into two peptides, which remain disulfide-linked. Glycoprotein B is modified by N- and O-glycosylation and forms homodimers in both virions and infected cells (Mocarski and Courcelle, 2001). Glycoprotein B appears to be the most immunogenic HCMV protein. Almost all persons develop antibodies to gB following HCMV infection, and gB-specific antibodies account for 40%–70% of the total HCMV neutralizing activity in HCMV seropositive individuals (Britt *et al.*, 1990; Cremer *et al.*, 1985; Kniess *et al.*, 1991; Marshall *et al.*, 1992). Glycoprotein B contains two well-characterized major antigenic domains, AD-1 and AD-2, that are capable of inducing neutralizing antibodies during infection (Britt *et al.*, 1988; Kniess *et al.*, 1991; Marshall *et al.*, 2000; Meyer *et al.*, 1992; Wagner *et al.*, 1992). The antibody response after natural infection is directed most frequently to AD-1, which is highly conserved in clinical isolates (Schoppel *et al.*, 1996; Wada *et al.*, 1997; Chou and Dennison, 1991). However, 11% of HCMV seropositive persons lacked antibodies to linear epitopes on either AD-1 or AD-2, but had neutralizing activity suggesting that for some individuals, different epitopes in gB or epitopes in other HCMV proteins may be more important in the generation of virus neutralizing responses (Marshall *et al.*, 2000).

Glycoprotein H is a relatively abundant component of the virion envelope and is also conserved among the mammalian herpesviruses, although it is much more divergent than gB (Mocarski and Courcelle, 2001). HCMV gH has been shown to participate in membrane fusion, and it may play role in virus entry at a step following attachment (Britt and Mach, 1996; Mocarski and Courcelle, 2001; Keay and Baldwin, 1991; Rasmussen *et al.*, 1984). Glycoprotein H is also an important target of host immune responses, and almost all persons infected with HCMV develop gH-specific antibodies (Urban *et al.*, 1996). In some cases, gH may be the dominant target of neutralizing antibodies as it has been shown to account for 0–58% of the total virus neutralizing activity in persons with a past history of HCMV infection (Urban *et al.*, 1996). Like gB, antigenic domains have been identified in gH (Simpson *et al.*, 1993). Interestingly, HIV-infected persons with CD4 counts less than 100 cells/mm^3 who had histories of past HCMV infections rarely had detectable gH antibody titers compared to persons with higher CD4 counts, while gB titers were unaffected by the CD4 count (Rasmussen *et al.*, 1994). Given that HIV-infected persons with CD4 counts less than 100 cells/mm^3 are at high risk for retinitis due to reactivated HCMV, this finding raises the possibility that gH antibodies may be necessary for containing reactivated virus in some settings.

Recently, the gM-gN complex was recognized as an important target of antibody responses in seropositive adults (Kari and Gehrz, 1990; Mach *et al.*, 2000). Sera from HCMV-infected adults failed to recognize gM or gN when they were expressed alone; however, sera from 62% of previously infected individuals reacted with the gM–gN complex. The importance of gM–gN antibodies in preventing HCMV disease is unknown. A possible link between gM–gN antibodies and human disease, however, was suggested by the observation that the 14 of 16 congenitally infected infants lacked detectable antibodies against this complex, whereas most adults in the same study had gM–gN antibodies (Mach *et al.*, 2000).

In addition to gB, gH and gM–gN, antibodies to several non-envelope HCMV proteins, including pp65, IE1, pp150, pp28, pp71 and pp52, are commonly detected in seropositive people (Pass and Burke, 2002). It remains to be determined whether these antibodies contribute to protection against HCMV infection and disease.

The pivotal role for cell-mediated immunity in the control of HCMV infection is underscored by the fact that virtually all cases of severe HCMV disease not associated with congenital infection occur in persons with profoundly impaired cellular immunity, and the severity of HCMV disease typically correlates with the degree of immunosuppression. Specifically, HLA-restricted CD8$^+$ cytotoxic T lymphocyte (CTL) responses are crucial for the control of HCMV disease in immunocompromised persons (Quinnan *et al.*, 1982; Li *et al.*, 1994; Reusser *et al.*, 1991). Allogeneic marrow transplant recipients are at high risk for HCMV disease until their CD8$^+$ CTLs return. The fundamental importance of CTL responses in controlling HCMV disease was directly assessed by an adoptive transfer study in which marrow transplant recipients received serial transfusions of HCMV-specific CTLs (Walter *et al.*, 1995). None of the 14 very high-risk patients in this study developed HCMV

Table 71.2. Status of HCMV vaccines currently being tested

	Stage of testing			
		Human trials		
Vaccine	Preclinical	Safety	Immunogenicity	Efficacy
Towne vaccine	+	+	+	+

DNA vaccines	+	−	−	−
Peptide vaccines	+	−	−	−
Dense body vaccines	+	−	−	−

[a] This study is ongoing, and no efficacy data are yet available.

viremia or disease. Therefore, considerable effort has been devoted in recent years to identifying the HCMV targets of CTL responses since the induction of such responses may be imperative for the success of an HCMV vaccine. This work led to the discovery that the tegument protein pp65 is the dominant target of virus-specific CTLs. In persons with past HCMV infection, approximately 70–90% of all CTLs that recognize HCMV-infected cells are specific for this protein (Boppana and Britt, 1996; Kern *et al.*, 2002; McLaughlin-Taylor *et al.*, 1994; Wills *et al.*, 1996). Recently, specific peptides derived from the pp65 sequence have been identified that are able to induce HCMV-specific CTL in an HLA-A24-restricted manner (Akiyama *et al.*, 2002; Masuoka *et al.*, 2001).

While it is striking that a single protein induces so much of the CTL response directed against such a complex virus, other HCMV proteins have also been shown to contain CTL epitopes. Most notable among these are the HCMV immediate-early protein, IE1, and the tegument protein, pp150, which in some individuals appears to induce CTL responses with similar precursor frequencies to pp65 (Kern *et al.*, 2000; Gyulai *et al.*, 2000; La Rosa *et al.*, 2005). Like pp65, IE1- and pp150 derived peptides that induce CTL in an HLA-restricted manner have been identified (Frankenberg *et al.*, 2002; La Rosa *et al.*, 2005). In addition, other HCMV antigens that are capable of inducing CTL responses including gB, gH, pp150, pp28, pp50, US2, US3, US6, and US18 (Boppana and Britt, 1996; Gyulai *et al.*, 2000; Elkington *et al.*, 2003).

The effectiveness of an HCMV vaccine is likely to be enhanced by, and may absolutely require, the induction of HCMV-specific CTL responses. Such responses would be expected following inoculation with live attenuated vaccines. However, other vaccine approaches, such as vectored vaccines and DNA vaccines, as discussed below, may require the inclusion of specific CTL epitopes to achieve similar results. Moreover, multiple CTL epitopes may need to be included to ensure maximal coverage in the community at large.

Vaccine development

HCMV has been the target of active vaccine development efforts since the 1970s. Early work focused on the development of live-attenuated vaccines, which have now been tested in numerous human trials and, as a family, continue to show considerable promise. With advances in molecular techniques, and rapidly expanding knowledge of HCMV biology and immunology, several other approaches are currently being applied to the development of safe and effective HCMV vaccines (Table 71.2).

Replicating vaccines

The first HCMV vaccine tested in humans was AD169, a laboratory-adapted strain of HCMV made by passaging virus isolated from human adenoidal tissue a total of 54 times in four different cultured human fibroblast cell lines (Elek and Stern, 1974). A lysate containing infectious virus derived from sonicated AD169-infected cells was administered to HCMV seronegative adults. Twenty-five of 26 volunteers (96%) who received 10 000 plaque forming units (pfu) of virus subcutaneously seroconverted. The vaccine was safe and well tolerated with 12 of 26 recipients exhibiting minor local reactions and one person developing lymphadenopathy and lymphocytosis. None of the vaccinees excreted virus based on cultures of throat washings and

urine. Two vaccinees tested a year later showed no reduction in antibody titers. However, evaluation of some of these subjects 8 years later revealed that only half had detectable HCMV antibody or lymphocyte transformation responses (Stern, 1984).

A second clinical trial of AD169 was conducted a few years after the first (Neff *et al.*, 1979). The virus used in this trial was passaged an additional five times and prepared as a filtered sonicate of infected cells. Twenty-four adult men were vaccinated subcutaneously, and all 20 of the initially seronegative individuals developed antibodies to HCMV by one month following vaccination. One year later, immune adherence antibodies had declined slightly while complement-fixing antibodies had declined significantly. Participants with pre-existing immunity to HCMV exhibited no antibody response to vaccination. The vaccine virus could not be detected in leukocytes, urine or throat specimens from the vaccinated seronegative persons and was not transmitted to any of the 10 seronegative contacts of the vaccine recipients, which was taken as evidence for lack of contagiousness of the vaccine virus. AD169 was not pursued further as a vaccine candidate. Instead, attention turned to the HCMV Towne strain as a potential live attenuated vaccine, and Towne remains today the best-studied HCMV vaccine candidate.

The Towne strain of HCMV was isolated in 1970 from the urine of a 2-month old infant with congenital disease, then passaged 125 times exclusively in WI-38 human diploid fibroblasts, including three clonings (Plotkin *et al.*, 1975). It was characterized in 1975 prior to its use in clinical trials and was shown to possess several characteristics that distinguished it from native HCMV indicating that it had been altered by cell culture passage. These included increased production of cell-free virus, thermostability and trypsin resistance. In addition, safety tests in various animals and cell lines showed the virus stocks to be free of adventitious agents.

In the first published human trial describing Towne vaccination, all 10 seronegative adults inoculated intramuscularly seroconverted within four weeks while 11 seronegative adults inoculated both intranasally and orally failed to seroconvert (Just *et al.*, 1975). Five persons with pre-existing immunity to HCMV were vaccinated with Towne and showed no increase in antibody titers. None of the participants had systemic symptoms or atypical lymphocytosis; however, 7 of the original 10 seronegative vaccinees developed mild local reactions beginning 14–16 days following vaccination and lasting about a week. As with the AD169, Towne could not be isolated from the leukocytes or urine of any vaccinee, suggesting that Towne is attenuated and unable to persist in vaccinated persons.

A second early trial with Towne largely reinforced the findings from the first trial (Plotkin *et al.*, 1976). Once again, persons inoculated intranasally failed to seroconvert whereas all seronegative volunteers who were vaccinated subcutaneously acquired HCMV-specific antibodies, and no excretion of vaccine virus from these individuals could be documented. In contrast to the earlier study, however, all 4 seronegative participants in this trial acquired complement-fixing antibodies compared to 1 of 10 in the first trial. Also, both initially seropositive vaccinees developed IgM antibodies, raising the possibility that Towne may reinfect persons who had previously been infected with native HCMV.

Subsequent human trials with Towne confirmed its ability to elicit both binding and neutralizing antibodies, and demonstrated that Towne-induced antibodies have similar specificities to the antibodies arising from natural HCMV infection (Gonczol *et al.*, 1989). Early studies showed that both binding and neutralizing antibody titers in response to Towne vaccination were substantially lower than those following natural infection (Gonczol *et al.*, 1989; Adler *et al.*, 1995). However, a more recent study showed that a new lot of Towne vaccine induced titers of neutralizing antibodies comparable to those induced by natural infection and that the response was dose dependent (Adler *et al.*, 1998). In this study, as in earlier trials, the level of Towne-induced antibodies waned over the course of a year, while those in naturally seropositive women remained stable.

The ability of Towne to induce cellular immune responses is well documented. Towne vaccination of healthy seronegative adults uniformly results in HCMV-specific lymphocyte responses, a surrogate for CD4+ cell activation, which persist for at least 10 months (Gehrz *et al.*, 1980; Starr *et al.*, 1981; Fleisher *et al.*, 1982; Plotkin *et al.*, 1989; Adler *et al.*, 1995, 1998). In addition, Towne consistently elicits HCMV-specific CD8+ CTL responses in immunocompetent individuals (Quinnan *et al.*, 1984; Adler *et al.*, 1998).

Towne has also been tested in a series of studies in prospective kidney transplant recipients, a population that is at high risk for HCMV disease following transplantation (Glazer *et al.*, 1979; Marker *et al.*, 1981; Starr *et al.*, 1981; Plotkin *et al.*, 1984, 1991, 1994; Brayman *et al.*, 1988; Balfour, 1991). Most renal transplant candidates developed humoral and cellular immune responses following Towne vaccination. The responses, however, tended to be delayed or diminished when compared to those of healthy vaccinees (Starr *et al.*, 1981; Plotkin *et al.*, 1984, 1991). Three controlled trials have been conducted in which renal transplant candidates received either Towne vaccine or a placebo (Balfour, 1991; Plotkin *et al.*, 1991, 1994). Each of

Table 71.3. Protective efficacy of Towne vaccination in seronegative renal transplant recipients who received kidneys from seropositive donors

Trial	*n* (vaccine/ placebo)	All HCMV disease		Severe HCMV disease		% reduction of all disease	% reduction of severe disease
		Vaccine	Placebo	Vaccine	Placebo		
Plotkin *et al.*, 1991	67 (36/31)	14 (39%)	17 (55%)	2 (6%)	11 (35%)	46%	83%
Balfour 1991	35 (21/14)	8 (38%)	6 (43%)	2 (10%)	5 (36%)	12%	72%
Plotkin *et al.*, 1994	61 (37/24)	14 (38%)	14 (59%)	0 (0%)	4 (17%)	36%	100%
All	**163 (94/69)**	**36 (38%)**	**37 (54%)**	**4 (4%)**	**20 (29%)**	**30%**	**86%**

these trials yielded similar results (Table 71.3). Vaccination with Towne failed to prevent HCMV infection following transplantation, and while the incidence of total HCMV disease was decreased, this effect did not achieve statistical significance. However, in the highest risk population, namely HCMV seronegative persons who received a kidney from a seropositive donor, the incidence of severe HCMV disease was reduced by 72%–100%, a degree of protection comparable to that stimulated by natural infection (Plotkin *et al.*, 1991).

The efficacy of Towne vaccination was also assessed in a controlled challenge study. In that study, seronegative adults were vaccinated with Towne and challenged with the non-attenuated, low-passage Toledo strain of HCMV (Plotkin *et al.*, 1989). The ability of Toledo to cause disease was confirmed when all 6 seronegative, unvaccinated persons challenged subcutaneously with 10 or 100 pfu of Toledo developed clinical symptoms of HCMV disease as well as evidence of infection based positive viral cultures from their blood, urine and/or saliva. Twelve adults who had been vaccinated with Towne 1 year earlier were challenged with Toledo. All 5 who were challenged with 10 pfu of Toledo were protected from infection and disease. However, of the 7 Towne-vaccinated persons who were challenged with 100 pfu of Toledo, most (4/7) showed evidence of infection based on virus culture, one had clinical illness and 3 had laboratory abnormalities suggestive of HCMV infection. In contrast, naturally seropositive persons were protected from challenge with 100 pfu of Toledo; however, 5/5 seropositive individuals challenged with 1000 pfu of Toledo exhibited clinical disease, laboratory abnormalities and/or positive HCMV cultures. Therefore, in this small study, Towne appeared to afford some protection against HCMV infection and disease, but less than natural infection. This study and an earlier challenge study in seropositive, unvaccinated individuals (Quinnan *et al.*, 1984) provided valuable information not only on the protective efficacy of Towne relative to natural infection, but also on the dose dependence and natural history of HCMV disease in immunocompetent adults. However, challenge studies with HCMV may no longer be possible given contemporary regulatory standards designed to ensure volunteer safety.

To assess the protective efficacy of Towne in a more natural setting, a placebo-controlled study was performed in seronegative women with children in daycare. This was, in effect, a challenge study as the parents of children in daycare are at high risk for HCMV infection (Pass *et al.*, 1986). In this population, Towne vaccination failed to protect women from HCMV infection, while natural infection was highly protective against re-infection with HCMV (Adler *et al.*, 1995).

Towne remains the only HCMV vaccine candidate that has completed efficacy testing in any human population. In the final estimation, Towne vaccination induces both humoral and cellular immunity, and it is capable of providing some protection against HCMV disease in certain settings. However, it is clearly less protective than natural infection, particularly in its ability to prevent infection with native HCMV, which may be critical for preventing congenital disease. In an effort to enhance the immunogenicity of Towne, the co-administration of recombinant human IL-12 with Towne was evaluated in a recent clinical trial (Jacobson *et al.*, 2006). This combination proved to be well tolerated and resulted in enhanced HCMV-specific antibody and T cell responses.

The nature of the deficit in Towne's ability to stimulate protective immunity is unknown, but it has been suggested that the lower neutralizing antibody titers induced by Towne compared to natural infection may be at fault (Wang *et al.*, 1996). Regardless, the experience with Towne suggested that it is overly attenuated and prompted researchers to pursue less attenuated live vaccines that will, ideally, retain the excellent safety and tolerability profiles of Towne.

The high level of attenuation exhibited by Towne is presumably due to genetic mutations introduced during its extensive passage in cultured cells (Huang *et al.*, 1980; Prichard *et al.*, 2001). Furthermore, recent data indicate

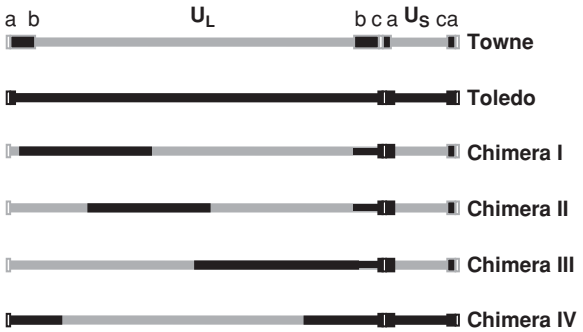

Fig. 71.1. Genomic structures of the two parental strains and four chimeras. The specific regions of each chimera's genome derived from Towne(▬) and Toledo(▬) are shown. The UL/b' region(▬) of Toledo is marked(courtesy of George Kemble)

that HCMV Towne contains numerous mutations throughout in its genome when compared to the non-attenuated Toledo strain of HCMV (G. Kemble, personal communication, 2003); however, the specific mutations causing attenuation are not known. In an effort to produce a vaccine that is intermediate in attenuation between HCMV Towne and wild-type virus, genetic recombinants were constructed in which regions from the HCMV Toledo genome were substituted for the corresponding regions of the Towne genome using cosmid-based mutagenesis (Kemble *et al.*, 1996). Four independent chimeric viruses (referred to as Chimeras I–IV) were produced in which every region of the Towne genome was replaced sequentially by Toledo sequences (Fig. 71.1). Each of the four chimeric vaccine candidates made using this approach contains the UL/b region of the HCMV genome. This region, which is predicted to encode 19 proteins, is universally found in the genomes of circulating HCMV isolates but is not present in it entirety in many HCMV strains that have undergone extensive passage in cell culture, such as AD169 (Cha *et al.*, 1996). It was hypothesized that by using this approach, one or more of the Towne/Toledo recombinants would contain some, but not all, of the mutations that confer attenuation on Towne. This, in turn, should result in a chimeric virus that is attenuated relative to Toledo, but less attenuated than Towne.

The four Towne/Toledo recombinant viruses were evaluated in a recently completed double-blinded, placebo controlled clinical trial (Heineman *et al.*, 2003). The study was designed to determine whether the vaccine candidates are safe and well tolerated, whether they are attenuated relative to Toledo and whether they are shed in the blood, urine or saliva of vaccinees. Healthy HCMV seropositive adults each received a single dose of 1000 pfu of one of the four investigational vaccines or an inactive placebo. Participants were evaluated weekly for 8 weeks, then less frequently for the remainder of a year, for clinical or laboratory evidence of HCMV infection and disease. All four vaccine candidates were safe and well-tolerated although as a group they produced more local reactogenicity than the placebo. As predicted, each of the Towne/Toledo chimeric vaccine candidates was attenuated relative to Toledo based on comparison to the previous Toledo challenge data discussed above (Quinnan *et al.*, 1984; Plotkin *et al.*, 1989). This attenuation was evident from the paucity of laboratory abnormalities suggestive of HCMV infection in the recipients of the chimeric vaccine candidates in contrast to those noted in HCMV seropositive persons who had received the same dose of Toledo (Table 71.4). However, the degree of attenuation of the four Towne/Toledo chimeras relative to each other could not be discerned from this initial trial. Like Towne, none of the vaccine candidates was cultured from the blood, urine or saliva of any vaccinee or any of their close contacts suggesting that systemic infection did not occur in this population. Immunogenicity data from this trial are pending. Future studies are planned to address the safety and immunogenicity of these vaccine candidates in seronegative persons, who comprise the target population for vaccination.

Table 71.4. Towne/Toledo chimeric vaccine candidates are attenuated relative to Toledo in natural seropositives inoculated with 1000 pfu

Vaccine	Laboratory abnormalities[a]	Virus isolated
Chimera I	0/5	0/5
Chimera II	1/5[c]	0/5
Chimera III	0/5	0/5
Chimera IV	1/5[d]	0/5
Chimeras I-IV	**2/20**	**0/20**
Placebo	1/5[c]	0/5
HCMV Toledo[b]	***5/5***	***2/5***

[a] Defined as elevated aspartate aminotransferase (AST) or atypical lymphocytosis.
[b] From Plotkin, *et al.*, 1989.
[c] Elevated AST. In the case of Chimera II, the volunteer had an elevated AST prior to vaccination.
[d] Atypical lymphocytosis of 9% at week 8 after vaccination only.

Subunit vaccines

Subunit vaccines, in which a single or a few specific proteins are used in combination with an adjuvant to

stimulate protective immunity, are attractive for several reasons. Most importantly, they are not infectious and contain no genetic material thus eliminating some safety concerns. Also, using modern molecular genetic methods, large amounts of the vaccine antigens can be produced easily and cheaply. Finally, subunit vaccines for numerous infectious diseases have been studied extensively in animals and, in some cases, have progressed to human trials. Of particular relevance, recent data suggest that a subunit vaccine derived from a single herpes simplex virus (HSV) type 2 protein may protect seronegative women from disease caused by primary HSV infection (Stanberry *et al.*, 2002).

As discussed above, HCMV gB is both highly immunogenic and highly conserved between HCMV isolates. For these reasons, and because it is the best studied HCMV glycoprotein, gB has been the primary antigen used in most HCMV subunit vaccine studies. Glycoprotein B used in vaccine studies has been modified to facilitate its purification. To that end, its hydrophobic transmembrane domain has been removed, and it has been mutated to eliminate its internal proteolytic cleavage site. Thus, the form of gB used in human trials is expressed in Chinese hamster ovary cells and is purified as an excreted protein consisting of a single 807 amino acid peptide (Pass *et al.*, 1999).

The choice of vaccine adjuvants has considerable impact on the immunogenicity of subunit vaccines. In the human trials reported to date, HCMV gB has been combined with either aluminum hydroxide (alum), the adjuvant used in the licensed hepatitis B vaccines, or MF59, a proprietary oil-in-water emulsion of squalene (Chiron Vaccines, Emeryville California) (Ott *et al.*, 1995). MF59 was previously shown to induce higher antibody titers than alum when combined with a variety of viral antigens (McElrath, 1995). Accordingly, virtually all healthy seronegative adults inoculated at 0, 1 and 6 months with HCMV gB combined with MF59 developed levels of binding and neutralizing antibodies comparable to those induced by natural infection, whereas persons vaccinated similarly with gB/alum produced significantly lower titers of gB-specific antibodies (Pass *et al.*, 1999). Also, IgG and IgA antibodies to gB were present in the saliva or nasal washes of most gB/MF59 recipients (Wang *et al.*, 1996). Dose comparison studies demonstrated that low doses of gB (5 μg) combined with MF59 elicited antibody responses similar to those observed with higher doses (30 or 100 μg) (Pass *et al.*, 1999; Frey *et al.*, 1999). Toddlers who received three 20 μg doses of gB/MF59 developed mean gB binding and neutralizing antibody titers six-fold higher than were observed in earlier adult studies (Mitchell *et al.*, 2002). Following vaccination with gB/MF59, neutralizing antibody titers waned rapidly, and it was suggested that insufficient $CD4^+$ responses might have contributed to this decline. Nonetheless, neutralizing antibody titers rebounded dramatically after an additional dose of vaccine (Plotkin, 2001; Pass and Burke, 2002). Vaccination with gB/MF59 also induced strong lymphocyte proliferative responses to both gB and HCMV, and these declined little during the year following vaccination (Pass and Burke, 2002). The HCMV subunit vaccines caused more injection site pain than placebo; however, both were generally well tolerated.

The studies described above laid the groundwork for efficacy trials of the gB/MF59 subunit vaccine. Currently, the ability of gB/MF59 to prevent congenital HCMV infection in the children of healthy seronegative women is being assessed in a double-blinded, placebo controlled trial (R. Pass, personal communication, 2006). In addition, a study is being planned to determine whether gB/MF59 vaccination protects adolescents from HCMV infection, a population that may ultimately be targeted for vaccination (D. Bernstein, personal communication, 2003). While HCMV subunit vaccines have thus far focused on the use of gB as the immunogen, future subunit vaccines may include gH, gM-gN, and perhaps other HCMV antigens.

Vectored vaccines

A number of viruses have been utilized as vectors to express potential vaccine antigens. Of these, the attenuated ALVAC strain of canarypox has been most extensively employed as a vector for the delivery of HCMV antigens (Baxby and Paoletti, 1992; Tartaglia *et al.*, 1992; Plotkin *et al.*, 1995). The ALVAC genome will accommodate the insertion of large exogenous DNA fragments providing great flexibility in the choice of antigen genes or combinations of genes. While it can infect human cells and express foreign antigens, its own genome is not replicated and progeny virions are not produced, thus reducing the risk of vaccine-associated complications. Most importantly from the perspective of vaccine efficacy, foreign antigens expressed by ALVAC are transported and processed authentically within cells allowing their presentation in the context of MHC class I molecules. This, in turn, may facilitate the stimulation of CTL responses that mimic those of natural infection (Pialoux *et al.*, 1995; Clements-Mann *et al.*, 1998; Taylor *et al.*, 1995; Plotkin *et al.*, 1995).

Because of its preeminence as target for neutralizing immunity, gB was the first HCMV antigen chosen for expression by ALVAC. Studies in mice and guinea pigs showed that two doses of ALVAC-gB induced neutralizing antibodies and also high levels of HCMV-specific $CD8^+$ CTL

responses (Gonczol *et al.*, 1995). UV-inactivated ALVAC-gB failed to induce CTLs indicating that de novo synthesis of gB was required. In addition, prior vaccinia virus exposure did not inhibit the gB-specific immunity induced by ALVAC-gB in mice, addressing an issue that may become more important if vaccinia vaccination rates increase in response to bioterrorism concerns. The promise of the initial animal studies, however, was not fully realized in early human trials. Even after three doses of ALVAC-gB, seronegative adults failed to develop significant HCMV neutralizing antibody titers perhaps reflecting low levels of antigen production (Adler *et al.*, 1999).

ALVAC-gB proved far more successful when it was used to "prime" the immune system in so-called prime-boost vaccination strategies. HCMV seronegative adults who were primed with two doses of ALVAC-gB at days 0 and 30, then boosted with a single dose of Towne at day 90 developed binding and neutralizing antibody titers at least as high as naturally seropositive individuals (Adler *et al.*, 1999). Similarly, individuals primed with two doses of ALVAC-gB, then boosted with gB/MF59 subunit vaccine developed high antibody titers and lymphoproliferative anti-HCMV responses. These humoral and cellular responses, however, were not significantly different from those elicited by three doses of gB/MF59 alone, thus demonstrating no clear benefit to priming with ALVAC-gB (Bernstein *et al.*, 2002).

The greatest value of canarypox-based vaccines may derive from their ability to stimulate specific CTL responses. ALVAC expressing pp65, an abundant tegument protein that is a major CTL target in naturally HCMV seropositive persons, induced $CD8^+$ CTL responses in all seronegative persons tested (Berencsi *et al.*, 2001). The CTL responses were detected after two doses of ALVAC-pp65 and were present at frequencies comparable to those seen in naturally seropositive individuals. Ultimately, canarypox-based vaccines that express both CTL and neutralizing antibody targets, such as pp65 and gB, may be used in prime-boost vaccination protocols. For example, two doses of an ALVAC-based vaccine may be followed by a boost with a subunit or live-attenuated vaccine, to confer high levels of both cellular and humoral immunity.

Peptide vaccines

The development of peptide vaccines for HCMV represents an effort to directly stimulate a protective CTL response. Toward this end, a 9 amino acid minimal cytotoxic epitope derived from HCMV pp65 was identified and lipidated at its amino terminus to allow its administration without an adjuvant (Diamond *et al.*, 1997; Martinon *et al.*, 1992). HLA A2.1 transgenic mice immunized with this peptide, in combination with the PADRE pan-HLA-DR T-helper epitope, developed HCMV-specific CTL. Subsequent studies showed that linking the HCMV pp65 epitope directly to the PADRE epitope in the same peptide elicited vigorous HCMV-specific CTL responses in HLA transgenic mice when delivered either subcutaneously or intranasally (La Rosa *et al.*, 2002). In either case, the response was significantly enhanced by the co-administration of CpG-containing single stranded DNA, which enhances the immune response and biases it in the direction of Th1 activity (Klinman, 2003). A repertoire of HCMV epitopes specific for different HLA alleles has been defined that should provide 90% coverage to the Caucasian population, although the derivation of four or more additional CTL epitopes would be needed to attain 90% coverage for African Americans or Asians (Longmate *et al.*, 2001). Peptide vaccination may have its primary utility in therapeutic rather than prophylactic vaccination as HLA allele-specific peptides may be limited in their ability to elicit immunity in the population at large (Gonczol and Plotkin, 2001). To that end, the HCMV-pp65-specific memory CTL response could be amplified in a hematopoietic stem cell donor prior to transplantation by administration of a peptide vaccine, thereby providing protection against HCMV disease in the recipient (La Rosa *et al.*, 2002).

DNA vaccines

The initially surprising discovery that direct injection of purified DNA encoding specific antigens can induce protective immunity led to the development of DNA vaccination strategies for many pathogens including HCMV (Wolff *et al.*, 1990; Ulmer *et al.*, 1993). In this approach, as with live attenuated and vectored vaccines, HCMV antigens are synthesized and processed using authentic cellular pathways thus allowing their expression in the context of MHC class I molecules (Tang *et al.*, 1992; Ulmer *et al.*, 1993; Raz *et al.*, 1994). This approach, therefore, has the potential to induce both humoral and cellular immunity to HCMV. While DNA vaccines for HCMV have yet to be studied in humans, compelling data, some of which is discussed below, has been generated in animal models.

The first DNA vaccine for HCMV consisted of a plasmid containing the gene for pp65 (Pande *et al.*, 1995). Most of the mice injected intramuscularly with this plasmid developed antibodies to pp65 confirming that vaccination with HCMV DNA was capable of eliciting an antigen-specific immune response. The protective efficacy of DNA vaccination was subsequently demonstrated in mice (Gonzales Armas *et al.*, 1996). After inoculation with the murine CMV

(MCMV) pp89 gene, the major target for $CD8^+$ T-cells (Reddehase and Koszinowski 1984; Holtappels *et al.*, 1998), mice exhibited 45% protection against lethal challenge as well as significantly lower viral titers in the spleen and salivary glands. A DNA vaccine expressing a different MCMV antigen, M84, which is homologous to HCMV pp65, also afforded some protection to mice. Coimmunization with both pp89 and M84 DNA vaccines provided the best protection suggesting that the most successful DNA vaccines may express multiple antigens (Morello *et al.*, 2000; Ye *et al.*, 2002).

Considerable evidence suggests that both humoral and cell-mediated immunity participate in the control of HCMV disease. Accordingly, DNA vaccines expressing gB were tested in mice and shown to elicit neutralizing antibodies (Hwang *et al.*, 1999). Therefore, a second generation of HCMV DNA vaccines was designed to stimulate both neutralizing antibodies to HCMV and HCMV-specific CTL responses. These vaccines consisted of a cocktail of plasmids encoding pp65, to stimulate CTL responses, and gB, to induce neutralizing antibodies (Endresz *et al.*, 1999; Schleiss *et al.*, 2000). After three immunizations, all mice developed gB- and pp65-specific antibodies, and about 60% developed pp65-specific CTL responses. Similarly, guinea pigs also developed antibodies to both antigens.

Recently, various innovative methods to enhance immune responses have been applied to HCMV DNA vaccines. Aluminum salts, which are licensed for use as adjuvants in humans, and CpG oligodeoxynucleotides have both been shown to enhance antibody responses to DNA vaccines (Ulmer *et al.*, 1999; Klinman *et al.*, 2000). A DNA vaccine containing the HCMV gB gene and administered with aluminum phosphate gel elicited significantly higher antibody responses in mice than the gB gene without aluminum phosphate gel, although no difference was seen in neutralizing antibody titers (Temperton, 2002; Temperton *et al.*, 2003). However, the addition of CpG oligodeoxynucleotides to aluminum phosphate gel enhanced the ability of the gB gene to stimulate neutralizing antibodies. Using a related approach, several laboratories have shown that coinoculation of animals with genes encoding immunostimulatory molecules in addition to viral antigens can provide enhanced protection against disease (Tsuji *et al.*, 1997; Xiang and Ertl, 1995; Cull *et al.*, 2002). Applying this approach, mice coimmunized with the MCMV gB and type I interferon genes exhibited enhanced protection against MCMV challenge when compared to mice that received the MCMV gB gene alone (Cull *et al.*, 2002). It is interesting to note that DNA vaccination with type I interferons alone also reduce the level of MCMV infection (Yeow *et al.*, 1998; Cull *et al.*, 2002; Bartlett *et al.*, 2002). Recently, the use of full-length murine and guinea pig CMVs cloned as bacterial artificial chromosomes (BACs) have been used as DNA vaccines. In principle, BAC vaccines would deliver the full complement of viral genes thereby inducing a wide range of antiviral immune responses (Cicin-Sain *et al.*, 2003; Schleiss *et al.*, 2006). Preconceptual maternal immunization of guinea pigs with a replication-disable guinea pig CMV BAC significantly protected their offspring against congenital CMV disease (Schleiss *et al.*, 2006).

DNA vaccines for HCMV are still in their infancy, and safety issues stemming from the inoculation of exogenous DNA still need to be resolved. Nonetheless, this approach is remarkably versatile and may ultimately have an important place in HCMV vaccine development.

Subviral particles

Upon infection with HCMV, cultured fibroblasts release not only infectious virions but also non-infectious particles (Craighead *et al.*, 1972; Fiala *et al.*, 1976; Sarov and Abady, 1975). These non-infectious particles may be either dense bodies, which are enveloped structures consisting of viral tegument proteins and glycoproteins but lacking a capsid, or non-infectious enveloped particles (NIEPs), which are similar to normal virions except for the absence of DNA and the presence of an additional polypeptide. Glycoprotein B and the tegument protein pp65 are major constituents of dense bodies, and sera from HCMV seropositive individuals react with these particles (Baldick and Shenk, 1996; Forghani and Schmidt, 1980; Gibson and Irmiere, 1984; Irmiere and Gibson, 1983; Roby and Gibson, 1986). For this reason, dense bodies have long been considered as possible HCMV vaccines (Bia *et al.*, 1980; Fiala *et al.*, 1976; Gibson and Irmiere, 1984; Sarov *et al.*, 1975; Stinski, 1976). More recent studies showed that dense bodies enter cells efficiently, presumably through the interaction of envelope glycoproteins with cellular receptors, thus mimicking normal infection (Pepperl *et al.*, 2000; Schmolke *et al.*, 1995; Topilko and Michelson, 1994). Mice transgenic for human HLA-A2 were immunized with dense bodies without an adjuvant. After only a single inoculation, the mice developed high virus neutralization titers, and those that received three doses retained substantial virus neutralizing activity for at least a year (Pepperl *et al.*, 2000). The immunized mice developed antibodies to gB, gH, pp65, pp150 and several unidentified proteins. Given the importance of cellular immunity in controlling HCMV disease, it is significant to note that the immunized mice also developed high levels of HCMV-specific CTLs despite the absence of HCMV protein synthesis. Recently, it was shown that genetically modified dense bodies containing

foreign proteins could be generated (Pepperl-Klindworth *et al.*, 2002). In light of this, it may be possible to produce dense body-based vaccines that are modified to improve their HCMV immunogenicity through the inclusion or enhanced expression of specific antigens. Dense body technology therefore, represents another innovative approach to HCMV vaccine development that deserves continued exploration.

Challenges for HCMV vaccine development

Species-specificity of HCMV

HCMV has a very limited host range, and no practical animal model for HCMV infection has been identified (Mocarski and Courcelle, 2001). While the CMVs of certain other animal species are well studied and very useful for addressing many aspects of vaccine development, they are genetically distinct from HCMV and may not behave identically during natural infection. Thus, for any new HCMV vaccine candidate initial safety and efficacy data can be derived from animal studies using analogous vaccines made from animal CMVs. However, this data will need to be interpreted cautiously, and valid safety and efficacy data will require human trials. Moreover, the species specificity of HCMV is an impediment for testing live, presumably attenuated vaccine candidates. Without the ability to assess HCMV virulence in an animal model, attenuation can only be confirmed through human trials. While this was accomplished for the Towne/Toledo chimeric vaccine candidates described above, it undoubtedly complicates vaccine development efforts.

Efficacy testing

The primary goal of HCMV vaccination is the prevention of congenital disease. However, given that the incidence of HCMV disease is about 0.1% of all births, a prospective trial to assess vaccine efficacy against HCMV disease would require tens of thousands of participants and a lengthy follow-up period to ensure that late sequelae of CMV infection, such as hearing and intelligence deficits, are not missed. However, an efficacy trial to determine the ability of a vaccine to protect newborns from HCMV infection could be done with a manageable number of subjects. Assuming a fetal infection rate of 1%, vaccine efficacy of 80% and a 2-year follow-up period, such a trial would require fewer than 5000 participants (Plotkin, 1999). Moreover, surrogate endpoints for vaccine efficacy could be tested initially to exclude less promising vaccine candidates from future large trials. For example, the ability of a vaccine to prevent infection in seronegative mothers with children in daycare would require less than 200 participants, given the high incidence of HCMV infection in that population (Plotkin, 1999).

