- Long-term benefit of low-carbohydrate diet: contributes to balanced nutrition and the prevention of obesity.

COMPLICATIONS

Although children tend not to suffer from the symptoms, parents are often worried and frustrated and require frequent reassurance.

 - 787.91 Diarrhea
- ICD10**
- K59.1 Functional diarrhea
 - R19.7 Diarrhea, unspecified

FAQ

- Q: How do I know that my toddler's diarrhea is not serious?
- A: Growth is usually normal and your child looks and feels well. His activity and development seem unaffected by the diarrhea. The change of diet results in improvement
- Q: What are the components of a successful treatment plan?
- A: Attention to the 4 Fs in the diet: Decreased fruit juice intake, increased fat intake, decreased fluid, and increased fiber intake.
- Q: Are probiotics useful in the treatment of toddler's diarrhea?
- A: There is no adequate data to support such a recommendation but evidence is emerging that probiotics are effective in IBS associated with diarrhea and bloating.
- Q: When should care by a pediatric gastroenterologist be sought?
- A: If no response after 2 weeks of compliance with dietary therapy, if growth is delayed, or if other GI or systemic complaints are present, seek a pediatric gastroenterologist's care.
- Q: Did my child get diarrhea because he goes to child care or because he is not clean?
- A. No. Functional diarrhea is not caused by infection.

FUNGAL SKIN INFECTIONS (DERMATOPHYTE INFECTIONS, CANDIDIASIS, AND TINEA VERSICOLOR)

William R. Graessle

BASICS

DESCRIPTION

Superficial mycoses (fungal infection) involving skin, hair, or nails, usually characterized by scaling, erythema, and/or change in skin pigmentation

EPIDEMIOLOGY

- Dermatophyte infections:
 - Tinea capitis:
 - Most common in prepubertal and African American children
 - Peak age ~4 years
 - Incidence has increased over past decade.
 - Tinea corporis usually seen in younger children
 - Tinea cruris, tinea pedis, and onychomycosis uncommon in preadolescent children
- Candidiasis: Vast majority of infants colonized with *Candida albicans*
- Tinea versicolor (pityriasis versicolor): Usually seen in adolescents and young adults

GENERAL PREVENTION

- Children should be discouraged from sharing clothing, especially hats.
- Hair utensils and hats should be washed in hot, soapy water at onset of therapy.
- Pets should be watched and treated early for any suspicious lesions.
- Isolation of hospitalized patient is unnecessary.

PATHOPHYSIOLOGY

- Fungal elements penetrate skin, hair shaft, or nail.
- Predisposing factors may include moisture, macerated skin, and immunocompromise.
- Fungistatic fatty acids in sebum after puberty may offer protection against tinea capitis.
- Host immune response is usually able to contain infection.
- Inflammatory response is variable; highly inflammatory forms may lead to pustular lesions and kerion (large inflammatory mass) formation.

ETIOLOGY

- Varies by geographic region
- Dermatophyte infections:
 - Tinea capitis: >90% *Trichophyton tonsurans* in North America; *Microsporum canis* is a predominant organism in other geographic regions.
 - Nonhairy sites: *M. canis*, *T. tonsurans*, *T. rubrum*, *M. audouinii*
 - Fomites and pets may be a source of infection. Cats and dogs are major sources of *M. canis*.
- Candidiasis: Usually *Candida albicans*
- Tinea versicolor (pityriasis versicolor): *Malassezia furfur* (also called *Pityrosporum ovale*)

DIAGNOSIS

HISTORY

- Onset is usually gradual, except for candidal diaper rash, which is often abrupt.
- Usually pruritic
- Contacts, including exposure to pets
- Immunocompromised state
- Medications
- Signs and symptoms:
 - Dermatophyte infections:
 - Tinea capitis: May have various presentations ranging from round, distinct lesions to a diffusely dry scalp.
 - Tinea corporis: Lesions may occur anywhere on the body.
 - Onychomycosis: Patients present with thickened, discolored, and/or chipping nails.

PHYSICAL EXAM

- Dermatophyte infections:
 - Tinea capitis: May have various presentations:
 - Round to oval patches of alopecia with erythema
 - Diffusely dry scalp
 - Seborrheic dermatitis-like pattern with minimal or no alopecia
 - Follicular pustules with crusting, resembling bacterial folliculitis
 - Boggy, tender plaque with follicular pustules (kerion)
 - Presence of occipital lymphadenopathy may be more likely in tinea capitis.
 - Tinea corporis:
 - Skin lesions usually annular, hence the term ringworm; may be flesh-colored, erythematous, or violet to brown in color
 - Highly inflammatory forms may be frankly pustular.
 - Lesions may occur anywhere on the body.
 - Onychomycosis:
 - White, yellow, or silvery discoloration of lateral border or distal portion of nail
 - Nail eventually becomes discolored, thickened, and deformed.
 - Affects toenails more often than fingernails
- Candidiasis:
 - Diffuse erythema (often “beefy” red)
 - Raised edge with sharp margin
 - Pustulovesicular, satellite lesions
 - Prefers dark, warm, moist environments; favors skin folds/creases (axillae, groin, below breasts, and in infants, diaper area)
- Tinea versicolor (pityriasis versicolor):
 - Scaling, oval macular patches
 - Hypopigmented or hyperpigmented, depending on sunlight exposure and complexion
 - Distributed on upper trunk, neck, and proximal arms (high amount of sebum and free fatty acids, which organism requires); occasionally occurs on face

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- KOH preparation:
 - Clean site with alcohol.
 - Scrape lesion along scaling edge with a scalpel blade; obtain material from hair follicles and crusts.
 - Place material on glass slide with 1 drop of 10% KOH.
 - Warm slide gently or let sit for 30 minutes.
 - Place cover slip on slide.
 - Examine slide under microscope at low power under low light. Look for:
 - Dermatophytes: Arthrospores around or within hair shaft; long, branching hyphae for skin infections
 - Candidiasis: Budding yeast, pseudohyphae
 - Tinea versicolor (pityriasis versicolor): Hyphae and spores (“spaghetti and meatballs”)
- Fungal culture:
 - Obtain specimen with scalpel blade as described above or damp cotton swab for nonhairy sites.
 - For scalp, sample is obtained by rubbing toothbrush or cytology brush over dry scalp or area of concern; can be plated on appropriate media.
 - Results are available in several weeks.
 - Some laboratories provide drug susceptibility testing in addition to identification of fungus.
 - Distinguishing normal skin colonization from infection may be difficult.

Diagnostic Procedures/Other

Diagnosis usually made by characteristic lesions; if in doubt, may do:

- Potassium hydroxide (KOH) preparation
- Fungal culture
- Wood’s lamp examination (short-wave ultraviolet light):
 - Examine in completely darkened room.
 - Dermatophytes: Hair infections caused by microsporum species will give a green fluorescence, but trichophyton does not fluoresce; not helpful for skin or nail infections.
 - Tinea versicolor: Yellow, coppery-orange, or bronze fluorescence

DIFFERENTIAL DIAGNOSIS

- Dermatophyte infections:
 - Dermatologic conditions:
 - Tinea capitis: Seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania, folliculitis, impetigo, atopic dermatitis
 - Tinea corporis: Herald patch of pityriasis rosea, nummular eczema, psoriasis, contact dermatitis, tinea versicolor, granuloma annulare
 - Systemic diseases: Cutaneous T-cell lymphoma, histiocytosis, primary skin cancer, sarcoïd
- Candidiasis:
 - Dermatologic conditions: Contact dermatitis, seborrheic dermatitis, atopic dermatitis, bacterial infection
 - Systemic diseases: Acrodermatitis enteropathica, histiocytosis
- Tinea versicolor (pityriasis versicolor): Dermatologic conditions: pityriasis alba, postinflammatory hypopigmentation, vitiligo, seborrheic dermatitis, pityriasis rosea

TREATMENT

MEDICATION (DRUGS)

First Line

- Dermatophyte infections:
 - Tinea capitis (requires systemic therapy):
 - Griseofulvin: 20–25 mg/kg once daily, taken with high-fat food (e.g., milk or ice cream) for 6–12 weeks. Side effects include vomiting, diarrhea, headache, hepatotoxicity, and photosensitivity. Concomitant therapy of 2.5% selenium sulfide or ketoconazole shampoo twice weekly will suppress viable spores and decrease spread. Laboratory monitoring is considered unnecessary.
 - Tinea capitis with kerion:
 - Treat as tinea capitis.
 - May require oral steroids if significant inflammation present alone
 - Tinea corporis:
 - Topical imidazole (1% clotrimazole, 2% ketoconazole) or 1% terbinafine cream applied twice daily for 2–4 weeks
 - Onychomycosis:
 - Terbinafine 3–6 mg/kg/d for 6–12 weeks. May be associated with hepatic failure; should not be used in patients with underlying liver disease. Strongly consider liver enzymes before and during treatment.
 - Itraconazole in weekly pulses for 3–4 months is effective; 200 mg twice daily for 7 days, then off for 3 weeks.
- Candidiasis: topical nystatin cream or ointment 3–4 times daily for 7–10 days.
- Tinea versicolor (pityriasis versicolor):
- Selenium sulfide 2.5% applied to affected skin for 10 minutes. Wash off thoroughly. Apply daily for 7–10 days. Monthly applications may help prevent recurrences.

ALERT

- Topical steroids: Application will decrease inflammation and may mask infection (“tinea incognito”).
- Systemic therapies are associated with elevated hepatic enzymes and hepatic failure.
- Possible interactions:
 - Many antifungals have drug interactions.
 - Consult a reference (e.g., *Physician’s Desk Reference*) when prescribing them to a patient already on medication.

Second Line

- Dermatophyte infections:
 - Tinea capitis:
 - Itraconazole: 3–5 mg/kg once daily for 4–6 weeks. May also use terbinafine 3–6 mg/kg/d for 2–4 weeks or fluconazole 5 mg/kg/d for 4–6 weeks. All of these may be associated with hepatic failure and should not be used in patients with underlying liver disease. Liver enzymes before and during treatment are recommended.
 - Tinea corporis:
 - Oral griseofulvin 15–25 mg/kg/d for 4 weeks may be used for persistent or extensive involvement.

- Candidiasis:
 - Oral fluconazole:
 - 6 mg/kg on day 1, then 3 mg/kg/d for 2 weeks
 - May be used if poor response to topical therapy
- Tinea versicolor:
 - Topical imidazoles are effective but more expensive.
 - Oral ketoconazole 200–400 mg/d for 5–10 days, or itraconazole 200 mg/d for 5–7 days may be used if extensive, recurrent, or persistent.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Watch for signs of secondary bacterial infection.
- Highly inflammatory lesions may require systemic steroids.
- Repeated infection may indicate a source that needs to be diagnosed and treated (e.g., family member or pet).

DIET

Griseofulvin is better absorbed with a fatty meal. It may be taken with foods such as milk, eggs, or ice cream.

PROGNOSIS

- Dermatophyte: Inflammation should improve within several days, but may take several weeks to resolve completely; nail infections may take 6–12 months to show improvement.
- Candidal skin lesions improve within 24–48 hours and resolve by 1 week.
- Tinea versicolor may take weeks to improve; repigmentation may take months and requires exposure to sunlight.
- Relapses and recurrences are not uncommon.
- Areas with significant inflammatory component may become scarred and permanently alopecic.

COMPLICATIONS

- Dermatophyte infections:
 - Secondary bacterial infection (which may obscure diagnosis of dermatophyte infection)
 - Kerion may lead to scarring alopecia.
- Candidiasis:
 - Scarring in severe disease
 - Fungemia in immunocompromised host

CODES

ICD9

- 110.9 Dermatophytosis of unspecified site
- 111.9 Dermatomyces, unspecified
- 112.9 Candidiasis of unspecified site

ICD10

- B35.0 Tinea barbae and tinea capitis
- B37.9 Candidiasis, unspecified
- B49 Unspecified mycosis

FAQ

- Q: What is the role of topical and systemic steroids in the treatment of dermatophyte infections?
- A: Topical corticosteroids may be used in conjunction with antifungal therapy to reduce inflammation for fungal skin infections. Only mildly potent steroids should be used. Combination products containing a potent corticosteroid and an antifungal should be avoided, especially in the diaper area, where absorption may be increased. For tinea capitis, significant inflammation and kerion formation may benefit from a short course of systemic steroids. Reducing the inflammation with steroids may help prevent scarring alopecia.
- Q: What can be done to prevent recurrent tinea versicolor in an adolescent?
- A: *Malassezia furfur* is a ubiquitous organism and is present on the skin of postpubertal individuals. Humid environments, excessive sweating, and unclear genetic factors result in infection. Recurrences are common and can be prevented by monthly application of selenium sulfide 2.5%.
- Q: What is the role of the newer antifungal agents in the treatment of tinea capitis?
- A: Griseofulvin has long been considered the gold standard for the treatment of tinea capitis, because of its efficacy and safety profile. Development of resistance to griseofulvin has required the use of larger doses and longer courses, which increase the likelihood of noncompliance and treatment failures. In addition, longer courses increase the cost of griseofulvin therapy. The newer antifungals, terbinafine and itraconazole, offer some advantages over griseofulvin. Concentration of these drugs in nails and hair may allow for shorter courses of therapy, with improved compliance and lower cost than griseofulvin. Fluconazole has also been used for treatment of dermatophyte infections. It is available in a liquid formulation and is already FDA approved for treatment of candidal infections in children. Although still considered by many to be the preferred drug for tinea capitis, griseofulvin is likely to be replaced by these newer antifungals as experience with their use increases.

GASTRITIS

Janice A. Kelly

BASICS

DESCRIPTION

Microscopic inflammation of mucosa of stomach. Most common cause of upper GI tract hemorrhage in older children

EPIDEMIOLOGY

Prevalence

- 8 out of every 1,000 people
- >2% of ICU patients have heavy bleeding secondary to gastritis.

ETIOLOGY

- *Helicobacter pylori* (children more likely to have more severe gastritis, specifically located in antrum of stomach). Classified by WHO as a class I carcinogen in 1994.
- Physiologic stress (e.g., in CNS disease, overwhelming sepsis, ICU patients)
- Major surgery; severe burns; renal, liver, respiratory failure; severe trauma
- Idiopathic
- Caustic ingestions (e.g., lye, strong acids, pine oil)
- Celiac Disease: Lymphocytic gastritis
- Drug-induced (e.g., NSAIDs, steroids, valproate; more rarely, iron, calcium salts, potassium chloride, antibiotics)
- Ethanol
- Protein sensitivity (e.g., cow's milk-protein allergy), allergic enteropathy
- Eosinophilic gastroenteritis
- Crohn's Disease:
 - Up to 40% of Crohn patients have gastroduodenal involvement.
 - Gastric Crohn may manifest itself as highly focal, non-*H. pylori*, non-granulomatous gastritis.
- Infection (e.g., tuberculosis, *H. pylori*, cytomegalovirus, parasites)
- Less common causes:
 - Radiation
 - Hypertrophic gastritis (Ménétrier disease)
 - Autoimmune gastritis
 - Collagenous gastritis
 - Zollinger–Ellison syndrome
 - Vascular injury
- Direct trauma (nasogastric tubes)

DIAGNOSIS

HISTORY

- Epigastric pain
- Abdominal indigestion
- Nausea
- Vomiting postprandially
- Vomiting blood or coffee ground-like material
- Diarrhea
- Dark or black stools (or bright red blood from rectum, if bleeding is brisk and intestinal transit time is short)
- Irritability
- Poor feeding and weight loss
- Less often: Chest pain, hematemesis, melena

PHYSICAL EXAM

- Epigastric tenderness is physical finding that most closely correlates with gastritis on endoscopy.
- Normal bowel sounds

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Heme-test all stools.
- CBC for anemia with other signs of chronic blood loss (e.g., microcytosis, low reticulocyte count)
- *H. pylori* identification:
 - Noninvasive *H. pylori* tests, including antibody (from serum, whole blood, saliva, or urine), antigen (from stool), or urea breath testing (UBT). UBT (using C₁₃) and stool antigen tests are more reliable and sensitive than antibody testing; serologic testing is not recommended. However, UBT is not widely available, and is used primarily in adults.
 - Rapid urease test from gastric biopsy specimen for *H. pylori*
 - Silver Warthin–Starry stain, Genta stain, modified Giemsa stain, or cresyl violet stain of gastric biopsy for *H. pylori*
 - Culture of homogenized gastric biopsy for *H. pylori* (difficult to perform outside of research setting)

Imaging

- Upper GI radiography when endoscopy not available
- Chest radiograph may detect free abdominal air secondary to perforation.

DIFFERENTIAL DIAGNOSIS

Of epigastric abdominal pain:

- Gastroesophageal reflux with esophagitis
- Peptic ulcer disease
- Biliary tract disorders
- Pancreatitis
- Inflammatory bowel disease
- Genitourinary pathology (renal stones, infection)
- Nonulcer dyspepsia
- Functional pain
- Allergic enteropathy

TREATMENT

MEDICATION (DRUGS)

- Proton pump inhibitors drug of choice as first-line therapy. Can also use antacids or H₂ blockers to maintain gastric pH >4–5:
 - Ranitidine: 2–3 mg/kg/dose b.i.d. to t.i.d. in children
 - Cimetidine: 10 mg/kg/dose q.i.d. (can be used prophylactically for hospitalized patients at risk for physiologic stress)
 - Famotidine: 0.5–2 mg/kg/d divided twice
 - Omeprazole, lansoprazole, rabeprazole, or esomeprazole: 1 mg/kg/d
- Misoprostol may reduce risk of progression of gastritis to ulcers in patients taking NSAIDs; concerns exist for increased cardiovascular events in adults when using misoprostol.
- Discontinue NSAIDs
- *H. pylori*:
 - Triple therapy with proton pump inhibitor and antibiotics, e.g., omeprazole, amoxicillin, and clarithromycin
 - If eradication unsuccessful, quadruple therapy is recommended for 7–14 days, including:
 - Bismuth (of note, may need to avoid bismuth subsalicylate and choose instead bismuth subcitrate)
 - Metronidazole
 - A proton pump inhibitor
 - Another antibiotic (either amoxicillin, clarithromycin, or tetracycline)
 - Drug regimens change frequently; clarithromycin resistance becoming increasingly problematic.

- Precautions:
 - Antacids are not palatable to children and can lead to diarrhea or constipation. Prolonged use of large doses of aluminum hydroxide-containing antacids may lead to phosphate depletion and aluminum-related CNS toxicity (particularly in patients with renal disease).
 - If *H. pylori* eradication is attempted, important to use a tested regimen. Untested substitutions in the triple or quadruple regimens should be avoided.
- Interactions: Ranitidine is less effective and can increase toxicity when given to patients receiving other medicines metabolized by cytochrome P-450 system (e.g., theophylline).

SURGERY/OTHER PROCEDURES

Upper endoscopy with biopsies:

- Sensitivity greatest
- Possible findings:
 - Edema around small ulcers
 - Thickened hyperemic mucosa
 - Atrophic mucosa
 - Antral micronodules (represent lymphoid follicles) commonly seen in children with *H. pylori* infection
 - Antral and prepyloric edema with retained gastric secretions

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- For stress gastritis with hemorrhage, provide vigilant supportive care with close monitoring of hemodynamics, fluids, and electrolytes.
- Monitor for hemoccult-positive stools
- Follow CBCs
- May elect to repeat endoscopy in severe cases

DIET

- Benefit of changes in diet is inconclusive.
- Eliminate alcohol, tobacco, and caffeine

PROGNOSIS

Significant gastritis relapse rates for children who remain infected with *H. pylori*

COMPLICATIONS

- Bleeding (from mild to hemorrhagic)
- When gastritis caused by acid/alkali ingestions, outlet obstruction may result from prepyloric strictures (4–8 weeks after ingestion)

CODES

ICD9

- 041.86 *Helicobacter pylori* [*H. pylori*]
- 535.50 Unspecified gastritis and gastroduodenitis, without mention of hemorrhage
- 535.51 Unspecified gastritis and gastroduodenitis, with hemorrhage

ICD10

- B96.81 *Helicobacter pylori* as the cause of diseases classd elswhr
- K29.70 Gastritis, unspecified, without bleeding
- K29.71 Gastritis, unspecified, with bleeding

FAQ

- Q: Will a bland diet help to resolve gastritis?
- A: Dietary changes have not been shown to affect the natural course of gastritis.
- Q: What is *Helicobacter pylori*?
- A: *H. pylori* is a bacterium frequently found in the gastric mucosa of patients with gastritis and peptic ulcer disease. It can be diagnosed by a variety of means, often including a combination of upper endoscopy and urea breath tests. Relapse rates for gastritis secondary to *H. pylori* are high when the infection is left untreated.
- Q: Is it appropriate to treat cases of gastritis, not proven by culture?
- A: No. It is important to treat only confirmed *H. pylori* infections, not to treat on suspicion of infection.
- Q: If a patient is treated for *H. pylori* and they still have symptoms and a positive stool *H. pylori* Ag, what would be the next course of action?
- A: Consider re-treating with a proton pump inhibitor, amoxicillin and flagyl, as clarithromycin resistance in *H. pylori* infection is an increasingly frequent cause for treatment failure.
- Q: What are newly recognized complications of treating patients with proton pump inhibitors?
- A: Some adult studies show hypomagnesemia, increased risk of pneumonia, hip fracture, and clostridium difficile infection are associated with proton pump inhibitor use.

GASTROESOPHAGEAL REFLUX

Jessica Hoseason
Yasemen Eroglu
Joel Friedlander

BASICS

DESCRIPTION

- Effortless regurgitation of gastric contents. Occurs physiologically at all ages, and most episodes are brief and asymptomatic. Important to identify the rare child with pathologic reflux, to perform appropriate diagnostic studies, and to start effective therapy.
- Divided into physiologic and pathologic processes:
 - Physiologic reflux (normal gastroesophageal reflux [GER] of infancy) is the more common form. Symptoms peak around 4 months of age in the majority of children. Most children outgrow their symptoms by 1 year of age. GER measured via pH probe is acceptable if it occurs ≤ 4 –6% per 24 hours in children and adolescents and $\leq 11.6\%$ per 24 hours in infants, if there are no more than 50 episodes in 24 hours, and if there are no prolonged episodes.
 - Pathologic reflux or gastroesophageal reflux disease (GERD) is defined by increased number of reflux episodes according to age-accepted norms with symptoms and/or complications of GER. Often includes complications such as esophagitis, bleeding, esophageal stricture, failure to thrive, or chronic/recurrent respiratory tract disease.

EPIDEMIOLOGY

Prevalence

- Pathologic GERD: 10% of adults, 2–8% of children, 7% of infants
- 80% of children with documented GERD at age 5 may have persistent symptoms as an adult.

RISK FACTORS

Neurologic disorders (cerebral palsy/quadruplegia), esophageal atresia, tracheoesophageal fistula, cystic fibrosis, asthma, gastroparesis, hiatal hernia

PATHOPHYSIOLOGY

Transient relaxation of the lower esophageal sphincter during episodes of increased abdominal pressure; multifactorial process involving number of reflux events, acidity, emptying, mucosal barriers, visceral hypersensitivity, and airway responsiveness.

DIAGNOSIS

- Complicated GERD:
 - Vomiting
 - Irritability
 - Chest/abdominal pain
 - Heartburn
 - Hematemesis, melena
 - Blood loss
 - Dysphagia
 - Food refusal
 - Cough, wheezing
 - Obstructive apnea
 - Dysphonia
 - Aspiration pneumonia
 - Posturing (Sandifer syndrome)
- Other suspected complications include chronic or recurrent otitis media and sinusitis.
- GERD may be asymptomatic and still carry risk of complications.

HISTORY

- Infant:
 - Pay attention to feeding volume and frequency in addition to weight gain, failure to thrive, irritability.
 - Identify episodes of pneumonia, obstructive apnea, chronic cough, laryngitis, stridor, wheezing.
 - Identify additional signs/symptoms that suggest formula allergy (rash, diarrhea, hematochezia, irritability, failure to thrive).
 - Exclude evidence of bowel obstruction (emesis, polyhydramnios during pregnancy).
 - If vomiting is atypical or associated with other signs/symptoms, rule out infection, metabolic disease, anatomic abnormality, or neurologic disease.
 - Special questions:
 - Presence of polyhydramnios or bilious emesis?
 - Family history of metabolic disease?
 - Family history of allergies/atopy?
 - Perinatal asphyxia (and other neurologic disorders)?
 - History of prematurity?
- Older child:
 - Identify typical adult GERD complaints (chest pain, heartburn, regurgitation, dysphagia), but recognize that children describe discomfort poorly (isolated abdominal pain).
 - Identify episodes of pneumonia, choking, chronic cough, laryngitis, stridor, wheezing.
 - Consider evidence suggesting food allergy (rash, diarrhea, reactive airways disease).
 - Special questions:
 - Family history of GERD?
 - Family history of allergies/atopy?

PHYSICAL EXAM

- May be normal
- Growth failure
- Blood in stool
- Reactive airway disease and other manifestations of pulmonary complications
- Anemia
- Erosive dental (molar) disease
- Pharyngeal erythema/edema

DIAGNOSTIC TESTS & INTERPRETATION

Diagnosis of GERD is made clinically. Testing is only needed to identify questionable cases, potential causes, complications, or symptom-reflux correlations. Evaluation should include:

- Stool heme-occult
- Growth parameters

Imaging

- Barium swallow or upper GI series: Evaluate anatomy.
- Chest x-ray: Evaluate for recurrent pneumonia.
- Milk scan/gastric-emptying study: Evaluate gastric motility and/or pulmonary aspiration.
- Salivagram: Evaluate for aspiration.

Diagnostic Procedures/Other

- Medication trial
- pH probe:
 - Attempts to correlate acid GERD with symptoms over a 24-hour period
 - Simple (single-channel)
 - Double-channel
 - Combined pH/multichannel intraluminal impedance: New technology that allows detection of both acid and nonacid GERD events. Recent

studies suggest may be able to detect 45% additional pathologic refluxes than pH probe.

- pH/thermistor (apnea) study
- Wireless pH monitoring
- Esophagogastroduodenoscopy
- Laryngoscopy
- Bronchoscopy
- Manometric studies
- Esophageal manometry
- Antroduodenal manometry

Pathological Findings

Evidence of esophagitis, Barrett's esophagus, adenocarcinoma, stricture

DIFFERENTIAL DIAGNOSIS

Not all pediatric vomiting is reflux. Other causes of vomiting include:

- Cardiac: Congestive heart failure
- Toxin:
 - Lead
 - Fe
 - Medications
- Renal:
 - Obstructive uropathy
 - Uremia
- Infection:
 - Gastroenteritis
 - Urinary tract infection
 - Sepsis
 - Pneumonia
 - Hepatitis
 - Otitis media
 - Pancreatitis
 - Cholecystitis
- Neurologic:
 - Meningitis/Encephalitis: Intracranial injury
 - Brain tumor
 - Hydrocephalus
 - Subdural hematoma
- Metabolic:
 - Urea cycle defects
 - Aminoacidopathies (phenylketonuria, maple syrup urine disease)
 - Adrenal hyperplasia
 - Galactosemia, fructosemia
- Food intolerance:
 - Milk/Soy protein allergy
 - Eosinophilic esophagitis
 - Celiac disease
 - Hereditary fructose intolerance
- Anatomical malformation:
 - Diaphragmatic hernia
 - Gastric outlet obstruction
 - Esophageal atresia
 - Pyloric stenosis
 - Antral/Duodenal web
 - Volvulus/Malrotation
 - Meconium ileus
 - Enteral duplications
 - Intussusception
 - Trichobezoar
 - Foreign body
 - Incarcerated hernia
- Drugs that affect lower esophageal sphincter pressure:
 - Nitrates
 - Nicotine

- Narcotics
- Caffeine
- Theophylline
- Anticholinergic agents
- Estrogen
- Somatostatin
- Prostaglandins

TREATMENT

Several modes of therapy are available, depending on severity, duration of reflux, and complications. Treatment should be individualized, and cost effectiveness should be considered.

MEDICATION (DRUGS)

First Line

H₂ blockers: For initial therapy of pain, esophagitis, or respiratory complications

- Ranitidine (Zantac):
 - 2–8 mg/kg/d split b.i.d. to t.i.d. OR
 - Adults 150 mg b.i.d. or 300 mg nightly
- Famotidine (Pepcid):
 - <3 months: 0.5 mg/kg daily
 - 3 months to 1 year: 0.5 mg/kg b.i.d.
 - 1–12 years: 1 mg/kg/d divided b.i.d. (max 80 mg/d)
 - 12 years–adults: 20 mg b.i.d.
- Side effects: Low incidence
- Medication interactions: Few

Second Line

- Proton pump inhibitors: For symptoms refractory to H₂ blockers or severe esophagitis:
 - Omeprazole (Prilosec):
 - < 1 year: 1 mg/kg (daily or b.i.d.); studies demonstrate no clinical symptom (crying, irritability) improvement.
 - > 1 year: 1 mg/kg (daily or b.i.d.) to adult dose range
 - > 20 kg: 20–40 mg/d once daily or b.i.d.
 - Up to 3.5 mg/kg/d have been used
 - Lansoprazole (Prevacid):
 - < 1 year: 0.4–1.8 mg/kg/d (daily or b.i.d.); studies demonstrate no clinical symptom (crying, irritability) improvement.
 - 1–11 years: < 10 kg 7.5 mg/d
 - 10–30 kg: 15 mg/d or b.i.d.
 - > 30 kg: 30 mg/d or b.i.d.
 - Up to 2.88 mg/kg/d have been used
 - Children often require a higher mg/kg. Side effects (uncommon) include headache, abdominal pain, and diarrhea.
 - Maximal effect not obtained until after 2 weeks of completed therapy
- Prokinetics: As adjunctive therapy for more severe GERD complications and hypomotility:
 - No single drug has optimal prokinetic effect and minimal side effects. There are many side effects associated with these medications, and they are not recommended as routine therapy.
 - Metoclopramide (Reglan):
 - 0.1 mg/kg q.i.d. 30 minutes before meals (0.3–0.8 mg/kg/d is acceptable)
 - Adults: 10–15 mg q.i.d. 30 minutes before meals
 - Side effects: May cause dystonia or oculogyric crisis
 - Cisapride use has been withdrawn in the U.S., but a limited-access program is available for special situations.
 - Calcium and aluminum/magnesium-containing antacids:
 - Require multiple dosing

- Side effects: Carry risk of diarrhea and aluminum toxicity
- Interactions: May lead to malabsorption of other medications
- Mucosal protective agents: Sucralfate (Carafate) for erosive esophagitis; maximally effective at pH 4 and on mucosal lesions

ADDITIONAL TREATMENT

General Measures

- Parental reassurance and education. Small, frequent feedings
- Thickening of feedings (~1 tablespoon cereal/ounce of formula): Helps with actual vomiting, not with stopping GER.
- Positioning: Prone positioning not recommended, keeping infant upright after feeds, head elevation in older children only (in infants, it increases GER)

SURGERY/OTHER PROCEDURES

- Fundoplication (open or laparoscopic)
 - To increase lower esophageal sphincter tone by wrapping portion of gastric fundus around lower esophagus to provide for a more effective barrier to GERD
 - Variations may include addition of a gastric emptying procedure (i.e., pyloroplasty) or gastrostomy placement.
 - Indications: Failure of aggressive medical management resulting in complications (i.e., esophageal stricture; high-grade intestinal metaplastic changes, as in Barrett esophagus), presence of large hiatal hernia, poor airway protection leading to aspiration of gastric contents (i.e., severe neurodevelopmental delay)
- Complications include:
 - Gas bloating syndrome
 - Intractable retching
 - Bowel obstruction
 - Dumping syndrome
 - Dysphagia
 - Paraesophageal hernia
 - Wrap failure with recurrent GERD (up to 6% failure at 48 months)
 - Limited long-term clinical effectiveness
- Greater morbidity associated with fundoplication in cohort of children with severe physical and mental disabilities

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Recurrent endoscopy for evidence of pathological changes of esophagus

DIET

- Consider use of hypoallergenic formula or eliminating milk/soy from mother’s diet for patients with associated food allergy
- Dietary restrictions in older child: Caffeine, chocolate, acidic/spicy food, peppermint, but recent adult studies show this is on an individual basis only.

CODES

ICD9
530.81 Esophageal reflux

ICD10

- K21.0 Gastro-esophageal reflux disease with esophagitis
- K21.9 Gastro-esophageal reflux disease without esophagitis

FAQ

- Q: How long will my baby suffer with GERD?
- A: Most infantile reflux resolves by 9–12 months of age, but symptoms may persist up to 24 months. If GERD continues after 2–3 years, it is more likely to behave clinically like adult GERD.
- Q: Should all babies with reflux be treated with medication?
- A: No. It is reasonable to 1st try conservative treatments such as thickened feedings and frequent small feedings.
- Q: Is there an association between asthma and GERD?
- A: The relationship between GERD and asthma is unclear based on recent studies and reviews.
- Q: What are the long-term effects of giving my child antacid medications?
- A: Although the effect of long-term acid suppression remains unknown, most medications used to treat GERD are quite safe. Although safe, some new adult research data suggest a possibility of osteoporosis and pneumonia after many years of treatment. Newer studies also demonstrate a very slight increased risk of *C. difficile* infection with their use. One must also recognize, however, that untreated reflux has the potential to lead to serious complications (Barrett esophagus, which can predispose patients to esophageal cancer). When considering safety, not treating reflux disease and esophagitis may be the more dangerous course of action.
- Q: Will the usage of PPI therapy stop my infant’s crying and irritability from reflux?
- A: Recent studies demonstrate that although PPI therapy will decrease acid in the stomach and allow for mucosal healing of the esophagus, infants under 1 year had no significant change in the reported reflux symptoms of crying and irritability.

GERMAN MEASLES (THIRD DISEASE, RUBELLA)

Michael J. Smith

BASICS

DESCRIPTION

- *Rubella* derived from Latin, meaning "little red"
- Disease initially considered variant of measles
- Viral infection characterized by mild symptoms (often subclinical), with an erythematous rash progressing from head to toes
- Congenital rubella syndrome can be devastating.
- Rubella virus:
 - Classified as a Rubivirus in the *Togaviridae* family:
 - RNA virus with single antigenic type
 - 1st isolated in 1962 by Parkman and Weller

EPIDEMIOLOGY

- Spread person-to-person via airborne transmission; worldwide infection
- Infection most contagious when rash is erupting. However, virus may be shed beginning 7 days before rash to 14 days after
- Infants with congenital rubella syndrome may shed virus for up to 1 year

Incidence

- In temperate regions, peaks in late winter and early spring
- In prevaccine era, incidence of infection in U.S. was ~58 per 100,000 population
- From 2001–2004, nearly 1/2 of the 57 cases reported to the CDC occurred in persons born outside the U.S.
- 2004: No longer endemic in the U.S.
- Infection occurs equally in following age groups: <5 years, 5–19 years, and 20–39 years
- Congenital rubella syndrome:
 - 1964: 20,000 newborns
 - 1980s: Reported rarely, with <5 cases annually
 - 1990–1991: ~30 cases reported annually
 - 2001–2004: Total of 4 cases reported to CDC, only one with mother born in the U.S.

GENERAL PREVENTION

- Prevention of congenital rubella syndrome is main objective of vaccination programs
- Rubella vaccine:
 - Current strain of vaccine (RA 27/3, developed at the Wistar Institute in Philadelphia) was licensed in 1979 and has replaced all other strains
 - Given as part of MMR vaccine at 12–15 months and again at 4–6 years
 - Immunity occurs in 95% of vaccinees and is thought to be lifelong
 - Important to ensure full vaccination for preschool-aged children
 - Vaccine virus is not communicable: Pregnant women and persons who are immunodeficient (except asymptomatic HIV infection) should not receive vaccine, but household contacts should
- Isolation:
 - Pregnant women should avoid contact with source patient
 - Postnatal: Droplet precautions and/or school exclusion is indicated for 7 days after onset of rash
 - Congenital: Contact isolation until 1st birthday, or until 2 nasopharyngeal and urine cultures consecutively negative

PATHOPHYSIOLOGY

- Respiratory transmission
- Replication in nasopharynx and regional lymph nodes
- Viremia 5–7 days after exposure, with spread of virus throughout body
- In congenital rubella syndrome, transplacental infection of fetus occurs during viremia

ETIOLOGY

Rubella virus

COMMONLY ASSOCIATED CONDITIONS

Congenital rubella syndrome (see "Complications")

DIAGNOSIS

If rubella is suspected, case should be reported to local public health authorities

HISTORY

- In children, prodrome is not often recognized
- In adults, a 1–5-day prodrome of low-grade fever, malaise, and cervical adenopathy may precede rash
- Inquire about immunizations and exposures

PHYSICAL EXAM

- Rash:
 - Begins on face, then progresses to trunk and extremities
 - Does not usually coalesce
 - Lasts for 3 days
- Adenopathies, especially postauricular, posterior cervical, and suboccipital, are commonly noted, along with conjunctivitis
- Arthralgia/arthritis may be seen in adolescents and adults

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Congenital infection:
 - Serologic testing should be performed on both mother and infant
 - Rubella-specific IgM in infant is highly suggestive
 - Viral isolation from throat or nasal specimen can confirm diagnosis. Blood, urine, and CSF samples may also be diagnostic
 - Diagnosis is difficult to verify after neonatal period
- Postnatally acquired:
 - Rubella-specific IgM or a ≥ 4 -fold rise in rubella-specific IgG antibodies between acute and convalescent titers is diagnostic

DIFFERENTIAL DIAGNOSIS

Infections that are sometimes confused with rubella include:

- Modified measles
- Scarlet fever
- Roseola
- Erythema infectiosum (fifth disease, parvovirus B19 infection)
- Enteroviral infections
- Infectious mononucleosis
- Drug eruptions

ONGOING CARE

PROGNOSIS

- Quite good; as many as 50% of infections are asymptomatic
- Rubella infection in pregnant woman can be devastating for infant (see "Complications")

COMPLICATIONS

- Tend to occur in adults; most are uncommon.
- Arthritis or arthralgia:
 - Occur in 70% of adult women, lasting up to 1 month
 - Usually affects small joints
- Encephalitis:
 - 1 in 5,000 cases
 - May be associated with mortality
- Bleeding:
 - 1 in 3,000 cases
 - Occurs in children more than in adults
- Thrombocytopenia: Commonly noted
- Orchitis and neuritis: Rare
- Congenital rubella syndrome:
 - Rubella infection in early gestation can lead to fetal death, premature delivery, and congenital defects

- Severity of defects is worse the earlier in gestation the infection occurs
- 85% of infants are affected if infection occurs in 1st trimester
- Defects are rare if infection occurs after 20th week
- Common defects of congenital rubella syndrome:
 - Deafness: Most common defect
 - Ophthalmologic defects: Cataracts, glaucoma, microphthalmia
 - Cardiac defects: Patent ductus arteriosus, ventricular septal defect, pulmonic stenosis, coarctation of aorta
 - Neurologic defects: Mental retardation, microcephalism
- Some manifestations of congenital rubella syndrome (diabetes mellitus, progressive encephalopathy) may be delayed for years

CODES

ICD9

- 056.9 Rubella without mention of complication
- 771.0 Congenital rubella

ICD10

- B06.9 Rubella without complication
- P35.0 Congenital rubella syndrome

FAQ

- Q: While pregnancy is a contraindication to rubella vaccination, if a pregnant woman is inadvertently vaccinated, will there be harm to the fetus?
- A: Data collected since 1979 by the CDC show no evidence of congenital rubella syndrome in 321 susceptible women who were vaccinated while pregnant.
- Q: Is there any evidence that the MMR vaccine causes autism spectrum disorder?
- A: No. Multiple epidemiologic studies have shown no difference in the rates of autism spectrum disorder in children who received the MMR vaccine versus those who did not. The original paper that suggested a link between vaccines and autism was retracted in 2010.

GIARDIASIS

Lindsay Abenberg

Alan D. Baldrige (5th edition)

BASICS

DESCRIPTION

Infection of duodenum and jejunum with flagellated protozoan *Giardia lamblia*

EPIDEMIOLOGY

- Giardiasis has a worldwide distribution.
- *Giardia lamblia* is the most common intestinal parasite of humans identified in the U.S.
- Peaks at ages 1–9 years; 2nd peak at ages 35–44 years
- More common in summer and fall
- Water-dwelling mammals and household pets can become infected and may serve as reservoir of infection.

Incidence

U.S. average is 9.5 cases per 100,000.

Prevalence

- Direct person-to-person transmission accounts for the very high prevalence rates in institutions, daycare centers, and family contacts.
- High prevalence rates have been reported in patients with cystic fibrosis as well as Crohn disease.
- Waterborne transmission is an important source of endemic or epidemic spread, especially when water is supplied by surface source such as streams and reservoirs (outdoor recreation and international travel).
- Foodborne infection is uncommon and generally from uncooked or undercooked food or food contaminated after cooking by water source.

RISK FACTORS

- Daycare attendance
- International adoption
- Hypochlorhydria (previous gastric surgery)
- Hypogammaglobulinemia/immunodeficiency
- Blood group A
- Certain human leukocyte antigen alleles

GENERAL PREVENTION

- Maintenance of good sanitary conditions (strict handwashing and diaper disposal)
- Breastfeeding
- Family members and close contacts should be examined and treated if necessary.
- Examine water source in endemic areas.
- Boiling or iodine-based water treatment for camping and hiking

ETIOLOGY

- *G. lamblia*:
 - 2-form life cycle: Cyst (transmission) and trophozoite (infection):
 - Trophozoites adhere to duodenal mucosa with a ventral disk leading to mucosal damage and symptoms. Organism is noninvasive and does not lead to mucosal necrosis.
 - Cyst formation occurs in the colon and is passed into the environment. It can survive for a prolonged time if moist.
- Infection occurs after cyst ingestion from fecally contaminated water or by direct fecal–oral transmission in poor sanitary conditions; ingestion of between 10 and 100 cysts can produce infection.
- Anti-*Giardia* properties in breast milk may be related to free fatty acids cleaved from milk triglyceride by a bile salt-stimulated lipase present in human milk.
- *Giardia* also exhibits antigenic variation over the course of an infection.
- Mechanism of diarrhea is poorly understood but could include:
 - A glycoprotein located on the surface of *G. lamblia* trophozoites has been demonstrated to induce fluid accumulation in ligated ileal loops in rabbits.
 - Giardiasis results in decreased jejunal electrolyte, water, and 3-O-methyl-D-glucose absorption, thus leading to electrolyte, solute, and fluid malabsorption.
 - Damage to the intestinal brush border and the corresponding decrease in disaccharidase activity may lead to increased quantities of disaccharides in the intestinal lumen, which can result in osmotic diarrhea.
 - *Giardia* infection in gerbils accelerates intestinal transit time and increases smooth muscle contractility, both of which may play a role in giardial diarrhea.

DIAGNOSIS

- Most (60%) infected individuals are asymptomatic.
- Common manifestations:
 - Sudden-onset watery, foul-smelling diarrhea without blood
 - Abdominal cramps
 - Bloating/flatulence
 - Anorexia
 - Dyspepsia
 - Nausea
 - Malaise
- Chronic course is associated with:
 - Weight loss
 - Loose, semiformed stool
 - Abdominal distention
 - Anorexia
 - Flatulence
 - Depression
- Malabsorption syndrome may include:
 - Steatorrhea
 - Secondary lactase deficiency
 - Deficiencies of iron, folic acid, vitamins A, B₁₂, and E
 - Protein-losing enteropathy

HISTORY

- Exposure to well water
- Habitation in endemic area
- Attendants of child care centers or inhabitants of institutions
- Asymptomatic infection can occur.
- Camping or hiking near fresh water
- Exposure to infected individual
- Immune function

PHYSICAL EXAM

- Abdominal distention
- Aphthous ulcers in oral mucosa
- Urticaria
- Arthralgia/Arthritis

DIAGNOSTIC TESTS & INTERPRETATION**Lab****Initial lab tests**

- Identification of trophozoites or cysts in stool specimens, duodenal fluid, or small bowel tissue using staining methods
- Commercial ELISA test for detection of *G. lamblia* antigen in stool
- Empiric therapeutic trial of antiparasitic therapy in endemic area or populations
- If immunodeficiency is suspected, check immune function, especially IgA.

Diagnostic Procedures/Other

If strong suspicion of giardiasis, but 3 negative stool samples:

- Small intestinal aspirate sample may be obtained from duodenum.
- Duodenal biopsy specimen appears to be most sensitive.

Pathological Findings

Mucosal lesions vary from normal to subtotal villous atrophy, with crypt hyperplasia and proliferation of intraepithelial and lamina propria lymphocytes. Trophozoites may be seen on biopsies as an S-like curled shape on longitudinal sections.

DIFFERENTIAL DIAGNOSIS

- Celiac disease
- Cystic fibrosis
- Lactose intolerance
- Irritable bowel syndrome
- Inflammatory bowel disease
- Nonulcer dyspepsia

**TREATMENT****MEDICATION (DRUGS)**

- Metronidazole (not approved by FDA):
 - Most effective and best tolerated
 - Dose: 15 mg/kg/d divided t.i.d. for 5–7 days
- Tinidazole (approved for children ≥ 3 years)
 - 50 mg/kg to 2 g; single dose
 - Available in tablet form only
- Nitazoxanide (approved for ages 1–11 years)
- Furazolidone: Lower efficacy but better tolerated than metronidazole
- If therapy fails, a course can be repeated with the same drug.
- Asymptomatic giardiasis, in absence of risk factors, should not be treated.
- Treatment of patients with cystic fibrosis and household contacts of pregnant or immunocompromised persons may be considered.
- Repeat ova and parasite exam and antigen detection with recurrence of symptoms.
- May need to test for cure in patients with multiple organism infections

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

- Incubation period usually 1–4 weeks
- Reinfection common if source not eradicated
- If symptoms persist, with negative diagnostic studies, consider alternative etiology or another enteropathogen.

DIET

- High-fiber diet may aid in clearance.
- Low-lactose diet to prevent bloating and diarrhea for 1 month after treatment
- Probiotics may aid in prevention and clearance of infection.

PROGNOSIS

- Remains good for symptomatic patients
- Combination therapy with 2 medications has been successful when repeated courses of single drug have failed.

COMPLICATIONS

- Malabsorption syndrome
- Steatorrhea
- Lactose deficiency
- Deficiencies of iron, folic acid, and vitamins A, B₁₂, and E
- Protein-losing enteropathy
- Urticaria
- Arthralgia
- Growth retardation

**CODES****ICD9**

007.1 Giardiasis

ICD10

A07.1 Giardiasis [lambliasis]

FAQ

- Q: Where is a likely place that *Giardia lamblia* occurs?
- A: Well water is a common place.
- Q: What do I do if I suspect *Giardia*, but the stool sample is negative?
- A: 3 samples are needed. If you are in an endemic area, you may choose to treat empirically.

GINGIVITIS

Daniel Walmsley

BASICS

DESCRIPTION

Gingivitis is a reversible dental plaque-induced inflammation of the gingival tissues. Symptoms may include bleeding, swelling, ulceration, and pain; although gingivitis is usually mild and asymptomatic.

EPIDEMIOLOGY

Incidence

- Affects >90% of children between the ages of 4 and 13 years. Most of these children have low-grade gingivitis.
- 13–40% of children aged 6–36 months have eruption gingivitis, which commonly resolves after teeth eruption.
- The prevalence of gingivitis increases with age; by puberty nearly 100% of all children are affected. This pubertal peak is likely due to hormonal influences and inconsistent dental hygiene.
- After puberty, the prevalence remains relatively constant at 50% of all adults.

RISK FACTORS

- Behavioral factors: Smoking, stress, alcohol consumption
- Medications: Antiepileptics, cyclosporine, calcium channel blockers
- Hormonal changes: Puberty, pregnancy
- Chronic illnesses: Diabetes mellitus, chronic renal failure, histiocytosis X, scleroderma, secondary hyperparathyroidism
- Immunologic deficiencies: HIV, Chediak–Higashi, cyclic neutropenia
- Neurologic problems: Cerebral palsy, mental retardation, seizures, and other conditions where routine dental care is difficult
- Miscellaneous: Chronic mouth breathing, malnutrition, viral illnesses

GENERAL PREVENTION

- Consistent daily oral hygiene described as the following by age:
 - Infants: Gum massage, washcloth to remove plaque; toothbrush using baby toothpaste (i.e., enzyme-based; no fluoride)
 - Young children: Assistance with brushing with a small amount of fluoridated toothpaste
 - School-aged children: Supervise brushing and assist if necessary
 - Older children and adolescents: Brush teeth twice a day with fluoridated toothpaste in addition to daily flossing. Some dentists recommended flossing as early as age 4 years.
 - Children with fixed orthodontics: Careful brushing and flossing is critical.

- Fluoride: Supplements are appropriate if the water supply is not fluoridated. It is important to be careful to treat with the appropriate amount of fluoride in order to prevent fluorosis.
- Sealants: Adherent plastic coating may be applied to the pits and fissures of the permanent teeth to provide a mechanical barrier.
- The AAP recommends that children at high risk for dental caries should establish routine dental care by their first birthday. Children should then continue routine dental checkups at a minimum of every 6 months.

ETIOLOGY

- Poor dental hygiene
- Bacterial plaque, calcified and noncalcified
- Caries
- Orthodontic appliances
- Malocclusion
- Crowded teeth
- Mouth breathing
- Erupting teeth margins
- Poor nutrition: Vitamin deficiencies (e.g., vitamin C deficiency), diet low in coarse detergent like foods (e.g., raw carrots, celery, apples), high prevalence of anaerobic microflora
- Infections: Herpes simplex virus (HSV) type 1, *Candida albicans*, HIV, bacterial pathogens
- Drugs: Phenytoin, cyclosporine, nifedipine, oral contraceptive pills
- Trauma

DIAGNOSIS

HISTORY

- Review the frequency of dental care visits and the home dental hygiene regimen.
- Review significant medical history, asking about chronic illnesses, bleeding disorders, and immunodeficiency.
- Review the diet of the child to assess for nutritional deficiencies.
- Dental appliances worn by patient:
 - Orthodontic equipment makes gingiva more difficult to clean, and reactive tissue growth is more common.
- Regular medications taken by patient:
 - Phenytoin may result in gingival hyperplasia, and chemotherapeutic agents, exogenous hormone therapy, and calcium channel blockers may result in gingivitis.
- Signs and symptoms:
 - Edema and erythema of the gingiva
 - Bleeding at gum line
 - Pain near the gingival margin

PHYSICAL EXAM

- Evaluate the gingival tissue for erythema, swelling, ulceration, fluctuance, or drainage. Erythema and edema are the most common findings in gingivitis.
- In severe cases, the gingival tissues may bleed spontaneously from ulcerations in the sulcus and there may be significant gingival hypertrophy.
- In herpetic gingivostomatitis, there is often significant ulceration and swelling of the gingiva associated with systemic symptoms such as fever, malaise.
- Evaluate the teeth for caries, fractures, looseness, malocclusion, pain, and plaque.
- Examine the face and neck for signs of swelling, erythema, warmth, or enlarged maxillary lymph nodes which may be signs of more extensive bacterial infection.
- Tanner staging: Normal pubertal changes seem to aggravate gingival inflammation so paying special attention to the gingiva of patients entering puberty is important.
- Assess the patient's oral hygiene technique in the office. This is the single largest contributor to gingivitis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Most patients will not need laboratory evaluation.
- If there is a concern for excessive bleeding, a CBC with differential, PT, PTT may be helpful to rule out thrombocytopenia, pancytopenia, or a clotting disorder.
- Blood culture: If there is concern for sepsis.
- Direct fluorescent antibody testing for HSV-1: If herpes is suspected (stomatitis is usually present), swab the base of a stoma/vesicle and smear on a slide. HSV culture is the gold standard.
- Biopsy is rarely necessary.

Imaging

Panoramic or individual tooth radiographic imaging is important to assess the bones for evidence of periodontal extension of the gingivitis in the more severe cases.

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Abscess
 - Herpetic gingivostomatitis—ulcerative lesions of the gingiva and mucous membranes of the mouth
- Traumatic:
 - Food impaction
 - Orthodontic appliances
 - Self-inflicted minor injury
- Hematologic:
 - Gingival bleeding due to hemophilia (factor VIII or IX deficiency)
 - Thrombocytopenia

- Immunologic:
 - Neutrophil disorders
 - Leukemia
 - HIV
 - Graft-versus-host disease (infiltrative gingivitis)
- Miscellaneous:
 - Gingival hyperplasia due to medications (i.e., phenytoin and nifedipine)
 - Periodontitis
 - Aphthous stomatitis
 - Vitamin C deficiency
 - Behçet's disease
 - Acute necrotizing ulcerative gingivitis (ANUG)—painful gingivitis associated with rapid onset and tissue ulceration and necrosis
 - Peaks in adolescence and young adulthood
 - Related to high oral concentrations of spirochetes and/or *Prevotella intermedia*

TREATMENT

MEDICATION (DRUGS)

Mouth rinses for plaque inhibition can be used to augment daily oral care routine. The most commonly used rinses include 0.12% chlorhexidine and 0.075% or 0.1% cetylpyridinium chloride.

ADDITIONAL TREATMENT

General Measures

A daily oral care routine, including brushing and flossing, is essential to prevent gingivitis.

- Mild gingivitis:
 - Careful daily dental hygiene, including meticulous brushing and flossing
 - Mechanical plaque and calculus removal by scaling or root planing. This is then followed by frequent dental cleanings every 3–6 months to prevent recurrence.
- Moderate-to-severe gingivitis:
 - Care as outlined for mild gingivitis
 - Should be evaluated by a pedodontist in addition to a general dentist
 - Mouth rinses for plaque inhibition using either 0.12% chlorhexidine or 0.075% or 0.1% cetylpyridinium chloride
 - Irrigation devices
 - Sonic toothbrushes
 - Gingivectomies in cases of overgrowth to permit better cleaning
 - Antibiotics to cover mouth flora in more severe cases when bacterial superinfection is suspected

ISSUES FOR REFERRAL

- It is important for providers to evaluate the oral health of all children. When gingival inflammation is noted, the patient should be referred to a dentist.
- Routine dental care with professional cleaning and plaque removal is recommended for all children and adults.

- If the extent of involvement is great or the underlying disease of the patient requires more aggressive care, a periodontist should be consulted.
- The inability to resolve gingivitis by oral hygiene measures necessitates the consideration of other causes such as leukemia, vitamin C deficiency, or other chronic disease.

SURGERY/OTHER PROCEDURES

Only the most severe cases require gingivectomy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Routine dental care with professional cleaning and plaque removal is recommended for all children and adults.
- Children with gingivitis should have frequent dental visits; most dentists recommend every 3 months.

Patient Monitoring

Routine dental exam and cleaning should be performed every 6 months to monitor for signs of inflammation.

DIET

- Avoid high sugar content food and beverages.
- Xylitol-containing chewing gum can improve oral hygiene by reducing plaque adherence to the gum line.

PATIENT EDUCATION

- Establish a daily mouth care routine.
- Brushing and flossing each morning and at bedtime will reduce plaque formation.
- Mouth rinses, if recommended by your dentist, can also reduce plaque formation.
- See the dental health professional every 6 months beginning at your child's first birthday for examination and cleaning.

PROGNOSIS

- Good oral hygiene may reverse mild-to-moderate gingivitis within several months.
- Periodontal disease is not reversible; therefore, prevention is essential.

COMPLICATIONS

- Periodontal disease
- Osteomyelitis
- Tooth decay

ADDITIONAL READING

CODES

ICD9

- 523.00 Acute gingivitis, plaque induced
- 523.10 Chronic gingivitis, plaque induced

ICD10

- K05.00 Acute gingivitis, plaque induced
- K05.5 Other periodontal diseases
- K05.10 Chronic gingivitis, plaque induced

FAQ

- Q: Are there differences among toothpastes and prevention of gingivitis?
- A: Yes. A study demonstrated that stabilized stannous fluoride toothpaste is effective in preventing gingivitis. When essential-oil mouthwashes (e.g., Listerine) are added, there is additional reduction in the amount of gingivitis noted.
- Q: What dietary changes may improve gingival health?
- A: Avoiding frequent carbohydrate intake may reduce gingivitis. Carbonated beverages, sugared chewing gum, and candy often adhere to teeth. When daily dental care is inconsistent, plaque formation is increased and gingivitis is much more likely.
- Q: Why do children generally not have the significant periodontal disease that adults get?
- A: No one knows for sure; however, it is known that the gingiva of the primary dentition is rounder and thicker and contains more blood vessels and less connective tissue than the gingival seen later in life. Whether these differences mask disease or are helpful is unclear.
- Q: How do intraoral piercings impact gum health?
- A: In addition to fractured teeth, gingival recession and gingivitis are complications of the trauma inflicted by a foreign body in the oral cavity.
- Q: Why is smoking associated with gingival disease?
- A: Nicotine inhibits phagocyte and neutrophil function, reduces bone mineralization, impairs vascularization, and reduces antibody production. Smokers do not respond as well as nonsmokers to surgical and nonsurgical treatments.

GLAUCOMA—CONGENITAL

Julie Y. Kwon

Graham E. Quinn

BASICS

DESCRIPTION

Improper development of drainage system for aqueous humor, leading to elevated intraocular pressure with enlargement of eye and damage to optic nerve

EPIDEMIOLOGY

- 1:10,000 births
- Male > Female (5:2)
- 70% bilaterally affected
- Primary congenital glaucoma accounts for ~1/2 of all cases of glaucoma in children.

PATHOPHYSIOLOGY

- Primary congenital glaucoma caused by structural abnormalities of aqueous outflow mechanism, which includes trabecular meshwork, iris, and cornea
- Secondary glaucoma may be associated with systemic abnormalities such as Lowe's syndrome, aniridia, rubella, and Sturge–Weber syndrome.
- Glaucoma may also be acquired from an ocular abnormality such as cataract, from trauma, or after intraocular surgery.
- Glaucoma may be caused by certain medications, most notably steroids. Angle closure glaucoma has been associated with Topiramate use.

ETIOLOGY

- Aqueous humor, a clear fluid produced by ciliary body at posterior base of iris, passes through pupil and exits through trabecular meshwork and Schlemm canal, which are located at the junction of the cornea and anterior iris
- Outflow blockage of aqueous may cause pressure to build in eye, resulting in enlargement of eye in younger children and destruction of fibers of the optic nerve in children with abnormally high intraocular pressures. The blockage may be microscopic (open-angle glaucoma) or due to obstruction of the outflow by iris (angle-closure glaucoma).

COMMONLY ASSOCIATED CONDITIONS

- Aniridia
- Axenfeld–Rieger's syndrome
- Sturge–Weber syndrome
- Neurofibromatosis Type 1
- Marfan syndrome
- Pierre Robin syndrome
- Homocystinuria
- Lowe (oculocerebrorenal) syndrome
- Rubella
- Chromosomal abnormalities
- Persistent fetal vasculature-type cataract
- Congenital cataract
- Ocular trauma or surgery
- Uveitis (juvenile rheumatoid arthritis)

DIAGNOSIS

SIGNS AND SYMPTOMS

- Corneal enlargement (11 mm suspicious in patients younger than 1 year) or asymmetry.
- Corneal haze from edema and/or scarring, often seen with acute ruptures in Descemet's membrane
- Buphthalmos (ocular enlargement) due to stretching of immature collagen in infants
- Myopia, often extreme degrees
- Usually painless loss of vision without ocular inflammation
- Optic nerve cupping develops rapidly in infants but may be reversible with control of glaucoma in very young children.
- General signs of many systemic syndromes associated with glaucoma (neurofibromatosis, Sturge–Weber syndrome)
- Elevated intraocular pressure (IOP) > 21 mm Hg in one or both eyes in at least two occasions

HISTORY

- Epiphora (tearing), photophobia (light sensitivity), and blepharospasm (lid squeezing) may be present due to corneal edema from increased intraocular pressure.
- Acute pain, redness, and blurry vision in acute angle-closure glaucoma
- Loss of vision in advanced cases.

PHYSICAL EXAM

May have red eye or asymmetry of eye size, in particular the corneal size and clarity. Nystagmus may be noted if corneal haze is very severe

Imaging

Ultrasound: Axial length using A-scan:

- Eye usually abnormally long for age
- Longitudinal data very useful in determining progression of glaucoma

Genetics

- Primary congenital glaucoma is generally sporadic; an autosomal recessive form has been associated with P4501B1 (CYP1B1) gene

Diagnosis Procedures/Surgery

- Intraocular pressure measurement:
 - An awake child is ideal; use bottle or breast to quiet, along with low lighting
 - If examination under anesthesia is needed, check intraocular pressure as soon as possible after induction, as intraocular pressure drops with anesthetic agents

- Corneal inspection:
 - Diameter measured with calipers:
 - Normal newborn: 10–10.5 mm
 - > 11.0 mm suspicious
 - Watch for asymmetry
 - Clarity: Haze may be due to edema or breaks in Descemet membrane (called Haab striae)
 - Refractive error:
 - High myopia common
 - Useful as office measure of change over time
 - Optic disc assessment
 - Cupping of nerve head is early sign
 - May reverse with good intraocular pressure control in the very young
- Gonioscopy: Evaluation of anterior chamber angle (between iris and cornea)
 - In trabeculodysgenesis, insertion of iris into corneoscleral angle often flat or concave
 - Iris defects may suggest type of abnormality causing glaucoma
 - Abnormal iris vessels may influence surgical plan
 - In angle-closure glaucoma: Diagnostic apposition of iris on cornea

DIFFERENTIAL DIAGNOSIS

- Excessive tearing, most commonly due to nasolacrimal duct obstruction
- Megalocornea:
 - May be associated with high myopia
 - Often familial
- Corneal haze
- Birth trauma, forceps
- Congenital corneal dystrophies
- Developmental anomalies
- Intrauterine inflammation (rubella, syphilis)
- Mucopolysaccharidoses
- Cystinosis

TREATMENT

ADDITIONAL TREATMENT

General Measures

Immediate:

- Medical treatment for glaucoma in children is usually a temporizing measure prior to surgical intervention.
- In other types of pediatric glaucoma, medical treatment involves use of the same medications as those used in adults, such as β -blockers, adrenergic agents, and carbonic anhydrase inhibitors. In general, miotics are not used because they may cause a paradoxical rise in intraocular pressure in children.

MEDICATION (DRUGS)

- Ensure that potential systemic medicines do not increase intraocular pressure
- Topical α -adrenergic agonists are associated with mental status changes, hypersomnolence, and apnea and are contraindicated in infants and children.

First Line

- Carbonic anhydrase inhibitors:
 - Systemic:
 - Acetazolamide
 - Methazolamide
 - Topical:
 - Brinzolamide
 - Dorzolamide
- β -Blockers, topical:
 - Timolol
 - Betaxolol
 - Levobunolol
 - Metipranolol
- Prostaglandins, topical:
 - Latanoprost
 - Bimatoprost
 - Travoprost

SURGERY/OTHER PROCEDURES

- Treatment of infantile glaucoma is typically surgical; medications usually not effective for long-term control
- Goniotomy/trabeculotomy: Both procedures open portions of Schlemm canal (goniotomy approaches Schlemm canal from inside eye and trabeculotomy from outside) into anterior chamber, allowing easier outflow of aqueous humor to subconjunctival space.
- Trabeculectomy: Similar to trabeculotomy but includes excision of a small portion of Schlemm canal and trabecular meshwork
- Seton procedures: Various devices inserted from subconjunctival space into anterior chamber, allowing free flow of aqueous humor from eye
- Cyclodestructive procedures: Procedures involving destruction of ciliary body (which produces aqueous humor) decrease production of aqueous humor.
- Iridectomy: If mechanism of glaucoma is angle closure (limited outflow of aqueous humor due to anatomic blockage with iris), then removal of portion of iris may eliminate obstruction

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Early postoperative:

- Postoperative steroids and cycloplegic drops to decrease pain and prevent adhesions due to inflammation.
- Corneal edema clears slowly, but intraocular pressure falls quickly if surgery is successful.
- Examination under anesthesia may be required frequently during the first 3–4 years of life, to ensure adequate control of intraocular pressure.