When to vaccinate

To prevent congenital disease, HCMV vaccination should be administered to women prior to their becoming pregnant, and it has been proposed that vaccination of girls between the ages of 11 and 13 would be appropriate (Plotkin, 1999). However, the persistence of the immune response would need to be determined before a final schedule could be recommended. If a vaccine induced long-lived immunity, early childhood vaccination should be considered. If, however, immunity is less durable, later vaccination or regular boosters may be appropriate.

Summary

At present, vaccination remains the best hope for preventing most cases of congenital HCMV disease. Several new HCMV vaccination strategies have emerged in the past decade that take advantage of our current understanding of the host immune response to HCMV infection. Moreover, some older approaches, such as live attenuated vaccines, are being readdressed using modern molecular genetic approaches to enhance protective efficacy. More than ever, the development of a safe and effective HCMV vaccine seems to be an achievable goal. The most important scientific challenge that remains is to refine our understanding of the immunology of HCMV disease protection in order to rationally design vaccines that are both safe and effective. In addition, agreement must be reached within the medical and scientific communities on the best approaches for efficacy testing of new HCMV vaccines before the large trials necessary for licensure can be conducted.

Introduction

Primates and their γ-herpesviruses enjoy a largely peaceful coexistence where a balance of power has been reached over evolutionary time. Coevolution probably began before primate speciation and has allowed these viruses to develop sophisticated systems for the evasion of host immune responses. As a consequence, herpesvirus vaccines have been especially difficult to design because of viral latency, persistence, and immune modulation. Epstein–Barr virus (EBV) persists for the life of the individual in the face of a range of antibody responses, some of which are virus-neutralizing in vitro and a multitude of cell-mediated responses, including viral-specific CD8+ T-cells, CD4+ T-cells and NK cells. At least 95% of the adult population is infected with EBV and, for the vast majority, there are no clinical consequences whatsoever and an asymptomatic carrier state is maintained. It is not clear whether advantages are conferred to humans by lifelong EBV infection, but it is possible that some immunological effects, such as bias of the T-cell receptor repertoire are provided on a population-wide basis. Whether unselective mass vaccination of healthy individuals to prevent or modify EBV infection may cause more problems than it would solve must be considered.

M.A. Epstein first put forward ideas on the development of EBV vaccines in 1976. These original proposals were based on the notion that vaccination might prevent EBV infection and break the link in the complex chains of events that lead to EBV-associated disease. Since that time, a better understanding of EBV biology has led to the elaboration of more sophisticated vaccination strategies. Presently, it seems most unlikely that vaccination of any kind will achieve sterilizing immunity against herpesviruses. The murine γ-herpesvirus, MHV68, establishes the same steady-state levels of lytic and latent infection whatever the route of infection or dose. It may be that a single virus particle successfully infecting a single target cell will be enough to establish persistent infection in a susceptible subject (Tibbetts, 2003). The goal of EBV vaccination is the prevention of disease and not of infection. Vaccination that could modify infection, or at least the subsequent immunological status of the infected person with respect to EBV, may prevent or minimize disease. It should be noted that EBV will not have evolved to evade vaccine-induced immune responses where they are qualitatively and/or quantitatively different from naturally occurring immune responses. An important precedent for herpesvirus vaccination is the attenuated varicella zoster virus (VZV) Oka strain vaccine that may not prevent infection but is able to prevent disease. More recently, the concept of therapeutic vaccination to treat EBV-associated tumors themselves has begun to emerge (Khanna *et al.*, 2001; Ong *et al.*, 2003; Khanna *et al.*, 2005).

An understanding of the life cycle and cellular habitats of EBV should be an essential prerequisite in the rational design of EBV vaccines. Unfortunately, the biology of EBV in vivo remains poorly understood and the various approaches to EBV vaccine design discussed below are, of necessity, based on a number of unproven assumptions. EBV is an orally transmitted infection and is able to infect B-cells travelling in the circulation in the oropharynx or resident in lymphoid tissue in this region. The point of infection is presumed to be the oropharyngeal epithelium but the identity of the primary target cell is not clear. It has not been possible to convincingly demonstrate the presence of EBV in oropharyngeal epithelial cells in vivo. Nevertheless, it has been shown recently, using polarized tongue and orophayngeal epithelial cells in vitro, that EBV-infected donor cells in saliva are very efficient at infecting recipient epithelial cells at their apical surface by cell–cell contact. However, these same epithelial cells are refractory to

infection with free virus at their apical surface. It is also shown that neighboring epithelial cells are infected by cell–cell transmission and free virus is produced at both the apical and basolateral epithelial surfaces (Tugizov *et al.*, 2003). Presumably, it is the latter cell-free virus that subsequently infects B-cells circulating within the oropharyngeal epithelium and oropharyngeal lymphoid tissues.

EBV infects and transforms B-cells in vitro and six EBV nuclear antigens, EBNAs 1 to 6 and two viral latent membrane-proteins, LMP1 and 2, expressed in the transformed B-cells are responsible for their changed growth and phenotype. These latency antigens potentially offer a range of targets for vaccine-induced cell-mediated immune responses. Healthy seropositive individuals carry CD8+ T-cells that are specific for epitopes in the latent antigens, in particular EBNA3, 4 and 6. However, EBV gene expression in infected B-cells in vivo is quite different and the growth-transformed phenotype has only been detected in the B-cell follicles of tonsils while in peripheral blood, EBV is detected only in a very small number of resting memory B-cells when EBV gene expression is restricted to LMP2 or does not occur at all (Thorley-Lawson, 2001).

A normal healthy immune response appears to be essential in maintaining the asymptomatic carrier-state as demonstrated by the occurrence of post-transplant lymphoproliferative disease (PTLD) in immunosuppressed organ transplant recipients and Non-Hodgkin's B-cell lymphomas in AIDS patients whose immune systems are seriously impaired. This strongly indicates that some aspects of EBV infection are under immune control and that vaccine-induced immune responses may be able to regulate primary infection and/or modify subsequent persistent infection. Most primary infections occur in the first few years in life and any prophylactic vaccine to control EBV diseases must allow for this. It would be a daunting task to deliver an EBV vaccine to large populations in Africa and China where primary infection occurs soon after birth.

Each EBV-associated disease probably arises for a complex set of different reasons and each may require a different vaccination strategy. Present approaches can be divided into those that seek to prevent or modify infection and those that might be used therapeutically to direct existing or de novo immune responses against the EBV-associated tumors. The therapeutic approach may prove to be particularly difficult, as, despite extensive efforts over a number of years, no tumors to date have consistently been controlled in humans by vaccine-induced immune responses. Modification of EBV infection may yet prove to be the correct approach and an interesting parallel may be drawn with a recent trial of a human papillomavirus (HPV) virus-like particle vaccine. In a trial involving 2392 young women, no cases of HPV 16 infection or cervical intraepithelial neoplasia were detected in vaccinated women in contrast to the control group (Koutsky *et al.*, 2002). Immunotherapeutic approaches to the treatment of cervical carcinoma have so far been unsuccessful. The logistics and costs associated with mass HPV vaccination of populations at risk will probably exceed those likely to be incurred with a prophylactic EBV vaccine and would at least set an important precedent if adopted as a public health measure.

Infection by more than one strain of EBV in both healthy and immunocompromised individuals appears to be unexceptional (Walling *et al.*, 2003). This raises difficult questions about the induction of immunity by EBV infection itself and about what vaccine-induced immune responses could realistically be expected to achieve. Infection by more than one strain simultaneously from one donor would not rule out the presence of subsequent virus-induced protective immune responses. However, if a second strain were able to infect an individual following an earlier infection with another strain, then it would suggest that the second EBV strain is able to evade the broad spectrum of humoral and cellular immune responses induced by the first EBV infection. A precedent for this situation has been found earlier with cytomegalovirus (Bale *et al.*, 1996). Another consequence of the existence of several strains of EBV is that strain differences will have to be incorporated into any prophylactic or therapeutic vaccine formulations that contain elements that differ between strains.

Since EBV infection is almost completely non-permissive in vitro, it is still not technically feasible to produce EBV itself on a large enough scale to support even a small vaccine trial where killed or attenuated forms could be used. Moreover, since EBV has been formally classified as a Grade I carcinogen (Ablashi *et al.*, 1997), and a number of its genes can independently transform certain cell types, the use of killed, attenuated or recombinant EBV vaccines can probably be ruled out for the time being. The possible composition of an EBV vaccine must be restricted to viral components that are non-transforming, however, this need not exclude non-transforming derivatives of viral transforming gene products such as synthetic peptides.

EBV causes infectious mononucleosis (IM), post-transplant lymphoproliferative disease (PTLD) and is associated with undifferentiated nasopharyngeal carcinoma (NPC), certain types of Hodgkin's lymphoma (HL), certain T-cell lymphomas, a subset of gastric carcinomas, and endemic Burkitt's lymphoma (BL). It is conceivable that a prophylactic vaccine or a postinfection vaccine that could modify but not prevent EBV infection could reduce the incidence of all diseases associated with EBV. The fact that increased antibody levels against virus capsid antigen

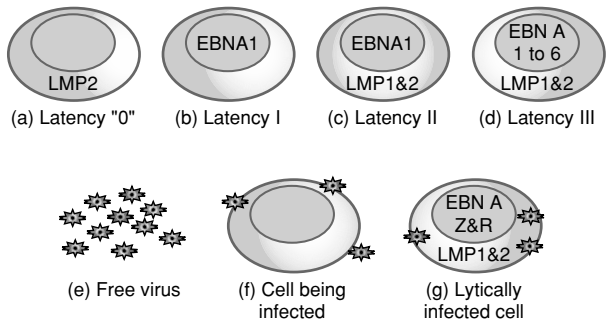

Fig. 72.1. Potential targets for EBV vaccine-induced immune responses.

In addition to the virus itself there are at least six different potential cellular targets for vaccine-induced immune responses. (**a**) Resting memory B-cells in which only LMP2 transcripts have been detected (Latence 0). These cells are few in number, there being only ~1 per 10^6 B-cells in the peripheral circulation, and are probably immunologically invisible; (**b**) BL cells are the only known example where EBNA1 is the sole EBV product and is usually referred to as Latency I. EBNA1 is not presented in an MHC class I context but is probably presented in a MHC class II context to CD4+ T-cell; (**c**) Infected B-cells in the default program where EBNA1, LMP1 and LMP2 are expressed. It has been hypothesized that this program allows for the differentiation of infected B-lymphoblasts into memory cells and provides signals necessary to maintain the infected blast cell against a background of immunological signals that would normally promote either proliferation or apoptosis. This program is often referred to as Latency II and the same or similar EBV latency gene expression profile is found in NPC and HD tumor cells; (**d**) All EBV latency genes are expressed and the cell is activated to become a proliferating lymphoblast and is referred to as being in the growth program or Latency III. This latency type is found in PTLD and some BL and could represent a good target for vaccine-induced immune responses through the EBNA3 family of products. (**e**) Free virus found in the oropharynx and at the basolateral face of the oropharyngeal epithelium may be subject to control by virus-neutralizing antibodies; (**f**) B-cells in the process of being infected may be the subject of antibody and cell-mediated control; (**g**) A small minority of infected B-cells will enter the lytic cycle and are potential targets for both cell-mediated and humoral responses.

(VCA) are prognostic for both BL and NPC suggests that immune intervention prior to the onset of disease could be beneficial. The success of such approaches will depend on whether the apparent reactivation of EBV is associated with the cause of NPC or is simply a consequence of tumor development.

Figure 72.1 illustrates the possible targets for vaccine-induced immune responses. These include free virus itself that might be susceptible to inactivation by vaccine-induced circulating or mucosal neutralizing antibodies. Naturally occurring virus-neutralizing antibodies are generated mainly against the major envelope glycoprotein, gp350 and much early work in EBV vaccine development focused on producing recombinant forms of this molecule (Morgan, 1992). Gp350 is also a target for cell-mediated responses (Khanna *et al.*, 1999a,b,c; Wilson *et al.*, 1999; Adhikary *et al.*, 2006). Other lytic cycle products such as gp85, gp42, the gB homologue and the products of the BZLF1, BMRF1, BDLF3 and BILF2 open reading frames have not been investigated in the context of vaccine development. CD8+ T-cell responses against BZLF1 predominate in healthy seropositives and vaccine-induced immune responses against BZLF1 in EBV seronegatives might have a role to play. It is not known how many EBV-infected B-cells enter the lytic cycle or the location of the cells that do. Very few B-cells infected and transformed with EBV in vitro enter the lytic cycle, being less than 5%. Since free virus is shed in the oropharynx, it is assumed that epithelial cells and/or B-cells in this region are responsible and might therefore be regulated by immune responses. It must be assumed for the time being that vaccine-induced immune responses against lytic cycle products would act on these cells and/or the virus they produce. The increased oral shedding of EBV in immunosuppressed patients is consistent with this view (Preiksaitis *et al.*, 1992). Current strategies to control EBV disease by vaccination are described below, while adoptive T-cell immunotherapy for these diseases is described elsewhere in this volume.

Vaccines to prevent infectious mononucleosis

In the wealthier Western societies primary EBV infection is often delayed until adolescence whereupon it gives rise to IM in 30% and 50% of individuals. It is still an open question as to why the remaining 50% to 70% of individuals become infected without symptoms or disease. However, it has been found that asymptomatic individuals display broad expansions of their TcR repertoire, while acute IM donors show oligoclonal expansion of TcR families (Silins *et al.*, 2001). Perhaps of even greater interest is the small minority who apparently never become infected. A higher production of IFNα and IL-6 and a greater number of monocytes were detected in cultures of peripheral blood lymphocytes from EBV-seronegative adults (Jabs *et al.*, 1996). The genetic and immunological differences between EBV seropositives and seronegatives remains obscure but would be informative as far as vaccine design is concerned. Since these immunological parameters are unknown, a vaccine cannot be designed on an entirely rational basis. IM almost always

resolves itself over a relatively short time and is only very rarely fatal. The question arises as to whether large-scale vaccination of otherwise healthy children is justified when set against the actual risks of illness and its socio-economic consequences.

Which stages in the process and maintenance of EBV infection are susceptible to control by vaccination? What target antigens need to be recognized by vaccine-induced immune responses to prevent IM? The differentiation pathways of EBV-infected cells, the types of B-cell that are infected and the EBV proteins expressed in vivo have been tentatively identified and include a memory B-cell that may only express LMP2, a proliferating and activated B-cell expressing the full panel of EBV latent genes in the growth program or Latency III, and B-cells in Latency II which may subsequently generate the memory reservoir B-cells (Thorley-Lawson, 2001). Cells in Latency III have only been found in the germinal center of lymphoid follicles and these are regions in which cytotoxic T-cells (CTL) are poorly represented probably because EBV-specific CD8 T-cells lack homing receptors for lymphoid infection sites (Chen *et al.*, 2001). CD4+ T-cells are detectable at low frequency within B-cell follicles and may, therefore, interact directly with EBV-infected B-cells at this site. It is possible that CD4+ T-cells primed by gp350 or latency antigen vaccination would become reactivated on viral challenge (Adhikary *et al.*, 2006). Such cells could influence the course of IM by inducing apoptosis of EBV-infected B-cells within infected lymph nodes and by down regulating the large monoclonal or oligoclonal populations of CD8+ T-cells that account for much of the lymphocytosis that is symptomatic of IM.

Prophylactic EBV vaccine development has focused on the gp350 and EBNA3 antigens. Systemic virus neutralizing antibodies can be easily induced by vaccination with gp350 and an appropriate adjuvant and, while epithelial cell infection may be unaffected, it is conceivable that free virus liberated on the basolateral surface of infected oropharyngeal epithelium could be neutralized and minimize transmission to circulating naïve B-cells. While infection itself will not be prevented, the effective virus dose at the B-cell level would be greatly diminished. The induction of mucosal immune responses in the orapharynx may prove to be more effective and the oral/nasal administration of gp350 in conjunction with mucosal adjuvants such as Iscoms (Wilson *et al.*, 1999), cholera toxin B-subunit or the *E.coli* heat labile enterotoxin B-subunit, EtxB (Williams *et al.*, 1999), should be investigated. However, there is some evidence that mucosal IgA specific for gp350 actually enhances infection of certain epithelial cells in vitro (Gan *et al.*, 1997).

The strategy would be to prevent or modify primary EBV infection by vaccination of children before primary infection. The disease itself is caused by excessive CD8+ T-cell responses to EBV infection, and in particular, to EBV lytic antigens. Any vaccine that could allow a more rigorous control of the primary infection phase may therefore prevent the disease or reduce its severity. Other explanations for the pathogenesis of IM, unconnected to the dose of virus at primary infection, are possible and include differences in NK and CD4+ T-cell responses (Wilson & Morgan, 2002), expansion of a CD28 subset of CD4+ T-cells (Uda *et al.*, 2002) and autoimmune responses (McClain *et al.*, 2003). Until these issues are better understood, it will be difficult to take account of them.

Gp350

The major EBV envelope glycoprotein, gp350, binds to the CR2 complement receptor on B-cells and is consistent with it being a target for neutralizing antibodies. Following attachment the virus infects the target cell through envelope fusion events involving other EBV envelope glycoproteins gp85, gp42 and gp25 (Borza & Hutt-Fletcher, 2002). More recent work has shown that gp350 is not an absolute requirement for EBV infection to take place. A recombinant EBV in which the gp350 gene had been deleted was able infect a range of B-cell lines and epithelial cells, albeit at a lower efficiency (Janz *et al.*, 2000). The early observation that serum EBV neutralizing antibodies largely recognized the major viral envelope glycoprotein, gp350 set the scene for subsequent work over a number of years involving a New World primate, the cottontop tamarin (*Saguinus oedipus Oedipus)*. Oligoclonal B-cell lymphomas closely resembling those seen in post-transplant lymphoproliferative disease (PTLD) can be routinely induced in these animals by injection of EBV. The characterization and purification of tractable quantities of the gp350 viral envelope glycoprotein from both natural sources and by recombinant DNA methods was carried out. Recombinant gp350 in combination with adjuvants or when expressed in vaccinia or adenovirus vectors, induced protective immunity in cottontop tamarins susceptible to EBV-induced B-cell lymphoma. Protective immunity was not dependent on the induction of gp350-specific neutralizing antibodies but was achieved through cell-mediated immune responses (Morgan, 1992). Gp350 vaccine formulations have since been shown to induce CTL responses as well as neutralizing antibody (Khanna *et al.*, 1999c, Wilson *et al.*, 1996). The mechanism of protection in this animal model is unknown. Did the protective responses induced in the tamarin act on the virus or on tumor cells? Since the tumor cells have

a Latency III phenotype and do not express gp350, the induced immune responses were probably able to reduce the effective virus dose on challenge since the induction of tumors by EBV is dose dependent. Derivatives of the gp350 vaccines described above (Jackman *et al.*, 1999) have been evaluated in human trials (Denis, 2005). The results of these trials strongly indicate that gp350 vaccination of seronegative young adults prevents IM but does not prevent EBV infection. Surprisingly, little attention has been placed on developing DNA vaccines coding for gp350. Immunization of mice with such a vector gave rise to antibodies to gp350, antibody-dependent cellular cytotoxicity (ADCC) and gp350-specific CTLs (Jung *et al.*, 2001).

The cottontop tamarin has a number of shortcomings as a model of EBV infection and disease. This species is not infected by the oral route and does not sustain a persistent infection. A further complication is that the tamarin has an unusually restricted histocompatibility complex polymorphism and only expresses the alleles G, F. and E, associated primarily with NK cell function (Cadavid *et al.*, 1999). Moreover, contrary to earlier beliefs, tamarins and marmosets have been found to carry their own resident γ-herpesviruses (de Thoisy *et al.*, 2003).

A recombinant derivative of the Chinese vaccinia Tien Tan strain expressing gp350 was used to vaccinate a small group of both seronegative and seropositive children in Southern China. Antibody levels to gp350 were raised in seropositive subjects and were induced in those who were seronegative at the beginning of the trial. Six out of nine vaccinated children who were seronegative for EBV at the time of vaccination remained seronegative for at least three years after vaccination (Gu *et al.*, 1995). The particular vaccinia recombinant used in this trial would not be currently acceptable for large-scale use on safety grounds. The Modified Vaccinia Ankara (MVA) strain would provide an acceptable alternative vector (Stittelaar *et al.*, 2001).

Some development work has been carried out on the generation of a recombinant varicella zoster virus (VZV) vaccine vector for the delivery of EBV genes and VZV recombinants were produced which are able to express EBV gp350 (Lowe *et al.*, 1987). It may be timely to explore this option further given the success of the Oka VZV vaccine strain and its incorporation into national vaccine programs in the USA, Japan and elsewhere.

A murine γ-herpesvirus (MHV 68) is increasingly being used to model EBV biology and this virus induces a mononucleosis-like syndrome in mice (Blackman *et al.*, 2000). Vaccination studies have been carried out using this model and the MHV 68 major envelope glycoprotein gp150, an analogue of EBV gp350 (Stewart *et al.*, 1996) was incorporated into a recombinant vaccinia virus vector and used to vaccinate mice prior to intranasal challenge with MHV 68. Virus-neutralizing antibodies were induced and the mononucleosis-like syndrome normally caused by MHV 68 was almost completely eliminated. MHV 68 latency was established in the vaccinated mice nevertheless (Stewart *et al.*, 1999). These results are a cause for some optimism in that appropriately administered EBV gp350 could prevent IM even if the establishment of latent, persistent EBV infection was unaffected.

EBNA3

Another approach using synthetic peptides based on the EBNA3 latent antigen, to induce cell-mediated immune responses, was developed in parallel and has also been the subject of small-scale human trials (Khanna *et al.*, 1999a,b,c). This approach utilizes latent antigen epitopes restricted through common MHC class I alleles to induce CD8+ T-cell responses in the vaccinee. Strong support for this approach came from the demonstration that autologous CD8+ T-cells against EBNA3, propagated ex vivo and introduced into immunosuppressed patients at high risk of PTLD, were able to prevent PTLD and in some cases cause PTLD to regress (Gottschalk *et al.*, 2002). In other words, CTLs specific for some EBV latent antigens can control the propagation of EBV-infected B-cell tumors *in vivo*. A Phase I human trial has been carried out to establish whether an EBNA 3 synthetic peptide, FLRGRAYGL, incorporated into a water-in-oil emulsion adjuvant, can be safely used to induce epitope-specific CTL responses (Moss *et al.*, 1998). Ultimately, a collection of epitopes will be used to span the majority of HLA types and encompass strain variation in target populations. Similar strategies may be adopted with peptide epitopes from lytic cycle antigens such as gp350 and BZLF1. Until it is known which T-cell specificities are important in protecting against IM, there may be a case for constructing an epitope vaccine using epitopes from both lytic and latent antigens. Vaccination with a latency antigen inserted into a DNA plasmid expression vector has been tested in the MHV 68 murine γ-herpesvirus model using the M2 latency-associated gene. M2 DNA vaccination had no effect on virus replication in the lung but did reduce the latently infected cell burden in the early, but not the later, stages of infection (Usherwood *et al.*, 2001).

One serious hurdle for peptide-based vaccines is the relatively large number of epitopes that would need to be incorporated into a single vaccine so that it could be delivered to a wide range of individuals with different HLA types. A vaccine formulation with so many components may face difficulties with regulatory approval. This problem can be overcome using polyepitope constructs (Thomson *et al.*, 1996). The polyepitope corresponds to the linking of minimalized CTL epitopes within a single coding sequence

as a "string of beads" and has been shown to be highly efficient in inducing protective CTL responses when delivered as part of a live viral vector or a recombinant DNA plasmid (Thomson *et al.*, 1998, 1996). Gp350 subunit vaccines avoid these problems since all possible epitopes are contained within the whole protein and sequence variation between different EBV isolates appears to be minimal. To what extent do CTLs reactivated from memory T-cells by autologous LCLs and assayed against peptide-coated targets, or targets infected with vaccinia recombinants, reflect *in vivo* CTL activities? The therapeutic effects on PTLD, of EBV-specific CTLs grown ex vivo, support the view that CTLs of one or other latent antigen are responsible for these effects (Sherritt *et al.*, 2003). Which cell types and which antigen specificities are responsible for the beneficial effects of infusion of *ex vivo* grown T-cells, is not yet clear.

Vaccines to prevent post-transplant lymphoproliferation disease

Approximately 10% of seronegative children receiving solid organ transplants develop PTLD during the first year after transplant. The five-year survival of patients who develop PTLD is poor being only 35% for renal transplant recipients and 26% for heart transplant recipients. The risk of developing significant morbidity or PTLD following primary EBV infection in non-immune transplant recipients is about 20 times greater than in seropositive transplant recipients. Pediatric transplant patients are much more likely to be seronegative than adult patients since EBV infection increases with increasing age. Primary EBV infection occurs in about 70% of all seronegative recipients during the first 6 months following transplantation. This is the period during which the most intensive immunosuppression occurs. Immunization of seronegative patients before transplantation provides a realistic opportunity to test whether the presence of antibody to EBV or residual EBV-specific T-cell responses still active during immunosuppression will protect against infection, spread or pathogenic effects of EBV following transplantation.

Therapeutic vaccines to prevent Hodgkin's disease and nasopharygeal carcinoma

Of the interventions designed to treat human malignancies, immunotherapy with CTL is increasingly being recognized as potentially the most efficient strategy with minimal side effects (Savoldo *et al.*, 2000; Bollard *et al.*, 2004; Straathof *et al.*, 2005). The key factors in the development of a CTL-based therapeutic strategy are the characterization of therapeutic immune correlates, and the delineation of the specific portions of the tumor-associated antigens that elicit these responses. $CD8^+$ CTLs are considered important for protection against various virus-associated malignancies and have emerged as the major element in the immune control of malignant cells (Khanna *et al.*, 1999b). Indeed, a number of studies have recently been published, which have shown that adoptive immunotherapy can be successfully used to reverse the outgrowth of polyclonal B-cell lymphomas in transplant patients (Khanna *et al.*, 1999a,b,c; Rooney *et al.*, 2002).

Approximately half of HD cases involve EBV-positive tumor cells while all cases of undifferentiated NPC are EBV positive. Prophylactic vaccination of seronegative children or seropositive adults could lead to the reduction or elimination in the incidence of HD and NPC. However, the logistics, potential costs, and timescale of such a program may be disproportionate when seen in the context of other health priorities such as hepatitis, cervical carcinoma, malaria, HIV and others.

Despite being quite different cell types and at different locations, HD and NPC tumor cells express the EBV latent antigens, EBNA1, LMP1 and LMP2 and these are potential targets for the immune system. It is, therefore, surprising that the immune system is not able to kill these cells and indicates that viral immune evasion mechanisms are operating. One aspect of this phenomenon is already partly understood in so far as EBNA1 includes a glycine-alanine repeat (GAr) domain that not only may block its proteasomal degradation but also inhibits EBNA1 mRNA translation in *cis* (Yin *et al.*, 2003). Whether EBNA1 is degraded and processed in an MHC class I pathway in epithelial cells seems to depend on the type of epithelial cell. When EBNA1 is artificially expressed in epithelial cells of squamous origin, it appears to both inhibit growth and be degraded in a way that renders the cells targets for HLA-matched EBNA1-specific CTLs. Neither of these phenomena were observed when EBNA1 was expressed in epithelial cells of glandular origin (Jones *et al.*, 2003). Despite the presence of significant numbers of EBNA1-specific T-cells generated by cross-priming (Blake *et al.*, 2000), NPC and HD cells are not effectively targeted. More recent studies have shown that epitopes from EBNA1 can be endogenously processed and presented on the cell surface. These epitopes are primarily derived from newly synthesized protein as defective ribosomal products (Tellam *et al.*, 2004). LMP1 and LMP2 are potential targets and CTLs specific for epitopes in these proteins are found in the circulation, albeit at relatively low levels and CTL responses to LMP epitopes are said to be subdominant in relation to CTL responses to epitopes in EBNA3 and in BZLF1. T-cell

responses and antibody responses against LMP1 have been difficult to detect in humans (Khanna *et al.*, 1998a; Meij *et al.*, 2002). Both LMP1 and LMP2 may interfere with their own MHC class I presentation and may be poor targets and/or weak inducers of CTLs (Dukers *et al.*, 2000; Ong *et al.*, 2003). LMP1 and LMP2 have a plethora of effects on the biochemistry of EBV-infected cells some of which could impact on antigenic processing and presentation as well as on cell growth and differentiation (Dawson *et al.*, 2003; Portis and Longnecker, 2003). Another important observation in regard to CTL recognition of LMP1 and LMP2 is that the majority of the T-cell epitopes from these proteins are processed through a TAP-independent pathway (Khanna *et al.*, 1996; Lee *et al.*, 1996). TAP-deficient LCLs expressing LMP proteins are more efficiently recognized by LMP-specific CTLs than TAP-positive LCLs. These observations suggest that in the absence of TAP, ER generated LMP epitopes are presented more efficiently. On the other hand, presentation of these epitopes may be significantly reduced if TAP is expressed, as the peptides originating from the cytoplasmic compartment compete with ER generated LMP epitopes. It is therefore tempting to speculate that LMP-positive NPC and HD cells may have evolved to maintain TAP expression which limits the presentation of CTL epitopes from LMP1 and LMP2 and thus allows these tumors to escape CTL recognition in vivo.

Broadly speaking, two types of approach to therapeutic vaccination to treat NPC, HD and BL can be adopted. First, specific enhancement of effector cell responses to EBV proteins expressed in these cancers and secondly, enhancement of the presentation of the antigens in question by the tumor cells themselves. CTLs specific for LMP2 are detected in the circulation of NPC patients but are not found in the tumor lymphocyte infiltrate. NPC and HD cells also appear to have a normal MHC class I presentation pathway, at least in terms of MHC class I and TAP expression (Khanna *et al.*, 1998b; Lee *et al.*, 1998). Since both these cancers express identical viral proteins, it is anticipated that common immunotherapeutic protocols may be developed. It is important to remember that even if antigen presentation is unimpeded and specific CTLs are present at the tumor site in sufficient numbers, numerous other mechanisms, not necessarily related to EBV products, may prevent tumors cells being removed by the immune system (Gandhi *et al.*, 2006). There are many elements of the CTL recognition and target cell destruction process that have not yet been evaluated for NPC and HD tumor cells. These could include the expression of coreceptors and adhesion molecules, production of cytokines that provide an inappropriate milieu for CTLs, production of T-cell inhibitory receptors such as Fas, altered proteasome function and other tumor cell-specific factors.

Recent studies on HL patients have indicated that regulatory T-cells and LAG-3 play a pivotal role in suppressing EBV-specific T cell immunity (Gandhi *et al.*, 2006.)

LMP polyepitope vaccines

Although adoptive transfer of EBV-specific T cells has recently been tested for the treatment of relapsed HD, only a limited long-term therapeutic benefit was observed (Roskrow *et al.*, 1998). One of the major limiting factors in the development of an efficient therapeutic strategy is the viral antigens expressed in these malignancies are not only poorly immunogenic but also in some cases have the potential to initiate an independent neoplastic process in normal cells. Thus a strategy which can overcome both these potential limitations is likely to provide a safe and long-term therapeutic benefit to cancer patients.

One such strategy involves the delivery of immunogenic determinants from LMP1 and LMP2 as a polyepitope vaccine. Indeed, initial studies from one of our laboratories have shown that multiple HLA class-I-restricted LMP1 CTL epitopes, when used as a polyepitope vaccine in a poxvirus vector, efficiently induced a strong CTL response and this response could reverse the outgrowth of LMP1-expressing tumors in HLA-A2 K^b mice (Duraiswamy *et al.*, 2003b, 2004). A polyepitope-based vaccine for HD and NPC has a number of advantages over the traditionally proposed vaccines, which are based on full-length LMP antigens. Previous studies from our laboratory have indicated that polyepitope proteins are extremely unstable within the cytoplasm and may be rapidly degraded as a result of their limited secondary and tertiary structure. In contrast, full-length LMP antigens are unlikely to be degraded rapidly and may initiate various intracellular signalling events leading to the development of secondary cancers at the site of injection. Another important advantage includes the ability of a polyepitope vaccine to induce long-term protective CTL responses against a large number of CTL epitopes using a relatively small construct without any obvious need for a cognate help. Finally, the polyepitope-based vaccine is also likely to overcome any potential problem with the prevalence of LMP1 genetic variants in different ethnic groups of the world (Duraiswamy *et al.*, 2003a).

Although the poxvirus polyepitope vaccine vector provides long-lived expression of encoded epitopes, there are concerns in terms of its safety profile with adverse side effects including postvaccine encephalitis when used in humans. Moreover, the poxvirus-based LMP1-polyepitope vaccine contained only HLA A2-restricted epitopes and the

HLA A2 allele is carried by only about 55% of the individuals in most populations. If a CTL-based therapy for NPC and HD is to be applicable to a significant number of patients, the target population must be presented through HLA alleles present at high frequency in the patient population. In this context, in addition to LMP1, LMP2-specific responses restricted through A11, A24 and B40 are of particular interest because these alleles are very common in the Southern Chinese population (A11, 56%; A24, 27%; B40, 28%), particularly where NPC is endemic. To overcome these potential limitations, a novel approach has been devised of activating LMP-specific CTL responses with a replication-incompetent adenovirus encoding multiple epitopes from LMP1 and LMP2 (Duraiswamy *et al.*, 2004). This replication-incompetent adenovirus vaccine contains both LMP1 and LMP2 epitopes restricted through HLA alleles common in different ethnic groups including NPC endemic regions (HLA A2, A11, A23, A24, B27, B40 and B57). It has been estimated that these optimally selected MHC class I-restricted epitopes would include more than 90% of the Asian, African and Caucasian populations. Attractive features of adenovirus-based vaccines are their well-characterized genetic arrangement and function, as well as their extensive and safe usage in North American army recruits without inducing adverse side effects (Imler, 1995). Adenovirus-based vectors are being increasingly recognized for high efficiency and low toxicity and have been used in multiple human gene therapy clinical trials and preclinical vaccine applications. These vectors are also increasingly being used for cancer immunotherapy (Kusumoto *et al.*, 2001). Two of the most promising recent reports were studies in non-human primate models of the Ebola virus and HIV (Shiver *et al.*, 2002; Sullivan *et al.*, 2000). In each study, an immunization regimen that included priming with plasmid DNA followed by boosting with adenovirus vector particles showed the induction of effective CTL responses when compared with the plasmid DNA alone (Sullivan *et al.*, 2000). This new polyepitope vaccine is based on an E1/E3-deleted recombinant adenovirus comprising a chimeric Ad5/F35 vector that has been engineered to substitute the shorter-shafted fiber protein from Ad35 strain. This expression system provides an advantage over previous Ad5 vectors with respect to efficiency of expression of recombinant protein in hematopoietic stem cells and dendritic cells (Yotnda *et al.*, 2001). Our studies with the Ad5F35 LMP polyepitope vaccine have shown that each of the epitopes in this vaccine is not only efficiently processed endogenously by the human cells but also recalls memory CTL responses specific for LMP antigens in healthy virus carriers and HD patients. Furthermore, the adenoviral polyepitope vaccine is capable of inducing a primary T-cell response, which was shown to be therapeutic in a tumour challenge system (Smith *et al.*, 2006).

Altered antigen processing of LMPs using bacterial toxins

Since NPC is an epithelial tumor at a mucosal surface, the question of whether mucosal vaccine adjuvants might have a role to play in their treatment has been considered. One such adjuvant that has reached an advanced stage of development is the cholera toxin-like *E. coli* heat labile enterotoxin B-subunit (EtxB) (Williams *et al.*, 1999). Bacterial protein toxins are molecules that combine unique cell binding with efficient cytosolic delivery properties. Toxoid derivatives of the adenylate cyclase toxin of *Bordetella pertussis*, pertussis toxin, anthrax toxin, and Shiga toxin B subunit have been investigated as potential vehicles for delivery of exogenous peptides or proteins into the MHC class I presentation pathway (de Haan and Hirst, 2002). Recent work has established that EtxB possesses important features that makes it uniquely placed to be used as a delivery vehicle for MHC class I-restricted T-cell responses (De Haan *et al.*, 2002).

LMP-1 and LMP-2 are colocalized within plasma membrane GM_1-rich lipid rafts in LCLs (Higuchi *et al.*, 2001). LMP1 can be ubiquitinated and degraded through a proteasome pathway (Aviel *et al.*, 2000) while the LMP2 intracellular N-terminal polypeptide binds Nedd4-like ubiquitin ligases and is also subject to proteasomal processing (Ikeda *et al.*, 2002). MHC class I-restricted antigen presentation of LMP2 is unusual as some, but not all, epitopes are presented independently of TAP (Khanna *et al.*, 1996; Lee *et al.*, 1996). It is unclear at present why LMPs are not always effectively presented to CTL by LCLs in the absence of peptide epitope pre-sensitization or LMP2 expression by recombinant vaccinia. However, it has been shown that the treatment of EBV-positive LCLs with EtxB results in colocalization, capping and internalisation of LMP1 and 2. EtxB itself binds the ganglioside, GM_1, at the plasma membrane, enters the cell by endocytosis, and then the trans-Golgi network or endoplasmic reticulum by retrograde trafficking. LCLs treated with EtxB show a greatly increased susceptibility to killing by LMP1 and LMP2-specific CTLs (Ong *et al.*, 2003). The mechanism by which EtxB causes this enhancement of antigen presentation by LCLs requires further investigation but these results indicate that EtxB interferes with the normal distribution and pathways of LMP turnover (Ong *et al.*, 2003). The possibility therefore exists that EtxB could serve both as a mucosal adjuvant in the conventional sense by enhancing mucosal immune responses in the nasopharynx and also by enhancing the

presentation of LMP1 and LMP2 in NPC tumor cells in vivo. Further work is needed to establish whether EtxB can enhance the CTL killing of EBV-infected epithelial cells expressing LMP1 and/or LMP2 as it does for LCLs. To this end, it has recently been shown in one of the authors' laboratories that EtxB enhances the killing by LMP2-specific CTLs of H103 oral epithelial carcinoma cells expressing LMP2 (O. Salim, A. D. Wilson and A. J. Morgan, unpublished data).