Longer term:

- Follow-up needed throughout life
- Contact with social services for blind and visually handicapped individuals must be made for children even if the child is only suspected of being visually impaired. Encourage families to make contact even when child may be too young to provide objective data on extent of visual handicap.

PATIENT EDUCATION

Children and parents must understand that glaucoma may recur at any point, and that continued, long-term surveillance is essential.

PROGNOSIS

Guarded; even if pressure well controlled and amblyopia treatment undertaken vigorously, child still at high risk for visual impairment. Must be carefully followed for:

- Amblyopia
- Abnormal refractive errors
- Recurrence of glaucoma

COMPLICATIONS

- Severe visual impairment or blindness due to optic nerve damage, amblyopia, and corneal scarring likely if glaucoma is undetected or uncontrollable
- If glaucoma controlled, the following are relatively common:
 - Unrecognized and untreated amblyopia (most serious threat to child's vision)
 - High degrees of myopia
 - Anisometropia (difference in refractive error between fellow eyes)
 - Buphthalmos and corneal scarring

FAQ

- Q: Can glaucoma be painful?
- A: If the ocular pressure rises quickly (hours), pain occurs frequently. Very high intraocular pressures may be present without pain if they occur slowly (months to years). However, most patients with glaucoma are asymptomatic until they have advanced vision loss.
- Q: Can glaucoma occur after eye trauma?
- A: Yes. This is a very common cause of glaucoma and may be asymptomatic, thus requiring periodic follow-up ophthalmic examinations for early detection and treatment.
- Q: Is infantile glaucoma heritable?
- A: Yes, both primary infantile glaucoma and glaucoma related to systemic or ocular syndromes may be inherited. Siblings and children of affected individuals should be examined for glaucoma.

GLOMERULONEPHRITIS

Christine B. Sethna

Kevin E.C. Meyers

BASICS

DESCRIPTION

- Glomerulonephritis (GN) presents with nephritic syndrome: Hematuria with RBC casts, hypertension, azotemia and edema. Proteinuria and oliguria may also be present.
- Acute glomerulonephritis is associated with inflammation and proliferation of the glomerular tuft. It may be rapidly progressive.
- Chronic glomerulonephritis indicates permanent damage has occurred.

EPIDEMIOLOGY

Acute poststreptococcal glomerulonephritis can occur in anyone >2 years, but is most frequently found in boys 5–15 years old.

Incidence

- Incidence of acute poststreptococcal glomerulonephritis in the U.S. has declined over the last 2 decades.
- Chronic glomerulonephritis occurs more often at the end of the 1st decade of life and in adults.

Genetics

Genetic predisposition: Familial glomerulonephritis (e.g., Alport syndrome, X linked)

ETIOLOGY

- Low serum complement level: Systemic diseases:
 - Vasculitis and autoimmune disease (e.g., systemic lupus erythematosus [SLE])
 - Subacute bacterial endocarditis (SBE)
 - Shunt nephritis
 - Cryoglobulinemia
- Low serum complement level: Renal diseases:
 - Acute poststreptococcal glomerulonephritis
 - Membranoproliferative glomerulonephritis (types 1, 2, and 3)
- Normal serum complement level: Systemic diseases:
 - Microscopic Polyangiitis
 - Wegener vasculitis
 - Henoch-Schönlein purpura
 - Hypersensitivity vasculitis
 - Visceral abscess
- Normal serum complement level: Renal diseases:
 - IgA nephropathy
 - Idiopathic rapidly progressive glomerulonephritis
 - Immune-complex disease
- Pauci-immune glomerulonephritis

DIAGNOSIS

SIGNS AND SYMPTOMS

- Macroscopic hematuria (tea-colored urine)
- Sore throat
- Impetigo
- A prior upper respiratory infection in the previous 7–14 days or skin lesions in the preceding 14–21 days suggests acute poststreptococcal glomerulonephritis.
- An upper respiratory infection in the previous few days suggests IgA nephropathy.
- Reduced output of urine
- Dyspnea, fatigue, lethargy
- Headache
- Seizures (hypertensive encephalopathy)
- Symptoms of a systemic disease such as fever, rash (especially on the buttocks and legs, posteriorly), arthralgia, and weight loss
- Special questions:
 - Establish the time relationship between a sore throat and the acute glomerulonephritis. The onset of acute poststreptococcal glomerulonephritis is usually associated with a time delay of >1 week.

PHYSICAL EXAM

- Hypertension
- Pallor
- Signs of volume overload (e.g., edema, jugular venous distention, hepatomegaly, basal pulmonary crepitation, and a triple cardiac rhythm)
- Impetigo or ecthyma (pyoderma)
- Signs of vasculitis such as rash, loss of fingertip pulp space tissue, Raynaud phenomenon, and vascular thrombosis
- Signs of a systemic disorder (see comment on vasculitis)
- Signs of chronic kidney disease, such as short stature, pallor, sallowness, edema, excoriations, pericardial friction rub, pulmonary rales and effusion, breath that smells of urine, asterixis, myoclonus, and neuropathy

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Urine:
 - Microscopy of the urine for crenated erythrocytes and erythrocyte casts—hallmark of nephritis
 - Proteinuria
- Evidence of previous strep infection:
 - Throat culture for beta-hemolytic *Streptococcus* (result is positive in 15–20% with acute poststreptococcal glomerulonephritis)
 - Antistreptolysin O titer: Positive result in 60% of patients with acute poststreptococcal glomerulonephritis
 - Streptozyme test: A mixed antigen test for β -hemolytic streptococcus. Together, the antistreptolysin O titer plus streptozyme tests have a >85% sensitivity.
 - Complement C3 serum level will be low in acute poststreptococcal glomerulonephritis and in other causes of acute glomerulonephritis as detailed herein.
- Blood chemistry:
 - Can be normal in acute glomerulonephritis
 - In chronic glomerulonephritis, serum chemistries will reflect the degree of chronic kidney disease (i.e., raised serum urea and creatinine). The serum potassium and phosphate levels will be elevated and the calcium level decreased.
 - With chronic kidney disease: Normocytic, normochromic, or hypochromic microcytic anemia

Imaging

- Chest radiograph to look for pulmonary edema and determine cardiac size
- Renal ultrasound if presentation or course not typical of acute poststreptococcal glomerulonephritis. The ultrasound is to assess the size and parenchymal texture.

Diagnostic Procedures/Other

Electrocardiogram to assess ventricular size and for hyperkalemia

Pathological Findings

In acute poststreptococcal glomerulonephritis, light microscopy reveals enlarged swollen glomerular tufts, mesangial and epithelial cell proliferation, with polymorphonuclear cell infiltration. There is granular deposition of C3 and IgG on immunofluorescence, and electron-dense subepithelial deposits or humps are seen on electron microscopy. The histology varies in chronic glomerulonephritis and depends on the cause. Rapidly progressive glomerulonephritis is associated with crescent formation.

DIFFERENTIAL DIAGNOSIS

- Acute postinfectious glomerulonephritis (Lancefield group A β -hemolytic streptococci, *Pneumococcus*, *Mycoplasma*, mumps, Epstein-Barr virus)
- Infection-related (hepatitis B and C, syphilis)
- IgA nephropathy
- Membranoproliferative glomerulonephritis
- Autoimmune glomerulonephritis (e.g., SLE)
- Familial glomerulonephritis
- Acute interstitial nephritis
- Hemolytic uremic syndrome
- Pyelonephritis

TREATMENT

MEDICATION (DRUGS)

- The following may be required:
 - Loop diuretics (furosemide) for volume, BP, and potassium control
 - Antihypertensive agents; vasodilators such as calcium channel blockers (e.g., nifedipine, isradipine, amlodipine), and loop diuretics are useful as first-line agents; IV hydralazine, labetalol, nicardipine, or nitroprusside may be required to treat severe refractory hypertension.
 - Serum potassium-lowering agents (sodium polystyrene sulfonate [Kayexalate], furosemide, bicarbonate, insulin/glucose, β -agonists). IV calcium is used to stabilize the myocardium in severe hyperkalemia.
 - Phosphate binders (calcium carbonate, sevelamer)
 - Immunosuppressive agents such as prednisone, cyclophosphamide, mycophenolate mofetil, and sometimes rituximab are used in the treatment of vasculitis-associated glomerulonephritis, membranoproliferative glomerulonephritis, and rapidly progressing glomerulonephritis. Plasmapheresis may be used to treat rapidly progressing glomerulonephritis. Penicillin is used in acute poststreptococcal glomerulonephritis to prevent rheumatic fever, but does not affect the course of the disease.

ADDITIONAL TREATMENT

General Measures

- Acute poststreptococcal glomerulonephritis is a self-limiting disease. Acute therapy is usually sufficient.
- The therapy of chronic glomerulonephritis depends on the underlying disease process; it may include immunosuppressives and, ultimately, the management of chronic kidney disease.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Treat hypertensive encephalopathy and life-threatening electrolyte disturbances immediately.

Admission Criteria

- Hypertension
- Edema
- Acute kidney injury

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

In acute poststreptococcal glomerulonephritis, improvement usually occurs within 3–7 days, hypertension is not sustained, and macroscopic hematuria is transient. Watch for ongoing oliguria, unresolved hypertension, increasing proteinuria, or progressive azotemia. Complement levels return to normal within 6–8 weeks of the initial presentation.

ALERT

- Microscopic hematuria may be present up to 2 years after an episode of poststreptococcal glomerulonephritis.
- If complement levels do not return to normal after presumed poststreptococcal glomerulonephritis, consider SLE and MPGN.

PATIENT MONITORING

- Look for and treat hyperkalemia.
- To control seizures, treat the hypertension; anticonvulsants play a secondary role.
- Monitor the degree of acute kidney injury.
- Home testing: BP monitoring may be required.
- Do not fail to check serum potassium levels.
- Be certain to recognize fluid overload.
- Be certain to recognize the severity and type of renal failure.

DIET

Restrictions of intake of fluid, sodium, potassium, and phosphate are initially required.

PROGNOSIS

- Prognosis is excellent in acute poststreptococcal glomerulonephritis and variable for other causes of glomerulonephritis in childhood.
- Acute poststreptococcal glomerulonephritis rarely recurs.

COMPLICATIONS

- Acute renal failure
- Hyperkalemia
- Hypertension
- Volume overload (e.g., congestive cardiac failure, pulmonary edema, hypertension)
- Chronic kidney disease

ADDITIONAL READING

- Ahn SY, Ingulli E. Acute poststreptococcal glomerulonephritis: An update. *Curr Opin Pediatr.* 2008;20(2):157–162.

CODES

ICD9

- 580.9 Acute glomerulonephritis with unspecified pathological lesion in kidney
- 582.9 Chronic glomerulonephritis with unspecified pathological lesion in kidney
- 583.9 Nephritis and nephropathy, not specified as acute or chronic, with unspecified pathological lesion in kidney

ICD10

- N00.9 Acute nephritic syndrome with unspecified morphologic changes
- N03.9 Chronic nephritic syndrome with unspecified morphologic changes
- N05.9 Unspecified nephritic syndrome with unspecified morphologic changes

FAQ

- Q: When does the complement return to normal?
- A: Hemolytic complement levels (C3) return to normal within a 6–8-week period in acute poststreptococcal glomerulonephritis. Persistently low C3 levels suggest a cause other than acute poststreptococcal glomerulonephritis.
- Q: What are the indications for renal biopsy in acute glomerulonephritis?
- A: Patients in whom there is sustained hypertension, ongoing or progressive azotemia, or persistent proteinuria of > 1.5 g/d should be biopsied.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Michele P. Lambert

BASICS

DESCRIPTION

Deficiency of the enzyme glucose-6-phosphate dehydrogenase (G6PD) in the RBC, which may result in hemolytic anemia. Several types of genetic mutations result either in deficient enzyme production or in production of an enzyme with diminished activity:

- Although most patients with this deficiency are never anemic and have mild to no hemolysis, the classic manifestation is acute hemolytic anemia in response to oxidative stress.
- World Health Organization classification of G6PD:
 - Class 1: Congenital nonspherocytic hemolytic anemia: Rare. Chronic hemolysis without exposure to oxidative stressors—splenomegaly in 40%. Affected individuals tend to be white males of Northern European background.
 - Class 2: Severe deficiency (1–10% enzymatic activity): Oxidative stress–induced hemolysis. Prototype is G6PD-Mediterranean.
 - Class 3: Mild deficiency (10–60% enzymatic activity): Most common type. Acute hemolytic anemia uncommon, occurs only with stressors
 - Class 4: Nondeficient variant (60–100% enzymatic activity): No symptoms, even during oxidant stressors, e.g., G6PD A+ (variant with normal activity); 20–40% allelic frequency in Africans
 - Class 5: > 150% of normal activity
- Deficient neonates may have hyperbilirubinemia out of proportion to their anemia. May, in part, account for increased prevalence of African Americans among patients with bilirubin encephalopathy. Should be considered as cause of hyperbilirubinemia in neonates of appropriate racial background and may contribute to kernicterus

GENERAL PREVENTION

Avoid drugs and toxins known to cause hemolysis. Prompt follow-up with febrile illness and signs of hemolysis.

EPIDEMIOLOGY

Prevalence

- Most common of all clinically significant enzyme defects, affecting ~400 million people worldwide
- X linked (Xq28): Primarily affects males
- Almost 400 allelic variants
- Frequency of different mutations varies by population:
 - Africans: 20–40% of X chromosomes are G6PD A+ (mutant enzyme with normal activity)
 - Sardinians (some regions): 30% have G6PD-Mediterranean
 - Saudi Arabians: 13% have G6PD deficiency
 - African Americans: 10–15% have G6PD A– (mutant enzyme with decreased activity).
- High incidence of mutant genes in some regions may relate to survival advantage against malarial infection (*Plasmodium falciparum*).

Genetics

Gene is on the X chromosome (Xq28).

- Males express the enzyme (mutant or normal) from their single X chromosome (hemizygotes).
- Female homozygotes (rare) are more severely affected than female heterozygotes.
- Heterozygote females show variable intermediate expression because of random X inactivation.

PATHOPHYSIOLOGY

- RBCs lose G6PD activity throughout their life span; therefore, older cells are more prone to oxidative hemolysis.
- Normal RBC life span of ~120 days is unaffected in unstressed states, even with severe enzyme deficiency, but may be shortened during oxidant stress.
- Enzyme-deficient RBCs are destroyed by intravascular hemolysis on exposure to the oxidative stressor, and acute hemolytic anemia results.
- Oxidant stressors include infections and chemicals (mothballs, antimalarials, some sulfonamides, methylene blue).
- Hemolysis usually follows stressor by 1–3 days, and nadir occurs 8–10 days postexposure. Obtain hemoglobins for > 1 week after the initial exposure.
- Favism: Severe hemolytic anemia in patients with more severe forms of G6PD deficiency after fava bean ingestion.
- Normal G6PD activity is 7–10 IU per gram of hemoglobin.

DIAGNOSIS

HISTORY

- Symptoms of anemia include fatigue, irritability, and malaise.
- Dark urine (cola or tea colored) may follow moderate-to-severe hemolysis. May develop jaundice (particularly scleral icterus).
- Patient may have required phototherapy in newborn period for hyperbilirubinemia.
- Recent drug, chemical, or food (fava bean) exposures may precipitate moderate-to-severe hemolysis.
- Family history of intermittent jaundice, splenectomy, cholecystectomy, or blood transfusion may indicate an inherited condition.
- Ethnicity may help determine type/severity of disease.

PHYSICAL EXAM

- Tachycardia, a flow murmur, or pallor: Signs of anemia
- Jaundice or scleral icterus: Signs of hemolysis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC:
 - Usually reveals a normochromic normocytic anemia with appropriate reticulocytosis
 - Hemoglobin can drop precipitously; should be monitored closely until stable or trending upward; checking a single hemoglobin the day of exposure to the stressor is not sufficient.
- Peripheral blood smear:
 - Often shows bizarre RBC morphology with marked anisocytosis and poikilocytosis
 - Can see schistocytes, hemighost cells (uneven distribution of hemoglobin), bite cells, blister cells, and occasional Heinz bodies (on supravital staining)
- Hemoglobinemia: Seen as plasma (pinkish red supernatant) or measured as free serum hemoglobin
- Hemoglobinuria: Occurs when hemoglobin-binding sites in the plasma (haptoglobin and hemopectin) are saturated; may be visible as dark urine—heme positive on dipstick and no RBC on microscopy.
- Free haptoglobin levels decrease.
- Direct and indirect Coombs tests:
 - Must be done to exclude autoimmune hemolytic anemia
 - Should be negative in G6PD deficiency
- Other: Plasma indirect bilirubin, lactate dehydrogenase, and aspartate aminotransferase may be elevated; hemosiderin may be found in the urine several days after hemolysis. Liver function tests should be normal. Renal functions to rule out thrombotic thrombocytopenic purpura and hemolytic uremic syndrome:
 - Rapid screening tests for G6PD activity in RBCs are qualitative; will miss some female heterozygotes with measurable but low enzyme levels
 - Necessary to confirm a deficiency or to diagnose a suspected heterozygote with a test to quantify G6PD activity
 - Normal activity: 7–10 IU/g hemoglobin
 - Accurately detects deficiency in males and homozygous females with no recent hemolysis
 - Helpful with heterozygous women

- Newborn screening for G6PD deficiency
 - Included in some panels of genetic screening tests performed on newborns
 - Typically performed by DNA-based methods that detect a few of the most common variants in US populations. Does not screen for all G6PD variants and can miss severe but rare variants.
 - Results may be reported in terms of predicted enzyme levels but not a true measurement of enzymatic activity.

ALERT

Confirm with G6PD enzyme activity; measured enzyme levels will be higher immediately after an acute hemolytic event because younger RBCs (reticulocytes) with normal levels of enzyme will have replaced the older, more deficient population.

- Screening tests may be falsely negative during this time.
- Most cost-effective approach: Defer screening until 1–2 weeks after resolution of hemolysis.
- Heterozygote female detection:
 - 2 RBC populations exist because of mosaicism from random X inactivation.
 - On average, 50% are normal and 50% are deficient, but there may be variability.

DIFFERENTIAL DIAGNOSIS

Intravascular hemolysis is very rare in children, but other causes include:

- Acute hemolytic transfusion reactions (Coombs test is positive)
- Microangiopathic hemolytic disease, such as hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and prosthetic cardiac valves
- Physical trauma (e.g., March hemoglobinuria); severe burns (uncommon)
- Other inherited RBC enzyme deficiencies
- Paroxysmal nocturnal hemoglobinuria.

Extravascular hemolysis can also be confused with G6PD deficiency and includes: Hereditary spherocytosis (spherocytes on smear); autoimmune hemolysis and delayed hemolytic transfusion reactions (both Coombs positive); hemoglobinopathies; hypersplenism or severe liver disease; Gilbert disease

TREATMENT

General Measures

- Removal of the oxidant stressor is of primary importance:
 - Discontinue the suspected drug and/or treat the infection.
 - In class 3 and 4 patients, essential drug therapy may be continued while monitoring for signs of severe hemolysis.
 - Transfusion is may be necessary (esp. in some type 1 and 2 deficiencies), but any patient who is symptomatic with anemia or has a low hemoglobin and signs of ongoing brisk hemolysis should be transfused immediately with packed RBCs.

– Supportive care, evaluation of renal function (risk of acute tubular necrosis with brisk hemolysis), and monitoring degree of anemia and ongoing hemolysis are important.

- For the affected neonate:
 - Monitor the bilirubin closely and start phototherapy early.
 - If necessary, exchange transfusion should be carried out.
 - Phenobarbital may decrease bilirubin level.
 - Early discharge is not recommended in infants with jaundice and known risk for G6PD deficiency.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Most deficient individuals remain asymptomatic.
- When hemolysis does occur, it tends to be self-limited and resolves spontaneously, with a return to normal hemoglobin levels in 2–6 weeks.
- Development of renal failure is extremely rare in children, even with massive hemolysis and hemoglobinuria.

DIET

- Avoid fava beans. Fava beans have a variety of names in different cultures.

PROGNOSIS

- For those with the milder forms, the prognosis is excellent.
- Can cause significant morbidity, but rarely mortality, in those with the more severe forms

COMPLICATIONS

Neonates can be at risk for hyperbilirubinemia requiring treatment. Kernicterus has been reported in infants with G6PD deficiency.

282.2 Anemias due to disorders of glutathione metabolism

ICD10

D55.0 Anemia due to glucose-6-phosphate dehydrogenase deficiency

FAQ

- Q: Do I need to follow a special diet or avoid medications if I have G6PD deficiency?
- A: Although most patients will have no symptoms of their disease, certain medications may cause transient hemolytic anemia, and these should be avoided. When prescribing medications, your physician and pharmacist should know about your G6PD, but most necessary medications are safe and well tolerated. People with severe variants of the deficiency should also avoid fava beans, but otherwise no dietary restrictions are necessary.
- Q: Do I need to know which variant of G6PD I have?
- A: It may be clear which variant you are likely to have based on your clinical symptoms and ethnic background.
- Q: Should my family be screened if someone has G6PD deficiency?
- A: In families of patients with G6PD, screening members may help provide meaningful genetic counseling to female carriers and affected but asymptomatic males.
- Q: How does G6PD affect sickle cell anemia and vice versa?
- A: Having sickle cell disease is somewhat protective in patients with G6PD A deficiency, because their RBC population is young and, therefore, has higher enzymatic activity. On the other hand, G6PD has no effect on the clinical characteristics of sickle cell disease.

GOITER

Adda Grimberg

BASICS

DESCRIPTION

Goiter is enlargement of the thyroid gland.

EPIDEMIOLOGY

- The most common cause of pediatric goiter in the US is chronic lymphocytic thyroiditis.
- Prevalence of goiter in the US is 3–7%, although the incidence is much higher in regions of iodine deficiency.
- Thyroid cancers make up 0.5–1.5% of all malignancies in children and adolescents.
- Both thyroid tumors and autoimmune thyroid disease are more common in females than males.

Prevalence

World Health Organization (WHO) Global Database on Iodine Deficiency (1993–2003):

- Global goiter prevalence is 15.8% of the general population.
- Insufficient iodine intake among school-aged children ranged from 10.1% in the Americas to 59.9% in Europe.
- 54 countries had iodine deficiency, 29 countries had excessive iodine intake, and 43 countries achieved optimal iodine intake.

ETIOLOGY

- The multinodular goiter 1 (MNG1) locus has been identified on chromosome 14q and on chromosome Xp22.
- Germline mutations in DICER1 (chromosome 14q31) have been found in familial multinodular goiter, with and without ovarian Sertoli-Leydig cell tumors.
- Germline mutation in thyroid transcription factor-1 (TTF-1/NKX2.1) has been found in patients with papillary thyroid carcinoma and a history of multinodular goiter.
- Other genes implicated in simple goiter formation: Thyroglobulin, thyroid-stimulating hormone (TSH) receptor, and Na⁺/I⁻ symporter.
- Thyroid peroxidase mutations lead to iodide organification defects and goitrous congenital hypothyroidism.
- Twin and family studies show a modest to major effect of environmental factors, especially iodine deficiency and cigarette smoking.
- Excessive maternal ingestion of iodine during pregnancy can lead to congenital goiter with increased iodine uptake on scan and in some babies, a transient hypothyroidism.
- Autoimmune goiters, such as chronic lymphocytic thyroiditis, occur in children with a genetic predisposition.
- Thyroid cancers are usually sporadic. Medullary carcinoma can be familial (autosomal dominant), as part of multiple endocrine neoplasia (MEN) type 2A and 2B, or as isolated malignancy.
- Pendred syndrome (autosomal recessive) causes congenital sensorineural deafness and an iodine organification defect that leads to goiter.

DIAGNOSIS

HISTORY

- Symptoms of hypothyroidism:
 - Increase in sedentary behavior
 - Lethargy
 - Weight gain
 - Constipation
 - Cold intolerance
 - Dry skin and/or hair
 - Hair loss
- Symptoms of hyperthyroidism:
 - Hyperactivity
 - Irritability
 - Difficulty concentrating or focusing in school
 - Hyperphagia
 - Weight loss
 - Diarrhea
 - Heat intolerance
- Careful dietary and medication history
- History of head, neck, or chest irradiation is associated with increased risk of carcinoma.
- Family history of thyroid carcinoma or MEN syndrome

PHYSICAL EXAM

Inspect, palpate, and auscultate the neck:

- Neck extension aids inspection.
- Palpation is best performed standing behind the child.
 - Determine if the thyroid is diffusely enlarged or asymmetric, evaluate gland firmness, and assess for any nodularity.
 - Check for cervical lymphadenopathy.
 - Pain on palpation suggests acute inflammation.
- Auscultate with the stethoscope diaphragm (while patient holds his or her breath) for a bruit, which indicates the hyperthyroidism-associated hypervascularity.
- Careful examination for signs of hypothyroidism or hyperthyroidism:
 - Pulse
 - Linear growth and weight pattern
 - Sexual development
 - Deep tendon reflexes
 - Skin
- Have patient drink water during inspection of gland.

DIAGNOSTIC TESTS & INTERPRETATION

- Thyroid function tests: Total T₄ and TSH are the best screens for hypothyroidism or hyperthyroidism.
- T₃ radioimmunoassay in cases of suspected hyperthyroidism (Note: Radioimmunoassay, which measures total T₃, and not resin uptake, which indirectly assesses thyroid hormone-binding capacity!)
- In cases of suspected chronic lymphocytic thyroiditis: Antithyroglobulin and antimicrosomal (antiperoxidase) antibodies
- In cases of suspected Graves disease: Thyroid-stimulating immunoglobulins (or TSH-receptor antibodies)
- Fine-needle aspiration biopsy in children should be considered only for evaluation of low-risk or purely cystic thyroid nodules. (A higher percentage of solitary thyroid nodules are malignant in children compared with adults.)
- Calcitonin levels: Elevated in 75% of patients with medullary carcinoma

Lab

Urinary iodine (UI) concentration is the best measure of the adequacy of iodine intake.

Imaging

- Ultrasound to determine the number, size, and nature (cystic, solid, or mixed) of nodules
- ¹²³I thyroid scans in cases of solitary nodules to establish whether the nodule concentrates iodide:
 - “Cold” nodules (no I uptake) suggest neoplasia and require immediate evaluation by a pediatric endocrinologist and surgeon.
- Barium swallow studies can reveal a fistulous tract between the left piriform sinus and the left thyroid lobe in children with recurrent acute suppurative thyroiditis. Such fistulas are amenable to surgical resection.

ALERT

False positives:

- Fat neck: Adipose tissue, large sternocleidomastoid muscles
- Thyroglossal duct cysts
- Nonthyroidal neoplasms: Lymphoma, teratoma, hygroma, ganglioneuroma

DIFFERENTIAL DIAGNOSIS

- Immunologic:
 - Chronic lymphocytic thyroiditis (often referred to as Hashimoto thyroiditis)
 - Graves disease
 - Amyloid deposition (familial Mediterranean fever, juvenile rheumatoid arthritis)
- Infectious:
 - Acute suppurative thyroiditis (most often *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*)
 - Subacute thyroiditis (often viral)
- Environmental:
 - Goitrogens: Iodide, lithium, amiodarone, oral contraceptives, perchlorate, cabbage, soybeans, cassava, thiocyanate in tobacco smoke (smoking is especially goitrogenic in iodine-deficient areas)
 - Iodine deficiency (exacerbated by pregnancy)
- Neoplastic:
 - Thyroid adenoma/carcinoma
 - Follicular adenoma: Benign
 - Follicular, papillary, or mixed carcinoma: Well differentiated; follicular 90%
 - Medullary carcinoma: 4–10% as part of the MEN type 2 syndrome
 - TSH-secreting adenoma
 - Lymphoma
- Congenital:
 - Ectopic gland
 - Unilateral agenesis of gland
 - Dyshormonogenesis
 - Thyroxine resistance
- Miscellaneous:
 - Simple colloid goiter
 - Multinodular goiter

TREATMENT

ALERT

Possible conflicts: In manic depressive patients on lithium and cardiac patients on amiodarone, medication-induced thyroid abnormalities can be a significant problem that should be addressed by the endocrinologist and appropriate subspecialist.

MEDICATION (DRUGS)

- Goiters with hypothyroidism: L-thyroxine
- Goiter with hyperthyroidism: Treatment consists of antithyroid drugs (methimazole); if remission is not achieved after 1 or 2 years, radioactive iodine ablation [(131)I] or surgery (near-total or total thyroidectomy) may be considered.
- Duration depends on the cause of the goiter.

ALERT

FDA issued a black box warning (6/4/2009) against propylthiouracil (PTU) use in treating Graves disease owing to risk of severe liver injury including life-threatening acute liver failure.

ADDITIONAL TREATMENT

Additional Therapies

Intra-amniotic injections of L-thyroxine may treat fetal goitrous hypothyroidism. Large fetal goiters pose a risk of airway compromise at birth.

SURGERY/OTHER PROCEDURES

- Surgery solely to decrease the size of a goiter is indicated only if adjacent structures are compressed.
- Rates of complications after pediatric total thyroidectomy are similar for benign and malignant thyroid diseases; the most common is transient hypocalcemia.

Cancer:

- Surgery is recommended for a nonfunctioning nodule if there is:
 - A history of radiation
 - Rapid growth of a firm nodule
 - Evidence of satellite lymph nodes
 - Evidence of impingement on other neck structures
 - Evidence of distant metastases
- Following surgery, radioiodine therapy is administered if a follow-up iodine scan reveals any residual tissue or metastases.
- Suppressive doses of exogenous thyroid hormone are then given to maintain TSH levels <0.2 uIU/mL.
- Thyroglobulin levels are useful as markers of thyroid tissue; calcitonin level serves as tumor marker for medullary carcinoma.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Potential for goiter regression depends on its cause. Goiters associated with chronic lymphocytic thyroiditis and Graves disease may or may not decrease in size with treatment.

- A goiter patient who is clinically and biochemically euthyroid still requires careful follow-up for the detection of the early signs of developing thyroid dysfunction.
- Potential complications of thyroid surgery include laryngeal nerve damage and hypoparathyroidism. Complication rates are lower in high-volume centers.

ALERT

Work up solitary thyroid nodules aggressively; remember, incidence of malignancy in these nodules in children is 15–40% (less in adults).

- Malignancy is more likely in euthyroid pediatric patients with nodules that have palpable lymph nodes, compressive signs, microcalcifications, intranodular vascularization, and lymph node alterations.
- Differentiated thyroid carcinoma in prepubertal children, compared to pubertal adolescents, has a more aggressive presentation and more frequently a family history of thyroid carcinoma.

DIET

- Depends on the cause of the goiter
- Incidence of iodine deficiency (endemic) goiter has greatly declined since the addition of potassium iodide to table salt.
- Iodide can also be added to communal drinking water or administered as iodized oil in isolated rural areas.

PROGNOSIS

- Depends on the cause of the goiter
- Thyroid cancers usually follow an indolent course with excellent prognosis, especially the well-differentiated follicular cell carcinoma. Mortality is most common in medullary and undifferentiated carcinomas, which are relatively rare in children.

COMPLICATIONS

- Depending on gland size, goiters can produce a mass effect on midline neck structures. If the goiter is intrathoracic, it may cause pleural effusions or chylothorax.
- Typically, the child is euthyroid, but clinical hypothyroidism or hyperthyroidism may result from certain types of goiters.
- Therapy for thyroid cancer may induce permanent hypothyroidism.

FAQ

- Q: Does a bigger thyroid gland mean increased thyroid functioning?
- A: Goiters can be euthyroid, hypothyroid, or hyperthyroid, depending on cause.
- Q: Will the goiter decrease in size with treatment?
- A: This depends on the cause of the goiter.
- Q: Does a bigger thyroid gland mean cancer?
- A: Most pediatric goiters are benign, and thyroid cancers often are detected as solitary nodules within an otherwise normal gland (in children with solitary nodules, up to 40% are carcinomas). Patients with a history of goiter or benign nodules/adenomas have an increased risk of developing thyroid cancer.
- Q: Does thyroid cancer usually present with hyperthyroidism?
- A: No. The usual chief complaint is a solitary, hard, painless nodule in a euthyroid patient.
- Q: Is there an increased risk of thyroid cancer from diagnostic radiographs (chest radiographs, lateral neck films)?
- A: Routine diagnostic radiographs should fall well below the levels of radiation thought to increase risk of thyroid neoplasia. During more prolonged radiologic procedures that might expose the thyroid to higher doses of radiation, a lead neck shield is used.
- Q: Should prophylactic thyroidectomy be performed in children identified genetically as having familial medullary carcinoma?
- A: Yes, because of the poorer prognosis associated with development of this cancer.