One explanation for the failure of the immune system to kill HD and NPC tumor cells is that expression levels of the main potential immunological target, LMP2, are too low. Indeed, the unequivocal detection of LMP2 protein as opposed to RNA transcript in NPC cells has yet to be achieved. An EBV-transformed LCL, stably transfected with a plasmid expressing LMP2A under the control of an ecdysone analogue Ponasterone A (No *et al.*, 1996), has been created in one of our laboratories. Following exposure to Ponasterone A, the level of LMP2A was increased ten fold and was localized in the plasma membrane. Increased LMP2A expression resulted in the up-regulation of LMP1 expression, and had a blocking effect on the EBV spontaneous lytic cycle by down-regulating the expression of both the BZLF1 and BRLF1 genes. In normal LCL, LMP2 is not efficiently processed or presented to CTLs by MHC class I (Dukers *et al.*, 2000; Ong *et al.*, 2003). The tenfold increase in LMP2A expression induced by Ponasterone A did not result in any increase in lysis by an MHC class I restricted LMP2A specific CTL line. Susceptibility to CTL lysis was enhanced by treatment with EtxB but the enhancement was only marginally higher in the Ponasterone A-induced targets compared to the controls with normal levels of LMP2 (G. Patsos, A.D. Wilson, and A.J. Morgan, unpublished data). These data suggest that LMP2 processing and presentation is impaired in some way and that access to different, more efficient presentation pathways, will render LMP2-expressing cells more susceptible to specific CTLs.

Therapeutic vaccines for Burkitt's lymphoma

Whether prophylactic vaccination with EBV gp350 or latent antigen polyepitope formulations would prevent or reduce the incidence of endemic BL remains an open question. Raised levels of antibody against VCA are prognostic for BL and it has been suggested that control of EBV replication by vaccination before primary infection or before ant-VCA levels rise may have a protective effect. The prospect of devising a therapeutic vaccine for BL is rather problematical because of the absence of MHC class I-mediated antigen targets. Endemic BL cells were thought to express EBNA1 only but it has recently been found that three out of fifteen EBV-positive endemic BLs tested also expressed a truncated EBNA LP, EBNA3a, 3b and 3c (Kelly *et al.*, 2002). Although CTLs specific for the EBNA3 family may be abundant in these patients, it has been argued that the absence of LMP1 expression in the tumor cells does not allow the up regulation of antigen processing machinery. LMP1 may upregulate antigen-presenting functions in B-cells through an NF-κB pathway (Pai *et al.*, 2002).

The restriction of EBV gene expression to EBNA1 and a consistent loss of antigen processing function through the MHC class I pathway in BL cells, severely restricts the potential use of antigen-specific immunotherapeutic strategies. However, recent studies have provided some promising alternative therapeutic strategies for these malignancies. One such strategy involves targeting the tumor cells through virus-specific CD4+ CTLs. Previous studies from one of our laboratories have shown that BL cell lines displaying antigen processing defects through the MHC class I pathway are efficiently recognized by EBV-specific CD4+ CTLs. Furthermore, these tumor cells also express normal levels of all the essential components involved in the processing of T-cell epitopes through the MHC class II pathway. The importance of these studies has been further strengthened by the observation that CD4+ EBNA1-specific CTLs from healthy virus carriers can efficiently recognize virus-infected normal B-cells as well as BL cells expressing EBNA1 only (Munz *et al.*, 2000; Paludan *et al.*, 2002). These observations demonstrate that it may be possible to target EBNA1 through the MHC class II pathway (Paludan *et al.*, 2005). It raises the possibility that a vaccine based on EBNA1 that induces a strong CD4 T cell response may provide therapeutic benefit to BL patients.

One attractive way to deliver EBNA1 through the MHC class II pathway is to enable this antigen to gain access to endosomal or lysosomal compartments. There are two major pathways by which antigens are targeted to these compartments. The traditional pathway involves the phagocytosis or endocytosis of exogenous antigens, followed by degradation by acid proteases in the endosomal or lysosomal compartments. On the other hand, MHC class II-restricted presentation of endogenously synthesized proteins mainly involves membrane antigens that are thought to enter the endosomal or lysosomal pathway by internalization from the cell surface. The lysosome-associated membrane protein (LAMP-1) and the invariant chain are transmembrane proteins, which are predominantly localized in the lysosomes and endosomes, respectively. The cytoplasmic domains of these proteins contain specific targeting or address signals that mediate their translocation to the specific compartments. Previous studies from one

of our laboratories have shown that these targeting signal sequences can be utilized to direct multiple MHC class II-restricted CTL epitopes into the endosomal and lysosomal compartments (Thomson *et al.*, 1998). This approach not only preferentially translocates the polyepitope protein to these compartments but also enhances endogenous presentation of CTL epitopes. Furthermore, this strategy was successfully used to activate a virus-specific memory CTL response from peripheral blood lymphocytes. Endosome/lysosome-targeted EBNA1 is currently being tested as a therapeutic vaccine in a non-immunogenic murine B cell tumor model in which the tumor cells express EBNA1. If this vaccine strategy is successful in reversing the outgrowth of these tumor cells, it is possible that an EBNA1 vaccine may not only be applicable to BL but also against other EBV-associated malignancies such as HD and NPC.

Another interesting strategy involves treatment of the BL cells with soluble CD40 ligand (CD40L) (Khanna *et al.*, 1997). This treatment is highly effective in reversing the down-regulated expression of antigen processing genes involved in MHC class I-restricted presentation. Moreover, CD40L-treated BL cells regain susceptibility to EBV-specific CTL-mediated lysis. These data suggest that direct infusion of soluble CD40L at tumor sites or cytokine-mediated induction of CD40 ligand on bystander lymphocytes should be considered as an alternative approach to restoring immunogenicity of malignant cells. Taken together, these preclinical studies provide an important platform for the development of a therapeutic strategy for BL based on a combination of EBNA1 vaccination and CD40L injection.

Recently, a novel approach to override the GAr-mediated proteosomal block on EBNA1 by specifically targeting this antigen for rapid degradation by a process of cotranslational ubiquitination combined with N-end rule targeting, has been explored (Tellam *et al.*, 2001). These studies showed that enhanced intracellular degradation of EBNA1 was coincident with an induction of a very strong EBNA1-specific CTL response, and restored the endogenous processing of MHC class I-restricted CTL epitopes within EBNA1 for immune recognition by EBV-specific CTLs. It has also been shown recently that EBNA1 can be degraded in some epithelial cells of squamous origin and these cells are subsequently susceptible to MHC class I-restricted, EBNA1-specific CTLs (Jones *et al.*, 2003). These observations raise the possibility of developing therapeutic strategies to modulate the stability of EBNA1 in normal and malignant cells. These schemes may involve treatment of virus-infected cells with synthetic or biological mediators capable of enhancing stable ubiquitination and rapid intracellular degradation of EBNA1 in vivo. Because the substrate specificity of the ubiquitin-proteasome pathway is conferred by the E3 ubiquitin-protein ligases, then one approach may involve manipulation of the ubiquitin-dependent proteolytic machinery by targeting specific E3 ubiquitin-protein ligases to direct the degradation of otherwise stable cellular proteins, such as EBNA1. Potentially, this engineered proteolysis system could be utilized as a therapeutic method to counteract the proteasomal block conferred on EBNA1 through the *cis*-acting inhibitory GAr domain.

The MHV 68 model of γ-herpesvirus infection has indicted a role for CD4+ T-cells in both the control of infection (Hogan *et al.*, 2001) and in the control of tumor cells expressing MHV 68 antigens. When MHV 68-infected S11 cells were injected subcutaneously into nude mice, adoptively transferred lymphocytes caused the regression of S11 tumors and CD4+ T-cells were most effective in preventing tumor formation. CD4+ T-cells were also present in the regressing tumors (Robertson *et al.*, 2001).

Conclusions

The limitations imposed on EBV vaccine design include (1) the behavior of EBV in vivo is poorly understood such that the anatomical location of infected cells, the site at which they become infected, and the site at which new virus is produced, are not known with confidence; (2) the correlates of immune protection against, or modification of, in vivo EBV infection are unknown; (3) killed or attenuated variants of EBV cannot be used as vaccines because of the oncogenic potential of the virus and a number of its components; (4) the virus infection persists for life in the face of humoral and cell mediated immune responses; (5) although numerically very significant, only a very small proportion of the infected population will develop disease. Despite the fact that recent human trials have indicated that gp350 vaccination can prevent IM, but not EBV infection, in seronegative young adults (Denis, 2005), the immunological basis for this is remains unclear. Until further human trials have taken place it is unlikely that any correlates of protective immunity against either infection or disease will become known with only limited information coming from animal models of related viruses. It is impossible to say at this stage what effects gp350 vaccine-induced mucosal or systemic immune responses might have on primary EBV infection or existing EBV infection. Once latency has been established, will immune responses in the vaccinee be more effective in preventing EBV disease than in a normal unvaccinated seropositive? Large scale and unselective prophylactic mass vaccination are presently impractical given current public health priorities

and may even be unwise. Unless a clear benefit of such vaccination in a sizeable population can be demonstrated, such as in young seronegative adults in Western countries, resources will inevitably be focussed on therapeutic strategies for those who have already developed disease. Our increased knowledge of the antigen presentation and processing pathways of the main EBV-associated tumours, NPC and HD, has given rise to rational and novel immunotherapeutic strategies based on the enhancement of either LMP-specific CTLs or enhancement of LMP antigen presentation in the tumours themselves. Until recently, there were no immunotherapeutic strategies for treating endemic BL but the induction of appropriate CD4+ T-cells by vaccination may offer a way forward. The conducting of properly controlled human trials to evaluate the options set out above is clearly the first priority and little further progress can be expected until they take place.

DNA vaccines for human herpesviruses

Thomas G. Evans and Mary Wloch

Vical Incorporated, San Diego, CA, USA

General design of DNA vaccines

DNA vaccines are circular, double-stranded plasmid DNA (pDNA) molecules, which are capable of initiating the expression of protein antigens of interest when introduced into cells. For this purpose, the pDNA contains an eukaryotic expression cassette consisting of a transcriptional promoter, a protein coding sequence derived from the target antigen gene, and a transcriptional terminator (Fig. 73.1). Although many different promoters have been investigated, none have been shown to be clearly superior to the constitutive CMV IE promoter. DNA vaccines can consist of single genes on one plasmid, multiple genes on one plasmid, multiple plasmids, or a combination of the above. In biscistronic or tricistronic constructs, internal ribosomal entry sites (IRES) or equivalent sequences, dual or triple promoters, or cleavable linkage regions in fusion proteins can be used for expression of multiple genes. Upon transfer into cells, the pDNA enters the nucleus and transcribes a messenger RNA (mRNA) encoding the antigen of interest. The antigen can be identical to the wild-type protein of the pathogen, or can be genetically modified to improve immunogenicity and/or reduce toxicity to the host. The pDNA may also contain an antibiotic resistance gene and a bacterial origin of replication for growth and propagation in *E. coli*. Constructs using selection elements for bacterial replication other than antibiotic elements have also been utilized.

For vaccination, the purified pDNA is reconstituted in aqueous vehicles, or formulated and injected. A variety of delivery routes have been used, including intramuscular, intradermal, subcutaneous, transcutaneous, and mucosal (Ulmer, 2001). In the mouse, the route of delivery (e.g., intradermal versus intramuscular) may affect the antibody levels as well as the production of antigen specific Th1-like or Th2-like cytokines (Feltquate *et al.*, 1997). DNA vaccines, in which *de novo* production of the relevant immunogen is achieved without the use of live agents, combine some of the positive aspects of immune stimulation inherent in live-attenuated vaccines, such as enhanced cellular immune responses, with the safety and defined antigenicity of recombinant subunit vaccines. Furthermore, pDNAs expressing different antigens can easily be co-administered in a single formulation, enabling multivalent vaccines to be designed and tested with relative ease.

Mechanism of action

To develop rational approaches for enhancing DNA vaccine potency, an understanding of the mechanism of action of DNA vaccines is essential. The mechanism by which immune responses are initiated after intramuscular DNA vaccination has been a subject of debate for many years. Early discussions centered around three possible mechanisms: direct transfection of APCs, transfer of antigen from transfected muscles to APCs, or direct T cell priming by transfected myocytes (Padoll and Beckerleg, 1995). Data from experiments in which transfected myoblasts from H-2^k mice were transplanted into naïve H-2^d $\times$ H-2^k mice indicated that transgene encoded antigen could be transferred from the transfected myoblasts to host APC for generation of an antigen specific immune response (Ulmer *et al.*, 1996). Additional reports from experiments in which chimeric mice were used to characterize the role of bone marrow-derived APCs in priming immune responses after intramuscular DNA vaccination supported the hypothesis that antigen produced by muscle cells is transferred to APCs for initiation of antigen specific immune responses (Doe *et al.*, 1996; Corr *et al.*, 1996). While these experiments ruled

out a major role for direct T-cell priming by muscle cells, and indicated that antigen could be transferred to bone marrow-derived APC for T-cell priming, other experiments suggested that muscle expression is not critical for the generation of antigen specific immune responses after intramuscular DNA vaccination. Experiments in which injected muscles were removed within 1 to 10 minutes after injection, without diminishing the resulting B- and T-cell immune responses, argued for direct APC transfection (Torres *et al.*, 1997). A more recent study suggested that both mechanisms, direct transfection of bone marrow derived APC and cross-priming with antigen produced by muscle cells, are involved, and that cross-priming by antigen transfer is the predominant mechanism (Corr *et al.*, 1999). Increased local inflammatory responses with a resultant increase in APC migration to the muscle may play as great a role in cross-priming as the actual expression of gene product in the muscle. Furthermore, much of the pDNA injected into the muscle may be transported directly to the lymph nodes via the lymphatics, and thus the studies of Torres *et al.* may involve mechanisms other than direct APC transfection (Mena *et al.*, 2001).

The role of dermal cell expression of DNA vaccine-encoded antigens after intradermal or gene gun vaccination is still unclear. Direct transfection of APCs upon dermal injections of DNA vaccines may play a more extensive role in the induction of immune responses to DNA vaccination than the cross-priming that occurs in muscle cells. APCs such as Langerhans cells and macrophages are more numerous in the dermis and direct transfection of these cells has been shown after intradermal DNA vaccination and DNA vaccination by gene gun (Raz *et al.*, 1994). However, ablation of transfected dermal tissue within 24 hours of gene gun inoculation greatly diminished the antigen specific antibody response and precluded the generation of antigen specific CTL, suggesting a role for transfected dermal cells, other than migrating APCs, in the generation of an immune response after gene gun vaccination.

It is now generally believed that multiple mechanisms: cross-priming of APCs in the muscle or skin, direct transfection of APCs transiting the tissues, and uptake of pDNA by cells in the lymphatics or lymph nodes, are involved in immune response induction after DNA vaccination. However, in all of these cases, there is reason to believe that improved transfection of APCs, facilitated by the appropriate signals to allow for increased antigen or pDNA uptake, maturation, and migration to the local lymph tissues, will be critical in improving responses to DNA vaccines.

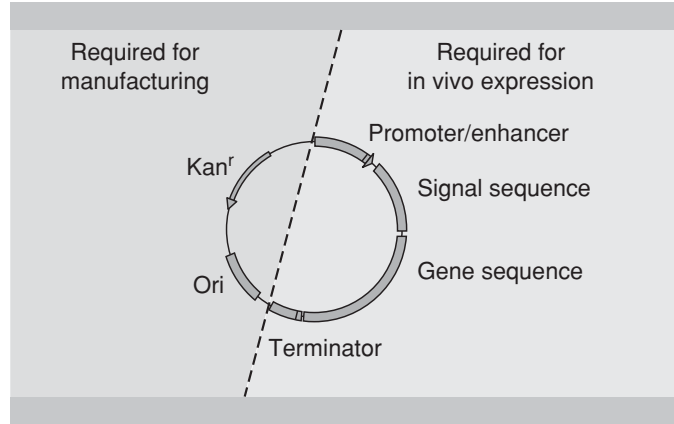

Fig. 73.1. Basic technology: plasmid DNA.

DNA vaccines: advantages and disadvantages

DNA vaccines have many advantages over other platforms, with the result that these products are used extensively as vaccine research tools. Many of these same advantages may facilitate development of therapeutic or prophylactic vaccination for herpesvirus infections (Table 73.1). In general, because gene constructs are easily modified, a very large number of differing constructs and combinations of immunogen genes can be rapidly developed and tested, which is not feasible with recombinant proteins. Injection of DNA can be readily used to investigate the function or protective effect of specific genes, combinations of genes, or effect of gene modifications. The combination of predictive algorithms for MHC Class I and II epitopes, combined with DNA vaccination in transgenic mice, has proven to be a powerful approach in antigen discovery for vaccination strategies targeting T-cell immunity.

In order to increase safety, target immunogens can be genetically modified to specifically, stably and uniformly remove biologically active regions of the proteins. For example, kinase or transactivating activity of key herpesvirus proteins can be removed, and yet the genes that contain the key T-cell or B-cell epitopes, regions, or exons of the gene can be retained. The effect of using a secretory leader or removal of transmembrane and cytoplasmic sequences can also be readily evaluated. Furthermore, the effect of glycosylation sites, minor amino acid changes, or the effects of combination genes that may form neutralization complexes (such as the gH/gL/gO complex in CMV, gH/gL complex in HSV, or gE/gI complex in VZV) can be much more quickly investigated, than when using techniques that apply recombinant protein or viral vectors.

Table 73.1. DNA vaccination approaches for herpes viruses

Advantages	Disadvantages
• Manufacture process and analytical testing are the same across different constructs • Stability • Time to clinic • Safety • Ability to titrate immune response to humoral or T-cell arms based on formulations/adjuvants • Ease of multivalent approaches • Ability to modify or detoxify the genes of interest • Lack of prior immunity or immune responses to the plasmid backbone	• Suboptimal responses in human trials to date • Regulatory pathway influenced by gene therapy • Population fear of "genetic" immunization • Not yet manufactured to scale • Possible need for more than a single injection to induce responses in humans

Herpesvirus subgroup	Virus	Tumor association
alpha	HSV-1	none
	HSV-2	none
	VZV	none
beta	CMV	none
	HHV-6	none
	HHV-7	none
gamma	EBV	Burkitts lymphoma, Gastric carcinoma, Nasopharyngeal carcinoma, Hodgkin's disease, Post-transplant lymphoproliferative disease, T-cell lymphoma, Leiomyosarcoma
	HHV-8	Kaposi sarcoma of HIV positive and negative patients, body cavity lymphoma, Castleman's disease

In the past decade, improvements in both plasmid design and formulations have led to approximately a 5-log increase in expression in muscle of the reporter gene, luciferase. The last log of this increase has been achieved using electroporation, which is being studied in man (Fig. 73.2). However, it is important to realize that *in vitro* or *in vivo* expression of the gene construct does not strictly equate with immunologic response to the DNA vaccine.

For the administration of plasmid DNA, both in animals and humans, a range of suitable DNA formulations have been established that can enhance either humoral or cellular immune memory to provide appropriate immune

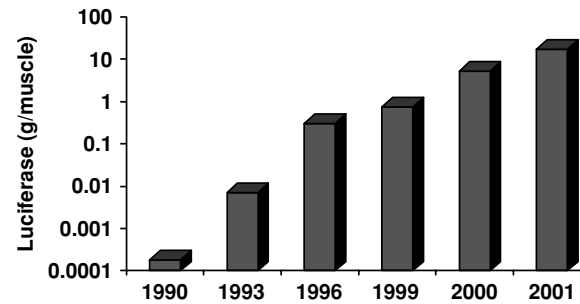

Fig. 73.2. Increase in the expression of the luciferase gene in vivo in muscle over the past decade (Vical in house data)

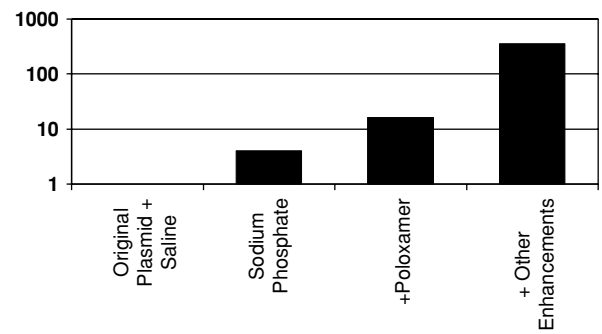

Fig. 73.3. Improvements in T-cell responses by formulation and delivery mechanism

responses for protection against the target pathogen. For example, the use of cationic lipids such as Vaxfectin drives a stronger humoral response than is achieved with unformulated pDNA, (Hartikka *et al.*, 2001), whereas formulation of DNA vaccines with poloxamers tends to enhance T cell responses but has less of an effect on B cell responses (Shiver *et al.*, 2002) (Fig. 73.3).

Thus, a single plasmid DNA vaccine can be used in animal models to define potential correlates of protection by simply changing the DNA vaccine formulation or route of administration. As an example, in the influenza murine model, the use of pDNA encoding NP is protective when given intramuscularly and generates CD8+ T-cell responses, (Ulmer *et al.*, 1993) but is less effective when given intradermally by the gene gun route which generated greater antibody responses (Robinson *et al.*, 1997).

Unlike genetic vaccines that use viral or bacterial vectors to deliver DNA encoded antigens, with DNA vaccines there are no problems with pre-existing or induced immunity to the DNA vaccines that could blunt or abrogate the desired immune response. Thus, repeated boosting over many years appears feasible, if necessary. In this regard, DNA vaccines may also be superior to the use of HSV or CMV as homologous or carrier vaccine vectors to induce

an immune response to a subdominant, but possibly more protective antigen.

A major advantage of DNA vaccines or DNA immunotherapeutics is that they are well tolerated and have been demonstrated to be safe in animals and in over 1000 humans. There has been persistent concern in the use of DNA vaccines with the potential for integration into the cellular DNA, but no published preclinical animal studies or human trials have demonstrated integration. In the preclinical studies published to date, the rate of integration has been shown to be at least 1000-fold lower than the risk posed by spontaneous mutations in the human genome (Martin *et al.*, 1999; Ledwith *et al.*, 2000).

DNA vaccines with many different antigen configurations can be produced with the same manufacturing platform, greatly simplifying the production process. Likewise, analytical testing of the plasmid varies little from one DNA vaccine to another, and downstream processing is relatively straightforward. Therefore, the time required to move from concept to animal testing and to the clinic is markedly shortened. Multiple plasmids can be processed in the same facility, and then combined in a final vaccine formulation. Properly formulated DNA vaccines can be stored in liquid form at refrigerated or room temperature for many years. Lastly, DNA vaccines do not require the handling of the pathogen or any mammalian cell substrates (with the associated risk of adventitious agents) at any point in the manufacturing process.

At present, the disadvantages of a DNA vaccine approach are similar to those of many emerging, disruptive technologies. The greatest criticism is the lack of substantive data in humans (see discussion below). The regulatory hurdles surrounding DNA have been originally placed nearly on level with those of gene therapy, and are only now beginning to be adjusted for the safety profile and knowledge of the technology that has emerged in the past decade. In addition, there will be a need to overcome the general fear in the public that this is not a "DNA altering" technology. Lastly, although DNA vaccines will eventually be quite inexpensive to produce, the technology is only now beginning to achieve the efficiencies of scale (such as in line fermentation, lysis, and column purification) that will drive down the costs of manufacture.

Standard DNA technology involves selecting individual genes and cloning them into a vector. A unique method of using DNA for herpesvirus vaccine studies is to inject the DNA as a provirus, which has been modified to remove only one or a few genes. This is now feasible with the advent of recombinant bacmid (bacterial artificial chromosome) technology, which allows for an infective proviral DNA construct to be made using *E. coli.* (Hahn *et al.*, 2003; Suter *et al.*, 1999). Such an approach has focused on removal of the immune evasion genes, to both decrease virulence and promote a greater immune response to the defective virus. Unfortunately, the bacmid can usually only be propagated as a single plasmid per single bacterium, and thus the yield from a fermentation is quite low. In general, the bacmid is then often propagated as a defective virus using a classic CMV-competent or trans-supplying cell line, and results in a replication defective virus for use in the vaccine trials. Although the injection of the bacmid into the host would likely result in some degree of defective virion production, the regulatory and safety hurdles surrounding such an approach would not be trivial.

Features of pDNA constructs especially conducive to herpesvirus vaccine development

As reviewed in previous chapters, there is minimal data that true sterilizing immunity to herpesvirus infections can be easily achieved through any present vaccine strategy. It may be a more realistic goal to limit the initial viral spread and thereby reduce the number of initially infected neurons (for HSV and VZV), or to limit the extent of reactivation of virus (EBV and CMV). Whether control of viral replication can best be achieved by use of a vaccine designed to induce antibody or T-cell-based immunity may depend on the clinical setting. As discussed below, prevention of CMV maternal-fetal transmission may be mostly antibody mediated, whereas prevention of CMV disease following infection in the hematopoietic cell transplant patient appears to be mostly T cell mediated. Nevertheless, most vaccine approaches to herpesvirus infections may require a greater degree of T-cell-mediated immunity than an approach to some other acute viral infections. The result of the HSV subunit trials has shown that adjuvants that bias toward a Th1 response may play a role in protective efficacy (Koelle and Corey, 2003).

DNA vaccines administered intramuscularly have been shown to induce balanced B- and T-cell responses, and will elicit CD8+ T-cell responses, which protein subunit vaccines, in general, cannot (Ulmer, 2001). Recent studies in macaques have shown that the T-cell responses induced by plasmid vaccination tend to be evenly balanced between $CD4^+$ and $CD8^+$ T-cells, whereas responses to adenovirus vectors are generally skewed toward $CD8^+$ T-cell responses (Casimiro *et al.*, 2003). A balanced T-cell response may be important in Herpesvirus infections, in which the role of $CD4^+$ T-cells as well as $CD8^+$ T-cells has been implicated in protection (Koelle and Corey, 2003).

In addition, as demonstrated in prime-boost experiments, DNA vaccines may be superior to other vaccine modalities in promoting long-term memory (McShane, 2002). This priming of memory responses may lead to a greater degree of recall responses, both T-cell and antibody, upon boosting by natural primary infection or viral reactivation. For example, monkeys that were immunized with a candidate authrax DNA vaccine were protected from a fatal challenge and manifested a rapid and rigorous recall response, despite a lack of protection neutralizing antibody at the time of challenge of viral data (Letvin *et al.*, 2006). It is not presently known whether this long-term T-cell memory response may be more critical in vaccine induced protection than the present focus on increasing the number of antigen specific effector cells quantified shortly after vaccination at the peak of the response.

DNA vaccines also have an advantage over the use of conventional live attenuated herpesvirus vaccines, such as the CMV Towne strain vaccine, in that they can be designed to encode relevant antigens without including the multiple immune evasion genes carried by human herpesviruses (Mocarski, 2002). In natural infection, many of these immune evasion gene products are designed to downregulate the T-cell response, and thus avoid recognition and lytic or non-lytic removal by $CD4^+$, $CD8^+$ or NK positive T-cells. Because immune evasion gene products may preclude responses to antigens produced during late infection, the antigens likely to be efficiently recognized by T-cells are those produced early in the infection process such as those encoded by immediate early genes. In addition, preformed structural proteins carried in by the virus may access the Class I pathway directly following infection of the cell or the Class II pathway as exogenous antigen (Tabi *et al.*, 2001; McLaughlin-Taylor *et al.*, 1994) and result in T-cell responses.

Additionally, the amount of early antigen proteins made by conventional live attenuated vaccines may be small as compared to the physical mass of structural proteins, and thus the immune response may be skewed in part by attenuated or vectored vaccines to these late gene products that are not as well presented on the infected cell surface during natural infection. By using DNA vaccines that can promote the production of early antigen gene products in mass equivalent to those of the structural genes, T-cells can potentially be "taught" to recognize and destroy infected cells at an early stage by focusing the immune response on viral proteins that are expressed early in infection, before the Class I or Class II presentation is down-regulated by the ongoing natural infection.

Likewise, the antigens and epitopes recognized in chronic herpesvirus infection, during which the virus is continually replicating and shedding structural genes, may not be equivalent to those that would be recognized during acute infection or during initial reactivation. That is, the focus on the T cell epitopes that are dominant during ongoing chronic infection and therefore easily identified, as has also occurred in the HIV vaccine arena, may not be predictive of the epitopes that are important in actual virus control (Letvin *et al.*, 2006). Identification and measurement of the specific immune effectors that limit viral replication after acute infection or reactivation may be much more useful for predicting prophylactic vaccine outcome.

Animal and human experience with DNA vaccines

Many of the studies in larger animal models with DNA vaccines have focused on using this technology to induce cytotoxic T-cells (CTL). Several studies have demonstrated induction of strong CTL responses by parenteral immunization of primates with DNA encoding SIV and/or HIV proteins. In addition, DNA vaccines have been used successfully as priming vaccines in non-human primate models of prime-boost vaccination. Notably, Robinson *et al.* demonstrated that priming with a DNA vaccine containing genes encoding antigen from non-infectious SHIV 89.6, followed by a boost with recombinant modified vaccinia Ankara (MVA) encoding SHIV 89.6 genes, protected 24 of 24 macaques from disease progression following intrarectal challenge with the homologous virus (Amara *et al.*, 2002). Merck and the NIH have used DNA alone or formulated with poloxamers or alum, and then boosted with adenovirus, to protect macaques from SIV challenge (Shiver *et al.*, 2002).

In humans, the immune responses to date have been less robust. In a clinical trial conducted by Hoffman *et al.* a malaria DNA vaccine induced $CD4^+$ or $CD8^+$ T-cell responses in all subjects; however; the responses were not of large magnitude (Wang *et al.*, 2001). In the Merck trials of over 300 subjects to date, approximately 37% of subjects have had measurable gamma interferon positive ELISPOT responses after three or four vaccinations with 5 mg of formulated (aluminum or the poloxamer CRL 1005) or unformulated DNA encoding HIV Gag. (Emini, 2003 Keystone meeting). Although the frequency of response was not 100%, the number of spots induced were similar to the number of T cell responses (both $CD4^+$ and $CD8^+$ T cells) reported by Merck after use of a live attenuated varicella vaccine in the elderly (about 100 spots/million T cells) (Caufield, ICAAC, 2003).

The low response rate in humans to the HIV gag DNA vaccine have been due to the inherently poor immunogenicity of the Gag antigen. This can be hypothesized due to the fact

that canarypox vectors encoding Gag have induced CTL responses in about one third of subjects (Belshe *et al.*, 2001) whereas the same vector encoding CMV pp65 induced CTL responses in 100% of naïve subjects (Berencsi *et al.*, 2001). Similarly, DNA vaccines encoding highly immunogenic antigens such as CMV pp65 may be more effective in inducing robust T cell responses in humans than those reported for the HIV gag DNA vaccine. However, initial data from a bivalent pp65, gB DNA vaccine formulated in the poloxamer CRLI005 also appeared to have an approximate 41% response rate (unpublished viral data.)

While it is well known that DNA vaccination stimulates $CD4^+$ and $CD8^+$ T-cell immune responses in the vaccinated host, the ability to generate a protective humoral response is not as well characterized, especially in humans. Reasonable, but not robust, vaccine-induced antibody levels have been measured in clinical trials of hepatitis B vaccine administered by gene gun (Roy *et al.*, 2000; Letvin *et al.*, 2006). In a recent malaria vaccine trial, DNA immunization primed for increase antibody responses following experimental challenge (S. Hoffman, personal communication). A single dose of DNA, given by electroporation or in an antibody-inducing formulation, is able to protect cats and dogs from rabies challenge for up to one year (Osorio *et al.*, 1999). A DNA vaccine given intramuscularly has generated protective levels of antibody and protected horses from encephalitic West Nile Virus challenge (Davis et *al.*, 2001). In addition, DNA has protected non-human primates from challenge with malaria, influenza, and herpes viruses (Ulmer, 2001). Two vaccines based on induction of antibody are now licensed in animals – a hemorrhagic necrosis virus vaccine for Salmon and a WUV vaccine for horses (Ulmer *et al.*, 2006).

Improving DNA vaccine potency

There are several possible approaches to increasing the potency of DNA vaccines. First, modification of the plasmid DNA vector to increase expression levels has resulted in increased immunogenicity in vivo (Fig. 73.2) (Hartikka *et al.*, 2001; Norman *et al.*, 1997). Changing the nucleotide sequence of certain genes to better reflect preferential codon usage in mammalian cells can result in markedly higher levels of expression in eukaryotic cells *in vitro* and, when incorporated into a DNA vaccine vector, can increase immunogenicity substantially (Andre *et al.*, 1998; Uchijima *et al.*, 1998).

Another general approach to improving DNA vaccines involves adjuvants. Adjuvants can include proteins, small molecule compounds or DNA plasmids encoding immunomodulating proteins, such as cytokines, chemokines and costimulatory molecules. The specific examples are too numerous to list here, but are reviewed elsewhere (Sasaki *et al.*, 1998; Ulmer *et al.*, 2006). We and others have shown that simple mixtures of DNA vaccines with adjuvants are sometimes effective, but appropriate formulation may be required. For example, certain aluminum gels, such as aluminum phosphate, when mixed with DNA vaccines, enhance antibody responses, (Ulmer *et al.*, 1999) while others, such as aluminum hydroxide, inhibit responses as a consequence of electrostatic interaction between the negatively charged DNA and positively charged adjuvant. This detrimental effect can be overcome with appropriate formulation to prevent such binding. We have assessed the effects of cationic lipids, and shown them to enhance the B-cell response without down-regulating the T-cell induction (Hartikka *et al.*, 2001). On the other hand, in our laboratories and others the use of poloxamers has led to an increase in T-cell responses with no detrimental effect on antibodies (Fig. 73.3).

DNA vaccines for specific human herpesviruses

Cytomegalovirus

Genes of interest

The immune response to CMV during acute or chronic infection has been determined by the study of acute and chronic infection in animal models and in man. Antibody appears critical in the prevention of maternal-fetal transmission, and is primarily directed to the envelope glycoproteins, especially gB (Plotkin, 1999). The control of CMV infection in transplant recipients and HIV-infected persons is associated with preserved cellular immune responses, including $CD4^+$, $CD8^+$, and NK T-cells. The $CD8^+$ T cell responses are directed primarily at the immediate early (IE) genes of CMV and at the abundant tegument protein pp65. Approximately 92% of persons have $CD8^+$ responses to pp65 and another 76% to exon 4 of IE1 (Gyulai *et al.*, 2000; Wills *et al.*, 1996). In addition, another one-third of infected individuals have CTL responses to gB. Although pp150 responses have been noted, the degree of these responses are not of the magnitude of those induced by pp65 or IE1.

Almost all infected persons have $CD4^+$ responses to CMV, although the antigen and epitope mapping is not as fully investigated as those for $CD8^+$ T-cells (Kern *et al.*, 2002).

The use of DNA to protect in the maternal fetal situation would likely rely on greater antibody induction, although whether antibodies to gB are sufficient is still debated. An advantage of a DNA approach would be to use polycistronic constructs, such as those encoding the gH/gL/gO or

gM/gN complexes or individual envelope proteins, to elicit antibodies that neutralize via fusion inhibition or other mechanisms.

Animal studies

The plasmid DNA approach to CMV disease has already been validated in a series of recent animal studies. Almost all of these studies have concentrated on the use of gB, the pp65 homologues, or IE1, and in each case have needed to use the species specific strains for the source of the encoded gene (Hwang *et al.*, 1999; Morello *et al.*, 2000; Schleiss *et al.*, 2000; Endresz *et al.*, 1999, 2001). pDNA vaccines encoding murine CMV IE1 and pp65 homologues have elicited immunity associated with 100–1000-fold reduction in viral titers in a mouse model of CMV infection (Ye *et al.*, 2002). In the guinea pig model of maternal-fetal transmission of CMV, DNA encoding gB, but not the pp65 homologue, was capable of partial protection of the newborn pup (Schleiss *et al.*, 2000). (Schleiss, 2004). In addition, the use of pDNA encoding a secreted, transmembrane deleted, form of the gB protein has been shown to elicit higher antibody titers than full length gB in the murine model. (Endresz *et al.*, 2001).

Human trials

Vical Inc. of San Diego moved a poloxamer-formulated bivalent CMV DNA vaccine encoding gB and pp65 into human clinical trials in 2003. The gB gene can be truncated to remove the transmembrane and cytoplasmic domain, thus allowing for greater secretion. The pp65 construct may need modification to remove a published putative kinase encoding region (Gallez-Hawkins *et al.*, 2002). The IE1 constructs being considered for a trivalent vaccine can be engineered to remove both the potential transactivation regions and other biologic activities. A trivalent product that includes the IE1 gene is now in late preclinical development.

The bivalent gB/pp65 vaccine has been tested in both rabbits and mice, and was found to be highly immunogenic for the production of both antibodies (gB) and T cells (pp65). The majority of the vaccine-induced T cell responses in BALB/c mice, as measured in a gamma interferon ELISPOT assay using overlapping peptides encoding the entirety of pp65, are found in the amino terminal half of the protein. The frequency of spot forming cells in mice is higher than that seen with influenza NP, IE1, or similar antigens, when administered on a similar schedule at a similar dose. Studies with the murine pp65 homologue, hCMV pp65, and NP have all shown an improved T cell response using the poloxamer CRL1005. In studies in seropositive, non-vaccinated humans, the gamma interferon positive T cell responses to chronic infection, which may not mirror responses to vaccination, are found to be more frequent in the C-terminal region of the protein, as in contrast to the vaccine induced responses in mice.

Phase 1 studies of this vaccine revealed that three doses of up to 5 mg total DNA induced T cell responses in approximately half of vaccinated individuals. This vaccine has now moved into a Phase 2 study, in which the clinical endpoint is the prevention in CMV seropositive stem cell transplant recipients of detectable CMV viremias after vaccinations of both the donor and the recipient.

Herpes simplex virus 1 and 2

Genes of interest

There appear to be two different approaches to using DNA vaccines in HSV, which may be independently moved forward, or possibly combined. The first would be to increase the antibody response to gB, and/ or gD, or to the gH/gL complex by the use of DNA-augmented by adjuvants, formulations, or cytokines. The second would be to limit viral growth by the recognition and destruction of cells that are in the earliest phases of replication, and prior to the numerous HSV-directed immune evasion mechanisms. In such a scenario, the DNA vaccine would be focused on the early antigens, and those most carefully scrutinized include ICP4, ICP0, and ICP27. ICP 47, which blocks antigen presentation to $CD8^+$ T cells, would be another early antigen for vaccine inclusion, but some biologic modification may be necessary. Other proteins of interest include those that are more abundantly expressed in later stages of virion formation, including the structural proteins VP5, VP13/14, VP16 and VP22.

Animal studies

The concept of direct DNA vaccination for HSV was investigated by a number of different investigators shortly after the discovery of the DNA vaccines (Wolff *et al.*, 1990). In 1994, Rouse *et al.* showed that an *in vitro* model of DNA transfection could be used to generate gB or ICP27-specific CTL from splenocytes (Rouse *et al.*, 1994). Initial reports of low level antibody production and partial protection in mice using gD constructs, (Ghiasi *et al.*, 1995), were followed by more impressive mouse or guinea pig studies using both gB and gD (Bourne *et al.*, 1996a,b; Kriesel *et al.*, 1996; McClements *et al.*, 1996, 1997). The versatility of the DNA approach has been used to study most of the

putative targets of neutralization, including gB, gC, gD, gH/gL or combinations of these (Nass *et al.*, 1998; Cha *et al.*, 2002; Lee *et al.*, 2002). Protection in some experiments using the recurrent zosterform model of HSV appeared to be mediated by T-cells to either gB or ICP27 (Manickan *et al.*, 1995a,b).

Whether these models could be used to predict the need for mucosal versus systemic immunization is not known; however, some studies take advantage of the availability of the DNA constructs in the relapsing guinea pig or acute murine HSV models to test such concepts (Shroff *et al.*, 1999; Eo *et al.*, 2001). In addition, as the results from protection were almost never 100% in early studies, HSV DNA vaccine models have been used extensively to study improvements to the technology, include the use of plasmid or gene modification, (Higgins *et al.*, 2000) alphavirus replicons, (Hariharan *et al.*, 1998) adjuvants, (Bernstein *et al.*, 1999) and cytokine, chemokine or co-stimulatory enhancements (Sin *et al.*, 1998, 1999b; Flo *et al.*, 2000; Sin *et al.*, 2000a,b; Harle *et al.*, 2001; Sin *et al.*, 2001). As in other vaccine systems, the highest titers are often achieved by using a prime-boost approach of initial DNA vaccination, followed by another modality (protein, another vector, or killed virus) (McShane, 2002; Sin *et al.*, 1999a). A DNA prime followed by an inactivated virion was capable of inducing a 4 log reduction in virus shedding in calves that were challenged with bovine herpesvirus-1 (Toussant *et al.*, 2005).

Human trials

No trials of candidate HSV DNA vaccines have been reported in humans despite extensive preclinical work. The relative success of the GlaxoSmithKline vaccine, which used an MPL-based adjuvant to promote a greater T-cell response with Th1 bias, may lead to renewed interest in this approach. Encouraging trial results using replication-defective viruses, such as the DICS-virus, would also be likely to speed the movement of plasmid-based products into humans. Trials of DNA vaccines encoding the early antigens of HSV for use in the therapeutic setting have been planned using gene gun technology, but whether those trials will move forward is not known.

Varicella-zoster virus

Genes of interest

The transmembrane glycoprotein gE, and to a lesser extent gB, contain the major neutralizing antibody targets after VZV natural infection or OKA vaccination. Mapping of CTL targets indicates that immediate early antigens, along with gE, are common (Arvin *et al.*, 2002). The most extensively studied, and first likely target for DNA vaccination is IE62 (Abendroth *et al.*, 1999). There are several biological activities associated with IE62 that may need to be deleted from a vaccine candidate in an attempt to decrease potential transactivation. Other genes that have been suggested to be used as CTL targets in VZV vaccines include IE63 and the thymidine kinase. IE63 is expressed during latency in seropositive subjects, and thus inclusion of this gene in a DNA vaccine may raise concerns about immunopathology (Debrus *et al.*, 1995).

Animal studies

As has been found in CMV and HSV, attempts to augment the generation of a B-cell response have used secreted forms of surface glycoproteins; for example, by removing the transmembrane portions of gE. Publications using a 1.8 kb secreted gE plasmid construct made in the vector pRC/CMV have demonstrated that secreted-gE is expressed very poorly in vitro and elicits suboptimal immunogenicity in mice or guinea pigs (Massaer *et al.*, 1999; Hasan *et al.*, 2002). Normally the glycoprotein gE forms a heterodimer with gI, with gI providing chaperone activity that modulates the trafficking of the gE-gI heterodimer through the golgi and ultimately to display on the cell surface. The lack of gI chaperoning activity may explain the low titers seen in these DNA vaccination studies when injecting the gE plasmid alone. Other studies have shown improvement in titers of gE when administered intradermally by gene gun, although this approach again favored a Th2 bias (Stasikova *et al.*, 2003).

Human trials

No VZV DNA vaccine has moved into the clinic, although the clearest indication would be for use in the immunocompromised setting, in which the use of the licensed live-attenuated vaccine is either contraindicated or not recommended. A bivalent or trivalent vaccine using gE and early antigens formulated in a way to bias toward T-cell over antibody responses is presently a favored approach.

Epstein–Barr virus

Genes of interest

Studies of $CD8^+$ T-cell immune response to EBV have shown that there is often a massive proliferation of T-cells that are narrowly focused on either one or a few MHC

Class I-restricted epitopes (Rickinson *et al.*, 2001). The T-cell response is needed to prevent unchecked viral-driven B cell proliferation. In T-cell deficiency, the emergence of certain EBV-related tumors occurs (for review see else where in this volume), and little role has been observed for antibody-mediated control.

Nonetheless, an antibody-based approach has been used to attempt to prevent or control primary infection, with the majority of investigations focused on the major surface glycoprotein gp350, using Type 1 strains that are most prevalent in Western populations. Little work has been accomplished with other potentially important surface glycoproteins.

For T-cell response induction, initial studies focused on the key early and latency antigens, EBNA1, EBNA2, and LMP1. During the acute infection, T-cells are also rapidly expanded to the lytic antigens, particularly BZLF1, BRLF1 and BMLF1. $CD8^+$ T cell epitopes to most of these genes have been mapped to the HLA-allele for which they are restricted (Rickinson *et al.*, 2001). In persistent infection there is a change in the hierarchy of the genes recognized, with greater responses focused on EBNA3A, EBNA3B, EBNA3C, and LMP2. Since the responses to EBV appear to be narrowly focused, and yet to cover a broad array of HLA haplotypes, this virus may represent an ideal situation to use DNA vaccines based on the polytope approach (Thomson *et al.*, 1998). In such a model, which has been moved to human clinical trials in the HIV vaccine field, multiple epitopes, or epitope dense regions are linked in a plasmid construct using designs that optimize proteosomal cleavage and class I presentation (Livingston *et al.*, 2001). The use of a helper epitope is often employed to improve $CD4^+$ responses and enhance $CD8^+$ T-cell memory.

As with other herpesviruses, it will be necessary to study and potentially modify biologically active elements that may appear to pose safety risk, especially for a known carcinogenic virus. Removal of immune evasion elements could be accomplished for EBNA1 removal of the glycine-arginine repeat (Gar) site responsible for preventing the protein from undergoing degradation by the protesosome (and thus lack of presentation to the Class I system) (Koelle and Corey, 2003).

Animal studies

Studies using DNA vaccines have been quite limited in EBV. A vaccine based on a few HLA-restricted CTL epitopes has been evaluated in mice, but no human studies have been published (Thomson *et al.*, 1998). Studies in mice have shown the expected immunogenicity using DNA constructs encoding gp350 (Jung *et al.*, 2001).

Human trials

No trials of DNA vaccines have been undertaken in EBV.

Summary

DNA vaccination, as with any new emerging technology, has passed through a series of unreasonable positive expectations, and has suffered at the hands of poorly defined negative criticisms. Although no definitive human efficacy data exist, however, the technology is only a little more than a decade old. The results in human trials to date have been encouraging, but suboptimal, and may have suffered form use of first generation vectors, lack of formulations, and poorly selected immunogens and disease states. Human herpesvirus diseases represent a frontier in which this technology is likely to prove whether it can live up to its enormous promise and potential. If initial trials in CMV or HSV show promise in the coming two years, renewed enthusiasm for moving this approach into humans with the remaining herpesviruses should follow.

Adoptive immunotherapy for herpesviruses

Ann M. Leen, Uluhan Sili, Catherine M. Bollard, and Cliona M. Rooney

Center for Cell and Gene Therapy, Baylor College of Medicine, Houston, TX, USA

Introduction

Herpesvirus infections rarely cause significant problems in the immunocompetent human host. However, in the immunosuppressed, for example, recipients of hematopoietic stem cell transplants (HSCT) (Rooney *et al.*, 1998), solid organ transplants (SOT), or human immunodeficiency virus (HIV)-infected individuals, viral infections/reactivations are common and are associated with considerable morbidity and mortality. The resultant uncontrolled infections correlate with a lack of cellular immunity against viral antigens (Weinberg *et al.*, 2001). While effective antiviral drugs are available for the treatment of some herpesvirus infections, adoptive immunotherapy, which is the artificial reconstitution of virus-specific T-cells with *in vitro* expanded cytotoxic T-lymphocytes (CTLs), for the prophylaxis and/or treatment of herpesviruses is an attractive option. The γ-herpesvirus, Epstein–Barr virus (EBV) is also associated with a heterogeneous range of malignancies and diseases that occur in apparently immunocompetent individuals and since these malignancies also express "foreign" viral antigenic targets they may also be good candidates for immunotherapy (Rickinson and Kieff, 2001). The advances in such adoptive immunotherapeutic approaches will be discussed in this chapter.

Therapy for herpesvirus-related infections and diseases

Infectious complications relating to herpes simplex virus (HSV), varicella zoster virus (VZV) (Asanuma *et al.*, 2000), Kaposi's sarcoma virus (KSV) (Wang *et al.*, 2000), human herpesvirus (HHV)-6, -7 (Clark, 2002; Clark *et al.*, 2003; Clark and Griffiths, 2003), cytomegalovirus (CMV) (Michaelides *et al.*, 2002) and EBV (Heslop *et al.*, 1994) are common in immunocompromised individuals. In particular, during allogeneic HSCT and SOT, conditioning regimens involving a combination of immunosuppressive drugs and radiation therapy eliminate the recipient immune system. T-cell depletion, delayed T-cell recovery *in vivo*, and prolonged immunosuppressive treatments are all associated with a significant risk of herpesvirus reactivations post-transplant. In the HSCT setting, immune recovery occurs after engraftment and expansion of the recipient immune system, in vivo (Weinberg *et al.*, 2001). However, following SOT the patient remains in an immunosuppressed state lifelong, and thus the recipient immune system can never achieve its full potential. Treatments for herpesvirus infections include vaccination approaches, which aim to evoke an immune response by administration of an immunogen, as a peptide or DNA, directly into patients. However, in the immunocompromised host, vaccines may not function optimally. Anti-viral drugs, such as acyclovir and ganciclovir inhibit productive virus replication in vivo, and can effectively control α- and β-herpesvirus infections, in which disease is associated with the lytic life cycle. However in the case of CMV, antiviral drugs appear to alter subsequent reactivations such that antiviral T-cells recover less effectively, leading to a late, chronic CMV-reactivation, particularly in association with chronic graft vs. host disease (GvHD) (Junghanss *et al.*, 2002; Nguyen *et al.*, 1999). In addition, drug resistant escape mutants have been reported (Springer *et al.*, 2005; Razonable and Paya, 2003).

Most antiherpes viral agents are prodrugs that are activated by lytic cycle kinases, and thus have limited efficacy against γ-herpesviruses, such as EBV, whose pathology is associated with its latent cycle. EBV-associated lymphoproliferative disease (LPD) in which virus-transformed

Table 74.1. Human herpesviruses

Herpesvirus subgroup	Virus	Tumor association
alpha	HSV-1	none
	HSV-2	none
	VZV	none
beta	CMV	none
	HHV-6	none
	HHV-7	none,
gamma	EBV	Burkitt's lymphoma, Gastric carcinoma, Nasopharyngeal carcinoma, Hodgkin's disease, Post-transplant lymphoproliferative disease, T-cell lymphoma, Leiomyosarcoma
	HHV-8	Kaposi sarcoma of HIV positive and negative patients, body cavity lymphoma, Castleman's disease

B-cells proliferate in an uncontrolled manner, has emerged as a significant complication of both HSCT (d'Amore *et al.*, 1991) and SOT (Straathof *et al.*, 2002; Savoldo *et al.*, 2001). EBV is also linked with a number of tumors that are not associated with iatrogenic or intrinsic immunosuppression including Hodgkin's disease (HD), nasopharyngeal carcinoma (NPC), and Burkitt's lymphoma (BL). (Rickinson and Kieff, 2001.) A recent advance in the treatment of EBV-LPD in HSCT recipients has been the humanized anti-B cell monoclonal antibody, rituximab, designed for the treatment of follicular lymphoma, but which has proved effective for the treatment of EBV positive B-cell lymphomas (Kuehnle *et al.*, 2000). However, rituximab has little efficacy against HD, which rarely express CD20, or NPC (Table 74.1).

The potential for using in vitro expanded virus-specific CTLs as either prophylaxis or treatment for viral infections/reactivations stemmed from the observation that viral reactivations post-transplant were clearly associated with the lack of recovery of virus-specific T-cells. Donor leukocyte infusions (DLIs) had therapeutic benefits for the treatment of EBV positive lymphomas occurring after HSCT (Papadopoulos *et al.*, 1994). However, GvHD resulting from the presence of alloreative T cells was a common side effect, and a pure population of virus-specific cells was predicted to be safer and therapeutically beneficial. Since CMV- and EBV-associated diseases remain potentially fatal complications in the immunosuppressed these viruses have been the focus of adoptive immunotherapy approaches. A variety of strategies have been developed, some of which have been translated into the clinic and assessed for safety and efficacy and a number of these will now be reviewed.

Cytomegalovirus

As many as 80% of healthy individuals show evidence of past CMV exposure and persisting humoral and cellular immunity. The virus remains latent in cells of the myeloid lineage but reactivation from their resting state occurs sporadically, (Mocarski and Courcelle, 2001; Pass, 2001). Analysis of the T cell immune response to individual CMV proteins has indicated that there is a hierarchy of immunodominance, i.e. certain proteins tend to be strong targets of T-cell immunity while other proteins are subdominant. In the case of CMV the bulk of the CD8+ T cell immune response is directed against two immunodominant proteins, pp65 and IE (Bunde *et al.*, 2005; Kern *et al.*, 2000). pp65 is a matrix protein produced during the late phase, and it is thought that during primary infection, the initial viral input dominates the immune response, since the presentation of subsequently expressed viral proteins to the immune response is inhibited. Conversely, reactivation of virus from a resting state may result in the formation of T-cell memory dominated by the immediate early (IE) protein, which is transcribed prior to the initiation of viral immune evasion strategies. Thus IE may also be an important target for CTL infusions.

Epstein–Barr virus

The γ-herpesvirus, EBV, establishes latent infections in target B-lymphocytes, (Rickinson and Kieff, 2001; Rickinson and Moss, 1997)). In type III latency the eight virally encoded latent cycle proteins; nuclear antigens EBNAs 1, 2, 3A, 3B, 3C, -LP and latent membrane proteins LMPs 1 and 2, along with two small non-polyadenylated RNAs (or EBERs) and the BamHI A RNAs cause continuous B-cell proliferation resulting in EBV-transformed lymphoblastoid cell lines (LCLs). Latency types I and II demonstrate a more restricted pattern of latent gene expression. Latency II was first described in EBV-positive Hodgkin's disease where the EBERs, the BamHI A RNAs, EBNA1, and LMP1 and 2 are expressed. EBV-associated nasopharyngeal carcinoma (NPC) also expresses a latency II pattern of gene expression. Latency I was first described in EBV-positive Burkitt's lymphoma (BL) lines, which express EBERs, the BamHI A RNAs, and EBNA1 (Rickinson and Kieff, 2001). Note that EBNA1 is the only viral protein expressed in all the different forms of malignancy-associated latency, and in each type of latency a different transcriptional promoter is used for EBNA1 expression (Amyes *et al.*, 2003). This protein is absolutely required for episomal maintenance of the viral genome. However, in a cell, which is not cycling, it is thought

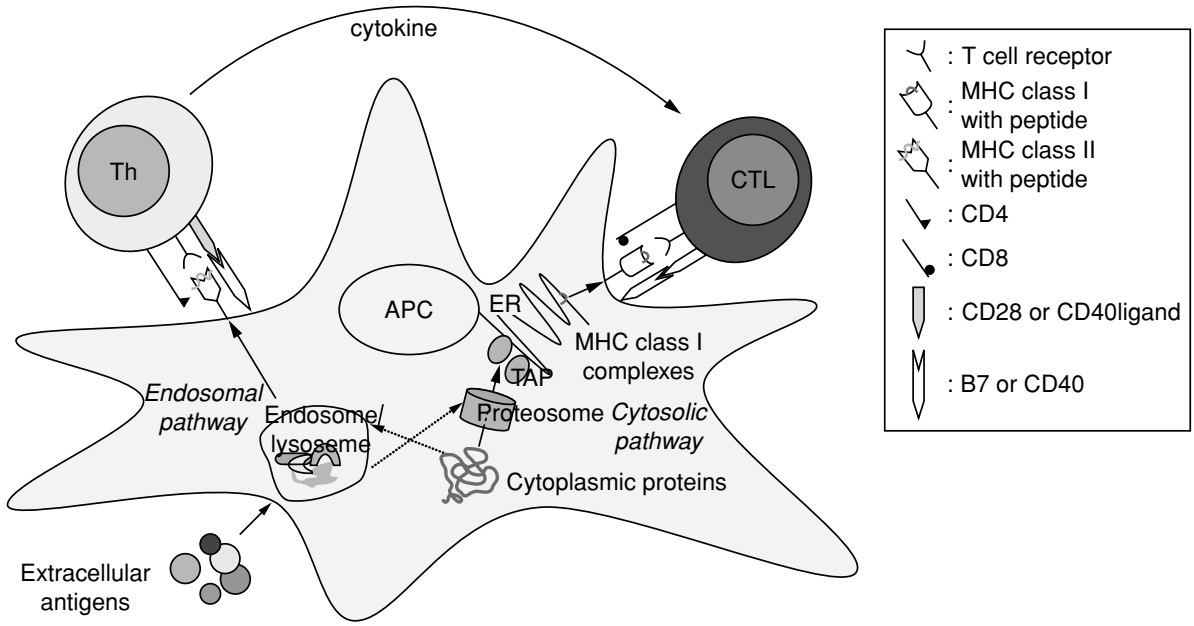

Fig. 74.1. Generation of cell-mediated immune response. (See color plate section.)

that virus persists without the expression of EBNA1, and only LMP2 can be detected in EBV-infected resting B-cells (type 0 latency) (Qu and Rowe, 1992; Tierney *et al.*, 1994; Miyashita *et al.*, 1997).

Initial work identifying the targets of the strong specific memory T-cell response in healthy seropositive donors demonstrated the dominance of reactivities against early lytic cycle proteins and the latent antigens EBNA3A, -B, and –C in the majority of individuals tested, restricted through a wide range of MHC class I alleles. LMP2 is also a common target for specific T-cells but reactivity is generally weak and of low frequency, when compared to that of the immunodominant antigens. In contrast, only rare reactivities specific for epitopes derived from EBNA1, EBNA2, EBNA-LP, and LMP1 have been identified (Rickinson and Moss, 1997). Memory T-cells specific for the latency-associated antigens persist throughout the lifetime of the normal healthy host and the frequency of CTL precursors directed against different viral epitopes remains relatively stable within an individual (Hislop *et al.*, 2002; Amyes *et al.*, 2003).

T-cell activation

The design of successful immunological strategies to treat human virus-associated diseases and malignancies requires an understanding of the effector processes that control viral infection and the mechanisms viruses use to evade such responses.

Virus-specific CD4+ Th cells and CD8+ CTLs mediate the effector mechanisms necessary to resolve acute infection as well as providing immune memory, which protects against re-exposure to acute virus infection and controls the reactivation of latent viruses (Abbas *et al.*, 1996). CD8+ CTLs recognize virus-infected cells through interaction of their T-cell receptor with virus-derived peptides bound to the major histocompatibility complex (MHC) class I molecule of the infected cell. Viral proteins endogenously synthesized in the infected cell are degraded into short antigenic peptides by the cellular antigen-processing machinery, carried to the cell surface by MHC molecules, where they are presented to T-cells circulating through lymphoid tissues. These peptides are generally 8–10 amino acids long, generated within cells by a cytoplasmic proteolytic complex known as the proteosome and then transported into the endoplasmic reticulum by TAP (transporters associated with antigen processing), where they are complexed with MHC class I molecules for cell surface presentation (Jondal *et al.*, 1996; Pamer and Cresswell, 1998). Since virtually all nucleated cells express MHC class I, any virus-derived protein may be presented by MHC class I molecules and should be susceptible to subsequent recognition by specific CD8+ T-cells. A role for CD8-mediated viral control has clearly been documented in animal models, further supported by the identification of a number of mechanisms whereby viruses have evolved ways of evading the MHC class I antigen presentation pathway (McMichael, 1998) (Fig. 74.1).

For activating (priming) naïve CTL precursors, antigenic peptides must be presented by professional APCs, which also provide the necessary co-stimulatory signals (i.e., interaction of B7 or CD40 on APC with CD28 or CD40L on T-cells, respectively) (Sigal *et al.*, 1999). If the T-cell receptor is engaged without costimulatory signals, T-lymphocytes can become anergized. However, activated CTLs do not need costimulatory molecules to exert their effector functions, namely, cytolysis or induction of apoptosis of the target cell. Importantly, target cells frequently do not express co-stimulatory molecules. CMV and EBV are interesting exceptions in which latency occurs in professional APCs.

CD4+ T-cells play a role in antibody responses and also recognize antigens that are phagocytosed from an exogenous source, and processed and presented in the context of MHC class II molecules. Only APCs that are MHC class II-positive can activate CD4+ T-cell precursors. CD4+ T-cells also play a role in anti-viral immunity; activated Th cells produce a variety of cytokines including IL-2, IFN-γ, and TNF-α, which have direct anti-viral activity. Simultaneously, these activated T-cells also serve to condition APCs to activate virus-specific CTLs. When the infected cell is MHC class II positive, CD4+ T-cells can also be cytolytic to the target cells and this function has been clearly demonstrated for herpesvirus infections including CMV, EBV, HSV, and VZV (Lanzavecchia, 1996; Borysiewicz and Sissons, 1994).

Strategies for producing T-cells for adoptive immunotherapy

The generation of virus-specific CTLs or T-cell clones for adoptive immunotherapy is an attractive alternative to anti-viral drug therapy as infused CTLs have the potential to persist in vivo without related toxicity. Prior to using in vitro expanded CTLs for infusion purposes the cells must fulfil a number of requirements.

(i) All cell preparation must be carried out under good manufacturing practices (GMP).
(ii) CTL lines or T cell clones must be virus-specific and lack reactivity with recipient alloantigens or self-antigens.
(iii) CTL lines/clones should include both specific CD4+ and CD8+ T-cells.
(iv) Cells for infusion must be present in sufficient quantities for safety testing and infusion.

To meet these requirements the choice of antigen and APC to be used for activation and expansion purposes must be carefully chosen, and immunological and virological monitoring of patients post-infusion is desirable to demonstrate the safety and efficacy of T-cell therapy. Since immunodominant T-cell target antigens and sources of APCs have already been identified for both CMV and EBV, and related infections constitute a significant problem in the immunocompromised human host, initial adoptive immunotherapeutic strategies focused on these two herpesviruses.

Adoptive immunotherapy for cytomegalovirus

A number of factors are predictive of CMV infection post-HSCT transplant including:

(i) receiving a graft from an HLA-mismatched or unrelated donor,
(ii) recipient CMV seropositivity coupled with donor CMV-negativity,
(iii) the use of submyeloablative or reduced intensity, highly immunosuppressive conditioning regimens.

It has been shown that recovery of CD8+, CMV-specific CTLs in the early post-transplantation period inversely correlates with the development of CMV-related disease, and it has been reported that, in up to 65% of patients, CMV-specific CTLs do not develop during this period, leaving this cohort at high risk of virus-related complications (Pass, 2001). In a pioneering study by Walter and colleagues, CD8+ CMV-specific T cell clones were isolated and expanded from the blood of bone marrow donors and administered to 14 patients prophylactically at weekly intervals in doses escalating from 3.3×10^6/kg to 1×10^9/kg, beginning 30–40 days post-transplant (Walter *et al.*, 1995). The infused clones were reactive against CMV virion proteins, including the immunodominant T-cell target, pp65. Careful monitoring of the status of CMV-specific immunity pre-infusion indicated that 11 of the 14 donors lacked any evidence of anti-viral activity pre-infusion, while after the first infusion responses were detected in all donors. The magnitude of these responses increased with successive injections but specific CD8+ T-cell immunity did not persist in patients who did not have a concurrent recovery of CD4+ T-cells, highlighting the importance of Th cells in the maintenance of anti-viral activity *in vivo*. In a number of infused recipients the authors could directly correlate CMV T-cell immunity and the persistence (for up to 12 weeks) of transferred T-cells by following rearranged Vα and Vβ genes for the T-cell receptor (TCR) as molecular markers. Neither CMV viremia nor disease developed in any of the treated patients (Walter *et al.*, 1995).

A second CMV immunotherapy trial was published by Einsele and colleagues in 2002 (Einsele *et al.*, 2002). Polyclonal CMV-specific CTL lines were infused into eight HSCT recipients who had persisting or recurring CMV infection despite the prolonged use of anti-viral medications. Donors were CMV sero-positive and included HLA-matched

siblings, HLA-matched unrelated donors, or HLA mismatched related or unrelated donors. At the time of the first CTL infusion, seven of the eight patients treated were still receiving some form of immunosuppression as prophylaxis for GvHD.

Polyclonal CTL lines were prepared by stimulating PBMCs with CMV lysate, which is a source of multiple CMV antigens that could be phagocytosed and presented by peripheral blood monocytes. The CTLs were expanded using autologous, irradiated PBMC feeder cells to present CMV lysate, and IL-2. A total T-cell dose of $1 \times 10^7/m^2$ was administered without toxicity. In all cases the lines were predominantly CD4+ and CMV specificity was confirmed prior to infusion using proliferation assays. The advantage of this method is that CTL lines containing both CD4+ and CD8+ T-cells with a broad range of antigen and epitope specificities could be induced and infused. The efficacy of CTL infusions was assessed using immunological assays to measure the functional capabilities of PBMCs drawn from patients at two-weekly intervals postinfusion and viral load was assessed using quantitative or semi-quantitative PCR analysis.

Following T-cell therapy, six of the eight patients, all of whom lacked anti-CMV reactivity before adoptive transfer, responded in vitro to CMV protein and had no detectable levels of CMV in PBMCs. Viral load as determined by quantitative PCR showed significant reductions following therapy in 7/7 evaluable patients. This reduction in viral load was persistent in five, and transient in two patients. Two patients who did get a CMV reactivation received a course of intense immunosuppression for GvHD around the time of T-cell therapy. Immunological monitoring supported the assertion that infusion of virus-specific CD4+ T-cell lines hastened the *in vivo* recovery of virus-specific CD8+ T-cells, as significant expansions of peptide-specific CD8+ T-cells, detectable by tetramer, were discernible within 2 months of therapy.

This trial confirmed the efficacy of T-cell therapy, either as prophylaxis or treatment, for CMV infection and disease post-HSCT. It also provided a simple and rapid means to reconstitute long-term CD4 and CD8 CMV-specific immunity using CTL doses >2 logs lower than that used in the previous study.

Despite the positive outcome of both these trials there were also some associated difficulties. In the case of Walter and colleagues the methodology used for CTL clone generation required a skin biopsy for the generation of dermal fibroblasts for use as APCs. In addition, live virus was used to stimulate specific CD8+ T-cell reactivity. From a therapeutic point of view, each T-cell clone can only be specific for one epitope peptide from one antigen. Therefore the breadth of reactivities generated for infusion may be lacking in some donors depending on the number of different clones infused, and the paucity of CD4+ cells probably affected the persistence of these cells in vivo. Finally, from a practical point of view the generation of large numbers of specific T-cell clones for infusion is time consuming, technically difficult, and expensive.

In the second study, CTL lines could be generated for only 68% of patients, suggesting that CMV CTL generation using PBMCs pulsed with CMV lysate may be a suboptimal production method. Further optimization, perhaps by using professional APCs, may improve the overall percentage of successful lines generated. Both studies reported poor results achieved in patients receiving immunosuppressive therapy to counteract GvHD, illustrating one potential barrier to effective immunotherapy for HSCT recipients in the early post-transplant period.

Adoptive immunotherapy for EBV post-transplant lymphoproliferation disease

The majority of EBV-PTLD in HSCT recipients are of donor B-cell origin. Malignant B-cells usually express the complete panel of latent viral antigens, as well as abundant co-stimulatory molecules. Thus, they are highly immunogenic, and in healthy individuals are eliminated by circulating EBV-specific CTL. The incidence of EBV lymphoproliferation in high-risk patients, i.e. those receiving a T-cell depleted transplant from an unrelated donor or an HLA-mismatched, related donor, ranges from 1% to 25% (Curtis *et al.*, 1999). By contrast, removal of B-cells from the graft decreases the incidence to less than 2%, suggesting that uncontrolled EBV-driven lymphoproliferation may be favored when the ratio of T-: B-cells is severely disrupted (Hale and Waldmann, 1998). An increase in EBV DNA in peripheral blood, measured by quantitative real time PCR is used to predict the development of EBV-LPD, with several studies confirming that EBV load correlates with an increased risk of LPD (Rooney *et al.*, 1995a,b; Stevens *et al.*, 2001; van Esser *et al.*, 2002; Wagner *et al.*, 2003).

EBV-associated PTLD is a good target for immunotherapy since most donors are seropositive, and EBV-specific CTLs can readily be reactivated from PBMC using LCLs as APCs for stimulation and expansion. LCLs are easily made by infecting donor PBMCs with a laboratory strain of EBV, resulting in the outgrowth of B-cell lines expressing target antigens identical to those expressed in LPD. Since 1993, our group has infused over 60 stem cell recipients with donor-derived EBV-specific T-cell lines. 2×10^7CTL/m^2, was established as a safe and efficacious dose for both

prophylaxis and treatment (Rooney *et al.*, 1995a,b 1998a,b). In each case the CTL lines were polyclonal, with CD4:CD8 ratios ranging from 2:98 to 98:2. The first 26 patients enrolled in this study received CTLs which were genetically marked with a retroviral vector containing the neomycin resistance gene (*neo*), allowing the collection of data about the persistence and localization of infused cells in vivo. In addition, 6 patients received virus-specific CTL after the onset of lymphoma.

None of the patients treated with EBV-specific CTL as prophylaxis developed PTLD, in contrast with an incidence of 11.5% in a historical untreated control group (Heslop and Rooney, 1997). At study entry 9 patients had elevated EBV–DNA levels, which is highly predictive of the development of LPD. Analysis of EBV-DNA levels postinfusion showed direct evidence of anti-viral activity as DNA levels decreased by up to four logs within 1–3 weeks of the first T-cell infusion. In patients who received marked cells, specific CTLs could be detected for up to 78 months post CTL (Rooney *et al.*, 1998a,b).

Although CTL had proven effective at decreasing viral load, it was uncertain whether infusions of T-cells could be successful in treating an already established lymphoma. We treated a total of six patients with evident lymphoma and in five of the six patients complete remission was achieved. In the remaining patient, comprehensive in vitro characterization revealed the increased dominance of a virus deletion mutant after CTL infusion (Gottschalk *et al.*, 2001). The donor CTL line generated by co-culture of donor PBMCs with an LCL generated using the B95-8 virus strain revealed epitope reactivity directed predominantly against the immunodominant EBNA3B antigen, and specifically against two immunodominant epitope peptides within this antigen; namely AVFDRKSDAK (AVF), aa 399–408 and IVTDFSVIK (IVT), aa 416–424, both recognized in the context of the HLA A*11 allele (Gottschalk *et al.*, 2001). Sequence analysis of the resident patient tumor revealed two resident viruses. One harbored a deletion in the EBNA3B gene, which removed the AVF and IVT peptide sequences. Since the virus with the wild type EBNA3B could no longer be detected after CTL infusion, the CTL line had reduced ability to recognize the mutant virus. This is a concern for all adoptive immunotherapy protocols as this case illustrates that, even in a polyclonal system, a mutation in a tumor-specific antigen can ultimately result in tumor escape.

In total over 160 patients received CTLs, most as prophylaxis and 6 as treatment for established lymphoma. In one patient who received CTL for treatment of bulky nasopharyngeal disease, the infusion caused an inflammatory response which required mechanical ventilation. However the child made a full recovery and achieved complete remission (Straathof *et al.*, 2005). The authors were unsuccessful in generating a CTL line for two eligible patients whose donors were EBV-seronegative. An additional problem with CTL use is that the total time for LCL and CTL production and testing is approximately 12 weeks, while the aggressiveness of this lymphoma means that CTL should be administered prophylactically for high-risk patients. Despite this, in the absence of effective antiviral agents, adoptive immunotherapy was an attractive alternative as EBV-specific CTLs are safe and effective at controlling and treating EBV in high-risk patients post-transplant. More recently, monoclonal anti-B-cell antibodies such as rituximab demonstrated overall response rates of 69%–100% when used as a treatment for LPD post HSCT (Kuehnle *et al.*, 2000). Since rituximab is now widely available, it has now largely replaced CTL as the preferred treatment of EBV after HSCT. In the 6 months usually required for B cell recovery after treatment, endogenous antiviral immunity recovers and is able to control EBV when it reappears.

Adoptive immunotherapy for EBV post-solid organ transplant

Although it has been shown that adoptive immunotherapy is an effective treatment of EBV-LPD in the HSCT recipient, the optimal treatment for patients receiving solid organ transplants has yet to be established. In this cohort, LPD is usually of recipient origin, thus the preparation of EBV-specific CTLs requires the use of autologous or HLA-matched cells. Autologous EBV-specific CTL can be generated from the peripheral blood of SOT patients prior to transplant (Haque *et al.*, 1998), but a number of groups have also reported the successful generation of virus-specific CTL lines from patients receiving immunosuppression, including those with overt lymphoma, showing that EBV-specific CTL persist, but are unable to function in vivo (Straathof *et al.*, 2002; Savoldo *et al.*, 2001; Khanna *et al.*, 1999; Comoli *et al.*, 2002). Ten SOT patients with high viral load received autologous EBV-specific CTLs and eight showed a subsequent normalization of EBV–DNA levels and an increase in virus-specific CTL precursors (Haque *et al.*, 1998; Comoli *et al.*, 2002). Until recently, the persistence of infused CTL had not been examined (Savoldo *et al.*, 2001; Comoli *et al.*, 2002). Savoldo and colleagues have investigated the in-vivo safety, efficacy and persistence of autologous EBV CTL for the treatment of SOT recipients at high-risk for EBV-associated PTLD (Savoldo *et al.*, 2006). Twelve SOT recipients at high risk for PTLD,

or with active disease, received autologous CTL infusion without toxicity. Real-time PCR monitoring of EBV-DNA showed a transient increase in plasma EBV-DNA suggestive of lysis of EBV-infected cells, although there was no consistent decrease in virus load in peripheral blood mononuclear cells. Interferon-γ Elispot assay and tetramer analysis showed an increase in the frequency of EBV-responsive T cells, which returned to pre-infusion levels after 2–6 months. None of the treated patients developed PTLD. One patient with liver PTLD showed a complete response, and one with ocular disease had a partial response stable for over one year (Savoldo *et al.*, 2006). These data are consistent with an expansion and persistence of adoptively transferred EBV-CTL, that is limited in the presence of continued immunosuppression, but that nonetheless produced clinically useful anti-viral activity.

Adoptive transfer of EBV-specific CTL for Hodgkin's lymphoma

Having shown that EBV infected cells, which express a wide range of EBV encoded antigens, are susceptible to immunotherapy our group is now evaluating if the malignant cells of Hodgkin's disease, which express a more restricted pattern of antigens, are also targets for this approach. In a Phase I dose escalation study we have evaluated the use of autologous EBV-specific CTL for patients with EBV-positive Hodgkin's disease (Roskrow *et al.*, 1998). We treated eight patients with relapsed Hodgkin disease with two infusions ($2 \times 10^7/m^2$–$1.2 \times 10^8/m^2$) of EBV-specific CTL. In seven of these patients the CTL were retrovirally marked. Increases in anti-viral immunity, and decreases in virus load demonstrated the in vivo biological activity of the infused CTL and gene-marked T cells could be detected for up to 9 months. Trafficking to tumor sites was demonstrated in two patients by in situ hybridization to the *neo* marker gene in mediastinal tumor tissue and by PCR in a malignant pleural effusion. Further, partial tumor responses were observed. However, no patient with bulky disease was cured. In a second group, treated with CTL as adjuvant therapy after autologous stem cell rescue, four of five patients remain in remission over 24 months after CTL infusion, including one patient who had residual disease after HSCT and prior to CTL infusion.

Although these results have been promising the antiviral responses were transient, and no patient with aggressive relapsed Hodgkin's disease has been cured. This may be due to a lack of specificity of the EBV-specific CTL for the subdominant LMP1 and LMP2 antigens present on the Hodgkin's tumor. Using dendritic cells transduced with LMP2 to stimulate and expand the CTL, LMP2-specific CTL have been generated that have an increased cytolytic activity to LMP2 positive targets in vitro when compared to EBV-CTL (Gahn *et al.*, 2001; Rooney *et al.*, 2002; Bollard *et al.*, 2004). A clinical trial using LMP2-specific CTL for the treatment of Hodgkin's and non-Hodgkin's lymphoma expressing a type II latency has recently begun.