GONOCOCCAL INFECTIONS

Jane Nathanson

Samir S. Shah

BASICS

DESCRIPTION

Neisseria gonorrhoeae, an aerobic gram-negative diplococcus, is the etiologic agent of gonorrhea.

EPIDEMIOLOGY

- Gonorrhea is the most common STD found in sexually abused children.
- Gonococcal conjunctivitis, although rare in adults, occurs by autoinoculation of infected secretions in patients with anogenital infection.

Prevalence

- In the U.S., there are >700,000 new infections each year. Rates are highest among 15–19-year-old women and 20–24-year-old men.
- Pelvic inflammatory disease occurs in 10–20% of women with endocervical gonococcal infection.
- The risk of male-to-female transmission is 50% per episode of vaginal intercourse; the risk of female-to-male transmission is ~20% per episode. Rectal intercourse is also a mode of transmission.
- Racial disparities include an incidence of infection in African Americans 18 times that of Caucasians.

GENERAL PREVENTION

- Neonatal ophthalmia: Prophylactic ophthalmic ointment is mandatory in the U.S. Instillation of either 1% tetracycline or 0.5% erythromycin ophthalmic ointment in both eyes occurs immediately (or within 1 hour) after birth.
- Maternal infection: Routine screening cervical cultures should be performed at the 1st prenatal visit; repeat at term if high risk.

PATHOPHYSIOLOGY

- Incubation period is 2–7 days.
- Transmission results from contact with infected mucous membranes and secretions, usually through sexual activity, parturition, and (rarely) household contact in prepubertal children.
- Immunity is not induced by infection.

ETIOLOGY

N. gonorrhoeae

COMMONLY ASSOCIATED CONDITIONS

Pediatric gonococcal infections can be categorized by age group: Neonates, prepubertal children, and sexually active adolescents.

- Neonatal gonococcal diseases include ophthalmia neonatorum, scalp abscess (complication of fetal scalp monitoring), and, rarely, vaginitis or systemic disease with arthritis, bacteremia, funisitis, or meningitis.
- Prepubertal gonococcal disease usually occurs in the genital tract. Vaginitis is the most common manifestation. Pelvic inflammatory disease (PID), perihepatitis (Fitz-Hugh-Curtis syndrome), urethritis, proctitis, and pharyngitis rarely occur. Sexual abuse must be considered when genital, rectal, or tonsillopharyngeal gonococcal infections occur in prepubertal children.

- Gonococcal diseases in sexually active adolescents resemble those found in adults and are mostly asymptomatic:
 - Both sexes: Pharyngitis or anorectal infection.
 - Females: Genital tract infection may cause urethritis, vaginitis, and endocervicitis. Ascending genital tract infection may lead to PID and perihepatitis.
 - Males: Acute urethritis is the predominant manifestation. Epididymitis also occurs.

DIAGNOSIS

HISTORY

- Premature or prolonged membrane rupture is a risk factor for conjunctivitis. Fetal scalp monitoring places the infant at risk for gonococcal scalp abscess.
- Vaginal itching and discharge indicate vaginitis. In prepubertal children, genital infection is mild; ascending or disseminated infection rarely occurs. In adolescents, estrogenization protects the vagina from infection and instead serves as a conduit for cervical exudate.
- Urethritis: Purulent urethral discharge and dysuria without urgency or frequency.
- Abdominal pain:
 - Ascending infection is characterized by diffuse lower quadrant abdominal pain, including discomfort with ambulation. Low back pain, dyspareunia, and abnormal vaginal bleeding occasionally occur. Fever, chills, nausea, and vomiting may be present. Acute perihepatitis causes right upper quadrant pain and results from direct extension of infection from the fallopian tube to the liver capsule.
- Symptoms of extragenitourinary disease including pharyngitis, arthritis, dermatitis, meningitis, or endocarditis.

PHYSICAL EXAM

- Neonatal ophthalmia:
 - Typical findings include bilateral eyelid edema, chemosis, and copious purulent discharge. Onset is usually between 2–5 days of age but ranges from the 1st day of life (with prolonged rupture of membranes) to several weeks of age.
- Neonatal scalp abscess
- Pelvic inflammatory disease:
 - Signs include cervical motion tenderness, pelvic adnexal tenderness (usually bilateral), and lower or right upper quadrant abdominal pain (with perihepatitis). Most females with PID also have either mucopurulent cervical discharge or WBCs on microscopic evaluation of a saline preparation of vaginal fluid.
- Cervicitis and urethritis:
 - Purulent vaginal discharge. Associated bacterial vaginosis may be noted.
- Bacteremia:
- Classically discrete, tender, necrotic pustules on distal extremities though macules, papules, and bullae occasionally occur; also tenosynovitis, migratory arthritis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Gram stain (low sensitivity) and culture of infected exudate or body fluid:
 - Intracellular gram-negative diplococci on gram stain. Confirmation depends on isolation of *N. gonorrhoeae* from culture. Specimens are immediately inoculated onto Thayer-Martin or chocolate-blood agar-based media at room temperature and incubated in an enriched CO₂ environment. In cases of suspected sexual abuse, genital, rectal, and pharyngeal cultures should be collected.
- STD panel:
 - Test for other STDs including *Chlamydia trachomatis*, *Treponema pallidum* (syphilis), *Trichomonas vaginalis*, hepatitis B, and HIV in the child in whom sexual abuse is suspected or when evaluating the sexually active adolescent.
- Nonculture gonococcal tests:
 - Nucleic acid amplification tests (NAAT) for urine specimens (freshly voided specimens), male urethral, female endocervical or vaginal (self-administered introital) swabs are highly sensitive and specific, but should not be used in investigations of possible sexual abuse (owing to the possibility of false-positive results). NAATs also cannot provide antimicrobial susceptibility test results.
- CBC, ESR, and C-reactive protein:
 - Leukocytosis and elevated ESR and C-reactive protein occur in 2/3 of patients with PID.
- Synovial fluid cell count and culture:
 - In septic gonococcal arthritis, synovial fluid has >50,000 leukocytes/mm³ and the synovial fluid culture is positive, whereas the blood culture is usually negative. In arthritis-dermatitis syndrome, the synovial fluid contains <20,000 leukocytes/mm³, and the synovial fluid culture is sterile, whereas the blood culture is positive.

Imaging

Pelvic ultrasound may detect ectopic pregnancy and in PID reveals thick, dilated fallopian tubes or tubo-ovarian abscess.

DIFFERENTIAL DIAGNOSIS

- Ophthalmia neonatorum: Other causes of neonatal conjunctivitis include infection with *C. trachomatis*, *S. aureus*, *S. pneumoniae*, *Haemophilus* species, and herpes simplex virus.
- Scalp infection: Gonococcal scalp abscesses may be difficult to distinguish from abscesses caused by staphylococcal species, group B *Streptococcus*, *H. influenzae*, Enterobacteriaceae, and herpes simplex virus.
- Vaginitis: In the prepubertal child, other causes include chemical or environmental irritants, pinworms, foreign body, and infections (i.e., streptococci, *T. vaginalis*). In cases of sexual abuse, *C. trachomatis* and syphilis may occur.
- Genitourinary tract infection: In adolescents, other causes include *C. trachomatis*, syphilis, and *T. vaginalis*.

- Arthritis: Other bacterial causes of septic arthritis, Reiter syndrome, and reactive arthritis.
- Abdominal pain: Ectopic pregnancy, appendicitis, cholecystitis, and UTI/pyelonephritis.

TREATMENT

MEDICATION (DRUGS)

First Line

- Increased fluoroquinolone resistance in the U.S. led to extended-spectrum cephalosporin as initial therapy.
- Neonates:
 - Ophthalmia neonatorum or mother known to have gonorrhea: Ceftriaxone, 25–50 mg/kg IV or IM (single dose; maximum, 125 mg); alternate agent for infants with hyperbilirubinemia is cefotaxime, 100 mg/kg IV or IM (single dose).
 - Neonates with gonococcal ophthalmia also require eye irrigation with sterile saline at presentation and at frequent intervals until the mucopurulent drainage has ceased.
 - Disseminated infection: Ceftriaxone daily or cefotaxime b.i.d. for 7 days; continue treatment for 10–14 days for meningitis.
- Older children and adolescents:
- Uncomplicated gonococcal infection (including epididymitis or pharyngeal infection): A single IM dose of ceftriaxone, 125 mg, or a single PO dose of cefixime, 8 mg/kg (max 400 mg, use 400 mg if >45 kg and >8 years). Follow with a treatment regimen for *C. trachomatis*.
- If allergic to cephalosporins, use single IM dose of spectinomycin, 40 mg/kg (max 2 g) or consider cephalosporin desensitization.
- Pelvic inflammatory disease: See Pediatric Red Book for treatment regimens.
- Complicated gonococcal infection: Ceftriaxone or cefotaxime for 7 days (arthritis and septicemia), 10–14 days (meningitis), or ≥28 days (endocarditis). Include concomitant *C. trachomatis* therapy: For arthritis, add erythromycin, azithromycin, or doxycycline for 7 days; for meningitis or endocarditis, add erythromycin for 7 days.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Neonate: Hospitalize and obtain appropriate cultures (blood, CSF, conjunctival fluids, or those from any other site of infection).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Provide risk reduction education.
- Sexual contacts and mother and her partner(s) of patients with gonorrhea should be counseled and treated.
- Evaluate for concurrent infection with other sexually transmitted diseases, including syphilis, *C. trachomatis*, *T. vaginalis*, hepatitis B, and HIV. Patients whose age has progressed beyond the neonatal period should be treated presumptively for *C. trachomatis* infection.

- All cases of gonorrhea must be reported to public health officials.
- Contact isolation precautions recommended for all hospitalized patients with gonococcal disease in the neonatal and prepubescent age groups; no special policies are recommended for other patients.
- Consider and evaluate for abuse in prepubertal children.

ALERT

Pitfalls:

- Failure to consider the diagnosis of sexual abuse in a prepubertal child with a gonococcal infection. Cases of transmission via nonsexual contact have been reported (i.e., from freshly infected towels, or other fomites, or by digital transmission from an infected caregiver), but such mode cannot be assumed without first excluding sexual abuse.
- Failure to use culture to diagnose infection in cases of suspected abuse.
- Failure to differentiate *N. gonorrhoeae* by culture from other *Neisseria* species, especially in prepubertal children, given concern for sexual abuse.
- Failure to consider acute gonococcal perihepatitis/Fitz-Hugh-Curtis syndrome in females with right upper quadrant pain.
- Classic findings of fever, leukocytosis, and elevated erythrocyte sedimentation rate or C-reactive protein are not found in 1/3 of patients with laparoscopically diagnosed PID.

PROGNOSIS

Prognosis has been improved by treating all forms of infection with a 3rd-generation cephalosporin.

COMPLICATIONS

- Gonococcal infection during pregnancy is associated with spontaneous abortion, preterm labor, and perinatal infant mortality.
- Ophthalmia neonatorum of gonococcal origin may rapidly progress to corneal ulceration and perforation, with subsequent scarring and blindness.
- Pelvic inflammatory disease:
 - Endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis occur as a consequence of untreated vaginal disease.
 - Scarring secondary to salpingitis causes sterility in ≤20% of women with a single infection and ≤50% of women after 3 episodes of infection.
 - Risk of ectopic pregnancy increases sevenfold after 1 episode of PID.
- In males, rare complications include periurethral abscess, acute prostatitis, seminal vesiculitis, and urethral strictures.
- Disseminated disease:
 - Consider evaluation for complement deficiency in those with multiple episodes.
 - In neonates, arthritis is the most frequent systemic manifestation; symptoms develop 1–4 weeks after delivery. Involvement of multiple joints is typical, and most of these infants do not have ophthalmia neonatorum.

- In older children and adolescents, septic arthritis (1 joint) and a characteristic polyarthritis-dermatitis syndrome are predominant manifestations.
- Gonococcal meningitis, endocarditis, and osteomyelitis are rare in children.
- Gonococcal infection can serve as a cofactor in increasing HIV infection and transmission.

FAQ

- Q: What are the advantages of the nucleic amplification tests for making a diagnosis?
- A: The transcription mediated amplification (TMA) test of urine samples, approved by the FDA for women, can be used to simultaneously test for *C. trachomatis* and *N. gonorrhoea*.
- Q: When is this test not approved?
- A: For rectal and pharyngeal swabs and for cases of suspected abuse.

GRAFT VERSUS HOST DISEASE

Valerie I. Brown

BASICS

DESCRIPTION

Multiorgan inflammatory process that develops when immunologically competent T lymphocytes from a histoincompatible donor are infused into an immunocompromised host unable to reject them. Divided into acute and chronic, historically based on time of presentation, but best distinction based on clinicopathologic findings:

- Acute: Develops within 100 days after allogeneic stem cell transplant; with damage to skin, GI tract and/or liver
- Chronic: Develops 100–500 days after allogeneic stem cell transplant; with diverse features resembling autoimmune syndromes
- Chronic subtypes:
 - Progressive: Extension of acute GvHD
 - Quiescent: After resolution of acute GvHD
 - De novo: No prior acute GvHD

EPIDEMIOLOGY

- Acute GvHD (grades II–IV): 10–80% of patients receiving T-cell replete hematopoietic stem cell transplant (HSCT), 35–45% for human leukocyte antigen (HLA)-identical sibling donor bone marrow:
 - 60–80% if 1-antigen HLA-mismatched unrelated donor bone marrow or peripheral stem cells
 - 35–65% if 2-antigen HLA-mismatched unrelated umbilical cord blood
- Chronic GvHD: Most common late complication, cause of decreased quality of life, and late mortality of allogeneic HSCT
 - 15–25% if HLA-identical related marrow
 - 40–60% if HLA-matched unrelated marrow
 - 54–70% if HLA-matched unrelated peripheral stem cells
 - 20% if unrelated umbilical cord blood
- Flare-ups triggered by infection (usually viral)

RISK FACTORS

- HLA disparity (both major and minor antigens).
- Older donor or recipient age
- Stem cell source and dose: Highest with peripheral stem cells; lowest with umbilical cord
- Donor leukocyte infusions.
- Reactivation of viruses (e.g., HHV6, CMV)
- T-cell depletion decreases incidence.
- Acute disease specific:
 - Higher-intensity conditioning regimen
 - Prior pregnancies in female donors
 - Gender mismatch
- Chronic disease specific:
 - Severity of acute GvHD
 - Malignancy as indication for transplantation
 - Use of total-body irradiation
 - Type of immunosuppressive prophylaxis

Genetics

- HLA gene complex on chromosome 6; inherited as haplotype
- Full siblings: 25% chance HLA identical
- Minor histocompatibility antigen differences likely account for GvHD in HLA-identical sibling stem cell transplants.

GENERAL PREVENTION

- Transfusion: Irradiation of all cellular blood products for patients at risk
- Stem cell transplantation:
 - Selection of a histocompatible donor
 - Immunosuppression (gold standard): Cyclosporine or tacrolimus and a short course of methotrexate
 - Other options: Corticosteroids, usually with cyclosporine or tacrolimus, mycophenolate mofetil, sirolimus, and low-dose cyclophosphamide
 - Ex vivo depletion of donor T lymphocytes in graft and anti-T-cell antibodies to recipient

PATHOPHYSIOLOGY

- Acute GvHD: Interaction of donor and host innate and adaptive immune responses
 - Severity related to degree of HLA mismatch
 - 3 phases ending in “cytokine storm”:
 - Tissue damage by conditioning regimen
 - Priming and activation of donor T cells: Infiltration of activated T cells into skin, GI tract, and liver resulting in apoptosis
- Chronic GvHD: Findings similar to autoimmune disorders: Donor T cell directed against host antigens, donor T-cell autoreactivity, B-cell dysregulation, regulatory T-cell deficiency. Marked collagen deposition in target organs and lack of T-cell infiltration

ETIOLOGY

- Hematopoietic stem cell transplantation
- Transfusion of nonirradiated blood products to immunodeficient hosts: Viable donor lymphocytes engraft in the recipient.
- Transfusion of nonirradiated blood from a donor homozygous for 1 of the recipient’s HLA haplotypes (usually 1st- or 2nd-degree relative)
- Intrauterine maternal–fetal transfusions and exchange transfusions in neonates
- Solid organ grafts: Contain immunocompetent T cells into immune-suppressed recipient

DIAGNOSIS

HISTORY

- Acute GvHD: Median onset: 19 days posttransplant:
 - Rash: Usually 1st manifestation; pruritus or burning sensation can precede rash.
 - Diarrhea, abdominal pain, and intestinal bleeding: Unusual to precede skin disease
 - Anorexia, nausea, vomiting, and dyspepsia
 - Jaundice (liver involvement)
- Chronic GvHD:
 - Dry eyes and/or dry mouth (sicca syndrome)
 - Blurry vision, eye irritation, photophobia, and eye pain (keratoconjunctivitis)
 - Difficulty swallowing or retrosternal pain (esophageal strictures)
 - Sensitivity to mint, spicy foods, or tomatoes
 - Weight loss, failure to thrive, diarrhea, anorexia, nausea, and vomiting
 - Dyspnea, wheezing, and cough (bronchiolitis obliterans)
 - Poor wound healing, especially after trauma
 - Joint stiffness
 - Muscle cramps
- Infections: Pneumococcal sepsis, *Pneumocystis carinii* pneumonia, invasive fungal infections

PHYSICAL EXAM

- Acute/transfusion-associated GvHD:
 - Skin (most common site): Erythema of palms, soles, ears, malar cheeks, nape of neck:
 - Can become confluent erythroderma
 - Severe form: Bullae formation, even full-thickness necrosis
 - GI tract: Diarrhea is profuse, watery, and often green and bloody.
 - Liver: Jaundice; atypical: Painful hepatomegaly, ascites, rapid weight gain
- Chronic GvHD:
 - Skin (involved in almost every patient):
 - Hyperpigmentation or hypopigmentation, xerosis (skin dryness), pruritus, patchy erythema, scaling, poikiloderma, skin atrophy; lichenoid, eczematous, and/or sclerodermatous changes
 - Advanced scleroderma: Thickened, tight, and fragile skin
 - Hair: Thin, fragile; premature graying
 - Scalp: Dry or seborrheic
 - Nails: Vertical ridging; dystrophic and fragile; entire nail can be lost.
 - Mouth: Mucositis, ulcers, pseudomembranes. Whitish lacey plaques or ulcers on tongue or buccal surfaces: May be painful
 - Cannot open mouth fully owing to sclerosis
 - Esophageal strictures, stenosis, or webs
 - Blood: Thrombocytopenia, anemia, eosinophilia, hypo- or hypergammaglobulinemia, autoantibodies
 - Joints: Stiffness and/or swelling. Contractures may occur without joint swelling.
 - Eosinophilic fasciitis, myositis
 - Lung: Bronchiolitis obliterans (obstructive), bronchiolitis obliterans organizing pneumonia (restrictive)
 - Other: Pericardial/pleural effusions, cardiomyopathy, nephritic syndrome, peripheral neuropathy, genital ulceration

DIAGNOSTIC TESTS & INTERPRETATION

Diagnosis is often made on clinical grounds.

Lab

- Complete blood count with differential and Coombs test: Autoimmune thrombocytopenia (most common), hemolytic anemia, and neutropenia. Eosinophilia: Resolves with treatment
- Howell-Jolly bodies on blood smear: Functional asplenia of chronic GvHD
- Elevated ALT/AST without hyperbilirubinemia
- Vitamin D: May be low; risk for osteoporosis
- Urinalysis: May show protein, glucose, blood
- Schirmer test: Decreased tear production
- Pulmonary function tests
- Echocardiogram/electrocardiogram
- Fluorescein biomicroscopy: Punctate keratopathy

Imaging

- High-resolution chest CT: Bronchiolitis obliterans
- Barium swallow: Strictures, webs

Diagnostic Procedures/Other

- Endoscopy with biopsy: Upper GI tract GvHD
- Skin biopsy: Localized epidermal atrophy
- Liver biopsy: Bile duct damage reminiscent of primary biliary cirrhosis
- Buccal/labial biopsy: Rule out viral/fungal infections
- Analysis of pleural, pericardial fluid

DIFFERENTIAL DIAGNOSIS

- Acute GvHD:
 - Skin: Drug reaction, chemoradiotherapy, viral exanthema, engraftment syndrome; TEN for grade IV skin GvHD
 - Liver: Hepatic veno-occlusive disease, side effect of total parenteral nutrition, drug toxicity, bacterial sepsis, or viral infection
 - GI: Diarrhea secondary to transplant conditioning regimen, infectious causes (e.g., *Clostridium difficile*, CMV), or opiate withdrawal
- Chronic GvHD:
 - Skin: Keratosis pilaris, eczema, psoriasis

ALERT

- Do not give live vaccine if chronic GvHD is present. May result in symptomatic infection
- Sudden high fevers may indicate bacterial sepsis that can be overwhelming. Chronic GvHD patients often functionally asplenic and have profound immune function impairment

**TREATMENT****MEDICATION (DRUGS)**

- Treatment of acute GvHD (grades II–IV):
 - Systemic steroids (2 mg/kg/d) for 2 weeks, followed by a quick taper
 - Cyclosporine or tacrolimus if patient is not already receiving it as prophylaxis
 - Mycophenolate mofetil, sirolimus (rapamycin), antithymocyte globulin, and etanercept (experimental) as 2nd-line drugs
 - Infliximab (Remicade) for steroid-refractory GI tract disease
 - Other options: Extracorporeal photopheresis; mesenchymal stem cells (experimental)
 - Visceral organ involvement requires urgent start of 2nd-line therapy.
 - For isolated, mild skin GvHD, topical tacrolimus ointment and triamcinolone
- Treatment of chronic GvHD:
 - Steroids alone or with cyclosporine, sirolimus, tacrolimus, or mycophenolate mofetil
 - Goal: Steroids <0.5 mg/kg alternating days with cyclosporine or tacrolimus
- Steroid-refractory GvHD:
 - Mycophenolate mofetil, sirolimus, pentostatin (investigational)
 - Other options many off-label: Antithymocyte globulin; rituximab, especially for low platelets; low-dose methotrexate in liver GvHD; thalidomide; hydroxychloroquine; imatinib; low-dose cyclophosphamide; etanercept; alefacept alemtuzumab: High infection risk
- Extracorporeal photopheresis: Very effective for chronic skin GvHD; lower response rate if visceral organs involved
- Psoralen plus ultraviolet A is of some benefit in skin GvHD (lichenoid, not sclerotic).
- Oral rinses with dexamethasone: Oral GvHD
- Ursodeoxycholic acid: Hepatic GvHD

ADDITIONAL TREATMENT**General Measures**

- Prophylaxis for *Pneumocystis carinii* pneumonia and pneumococcal infection
- Antifungal coverage if on multiple immunosuppressive agents
- IV immunoglobulin if low serum IgG levels
- Monitor closely for viral reactivation.
- Skin care: Lubricate dry skin with petroleum jelly. Protect skin from injury. Avoid sunburn.
- Artificial tears for sicca syndrome.
- Correct electrolyte imbalances for muscular aches and cramps.
- Physical therapy/range-of-motion exercises to prevent contractures
- Inhaled corticosteroids and azithromycin (experimental) for bronchiolitis obliterans
- Nutrition consults for malnutrition and wasting
- If chronic GvHD persists past 2–3 months or prednisone needed at 1 mg/kg/d, alternative therapy should be used.
- Hospitalization may be required for hydration, nutritional support, IV medications, monitoring, treatment of infections, and other supportive care.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

- Steroids: Osteoporosis, diabetes
- Calcineurin inhibitors: Hypertension, renal dysfunction, hypomagnesemia
- Sirolimus: Hyperlipidemia, leucopenia, microangiopathic hemolytic anemia
- Mycophenolate mofetil: GI discomfort, diarrhea, leukopenia

PROGNOSIS

Prognosis of GvHD is based on severity:

- Acute GvHD: Graded from I to IV based on organ involvement, percent of body surface area involved (skin), volume of diarrhea (gut), and/or elevation of serum bilirubin (liver):
 - Grade I: One organ, usually skin; survival is the same as for patients without GvHD.
 - Grade II: > 1 organ, with skin rash >50% body surface area, severe nausea/vomiting, diarrhea, and/or bilirubin elevation
 - Grade III: Severe multiorgan involvement, 25% long-term survival
 - Grade IV: Generalized erythroderma with bullae and desquamation; stage 4 liver. Survival is only 5–15%.
- Acute GvHD: 50–60% of patients respond to corticosteroids plus cyclosporine or tacrolimus.
- Poor prognosis for survival: Extensive skin involvement, progressive onset, GI involvement, thrombocytopenia, weight loss, and low Karnofsky performance status (40–60% survival)
- 50% of patients still require therapy 5 years after diagnosis of chronic GvHD.

COMPLICATIONS

- Mortality from GvHD after stem cell transplantation is usually related to infection.
- Rarely, patients die of hepatic failure or abdominal catastrophe.
- In transfusion-associated GvHD, death is usually from bone marrow aplasia with destruction of the host's marrow by donor lymphocytes.

**CODES****ICD9**

996.85 Graft versus host disease

ICD10

- D89.810 Acute graft-versus-host disease
- D89.811 Chronic graft-versus-host disease
- D89.813 Graft-versus-host disease, unspecified

FAQ

- Q: If a child gets acute GvHD, does that mean that he will get chronic GvHD?
- A: No. ~30% of patients <10 years of age who receive HLA-identical sibling bone marrow transplantation will get acute GvHD, whereas only 13% will develop chronic GvHD. Of note, chronic GvHD can develop in a patient who did not have acute disease; the prognosis is much more favorable than for the progressive form.
- Q: Do patients with severe chronic graft versus host disease all die?
- A: No. Occasionally the graft versus host disease will “burn out.” This is rare, and the process by which it happens is not understood.

GRAVES DISEASE

Adda Grimberg

BASICS

DESCRIPTION

Multisystem autoimmune disorder that presents with the classic triad of hyperthyroidism (goiter), exophthalmos, and dermopathy (rare in children)

EPIDEMIOLOGY

Female > male (4–5:1)

Incidence

- 10–15% of all childhood thyroid disorders
- Incidence increases with age, peaking in adolescence and in the 3rd–4th decades.

RISK FACTORS

- No simple hereditary pattern (i.e., genetic susceptibility plus environmental factors):
 - Up to 60% of patients have a family history of autoimmune thyroid disease (hyperthyroidism or hypothyroidism).
 - Concordance rates of Graves disease: 17% in monozygotic twins (although another 17% had chronic lymphocytic thyroiditis and 10% had other nonthyroid autoimmune conditions); 2% in dizygotic twins; 4% of 1st-degree relatives
- Associated with higher frequency of HLA-DR3
- Increased incidence in genetic syndromes:
 - Down syndrome: Presents at a younger age, no female predominance as seen in the general population. Usually milder course
 - Turner syndrome

PATHOPHYSIOLOGY

- Autoimmune process that includes production of immunoglobulins against antigens in the thyroid, orbital tissue, and dermis
- IgG1 anti-TSH (thyroid-stimulating hormone receptor autoantibody, thyroid-stimulating immunoglobulin (Ig)) activates the receptor, causing constitutive stimulation; thyroid follicular cells increase production and release of thyroid hormone.

DIAGNOSIS

ALERT

Failure to recognize thyroid storm, which constitutes an endocrinologic medical emergency

HISTORY

- Growth acceleration also associated with precocious puberty
- Hyperthyroidism can accelerate the bone age (i.e., advance the developmental tempo).
- Declining school performance, mind racing, concentration difficulty. May be mistaken for ADHD
- Symptoms of hyperthyroidism and their duration (if child complains of these symptoms, evaluate for possible hyperthyroidism):
 - Restlessness, emotional lability, nervousness
 - Fine tremor
 - Insomnia and disturbed sleep pattern; may result in daytime fatigue
 - Weight loss, despite increased appetite
 - Palpitations or chest pain with minimal exertion or at rest; low exercise tolerance
 - Heat intolerance
 - Diarrhea and increased urination

- Muscle weakness (proximal)
- Plummer nails (separation of nail from bed)
- Menstrual irregularities
- Thyroid gland enlargement (duration and tenderness): Graves disease can present with goiter. Tenderness suggests an infectious cause.
- Bulging of the eyes, increased staring, change in vision or in facial appearance: Exophthalmos due to retro-orbital immune depositions is a hallmark of Graves disease.
- Familial history: Increased incidence of Graves disease in families with thyroid disease

PHYSICAL EXAM

- Accelerated growth, or height above expected genetic potential due to bone age advancement
- Symmetrically enlarged, smooth, nontender goiter in >95% of cases
- Auscultate the thyroid gland for bruit while patient holds his or her breath.
- Glandular hyperperfusion is associated with hyperthyroidism.
- Resting tachycardia with widened pulse pressure; hyperdynamic precordium: Cardiac effects of excessive thyroid hormone
- Slightly elevated temperature: Thyroid hormone controls basal metabolic rate and upregulates catecholamine-induced thermogenesis.
- Lid lag/stare; exophthalmos and proptosis: Severe ophthalmopathy is rare.
- Fine tremor especially visible in hands and tongue in ~60% of children with Graves disease.
- Proximal muscle weakness is common but seldom severe.
- Exaggerated deep tendon reflexes are variable.
- Skin warmth and moisture: Heat intolerance and excessive sweating in >30% of children

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total or free thyroxine: Elevated
- Triiodothyronine assessment by radioimmunoassay: Elevated (triiodothyronine radioimmunoassay, as direct measurement of triiodothyronine, and not triiodothyronine resin uptake, which indirectly evaluates thyroid hormone-binding capacity)
- TSH: Significantly suppressed or undetectable
- TSI titer: Positive in 90% of children.

False-positive test results: Elevated total thyroxine levels can also be caused by conditions involving increased protein binding, but they are not necessarily diagnostic for hyperthyroidism: Increased estrogen states (e.g., pregnancy and oral contraceptive use) lead to augmented hepatic thyroid-binding globulin (TBG) production. Familial dysalbuminemic hyperthyroxinemia: Mutation affecting the binding affinity leads to increased protein-bound pool.

Imaging

¹²³I scan: Not needed to diagnose Graves disease. Shows diffuse increased uptake at 6 and 24 hours. If palpation suggests a nodule, scan may reveal a hot nodule within a suppressed gland.

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Acute suppurative thyroiditis (i.e., transient thyroxine elevations)
 - Subacute thyroiditis after viral illness (also transient hyperthyroidism)

- Environmental:
 - Thyroid hormone ingestion
 - Ingestion of excess iodine (escape from Wolff-Chaikoff block due to impaired autoregulation)
- Tumors (all rare in childhood):
 - TSH-producing pituitary adenoma
 - Thyroid adenoma/hyperfunctioning autonomous thyroid nodule (most pediatric patients are euthyroid; incidence of nodule hyperfunctioning rises with patient age)
 - Thyroid carcinoma (rarely presents with hyperthyroidism)
- Congenital:
 - Neonatal Graves disease (transplacental antibody transfer from mothers with Graves disease or chronic thyroiditis)
- Genetic and developmental:
 - Pituitary resistance to thyroid hormones (dominant negative thyroid-receptor gene mutations causing loss of pituitary negative feedback loop and inappropriately elevated levels of TSH; can be isolated, with clinical hyperthyroidism, or associated with peripheral thyroid resistance and clinical euthyroidism or hypothyroidism)
 - TSH-receptor gene mutations (rare; germline activating TSH-receptor mutations cause autosomal dominant nonautoimmune hereditary hyperthyroidism)
 - McCune-Albright syndrome: Activating G-protein mutation can lead to indolent hyperthyroidism in addition to the classic features of this syndrome
 - Ectopic thyroid tissue
- Other causes of hyperthyroidism: See “Goiter.”