Adoptive transfer of EBV-specific CTL for nasopharyngeal carcinoma

Nasopharyngeal carcinoma is a malignant disease with a variable range of incidence depending on age, geographical location, race, and EBV exposure. It has an annual incidence of nearly 1 case per 100 000 children <21 yrs in the USA (Niedobitek, 2000). The non-keratinizing NPCs are uniformly associated with EBV. Despite the good overall survival rates, particularly in children, current NPC treatment regimens including radiotherapy and chemotherapy are still far from ideal. Follow-up reports have shown increased risks for treatment-related morbidity and mortality (Pao *et al.*, 1989). Late medical complications after treatment for NPC include growth hormone deficiency, hypothyroidism, pulmonary fibrosis, and secondary malignancies. It is therefore, desirable to develop novel therapies that could improve disease free survival in relapsed/refractory patients and which might ultimately reduce the incidence of long-term treatment related complications in all patients.

Chua *et al.*, treated four patients with advanced nasopharyngeal carcinoma with 5×10^7–3×10^8 autologous EBV CTL (Chua *et al.*, 2001). Although it was difficult to confirm improved tumor control in these patients who had significantly bulky disease, the treatment was safe and elevations in CTL precursor frequency were seen. In 3 patients, host surveillance of EBV replication was restored resulting in a reduction in the plasma EBV burden. Straathof and colleagues have treated 10 patients with advanced NPC with autologous CTLs. All patients tolerated the CTLs, although one developed increased swelling at the site of pre-existing disease. At 19 to 27 months after infusion, 4 patients treated in remission from locally advanced disease remain disease free. Of 6 patients with refractory disease prior to treatment, 2 had complete responses, and remain in remission over 11 to 23 months after treatment; 1 had a partial remission that persisted for 12 months; 1 has had stable disease for more than 14 months; and 2 had no response. These results demonstrate that administration of EBV-specific CTLs to patients with advanced NPC is feasible, appears to be safe,

and can be associated with significant antitumor activity (Straathof *et al.*, 2005).

For EBV+ve tumors, such as HD and NPC, which arise in patients with an intact immune system, approaches that overcome immune evasion strategies used by these immunogenic tumors may be required. Further improvements in the *in vivo* function and persistence of CTL may require genetic modification of CTL lines to provide resistance to tumor-derived immunosuppressive chemokines and cytokines (Bollard *et al.*, 2002; Foster and Rooney, 2006). Alternatively, modifications to the host or tumor environment may be sufficient (Dudley *et al.*, 2002).

Multivirus-specific CTL lines

Since both EBV and CMV reactivations are common side effects post-transplant, some groups have considered generating bi-virus specific CTLs for infusion purposes (Sun *et al.*, 1999, 2000). Lucas and colleagues carried out a phase I/II clinical protocol for the generation and infusion of EBV and CMV-specific CTL, initiated by culturing donor-derived PBMC with irradiated donor-derived LCL transduced with a retrovirus expressing pp65 (Lucas *et al.*, 2000). Two further stimulations with the transduced LCL were performed before assessing the CMV and EBV-specific cytolytic activity of the line. Clinical data is not yet available from this study. Our group has also generated multivirus-specific CTL lines for therapeutic purposes by genetically modifying APCs to enable production of $CD4^+$ and $CD8^+$ T lymphocytes specific for CMV, EBV, and multiple serotypes of adenovirus from a single cell culture. Eleven multivirus-specific CTL lines were administered as prophyaxis or treatment to immunocompromised patients. In all cases the single T lymphocyte line was able to expand in vivo into multiple discrete virus-specific populations that could supply clinically measurable antiviral activity, and all patients with evidence of active CMV, EBV or adenoviral infection had a relatively rapid reduction in viral titer and resolution of disease symptoms, which coincided with the expansion of virus-specific CTL. Therefore, we can conclude that monoculture-derived multispecific CTL could provide a safe and efficient means to restore virus-specific immunity in the immunocompromised host (Leen *et al.*, 2006b).

CMV and EBV immunotherapy in HIV positive individuals

Adoptive immunotherapy approaches have been applied to the treatment of acquired immunodeficiency syndrome (AIDS) where pathogenicity is synonymous with the depletion of CD4+ T-lymphocytes, and the consequent increased susceptibility to infections, either from *de novo* exposure or reactivation of latent viruses such as EBV (Riddell *et al.*, 1996). To date, no group has targeted the herpesvirus infections/reactivations that occur as a result of HIV-induced immunosuppression. Brodie and colleagues have assessed the safety and efficacy of expanding and transferring up to 3.3×10^9 cells/m^2 autologous HIV-1 specific, Gag-specific CD8+ T-cell clones to HIV-infected individuals, and reported the accumulation of the transferred cells at sites adjacent to HIV-infected cells in the lymph nodes (Brodie *et al.*, 1999; Brodie *et al.*, 2000). In addition, levels of circulating productively infected CD4+ T-cells transiently decreased. However within 7 days of infusion the percentage of productively infected cells had returned to pre-infusion levels, suggesting that adoptive immunotherapy may not be efficacious in this patient cohort. Since the advent of highly active antiretroviral therapy (HAART) the incidence of EBV+ve CNS lymphomas has decreased. Strangely and perhaps controversially however, the incidence of other EBV+ve lymphomas has not (Levine *et al.*, 2001). Since the overall health and life expectancy of patients with HIV has improved with HAART, the potential for adoptive transfer of herpesvirus-specific T-cells in these patients should perhaps be revisited.

Alternative approaches for activating virus-specific CTLs

In the outlined adoptive immunotherapy approaches there are a number of differences in terms of the phenotype of the infused cells, the choice of antigen for activation, the APC utilized to stimulate T-cells, the CTL expansion methods, and also the numbers of cells that are infused. The relative advantages and disadvantages of these methods, as well as alternative approaches which may be attempted in future studies, will be discussed.

Clones vs. polyclonal lines

The original Riddell CMV immunotherapy protocol, which proved efficacious in vivo, relied on the infusion of large numbers (3.3×10^6 cells/kg to 1×10^9 cells/kg) of CD8+ T-cell clones (Walter *et al.*, 1995). In contrast, infusion of smaller numbers (1×10^7–2×10^7/m^2) of polyclonal, virus-specific CD4+ and CD8+ CTL lines proved efficacious in the context of CMV and EBV prophylaxis and/or treatment in the transplant and tumor setting, suggesting that a mixed population of CD4+ and CD8+ T-cells rather than

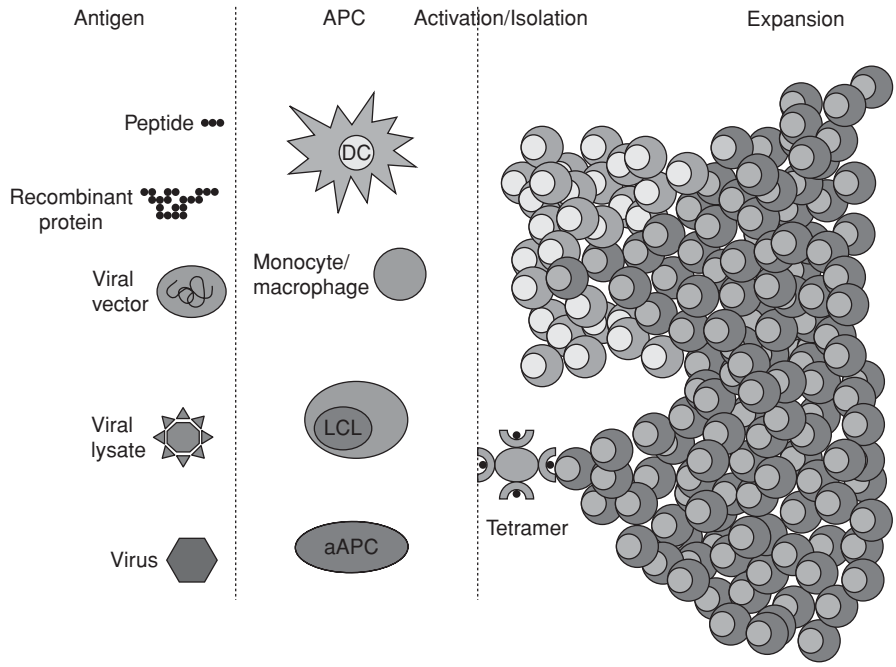

Fig. 74.2. Generation of antigen-specific T-cells.

the quantity of cells is the important factor for infusion purposes in situations where the recipient immune system has been depleted (Einsele *et al.*, 2002; Rooney *et al.*, 1995a,b; Peggs *et al.*, 2003).

Antigen

There are a number of options when choosing a source of antigen to stimulate an immune response. Riddell and colleagues used live CMV, (Walter *et al.*, 1995) and Einsele *et al.* utilized CMV lysate to stimulate CMV-specific immunity, (Einsele *et al.*, 2002) while Rooney and colleagues used an EBV-transformed B-cell line expressing EBV lytic and latent antigens to stimulate an immune response (Rooney *et al.*, 1995a,b). Alternative sources of antigen, which have been investigated in *in vitro* studies, include live or inactivated virus, recombinant protein, replication-defective viral vectors expressing one or more immunodominant T cell target antigens (Bonini *et al.*, 2001), or antigenic peptides (Fig. 74.2) (Foster *et al.*, 2003; Szmania *et al.*, 2001). Since the recipients of adoptively transferred T-cells are profoundly immunosuppressed, the use of live/attenuated virus is unwise, but replication incompetent viral vectors expressing a transgene may offer the ideal antigen source, capable of stimulating both CD4+ and CD8+ T cell simultaneously.

APC

The choice of APC for activation of an immune response may differ from that chosen to expand cells to the numbers necessary for infusion and GMP testing. In the case of EBV, LCLs provide an excellent APC with which to stimulate and expand polyclonal EBV-specific T-cells. However, when one considers the treatment of other EBV-associated malignancies such as Hodgkin's disease or NPC where gene expression is limited to the sub-dominant T-cell target antigens LMP1 (Gottschalk *et al.*, 2003), LMP2, and EBNA1, the use of LCLs is problematic since reactivity to early lytic cycle antigens and the immunodominant EBNA3 proteins is preferentially expanded (Rooney *et al.*, 2002; Gottschalk *et al.*, 2003; Rooney *et al.*, 1998, 2001). Thus, transducing LCLs, activated monocytes, or DCs with a viral vector which over-expresses the tumor-associated antigens may be advantageous for the simulation and expansion of a CTL line with more focused reactivity (Keever-Taylor *et al.*, 2001; Leen *et al.*, 2006a). In the case of CMV, where there is a distinct lack of an ideal APC, a number of groups have relied on the generation of DCs, which are then pulsed with CMV lysate or epitope peptide (Szmania *et al.*, 2001), or transduced with vectors expressing immunodominant T-cell antigens (Bonini *et al.*, 2001; Keever-Taylor *et al.*, 2001), as a means to stimulate reactivity (Fig. 74.2). However, although DCs are the most potent APCs available, their inability to

proliferate in vitro means that large blood volumes are required to produce sufficient DC for CTL expansion, therefore DC numbers are limiting, and DC generation is time consuming.

Selection of specific T-cells

More recently, tetramer technology has facilitated the isolation of antigen-specific T-cells directly from peripheral blood (Fig. 74.2). Tetramers consist of four biotin-labeled HLA molecules bound together with streptavidin (Altman *et al.*, 2001) and labeled with fluorochrome. Each HLA molecule is associated with a peptide epitope that binds to peptide-specific CTLs, which can then be directly visualized and isolated by fluorescence-activated cell-sorting (FACS). Once isolated, these cells can either be infused immediately or expanded ex vivo. This method precludes the carry-over of contaminating alloreactive T-cells, which could potentially induce GvHD in vivo. Cobbold and colleagues have recently used this approach to select CMV-specific T cells for the treatment of HSCT patients. CMV-specific $CD8^+$ T cells were isolated from the blood of stem cell transplant donors using HLA-peptide tetramers followed by selection with magnetic beads. The selected cells were infused directly into nine patients within 4 hours of selection. The cell dose was lower than those infused in conventional immunotherapeutic strategies (medium cell dosage was $8.6 \times 10(3)$/kg), however CMV-specific $CD8^+$ T cells became detectable in all patients within 10 days of infusion, and TCR clonotype analysis showed persistence of infused cells in two patients studied. CMV viremia was reduced in every case and eight patients cleared the infection, including one patient who had a prolonged history of CMV infection that was refractory to antiviral therapy. This novel approach to adoptive transfer has considerable potential for antigen-specific T cell therapy (Cobbold *et al.*, 2005). However, each tetramer is specific for only one epitope limiting the repertoire of infused T-cells and, as yet, there are limited HLA class II tetramers available. Thus infused CTL lines may not persist in vivo due to lack of CD4+ help, and can be made only for patients with specific HLA phenotypes.

CTL expansion

The ideal immunotherapy protocol requires the generation of polyclonal virus-specific CD4+ and CD8+ T-cells in the shortest time possible. As cells are activated they begin to expand and through subsequent rounds of expansion, more and more APCs are needed for restimulation purposes. In particular, the need to expand large numbers of virus-specific CTLs for infusion post-SOT is a persistent problem. The number of APCs required for such protocols is frequently a limiting factor. Vaz-Santiago and colleagues tried to circumvent this problem by using PBMCs pulsed with a soluble recombinant chimeric protein, IE1-pp65, to activate and expand memory CD4+ and CD8+ CMV-specific T-cells but while CMV-specific T-cells could be activated, the problems associated with the expansion of sufficient numbers of cells for infusion and testing purposes were not dealt with in this study (Vaz-Santiago *et al.*, 2002). Sili and colleagues have addressed this issue by utilizing Ad5f35pp65-transduced DCs to activate specific T-cells and then successfully expanded the stimulated population using autologous LCLs transduced with the Ad5f35pp65 vector, without loss of CMV specificity (Sili *et al.*, 2003). Alternative expansion programs rely on the use of activated B and T cells, or the use of artificial APCs (aAPCs) (Melenhorst *et al.*, 2006; Coughlin *et al.*, 2004; Mans *et al.*, 2003), but to date success has been limited by the loss of antigen specificity over time. An emerging option for both the activation and the expansion of virus-specific T-cells from a mixed PBMC population lies with the development of novel aAPCs based on the use of an antigen-HLA-epitope peptide complex coupled with a co-stimulatory molecule. Oelke and colleagues have recently pioneered such an approach by immobilizing a dimeric HLA immunoglobulin (HLA-Ig) onto beads together with CD28-specific antibody; the HLA molecules is then loaded with a known epitope peptide and used to activate and expand antigen-specific T cells from peripheral blood (Oelke *et al.*, 2003). Resultant CTL lines were compared with those attained by conventional DC stimulation, and aAPC-based CTL activation was found to be equivalent or even better than DC-induced activation, with no appreciable loss in antigen specificity or growth rate detected over time. Thus, future immunotherapy trials may adopt such HLA-based aAPCs as being more cost effective than current methods of CTL generation and expansion. In addition, aAPCs can be prepared in bulk in advance and stored for use at a later date without loss of function, thus a more standardized approach to the generation of CTL lines for immunotherapy purposes is available. However, this method is limited by the requirement for specific peptides for folding into the HLA molecule, which also restricts the breadth of the CTL repertoire.

Regulation

The final barrier to initiating an adoptive immunotherapy trial for the prophylaxis and/or treatment of herpesvirus infections in the human host relates to the extensive

regulations and time consuming applications which must be submitted to a number of regulatory agencies including the Internal Review Board (IRB), Recombinant DNA Advisory committee (RAC), and Food and Drug Administration (FDA) prior to initiation of any novel immunotherapy protocols. Few Institutions have the infrastructure and facilities required to fulfill all of these regulatory requirements. In addition, each reagent needed for the generation of a CTL line must be available as a clinical grade product, necessitating extensive and expensive analysis and testing. To date, for example, not all the components needed for the generation of mature monocyte-derived DCs are obtainable as clinical grade products due to the high costs of quality assurance and control costs which must be undertaken before a product is certified for human use.

Conclusions and future considerations

Herpesviruses are a significant cause of morbidity and mortality in immunocompromised individuals. Adoptive transfer of virus-specific CTLs has proven safe and effective at preventing and treating such infections in a number of instances, but there is room for improvement in the activation and expansion protocols utilized to allow the generation of virus-specific CTL lines in the shortest time possible. The major criticism of many immunotherapeutic approaches discussed is that they rely on the presence of a seropositive donor, from which specific T-cells can be activated and expanded. Thus, extension of this work to include seronegative SOT recipients or stem cell donors will increase the scope of this treatment to include all patients at risk of developing an infection or having a viral reactivation post-transplant (Savoldo *et al.*, 2002; Park *et al.*, 2006). New and more sensitive techniques to accurately monitor viral loads and thus predict viral reactivations in vivo have also been developed and used to predict EBV and CMV infections in immunocompromised individuals, allowing pre-emptive treatment, and monitoring of the efficacy post-treatment (Rooney *et al.*, 1995a; Wagner *et al.*, 2003b). In the future such monitoring may be extended to cover all herpesviruses, thereby utilizing a rational approach to the treatment of resultant infections either using adoptive immunotherapy or conventional antiviral reagents.

Immunotherapy of HSV infections – antibody delivery

David W. Kimberlin

Division of Pediatric Infectious Diseases, The University of Alabama at Birmingham, AL, USA

Passive immunization involves utilizing polyclonal or monoclonal antibodies as a form of immunotherapy. Antibodies can mediate their effects through several mechanisms, including opsonization and C-mediated lysis, but in particular antibody-dependent cell-mediated cytolysis (ADCC) and neutralization. Antibody immunotherapy has been demonstrated to be efficacious for the treatment and prevention of infection or disease caused by viruses other than herpes simplex virus (HSV) (Abzug *et al.*, 1995; Reed *et al.*, 1988; Feltes *et al.*, 2003; Saez-Llorens *et al.*, 1998; Subramanian *et al.*, 1998; The IMpact-RSV Study Group, 1998). While intriguing data exist in animal models suggesting that such a therapeutic intervention may also be of benefit in the management of HSV infections, to date no controlled studies have demonstrated the benefit of such an approach in humans. This chapter explores the potential of such an approach in people, as well as the limitations in current knowledge.

Immune responses following HSV infection

Host resistance to HSV infections includes non-specific mechanisms such as interferons, neutrophils, complement, macrophages, and natural killer cells, as well as specific mechanisms including humoral (antibody) immunity, T-cell-mediated immunity (such as cytotoxic T-cells and T-helper activity), and cytokine release. The relative importance of these various mechanisms is different for initial vs. recurrent HSV disease. Animal studies suggest that activated macrophages, interferons, and, to a lesser extent, natural killer cells are important in limiting initial HSV infection, whereas humoral immunity and cell-mediated immunity are important in controlling both initial and recurrent infections. Adoptive transfer studies suggest that either virus-specific antibody or lymphocytes can protect animals against initial HSV infection (as discussed below), but several lines of evidence suggest that cell mediated immunity responses play the central role in controlling recurrent HSV infections (Koelle *et al.*, 2000; Posavad *et al.*, 1996, 1997, 2000; Stanberry *et al.*, 2000). Mucocutaneous herpes is more severe in patients with impaired or defective cell mediated immunity (Posavad *et al.*, 1997; Whitley *et al.*, 1998), but not in patients with agammaglobulinemia.

Following acquisition of HSV-1 or HSV-2, IgM antibodies appear transiently and are followed by production of IgG and IgA antibodies which persist over time. Both neutralizing antibodies and antibody-dependent cellular cytotoxic (ADCC) antibodies generally appear between 2 weeks and 6 weeks following infection and persist for the lifetime of the host. The host response to virus-specific infected cell polypeptides and the development of neutralizing antibodies have been defined through immunoblot and immunoprecipitation assays (Bernstein *et al.*, 1985; Eberle *et al.*, 1981). Following infection, antibodies directed against glycoprotein (g)B, gC, gD, gE, gG1, gG2, and ICP-4 appear sequentially. Of note, the intensity of host antibody responses to virus-specific polypeptides and high concentrations of neutralizing antibodies are not protective against HSV recurrences.

Neonates

The host responses of neonates with HSV disease differ from those of older children and adults. Infected neonates will produce HSV-specific IgM antibodies (as detected by immunofluorescence) within three weeks of acquisition of the viral infection. HSV-specific IgM concentrations increase rapidly during the first 2 to 3 months, and in some infants may be detectable for as long as one year following

Table 75.1. Protective effect of neutralizing antibody in prevention of neonatal HSV disease

Neutralizing antibody titer (cord blood or 2 weeks of life)	Exposed during delivery but uninfected (n=33)	Exposed during delivery and infected (n=29)
<1:5	0 (0%)	12 (41%) $P<0.00001$
1:5 to 1:20	7 (21%)	15 (52%)
>1:20	26 (79%)	2 (7%) $P<0.0002$

From Prober *et al.* (1987).

neonatal infection. HSV IgG antibodies also appear by 3–4 weeks in most infants. The viral surface glycoproteins gB and gD are the most reactive immunodeterminants (Sullender *et al.*, 1987) and, indeed, account for the majority of neutralizing antibodies.

Human studies suggesting of protection by HSV antibodies

Adults

Type-specific antibodies against one type of HSV may have limited ability to protect against acquisition of the other HSV type. For example, pre-existing antibody directed against HSV-1 correlates with protection against acquisition of genital HSV-2 infection (Breinig *et al.*, 1990; Cowan *et al.*, 1994; Eberhart-Phillips *et al.*, 1998; Fleming *et al.*, 1997; Gibson *et al.*, 1990; Johnson *et al.*, 1989; Mertz *et al.*, 1992; Nahmias *et al.*, 1990; Rosenthal *et al.*, 1997). The influence of pre-existing type-specific HSV-1 antibodies on acquisition of HSV-2 infection can also be inferred from recent successes, although somewhat limited, in HSV vaccine development. A candidate HSV-2 glycoprotein D subunit vaccine adjuvanted with alum combined with 3-deacylated monophosphoryl lipid A (MPL) has recently demonstrated promising results. In two large Phase III studies, the vaccine has been demonstrated to be safe and, in a subset of volunteers, effective in preventing HSV-1 or -2 genital herpes disease (vaccine efficacy ~75%) and HSV-2 infection (vaccine efficacy ~40%) (Stanberry *et al.*, 2002). In both studies, efficacy was limited to women who were HSV-1 and -2 seronegative prior to vaccination. There was no evidence of vaccine efficacy in men or in women who were HSV 1+/2- prior to vaccination.

While there is some degree of cross-protection conferred by pre-existing HSV-1 antibody on the acquisition of HSV-2 infection, the protection is incomplete. Similarly, vaccines have been developed which generate robust humoral responses yet fail to protect against HSV-2 infection (Stanberry *et al.*, 2000). As such, it is difficult to envision a circumstance whereby passive antibody immunotherapy will play a role in the management of genital HSV infection and disease.

Neonates

Both maternal antibody status (Brown *et al.*, 2003; Prober *et al.*, 1987; Yeager and Arvin, 1984; Yeager *et al.*, 1980) and type of maternal infection (primary vs. recurrent) (Brown *et al.*, 1987, 1991, 2003; Corey and Wald, 1999; Nahmias *et al.*, 1971) influence transmission of HSV from mother to baby. Neonates with higher neutralizing antibody titers acquired transplacentally are less likely to become infected with HSV following perinatal exposure of passage through an infected birth canal (Prober *et al.*, 1987), illustrating the protective effects of preexisting antibody in preventing neonatal HSV disease (Table 75.1). Additionally, infants born to mothers who have a first episode of genital HSV infection near term are at much greater risk of developing neonatal herpes than are those whose mothers have recurrent genital herpes (Brown *et al.*, 1987, 1991, 2003; Corey and Wald, 1999; Nahmias *et al.*, 1971). This increased risk, however, is not solely due to lower concentrations of transplacentally passaged HSV-specific antibody, since women with first episode disease also shed virus for a longer period of time and in higher quantities. The largest assessment of the influence of type of maternal infection on likelihood of neonatal transmission involved almost 40,000 women without clinical evidence of genital HSV infection who were cultured within 48 hours of delivery (Fig. 75.1). Of these, 121 women were identified who both were asymptomatically shedding HSV and for whom sera were available for serologic analysis. In this large trial, 57% of babies delivered to women with first episode primary infection developed neonatal HSV disease, compared with 25% of babies delivered to women with first episode non-primary

Table 75.2. Protective effect of neutralizing antibody in limiting extent of neonatal HSV disease

Neutralizing antibody titer (1 week of life)	Extent of disease		
	SEM (n=17)	CNS (n=19)	Disseminated (n=11)
<1:5	6 (35%)	2 (11%)	8 (73%) P<0.01
1:5 to 1:20	8 (47%)	15 (78%)	3 (27%)
>1:20	3 (18%)	2 (11%)	0 (0%)

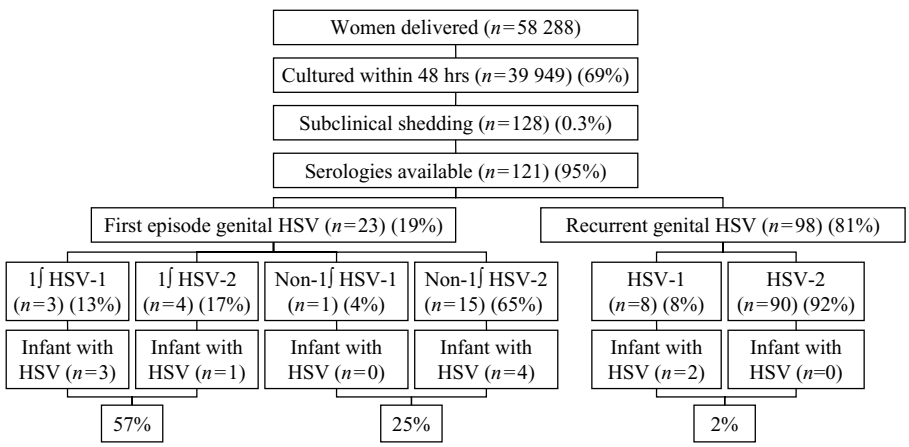

Fig. 75.1. Type of maternal infection and risk of HSV transmission to the neonate. (Data from Brown *et al.*, 2003.)

infection and 2% of babies delivered to women with recurrent HSV disease (Brown *et al.*, 2003).

Among HSV-infected neonates, anti-HSV neutralizing antibody titers have been shown to correlate with the extent of the disease (Sullender *et al.*, 1987), with babies with higher neutralizing antibody titers being more likely to have localized disease (and less likely to have disseminated disease) once they are infected (Table 75.2). Similarly, high maternal or neonatal anti-HSV ADCC antibody levels or high neonatal antiviral neutralizing levels are each independently associated with an absence of disseminated HSV infection (Kohl *et al.*, 1989) (Table 75.3).

Animal models of antibody immunotherapy in HSV infection and disease

The natural immune responses to HSV infection, both humoral and cellular, are strongly directed against the surface glycoproteins gB and gD, and both human and humanized antibodies directed against gB and gD have been shown to be beneficial as prophylactic and therapeutic agents in animal models of HSV infection (Baron *et al.*, 1976; Bravo *et al.*, 1996; Kern *et al.*, 1992; Lake *et al.*, 1992). In models of disease prevention, administration of polyclonal or monoclonal neutralizing antibodies prior to infection with HSV confers significant protection in mice. Similarly, administration of antibodies as late as 72 hours after infection dramatically decreases mortality as well as the quantity of virus detected in organs such as the brain and lungs (Kern *et al.*, 1992). In a murine model of neonatal HSV disease with a high challenge dose, protection was highly associated with ADCC activity (Kohl *et al.*, 1990). In a low dose challenge model, neutralizing activity of antibody alone was associated with protection in vivo (Kohl *et al.*, 1990). In a guinea pig model of neonatal HSV, combination therapy with passive anti-HSV antibody and acyclovir was effective even when administered on day 3 post-infection, reducing mortality from 82% to 44%. Acyclovir alone was effective only when begun on day 0, and antibody alone

Table 75.3. Protective effect of neutralizing and ADCC antibody in limiting extent of neonatal HSV disease

	Neonatal neutralizing antibody titer		
Neonatal ADCC	<1:5 (n=15)	1:5 to 1:20 (n=25)	>1:20 (n=6)

Disseminated			
$1:10^4$ to $1:10^6$	0	0	0
0 to $1:10^3$	7	3	1

From Kohl *et al.* (1989).

was effective when begun on or before day 2 (Bravo *et al.*, 1996). Also in guinea pigs, administration of HSV-specific antibody protects the sacral ganglia from HSV infection resulting from vaginal challenge (Bourne and Stanberry, 1993), suggesting a role for antibody in protecting the neuron early in primary HSV infection, possibly by blocking infection of the sensory nerve ending or alternatively by acting at the level of the ganglia (Stanberry *et al.*, 2000).

Limitations of antibody immunotherapy

As noted above, prospects for passive antibody immunotherapy for genital HSV infection and disease seem remote. However, the protection against infection and amelioration of disease severity afforded by neutralizing and ADCC antibodies in neonatal HSV may portend a future role for this manifestation of HSV infection. While antibody therapy offers promise for improving neonatal HSV disease prevention and outcome, studies in humans have yet to be performed. In addition, an HSV hyperimmune globulin preparation does not exist, and the amount of anti-HSV antibodies present in conventional intravenous gammaglobulin (IVIG) preparations is low and variable, such that unacceptable large volumes would need to be injected to potentially confer protective immunity. For these reasons, use of IVIG in the management of neonates with HSV disease cannot be recommended at this time.

The development of human and humanized monoclonal antibodies obviates the current problems with pooled IVIG preparations, and may allow for the systematic evaluation of the therapeutic benefit of passive immunization in neonatal HSV disease. Human monoclonal antibodies offer further potential advantages over murine and chimeric antibodies such as longer circulating half life and reduced or possibly undetectable immunogenicity. At least two human monoclonal antibodies exist which could one day be evaluated in neonatal HSV disease.

HSV 863 is an HSV gD group Ib human monoclonal antibody of IgG1gamma isotype. In vitro studies showed that HSV 863 reacts with all of the 99 strains of HSV-1 and HSV-2 tested. It has potent neutralizing activity in the absence of complement, with an IC_{50} range of 0.05–0.35 μg/ml, with IVIG being approximately 128 to 256 times less potent. The neutralization IC_{50} for HSV 863 in the presence of complement was identical. HSV 863 confers a marked dose-dependent increase in ADCC activity, with maximal ADCC efficacy being achieved with concentrations of HSV 863 as low as 1 μg/ml with HSV-1 and 5 μg/ml with HSV-2. The half life of this monoclonal antibody is approximately 19 days in monkeys, with no apparent side effects, toxicity or immunogenicity following single or multiple dose administration. In vivo, using a neonatal HSV model, HSV 863 proved effective both prophylactically and therapeutically. When administered prior to virus challenge, the ED_{50} was 1–8 mg/kg for protection against a $10 \times LD_{50}$ challenge with HSV-1 or HSV-2. The antibody was protective in dose of 30 mg/kg up to 2 days after viral challenge and up to 72 hours post-infection when administered in dose of 90 mg/kg. In combination treatment with acyclovir, there were indications of additive effects, but no interference. HSV 863 at 10 mg/kg given 72 hours after infection was 90% protective, and doses of 1.5 to 15 mg/kg reduced both skin lesion severity and abundance in a murine model of cutaneous HSV disease. In a murine ascending myelitis model, treatment with HSV 863 or acyclovir substantially reduced the extent of detectable latent ganglionic infection, especially when given prophylactically 24 hours prior to HSV inoculation. Production of this product, though, is currently on hold pending discussions with potential manufacturers of commercial-grade product.

HX-8 is a human monoclonal antibody which binds HSV-1 and -2. It is produced by Epicyte Pharmaceutical in genetically modified corn and neutralizes both HSV-1 and HSV-2. It is currently being developed as a topical human antibody, but to date has not been tested in humans.

Summary

The immunobiology of HSV infections is complex. Cell mediated and humoral immunities are both important in the immunologic response to HSV infection, but millennia

of evolution have provided the virus with the means by which to evade even the intact immune system, both maintaining latency and allowing for intermittent reactivation of disease. These facts likely limit the utility of passive antibody immunotherapy in the management of genital HSV infection. However, evidence for protection against infection and amelioration of disease severity afforded by neutralizing and ADCC antibodies in neonatal HSV may portend a future role for this manifestation of HSV infection. While antibody therapy offers promise for improving neonatal HSV disease prevention and outcome, studies in humans have yet to be performed.

Introduction

After more than a decade of intensive research and development efforts, the translation of promising viral-based gene therapies from the research lab to the clinic is both promising and unexpectedly challenging. Many of the same properties that make viral vectors attractive candidates to deliver genes for therapeutic purposes also impede the path to successful clinical development.

Vectors for clinical use must be manufactured in relatively high yields such that hundreds of thousands or even millions of "doses" can be generated in a safe and cost-effective manner. Moreover, the resulting vector must exhibit genetic as well as structural stability, withstand storage at various temperatures for up to several years, and cause little or no toxicity in animals, and ultimately in humans.

Herpes simplex viruses (HSV), while widespread in nature, have not been tested in human clinical studies as often as several other commonly used vectors, such as adenovirus, adeno-associated viruses (AAV), and retroviruses. In many ways however, HSV is emerging as a viable therapeutic platform and several clinical studies are either ongoing or planned for the very near future. The reason for this increased focus on HSV is due in part attributable to the unique properties that make HSV a stable and potentially potent vector for controlled gene delivery. In addition, the increasing experience with replication-competent vectors in human clinical studies has made it more familiar with clinicians.

Properties of therapeutic HSV vectors

Therapeutic HSV can be characterized as replication-competent or replication-defective. Replication competent vectors, such as the oncolytic vectors described in this chapter, are usually deleted for "non-essential" viral genes to render the vector less "toxic" as measured by the ability to cause disease in susceptible animal models. These vectors are often referred to as "replication-attenuated." If they are designed to treat cancer, they are "oncolytic" in the sense that they are at least partially replication competent in tumor cells, and largely replication defective in surrounding tissue.

This differential permissiveness has been shown in several studies to be due to the unique environment of the tumor cell vs. the "normal" surrounding cell. For example, HSV-1 mutants such as G207 are now being tested in clinical trials for anti-cancer activity. R3616, which is similar to G207, is an HSV-1 mutant that is deleted for the viral anti-PKR gene, $\gamma_1$34.5. The R3616 mutant infects *ras*-transformed but not untransformed cells, which suggests that the Ras-signaling pathway compensates for the loss of the virus' own anti-PKR mechanism (Farassati *et al.*, 2001). HSV-1, therefore, predominantly uses the host anti-PKR mechanism to infect transformed cells and its selectiveness for transformed cells makes it a good candidate for an anti-cancer therapeutic.

Replication defective HSV vectors are deleted for one or more genes that are known to be essential for viral replication in otherwise permissive cells. As a result, defective vectors can only be manufactured using cell lines that are modified to contain the complementing viral genes. These vectors often exhibit reduced toxicity in non-complementing cells compared to wild-type virus, and appear to be largely non-toxic when administered to animals. Although many different replication defective HSV vectors have been generated, only a few of them represent viable candidates for clinical development, and none have been tested in humans to date.

Properties of non-replicating HSV vectors for therapeutic use

There are two basic approaches to generating replication defective HSV vectors: amplicons and whole genome vectors.

Plasmid-based amplicon vectors

Amplicons, first described over 20 years ago (Spaete and Frenkel, 1982), are defective HSV particles produced from plasmids containing the gene of interest, an origin of replication and a packaging signal. Plasmids are incapable of replicating without HSV helper functions, either in the form of helper virus, or resident on cosmids or bacterial artificial chromosomes. The resulting vectors contain multiple copies of the therapeutic gene, and are capable of infecting cells via the HSV entry pathway. Despite the potential safety advantages of such a system, in practice it is relatively difficult to generate high titer stocks devoid of helper virus. Although advances in generating helper-free stocks have helped somewhat (Fraefel *et al.*, 1996), this is offset at least in part by an increase in the complexity of manufacturing. Moreover, the plasmid sequences transferred into cells by amplicons are not HSV genomes, so consistent, regulated expression has been difficult to achieve in animals. Amplicon vectors are unique in their ability to deliver up to 153 kb of heterologous DNA into a wide range of mammalian cells (Wade-Martins *et al.*, 2001).

In an attempt to extend the stability and duration of expression from amplicon vectors, and thus improve potential usefulness in gene therapy, hybrid amplicons consisting of elements of the AAV genome were constructed and tested for their ability to direct stable gene transduction by site-specific integration (Wang *et al.*, 2002). The vector constructs, which contained the AAV inverted terminal repeats and the Rep gene were packaged as amplicons and compared to a standard amplicon vector in cell culture. Interestingly, the hybrid vectors improved the stable transduction frequency compared with controls, and the transgene was integrated into the host cell chromosome. The ability of the HSV amplicon construct to integrate into the host cell chromosome may hold promise for further improvements in long-term gene expression in situations where long-term gene expression is a priority.

Another approach for improving the efficiency of HSV-derived amplicon vectors has been to re-target the amplicon to make it more cell-type specific by reducing its ability to attach to all but the target cells. Grandi *et al.* (2004) have developed a method to re-target amplicon vectors by replacing the gC heparan sulfate binding domain with a model ligand, in this instance the hexameric histidine tag. They demonstrated enhanced binding of modified virus to receptor-positive cells with no loss of infectivity. This approach holds promise for reducing the dose required for adequate therapeutic effect. This would also have the potential to improve the prospect for the manufacture of clinical supplies. These and other enhancements will first require optimization in animal models prior to their inclusion in HSV therapeutics intended for human use.

Replication defective whole genome vectors

The second vector type is represented by HSV genomes deleted for essential genes. To grow these viruses, cell lines approved for clinical manufacturing are modified to contain the viral gene or genes required to complement the defect in the defective vector. Deletion of one or other of the essential immediate-early genes (ICP4, ICP27) results in a virus that cannot replicate (DeLuca *et al.*, 1985; McCarthy *et al.*, 1989; Samaniego *et al.*, 1997, 1998; Wu *et al.*, 1996), except in cells that complement the null mutations by providing ICP4 or ICP27 in trans (DeLuca *et al.*, 1985; Samaniego *et al.*, 1998; Wu *et al.*, 1996). In practice, the only potentially clinically useful vector strains have two or more deletions to reduce the potential that a recombination event with the viral gene resident in the complementing cell will lead to a replication competent contaminant during manufacturing. Multiply deleted vectors cannot replicate in non-complementing cells and do not express early or late genes. These vectors can also contain additional defects in viral genes that lead to desirable properties such as increased yield, reduced cytotoxicity, genome stability or altered immune response.

Another approach for increasing the yield of non-replicating vectors is by modifying the complementing cells. For example, complementing cell lines can be made to express the complementing sequences only upon HSV infection, thereby reducing cytotoxicity and enabling robust replication and high yields during manufacture. Viruses generated in this manner can be designed to be relatively non-toxic, especially in neuronally- derived cell types (Palmer *et al.*, 2000; Lilley *et al.*, 2001).

Use of HSV vectors to modify the nervous system

Herpes simplex virus vectors are particularly well suited for the delivery of genes to neurons. In natural infections, the wild-type virus particle targets with high efficiency from peripheral inoculation to the nucleus of sensory neurons in the dorsal root ganglion. Once in the nucleus, the viral

genomes establish latency, in which they persist for the life of the host as intranuclear episomal elements. Although wild-type virus may be reactivated from latency, recombinant vectors that are entirely replication defective retain the ability to establish a persistent state in neurons, but are unable to replicate (or reactivate) in the nervous system.

Most viral gene expression is attenuated as the virus enters latency and is tightly regulated. Fortunately, the virus does express the LAT transcripts, which indicates that there is no absolute block to HSV-based gene expression in the neuron following the establishment of latency. Chimeric promoter constructs containing the LAT promoter enhancer region can confer long-term activity on otherwise silenced exogenous promoters (Palmer *et al.*, 2000; Lilley *et al.*, 2001). Vectors in which the LAT promoter is made to control exogenous gene expression have also been shown to express foreign genes in mouse dorsal root ganglia (DRG) for months following footpad inoculation (Marshall *et al.*, 2000). These vectors allow long term expression in dorsal root ganglia and the CNS of animal models. They also retain the ability to be transported via the axon to distant sites, a feature that may be useful for targeted delivery to the peripheral or central nervous system in the clinical setting.

Peripheral nervous system (PNS)

Latency of wild-type HSV occurs in the sensory ganglia of peripheral nerves and long-term expression of transgenes from HSV vector has proved feasible in the PNS (Goins *et al.*, 1999). Expression of NGF and other neurotrophic factors using the LAP2 and heterologous promoters to drive expression has persisted long enough to demonstrate the therapeutic potential of such constructs in the clinical setting for the treatment of neuropathy (Chattopadhyay *et al.*, 2002, 2003; Goss *et al.*, 2002a,b). Expression of enkephalin peptides from defective HSV vector backbones has also been demonstrated in animal models of chronic pain suggesting that as little as several weeks of gene expression might provide therapeutic benefit (Goss *et al.*, 2001, 2002a, b; Hao *et al.*, 2003).

Central nervous system (CNS)

It would normally be expected that infection of the CNS with HSV would cause encephalitis, by contrast with the latent infection established in the PNS. It has been demonstrated quite convincingly, however, that even replication competent HSV constructs such as the oncolytic vectors G207 and strain 1716 can be delivered safely to the human brain for the treatment of malignant glioma. Therefore it would be expected that replication defective HSV should be non-toxic following CNS delivery. In fact, this has been demonstrated in animals for certain HSV recombinants with multiple IE gene deletions (Krisky *et al.*, 1998), or with IE gene deletions (ICP4, 27) coupled with inactivating mutations in ICP34.5/open-reading frame P and VP16 (Lilley *et al.*, 2001). Vectors such as these would be highly appropriate vehicles to arm with therapeutic genes either to preserve or modify neuronal function or to destroy tumor cells. These vectors express minimal levels of any of the IE genes in non-complementing cells and transgene expression can be maintained for extended periods with promoter systems containing LAT promoter elements (Palmer *et al.*, 2000).

Additionally, HSV-based vectors allow highly effective gene delivery both to cultured neurons and to the CNS in animal models. Moreover, these vectors are efficiently transported from the site of inoculation to connected sites within the CNS and less so within the PNS. This has been demonstrated by gene delivery to both the striatum and substantia nigra following striatal inoculation, to the spinal cord, spinal ganglia, and brainstem following spinal cord infection, and to retinal ganglia neurons following injection in the superior colliculus and thalamus (Lilley *et al.*, 2001).

In a comprehensive study of vector delivery, Palmer *et al.* (2000) have identified combinations of deletions from the HSV genome that allow efficient gene delivery to spinal dorsal root ganglia (DRGs) following peripheral inoculation into the footpad or sciatic nerve of mice. This showed that LAT promoter elements can confer long term expression in the context of different exogenous promoters, and that partial replication-competence may be more efficient for gene delivery following footpad or nerve injection. The efficiency of retrograde transport and subsequent gene expression following footpad or sciatic nerve inoculation was determined to be dose dependent, and not as efficient as with replication competent vectors. This may be due to the need to penetrate a barrier of accessory cells or otherwise increase the relative amount of vector available at the site of inoculation.

These unique viruses show an encouraging lack of toxicity following injection as well as relatively long-term expression: capabilities that have important implications for therapeutic uses where target neurons are in regions of the nervous system that are relatively inaccessible by normal therapeutic techniques. These target cells might include the dopaminergic neurons of the substantia nigra that are affected in Parkinson's disease (Yamada *et al.*, 1999), the retinal ganglion cells, or delivery to the DRG for the treatment of pain, or to repair the spinal cord or nerves.

Malignant glioma

Malignant glioma is a malignancy of the CNS that can be treated by surgery, radiation, and chemotherapy. To date, only replication competent HSV has been tested in clinical studies with some success to treat refractory disease. Replication defective vector candidates have also been designed to arm the HSV vector in such a way to provide a more potent antitumor effect than has been demonstrated so far with the replication-attenuated vectors.

Interestingly, the TK gene of HSV has been introduced into a variety of non-HSV vectors and tested for its ability to kill tumor cells in the presence of ganciclovir, but never in the HSV vector itself. Candidate HSV vectors have been generated that are equipped with additional genes that might be useful to treat brain tumors. For example, connexin 43, which is the major component of astrocyte gap junctions, has been introduced into an HSV vector to increase the formation of intercellular junctions in a manner that may potentiate HSV/tk-based cancer treatment by promoting the transfer of activated ganciclovir from cell to cell (Sanson *et al.*, 2002). Likewise, inclusion of antitumor factors such as the cytokine TNF alpha appear to provide added benefit if expressed in high concentrations in the tumor and surrounding tissue from an HSV vector backbone (Moriuchi *et al.*, 1998).

Additional work has been performed in an attempt to regulate vector-directed gene expression such that it is either naturally activated in the tumor cell environment or induced at will through the use of exogenous inducers. In this regard, HSV-1 amplicon vectors that are regulated by the cell cycle have been developed to generate glioma-specific HSV amplicon therapeutics (Ho *et al.*, 2004). The design of one such construct is based on the observation that cell cycle dependent factor CDF-1 appears to be specifically expressed during the G(0)/G(1) phase of the cell cycle and its binding site is located within the cyclin A promoter. In non-dividing cells, transactivation of a cyclin A promoter via the interaction of a Gal4/NF-YA fusion protein with Gal4-binding sites is prevented by the presence of CDF-1, which acts as a repressor. By contrast, in proliferating cells such as those in actively growing tumor, CDF-1 is presumably absent and transactivation occurs. These regulatory elements have been incorporated, along with tissue-specific elements such as the GFAP enhancer, into HSV amplicon vectors to target expression to a specific group of cells. This construct has been shown to exhibit both cell-type specific and cell cycle dependent transgene expression in glioma-bearing animals. These vector properties, if active in animal models of disease, would reduce the need for targeting at the level of cell attachment and entry, and may represent an important step in developing a vector that can be delivered systemically or locoregionally to target the maximum number of tumor cells in the context of metastatic disease.

Another approach to gene regulation adapted to the HSV system that is not limited to glioma therapy, is the tetracycline-inducible gene expression system. Of the known eukaryotic regulatory systems, the tet-inducible system is perhaps the most widely used because of its tight regulation and the availability of tetracycline, which is suitable for human clinical use. These constructs contain a tetracycline response element (TRE) linked to a promoter such as the heterologous promoter CMV, or the HSV ICP0 promoter (Schmeisser *et al.*, 2002). Studies have demonstrated that these constructs result in tetracycline inducible gene expression that is not cell type specific, and are capable of inducible expression for several days in irreversibly differentiated NT2 cells, which is a neuronally committed human teratocarcinoma cell line that differentiates into neuron-like hNT cells following treatment with retinoic acid. The ability to turn gene expression on and off following intratumoral or systemic delivery of an HSV-based cancer therapeutic could allow for the inclusion of increasingly potent and potentially toxic gene products into HSV vectors to enhance antitumor efficacy.

Towards optimizing HSV vectors for therapeutic use

One of the most difficult problems in developing safe and efficient viral therapeutics is to determine the optimal dose of vector that will be effective in humans. In an effort to address this problem, the HSV TK gene has been shown to function as a useful marker gene for the direct in vivo localization of TK expression by positron emission tomography (PET). Several double and triple HSV amplicon vector constructs expressing HSV-1 TK, green fluorescent proteins, and *E. coli* cytosine deaminase have been generated and tested by injecting between 10^7 and 10^8 transducing units into subcutaneously Gli36dEGFR gliomas in nude mice. All amplicon vector constructs mediated GFP expression and sensitized the cells toward ganciclovir and 5-fluro-cytosine mediated cell killing in a drug-dose dependent manner (Jacobs *et al.*, 2003.). Moreover, functional proportional coexpression of the PET marker gene TK and the linked therapeutic E. coli CD gene was observed. TK expression could be imaged by PET in vivo even with apparent suboptimal transduction and gene expression. This raises the exciting possibility that the expression of HSV TK from

therapeutic HSV vectors could serve as a useful marker for non-invasive imaging of vector distribution following administration. This would be extremely useful in Phase I and Phase II clinical trials and could provide a powerful means for optimizing dose, formulation, and the rate and mode of delivery.

Non-replicating vectors: current trends

No replication-defective HSV vector has yet been tested in human clinical studies for the treatment of disease. This is somewhat surprising given that replication competent vectors were first introduced into humans in 1998 for the treatment of malignant glioma. It is likely that this situation will change now that the clinical experience with replication competent HSV has been largely positive. Replication defective HSV vectors have many desirable qualities for use as therapeutics. They can be engineered to express several genes at once, manufactured in complementing cell lines that have the potential to yield more replication-defective virus than the replication-attenuated vectors already in use, and they do not replicate following administration to the patient. Thus, the effective dose cannot increase following administration. In this way, replication-defective vectors are more "drug-like" than are the replication competent vectors. The possibility to equip the vector with potentially toxic gene products for cancer therapy or to effect long term gene expression in the nervous system for the treatment of pain, neuropathy or CNS disease will provide the motivation to move these novel therapeutics from the research laboratory to the clinic.

Oncolytic HSV

Introduction

The original genetically engineered viruses examined as antitumor oncolytic agents studied as it was already a well-studied, non-integrating, neurotropic virus with oncolytic were HSV-1 mutants utilized in a preclinical models of human glioma (Markert *et al.*, 1992; Martuza *et al.*, 1991). HSV-1 was properties whose essential and non-essential genes have been identified (Fig. 76.1(a)). Deletion of the neurovirulence genes from an oncolytic HSV vector can effectively produce selective targeting of tumor cells for oncolysis. It has been estimated that 30 kilobase-pairs of the HSV genome could be replaced with foreign DNA while maintaining virus replication. Clinically utilized anti-viral drug regimens already exist to interrupt HSV infection, which adds a margin of safety to its clinical use as an oncolytic agent.

The first engineered replication-competent HSV-1-derivative examined for oncolytic effects was *dl*sptk, a thymidine kinase deletion mutant (Martuza *et al.*, 1991). As a result of this mutation, *dl*sptk can only replicate in mitotically-active cells that can supply both thymidine kinase and pools of available nucleotides necessary for viral DNA replication. Efficacy was demonstrated in multiple animal models of glioma and other nervous system tumors (Martuza *et al.*, 1991; Markert *et al.*, 1993). However, clinical studies were not pursued with *dl*sptk because (i) evidence of low-level encephalitis was seen on histological examination of treated mice, and (ii) its tk mutation made it resistant to, the major antivirals in use for HSV infection, acyclovir and ganciclovir. Other HSV-1 vectors studied with markedly decreased virulence in the normal CNS but capable of oncolysis include R3616 (which contains a one kilobase deletion in both copies of the $\gamma_1$34.5 gene locus) (Chou *et al.*, 1990; Chou and Roizman, 1992)(Fig. 76.1(b)) and hrR3 (which contains a disabling *lacZ* insertion into the U_L39 locus) (Goldstein and Weller, 1988) (Fig. 76.1(c)).

The two $\gamma_1$34.5 gene copies that are deleted in R3616 are located in the inverted repeat regions flanking the Unique Long (U_L) segment of the HSV-1 genome, and encode a 263 amino acid protein with dual functions. First, $\gamma_1$34.5 is responsible for the neurovirulence properties of HSV-1. Second, the $\gamma_1$34.5 gene product (ICP34.5) subverts a major response of the host cell to HSV infection. Upon viral infection, double-stranded RNA is produced, and a stress response occurs in the host cell. Protein kinase R (PKR) is activated, shutting down translation in the infected cell as an antiviral protective mechanism by phosphorylating and inactivating eukaryotic initiation factor-2α (eIF-2α). ICP34.5 recruits protein phosphatase-1a in order to dephosphorylate eIF-2α and allow protein synthesis and viral replication to proceed (He *et al.*, 1997). Studies have demonstrated that HSV-1 mutants lacking functional ICP34.5 activity produce a lytic infection only in cells with defective PKR pathways (Chou *et al.*, 1990; Chou and Roizman, 1992). Over expression of Ras appears to allow $\Delta\gamma_1$34.5 HSV-1 replication in tumor cells due to a defective PKR pathway (Farassati *et al.*, 2001). R3616 produced no neurovirulence or encephalitis but maintained antiglioma activity in nude mouse models (Markert *et al.*, 1993).

U_L39 encodes the large subunit of the enzyme ribonucleotide reductase (ICP6) which HSV utilizes for nucleotide synthesis after infection of post-mitotic cells, such as neurons, which would otherwise not support the HSV

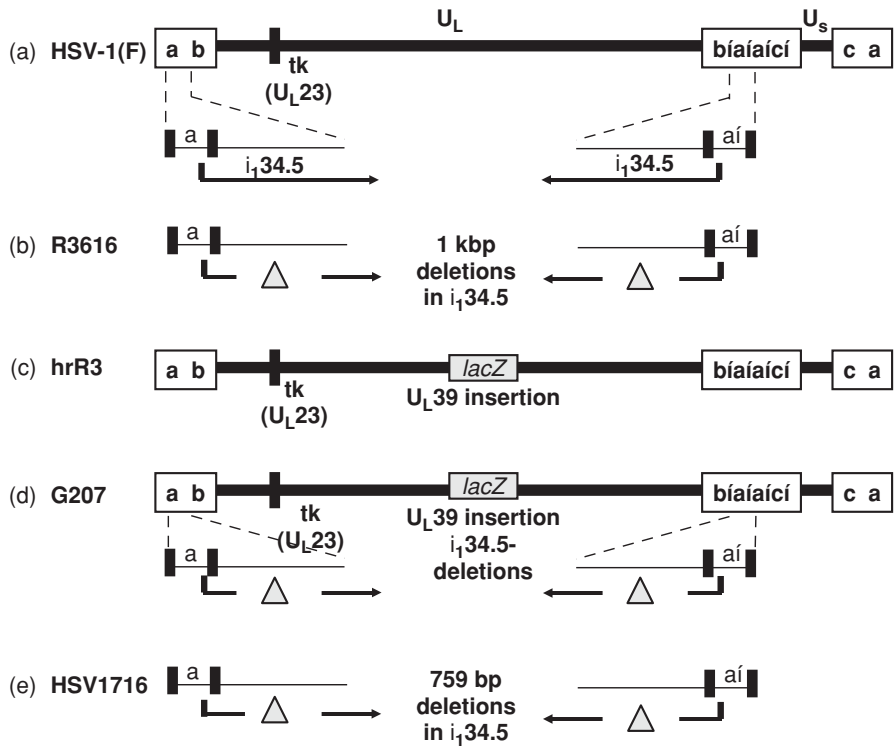

Fig. 76.1. The wild-type herpes simplex virus type 1 genome consists of two major adjacent segments (the Unique long and Unique short segments), each flanked by inverted repeats. The $\gamma_1$34.5 genes are located in the inverted repeats flanking the UL segment. 1b. The R3616 HSV-1 mutant possesses a 1 kilo-basepair deletion in both copies of the $\gamma_1$34.5 gene.1c. hrR3 contains a *lacZ* insertion in the UL39 locus, inactivating the ICP6 (ribonucleotide reductase) gene product.1d. G207 was constructed to possess both the *lacZ* insertion inactivating the UL39 locus and deletions in both genes $\gamma_1$34.5.1e. HSV1716 is similar to R3616 in that too contains deletions in both copies of the $\gamma_1$34.5 gene, inactivating the ICP34.5 protein.(62)

replication cycle. Dividing cells however, can provide cellular ribonucleotide reductase *in trans* obviating the need for the viral protein (Goldstein and Weller, 1988). The oncolytic HSV-1 hrR3 has a *lacZ* insertional mutation in U_L39 renders the viral ribonucleotide reductase nonfunctional. As a result, the virus produces a lytic infection only in dividing cells, including those found in neoplasms, such as malignant glioma (Mineta *et al.*, 1994). A potential additional benefit is that the ribonucleotide reductase-deficient virus is hypersensitive to the anti-viral effects of acyclovir and ganciclovir (Coen *et al.*, 1989)

Oncolytic HSV in malignant glioma

To decrease the possibility of recombination to wild-type virus and further increase the safety of oncolytic HSV-1, a new mutant, G207, was constructed. This virus is a double mutant with deletions in both copies of the $\gamma_1$34.5 gene locus as well as a *lacZ* insertion into the U_L39 locus (Mineta *et al.*, 1995) (Fig. 76.1(d)). G207 retains susceptibility to standard anti-HSV therapies such as acyclovir, since the thymidine kinase gene is intact; due to the inactivation of U_L39, G207 is in fact modestly hypersensitive to acyclovir (Coen *et al.*, 1989; Mineta *et al.*, 1995).

G207 was shown to produce antiglioma effects in multiple preclinical glioma models (Mineta *et al.*, 1995), and was shown to be safe for inoculation at high titers in mice and subsequently in non-human primates (New World owl monkeys *Aotus nancymae*) (Hunter *et al.*, 1999). Of 16 *Aotus*, 13 received intracerebral inoculations of either 1×10^7 or 1×10^9 pfu of G207, two received vehicle and one received 1×10^3 pfu of the wild-type parent HSV-1(F). None of the G207-inoculated animals died due to virus-induced complications (three died from non-neurologic reasons), whereas the control HSV-1(F)-infected monkey succumbed quickly to HSV encephalitis as expected (Hunter *et al.*, 1999). Although no clinical signs of HSV-incited illness were evident in the G207 administered animals, increased levels of anti-HSV antibodies were reported.

Based on these safety and efficacy reports, G207 was moved into a Phase I clinical trial (Markert *et al.*, 2000a,b). Twenty-one patients with recurrence or progression of malignant glioma after standard therapy were enrolled. All patients had to have undergone prior external beam radiotherapy (minimal dose 5000 cGy) in addition to either craniotomy and surgical debulking (seventeen patients) or biopsy alone (four patients). Ten patients also had been given one or more chemotherapeutics. A Karnofsky performance score of $\geq$70 were required for entry. Primary tumor histologies included fifteen glioblastomas, one gliosarcoma, four anaplastic astrocytomas, and one anaplastic mixed glioma.

This dose-escalation study was intended to determine the maximally tolerated dose (MTD) and any dose-limiting toxicities of G207. Patients were allocated to cohorts by dose level (three patients per cohort); a standard dose escalation scheme using half-log increments was used, with a maximal achievable dose of 3×10^9 pfu established as the ultimate upper limit of G207 to potentially be administered. A waiting period of 10 days between each patient within a cohort and of 28 days between each cohort was included to monitor signs of acute toxicity and/or the development of encephalitis. All patients were given one intratumoral injection into the enhancing portion of the tumor (according to MRI or CT scan), except those treated at the highest dose level. All patients treated with this dose, 3×10^9 pfu, had their tumors stereotactically inoculated in five different enhancing tumor loci as demonstrated by pre-operative imaging studies.

The results demonstrate the safety of G207 administration. An MTD was not established, as even with inoculation of 3×10^9 pfu, there were no definitive dose limiting toxicities, nor any requirement for the use of anti-viral drugs. In the few post-treatment histologic specimens available for review due to subsequent biopsy, tumor resection, or autopsy, there was no evidence of encephalitis (determined by H&E staining) or major inflammatory changes observed. Of the nineteen patients who underwent serologic testing, five were seronegative prior to treatment with G207. Of these five, one patient (treated at the highest dose level) seroconverted after inoculation. Thus, the virus was shown to be extremely well tolerated, even at very high doses.

While efficacy was not the primary endpoint of this study, certain findings support the antiglioma effects of G207 in this trial. Efficacy endpoints of average time to progression by MRI was 116 days and overall median survival of 190 days were only modestly above average in this dose escalation study of patient with recurrent tumors. However, eight of twenty patients revealed reduced enhancement volumes of their tumors at one month after treatment, suggesting that treatment at higher doses and perhaps under a different dosing regimen might improve the response to G207 therapy.

In an effort to gain additional data regarding G207 in the treatment of human glioma, a follow-up Phase Ib study was developed. Objectives of the Phase Ib study include validating the safety and tolerability (MTD) of G207 administration via divided escalating doses given both intratumorally and into functional brain adjacent to the resected tumor. This trial was also designed to evaluate the ability of G207 to replicate within the tumor post-inoculation, define the characteristics of G207 replication in these patients (e.g., virus shedding and reactivation, immunogenicity, impact of cell-mediated immune responses), as well as determine the mean time to disease progression and overall survival. Enrollment in this study has been completed, and data analysis is in progress.

A third study of G207 in patients with malignant brain tumors is scheduled to begin at the University of Alabama, Birmingham in January, 2005. This study will examine the effects of post-inoculation radiation on G207 treatment. The study is based on extensive preclinical data which demonstrates that a single fraction of radiation, when administered approximately 24 hours after G207, increases the replication and spread of viral infection within brain tumors as well as many other neoplasms.

Almost simultaneously with the Phase I trials of G207, HSV1716, derived from the parent wild-type strain HSV-1 17+, also underwent clinical trials to evaluate its toxicity in patients with recurrent malignant glioma (Rampling *et al.*, 2000). This single-mutant replication-selective virus has a genetically engineered deletion of 759 base-pairs within both copies of the $\gamma_1$34.5 gene (Fig. 76.1(e)). HSV1716 was demonstrated to be avirulent in SCID mice, and therefore safe enough to pursue as a possible oncolytic vector therapy candidate in 1994 (Valyi-Nagi *et al.*, 1994). Moreover, efficacy studies in animal models supported utilizing HSV1716 as a possible novel treatment approach to malignant gliomas. Based on preclinical safety and efficacy profiles, HSV1716 was pursued as an anti-glioma agent for humans. Safety and toxicity of HSV1716 administration to patients was first examined in a study that enrolled nine total patients, eight of whom were diagnosed with GBM and one with anaplastic astrocytoma (Rampling *et al.*, 2000). All patients had been treated with prior radiotherapy, and had a KPS of at least 60. In addition, all subjects had also undergone previous surgery and six had received chemotherapy at the time of enrollment. Immunohistochemistry of injected regions when available showed no signs of immunoreactivity for

HSV-1, and the only HSV seronegative patient in the trial did not demonstrate seroconversion. No maximum tolerated dose was established because at the highest dose tested, 1×10^5 pfu, HSV1716 was well tolerated, with no evidence of encephalitis.

A second clinical trial examining HSV1716 suggested that replication occurs in at least some of the high-grade gliomas treated with intratumoral injection (Papanastassiou *et al.*, 2002). Twelve patients with KPS between 60 and 90 were enrolled in this study; eleven GBM patients and one anaplastic astrocytoma patient. Of the GBM patients, there was one newly diagnosed patient; the remaining patients were treated at tumor recurrences. Eleven patients had prior surgery, ten patients had prior radiation therapy, and three had been given some previous chemotherapy. For this trial, all the enrollees were inoculated with 1×10^5 pfu HSV1716 intratumorally, and then underwent surgical resections four to nine days afterwards. Again, no acute toxicity was observed, nor was virus administration responsible for any adverse events. Unlike the first study, both seronegative patients became seropositive by the end of the study. In two patients, HSV1716 was recovered from the resected tumors, but semiquantitative PCR detection methods identified the virus within the tumor tissue of ten patients. The results from the two patients supported the possibility of HSV1716 replication within the tumor. The authors concluded that HSV1716 could feasibly replicate in situ within tumors without toxicity in patients with malignant glioma.

Recently, it was reported that tumor tissue from one of the patients inoculated intratumorally with HSV1716 was cultured in vitro and tested for the presence of that virus (Harland *et al.*, 2002). Though none was found, when the cells were re-infected in vitro, a small fraction was found to not undergo lysis. These cells – which themselves began to proliferate – continued to shed HSV716 at low levels. The authors concluded that this suggested the possibility that, in vivo, a similar persistence of HSV may occur, allowing the virus to continue killing tumor cells over extended periods of time. Further studies of HSV1716's efficacy and safety are ongoing. The virus will be injected into the surrounding brain tissue around the tumors after surgical resection, similar to the Phase Ib trial in progress with G207.

In a recently reported study aimed at examining the safety of HSV1716 inoculation into the brain surrounding the enhancing tumor, twelve patients with newly-diagnosed or recurrent malignant glioma underwent resection followed by inoculation of 10^5 pfu of HSV1716 into the tumor bed. No dose limiting toxicities were observed. Three patients remain alive and clinically stable at 15, 18 and 22 months postsurgery and HSV1716 injection (Harrow *et al.*, 2004).

Oncolytic HSV for Non-CNS malignancies

While the concept of genetically engineered oncolytic HSV-1 was originally developed for the treatment of malignant glioma and other CNS tumors, it was soon explored in preclinical models of other difficult to treat tumors, that developed outside the CNS, including neurofibrosarcomas, melanoma, and non-small cell lung carcinoma, as well as cancer of the breast, liver, pancreas, ovary, head and neck, gallbladder, bladder, prostate, stomach, and colon. Of these, HSV1716 has been studied clinically in patients with melanoma, and NV1020 in patient with colorectal metastases to the liver.

HSV1716: melanoma

Genetically-engineered HSV has been demonstrated to be effective as an oncolytic agent against melanoma in a wide variety of preclinical studies (Miller *et al.*, 2001; Miller and Fraser, 2000; Randazzo *et al.*, 1997; Toda *et al.*, 1999) To explore the possible use of HSV in the treatment of metastatic melanoma (Mackie *et al.*, 2001) performed a pilot study in which five patients with stage 4 melanoma underwent inoculation of HSV1716 into subcutaneous melanoma nodules. Two patients received a single injection of 10^3 pfu of 1716, two received two injections, and one received four injections. Flattening of injected nodules was seen in a single patient, and follow-up biopsies demonstrated tumor necrosis in patient receiving multiple injections; no necrosis was seen in control nodules treated with saline. Immunohistochemical staining was positive for the HSV UL42, a 65 kD DNA-binding protein which is essential for HSV DNA replication and virus growth. Patients tolerated the treatment well, and no change in IgG and IgM titers to HSV were seen. No evidence of response was seen in non-treated lesions, however. Further studies of HSV in melanoma have not yet been reported.

NV1020: colorectal metastases

The third conditionally replication competent HSV-1 to be tested in clinical trials as an oncolytic virus was actually the first such HSV ever to be studied in humans. NV1020 is a purified, mapped form of the virus R7020, which was initially tested in humans as a vaccine against wild-type HSV-1 and 2. R7020 is a genetically engineered virus initially engineered as a candidate for prophylactic immunization against HSV-1 and HSV-2 infection (Meignier,

1991) NV1020 was constructed with a deletion of a 15 kbp region encompasses the UL56 gene and the internal inverted long repeat, extending to the promoter regulatory elements of the ICP 4 gene of the HSV-1 viral genome and includes one copy of the $\gamma_1$34.5 gene. Additionally, a 700 base pair deletion of the native thymidine kinase gene is present that also presents expression of the overlapping transcripts of the UL24 region. Because it was originally designed as a vaccine, a 5.2 kb fragment of the HSV-2 DNA encoding HSV-2 glycoproteins G, D, I and a portion of E is included, as well as a copy of the HSV-1 thymidine kinase gene under the α4 promoter. This maintains sensitivity to antiviral agents such as acyclovir. The virus was extensively tested for genetic stability, with no increase in virulence after nine passages in mouse brain. It has been tested for virulence in mice, guinea pigs, rabbits and the sensitive primate species, *Aotus nancymae* (Meignier, 1991; Meignier *et al.*, 1988, 1990). It has been demonstrated to be safe in *Aotus* at doses up to 10^7 pfu by a variety of routes, including intravenous, oral, subcutaneous, and intramuscular. It retains toxicity when administered intracranially, likely due to the retention of an intact copy of the $\gamma_1$34.5 gene.

Safety has been demonstrated in humans at doses up to 10^8 pfu when administered peripherally in the vaccine trial, and while the virus retained immunogenicity in humans, two doses were required to induce antibody formation. R7020 has been examined as a candidate antitumor agent for a variety of non-CNS tumors in a variety of preclinical models, including hepatoma, colorectal carcinoma, head and neck epithelial squamous cell carcinoma and prostate adenocarcinoma xenografts.

A Phase I study of NV1020 has been conducted in patients with colorectal carcinoma metastatic to the liver. NV1020 was delivered via percutaneous hepatic artery infusion in patients with hepatic metastatic colorectal. Three days after infusion, patients underwent surgery for placement of a hepatic infusion pump; at that time, both tumors and non-malignant liver were biopsied. Patients were observed for 28 days before starting regional chemotherapy. Preliminary results presented at the American Society of Clinical Oncology showed no dose limiting toxicities in the first nine patients, treated at three dose levels (1.3×10^6, 10^7, 1.3×10^7 pfu). Some patients did develop fever, nausea, and headache. Viral DNA but not infectious virus was demonstrated by PCR examination of the hepatic venous outflow. Virus was demonstrated by immunohistochemistry in tumor tissue but not normal liver, and all patients demonstrated a decrease in CEA, a marker for colorectal cancer, over a 28-day period (Fong *et al.*, 2002). A report on the complete trial of all twelve patients treated up to a dose of 1×10^8 pfu is expected shortly. A Phase I//II trial is under way which is designed to examine safety and tolerability of NV1020 in this setting, as well as possible synergies with chemotherapy.

HSV and other cancers

While trials have been opened for patients with other cancers including mesothelioma and head and neck cancers, results remain unpublished at the time of this writing.

Oncolytic HSV: current directions

The potential of HSV used alone as an oncolytic virus is clearly illustrated through these trials (Table 76.1). However, it is likely that recalcitrant tumors such as malignant glioma may require a multi-pronged approach for successful treatment. The proven safety of these engineered viruses permits us to consider the use of HSV-1 mutants that serve not only to kill tumors via infecting, replicating and lyzing them, but also by functioning as vectors to deliver antitumor genes. Preclinical studies using engineered HSV-1 mutants in combination with standard treatment modalities are promising. The enhancement of anti-tumor activity of G207 or other HSV-1 mutants (4009, 7020, 3616) with low-dose and high-dose irradiation has been shown in models of malignant glioma as well as other tumors, including hepatoma, radioresistant squamous cell carcinoma (Advani *et al.*, 1998; Bradley *et al.*, 1999), and cervical cancer (Blank *et al.*, 1999). Combination therapy administering both the $\gamma_1$34.5-deletion mutant R3616 followed by ionizing radiation to mice with human U87 malignant glioma xenografts showed significant growth delay of flank tumors and extended survival of animals with intracranial tumors over the use of either treatment alone (Bradley *et al.*, 1999). These findings have also been demonstrated in intracranial U87 tumors treated with G207 followed by treatment with or without radiation (Markert *et al.*, 2000a,b). In at least some models, this interaction is not simply additive but appears synergistic, possibly due to enhanced viral replication and better dissemination of the virus allowing greater reduction of tumor volume after combination therapy. Increased efficacy has been shown when HSV-1 has been given in conjunction with chemotherapeutic agents, although the purported mechanisms of this increased efficacy vary (Chahlavi *et al.*, 1999).

The demonstrated safety and promise demonstrated by the mutant viruses G207, HSV1716, and NV1020 warrants the further investigation of novel HSV-1 gene therapy vectors. Transgene expression of interleukins or cytokines to enhance immune response against neoplastic cells,

Table 76.1. HSV for the oncolytic viral treatment of tumors

VIRUS	Tumor-selective virus-derivative	Engineered mutation(s) to target tumors	Clinical trials	Tumors targeted
Herpes simplex virus-1	**G207**	1. Deletion of both $\gamma_1$34.5 copies 2. *LacZ* insertion in UL39 (ICP6-inactivation)	Phase I, IB completed Phase I XRT trial approved	Glioma
	HSV1716	1. Deletion of both $g_1$34.5 copies	3 Phase I studies, pilot completed	Glioma, melanoma
	NV1020	1. Deletion, 15 kbp region (UL56 gene to internal ILR) 2. Insertion of HSV-2 gG, gD, gI, partial gE 3. Insertion of HSV-1 tk under alpha-4 4. 700 kbp deletion of UL23-UL24	Phase I completed, Phase I/II underway	Colorectal metastases

anti-angiogenic factors to impede growth of vascular supplies to tumors, or suicide genes to augment the cytotoxic effects of chemotherapeutic agents are all possibilities under study that may demonstrate improved efficacy against human malignancies. Thus, the use of HSV as a portion of a multi-modality treatment regimen involving radiation, chemotherapy and gene therapy, as well possibly oncolytic viral therapy, may hold an important place in the future treatment of patients suffering from these conditions.

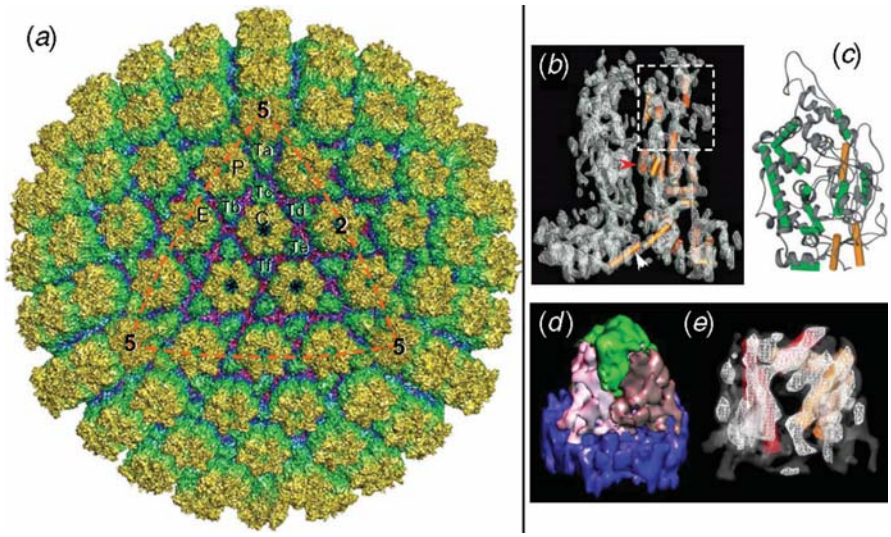

Figure 3.3. Herpesvirus capsid at 8 Å resolution (Zhou *et al.*, 2000) and atomic model of upper domain of the HSV-1 major capsid protein (MCP), VP5 (Bowman *et al.*, 2003). (*a*) Radially color-coded surface representation of the herpes simplex virus type 1 B capsid structure at 8.5 Å. One of the 20 triangular faces is denoted by dashed triangle. The penton and three types of hexons are indicated by '5', P, E and C. Also labeled are the six quasi-equivalent triplexes, Ta, Tb, Tc, Td, Te, Tf. (*b*) Two hexon subunits were shown in wire frame representation with α helices identified in one of the VP5 subunit illustrated by orange cylinders (5 Å in diameter). The red arrowhead points to the 7 helix bundle in the middle domain and the white arrow identifies the long helix in the floor domain that connects adjacent subunits. (*c*) Ribbon representation of the atomic structure of the HSV-1 MCP upper domain determined by X-ray crystallography (Bowman *et al.*, 2003). The helices identified in the hexon VP5 subunit in the 8.5 Å HSV1 capsid map (Zhou *et al.*, 2000) are shown as cylinders: those in green match with helices present in the X-ray structure and those in yellow are absent in the X-ray model, suggesting possible structural differences of MCP packed in the crystal and inside the virion. (*d*) One single triplex is shown as shaded surface representation with individual subunits in different colors: VP19c in green and the two quasi-equivalent VP23 subunits in light and dark grey, all situated on the capsid shell domains of VP5 (blue). (*e*) α-helices identified in the two quasi-equivalent VP23 molecules (in red and yellow cylinders of 5 Å diameter, respectively). Adapted with permissions from publishers.