TREATMENT

Radiotherapy

¹³¹I ablation therapy:

- 90–100% effective; safe and definitive, with predictable outcome
- Results in permanent hypothyroidism requiring lifelong thyroxine replacement
- Adequate dose should be used (>150 μ Ci/g of thyroid tissue) to prevent residual tissue that would be at risk of developing thyroid cancer.
- Current recommendations advise avoiding ¹³¹I ablation in children <5 years of age owing to theoretical concerns relating radiation exposure and cancer risks.
- Radioiodine ablation may exacerbate the ophthalmopathy, but this effect can be prevented with concomitant glucocorticoid administration.

MEDICATION (DRUGS)

ALERT

- Antihistamines and cold medications may worsen sympathetic nervous system symptoms.
- Stopping antithyroid drugs because of low thyroxine values where TSH is still suppressed, reflecting continued TSI activity, will likely result in relapse. Antithyroid medication dosage should be decreased, or L-thyroxine should be added.
- FDA issued a black box warning (6/4/2009) against propylthiouracil (PTU) use in treating Graves disease owing to risk of severe liver injury including life-threatening acute liver failure.

First Line

- Drug therapy is the 1st-line choice in children.
- Antithyroid medications (thiourea derivatives): 65–95% effective:
 - Medications block thyroid hormone synthesis but not the release of existing hormone.
 - Methimazole
 - Propylthiouracil (PTU): Note black box warning. Limited, short-term use of PTU may be considered for patients requiring antithyroid medication (neither I^{131} ablation nor prompt surgery are options) or after a toxic reaction to methimazole. PTU is preferred during 1st trimester of pregnancy (teratogenic effects of methimazole).
- Propranolol and atenolol block adrenergic symptoms; should be used along with antithyroid medications at the start of treatment and whenever cardiac symptoms are prominent.
- Duration of treatment:
 - Antithyroid medications can be tapered and potentially discontinued after 2–3 years of therapy, depending on the patient's course.
 - β -Blockers: Continue until thyroxine and triiodothyronine are under control (~6 weeks).
 - If remission not achieved in 1–2 years, ablation with radioactive iodine [I^{131}] or total or subtotal thyroidectomy may be considered.

SURGERY/OTHER PROCEDURES

Total or near-total thyroidectomy:

- Effective, rapid, and definitive (vs. 30% recurrence rate for subtotal thyroidectomy)
- Lifelong thyroxine replacement needed
- Surgical complication rates higher for children age 0–6 years and in lower-volume centers

ISSUES FOR REFERRAL

Treatment for severe ophthalmopathy: Must refer patient to an ophthalmologist:

- 3 options: High-dose glucocorticoids, orbital radiotherapy, or surgical orbital decompression
- Rehabilitative surgery for eye muscles or eyelids is often needed after the ophthalmopathy has been treated.

**ONGOING CARE****PROGNOSIS**

- Good, if compliant with treatment
- Mortality in severe thyrotoxicosis is possible from cardiac arrhythmias or cardiac failure.
- Spontaneous remission occurs in 20–30% of children after 1–2 years, but can relapse in 30%. Large thyroid gland size (by ultrasound) and high titers of TSH-receptor antibody (TRAb) predict lower chance of remission.
- Neonatal hyperthyroidism remits by 48 weeks and more commonly by 20 weeks.
- Propranolol or atenolol should result in rapid relief of symptoms of sympathetic hyperactivity.
- 4–6 weeks of medical treatment should result in normalization of levels of thyroxine and triiodothyronine, although TSH levels may remain suppressed owing to persistent underlying activity of the thyroid-stimulating Ig.

- Persistent suppression of TSH is associated with pretreatment presence of thyrotropin-binding inhibitory Ig, severity of thyrotoxicosis, and time to recovery of thyroid hormone levels.
- Duration and type of treatment depend on patient age and remission and relapse pattern.

COMPLICATIONS

- Endocrine disturbances: Delayed/early puberty, menstrual irregularity, hypercalcemia
- Ophthalmologic: 3–5% of patients develop severe ophthalmopathy, including eye muscle dysfunction and optic neuropathy, requiring specific treatment by an ophthalmologist. Pediatric ophthalmologic findings (lid lag, soft tissue involvement, and proptosis) are more common but usually less severe than in adults.
- Bone: Osteopenia common at diagnosis due to high bone turnover. Corrects with treatment of Graves disease and return to euthyroid status.
- Fetal/Neonatal: Intrauterine growth retardation (IUGR), nonimmune hydrops fetalis, craniosynostosis, intrauterine death, goiter that complicates labor and can cause life-threatening airway obstruction at delivery, hyperkinesia, failure to thrive, diarrhea, vomiting, cardiac failure and arrhythmias, systemic and pulmonary hypertension, hepatosplenomegaly, jaundice, hyperviscosity syndrome, thrombocytopenia.
- Medication side effects: Agranulocytosis (in 0.2–0.5% of patients), rash (most common side effect), gastrointestinal upset, headache, transient transaminitis/hepatitis and life-threatening liver failure with PTU, vasculitis with PTU (frequently associated with perinuclear antineutrophil cytoplasmic antibody [pANCA] titers)

**CODES****ICD9**

- 242.00 Toxic diffuse goiter without mention of thyrotoxic crisis or storm
- 242.01 Toxic diffuse goiter with mention of thyrotoxic crisis or storm

ICD10

- E05.00 Thyrotoxicosis with diffuse goiter without thyrotoxic crisis or storm
- E05.01 Thyrotoxicosis with diffuse goiter with thyrotoxic crisis or storm

FAQ

- Q: Does Graves disease lead to thyroid cancer?
- A: No, although controversy surrounds the role of TSH and the closely related TSH-receptor antibodies of Graves disease in thyroid cancer's incidence and aggressiveness. There is an increased incidence of benign thyroid adenoma from 0.6–1.9% after therapy involving I^{131} ablation.
- Q: Does hyperthyroidism affect long-term growth or final adult height?
- A: No. Hyperthyroidism can cause tall stature and acceleration of skeletal maturity, but does not typically affect final adult height.
- Q: Should WBC counts be monitored routinely while patients are on antithyroid medications?
- A: No. Routine monitoring is not cost effective because agranulocytosis is rare and sudden in onset. WBC counts should be checked when a patient on antithyroid medication develops fever.
- Q: Will the ophthalmopathy correct with antithyroid treatment?
- A: Not necessarily. It may require specific intervention by an ophthalmologist.
- Q: Can mothers breastfeed while they are being treated for Graves disease?
- A: Yes. PTU has a lower milk/serum concentration ratio than methimazole (0:1 and 1:0, respectively). In 1 study, 3 of 11 infants exclusively breastfed by women on 300–750 mg daily PTU had high levels of TSH; of these 3, 1 was just above the normal range and the other 2 completely corrected while the mother was still being medicated.

GROWTH HORMONE DEFICIENCY

Jeffrey D. Roizen

Craig A. Alter

Preneet Brar (5th edition)

BASICS

DESCRIPTION

Growth hormone deficiency (GHD) is one of the rare causes of growth failure due to a lack of growth hormone action caused by a defect in GH synthesis (insufficient hormone), release or signalling (decreased responsiveness to normal or high levels of hormone).

EPIDEMIOLOGY

- Incidence in the USA is 1:4,000.
- Males are more commonly diagnosed than females.
- 2 peak ages of diagnosis:
 - infantile at <1 year of age, usually because of associated hypoglycemia
 - childhood >4 years of age, usually because of poor linear growth

Prevalence

~1:3,500 in school age children

Genetics

- Spontaneous
- Autosomal recessive
- Autosomal dominant
- X-linked forms

PATHOPHYSIOLOGY

Absence of GH action leads to decreased levels of insulin like growth factor I (IGF-I, formerly somatomedin-C), a protein that acts on cartilage at the growth plate to stimulate linear growth. GH has some direct effect on growth as well.

ETIOLOGY

- Idiopathic (the most common cause, a diagnosis of exclusion).
- Congenital idiopathic: Congenital malformation of the pituitary which can be associated with:
 - Holoprosencephaly
 - Septo-optic dysplasia
 - Midline defects: Cleft lip, cleft palate, central maxillary incisor
 - Ectopic posterior pituitary, small anterior pituitary, and/or hypoplastic infundibulum
- Genetic mutations:
 - Familial multiple anterior pituitary hormone deficiency (Pit-1, Prop-1)
 - GH gene mutations (Type Ia, Ib, II, III)
- GH insensitivity:
 - Laron dwarfism, which is an autosomal recessive disorder classically caused by mutation of the GH receptor, presents with the phenotype of severe GH deficiency (severe short stature, hypoplastic nasal bridge, sparse hair, high-pitched voice, and delayed bone age).
 - Postreceptor and second messenger defects such as IGF-I gene deletion, IGF-I receptor mutation, STAT5b mutation

- Acquired idiopathic (many likely due to hypophysitis):
 - Tumors: Craniopharyngioma, Germinoma, Medulloblastoma, Glioma, Pinealoma
 - Pituitary or hypothalamic irradiation
 - Trauma: Child abuse or closed head injury
 - Surgical resection/damage of the pituitary gland/stalk
 - Birth injury/Perinatal insult
 - Infection: Viral encephalitis, Bacterial or fungal infection, Tuberculosis,
 - Vascular: Pituitary infarction or aneurysm
 - Infiltration affecting pituitary gland or sella turcica: Histiocytosis, Sarcoidosis
 - Psychosocial deprivation.

DIAGNOSIS

HISTORY

- Family history:
 - Parents' height
 - Family history of short stature (women <4 feet 11 inches or men <5 feet 4 inches) indicates genetic shortness.
 - Family history of delayed puberty "late bloomer" (growth after high school, menarche at ≥14 years): Constitutional delay of growth and development tends to occur in family members.
- Birth history
 - Babies born small for gestational age. 10–15% will not show "catch up growth," but are not typically GHD
 - Babies with congenital GHD may not be short at birth but will grow poorly over the next few years.
- Medication history: Look for overusage of corticosteroids, either systemic or inhaled. Ask about nonprescription drugs and health food store supplements.
- Dentition history: "Poor man's bone age," i.e., when first tooth was lost as an indicator of delay in skeletal maturation.
- Psychosocial history: Poor growth occurring at the time of a major stressful event may be due to psychosocial deprivation.
- Clues to etiology:
 - Hypopituitarism: Hypoglycemia, prolonged jaundice, micropenis
 - Increasing weight for height indicates an endocrinologic cause for the poor growth (GHD, hypothyroidism, hypercortisolism).
 - Hypothyroidism: Lethargy, weight gain, constipation, and dryness of skin
 - Turner syndrome: Wide-spaced nipples, marked short stature, cubitus valgus, scoliosis, and delayed puberty
 - Celiac disease or inflammatory bowel disease: Poor weight gain, vomiting, loose stools diarrhea, food-provoked GI distress

- Cardiac disease, renal tubular acidosis, chronic renal insufficiency, HIV, tuberculosis
- Prader-Willi or Down syndrome: Hypotonia and developmental delay
- Skeletal changes such as achondroplasia/hypochondroplasia; often have abnormal body proportions.

PHYSICAL EXAM

- Measure accurate weight and height with wall stadiometer.
- Neurologic examination, including visual fields and fundoscopic examination for evaluation of brain tumors
- Dental age, scoliosis, and proportionality of limbs relative to height are good skeletal indicators.
- Cubitus valgus and shortened 4th metacarpal for girls with Turner syndrome
- Midline facial defects such as submucous cleft, cleft lip and palate are associated with hypopituitarism.
- Tanner stage: Micropenis is associated with congenital hypopituitarism; delayed puberty suggests constitutional delay, but may also be indicative of panhypopituitarism
- Cherubic facies with frontal bossing, thin hair, high pitched voice, and relative truncal obesity with adiposity are seen in GHD.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- IGF-I and IGF binding protein-3 (IGFBP-3) production is regulated directly by GH. IGF-I values are low early in life and in conditions other than GHD such as hypothyroidism, diabetes, renal failure, and undernutrition.
- GH provocative testing: A random GH level is generally of little value to diagnose GHD beyond the neonatal period, after this time, GH is mostly secreted only in brief pulses during deep sleep (at night). Fully 20% of healthy GH-replete children can fail any provocative test. False-positive and negative results are common.
- CBC with differential: Anemia, malignancy, cell-based immunodeficiency and inflammatory processes
- Sedimentation rate and CRP: Inflammatory processes such as in Crohn disease
- Hepatic and renal function tests: Hepatic or renal disease
- Chromosomes in females (to exclude Turner syndrome)
- Thyroid function tests [thyroid-stimulating hormone (TSH) and either a T4 or a Free T4]

Imaging

- Bone age: Radiography of left hand and wrist
- If provocative testing shows GH deficiency an MRI with contrast of the pituitary and hypothalamus to look for central nervous system tumor or anomaly of the hypothalamus/pituitary

DIFFERENTIAL DIAGNOSIS

- Constitutional delay of growth and adolescence
- Familial short stature
- Malnutrition
- Intrauterine growth retardation
- Renal failure
- Inflammatory bowel disease
- Celiac sprue
- Hypochondroplasia, achondroplasia, or other skeletal dysplasia
- Turner syndrome
- Noonans syndrome
- Russell–Silver syndrome
- Prader–Willi syndrome
- Other genetic syndromes
- Congenital heart disease
- Hypothyroidism
- Hypercortisolism
- Metabolic disorders
- Rickets

ALERT

- Children with constitutional growth delay or pubertal delay show poor growth when peers are going through their pubertal growth spurts, and have a delayed bone age, mimicking GH deficiency.
- GH provocative testing may yield false-positive or false-negative results:
 - 20% of normal children will fail at least 1 GH provocative test.
 - Obese but otherwise normal children are more likely to fail provocative GH testing.
 - When GH testing is done in a child at high risk for GHD or if the growth pattern is concerning, the predictive value of GH testing is markedly improved.
- Malnutrition can cause low IGF-I.
- Psychosocial deprivation mimics GHD. Such deprived patients may have low growth factors and respond poorly to GH provocative testing.
- rhGH is associated with idiopathic intracranial hypertension (pseudotumor cerebri). This side effect is usually transient and often reverses without cessation of therapy.
- rhGH is usually not given in cancer patients until 1 year has elapsed without recurrence
- Carefully evaluate any limp, or hip or knee pain in patients on rhGH therapy because these symptoms may be associated with SCFE; SCFE necessitates orthopedic consultation.

**TREATMENT****MEDICATION (DRUGS)**

- Recombinant human GH (rhGH) was approved by FDA for use in 1985 by SQ injection daily.
- IGF-I therapy for the rare cases of GH insensitivity
- Duration of therapy (in children and adolescents):
 - Until growth velocity drops to 2.5 cm/year
 - When puberty is complete
 - GH-deficient adults may benefit from lifelong rhGH therapy due to its effects on body composition, lipids, bone density, and general sense of well being.
 - Adult patients should undergo repeat GH provocative testing (off rhGH therapy unless there is panhypopituitarism).

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

Every 3 months by an endocrinologist:

- When to expect improvement:
 - Immediate effect on hypoglycemia
 - Growth velocity improves within 3–6 months
- Signs to watch for:
 - Pseudotumor cerebri (headache, vision problems)
 - Slipped capital femoral epiphysis
 - Theoretically, increased risk of leukemia (although most studies indicate no significant increased risk)
 - In adults, edema and carpal tunnel syndrome, but uncommon in children

PROGNOSIS

Excellent with treatment

COMPLICATIONS

- Short stature
- Lack of self-esteem because of short stature
- Delay in pubertal changes (sexual characteristics and growth spurt) due to delayed bone age
- Hypoglycemia (in the newborn period)
- Osteopenia

FAQ

- Q: Does GH increase adult height in patients with familial short stature?
- A: Clinical studies have shown that rhGH may improve final adult height in some children; however, the results are unpredictable. The FDA recently added severe idiopathic short stature (predicted adult height <3rd percentile) as an approved indication for human GH therapy, but its use in this setting is not uncontroversial—with a treatment duration of 4–7 years, these children gain an average of roughly 3.5–7.5 cm in their adult height, but there is significant variation and many children have no final adult height gain..
- Q: Does GH cause tumors?
- A: Clinical studies have not confirmed an association.

GUILLAIN-BARRÉ SYNDROME

James Boyd

BASICS

DESCRIPTION

Guillain-Barré syndrome (GBS) is an acute disorder of the peripheral nerves—an inflammatory polyradiculoneuropathy. It causes progressive weakness in the limbs, face, and respiratory muscles. Autonomic and sensory disturbance occur with loss of sensation or pain. Neurologic deficits peak by 4 weeks or sooner.

EPIDEMIOLOGY

Incidence

Overall yearly incidence rate of 0.6–1.9 cases per 100,000. Of 95 reported pediatric GBS patients, 45 were aged 1–5 years, 36 were aged 6–10 years, and 14 were aged 11–15 years.

RISK FACTORS

Genetics

Particular subtypes of GBS are more common among certain human leukocyte antigen (HLA) types. No data indicate an increase in GBS among first-order relatives.

PATHOPHYSIOLOGY

Inflammatory cell-mediated and humoral-mediated immune mechanisms play a role in segmental demyelination on nerve biopsy; lymphocytes and macrophages participate in myelin destruction. Axonal variants of GBS feature axonal degeneration without demyelination. Circulating anti-ganglioside antibodies (e.g., GM1, GM2, GQ1B) found in particular subtypes suggest a molecular mimicry mechanism stimulated by infection.

ETIOLOGY

- Follows viral infection in >50% of cases. Cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, acute HIV infection, others
- Also associated with bacterial infection (especially *Campylobacter jejuni*), surgery, and vaccination
- Tetanus toxoid is the only vaccination in common use with a clear link to GBS. Often, no precipitating event can be identified.

COMMONLY ASSOCIATED CONDITIONS

- GBS is seen in a higher-than-expected rate in patients with sarcoidosis, systemic lupus erythematosus, lymphoma, HIV infection, Lyme disease, and solid tumors.
- Muscle atrophy, joint contractures, pressure ulcers, chronic pain, hypertension, voiding difficulty

DIAGNOSIS

HISTORY

- GBS has a variety of clinical presentations so that index of suspicion is critical. Typical features are progressive motor weakness and areflexia, often following distal sensory changes. Common presentations include decreased ambulation (or crawling in toddlers), facial weakness, back pain, or sensory changes in the extremities.
- After respiratory status has been stabilized, address autonomic dysfunction and pain. Close monitoring required for dysautonomic symptoms: Arrhythmias, BP lability/orthostasis, ileus, urinary retention.
- Most patients first note leg weakness or gait instability that progresses over days to weeks.
- Paresthesias and pain typically occur in a stocking/glove distribution frequently early in the course.
- 2/3 of patients will report symptoms of an infection 2–3 weeks earlier. Consider polio if fever is present at symptom onset.
- Weakness may lead to respiratory paralysis in 20–30% of children with GBS.

PHYSICAL EXAM

- Weakness and sensory changes:
 - Typical signs of GBS, classically with distal greater than proximal involvement. A proximal predominance of symptoms does not preclude the diagnosis.
 - Typically, deep tendon reflexes are lost within 1 week.
- Respiratory difficulty-impaired upper airway or restrictive/neurogenic, with decreased vital capacity, maximum inspiratory (PiMax) and expiratory (PeMax) pressures:
 - Respiratory failure leads to intubation in up to 25% of patients. Bulbar weakness and poor airway protection can also necessitate intubation. Impending respiratory failure can often be unpredictable, and blood gas determination is not a useful indicator of neuromuscular respiratory failure until intubation is imminent. If close monitoring of vital capacity, inspiratory, or expiratory pressures suggests >30% decline in 24 hours, monitor patient in ICU.
- Bilateral facial weakness occurs in ≤50% of cases.
- Neonates and infants may (rarely) present as floppy infants.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In atypical cases, consider heavy metal screen, HIV titer, Lyme titer, porphyria screen, acetylcholine receptor antibodies (myasthenia), conversion disorder:
 - See “Differential Diagnosis.”
- IgA level should be considered if the child has a history of frequent pulmonary infections: IgA deficiency could contraindicate intravenous immunoglobulin (IVIg) therapy (risk of anaphylaxis).

Imaging

MRI of the spine (with gadolinium enhancement): Consider MRI for spinal cord compression syndrome in a child presenting with paraparesis. Spinal nerve root enhancement on MRI can support the diagnosis of GBS.

Diagnostic Procedures/Other

- Electrodiagnosis:
 - Nerve conduction studies (NCS) and electromyography (EMG) can confirm diagnosis of GBS and are helpful when clinical or CSF findings are ambiguous. NCS and EMG are abnormal in 50% of patients in the first 2 weeks and in 85% of patients afterwards.
 - Initially, needle EMG may be normal. Consider serial studies if initially nondiagnostic, high clinical suspicion.
- Lumbar puncture: Elevated levels of CSF protein after the 1st week of symptoms. Minimal pleocytosis (<20 leukocytes/mm³), largely mononuclear leukocytes, may occur.

DIFFERENTIAL DIAGNOSIS

- Myasthenia gravis
- Botulism
- Intoxication (e.g., heavy metals, organophosphates)
- Myopathy/myositis
- Poliomyelitis and other acute (i.e., viral) motor neuron diseases
- Acute cerebellar ataxia (sometimes associated with neuroblastoma)
- Transverse myelitis

- Chronic inflammatory demyelinating polyneuropathy (CIDP)
- Vasculitic neuropathy
- Diphtheritic neuropathy (rare)
- Porphyric neuropathy
- Locked-in state
- Conversion, psychogenic weakness, astasia/abasia

ALERT

- Initially, gait instability may mistakenly be interpreted as having a psychogenic source.
- Reflexes may be preserved in early stages of illness.
- Proximal symptoms may predominate early on.
- Check for reflexes in patients with bilateral Bell palsy. Close observation for further development of symptoms or signs of GBS.

TREATMENT

ALERT

- Respiratory failure may occur quickly.
- Treat hypertension cautiously; catastrophic refractory hypotension may ensue.

ADDITIONAL TREATMENT

Additional Therapies

Physical therapy: Avoid contractures with lower extremity splinting and early passive range of motion. Aggressive physical and occupational therapy are essential for good outcomes.

COMPLEMENTARY & ALTERNATIVE THERAPIES

A combination of supportive therapy and immunotherapy is the mainstay of treatment for patients with GBS:

- Regular monitoring of vital capacity; strongly consider intubation if vital capacity reaches <50% of normal.
- IVIg and plasmapheresis have equivalent efficacy as first-line immunotherapy. Combination of the 2 therapies has not proven more effective than either monotherapy alone. Complications and discontinuation of therapy are less common with IVIg.
- Pediatric studies have shown IVIg and plasmapheresis to be well tolerated and efficacious.
- IVIg at 0.4 g/kg (body weight) for 5 consecutive days and initiated in ambulatory patients within 2–4 weeks of symptom onset

- Plasmapheresis requires placement of a central catheter. Total plasma exchange volume of 200–250 mL/kg divided in 3–5 treatments over 7–14 days. Therapy initiation is recommended within 4 weeks of symptom onset for patients who cannot walk and 2 weeks for patients who can.
- Corticosteroids have not been shown to be helpful and are not recommended.
- Pain from nerve root inflammation is common in GBS and should be treated aggressively.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Key elements center around respiratory management and deciding on hospitalization to monitor/treat progressive symptoms including heart block, hypotension, urinary retention, and neuropathic pain.

Admission Criteria

Admit patients with symptoms progressing over hours to days, with any respiratory or bulbar complaints, or who are nonambulatory.

Nursing

Particular attention to preventing skin breakdown, contractures, venous thrombosis, and secondary compressive neuropathies

Discharge Criteria

- Completion of immunotherapy
- Stabilization of symptoms
- Severity of bulbar, respiratory, and autonomic involvement dictates duration of hospital stay. Consider intensive inpatient rehabilitation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Improvement typically begins 2–3 weeks after onset of symptoms, up to 2 months in some patients.
- Improvement continues for up to 2 years.

PATIENT EDUCATION

Parent Internet Information: Guillain-Barré Syndrome Foundation International. <http://www.gbsfi.com>

PROGNOSIS

- ~85% have a good recovery; ultimate functional recovery depends on the degree of axonal injury, which can be predicted from electrodiagnostic studies in adults.
- Early prognosticators include the severity of weakness at the disease nadir and fulminant onset.
- Overall prognosis in children is better than in adults.

COMPLICATIONS

- Complications include respiratory failure, BP dysregulation (hypotension and/or hypertension), urinary retention, aspiration, pain syndromes, deep venous thrombosis, and infection.
- Death from early respiratory failure, autonomic instability, or other complications occurs in 3–6%.

FAQ

- Q: Is GBS contagious?
- A: No.
- Q: Will I get GBS again?
- A: Acute relapses occur in 1–5% of patients in large series. Treatment-related fluctuations (worsening after completion of immunotherapy) can occur in CIDP and can be indistinguishable from GBS.
- Q: Do all cases require hospitalization and immunomodulatory treatment?
- A: Some youngsters with mild, nondisabling symptoms may be observed as outpatients (≤10%).

GYNECOMASTIA

Julie A. Boom

BASICS

DESCRIPTION

Any visible or palpable proliferation of breast glandular tissue, unilateral or bilateral, owing to an increase in estrogen action in relation to androgen action at the level of the breast

EPIDEMIOLOGY

2 peaks in age distribution occur in the pediatric population:

- Neonatal period
- Puberty

Incidence

Peak incidence for pubertal gynecomastia in males is 14 years of age (range: 10–16 years), usually during Tanner stage 3–4.

Prevalence

- Neonatal gynecomastia occurs in 60–90% of all newborns.
- ~40% of boys develop transient gynecomastia (measuring ≥ 0.5 cm) during puberty.

RISK FACTORS

Any situation that leads to an increase in the net effect of estrogen action relative to androgen action at the level of the breast may lead to gynecomastia. These situations could include:

- Increased estrogen concentration (endogenous or exogenous)
- Normal estrogen levels with decreased androgen concentrations
- Congenital reduction in estrogen receptors
- Pharmacologic blockade of androgen receptors
- Increased breast or peripheral tissue aromatase, which converts androgens to estrogens
- Elevated leptin levels, which may increase aromatase enzyme activity, stimulate growth of mammary cells or increase breast receptor sensitivity to estrogen
- Testicular dysfunction
- High levels of serum gonadotropins or increased sex hormone-binding globulin
- Elevated estrogen levels, which may lead to proliferation of the ducts and surrounding mesenchymal tissue, resulting in breast enlargement

ETIOLOGY

- Physiologic:
 - Neonatal: Transient palpable breast tissue developing in newborns owing to elevated estrogen levels in the fetoplacental unit. This condition resolves as estrogen levels decline.
 - Pubertal: Benign transient gynecomastia occurring in otherwise healthy adolescent males. Breast tissue in pubertal gynecomastia measuring < 4 cm in diameter has a high likelihood of spontaneous regression.
 - Involutional: Breast enlargement occurs in elderly men.

- Pathologic:
 - Drug-induced:
 - Hormones: Estrogen, androgens, gonadotropins, anabolic steroids, growth hormone, antiandrogens, and cosmetics, foods, hair products, and herbal remedies that contain estrogenic or antiandrogenic compounds
 - Anti-infective agents: Ethionamide, isoniazid, ketoconazole, metronidazole, antiretrovirals
 - Antiulcer drugs: Cimetidine, ranitidine, omeprazole
 - Chemotherapeutic agents: Alkylating agents, methotrexate, vinca alkaloids
 - Cardiovascular agents: Amiodarone, captopril, digoxin, diltiazem, enalapril, methyl-dopa, nifedipine, reserpine, spironolactone, verapamil
 - Psychotropic agents: Diazepam, haloperidol, phenothiazines, tricyclic antidepressants
 - Drugs of abuse: Alcohol, amphetamines, heroin, marijuana, methadone
 - Miscellaneous: Metoclopramide, phenytoin, penicillamine, theophylline, gabapentin, clonidine, pregabalin
 - Hypogonadism: Primary or secondary
 - Tumors: Testicular, adrenal, ectopic tumors that produce human chorionic gonadotropin
 - Chronic disease: Hyperthyroidism, renal failure, liver disease, malnutrition with refeeding, HIV infection
 - Congenital disorders: Klinefelter syndrome, vanishing testes syndrome (also known as anorchism, gonadal agenesis, or testicular regression), androgen resistance syndromes, true hermaphroditism, excessive peripheral tissue aromatase
 - Acquired testicular failure: Viral orchitis, trauma, granulomatous disease, or castration
 - Chest wall trauma or intercostal nerve damage following surgery or herpes zoster
 - Psychologic stress
 - Spinal cord injury

DIAGNOSIS

ALERT

- Do not mistake pseudogynecomastia (i.e., fatty enlargement of the breasts) for true gynecomastia.
- Do not overlook a potentially drug-related cause. Drug-related gynecomastia is usually reversible if diagnosed within 1 year of onset.

HISTORY

- Family history: 1/2 of adolescents with gynecomastia will have a positive family history.
- Time of onset relative to puberty:
 - Genital maturation develops at least 6 months before onset of breast development.
- Rate of progression:
 - Rapidly enlarging, painful gynecomastia with acute onset is of more concern than longstanding enlargement.
- Drug exposures, including alcohol and substance abuse:
 - Marijuana and heroin addiction may cause gynecomastia.

- Exposure to exogenous estrogen
- Symptoms suggestive of hyperthyroidism
- Symptoms suggestive of liver disease, such as cirrhosis:
 - Liver disease may alter the estrogen-to-androgen ratio and thus cause gynecomastia. Damaged hepatic cells may lose the ability to inactivate estrogens. Impaired hepatic removal of androstenedione from the bloodstream; provides more androstenedione for the peripheral conversion to estrogen. Liver disease may result in the elevation of sex-steroid binding globulin, which reduces circulating free testosterone.
- Symptoms suggestive of renal failure:
 - Renal disease may alter the estrogen-to-androgen ratio and thus cause gynecomastia. Chronic uremia can cause direct testicular damage resulting in decreased plasma testosterone levels. Renal disease may also result in an increased luteinizing hormone level.
- Symptoms suggestive of neoplastic disease:
 - In patients < 10 years of age, consider pituitary, adrenal, or testicular tumor. Liver tumors may cause gynecomastia owing to increased aromatization of circulating adrenal androgens or by secretion of chorionic gonadotropins.
- Symptoms suggestive of hypogonadism, such as decreased libido, decreased erectile function, or infertility, may indicate an abnormal estrogen-to-androgen ratio.

PHYSICAL EXAM

- Assess height, weight, growth velocity, and BP.
- Assess for malnourishment: May result in hepatic dysfunction causing higher estrogen-to-androgen ratio.
- Perform a complete breast exam:
 - With patient in the supine position, grasp the breast between the thumb and forefinger and move digits toward the nipple: Look for a firm, rubbery, mobile, discoid mound of tissue arising concentrically below the nipple and areola. Measure the diameter of the disc of glandular tissue. Asymmetry and tenderness are common.
- Pseudogynecomastia:
 - If pseudogynecomastia (fatty enlargement of breasts) is present, no glandular disc will be palpable.
- Check for galactorrhea:
 - Seen in association with drug ingestion and pituitary tumor
- Determine whether macrogynecomastia (disc diameter > 5 cm with a secondary mound above the level of the breast) is present:
 - Macrogynecomastia may be physiologic or pathologic and is unlikely to regress.
- Examine the thyroid gland for the presence of a goiter:
 - Gynecomastia may be seen in hyperthyroidism.
- Gynecomastia is a physiologic process found in many males during early puberty. Perform a careful testicular exam with measurement of size. Consider Klinefelter syndrome if testes < 3 cm in length or 8 mL in volume. Check for the presence of a varicocele:
 - Boys 12–14 years of age with varicoceles are more likely to also have gynecomastia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- None indicated for pubertal and neonatal gynecomastia
- Karyotype: To rule out Klinefelter syndrome.
- Morning levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, testosterone, dehydroepiandrosterone (DHEA), and human chorionic gonadotropin (hCG):
 - To determine whether hypogonadism, precocious puberty, testicular tumor, or adrenal tumor could be present. An isolated elevated estradiol level in an otherwise normal prepubertal boy may suggest direct or indirect exogenous estrogen exposure.
- Morning prolactin level

Imaging

- None indicated for pubertal and neonatal gynecomastia
- Bone age (radiograph of the left hand and wrist):
 - Elevated estrogen levels may accelerate skeletal maturation.
- Testicular ultrasound:
 - To rule out testicular tumor, or elevated levels of human chorionic gonadotropin and estradiol, or finding of asymmetric testes on physical exam
- Chest radiograph with abdominal CT
- Adrenal CT or MRI:
 - To rule out adrenal neoplasm, if estradiol elevated, DHEA elevated, LH level decreased or normal, and testicular ultrasound normal
- Skull radiograph, brain MRI or CT: If pituitary tumor is suspected

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Breast abscess
- Neoplastic:
 - Breast neoplasm
 - Neurofibroma
 - Lymphangioma
 - Lipoma
 - Neuroblastoma metastasis
- Trauma:
 - Hematoma
- Miscellaneous:
 - Pseudogynecomastia: Excessive adipose tissue only; no discrete subareolar tissue
 - Dermoid cyst

TREATMENT

MEDICATION (DRUGS)

- Generally, drug therapy should proceed under the guidance of an endocrinologist.
- Raloxifene and tamoxifen (as unlabeled or investigational use) and testolactone (an aromatase inhibitor for which safety and efficacy in pediatric patients has not been established) have shown some benefit in adolescents with benign pubertal gynecomastia.
- If gynecomastia has been present for > 1 year, pharmacologic therapy is of little benefit. After 1 year, regardless of the cause of gynecomastia, epithelial growth becomes less prominent, whereas periductal fibrosis and hyalinization are more evident. Because of the increase in fibrosis, gynecomastia of longer duration is less amenable to medical treatment.