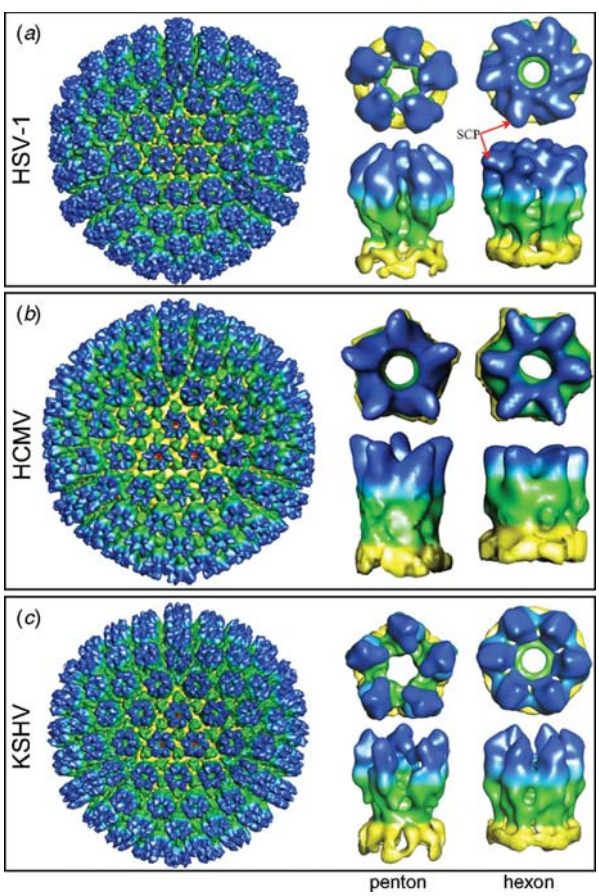

Figure 3.4. Comparison of the three-dimensional structures of alpha, beta and gammaherpesvirus capsids. The capsid maps of HSV-1 (*a*), HCMV (*b*) and KSHV (*c*) are shown as shaded surfaces colored according to particle radius and viewed along an icosahedral three-fold axis. The resolution of the HSV-1 and KSHV capsid maps is 24 Å and that of the HCMV capsid (Butcher *et al.*, 1998) is 35 Å. The right two columns are detailed comparisons of a penton and an E hexon, which were extracted computationally from each map and shown in their top and side views.

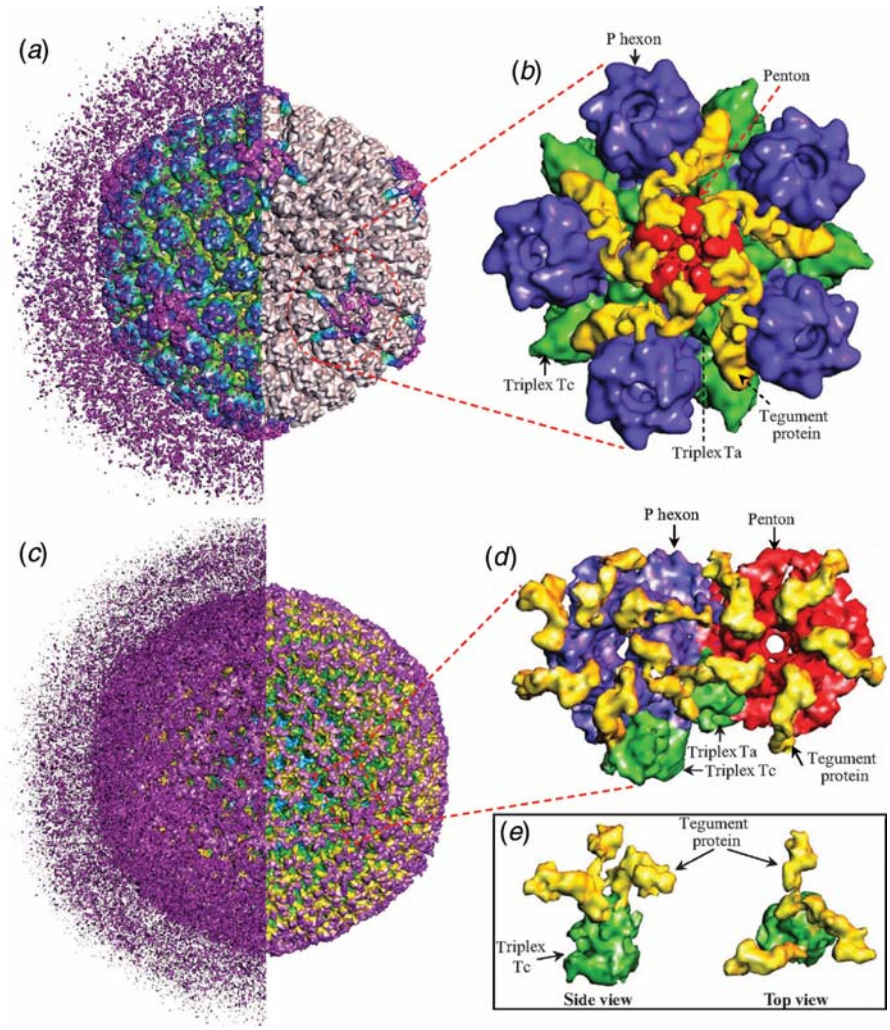

Figure 3.6. Difference of the anchored tegument proteins between HSV-1 ((*a*) and (*b*)) and HCMV ((*c*)–(*e*)). ((*a*) and (*c*)) Radially color-coded shaded surface views of the three-dimensional reconstruction of HSV-1 (*a*) and HCMV (*c*) virions as viewed along an icosahedral three-fold axis. The bulk of the tegument components and the viral envelope are not icosahedrally ordered or polymorphic, thus appearing as disconnected low densities in the icosahedral reconstruction. These disconnected densities were masked out for the right hemisphere to better reveal the icosahedrally ordered tegument proteins, which are shown in blue to purple colors in (*a*) and in purple in (*c*). ((*b*) and (*d*)) Close-up views of the region indicated in (*a*) and (*c*), respectively, showing the molecular interactions of the tegument proteins (yellow) with the penton (red), P hexon (blue) and triplexes (green). In HSV-1, contrary to the extensive tegument association with all hexons, the tegument densities do not interact with any hexon. (*e*) Extracted triplex HCMV Tc with its attached tegument densities. Three tegument densities interact with the upper domain of each triplex (insert Table 3.1).

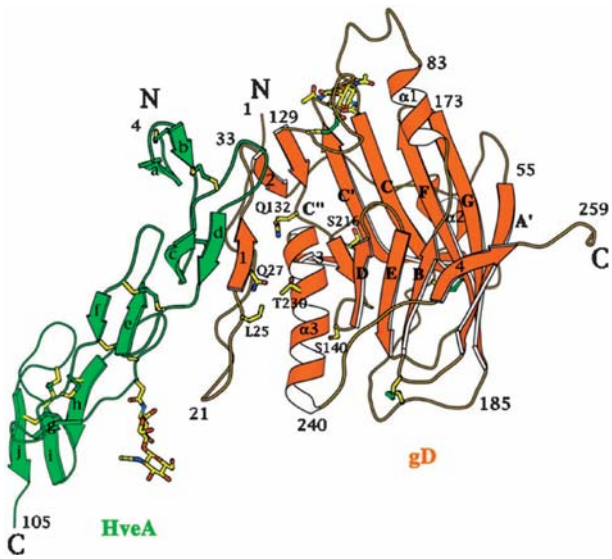

Figure 7.3. Ribbon diagram of the 3D structure of a soluble truncated form of gD (gD285t, colored in orange) bound to HVEM receptor (HveA, colored in green) as determined by X-ray crystallography. The N-terminus (residues 1–37) of gD is devoid of a specific structure when in the unbound state, but folds into a hairpin when bound to HVEM receptor. The β-strand formed by residues 27–29 (indicated with number 1) forms an intermolecular β-sheet with HVEM residues 35–37 (letter d). The core of gD (residues 56–184) has a V-type immunglobulin domain structure, composed of 9 parallel and antiparallel β-strands (letters A to G) that form two opposing β-sheets, and carries an additional α-helix (α1). The residues 185–259 form two α-helices that fold back to the N-ter (α2 and α3), and two β-strands (numbered 3 and 4). The α3 helix supports gD's N-terminal hairpin. An additional β-strand (number 2) is located in the connector sequence (residues 33–55) that precedes the Ig-like core. Reprinted from (Carfi *et al.*, 2001), with permission.

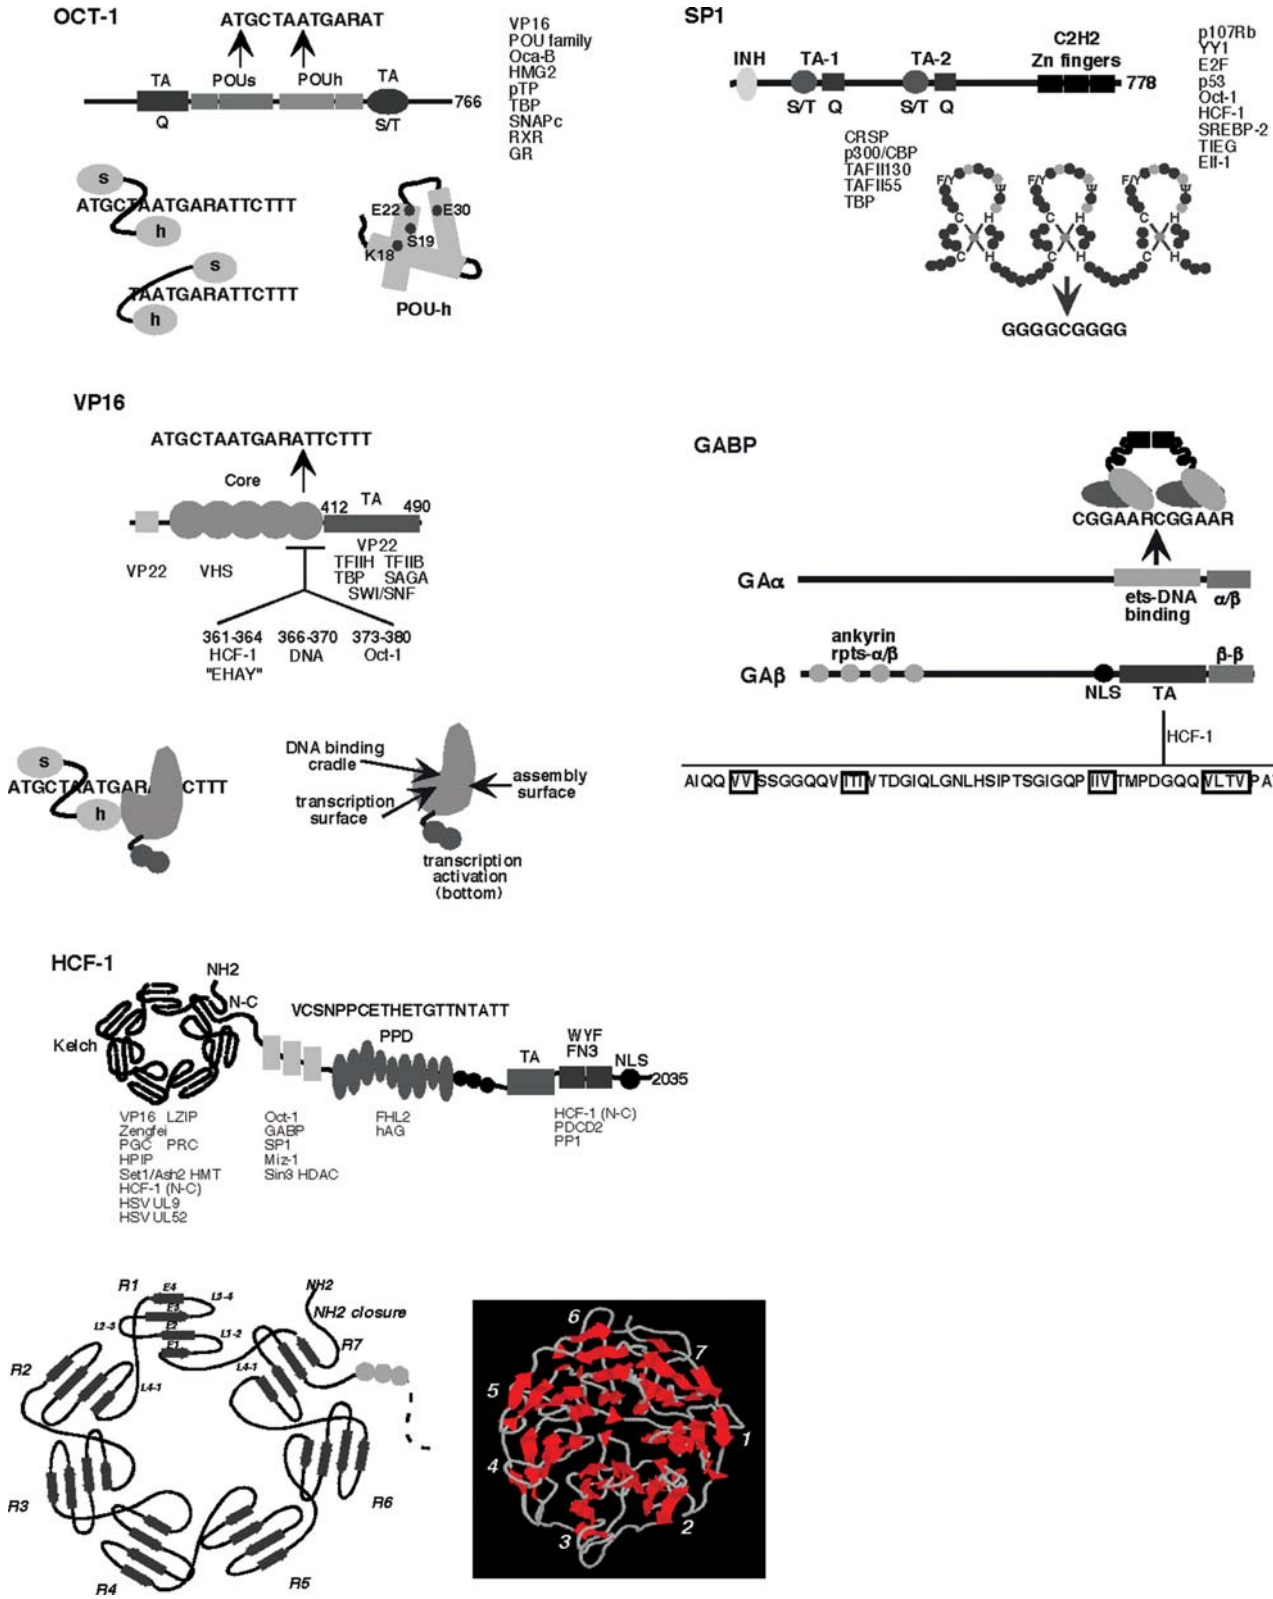

Figure 8.2. The protein components of the HSV IE enhancer complex.
Oct-1: The transactivation (TA-Q and TA-S/T) and POU (POUs and POUh) domains are shown. The POU-specific box recognizes ATGC while the POU-homeobox recognizes TAAT within the enhancer core element (ATGCTAATGARAT). Proteins that bind to the Oct-1 POU domain are listed. The inherent flexibility of the POU domain and the potential orientations of the POUs box in recognition of the core element are depicted. In the schematic representation of the Oct-1 POU-homeobox, the residues which are important for the recognition by VP16 are indicated. (*cont.*)

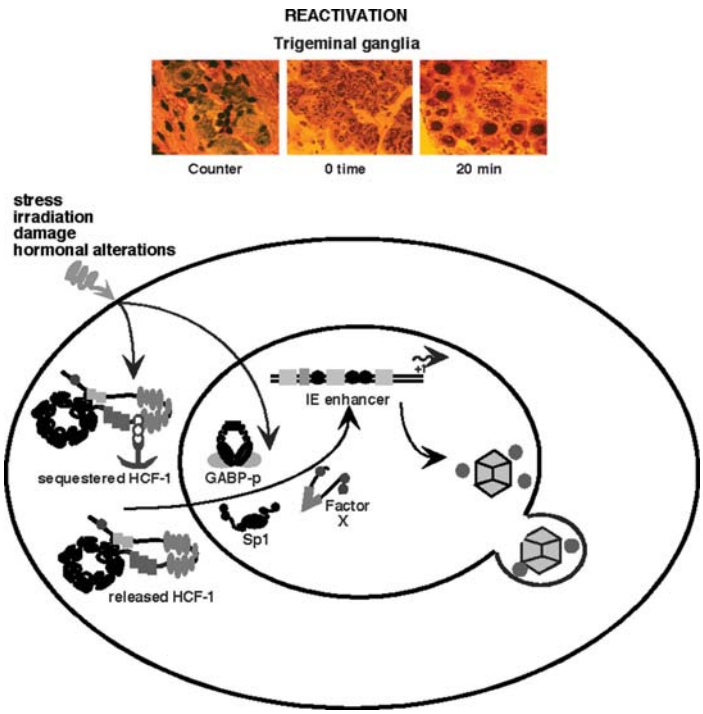

Figure 8.4. Model of the induction of the IE genes during HSV reactivation from latency. (Top) Immunohistochemistry studies of HCF-1 demonstrate that the protein is specifically sequestered in the cytoplasm of sensory neurons (0 time, middle panel) and rapidly transported to the nucleus under experimental conditions that reactivate HSV from latency (explant reactivation stimuli, right panel). (Bottom) Schematic depiction of the activation of IE enhancer components during the initiation of reactivation. Environmental signal(s) result in the release of cytoplasmically sequestered HCF-1 and the activation of DNA binding factors such as GABP, Sp1, or other factors which function in concert with HCF-1 to activate the IE genes and initiate the viral lytic cycle. (see colour plate section)

Figure 8.2. (*continued*) *VP16*: The structure and protein interactions of VP16 are represented. The core structure contains the clustered residues that are critical for the assembly of the IE enhancer complex (HCF-1, Oct-1, DNA) while the transactivation domain (TA, aa 412–490) interacts with a number of basal factors and chromatin modifying components. A schematic representation of the VP16 protein structure is shown (left) indicating the various protein interaction surfaces oriented in recognition of the Oct-1 POU-homeobox/ DNA complex.
HCF-1: The amino-terminal kelch, mid-aminoterminal, proteolytic processing (PPD), autocatalytic (Auto), transactivation (TA), WYF-rich, FN3 repeat, and nuclear localization signal (NLS) regions are represented. The proteins that interact with each region are listed below the appropriate domain. The PPD is represented as a series of consensus (large oval) and divergent (small oval) reiterations of the HCF-1 cleavage sequence shown above. (Bottom left) A stylized representation of the HCF-1 kelch domain is shown illustrating the seven predicted blades (antiparallel sheets, E1 through E4; loops, L1–2 through L4–1). For HCF-1, the predicted ring closure utilizes E4 from the animoterminus and E1-2-3 from the carboxyterminus of the domain (NH2 closure). (Bottom right) The derived molecular model of the HCF-1 kelch domain structure is depicted.
Sp1: The inhibitory domain (INH), transactivation domains (TA-1, TA-2), and DNA binding domains (C2H2, Zn fingers) are represented. Proteins or protein complexes that interact with Sp1 are listed. The structure of the C2H2 Zn finger domain is schematically represented: C, cysteine; H, histadine; F/Y, phenylalanine or tyrosine; y, hydrophobic residue. Light circles represent amino acids that are predicted to make DNA contacts.
GABP: The α subunit contains the ets DNA binding domain recognizing the GA box and the heterodimerization domain (α/β). The β subunit contains ankyrin repeats (α/β heterodimerization region), nuclear localization signals (NLS), transactivation domain (TA), and tetramerization sequences ($\beta-\beta$). The sequence of the transactivation domain is shown and the residues that are critical for both transactivation and interaction with HCF-1 are boxed. (see colour plate section)

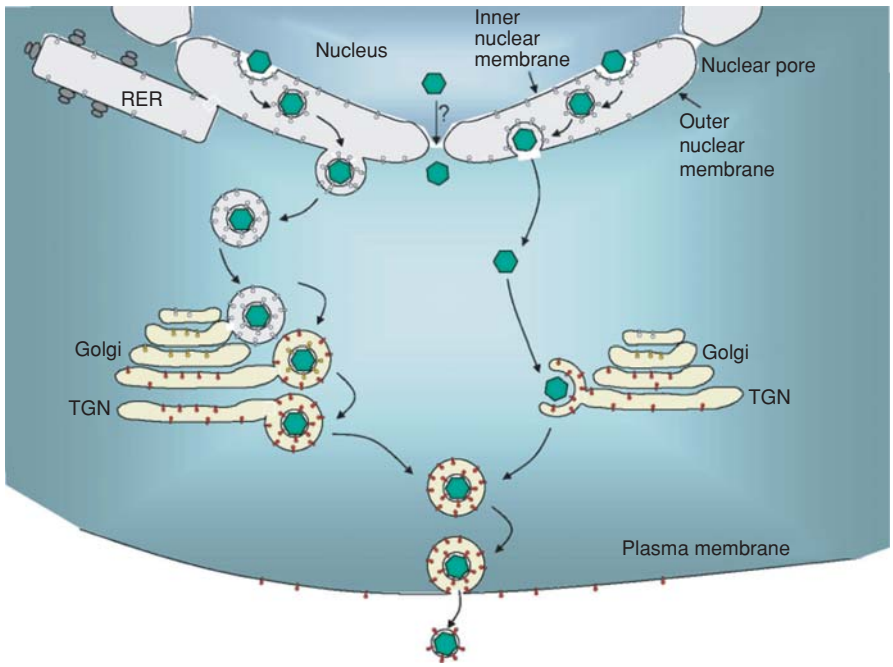

Figure 12.1. Schematic drawing showing the two alternative pathways of alphaherpesvirus egress from infected cells. The single envelopment pathway is depicted to the left, and the double envelopment, or de-envelopment-re-envelopment is depicted to the right of the illustration. The schematic drawing does not shows the gross ultrastructural modifications of the Golgi apparatus and TGN. Perinuclear virions and nuclear membranes are decorated with glycoproteins of different color than virions at the level of the Golgi apparatus and TGN, as well as extracellular virions, to emphasize that the oligosaccharide moieties of the viral glycoproteins are of the immature type in early exocytic compartment, but are of the mature type in the late exocytic compartments and in extracellular virions. The drawing considers also the possibility that nucleocapsids exit the nucleoplasm through modified nuclear pores, without transiting through the perinuclear lumen. (Drawing by courtesy of L. Menotti.)

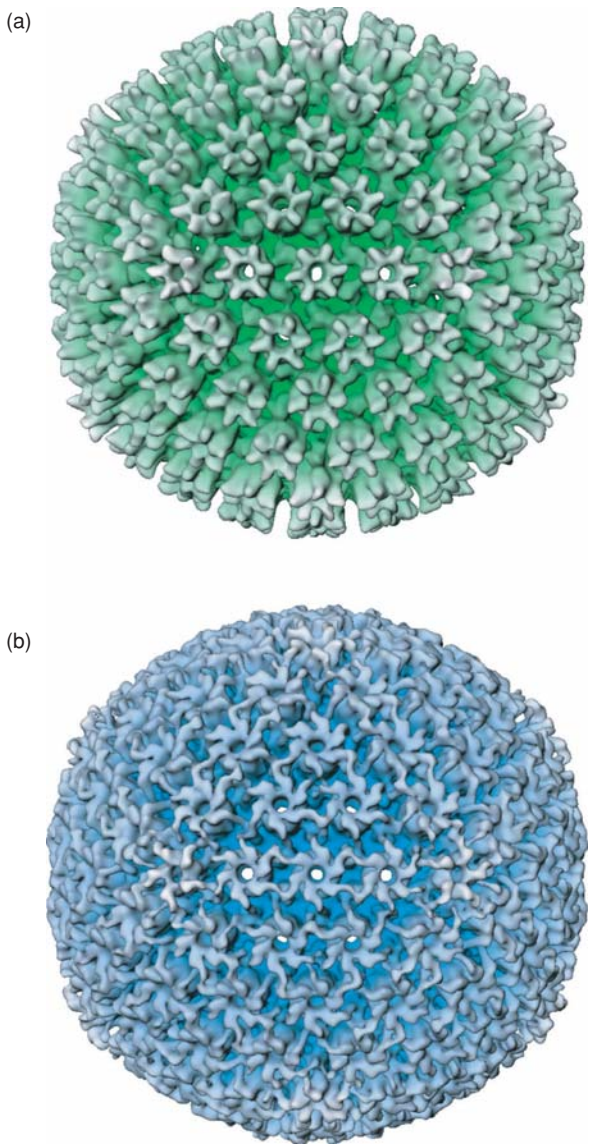

Figure 14.6. Three-dimensional reconstructions of (a) the HCMV B-capsid (adapted from Butcher *et al.*, 1998; with permission from Academic Press), and (b) the HCMV virion (adapted from Zhou *et al.*, 1999; with permission from the American Society for Microbiology). Both structures are viewed along the icosahedral twofold symmetry axes and are radially depth-cued so that darker regions are closer to the centre of the particle and lighter regions are further away.

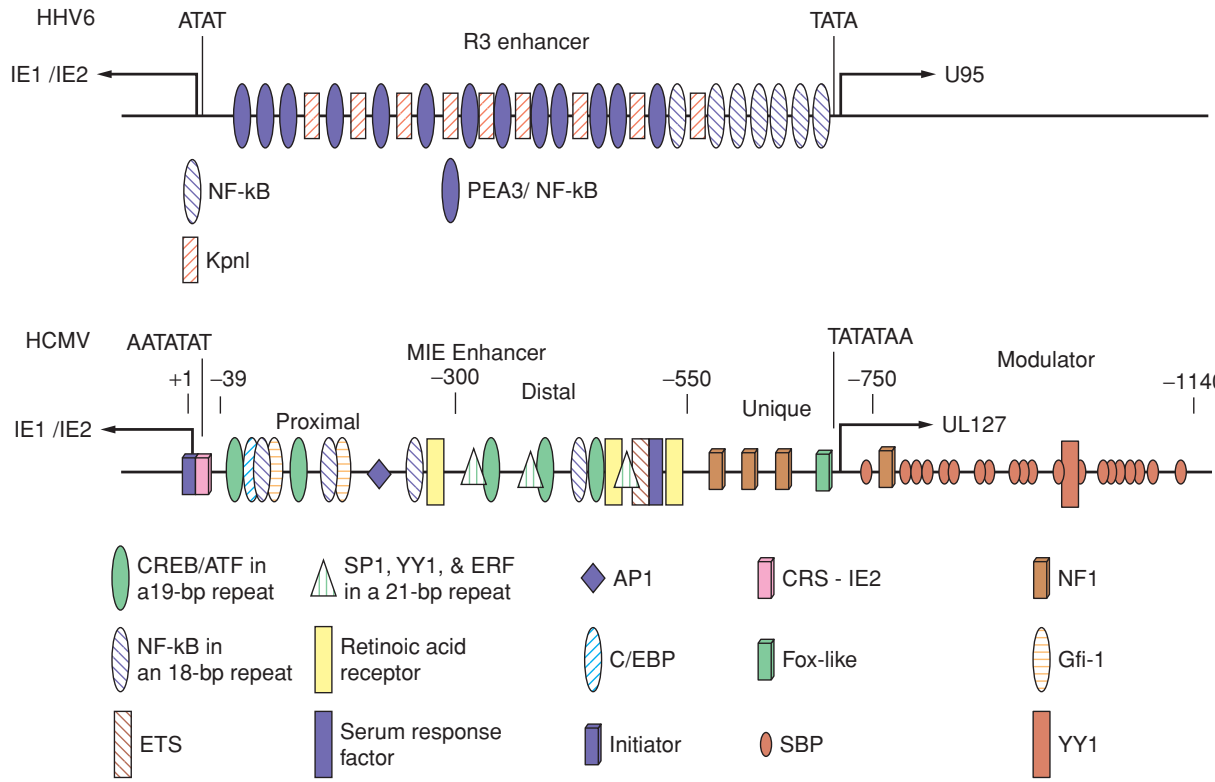

Figure 17.3. Comparison between the HCMV major immediate early (MIE) and the HHV-6 R3 enhancer. Viral genes and promoter/transcription start sites are designated by an arrow. The HCMV also has a unique region and a modulator discussed in the text. The various transcription factor binding sites identified for HCMV and HHV-6 are designated. The AP-2 sites in the R3 enhancer are not identified.

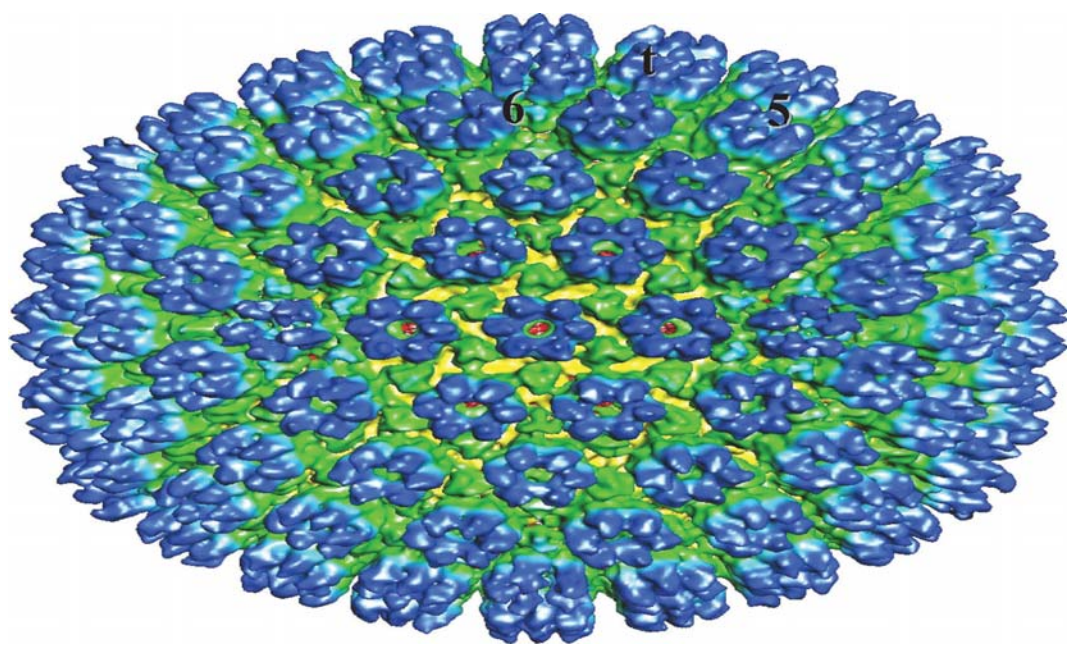

Figure 23.1. 3D structure of the KSHV capsid at 24-Å resolution by electron cryomicroscopy. The capsid is shown as shaded surface color-coded according to particle radius. The three structural component of the capsid are indicated, including 12 pentons ("5"), 150 hexons ("6") and 320 triplexes ("t"). (Wu *et al.*, 2000 with permission).

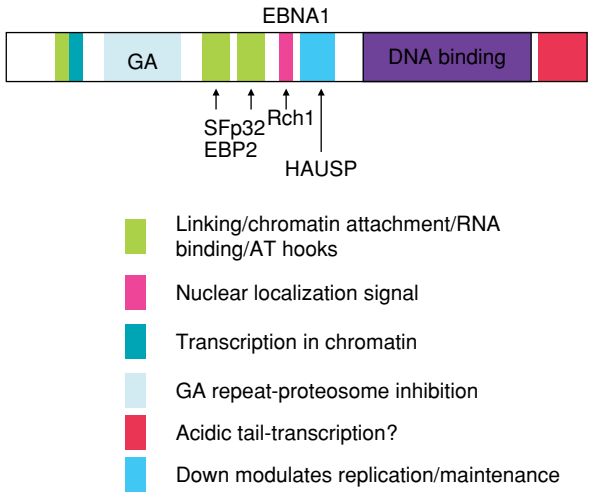

Figure 24.4. Functional protein domains of EBNA1. Amino acid residues are indicated for the boundaries of protein domains for DNA binding, dimerization, chromosome binding sites (CBS), nuclear localization (NLS), or protein–protein interactions (as indicated).

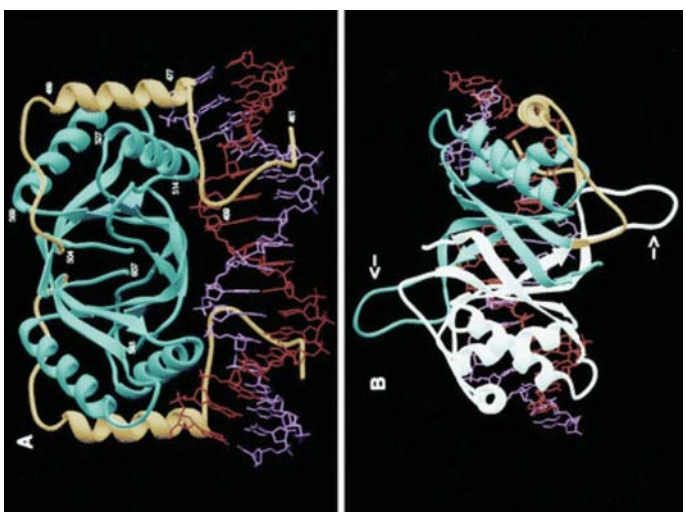

Figure 24.5. X-ray crystal structure of EBNA1 dimer bound to a consensus DNA recognition site (courtesy of Bocharev *et al.*, *Cell* in press). (a) Ribbon diagram showing the core domain (residues 504–607) from each monomer, in blue. Flanking domains are shown in yellow. (b) View down the non-crystallographic axis showing one monomer in white and the other in the same color scheme as used in (a). Proline loops are indicated by arrows.

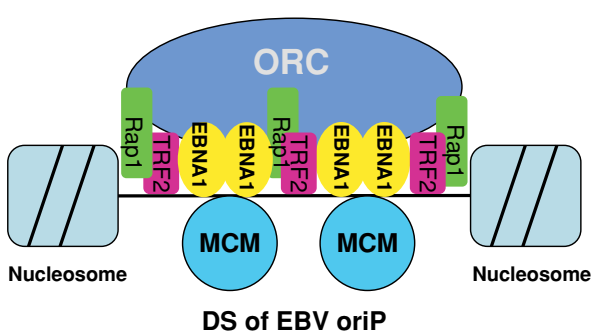

Figure 24.6. Model for *OriP* of EBV. Indicated are protein–protein and protein DNA interactions that are required for the initiation of DNA synthesis at *OriP*.

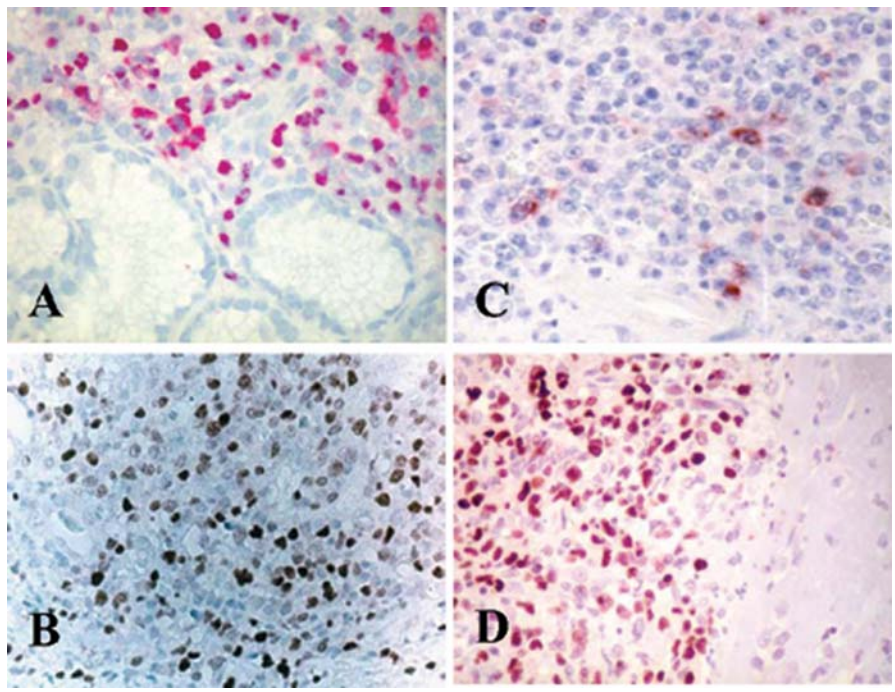

Figure 27.2. Latency III pattern characteristic of the majority of cases of post-transplant lymphoproliferative disease. All known EBV latent genes are expressed in this form of latency: (a) EBERs, (b) EBNA1, (c) LMP1, (d) EBNA2.

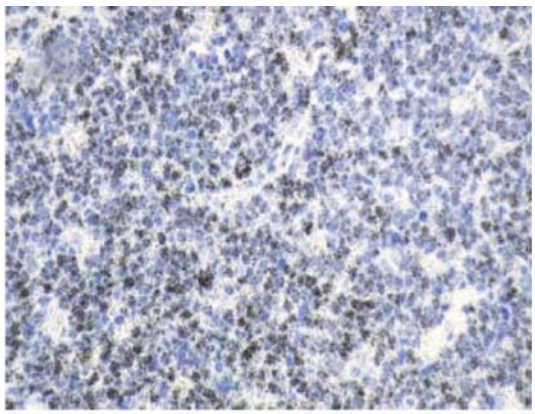
(a)



(b)

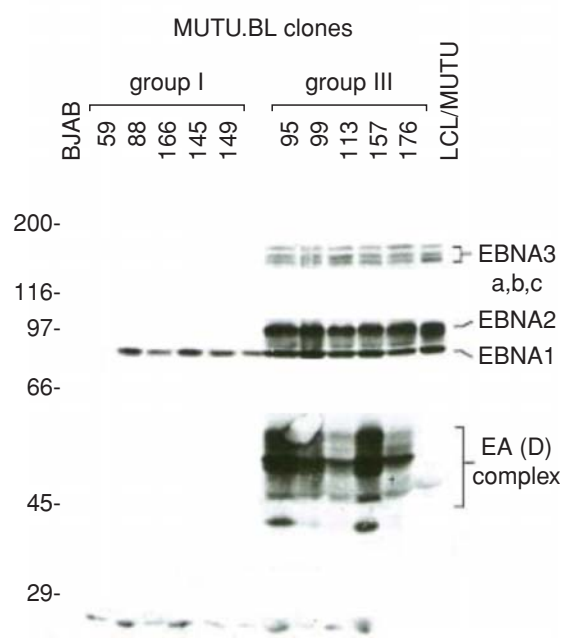


Figure 27.3. Latency pattern characteristic of Burkitt's lymphoma (BL). (a) Expression of EBERs in the tumor cells of BL tissue shown by isotopic *in* situ hybridization and (b) Immunoblotting demonstrating protein expression limited to EBNA1 in so-called 'group I' BL cell lines which recapitulate the in vivo expression profile. 'Group III' BL lines have an expression pattern similar to that of LCLs (Latency III) and represent cell lines that have 'drifted' from a latency I pattern in vitro.

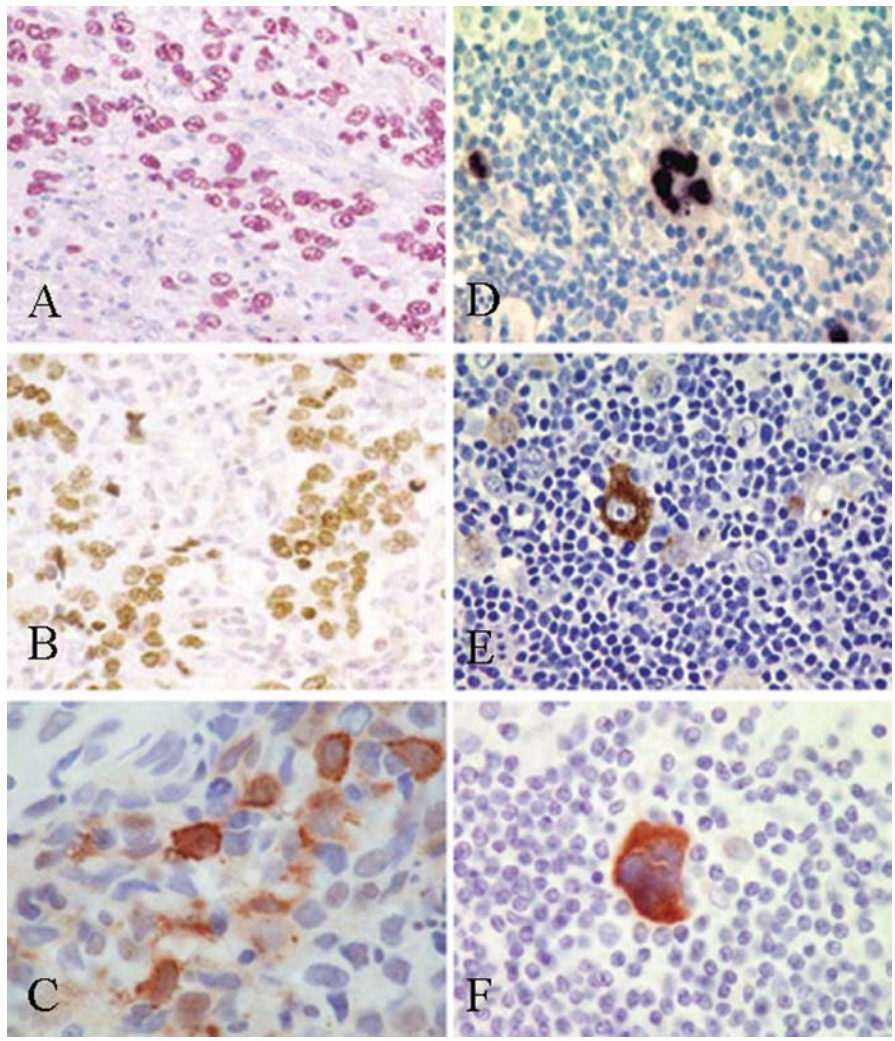

Figure 27.4. EBV latency type II. Left panel shows (a) Expression of EBERs, (b) EBNA1 and (c) LMP1, in the tumor cells of nasopharyngeal carcinoma (NPC). LMP1 expression is not a regular feature of these tumors. LMP2 protein has not yet been reported in NPC tumors, despite the detection of LMP2 RNA. Right panel shows EBV gene expression in the rare tumor cells of (HRS cells) Hodgkin's lymphoma. (d) EBERs, (e) LMP1 and (f) LMP2. EBNA1 protein is also detectable in the majority of cases (not shown). In contrast to NPC, both LMP1 and LMP2 protein are almost always detectable in EBV-infected HRS cells.

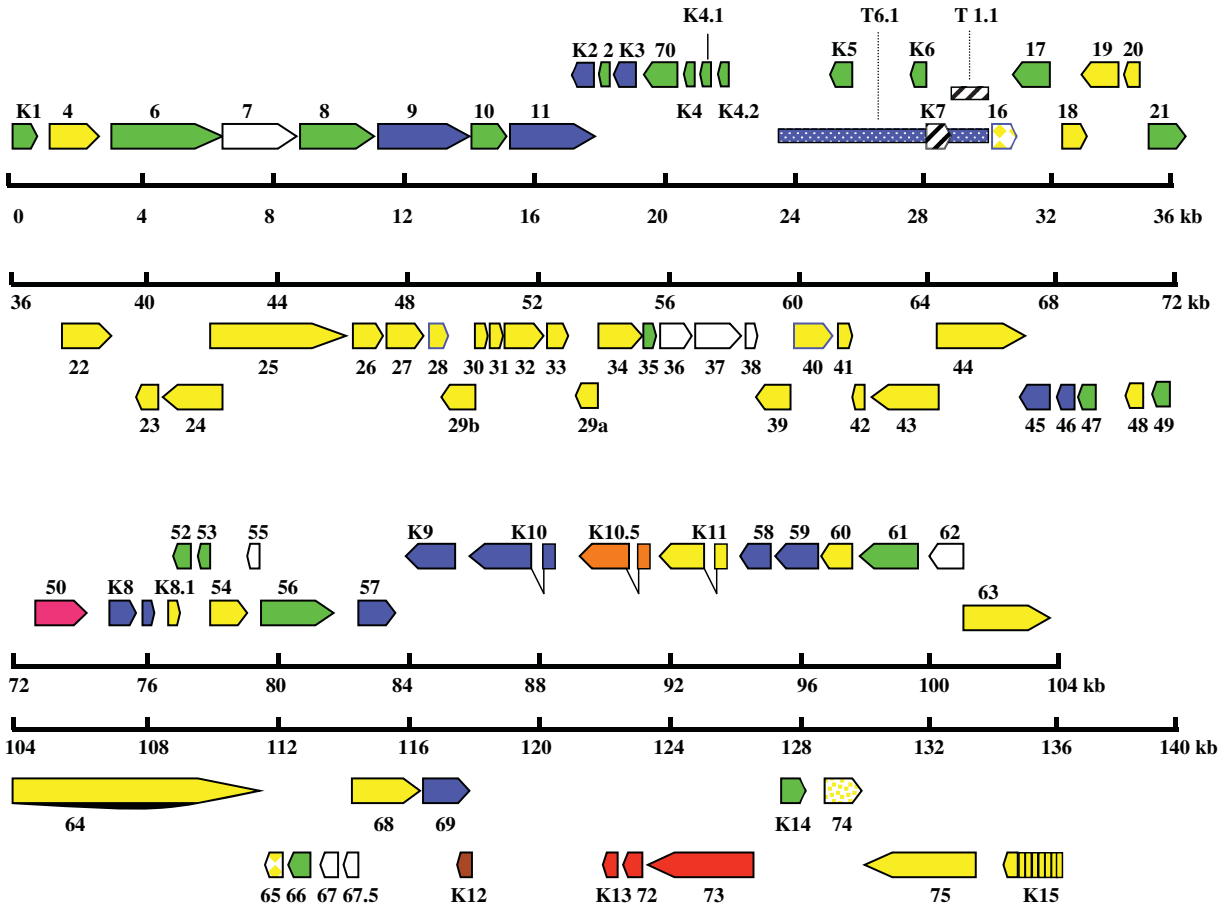

Figure 28.1. KSHV gene expression in PEL cell lines and biopsy samples. This Figure summarizes the expression of individual KSHV genes in PEL cells during latency and following reactivation of the lytic cycle by treatment with TPA, Na-butyrate or heterologous expression of RTA by transfection or transduction. Also included are results from in situ hybridization or immunohistochemistry studies on biopsy samples of KS, MCD or PEL tumors. As discussed in the text, the color-coding is based on a comparison of several reports that studied KSHV genes by Northern blot, real time PCR or DNA array. (See colour plate section)

- Latent gene
- Latent gene in B cells only
- Latent gene in KS spindle cells in vivo; early (in some studies delayed) expression kinetics in PEL cells in vitro
- Immediate–early gene as judged by cycloheximide resistance
- Very rapid onset of gene expression in at least 2 studies
- Early lytic transcript: TPA inducible, unaffected by PFA
- Delayed onset of gene expression
- Late gene expression profile
- Late gene expression profile confirmed by PAA sensitivity
- Discrepant results in different gene array studies

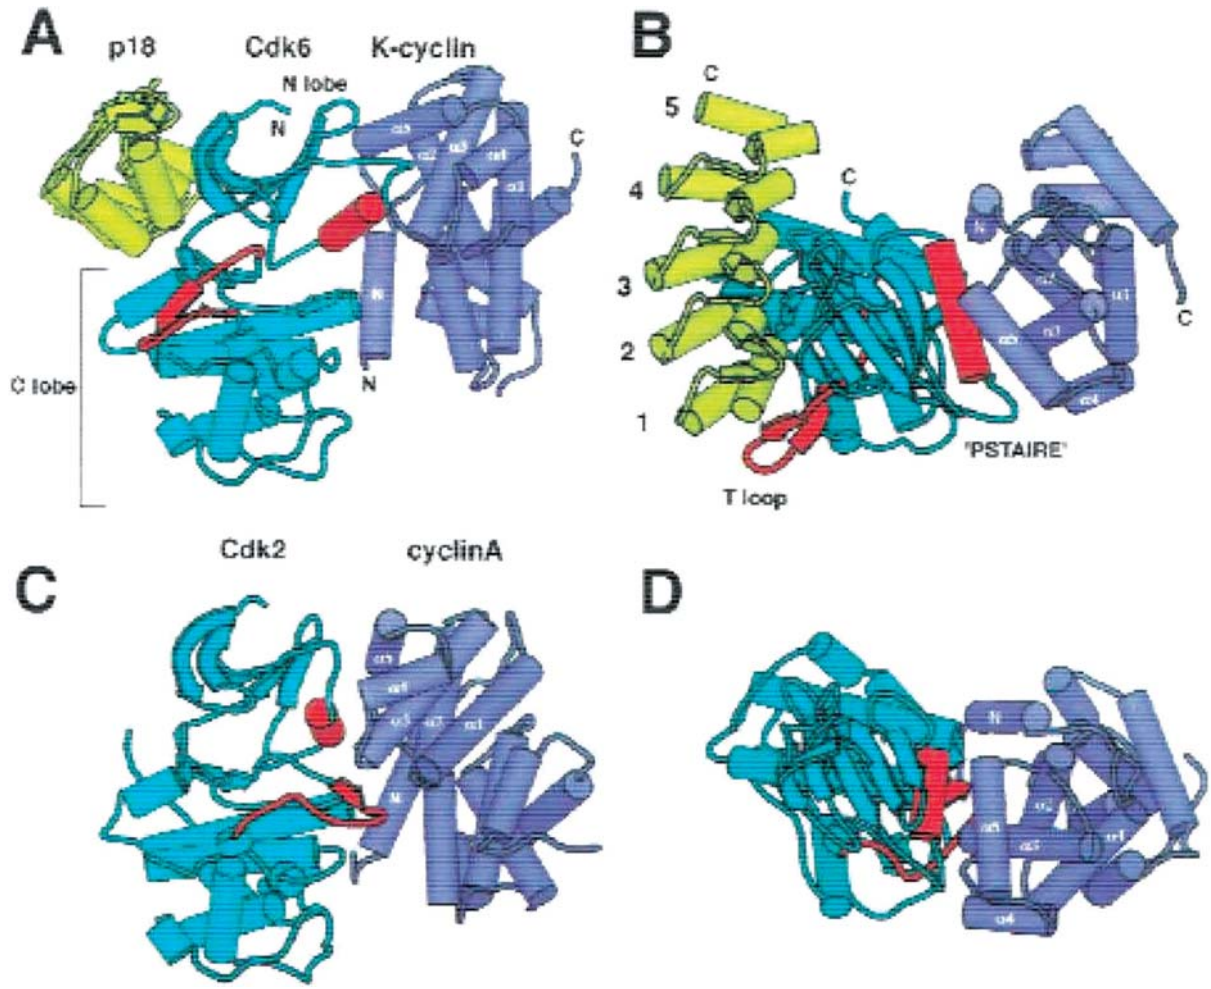

Figure 30.3. The structure of the vCYC (purple), CDK6 (cyan), p18Inkb (yellow) complex from side (a) and top (b) views, compared to cellular cyclin A (purple), CDK2 (cyan) side (c) and top (d) views. Unlike cellular cyclins, the regulatory T-loop of CDK6 is excluded from interaction with vCYC but the PSTAIRE regulatory helix of CDK6 still forms an interface with vCYC, The PSTAIRE helix forms part of the ATP binding domain required for kinase activity while the T loop acts as a negative regulator of kinase activity and must be phosphorylated by cyclin-activating kinases (CAK) in cellular cyclin–CDK complexes. While CAK phosphorylation may enhance vCYC-CDK6 stability, displacement of the T loop by vCYC allows this complex to be active in the absence of CAK activity. The structure of vCYC-CDK6 also reveals loss of the binding pocket used by cyclin-dependent kinase inhibitors (CDKI) of the CIP1/KIP1 family. These and other features support experimental data showing the vCYC-CDK6 not only have a broader target range than cellular D-type cyclins but also escape many normal negative regulatory controls imposed on the cellular cyclin machinery. Reprinted with permission (Jeffrey *et al.*, 2000).

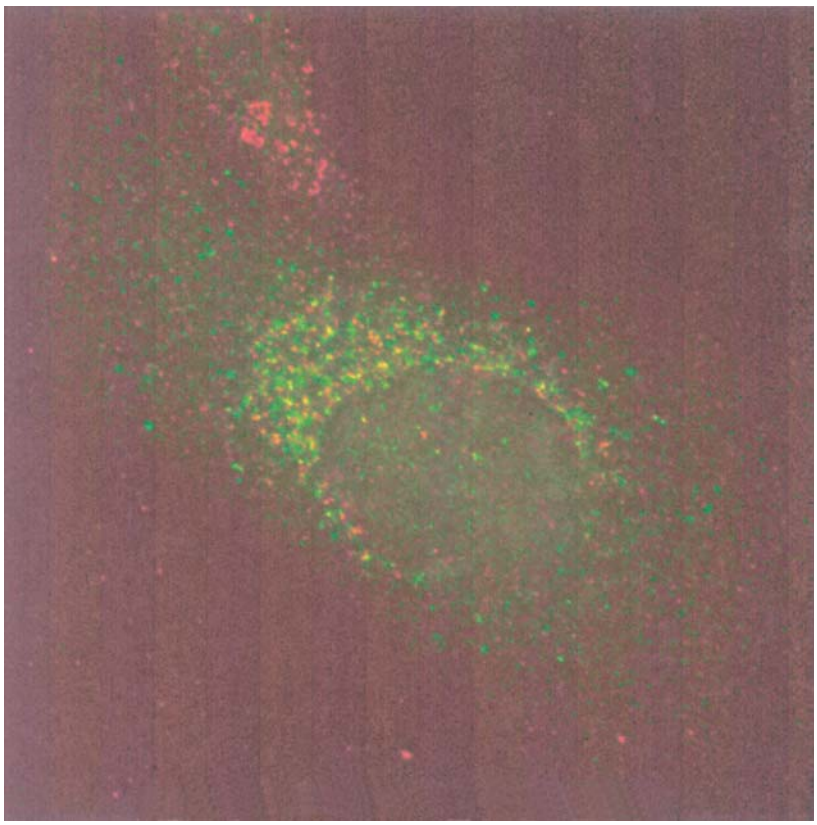

Figure 42.1. Immunofluorescent micrograph of HCMV-infected AEC. Telomerase life-extended human AEC were infected with HCMV. Cells were fixed and stained for the presence of HCMV protein, glycoprotein B (a late product; green) and a cellular marker of the *trans*-Golgi network (TGN46; red).

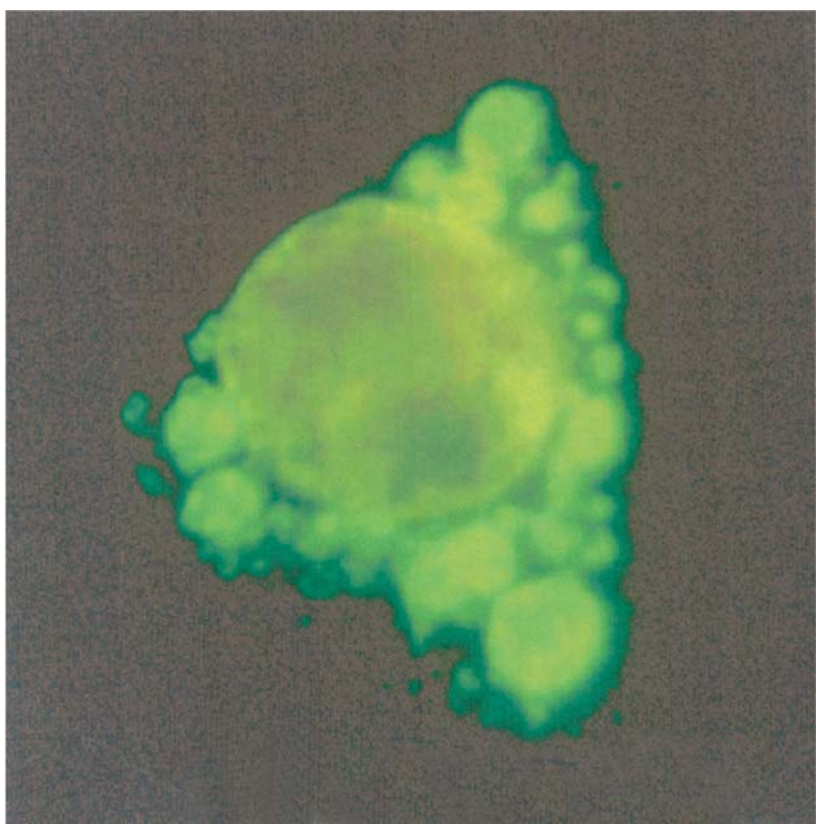

Figure 42.2. Immunofluorescent micrograph of HCMV-infected MDM. MDM were infected with HCMV. Cells were fixed and stained for the presence of HCMV proteins, pp65 (an early product; green) and IE-2 (an immediate-early productl; red).

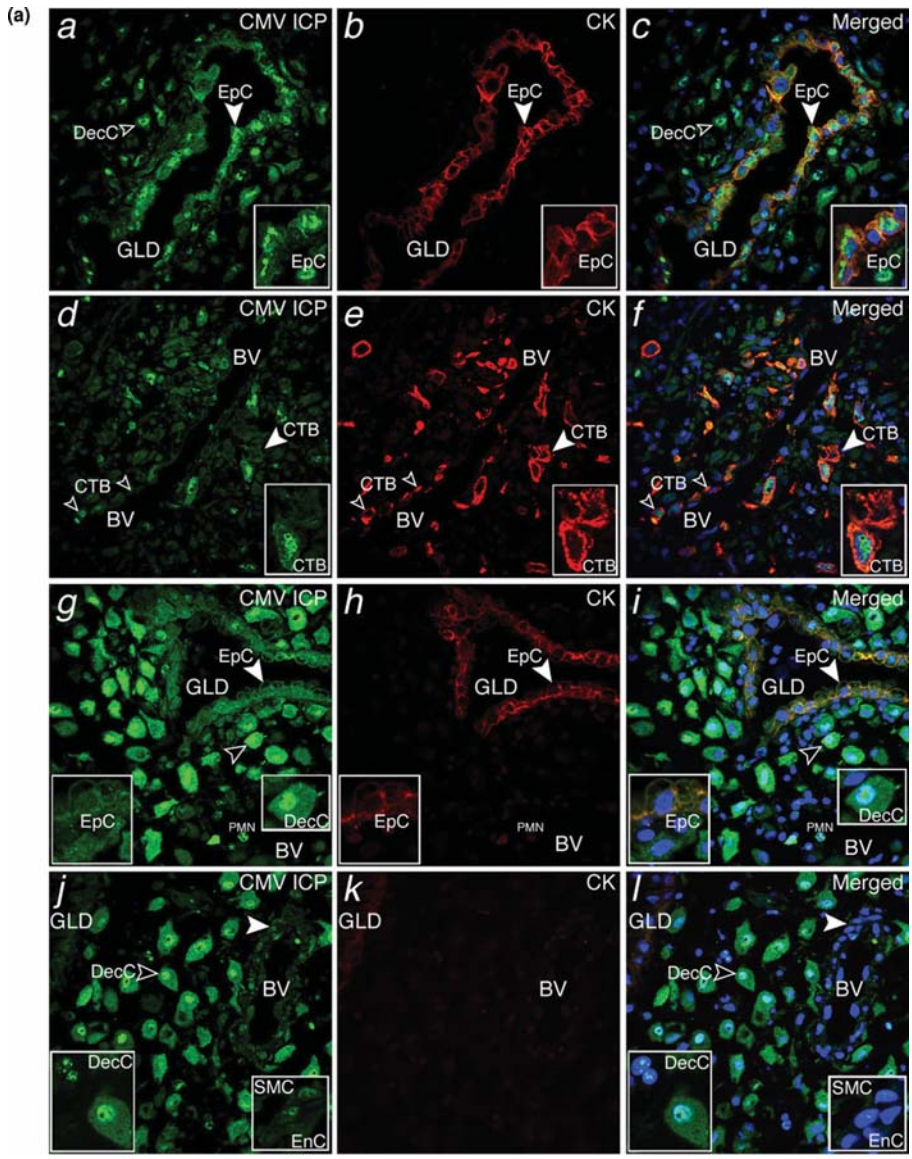

Figure 45.4a. Panel A: CMV replicates in diverse cell types in uterine decidua. CMV infects endometrial glands (GLD), uterine blood vessels (BV), resident decidual cells (DecC) and cytotrophoblasts (CTB) in the decidua. (*a*)–(*c*), Decidual biopsy specimens stained for CMV-infected-cell proteins (ICP, green) and cytokeratin (CK, red), which identified epithelial cells (EpC). (*d*)–(*i*), CMV-infected interstitial and endovascular CTB and DecC. (*j*)–(*l*), Endothelial cells (EnC) and smooth muscle cells (SMC) of uterine blood vessels (BV) are infected. Panel (*b*): Abundant innate immune cells infiltrating the decidua contain CMV proteins. (*a*)–(*c*) CMV gB (green), macrophages (Mφ/DC, CD68, red). (*d*)–(*f*) DC-SIGN+ (green) macrophage/dendritic cells (Mφ/DC) take up CMV gB (red). (*g* (and) *h*) CD56+ (green) natural killer (NK) cells target infection sites. (*i*) DC-SIGN+ cells containing gB. (*j*)–(*l*) Neutrophils (PMN) with phagocytosed proteins from virus-infected cells and endothelial cells (EnC) positive for von Willebrand factor (vWF) in blood vessels (BV). "Merged" indicates colocalized proteins (yellow). Large arrowheads indicate area shown in insets.

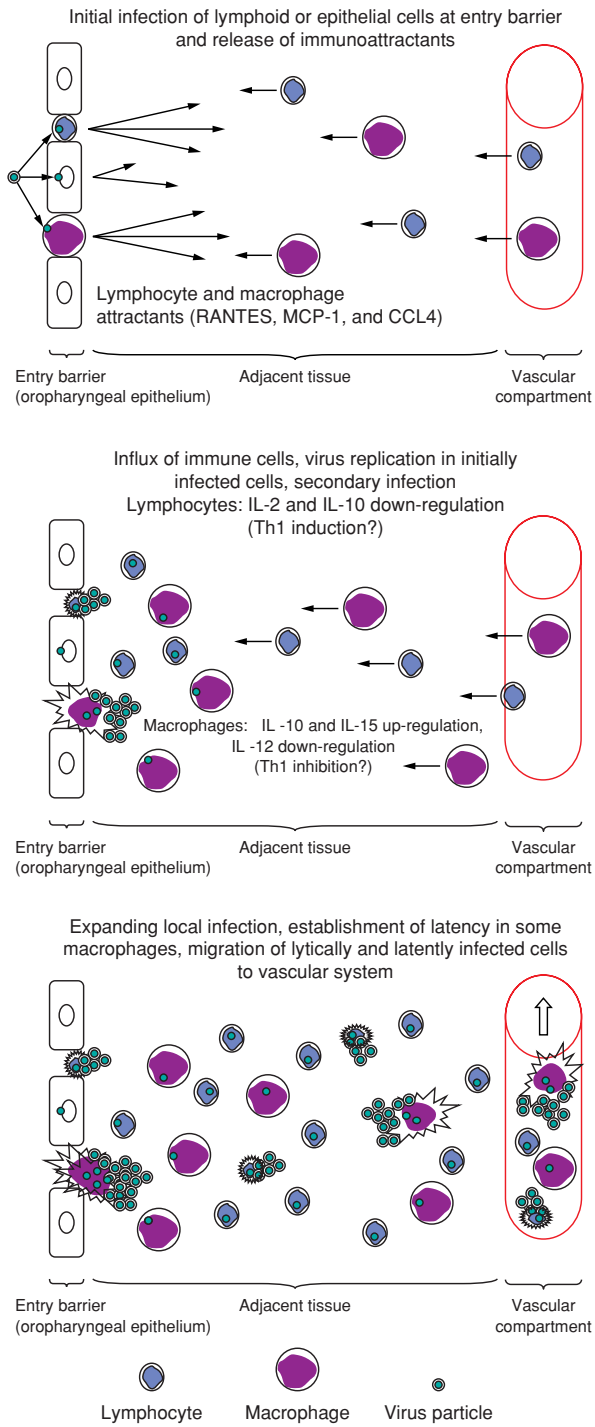

Figure 48.3. Immunobiological events during early primary HHV-6 infection and establishment of latency.

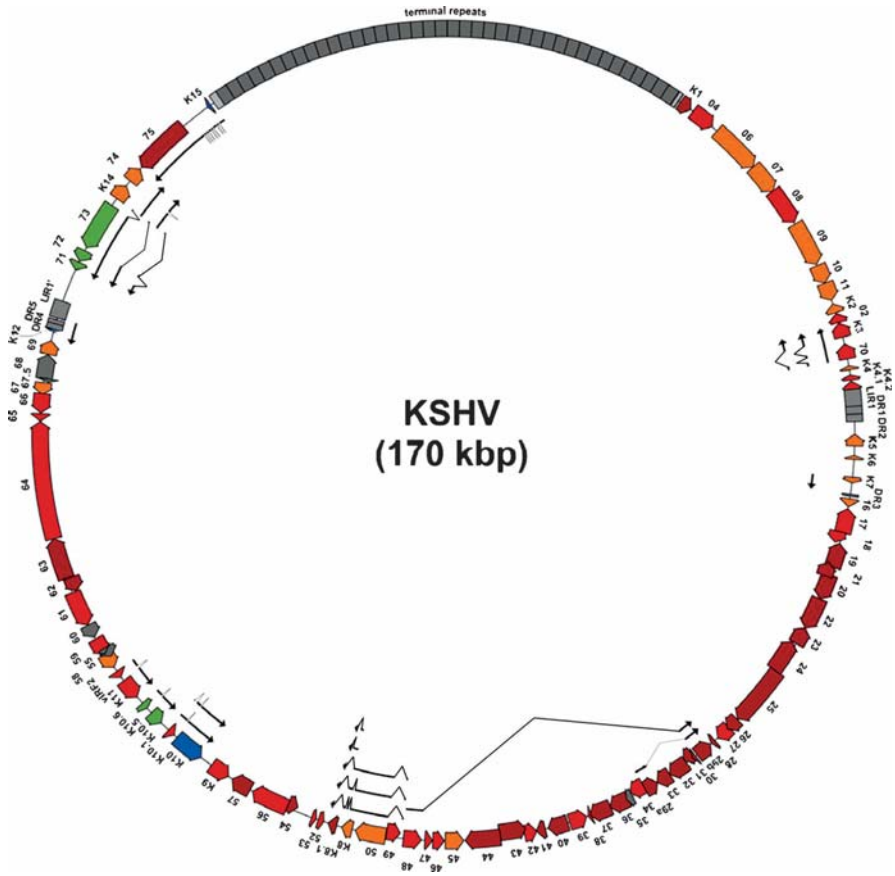

Figure 56.1. Latency genes of KSHV. Transcripts of latent genes are depicted as arrows, superimposed on the physical map of the circular latent viral genome.

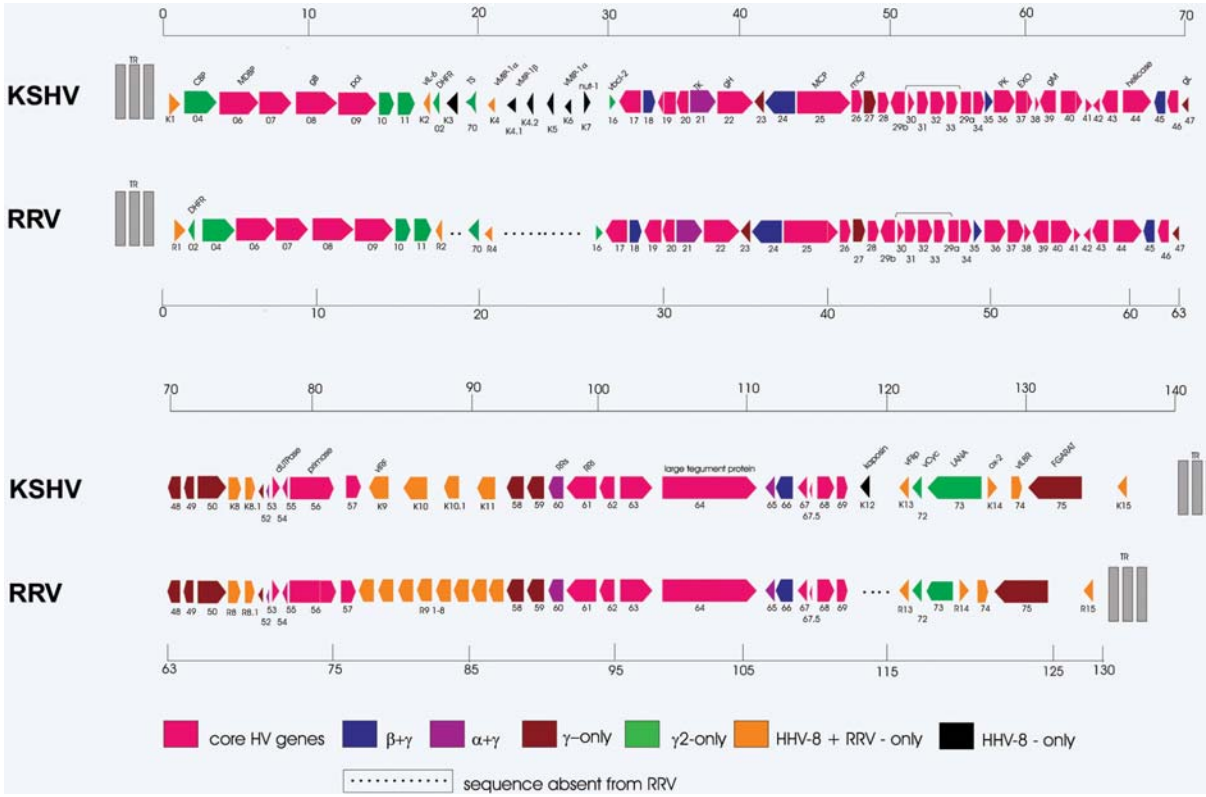

Figure 61.3. Alignment of the KSHV and RRV genomes. The different colors signify ORFs contained in KSHV and RRV 26–95 that are conserved in the indicated herpesvirus subfamilies or subgroups. The square side of the symbol signifies the 5′ end and the pointed side of the symbol signifies the 3′ end of the depicted ORFs. The ORFs are not drawn to scale. (Taken from Alexander *et al.*, 2000, with permission from the *Journal of Virology*.) (see colour plate section)

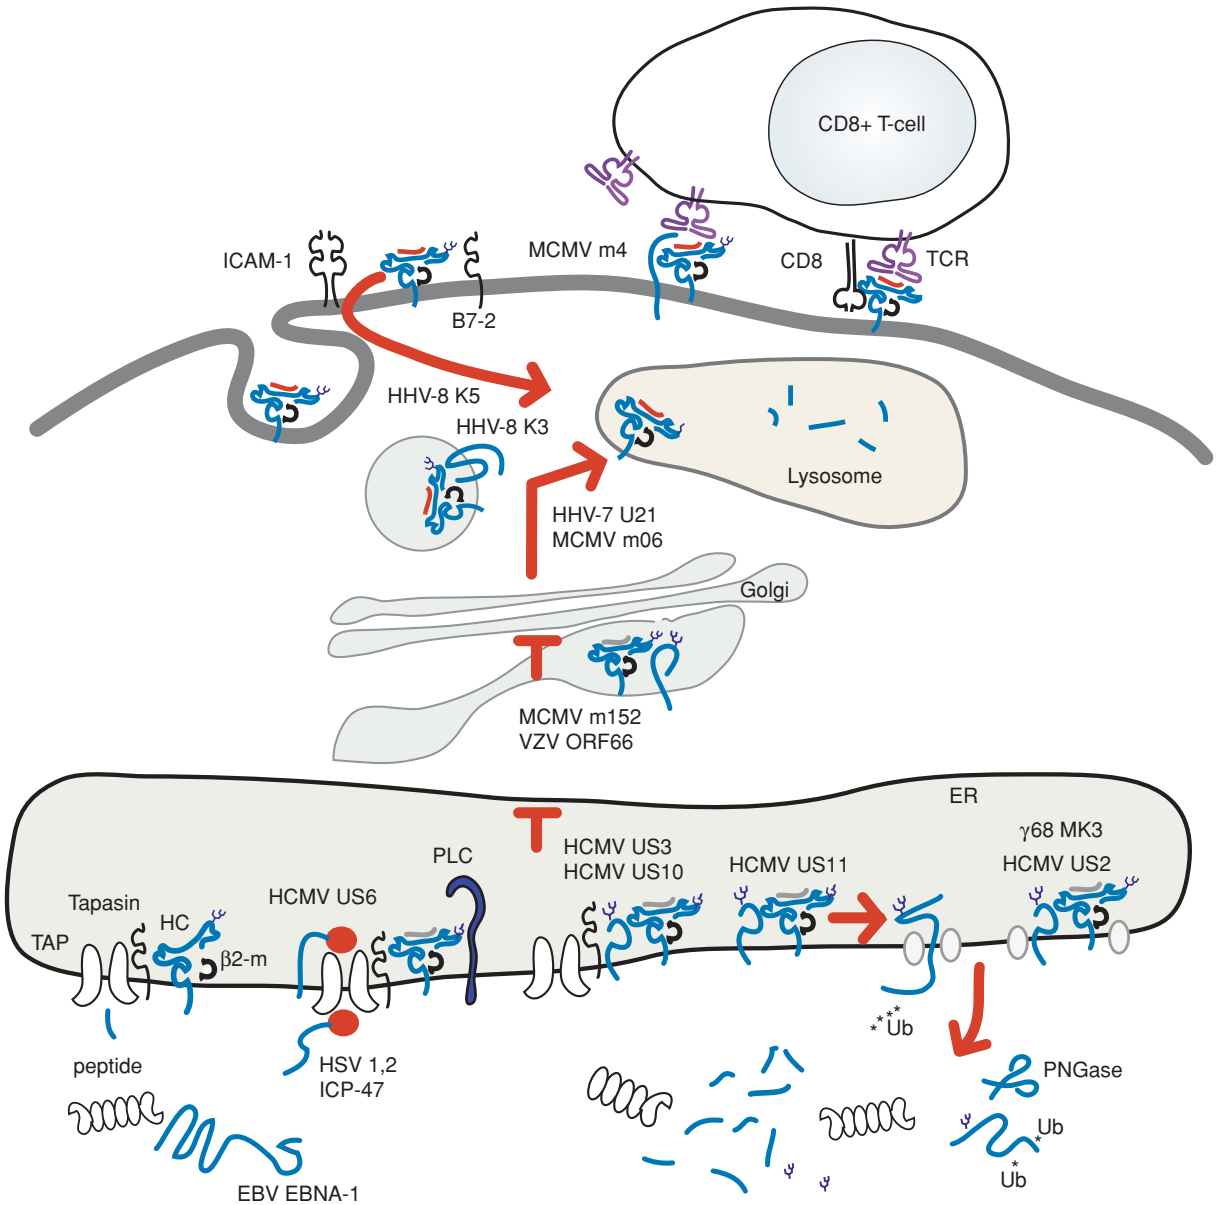

Figure 62.1. Herpesvirus immunoevasins that directly interfere with class I molecule biosynthesis. MHC class I molecules are assembled from free MHC class I HC and β-2 microglobulin within the ER, along with antigenic peptide. Peptides are produced by cytosolic 4m proteasome degradation via its GAr domain. Tapasin and the PLC facilitate loading of peptide cargo onto empty class I molecules. HSV ICP47 and HCMV US6 block TAP peptide transport, while HCMV US3 inhibits tapasin and retains class I complexes in the ER. Following receipt of peptide, the loaded class I molecules travel through the secretory pathway to the cell surface. HCMV US10 delays transport of class I molecules from the ER, while VZV ORF66 and MCMV m152 retain class I in the Golgi complex. HCMV US2, US11 and MHV γ68 MK3 dislocate class I molecules via an unidentified ER membrane pore to the cytosol. The dislocated class I heavy chains are ubiquinated (Ub) and deglycolylated by cellular PNGase prior to proteasomal cleavage. HHV-7 U21, MCMV m6, and HHV-8 K3 redirect class I molecules from the secretory to the endolysosomal pathway for degradation. HHV-8 K5 likewise targets MHC class I, B7-2 and ICAM-1 molecules to the endolysosmal pathway for destruction. MCMV m4 disrupts recognition of cell surface-disposed MHC class I-peptide complexes by the TCR 8of CD8+ T-cells.