ADDITIONAL TREATMENT

Additional Therapies

- Reassurance for patients with pubertal gynecomastia measuring <4 cm. Treatment guidelines are variable for gynecomastia measuring 4–5 cm. Surgical consultation in these patients should be considered.
- Re-examine at 3–6 month intervals.
- Discontinue any drugs known to induce gynecomastia, and follow-up in 1 month.

ISSUES FOR REFERRAL

Consider surgical consultation in patients with >4 cm diameter of glandular tissue.

SURGERY/OTHER PROCEDURES

- Surgery is the therapy of choice for macrogynecomastia or persistent gynecomastia refractory to medical therapy.
- Obesity should not preclude surgical intervention.
- Obese adolescents may experience greater preoperative psychologic impact than nonobese adolescents.
- Surgical options include periareolar incision with adjunctive liposuction or glandular tissue removal through 2 incisions in the anterior axillary regions.
- Ultrasound-assisted liposuction has emerged as a new alternative surgical option.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Watch for signs of psychologic stress.
- Watch for symptoms of chronic disease and abnormal physical changes.

PROGNOSIS

- Overall, good
- Pubertal gynecomastia: 75% disappears spontaneously within 2 years, and 90% within 3 years.
- Neonatal gynecomastia usually resolves within the 1st year of life.

COMPLICATIONS

- Physical pain, which may interfere with sports
- Psychologic stress
- Embarrassment
- Skin erosion of the nipple owing to rubbing against clothing
- Breast cancer: Patients with Klinefelter syndrome have a 16-fold increased risk of breast cancer; other causes of gynecomastia are not associated with an increased risk of breast cancer.

CODES

ICD9

- 611.1 Hypertrophy of breast
- 778.7 Breast engorgement in newborn

ICD10

- N62 Hypertrophy of breast
- P83.4 Breast engorgement of newborn

FAQ

- Q: When should a patient with gynecomastia be referred to a specialist?
- A: If macrogynecomastia is present, if there is an abnormal hormonal workup or an abnormal imaging study, or if there is an abnormal rate of progression.
- Q: For how long does neonatal gynecomastia persist?
- A: Studies of healthy term infants have shown that the diameter of the breast tissue may actually increase during the 1st 2 weeks of life. The breast tissue then decreases to an average diameter of 10 mm until about 4–6 months of age. The breast tissue of female infants is generally larger and may persist longer than in males. Occasionally, the breast tissue will fail to regress and remain after the 1st year of life.
- Q: Is it normal for a newborn baby's breasts to secrete milk?
- A: In the later stages of gestation, the developing breast undergoes a small amount of secretory activity. This produces the so-called "witch's milk" that is expressed from the breasts of many full-term infants from the day 5–7 of life. Witch's milk may persist for 1–7 weeks after birth. As fetal prolactin, placental estrogen, and progesterone decline, the breast tissue regresses.
- Q: How is gynecomastia distinguished from breast cancer?
- A: Breast cancer usually presents as a unilateral, eccentric hard or firm mass that is fixed to underlying tissues. Associated findings can include dimpling of the skin, retraction of the nipple, nipple discharge, or axillary lymphadenopathy. The incidence of breast cancer in the pediatric population is extremely low: <0.1% of all breast cancers occur in patients <20 years of age. Benign tumors, such as fibroadenomas, are much more common than malignant breast tumors.
- Q: Has the incidence of gynecomastia increased?
- A: As the prevalence of childhood and adolescent obesity has increased, the presence of pseudogynecomastia has also increased. If glandular tissue is not present, pseudogynecomastia should be treated with diet and exercise.

HAND, FOOT, AND MOUTH DISEASE

Ross Newman
Jason Newland

BASICS

DESCRIPTION

Hand, foot, and mouth disease is a viral illness with the characteristic clinical features of:

- Vesiculoulcerative stomatitis
- Papular or vesicular exanthem on the hands and/or the feet
- Mild constitutional symptoms such as fever and malaise

GENERAL PREVENTION

- Frequent hand washing, especially after changing diapers, and good personal hygiene are the most useful means to prevent spread of enteroviral illnesses.
- Contact precautions should be maintained with all hospitalized patients.
- The prodromal and exanthem periods appear to be the most contagious; however, some may shed virus in the stool 3 months after infection (see "FAQ").

EPIDEMIOLOGY

- In temperate climates, hand, foot, and mouth disease is most common in the summer and fall (a pattern common to many of the enterovirus infections).
- In tropical climates, disease is present year round
- Transmitted by oral–fecal route. Respiratory secretions may also transmit the virus.
- Incubation period is 3–6 days.
- Highly contagious, afflicting up to 50% of those exposed
- Close household contacts are particularly susceptible.
- Most common in children under 5 years, but may affect adults
- May occur as an isolated case or in an epidemic distribution

PATHOPHYSIOLOGY

- Enteroviruses are acquired primarily from oral-fecal contamination
- Lymphatic invasion leads to viremia and spread to secondary sites.
- Viremia ceases with antibody production.
- Direct inoculation of the extremities from oral lesions has been hypothesized with regard to hand, foot, and mouth disease.

ETIOLOGY

Coxsackie A16 virus is the most common causative agent. Other serotypes associated with HFMD:

- Coxsackieviruses A5, A7, A9, A10, A16, B1, and B3
- Enterovirus 71
- Echoviruses
- Other enteroviruses

DIAGNOSIS

HISTORY

- History of ill contacts:
 - Incubation period may be up to 1 week.
- Any fever, pain, or other symptoms:
 - A mild prodrome occasionally precedes the characteristic exanthem and exanthem by 1 or 2 days: Low-grade fever [usually near 101°F (38.3°C)], malaise, sore mouth, anorexia, coryza, diarrhea, abdominal pain.
- Bone pain:
 - Bone and joint aches infrequently accompany this illness.
- Lesions in mouth:
 - Oral lesions typically occur shortly before the hand and foot manifestations.
- Illness in family:
 - Family members or close contacts are often similarly affected.
- Hydration status:
 - Determine quality and amount of oral intake, quality and amount of urine output, recent weight loss, duration of symptoms.

PHYSICAL EXAM

- Exanthem:
 - Oral lesions begin as small, red papules.
 - Papules quickly evolve to small vesicles on an erythematous base.
 - Lesions progress to ulcerations.
 - Tongue, buccal mucosa, palate, gingiva, uvula, and/or tonsillar pillars may be involved.
 - Usually 2–10 lesions
 - Oral lesions may persist up to 1 week.
- Exanthem:
 - Less consistently present than oral lesions (occur in 1/4–2/3 of patients)
 - Maculopapular eruptions progress to vesicles.
 - Rarely tender or pruritic
 - Most frequent on the dorsal aspects of fingers and toes
 - May also occur on the palms, soles, arms, legs, buttocks, and face
- Adenopathy:
 - Enlarged anterior cervical, or submandibular nodes are present in one quarter of cases.
- Other:
 - Attention should be given to the patient's vital signs; general appearance; and respiratory, cardiac, and neurologic functioning to help identify the rare patient with a threatening complication of hand, foot, and mouth disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hand, foot, and mouth disease has unique clinical features and a relatively benign course. Laboratory confirmation of the diagnosis is seldom needed or indicated.
- Culture:
 - Causative viruses may be cultured from many sites:
 - Oral ulcers
 - Cutaneous vesicles
 - Nasopharyngeal swabs
 - Stool (Isolation of an enterovirus from the stool does not confirm it to be the cause of disease because the virus can be shed for many weeks after infection.)
 - Cerebrospinal fluid (in cases where meningoencephalitis is suspected). Reverse transcription-polymerase chain reaction (RT-PCR) can be used.

DIFFERENTIAL DIAGNOSIS

Few infectious diseases have such characteristic clinical findings. Oral ulcerations followed by lesions on the distal extremities are virtually pathognomonic. The most difficult diagnostic dilemmas may occur early in the disease course when isolated oral lesions predominate:

- Herpangina:
 - Also caused by Coxsackie A viruses
 - Associated with higher fever
 - Usually limited to the posterior oropharynx
- Herpetic gingivostomatitis:
 - Most common cause of stomatitis in children
 - Associated with higher fever
 - More frequently associated with lymphadenopathy
 - Gingival involvement severe
 - Aphthous ulcers
 - Generally occurs without fever or upper respiratory symptoms
 - Does not occur in outbreaks
- Stevens–Johnson syndrome:
 - Ulcerations frequently coalesce.
 - Usually affects other mucous membranes
 - Often appears with separate cutaneous manifestations
- The Boston exanthem:
 - Caused by echovirus 16
 - Mild febrile illness with a macular rash on the palms and soles occurring at time of or after defervescence
 - Oral lesions absent

TREATMENT

SUPPORTIVE CARE

No specific therapy is indicated or usually necessary. Most cases are mild and self-limiting and only require parental reassurance.

SPECIAL THERAPY

- Symptomatic relief from particularly painful oral ulcers may be accomplished by application of a topical antihistamine or anesthetic directly to the sores (see “FAQ”).
- Dehydration should be treated when present. IV fluids may be required in the more severe cases, especially in infants and young children.
- Good supportive care is generally sufficient to treat most complications.

MEDICATION (DRUGS)

Acetaminophen may relieve malaise and minor discomfort associated with the oral ulcers. It also may be used as an antipyretic in those children with fever.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Dehydration and inability to maintain adequate oral hydration

Discharge Criteria

Rehydrated and good oral intake

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Small children must be followed closely for signs of dehydration.

DIET

Dietary adjustments often improve oral intake from painful oral lesions and prevent or relieve dehydration:

- Avoid spicy or acidic foods.
- Provide cool or iced liquids in small quantities frequently.

PROGNOSIS

- Hand, foot, and mouth disease generally resolves spontaneously within 1 week after diagnosis.
- In nearly all instances, hand, foot, and mouth disease will resolve quickly, requiring only supportive care.
- Careful history and examination should distinguish those patients with the rare aforementioned complications.
- Rare cases may recur at intervals for up to 1 year.

COMPLICATIONS

- Hand, foot, and mouth disease is usually self-limited and uncomplicated, resolving within 7–10 days.
- Dehydration is the most frequent morbid complication:
 - Oral ulcerations are painful and interfere with feeding.
 - Infants and children are at highest risk.
- Rare reports of other complications include:
 - Neurologic complications such as aseptic meningitis, encephalitis, and acute flaccid paralysis
 - Pneumonia
 - Myocarditis
 - A possible association with first-trimester spontaneous abortions in previously infected women

FAQ

- Q: What is in the “magic mouthwash” often used to relieve the pain of stomatitis?
- A: Many health care providers will prescribe a “magic mouthwash” for symptomatic relief of oral ulcers, pharyngitis, and teething pain. The most common such treatment consists of an aluminum hydroxide/magnesium hydroxide gel suspension and diphenhydramine elixir (12.5 mg/5 mL) in a 1:1 formulation. It can be applied directly to the sores with a cotton swab or a small syringe before meals. Note: Some people will have a reaction to topical diphenhydramine.
- Q: Should lidocaine be used topically or in suspension with “magic mouthwash” for symptomatic relief of oral ulcers?
- A: The routine use of lidocaine in this situation is not recommended. Lidocaine is an effective topical anesthetic and comes in a 2% viscous suspension. In practice, the pain relief is short lived, which encourages frequent administration. Lidocaine is absorbed from the mucous membranes (bypassing first-pass liver metabolism) and has been frequently reported to cause poisoning of the cardiovascular and central nervous systems. Both pediatric and adult fatalities have occurred. Topical viscous lidocaine should be reserved for use by physicians knowledgeable about its proper dosage and potential side effects, and by educated, compliant parents or caregivers.
- Q: When may children with hand-foot-and-mouth disease return to school?
- A: Good hygiene will greatly reduce viral transmission. Isolation from school or day care contacts should occur while fever remains and/or while the enanthem persists. As mentioned, some patients may shed the virus in their stool for weeks after symptoms have resolved (again stressing the need for good personal hygiene).

HANTAVIRUS

Bruce Tempest

BASICS

DESCRIPTION

Hantavirus pulmonary syndrome (HPS) is a disease in humans caused by a Hantavirus; it is acquired from certain chronically infected rodent species. When acquired by humans, it results in a syndrome characterized by a flu-like illness, then by a rapidly progressive cardiac and respiratory failure with a high mortality.

EPIDEMIOLOGY

- The host rodent develops a chronic nonfatal infection and excretes virus in urine, feces, and saliva.
- Humans acquire the infection by inhaling virus-contaminated airborne particles from the dried rodent excreta. Typically, this occurs when sweeping or otherwise disturbing dusty areas in a rodent-infested building.
- Nosocomial transmission has been observed only with the Andes strain in Argentina, never in the US.
- In the US, HPS has occurred primarily in young healthy adults, although in South America a larger proportion of cases are in children.

Incidence

Human cases are more common in the spring and summer and also in years when the population of the rodent host has increased.

GENERAL PREVENTION

- Universal precautions are appropriate in caring for patients with HPS; person-to-person transmission has been demonstrated only with the Andes strain in the Southern Hemisphere, not in the US.
- Preventing infection depends on avoiding contact with airborne particles contaminated by rodent excreta.
- Eliminate rodents and seal off rodent access into the house.
- Reduce rodent shelter and food sources in the immediate vicinity of the home by cutting brush, removing trash, and storing grain and animal feed in rodent-proof containers.
- Wearing gloves, clean up rodent-contaminated areas by spraying nests and droppings with household disinfectants or dilute bleach, and seal material in bags for burning or burial.
- Ventilate closed areas before initiating cleanup.

PATHOPHYSIOLOGY

- The 2 most important pathophysiologic changes are:
 - Myocardial depression resulting in shock
 - Alveolar capillary leak pulmonary edema resulting in hypoxia
- The cardiac dysfunction is characterized by a falling cardiac output, increased systemic vascular resistance, and normal or low pulmonary artery wedge pressure.
 - Alveolar capillary leak pulmonary edema resulting in hypoxia
- The pulmonary alveoli are flooded with fluid devoid of erythrocytes but with a protein content similar to serum.

ETIOLOGY

The original human outbreak recognized in the southwestern US was caused by the Sin Nombre strain of Hantavirus transmitted from chronically infected deer mice (*Peromyscus maniculatus*). Subsequent cases were recognized throughout the seemingly ubiquitous distribution of the deer mouse. Since then, additional strains of Hantavirus have been recognized, each with a unique rodent host. The resulting human cases of HPS have now been identified from Canada to Argentina.

DIAGNOSIS

Pitfalls:

- Recognizing the prodrome of HPS is difficult and requires a careful history, evaluation of the risk of exposure, and rapid access to testing:
 - The diagnosis depends on serologic testing, which can take some time.
 - Lacking serologic confirmation, one mostly depends on clinical history and serial hematologic tests.
 - In anticipation of the rapid progression of the cardiopulmonary phase, it is preferable to have the patient closely observed in the hospital.

HISTORY

- Clinical symptoms, physical findings, and laboratory findings progress in sequence. Early suspicion of the syndrome allows the clinician to prepare for that phase of the illness characterized by the rapid onset of respiratory failure and shock:
 - Fever and myalgia are usually severe and characterize the prodromal phase lasting 3–6 days.
 - GI complaints are frequently prominent, including combinations of nausea, vomiting, diarrhea, and abdominal pain.
 - Headache is present in >50% of patients.
 - Cough is uncommon at the onset of the prodrome, but heralds the onset of dyspnea and tachypnea, which is then followed by the rapid progression of cardiorespiratory failure.
 - Coryza and sore throat are rarely part of the prodrome.
 - A history of activities that might expose the patient to airborne virus-contaminated particles should be sought.
 - HPS is acquired by inhalation of airborne particles.

PHYSICAL EXAM

- Tachycardia and hypotension are late findings.
- During the prodromal phase, fever is the only finding.
- With the onset of the cardiopulmonary phase, cough and dyspnea are associated with the production of frequently copious amounts of nonpurulent material.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Platelet count:
 - The platelet count falls on serial testing during the prodromal phase and may be the only abnormality measurable using laboratory methods.
- In addition to leukocytosis, myelocytes and immunoblasts appear in the peripheral blood.
- Hemoconcentration
- Liver function test results are only mildly abnormal.
- Hypoxemia accompanies the onset of the cardiopulmonary phase.
- Diagnostic serology demonstrates IgM antibody present at the time of clinical presentation.

Imaging

- Chest radiograph:
 - During the prodrome, chest radiography is normal. With the onset of cardiopulmonary symptoms, chest radiography will show evidence of interstitial fluid manifested by Kerley B lines, hilar indistinctness, and peribronchial cuffing. Alveolar flooding and pleural effusions develop in severe cases. Heart size remains normal.

DIFFERENTIAL DIAGNOSIS

- Septicemic plague
- Influenza
- Bacterial sepsis, especially that caused by *Pneumococcus* and other streptococci
- Other causes of shock and pneumonia or shock and pulmonary edema

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Because of the rapid progression of cardiorespiratory failure, all patients with HPS should be managed in an ICU setting with a pulmonary artery catheter to guide therapy.
 - Oxygen, intubation, and mechanical ventilation are frequently needed.
 - Use fluids cautiously in view of the capillary leak.
 - Extracorporeal membrane oxygenation has been used for patients who fail to respond to maximal inotropic and ventilatory support.
 - To date, antiviral agents have not been shown to be beneficial.

MEDICATION (DRUGS)

- If the patient develops hypotension, an inotropic agent such as dobutamine should be added; if the patient continues to be hypotensive on maximal doses of dobutamine, vasopressors can be added to maintain blood pressure.
- Use empiric antibiotics because serologic tests confirming HPS are usually delayed and the differential diagnosis includes sepsis from a variety of antibiotic-responsive organisms.

**ONGOING CARE****PROGNOSIS**

- Patients who survive the shock phase typically then diurese fluid. Recovery is then generally rapid.
- Easy fatigability and mild pulmonary function abnormalities may persist.

ICD10

B33.4 Hantavirus (cardio)-pulmonary syndrome [HPS] [HCPS]

FAQ

- Q: What should I do if I find a dead mouse indoors?
- A: Determine whether it is a house mouse or a species that could be infected with Hantavirus. If the latter, assume that it is infected and dispose of it as described previously and then seal off rodent access to the home and eliminate any individuals still left inside.
- Q: What should I do if I find what look like rodent droppings?
- A: Clean up with gloves and disinfectant as noted earlier. Then use traps to catch and identify the rodents involved and proceed as in the answer to the previous question.
- Q: Could a patient have hantavirus pulmonary syndrome without knowing it?
- A: In the US, asymptomatic hantavirus pulmonary syndrome infections would appear to be uncommon based on serum screening of household contacts of cases and other populations at high risk, which show only infrequent evidence of prior infection.

HEAD BANGING

Ana Catarina Garnechor

Yvette E. Yatchmink

BASICS

DESCRIPTION

- Head banging (HB) is defined as the hitting of head on solid object such as a wall, side of crib, mattress or floor.
- Tend to hit the front or side of the head
- Usually last for 15 minutes but can go on for > 1 hour
- Regular rhythm of 60–80 bpm
- Can be seen along with body rocking or head rolling

EPIDEMIOLOGY

- Average age on of onset is 9 months; usually extinguished by 3 years of age. Older patients with head-banging are more likely to have a developmental delay or other medical problems.
- More common in boys than girls (3:1)
- Occurs in 3–15% of typically developing children
- Estimated that 2–3% of kids with Intellectual disability have stereotypic movement disorder (SMD/HB) and 5% of kids with Tourette syndrome have SMD/HB)

ETIOLOGY

- Can be comforting and be a part of other self-soothing activities such as body rocking or head rolling
- Temper tantrum secondary to frustration or anger
- In typically developing children, as an expression of happiness or as a method of self-stimulation (sometimes secondary to sensory deprivation)

- Part of a sleep rhythmic disorder called *Jactatio capitis nocturna* (partial arousal during light, non-REM sleep); HB occurs when drowsy or falling asleep
- SMD is a repeated, rhythmic, purposeless movement or activity; these usually cause self-injury or severely interfere with normal activities. These are most prevalent in adolescence and tend to occur in clusters of symptoms. Diagnosis requires 4 weeks of duration.

COMMONLY ASSOCIATED CONDITIONS

- Medical causes: Teething (pain), ear infection, seizures, meningitis, headaches, drug use (cocaine, amphetamines)
- SMD is associated with: Cerebral palsy, Intellectual disability, schizophrenia, autism/PDD, Down syndrome, Lesch-Nyhan syndrome, blindness, deafness
- Tic disorder/Tourette syndrome
- Infantile spasms
- Rule out child abuse if significant scalp laceration, skull fracture, or intracerebral or subdural hemorrhage

DIAGNOSIS

- Determine factors associated with behavior, including age of child, degree of parental concern, location of behavior, associated behaviors, motivations of the child, benefits to the child.
- Determine if a medical cause exists, particularly if sudden onset.
- Determine if psychological factors are involved.

DIAGNOSTIC TESTS & INTERPRETATION

- Usually, no laboratory testing is needed for diagnosis.
- Physical exam to look for bruising, swelling, scratches, or minor lacerations
- If swelling or blood loss is involved, brain imaging may be necessary to rule out damage.
- If severe and persistent HB is reported, an ophthalmology exam is warranted to rule-out complications.
- Developmental screening to rule out possible developmental delay
- If developmental delay is suspected, formal psychoeducational testing can be recommended.

TREATMENT

- For patients with particularly violent movements of jactatio capitis nocturna, trials with clonazepam and citalopram have shown some success.
- For patients with SMD, medications may help, including: Antipsychotics, tricyclic antidepressants, SSRIs, and benzodiazepines. These should be closely monitored.

ISSUES FOR REFERRAL

- Referral to ophthalmologist is recommended, if vision disturbance appear. Such ophthalmologic complications include cataracts, glaucoma, or retinal detachment.
- Older children may need psychological/developmental follow-up to determine delay/cognition status and to determine if behavioral modification therapy could be beneficial in decreasing symptomatology

ONGOING CARE

PROGNOSIS

- Normally disappears by age 3–4 years
- Jactatio capitis nocturna is usually benign and resolves by age 5 years.
- SMD usually peaks in adolescence and then declines.

CODES

ICD9

307.3 Stereotypic movement disorder

ICD10

F98.4 Stereotyped movement disorders

FAQ

- Q: Can head banging lead to serious head injury or neurological damage?
- A: Typically developing children rarely bang their heads hard enough to cause bleeding or fracture.
- Q: What can a parent do to prevent injury or diminish head banging behavior?
- A: Remove sharp or breakable objects from child's environment to avoid accidental injury.
- Place a rubber pad on the floor or a thick rug.
- Secure the crib to the wall to decrease noise and vestibular input to the child.
- If behavior occurs during tantrum, ignore the behavior once safety is established. Reward the child for appropriate behaviors.

HEADACHE AND MIGRAINE

Katherine A. Wayman
Brad C. Klein (5th edition)

BASICS

DESCRIPTION

- Primary headache: No underlying condition (migraine, tension headache, cluster headache, autonomic cephalgias)
- Secondary headache: Symptomatic of a specific cranial, oral, dental, or cervical pathologic process (e.g., trauma or tumor)

EPIDEMIOLOGY

Prevalence

Headache prevalence approaches 60–80% by age 20. Migraines may start by age 3, but mean age of onset is 7 years for boys and 11 years for girls. About 7% of prepubertal children are affected; about 3% of younger school-age children and up to 20% of older adolescents are affected. Prevalence of chronic daily headache (a primary headache) in preadolescents is 4–5%.

DIAGNOSIS

Migraine in children is classified into the following groups

- Migraine without aura: Most cases. Mood changes or withdrawal from activity, sensitivity to light and sound
- Migraine with aura: Aura lasts <60 minutes and usually precedes migraine. May be visual (spots, colors, image distortions, scintillating scotoma), sensory (paresthesias, hemisensory changes)
- Basilar-type migraine (13–19% childhood migraines): Vertigo, diplopia, ataxia, visual field deficits, often occipital headache
- Childhood periodic syndromes that may be precursors to migraine (sometimes called migraine equivalents): Benign paroxysmal vertigo of childhood, cyclic vomiting, abdominal migraine, benign paroxysmal torticollis
- Alice in Wonderland syndrome: Distortions of vision, space, and/or time (e.g., micropsia, metamorphopsia, sensory hallucinations)
- Confusional migraine: Impaired sensorium, agitation, and lethargy; may progress to stupor. Likely an overlap of hemiplegic migraine and basilar migraine

HISTORY

- Clarify temporal pattern, location, duration, and intensity. Also, time of onset, associated symptoms, precipitating and ameliorating factors, response to therapy, and family history
- The following questions should be asked:
 - Is there more than 1 type of headache? How are they different from each other?
 - Since they started, have headaches gotten worse or stayed the same?
 - How is the pain described (e.g., pounding, squeezing, stabbing, or some other description)?
 - Do the headaches occur at any special time of day?
 - Do they wake the patient up?
 - What does the patient do during the headaches?
 - Does the patient have ideas about what is causing the headaches?

- Migraine = acute recurrent headache. Nausea, vomiting, photophobia, phonophobia, and transitory neurologic disturbances suggest migraine.
- Agitation, pacing, and loud crying are atypical for migraine and more consistent with cluster headache.
- Tension-type headache (TTH) usually presents as a chronic or episodic nonprogressive headache pattern. Pain is often bilateral, bandlike, diffuse, dull, nonpulsatile, and of mild to moderate intensity.
- Mixed headache patterns: Migraine superimposed on tension headache
- Red flags: First or worst headache, occipital location, recent headache onset, increasing severity or frequency, headache in the morning associated with vomiting, headache causing awakening from sleep
- Ask about common comorbidities: Motion sickness, allergic rhinitis, depression
- 70% of those with migraine have a family history of migraine, especially those with migraine with aura.
- TTH is associated with higher rate of divorced parents and fewer close friends, unlike migraine.

PHYSICAL EXAM

- Vital signs: Especially blood pressure and height and weight
- Obesity: Consider pseudotumor or sleep apnea syndrome.
- Skin changes consistent with neurocutaneous syndrome: Patients with neurofibromatosis commonly experience headache.
- Auscultation for bruits over the supraclavicular areas, neck, and temporal and occipital areas: Arteritis, vascular malformation
- Examination for sinus tenderness, limitation of jaw excursion, or occipital trigger points
- Funduscopic exam: The presence of venous pulsations, best seen at the origin of branch points of the veins, decreases chance of intracranial hypertension.
- Visual acuity exam may reveal eye strain–related headache.
- Neurologic exam should be normal in primary headache syndromes (migraine, tension), except during a migraine with prolonged aura or migraine variant. Stiff neck, head tilt, decreased alertness, abnormal eye movements, asymmetric deep tendon reflexes, asymmetric motor weakness or sensory deficit, ataxia, and gait disturbance may signal infection, stroke, hemorrhage, tumor, or demyelination.
- Migraine without aura criteria: In children, 5 or more headache attacks that:
 - Last 1–72 hours
 - Have at least 2 of the following:
 - Bilateral or frontal (2/3 of cases) or unilateral, frontal/temporal location
 - Pulsating or throbbing quality
 - Moderate to severe intensity
 - Aggravated by routine physical activities
 - At least 1 of the following accompanies headache:
 - Nausea and/or vomiting
 - Photophobia and/or phonophobia (may be inferred from behavior)

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Neuroimaging studies (CT or MRI): Emergency evaluation should focus on identifying acute processes that require urgent intervention. These include subarachnoid hemorrhage, meningitis, and mass lesions causing elevated intracranial pressure that may lead to herniation:
 - CT should be used if there is any suspicion for subarachnoid hemorrhage, but otherwise MRI is generally preferred.
 - Consider MR venogram if acute deficits/focal seizures present.
- Neuroimaging is not necessarily warranted in patients with acute recurrent or chronic nonprogressive headache who have normal findings on neurologic exam.
- Neuroimaging should be performed for:
 - Acute 1st episode of severe headache (“worst headache of my life”)
 - Headaches or vomiting in the morning
 - Headache worse in supine position
 - Seizures
 - Cognitive decline
 - New, focal/persistent neurologic symptoms or findings (e.g., papilledema, hemiparesis, ataxia, abnormal eye movements, alteration of consciousness, nuchal rigidity)
 - Presence of ventriculoperitoneal shunt

Diagnostic Procedures/Other

- EEG: Although 10% of children with migraine may show nonspecific abnormalities, there is no role for EEG in routine testing of patients with headache.
- Other modalities:
 - Sinus films or CT if concern for sinusitis
 - Sphenoid sinusitis may produce unremitting chronic frontal headache.
 - Migraine may mimic sinusitis and vice versa.
- Lumbar puncture (LP):
 - In addition to meningitis, diagnostic considerations include subarachnoid hemorrhage, sinus thrombosis, pseudotumor cerebri, and low-pressure headache.
 - CT (prior to LP): Considered in chronic progressive headache in a nonfebrile patient, even when chronic migraine or tension headache is (statistically) more likely.
 - Measure opening pressure (abnormal if >20 cm with patient recumbent to rule out pseudotumor cerebri (where result of cerebrospinal fluid analysis otherwise is normal).
 - Check urine drug screen in suspect cases.

DIFFERENTIAL DIAGNOSIS

The temporal pattern of headache can help clarify the differential. There are roughly 5 patterns:

- Acute, 1st severe headache:
 - Meningitis, encephalitis, cocaine or other substance abuse, medication (methylphenidate, steroids, psychotropic drugs, analgesics, cardiovascular agents), hypertension (usually secondary); hydrocephalus, pseudotumor cerebri (idiopathic intracranial hypertension), post-LP, subarachnoid hemorrhage, intracerebral hemorrhage, ventriculoperitoneal shunt malfunction, sinus thrombosis, migraine, upper respiratory tract infection, somatization
- Chronic progressive headache:
 - Brain tumor, abscess, hydrocephalus, vascular malformation, hematoma, chronic meningitis (e.g., Lyme disease), sinus thrombosis, idiopathic intracranial hypertension, depression, anemia, rheumatologic diseases
- Acute recurrent headache:
 - Migraine and variants, cluster, tension
- Chronic nonprogressive or daily headache:
 - Medication overuse, substance abuse, (rebound headache), caffeine, sinusitis, occipital neuralgia, temporomandibular joint syndrome, orthostatic headache, post-LP, other systemic disease, posttraumatic, sleep disorder, depression, anxiety, other psychiatric illness, tension headache, fibromyalgia
- Mixed headache = Migraine-superimposed tension headache

**TREATMENT****MEDICATION (DRUGS)**

- Acute treatment:
 - Abortives are generally most effective if given early in the acute migraine attack.
 - 1st line is ibuprofen (10 mg/kg).
 - Acetaminophen (10–15 mg/kg)
 - Naproxen sodium 2.5–5 mg/kg per dose
- Additional acute treatments for refractory patients:
 - Antiemetics (prochlorperazine, metoclopramide, ondansetron) also enhance effectiveness of analgesics and may abort migraines.
 - Sumatriptan (Imitrex), nasal in 5, 10, or 20 mg (Class 1 trials of 12–17-year-olds)
 - Sumatriptan, 25-mg oral tablets; rizatriptan (Maxalt, Maxalt-MLT) 5–10-mg tablets or oral dissolving wafers; and zolmitriptan (Zomig) 2.5–5-mg tablets or oral dissolving wafers may provide relief, although not proven statistically. An SC injection of sumatriptan may be necessary. SC dose is 0.06 mg/kg; 3 mg for children >6 years and weighing <30 kg; 6 mg for those >30 kg
 - Although safe, triptans are not currently FDA approved for use in children or adolescents.
 - Triptans/ergotamines not recommended in basilar, hemiplegic migraine, or with vascular risk factors
 - Drugs containing caffeine/isometheptene may cause rebound headaches.

- Status migrainosus:
 - Migraine lasting >72 hours
 - Hydrate patient with IV fluids: D5 1/2 NS or NS (dehydration exacerbates).
 - Raskin protocol: Dihydroergotamine: Not well studied in children and adolescents; use under guidance of neurologist.
 - IV valproate: Similar effectiveness to DHE-45 and metoclopramide for status migrainosus. Typical administration: 15 mg/kg at 3 mg/kg/min up to 1 g
 - Corticosteroids and IV ketorolac may be effective; remain controversial in children
 - Narcotics not recommended: Often lose efficacy, greater levels of sedation than pain relief. Addiction and rebound potential also of concern
- Prophylaxis:
 - > 10 headache days/month or 3–4 severe attacks per month (i.e., leading to missed school or social activities, etc.) constitutes a relative indication for prophylaxis.
 - Start medication at a low dose; increase weekly toward maximum until headaches relent or adverse effects supervene. Choose a drug that may address other comorbidities.
 - Consider limited duration of treatment (i.e., through the calendar school year and then taper off in the summer).
 - Calcium channel blockers (e.g., verapamil)
 - β -Blockers (e.g., propranolol, nadolol) are discouraged in patients with asthma, depression, or diabetes.
 - Tricyclic agents (e.g., amitriptyline, nortriptyline) may provide relief from insomnia or depression.
 - Anticonvulsants: topiramate (evidence level A) and valproic acid (evidence level B) may have dual efficacy in patients with epilepsy. Emerging evidence for levetiracetam
 - Cyproheptadine, an antihistamine/antiserotonin agent = prophylactic therapy in younger children (i.e., 5–12 years old).

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Relaxation techniques (meditation, progressive muscle relaxation, self-hypnosis)
- Stress management (cognitive behavioral therapy), biofeedback
- Some evidence for vitamins, supplements, and herbs such as riboflavin (300 mg/d), magnesium (200–300 mg/d), coenzyme q10, feverfew, and ginkgolide B

FAQ

- Q: What about allergy and headache?
- A: Many believe that headache may represent a symptom of hypersensitivity. Headache in the setting of allergic rhinitis/asthma may be a result of associated sinusitis/sinus congestion, a side effect of treatment (especially theophylline), or muscle tension.

HEAT STROKE AND RELATED ILLNESS

Patrick B. Solari

Paige L. Wright

George A. Woodward

BASICS

DESCRIPTION

- Heat stroke results from imbalance in heat production, absorption, and dissipation. It can result from excessive body heat generation and storage without appropriate dissipation, high ambient temperature, low radiation or convective heat loss, decreased evaporation, or inadequate fluid/electrolyte replacement in response to ongoing losses through sweat or GI disturbance.
- 2 forms of heat stroke exist:
 - Exertional heat stroke (EHS), which occurs during periods of intense exertion
 - Nonexertional heat stroke (NEHS), in which the body is unable to compensate for an increase in ambient temperature; more common in very young and elderly, and during heat waves.

RISK FACTORS

- Environmental predisposition: Hot and humid without wind, heat wave, overheated indoor environment, lack of air conditioning. Social isolation, inability to care for self, or entrapment in closed space (e.g., car, trunk; internal automobile temperature in sunlight with poor ventilation can reach 131–172°F; the sharpest temperature increase occurs within 1st 15 minutes).
- Medical: Obesity, low fitness level, cardiac disease, diabetes mellitus and insipidus, diarrhea, hyperthyroidism, dehydration, vascular disease, sweat gland dysfunction, sunburn, viral illness
- Drugs/Medications:
 - Anticholinergics
 - Antihistamines
 - Beta-blockers
 - Diuretics
 - Psychiatric medications
 - Recreational drugs and alcohol
- Behaviors:
 - Lack of recognition of risk factors or warning signs
 - Overexertion or inadequate fluid intake
 - Inappropriate clothing; heavy, dark, tight-fitting, overbundling
 - Lack of acclimatization and conditioning
 - Children in enclosed space within vehicle

GENERAL PREVENTION

- Avoid enclosed spaces (e.g., children in closed cars).
- Reduce activity levels, keep cool, use shaded areas. Adaptation to warmer climates may take 8–10 exposures of 30–45 minutes each daily or every other day.
- Air conditioning or fans during hot weather
- Cool or tepid baths
- Increase fluid intake before, during, and after scheduled exercise or strenuous activity (up to 200–300 mL q10–20min); do not wait until thirsty. Cool water and large volumes increase gastric emptying (high osmolality and carbohydrate content decrease gastric emptying).
- Loose, light-colored clothing, protective hat

- Acclimatization via gradual conditioning over 10–14 days in hotter environment.
- Liberal dietary sodium:
 - Avoid NaCl tablets (possible hypernatremia, potassium depletion, gastric irritation, delayed gastric emptying)
- Frequently flex leg muscles when standing.
- Avoid prolonged standing in hot environments.
- Avoid caffeine and alcohol.

PATHOPHYSIOLOGY

- Heat production is increased 10–20 times by strenuous exercise.
- When environmental temperature is greater than body temperature, body gains heat by conduction and radiation and can lose heat by evaporation.
- Children have greater body surface-to-mass ratio, higher metabolic rate, inability to increase cardiac output, decreased sweat production, and inability to independently change environments, compared to adults:
 - Dehydration results in loss of sweating, hence decreased evaporation.
 - Above 40°C, cell volume, membrane integrity, metabolism, acid–base balance is affected.
 - Extreme core temperatures >42°C can uncouple oxidative phosphorylation and allow enzyme systems to cease functioning.

COMMONLY ASSOCIATED CONDITIONS

- Miliaria rubra (prickly heat): Heat rash, usually caused by obstruction of sweat glands by clothes or lotions, produces an erythematous papular rash; usually self-limited
- Heat cramps/Spasms: Related to physical exercise in people who have not trained or are poorly acclimatized with mild dehydration; thought to be related to water and sodium depletion
- Heat tetany: Paresthesias and carpopedal spasm help distinguish tetany from heat cramps.
- Heat syncope: Alteration of consciousness (i.e., dizziness, syncope) at end of strenuous or upright event
- Heat edema: Swollen feet and ankles (i.e., vascular leak, orthostatic pooling)
- Heat exhaustion: Relatively slow onset. Water and/or salt depletion. Clinically copious perspiration with headache, nausea, vomiting, malaise, myalgias, pallor, light-headedness, visual disturbances, syncope, temperature 38–40°C, dehydration, electrolyte imbalance, hemoconcentration; can evolve into heat stroke

- Heat stroke: Core body temperature exceeding 40°C with altered mental status ranging from confusion, disorientation, and incoherent speech to delirium, decerebrate posturing, seizure, and coma. May have acute, sudden onset (80%) or slower onset (minutes to hours, 20%). Classic heat stroke is associated with dry skin and prolonged exposure to elevated temperatures at rest. Exertional heat stroke may present with dry skin or profuse sweating.

DIAGNOSIS

HISTORY

- Heat exhaustion:
 - Weakness, lethargy, thirst, malaise, diminished ability to work or play, headache, nausea, vomiting, myalgias, pale skin, dizziness
- Heat stroke:
 - History of CNS dysfunction in environment consistent with, or predisposing conditions conducive to, development of heat-related illness should suggest heat stroke.

PHYSICAL EXAM

- Heat exhaustion:
 - Visual disturbances, syncope, mild CNS dysfunction, impaired judgment, cramps, vertigo, hypotension, tachycardia, hyperventilation, paresthesias, agitation, ataxia, psychosis, temperature <40°C, sweating, environmental exposure, and activity; no coma or seizures
- Heat stroke:
 - Temperature >40°C (may be cooler owing to prehospital interventions and maneuvers)
 - Altered level of consciousness (confusion, drowsiness, irritability, neurologic deficits, euphoria, combativeness, obtundation), ataxia, posturing, incontinence, seizures, coma, purpura, or petechiae; 2/3 with constricted pupils; may have muscle rigidity with tonic contractions and dystonia that mimic seizures
 - Shock: Tachycardia, hypotension, widened pulse pressure, tachypnea
 - Hot, dry (classic), or clammy (exercise-induced) skin, pink or ashen color
 - Weakness, nausea, vomiting, anorexia, headache, dizziness
- Temperature measurement (continuous best):
 - Esophageal thermometry probably the best
 - Deep rectal thermometry a good approximation of core temperature
 - Tympanic, oral, axillary, temporal artery temperatures are less accurate measures of core temperature.

DIAGNOSTIC TESTS & INTERPRETATION**Lab****Initial lab tests**

Tests only to confirm diagnosis, evaluate extent of injury, or rule out other processes because treatment should be empiric:

- Heat cramps: Decreased levels of serum and urine sodium and chloride; BUN level normal or slightly increased
- Heat exhaustion: May see hyponatremia or hypernatremia (free water loss), hypochloremia, low urine sodium, and chloride hemoconcentration; normal LFTs
- Heat stroke:
 - Electrolytes abnormalities: Sodium chloride level normal or high, hypokalemia, increased BUN/creatinine; Low K⁺, Ca, P; hypoglycemia
 - Hematologic: Hemoconcentration, leukocytosis, thrombocytopenia
 - Prerenal azotemia
 - Elevated AST/ALT
 - Metabolic acidosis: Lactate high, especially with exertional heat stroke
 - Coagulopathy
- Others: Creatine phosphokinase (rhabdomyolysis), arterial blood gases (classic heat stroke: Respiratory alkalosis and hypokalemia early; lactic acidosis later; exertional heat stroke; lactic acidosis), urinalysis (casts, brownish color proteinuria, microscopic hematuria, myoglobinuria), CSF, EKG, chest radiograph

DIFFERENTIAL DIAGNOSIS

- Heat cramps: Rhabdomyolysis, tetany
- Heat edema: Thrombophlebitis, lymphedema, congestive heart failure
- Heat stroke: CNS process with fever (cerebrovascular stroke, meningitis, encephalitis), other infections, anticholinergic poisoning (dilated pupils), drug/medication-induced, temperature rise, severe dehydration. Chills suggest febrile illness, not heat stroke.
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Malignant hyperthermia

**TREATMENT****MEDICATION (DRUGS)**

- Antipyretics not useful because an intact hypothalamus is required for action.
- Avoid anticholinergic drugs (atropine), which can inhibit sweating.
- May require inotropic support
- Chlorpromazine may improve peripheral vasodilatation and prevent shivering.
- Benzodiazepine for sedation and/or seizures
- Dantrolene not shown to be effective

ADDITIONAL TREATMENT**General Measures**

- Heat stroke: Treat empirically, then rule out other causes of presentation. Maintain airway, breathing, and circulation including securing airway as indicated, supplemental oxygen delivery:
 - Fluid replacement: IV 0.9% NS or LR solution.
 - Rule out hypoglycemia.
 - Miscellaneous therapies:
 - Foley catheter to monitor urine output
 - Nasogastric tube
 - Myoglobinuria therapy (mannitol, bicarbonate, dialysis if necessary)
 - Electrolyte replacement if symptomatic from hypokalemia or hypocalcemia
 - Fresh frozen plasma for disseminated intravascular coagulation (DIC)

IN-PATIENT CONSIDERATIONS**Initial Stabilization**

- Rapid recognition and cooling imperative
- Specific therapy:
 - Heat cramps: Rest, salt, and water replacement
 - Heat syncope: Self-limited as return to horizontal position is treatment; rest and fluids, salted liquids
 - Heat exhaustion: Clinical findings (heart rate, BP, orthostatic changes, urine output) should direct therapy. Most treated as outpatient with rapid rehydration, cooling; mild case: Oral electrolyte solution (0.1–2% saline = ~1/4–1/2 teaspoon table salt in 1 quart of water); if nausea, vomiting, inability to drink: IV (0.5% [similar to sweat losses] to 0.9% normal saline solution (NS); avoid rapid overcorrection of hypernatremia (treat as with hypernatremic dehydration); if hyponatremic seizures, treat with 3% saline at ~5 mL/kg
 - Heat stroke: Immediate cooling and support of cardiovascular system. Remove clothing, remove patient from hot environment; use air conditioning, open vehicle for transport if possible; esophageal or rectal temperature probe (continuous temperature measurements); cooling should exceed 0.1–0.2°C/min; slow cooling down at 38.5–39°C to avoid overshoot
 - Cooling options: Cold water immersion (15–16°C) has lowest morbidity and mortality for exertional heat stroke, is as effective as ice bath without discomfort, shivering, or vasoconstriction
 - Also: Ice packs to neck, groin, axillae, wet sheet over patient; moisten skin with water spray, convection increase (fan) to increase evaporative cooling; cooling blankets; cool/ice water lavage (peritoneum, rectum, gastric); cold to room temperature IV fluids; massage with ice (decreases shivering response)

Admission Criteria

- Patients with symptoms suggestive of heat stroke require immediate cooling and should be watched closely.
- Patients with evidence of multisystem disease (altered mental status, electrolyte imbalances, hematologic abnormalities) should be admitted until such issues are resolved.

**ONGOING CARE****PROGNOSIS**

- Heat-related illness (e.g., heat rash, edema, cramps, tetany, syncope, exhaustion): Rapid recovery with supportive care
- Heat stroke: Poor prognosis if not recognized and aggressively managed. Morbidity and mortality directly proportional to how rapidly core temperature is reduced.

**CODES****ICD9**

992.0 Heat stroke and sunstroke

ICD10

- T67.0XXA Heatstroke and sunstroke, initial encounter
- T67.0XXD Heatstroke and sunstroke, subsequent encounter
- T67.0XXS Heatstroke and sunstroke, sequela

FAQ

- Q: How can one distinguish between heat exhaustion and heat stroke?
- A: Heat stroke involves temperature >40°C with CNS and LFT abnormalities, whereas heat exhaustion refers to inability to continue exercise.
- Q: When should heat stroke be suspected?
- A: Suspect heat stroke in a patient with or without sweating, who demonstrates alterations of CNS function.
- Q: Does the presence or absence of sweating help with the diagnosis of heat exhaustion versus heat stroke?
- A: No. Sweating will be present with heat exhaustion and may or may not be present with heat stroke.
- Q: Are children at increased risk of heat illness?
- A: Yes. They have a number of predisposing factors: Greater surface area-to-body mass ratio than adults, production of more metabolic heat/kg body weight, slower rate of sweating than adults, temperature when sweating starts is higher, lower cardiac output at a given metabolic rate than adults, rate of acclimatization is slower, thirst response is blunted, and access to fluids may be limited.

HEMANGIOMAS AND OTHER VASCULAR LESIONS

Carol A. Miller

BASICS

DESCRIPTION

- Vascular tumors: Neoplasms of the vasculature:
 - Hemangioma of infancy
 - Diffuse hemangiomatosis
 - Tufted angioma
 - Kaposiform: Hemangioendothelioma
 - Pyogenic: Granuloma
 - Hemangiopericytoma
- Vascular malformations (VM); anomalous blood vessels without endothelial proliferation:
 - Capillary (salmon patch, port-wine stain/nevus flammeus)
 - Venous malformations
 - Arterial malformations (arteriovenous malformations [AVMs], complex/combined)
- Lymphatic malformations (macrocytic and microcytic)
- Vascular malformations
- Other types of VM may occur in any part of the body and may be associated with overgrowth of the involved part.

EPIDEMIOLOGY

Incidence

Hemangiomas:

- ~10% of infants by 12 months of age
- Increased incidence in low-birth-weight infants
- Increased incidence if chorionic villus sampling was performed during pregnancy
- Other demographic risk factors include white non-Hispanic race, female sex, born of multiple gestations, advanced maternal age, maternal history of miscarriage, and positive family history.

COMMONLY ASSOCIATED CONDITIONS

- Hemangiomas:
 - Lumbosacral; be aware an underlying spinal dysraphism may be present.
 - Segmental: Commonly located on the face and involving a developmental unit (segment) and frequently associated with complications
 - PHACES: Rarely occurring segmental hemangioma associated with other developmental anomalies (Posterior fossa malformations; Hemangioma; Arterial anomalies; Cardiac anomalies, including aortic coarctation; Eye abnormalities; Sternum defects)
 - Congenital hemangiomas: Noninvoluting congenital hemangioma (NICH) and rapidly involuting hemangioma (RICH)
- Vascular malformations:
 - Port-wine stains may be present as part of syndromes (e.g., Sturge-Weber, von Hippel-Landau, Rubinstein-Taybi, Beckwith-Wiedemann, Cobb syndrome)

DIAGNOSIS

HISTORY

- Onset of lesions and timing of changes
- Hemangiomas are often inapparent at birth or present with precursor lesions followed by a rapid growth phase.
- Vascular malformations are present at birth. Some may fade slowly over time (salmon patches) and others remain, sometimes becoming more obvious with overall growth, or slowly enlarge over time.
- PMHx: Low birth weight, twin or other multiple gestation, premature
- FHx: Familial hemangiomas or syndromes associated with port-wine stains
- ROS: Other developmental anomalies (e.g., PHACES)

PHYSICAL EXAM

- Hemangiomas:
 - Neonate: Flat pale lesion, superficial telangiectasia with halo border, pinkish ecchymotic lesion
 - Infant: Raised red rubbery nontender lesion with well-demarcated borders. Overlying skin is usually intact although sometimes ulceration may be present.
 - Deep layer lesion: Raised soft mass with bluish-purplish discoloration with smooth, intact, overlying skin
 - Complex/combined: Lesions will have both cutaneous and deep layer features.
 - Involuting lesion: Flat, atrophic pale or gray center with surrounding raised reddish border with stippled texture. Bleeding from ulceration may be present.
 - The presence of large numbers of small to moderate-sized cutaneous hemangiomas may indicate a rare condition called diffuse neonatal hemangiomatosis. Internal organ involvement (liver, lungs, GI tract, CNS) is likely to be present if this condition is diagnosed.
- Vascular malformations:
 - Salmon patches (nevus simplex): Most notable at birth as pinkish-red macules that often blanch and are most commonly found at the nape of the neck, glabella, and upper eyelids. Frequently all three locations are involved in an individual newborn.
 - Port-wine stains (nevus flammeus): Rasily seen at birth and are deep red to purplish, nonblanching macules with well-demarcated borders. Most commonly located on the face and often cover a large area

- Matured port-wine stains are deeper in color and frequently develop raised nodules or a bleblike appearance.
- If an extremity is heavily involved, there may be underlying bony overgrowth and limb hypertrophy.
- AVMs: Raised pulsating lesions with bruits audible by stethoscope if large in size. Smaller lesions may vary in appearance from macular erythema to thin vascular plaques. Some lesions may show elements similar to venous malformations.
- Signs of cardiac compromise (i.e., tachycardia, gallop rhythm, shortness of breath, hepatomegaly) may be associated with very large AVMs.
- Venous malformations: Deep blue to purplish, soft, fleshy nodules in the skin and may be surrounded by superficial venules. The drainage pattern is generally obvious upon inspection. Mature lesions may include small calcifications (phleboliths).
- Lymphatic malformations: Present differently depending on size. Large lesions are rubbery, skin-colored, massive nodules with ill-defined borders, most often located in the head, neck, axilla, or chest (referred to as cystic hygromas). Lesions in the neck area may be associated with respiratory compromise if the airway is constricted. Microcystic lesions present as nodules or plaques, sometimes in clusters, with overlying skin changes such as discoloration. Complicated lesions may be hemorrhagic or leak translucent lymph fluid.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnosis is usually made by recognition of the typical physical exam findings.

Imaging

- Occasionally helpful in distinguishing hemangiomas from vascular malformations
- May be necessary to determine the extent of internal or visceral lesions or characterize complex lesions
- Preoperative MRI, CT angiography, or venography aids in planning resection of large or invasive lesions such as cystic hygromas.

Diagnostic Procedures/Other

- Biopsy: Rarely required but may be helpful to differentiate lesions suspicious for malignancy. Should be avoided if lesion is highly suspected to be vascular as significant bleeding may ensue
- Other diagnostic tests should be considered if concerns for syndromes or other complications (e.g., cardiac or respiratory compromise) exist.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Hemangiomas:
 - Most patients will not need treatment as lesions will spontaneously involute without complications.
 - Consider treatment of lesions interfering with critical organ functions, such as vision or breathing, large lesions causing consumptive coagulopathy, or lesions significantly affecting appearance, such as on the face.
 - Timing of surgical treatment of hemangiomas should be carefully determined to minimize the risk of undesirable cosmetic outcome.
- Intralesional and/or systemic steroids
- Propranolol either systemically or topically has increased in popularity in recent years as an alternative to steroid therapy.
- Interferon may be useful in refractory or severe lesions. The development of spastic diplegia has been reported as a complication of interferon therapy.
- Apply compresses and topical dressings for ulcerations.
- Topical or systemic antibiotics covering staphylococcal and streptococcal species for infected lesions
- Laser therapy useful for superficial lesions
- Liquid nitrogen has been used in selected situations.
- Vascular malformations:
 - Pulsed dye laser is the treatment of choice for port-wine stains and other superficial vascular malformations. Serial applications over several years may be necessary. Large lesions may not completely respond. Better outcomes noted in children treated < 1 year of age
 - Surgical resection, sclerotherapy, or embolization may be appropriate depending on the character of the malformation.

ISSUES FOR REFERRAL

Consider referral to specialty services if the following conditions are present:

- Lesions in locations where function may be impacted such as periorbital, ear canal, tip of nose, lips, or anogenital areas
- Lesions distributed in a “beardlike” format, which may constrict the airway

- Presence of numerous cutaneous lesions increasing the likelihood of visceral involvement (including the GI tract, liver, CNS, lungs)
- Lesions causing or likely to cause significant disfigurement
- Lesions located over the spine, which may be associated with spinal dysraphism
- Lesions located in a segmental distribution about the head and face
- Large AVMs impacting circulation and cardiac function (e.g., resulting in high output heart failure)
- Presence of dysmorphic features along with vascular lesions
- Lesions that are ulcerating or bleeding

ONGOING CARE

PATIENT EDUCATION

Vascular Birthmarks Foundation (www.birthmark.org)

PROGNOSIS

- Hemangiomas:
 - All infantile hemangiomas undergo spontaneous involution. By 9–10 years of age, 90% will have completed involution. Greater than 85% will resolve without need for treatment.
 - Residual areas of skin atrophy and/or discoloration are common.
 - Complicated lesions marked by ulceration, bleeding, or infection may result in scarring or disfigurement.
- Vascular malformations:
 - VMs generally do not involute or resolve.
 - Salmon patches fade over time and generally are not a cosmetic problem.
 - Port-wine stains may darken and become nodular with age.
 - Larger lesions can be associated with excessive growth of the involved body area resulting in hypertrophy.
 - Malignant transformation is rare.

COMPLICATIONS

- Hemangiomas:
 - Bleeding, ulceration, superinfection
 - Iron deficiency anemia
 - Interference with function of important organs (including vision, airway, GI tract, CNS)
 - Disfigurement and cosmetic problems
 - Kasabach-Merritt phenomenon or syndrome; thrombocytopenia (due to platelet trapping, coagulopathy, and microangiopathic hemolytic anemia), usually associated with rapidly enlarging lesions, kaposiform hemangioendothelioma, or tufted angiomas
 - Hypothyroidism may occur with large hemangiomas that stimulate increased breakdown of thyroid hormone.

- Vascular malformations:
 - High-output cardiac failure due to circulatory “steal” associated with AVMs
 - Skeletal overgrowth of the involved limb can occur with disfigurement and emotional distress.
 - Limitation of movement and pain from localized ischemia
 - Problems associated with lymphedema, such as excessive leg and foot swelling
 - Airway compromise from constriction by large neck lesions

HEMATURIA

Ann Salerno

BASICS

DEFINITION

Hematuria is defined as ≥ 5 RBCs per high-power field (hpf), using a standard urinalysis technique on a centrifuged sample. This correlates with a urine dipstick reaction of $\geq 1+$.

EPIDEMIOLOGY

- Asymptomatic microscopic hematuria (on > 1 sample): 0.5–2% of school-aged children
- Gross hematuria: 0.13% children in walk-in clinic
- Gross hematuria is more commonly observed in boys.

RISK FACTORS

Hematuria, hypercalciuria, nephrolithiasis, and nephritis can be inherited.

PATHOPHYSIOLOGY

Bleeding can occur from anywhere along the urinary tract or kidney. In glomerular hematuria, RBCs cross the glomerular basement membrane (GBM) into the urinary space.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Hematuria may originate at any site along the urinary tract. Nonglomerular causes are more common than glomerular causes.

- **Factitious causes:** Urine appears bloody, but no RBCs are present.
 - Endogenous pigments:
 - Myoglobin (rhabdomyolysis)
 - Hemoglobin
 - Bile pigments
 - Urate crystals (pink diaper syndrome)
 - Beets, blackberries
 - Exogenous pigments:
 - Food and beverage dyes
 - Drugs that cause urinary discoloration:
 - Phenazopyridine (Pyridium)
 - Deferoxamine
 - Rifampin
 - Sulfa
 - Others
 - *Serratia marcescens*
- **Glomerular causes**
 - Common:
 - Strenuous exercise
 - Acute postinfectious glomerulonephritis (GN)
 - IgA nephropathy
 - Thin basement membrane disease (benign familial hematuria)
 - Uncommon:
 - Alport syndrome, hereditary nephritis
 - Membranoproliferative GN
 - Nephritis of systemic disease (Henoch–Schönlein purpura [HSP], systemic lupus or other vasculitis)

• Nonglomerular (interstitial) renal causes

- Common:
 - Pyelonephritis
 - Hypercalciuria/nephrolithiasis/nephrocalcinosis
 - Renal trauma (contusion), particularly in hydronephrotic or cystic kidneys
 - Ureteropelvic junction obstruction
 - Hemoglobinopathies (sickle cell disease, sickle cell trait)
- Uncommon:
 - Drug-induced interstitial nephritis (penicillins, cephalosporins, NSAIDs, phenytoin)
 - Cystic disease (simple cyst, polycystic kidney disease)
 - Neoplasm: Wilms tumor
 - Coagulopathy
 - Renal venous thrombosis, renal arterial thrombosis
 - “Nutcracker” phenomenon

• Urinary tract causes

- Common:
 - Bladder catheterization, Foley catheter
 - Cystitis (bacterial, viral, occasionally chemical)
 - Perineal trauma or irritation
 - Urethrorrhagia
 - Meatal stenosis
 - Urethritis
 - “Terminal hematuria” syndrome (trigonitis)
 - Epididymitis
- Uncommon:
 - Bladder tumor
 - Polyp
 - Urethral or bladder trauma
 - Foreign body in bladder or urethra
 - Schistosomiasis

• External causes of “hematuria”

- Menstrual contamination
- Diaper rash, perineal irritation
- No identifiable cause is found in the majority (up to 80%) of children with asymptomatic microscopic hematuria and in up to 30% of children with a single episode of gross hematuria.

APPROACH TO THE PATIENT

Evaluate all children with gross hematuria and those children with microscopic hematuria confirmed on 2 of 3 consecutive samples over several weeks:

- **Phase 1:** Determine if the pigment in urine is from blood or another source. Are RBCs present on microscopy?
- **Phase 2:** Determine the source of bleeding: Glomerular or nonglomerular, kidney or urinary tract?
- **Phase 3:** Select those who will require referral vs. those who will simply require follow-up.

HISTORY

- **Question:** Blood on voiding?
- **Significance:** Glomerular or renal source will be constantly bloody; urethral bleeding is more likely at initiation of stream.

- **Question:** Prior episodes of gross hematuria or abnormal urinalyses?
- **Significance:** Chronic vs. acute process
- **Question:** Antecedent infection, streptococcal pharyngitis, or impetigo?
- **Significance:** Suggests postinfectious GN
- **Question:** Concurrent upper respiratory infection (URI) or gastroenteritis?
- **Significance:** Suggests IgA nephropathy
- **Question:** Any precipitating factors (trauma, exercise)?
- **Significance:** Renal contusion, exercise hematuria, or myoglobinuria
- **Question:** Voiding symptoms, dysuria, urgency, frequency?
- **Significance:** Suggests bacterial or viral (adenovirus) hemorrhagic cystitis
- **Question:** Renal colic or other pain?
- **Significance:** Suggests stones
- **Question:** Drops of blood or spotting in underwear after or between voiding in prepubertal boys?
- **Significance:** Suggests urethrorrhagia
- **Question:** Fever, rash, arthritis?
- **Significance:** Signs or symptoms of systemic illness or immune-mediated process
- **Question:** Bleeding from any other source (i.e., gums, GI tract)?
- **Significance:** Suggests coagulopathy
- **Question:** Symptom-less “terminal” hematuria?
- **Significance:** Suggests trigonitis, hemorrhagic cystitis
- **Question:** Medications and diet?
- **Significance:** Food or drug pigment, drug nephrotoxicity
- **Question:** Family history?
- **Significance:**
 - Hematuria in family members: Familial hematuria, kidney failure, or premature deafness suggests Alport syndrome
 - Sickle cell disease or trait in child or family members: Suggests sickle nephropathy, papillary necrosis, or hemoglobinuria
 - Renal stone disease in family members: Suggests renal stones, hypercalciuria, or metabolic disease
 - Cystic kidney disease in family members: Autosomal-recessive or autosomal-dominant polycystic kidney disease
 - Kidney failure or identified kidney disease/nephritis in family members: Suggests hereditary nephritis, cystic disease

PHYSICAL EXAM

- **Finding:** Head, ears, eyes, nose, throat (HEENT) exam (periorbital edema)?
- **Significance:** GN, renal failure, volume overload
- **Finding:** Cardiovascular exam (hypertension, tachycardia, murmur, gallop)?
- **Significance:** GN, renal failure, volume overload
- **Finding:** Abdominal exam (ascites, organomegaly, tenderness, or masses)?
- **Significance:** Volume overload, tumor, polycystic kidneys, venous thrombosis

- **Finding:** Back exam (flank tenderness)?
- **Significance:** Pyelonephritis, renal calculi, large cysts
- **Finding:** Genital exam (blood at urethral meatus)?
- **Significance:** Urethral trauma
- **Finding:** Perineal exam (skin breakdown, irritation)?
- **Significance:** External source of bleeding or infection
- **Finding:** Extremities (pretibial edema, arthritis)?
- **Significance:** GN, volume overload, systemic illness
- **Finding:** Skin and mucosal exam (petechial, vasculitic rash, ulcerations)?
- **Significance:** Systemic illness (lupus, HSP)

DIAGNOSTIC TESTS & INTERPRETATION

Positive test for blood on urine dipstick may be myoglobin or hemoglobin. If the urinary sediment does not show RBCs, investigate for problems such as rhabdomyolysis (elevated creatinine phosphokinase [CPK]) or hemolysis.

- **Test:** Repeated urinalysis to confirm persistent microscopic hematuria
- **Significance:**
 - Patient should be told not to exercise before the urine collection.
 - 2 of 3 positive specimens over several weeks should be documented in an otherwise well child before diagnostic testing is initiated.
- **Test:** Gross and microscopic analyses of fresh urine specimen
- **Significance:**
 - Absence of RBCs suggests factitious hematuria.
 - Dimorphic RBCs suggest glomerular source.
 - Eumorphic RBCs suggest nonglomerular source/collecting system etiology.
 - RBC casts: Diagnostic for GN
 - WBCs suggest cystitis.
 - WBC casts suggest pyelonephritis.
- **Test:** Screening of the family members for occult hematuria
- **Significance:** Familial benign hematuria or Alport syndrome
- **Test:** Testing for hypercalciuria (random urine calcium/creatinine ratio >0.2 in children >6 years; >0.6 in children 6–12 months; >0.8 in children <6 months)
- **Significance:** If elevated, 24-hour urine calcium collection >4 mg/kg/d in children >2 years of age: Hypercalciuria
- **Test:** Culture
- **Significance:** Bacterial, viral—cystitis, *S. marcescens*, adenovirus
- **Test:** Serum electrolytes, BUN, and creatinine levels
- **Significance:** Impaired renal function suggests inflammation, infection, or obstruction.
- **Test:** Evaluation for GN
- **Significance:**
 - Hematuria with RBC casts in combination with proteinuria, edema, hypertension, and/or impaired renal function
 - Streptococcal serology (ASOT, streptozyeme): Acute postinfectious GN
 - Complement studies (C3, C4): Hypocomplementemic GN—immune complex-mediated (lupus nephritis, postinfectious GN, membranoproliferative GN)
 - Antinuclear antibody (ANA) titer or anti-double-stranded DNA if hypocomplementemic: Vasculitis (lupus)
 - Quantitation of proteinuria and serum albumin concentration:

- 3–4+ proteinuria, urine protein/creatinine ratio >2 , and hypoalbuminemia suggest glomerular disease/nephrosis.
- 24-hour urine protein ≥ 1 g/d
- **Test:** CBC with platelets, coagulation times
- **Significance:** May suggest hemolysis, clotting disorder, or systemic illness
- **Test:** Hemoglobin electrophoresis should be considered in black patients.
- **Significance:** Sickle cell disease or sickle trait may cause hematuria.
- Rarely, additional studies, such as cystourethrogram, renal angiography, cystoscopy, and renal biopsy, will be required with an appropriate referral to urology or nephrology.
- **Significance:** Sickle cell disease or sickle trait may cause hematuria.
- Rarely, additional studies, such as cystourethrogram, renal angiography, cystoscopy, and renal biopsy, will be required with an appropriate referral to urology or nephrology.
- Audiometry may be indicated if hereditary (Alport) nephritis is suspected; should be performed on boys with familial hematuria.

Imaging

Every child with gross hematuria should have imaging of the kidneys and urinary tract. It may or may not be indicated in children with microscopic hematuria.

- Ultrasound of kidneys and bladder: Urinary tract obstruction, congenital malformation, cysts, stones, nephrocalcinosis, malignancy
- Abdominal CT scan: After trauma if there are >50 RBCs/hpf or if microscopic hematuria persists for several weeks
- Helical CT without contrast: Study of choice for the visualization of stones; however, must consider radiation exposure risk. Ultrasound is reasonable first test for stones.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- For children with microscopic hematuria, in the absence of other clinical, laboratory, or imaging findings, no specific treatment is indicated besides routine longitudinal follow-up.
- For children with glomerular hematuria, treatment depends on the histopathologic diagnosis, clinical features, renal function, and degree of proteinuria.
- For children with an anatomic/structural etiology, treatment is specific to abnormality.

ISSUES FOR REFERRAL

- Nephrology: Recurrent gross hematuria, proteinuria, RBC casts, nephrosis, edema, hypocomplementemia, hypertension, azotemia, cysts, hypercalciuria, family history of hereditary nephritis, deafness, or cystic kidney disease
- Urology: Congenital anomaly of urinary tract, uncontrollable bleeding after trauma, recurrent, painful or large stones, recurrent urinary infections
- Bleeding secondary to coagulopathy or sickle cell disease papillary necrosis

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

A healthy child with asymptomatic isolated hematuria and a negative workup should be reassessed annually with a complete physical exam, measurement of BP, and urinalysis. If hematuria is persistent, periodic assessment of renal function should also be performed. The development of significant proteinuria, hypertension, elevated creatinine, or other concerns should prompt evaluation by a pediatric nephrologist.

PROGNOSIS

- Most children with asymptomatic isolated microscopic hematuria detected on a well-child examination, without proteinuria, hypertension, or azotemia, will NOT be found to have serious underlying pathology and will simply require longitudinal follow-up.
- Many children with hematuria will not have an identifiable cause; however, long-term prognosis is still generally good.
- Children with asymptomatic microscopic or gross hematuria combined with proteinuria have a high likelihood of glomerular disease.
- Children with a history of stones or hypercalciuria are at increased risk of developing renal stones in the future.
- Familial hematuria secondary to thin GBM disease is a diagnosis of exclusion. Although it often has a benign prognosis, in some families it can progress to chronic kidney disease. Children should be examined yearly for the development of proteinuria or hypertension.

- R31.9 Hematuria, unspecified

HEMOLYSIS

Julie W. Stern

BASICS

DEFINITION

Premature destruction of RBCs, either intravascularly or extravascularly, leading to a shortened red cell survival time.

EPIDEMIOLOGY

Hereditary RBC membrane defects may be mild and may be diagnosed at an older age.

RISK FACTORS

Although many of these disorders are autosomal dominant, 20% of these patients represent new spontaneous mutations and have no affected family members.

GENERAL PREVENTION

Avoid glucose-6-phosphate dehydrogenase (G6PD) triggers such as fava beans, broad beans, and mothballs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See Table 1.

- **Congenital/anatomic**
 - ABO blood type incompatibility and Rh incompatibility between infant and mother
 - Cardiac lesions with turbulent flow; left-sided more common than right-sided
 - Prosthetic heart valve (especially aortic)
 - Kasabach–Merritt syndrome
 - Hypersplenism
- **Infectious**
 - Congenital infections with syphilis, rubella, cytomegalovirus, and toxoplasmosis
 - Malaria
 - Bartonellosis
 - *Clostridium perfringens* (via a toxin)
 - *Mycoplasma pneumoniae*
 - HIV
 - Hemolytic uremic syndrome
- **Toxic, environmental, drugs**
 - Immune-complex “innocent bystander” mechanism:
 - Quinidine
 - Acetaminophen
 - Amoxicillin
 - Cephalosporins
 - Isoniazid
 - Rifampin
 - Immune-complex drug-adsorption mechanism:
 - Penicillin
 - Cephalosporins
 - Erythromycin
 - Tetracycline
 - Isoniazid
 - Drug-induced autoimmune hemolytic anemia: Alpha-methyl dopa
 - Toxic drug-induced hemolysis: Ribavirin (generally mild and not clinically significant)
 - Snake and spider venoms
 - Extensive burns

- **Mechanical hemolysis**
 - Cardiac hemolysis
 - Abnormal microcirculation:
 - Thrombotic thrombocytopenic purpura (TTP)
 - Disseminated intravascular coagulopathy
 - Malignant hypertension
 - Eclampsia
 - Hemangiomas
 - Renal graft rejection
 - March hemoglobinuria (prolonged physical activity)
- **Tumor**
 - Lymphomas
 - Thymoma
 - Lymphoproliferative disorders
- **Genetic/metabolic**
 - RBC membrane defects:
 - Hereditary spherocytosis
 - Hereditary elliptocytosis
 - Pyropoikilocytosis
 - Paroxysmal nocturnal hemoglobinuria (can be acquired)
 - Enzyme defects:
 - PK deficiency
 - G6PD deficiency
 - Thalassemias (β -thalassemia major is the most severe)
 - Hemoglobinopathies:
 - Sickle cell anemia (Hgb SS and SC variants)
 - Unstable hemoglobins
- **Allergic/inflammatory/immune**
 - Autoimmune hemolytic anemia:
 - Warm antibody mediated
 - Cold antibody mediated
 - Hemolytic transfusion reaction

ALERT

Factors that constitute an emergency:

- Hemoglobin <5 g/dL, especially with signs of cardiovascular compromise
 - Attempts to stabilize cardiovascular compromise with volume should be undertaken with care since hemodilution may occur.
 - Transfusion may be riskier in autoimmune hemolysis because of potential problems with cross-matching.
- Renal failure may accompany severe hemolysis in TTP or hemolytic uremic syndrome.
- Hemolysis in the neonatal period secondary to ABO or Rh incompatibility may require exchange transfusion either for anemia or for hyperbilirubinemia.

ETIOLOGY

Table 1. Common mechanisms of hemolysis

Acquired disorders	Hereditary disorders
Infectious	Hemoglobinopathies
Drug induced	RBC membrane defects
Immune mediated	RBC enzyme defects
Microangiopathic	

APPROACH TO THE PATIENT

General goal is to establish existence of hemolysis rather than other causes of anemia, such as blood loss and hypoproduction.

- **Phase 1:** Determine acuity and severity of the anemia and hemolysis:
 - With acute onset, there will be evidence of unstable vital signs and possibly heart failure.
 - Parents may give a history of a rapid deterioration of the child’s physical and/or mental state.
 - Patients with chronic anemia that has progressed slowly may have a low hemoglobin yet be well compensated with fairly normal vital signs (except for tachycardia).
 - CBC with a corrected reticulocyte count will help determine if there is an appropriate bone marrow response to the level of anemia and, therefore, whether the process is hypoproduative or hemolytic.
- **Phase 2:** Determine the cause of hemolysis. Treatment approaches will vary depending on the underlying etiology.

HISTORY

Hemoglobinuria is a sign of intravascular hemolysis, whereas pallor, fatigue, and jaundice may occur with either intravascular or extravascular hemolysis.

- **Question:** History of anemia, splenectomy, or early cholecystectomy in multiple family members?
- **Significance:**
 - Although hereditary membrane defects and enzyme deficiencies may be autosomal dominant, recessive, and X-linked disorders, a negative familial history does not always rule out these diagnoses.
 - In some cases, the diagnosis of hereditary spherocytosis has not been identified, yet multiple members of a family have had their gallbladders removed at an early age, which may indicate the presence of this defect.
 - Thalassemia (especially β -thalassemia) and sickle cell anemia may present in early childhood with chronic hemolysis with or without a familial history.
- **Question:** History of travel?
- **Significance:** Malaria is endemic to Africa, India, and parts of Central America.
- **Question:** Drugs and diet history?
- **Significance:** Specifically ask about exposure to fava beans, mothballs, and antibiotics. Drugs can themselves cause hemolysis or can induce hemolysis if there is an underlying disorder such as G6PD deficiency.
- **Question:** Age at first signs and symptoms of hemolysis (pallor or jaundice)?
- **Significance:**
 - Hereditary causes of hemolysis are most often chronic or recurrent, although the diagnosis may be delayed until the child is older if the process is mild.
 - Acute, acquired hemolytic disorders may also recur.

PHYSICAL EXAM

Hemolysis that is a secondary problem (e.g., related to infection, tumors) may be found incidentally during evaluation of the primary process.

- **Finding:** Acute processes such as autoimmune hemolytic anemia (both warm and cold antibody mediated) may present with a child in extremis.
- **Significance:**
 - Tachycardia is a common finding in nearly all cases of acute hemolysis.
 - BP instability is a late finding.
- **Finding:** More chronic processes, such as hereditary spherocytosis, G6PD, pyruvate kinase (PK) deficiencies, thalassemia intermedia, and sickle cell disease, may be picked up at well visits or by laboratory examination.
- **Significance:** These children often appear well (except for jaundice) but may become more anemic with an acute illness.
- **Finding:** Splenomegaly (often impressive) and hepatomegaly are common findings in extravascular hemolysis.
- **Significance:**
 - Hepatomegaly may be more pronounced if the child is in heart failure due to acute, severe anemia.
 - Splenomegaly may be either the cause of or, more frequently, a result of a hemolytic process.
 - If significant lymphadenopathy is present, look for an underlying cause such as lymphoproliferative disorders or other tumors.
- **Finding:** Skin?
- **Significance:**
 - Pallor is nearly a universal finding in acute hemolysis and in exacerbations of chronic hemolysis.
 - Jaundice is more common in intravascular hemolysis.
 - Presence of ecchymoses or petechiae suggests disseminated intravascular coagulopathy or thrombocytopenia.

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** CBC with differential and reticulocyte count
- **Significance:**
 - Level of anemia and the reticulocyte count must be interpreted together. Chronic hemolysis in hereditary spherocytosis, for example, may have a nearly normal hemoglobin count but usually has an increased reticulocyte count.
 - With a rapid fall in hemoglobin, as in acute autoimmune hemolytic anemia, the reticulocyte count may be low at the start, rise in response to anemia, and fall during recovery.
 - Thrombocytopenia should raise suspicions about TTP or hemolytic uremic syndrome.
- **Test:** Peripheral blood smear
- **Significance:**
 - Fragmented RBCs, schistocytes, and helmet cells are seen in disseminated intravascular coagulopathy, TTP, hemolytic uremic syndrome, and cardiac valve hemolysis.
 - Helmet or bite cells are nearly pathognomonic for G6PD deficiency.
 - Other findings on the smear that may be helpful in the diagnosis are spherocytes (hereditary spherocytosis and warm autoimmune hemolytic anemia), target cells (hemoglobin C and thalassemias), and acanthocytes (anorexia nervosa).

- **Test:** Bilirubin
- **Significance:** Total and unconjugated bilirubins are elevated in most cases.
- **Test:** Urinalysis
- **Significance:**
 - Hemoglobinuria is present in intravascular hemolysis; established by a urine dipstick positive for heme with no intact red cells microscopically.
 - Myoglobinuria can also give this picture.
- **Test:** Coombs test
- **Significance:**
 - Direct Coombs test (direct antiglobulin test) detects antibodies or complement fragments present on the patient's RBCs.
 - Indirect antiglobulin test detects antibodies in the patient's serum that can bind normal RBCs.
 - Direct antiglobulin test provides direct evidence of immune-mediated hemolysis.
 - Warm antibody autoimmune hemolytic anemia is caused by an IgG antibody that coats RBCs, which are subsequently removed by the spleen.
 - Cold antibody autoimmune hemolytic anemia is caused by an IgM antibody that binds RBCs, fixes complement, and can cause both extravascular and intravascular hemolysis.
- **Test:** Haptoglobin, hemopexin, and lactate dehydrogenase
- **Significance:**
 - In intravascular hemolysis, haptoglobin levels may be undetectable, hemopexin is reduced, and lactate dehydrogenase is significantly increased.
 - In extravascular hemolysis, haptoglobin is decreased (but detectable) and lactate dehydrogenase may be increased, but not to the level seen in intravascular hemolysis.
- **Test:** Bone marrow aspiration
- **Significance:** Rarely indicated, but if performed, erythroid hyperplasia should be present.
- Blood for diagnostic RBC enzyme or hemoglobinopathy studies must be drawn prior to transfusion.

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Red cell transfusion may be indicated for symptomatic anemia regardless of cause: Amount of rate will depend on severity of anemia and speed of onset (generally slower transfusion rate needed in chronic anemia).
- Plasmapheresis for TTP
- Withdrawal of inducing drug/agent (G6PD)

ISSUES FOR REFERRAL

- Most patients with severe, acute hemolysis or an underlying chronic hemolytic disorder will need to be evaluated by a hematologist.
- Suspected RBC membrane and enzyme defects, as well as hemoglobinopathies, should be referred for initial evaluation.

Admission Criteria

Unstable vital signs with acute hemolysis, significant exacerbation of chronic hemolysis

- 282.7 Other hemoglobinopathies
- 773.1 Hemolytic disease of fetus or newborn due to ABO isoimmunization

ICD10

- D55.0 Anemia due to glucose-6-phosphate dehydrogenase deficiency
- P55.1 ABO isoimmunization of newborn
- D58.2 Other hemoglobinopathies

FAQ

- Q: When are blood transfusions indicated in patients with active hemolysis?
- A: Patients with severe, acute hemolysis that is causing cardiovascular compromise may require a transfusion if the process cannot be stopped with standard therapy (e.g., steroids for warm autoimmune hemolytic anemia, plasmapheresis for TTP). Transfusions must be given slowly if the hemolytic process has been chronic and the patient's blood volume is expanded.
- Q: Can hemolysis always be identified on a peripheral blood smear?
- A: No. Schistocytes, fragments, spherocytes, targets, and other morphology may provide clues to specific diagnoses but are not always present. The presence of a hemolytic process is inferred from a fall in hemoglobin, rise in the reticulocyte count, and elevation of the bilirubin and lactate dehydrogenase levels.

HEMOLYTIC DISEASE OF THE NEWBORN

Deborah A. Sesok-Pizzini

BASICS

DESCRIPTION

Hemolytic anemia occurring in the newborn owing to passive transfer of maternal RBC antibodies (IgG) against fetal RBCs

EPIDEMIOLOGY

- 15% of whites are Rh negative (dd)
- 48% are heterozygous (Dd)
- 35% are homozygous (DD)
- Prevalence of Rh-positive fetus in Rh-negative mother: 15%
- Incidence of Rh hemolytic disease: 6–7/1,000 live births
- Of all Rh-sensitized pregnancies:
 - 50% require no treatment.
 - 31% require treatment after a full-term delivery.
 - 10% are delivered early and require exchange transfusion.
 - 9% require intrauterine transfusion.
- Reasons for spectrum of clinical severity:
 - Rh immunization rarely occurs in 1st pregnancy.
 - Many subsequent infants may be Rh negative.
 - Only a fraction of women at risk develop antibodies.
- 50% of cases of ABO hemolytic disease of the newborn (HDN) occur in 1st pregnancy.

GENERAL PREVENTION

- Rh hemolytic disease can be prevented by administration of RhIG to an Rh-negative woman after any exposure to Rh-positive blood, prophylactically during pregnancy, and postpartum (within 72 hours) after birth of an Rh-positive newborn.
 - Standard dose of 300 mcg of RhIG given to unsensitized Rh(–) women at 28 weeks and at birth, or following an abortion or ruptured tubal pregnancy.
 - Calculate RhIG dose if fetal screen is positive and a Kleihauer-Betke or flow cytometry test is performed to determine the percentage of fetal cells in maternal circulation.
- Smaller doses of 50 mcg are indicated in the 1st trimester following sensitizing events.
- An Rh(–) woman known to be sensitized to Rh(D) (not due to antenatal RhIG administration) is not a candidate for RhIG.
- Severe HDN due to other RBC antibodies (i.e., Kell, Duffy) may be prevented by following maternal antibody titers and performing an analysis of amniotic fluid for bilirubin, ultrasound of the fetus, and Doppler ultrasonography of the middle cerebral artery.

PATHOPHYSIOLOGY

- Rh alloimmunization (or other antibody) results from passage of fetal RBCs that express surface Rh(D) antigen (or other RBC antigen) across the placenta into the circulation of an Rh-negative (or other antigen-negative) mother.
- The passage of fetal RBCs occurs as a result of transplacental hemorrhage.
- Initial exposure results in production of maternal IgM antibodies, which do not cross the placenta. This is followed by production of IgG antibodies, which can cross the placenta. On subsequent exposures, there is a rapid production of IgG antibodies.
- Mothers may have initial sensitization owing to transfusion or previous pregnancy.
- IgG produced in the maternal circulation crosses the placenta and coats fetal RBCs. These cells are then destroyed in the reticuloendothelial system, primarily the fetal spleen.
- Isoimmunization may lead to severe anemia, hydrops, and hyperbilirubinemia.
- Extramedullary hematopoiesis in the fetal liver and spleen occurs as a response to fetal anemia, leading to severe hepatosplenomegaly.
- ABO HDN occurs more frequently in type O mothers due to anti-A, B (IgG antibody) with type A or B fetus, and results in a clinically milder hemolysis and rarely requires intervention.
- HDN due to other RBC antibodies such as anti-Kell and anti-Ge may be a result of an additional mechanism that involves either suppression or destruction of RBC precursors.

ETIOLOGY

- Most common antigen system involved: ABO with mild HDN
- Failed or omitted anti-D prophylaxis
- 1% of cases involve other antigens.
- Other antigens include Kell*, Kidd, Duffy, MNS, C, E, c*, e, Ge, C^w, SARA, Jr^a (most severe HDN*)

DIAGNOSIS

HISTORY

- Previous stillbirths and/or abortions
- Neonatal hyperbilirubinemia requiring therapy in previous pregnancy
- Exposure of mother to blood products or previous pregnancy
- Father's ABO and Rh and other RBC antigen type
- RhIG not given after previous pregnancy or abortion

PHYSICAL EXAM

- Pallor, tachycardia, tachypnea due to CHF secondary to severe anemia
- Jaundice developing within 24 hours of birth
- Usually no jaundice at birth
- Generalized edema in cases with severe anemia and hydrops
- Massive hepatosplenomegaly in severe cases
- Milder cases manifest with neonatal hyperbilirubinemia only.
- ABO incompatibility usually manifests jaundice at 24 hours.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Antenatal:
 - ABO and Rh type of all mothers at 1st prenatal visit
 - Zygosity of the father: If the father is Rh-positive homozygous, then all children will be Rh positive; if the father is heterozygous, then only 50% of children will be Rh positive.
 - Fetal blood group genotyping can be performed from a maternal blood sample during 2nd trimester.
 - Monitor antibody titer.
 - Spectrophotometric assessment of bilirubin concentration in amniotic fluid
 - Amniotic fluid values in Liley zone 3 and high zone 2 indicative of severe fetal disease (Liley test measures optical density in amniotic fluid as an indicator for bilirubin levels; do not use for Kell sensitization as it is not a reliable indicator of severity of disease in these patients)
 - Fetal blood sampling in severe cases to assess degree of anemia
- Neonatal:
 - Cord blood or neonate red blood cells for ABO and Rh types
 - Cord blood or neonate blood for hemoglobin (Hb), hematocrit (Hct), bilirubin (direct and indirect), reticulocyte count
 - Direct Coombs test on cord or neonate red blood cells will be positive in immune hemolytic disease.
 - Indirect Coombs test on neonate's serum for passively transferred antibody
 - Identification of antibody after elution from RBC
 - Administration of RhIG during pregnancy may result in a positive indirect Coombs result (antibody screen), but no risk to the fetus
 - Peripheral smear: Nucleated RBCs (spherocytes in ABO disease)

Imaging

- Fetal ultrasound (visualize fetal size and organomegaly)
- Doppler ultrasonography of fetal middle cerebral artery peak systolic velocity

Diagnostic Procedures/Other

- Fetal cordocentesis (for fetal anemia)
- Amniocentesis
- Intrauterine transfusion

Pathological Findings

- Kernicterus
- Extramedullary hematopoiesis
- Hepatosplenomegaly
- Edema

DIFFERENTIAL DIAGNOSIS

- Neonatal hyperbilirubinemia:
 - Galactosemia
 - Glucose-6-phosphate dehydrogenase (G6PD) deficiency
 - Hypothyroidism
 - Pyruvate kinase deficiency
 - Crigler-Najjar syndrome
 - α -Thalassemia
 - Gilbert syndrome
 - Spherocytosis
 - Breast milk jaundice

- Hydrops fetalis:
 - Hematologic: α -Thalassemia, severe G6PD deficiency, twin-to-twin transfusion
 - Cardiac: Hypoplastic left heart syndrome, myocarditis, endocardial fibroelastosis, heart block
 - Congenital infections: Parvovirus, syphilis, cytomegalovirus (CMV), rubella
 - Renal: Renal vein thrombosis, urinary tract obstruction, nephrosis
 - Placental: Umbilical vein thrombosis, true knot of umbilical cord
 - Miscellaneous: Trisomy 13, 18, 21; triploidy; aneuploidy; diaphragmatic hernia

TREATMENT

ADDITIONAL TREATMENT

General Measures

- In severely affected fetuses (fetal Hct <25–30%) where early delivery is not possible owing to lung immaturity, intrauterine RBC transfusion is the therapy of choice. Usually not performed until after 20 weeks' gestation. Risks include fetal loss (2%), premature labor, rupture of membranes, chorioamnionitis, fetal bradycardia, cord laceration, and fetomaternal hemorrhage.
- Maternal plasma exchange and IVIG administration have been attempted as an alternative to intrauterine transfusion. Antibody titers are temporarily reduced.
- Early delivery and subsequent resuscitation may be required in severe HDN:
 - If there has been a previous stillbirth or hydrops and the fetus is high risk after amniocentesis, plan early delivery.
 - Careful fetal monitoring and induction of pulmonary maturation
 - After delivery, treatment depends on age, birth weight, severity, and other illness. Phototherapy starts as soon as possible.
- Exchange transfusion removes sensitized fetal RBCs and circulating bilirubin and also has the following benefits:
 - Corrects anemia in severely anemic infants
 - Prevents or corrects hyperbilirubinemia
 - Removes circulating antibodies
- Indications for early exchange transfusion:
 - Cord blood bilirubin >4.5 mg/dL and cord blood Hb <10 g/dL
 - Bilirubin rising at rate >1 mg/dL/hr despite optimal phototherapy
 - Indirect bilirubin \geq 20 mg/dL or rising to reach that level
 - Lower indirect bilirubin triggers are used in preterm or high-risk infants.
 - Hb between 11 and 13 g/dL and bilirubin rising at rate >0.5 mg/dL/hr despite optimal phototherapy
- In hydropic infants, immediate partial exchange may be needed to correct anemia and CHF.
- Double-volume exchanges may be needed for hyperbilirubinemia.
- Selection of blood for exchange transfusion:
 - As fresh as possible or washed, CMV-safe, and irradiated, hemoglobin S negative

- For Rh disease (if prepared before delivery): Type O Rh negative cross-matched against mother's blood
- For ABO disease: Type O Rh negative or Rh compatible cross-matched against mother or infant's serum
- For other antibodies: Antigen-negative RBCs selected to avoid the clinically significant antibody. ABO type-specific blood can be used if baby's type confirmed.
- Risks of exchange transfusion include prolonged neutropenia, thrombocytopenia, late anemia, metabolic abnormalities, arrhythmias, thrombosis, and death.
- Some studies indicate that administration of IVIG to the neonate diminishes hemolysis and may prevent the need for exchange transfusion.
- Most infants with ABO incompatibility require no treatment or phototherapy only.
- Some infants with milder Rh isoimmunization may have only exaggerated physiologic anemia at 12 weeks.
- Avoid drugs that interfere with bilirubin metabolism or its binding to albumin (sulfonamides, caffeine, and sodium benzoate).
- Infants who had HDN are at risk for late anemia owing to reticulocytopenia related to persistent high titers of circulating maternal antibody. They should have weekly Hct measured during the 1st few months of life. These infants may require small-volume transfusion.
- Erythropoietin and oral iron supplements may be used to avoid blood transfusion.

Additional Therapies

- Phototherapy
- Exchange transfusion

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Weekly Hct, especially for patients who had exchange transfusion
- Watch for exaggerated physiologic anemia at 12 weeks.
- Assess for neurologic damage.

PROGNOSIS

- ~50% of the infants have minimal anemia and hyperbilirubinemia and require either no treatment or phototherapy only.
- 1/4 will require exchange transfusions.
- Hydropic infants have high mortality.

COMPLICATIONS

- Hydrops fetalis
- Stillbirths
- Neonatal hyperbilirubinemia and kernicterus
- Fetal anemia

CODES

ICD9

773.2 Hemolytic disease of fetus or newborn due to other and unspecified isoimmunization

ICD10

P55.8 Other hemolytic diseases of newborn

FAQ

- Q: Does the condition become worse with each pregnancy?
- A: The fetus may be more affected in a 2nd or subsequent pregnancies with HDN due to Rh antibodies. Other antibodies, such as Kell, may result in severe HDN even in a 1st pregnancy.
- Q: Can maternal blood be used to transfuse the affected baby?
- A: Washed maternal blood may be used, but donor infectious disease testing protocols would need to be followed so it would not be routinely available in an emergency situation. However, for certain high-frequency antigens, such as Kp^b, maternal blood should be considered.
- Q: When are O red blood cells indicated for exchange transfusion?
- A: O red blood cells are indicated when the neonate's blood type is unknown or the reason for the HDN is ABO incompatibility between mom and neonate.

HEMOLYTIC UREMIC SYNDROME

Divya Moodalbail

Andres J. Greco (5th edition)

BASICS

DESCRIPTION

- HUS is a disease phenotype characterized by renal impairment, thrombocytopenia, and anemia with fragmentation of erythrocytes (schistocytes noted on peripheral smear).
- The kidney dysfunction may manifest as hematuria and/or proteinuria and/or azotemia.
- HUS is the leading cause of acute renal failure in infants and young children.
- ~90% of childhood cases follow a diarrheal prodrome (D+HUS or Stx HUS, or classic HUS).
- This syndrome can also be non-diarrhea-related (atypical) and represent a heterogeneous group of disorders: Hereditary (defects in complement proteins), *Streptococcus pneumoniae*-related HUS and HUS secondary to malignancies, bone marrow transplant, collagen-vascular disorder or drugs (calcineurin inhibitors).
- Non-Stx forms of HUS usually have a poor outcome.

EPIDEMIOLOGY

- Stx HUS (D+HUS):
 - Tends to occur in the summer months, and epidemics have been reported in daycare centers and nursing homes.
 - Occurs mainly in older infants and young children, between 6 months and 4 years of age.
- Atypical HUS (D-HUS):
 - Has no seasonal variation and can occur at any age; can occur sporadically or in families.

GENERAL PREVENTION

- Shiga toxin-producing *E. coli* (STEC) is found in the intestine of beef cattle. Ground beef may be contaminated throughout with Shiga toxin.
- For adequate prevention, it is imperative to wash hands and food well and to cook food, especially meat, thoroughly.

PATHOPHYSIOLOGY

- Vascular endothelial cell injury is central to the pathogenesis of all forms of HUS
- STEC colonize colonic mucosa, adhere to mucosal villi, and release Shiga toxin (Stx).
- Stx binds to cell surface receptors, translocates into the cell, interrupts protein synthesis, and causes cell death. This produces endothelial cell injury, exposing the thrombogenic basement membrane, and this causes platelet activation and local intravascular thrombosis.
- Recently, it has been shown that upregulation of chemokine and cytokine production occurs with Stx-1 and 2 and increased binding of the inflammatory cells to the endothelial cells.
- In vitro studies show that glomerular endothelial cells have receptors with very high affinity to the Stx.

ETIOLOGY

- Stx HUS: Most cases are caused by STEC, most often the O157:H7 subtype:
 - STEC most commonly infect children from 9 months to 4 years of age in the summer and the fall. The primary reservoir is cattle.
 - A negative stool culture in a patient who has HUS does not eliminate STEC as the cause.
- Atypical HUS: Mutations have been reported in the complement regulatory protein factor H in both sporadic and familial HUS, with mutations identified in 10–20% of cases.
- Mutations in other complement regulators (membrane cofactor protein CD46) have also been associated with familial HUS.
- One of the common causes of sporadic non-Stx-HUS is *S. pneumoniae* infection.

DIAGNOSIS

HISTORY

- GI prodrome: Stx HUS can develop 2–14 days after the onset of diarrhea (usually bloody). There can be associated vomiting and fever.
- Symptoms of pneumonia: *S. pneumoniae* associated HUS is associated with severe disease.
- Recent hamburger ingestion, consumption of unpasteurized milk, cheese, or apple cider
- Direct animal contact (petting zoos)
- Family history of HUS

PHYSICAL EXAM

- Pallor and petechiae
- Dehydration secondary to the gastroenteritis
- Edema
- Pulmonary edema (volume overload)
- Hypertension
- Irritability
- Behavioral changes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC: Anemia, thrombocytopenia (usually $<60,000/\text{mm}^3$ in most of the cases), leukocytosis (often seen in typical HUS)
- Blood smear: Fragmented RBCs or schistocytes
- Markers of hemolysis: Elevated LDH, circulating free hemoglobin, decreased haptoglobin, elevated unconjugated bilirubin, increased reticulocyte count
- Renal function: Elevated BUN and serum creatinine
- Serum electrolytes: Hyperkalemia (hypokalemia can be observed in severe GI involvement), metabolic acidosis, hyponatremia, hypocalcemia, hyperphosphatemia
- Serum albumin: Usually low due to enteral losses and/or hypercatabolic state

- Amylase/Lipase: Elevated in pancreatic involvement.
- Stool culture: Should be screened for *E. coli* O157:H7 (>90% cases), preferably before 6 days after the onset of diarrhea. The local health department should be notified of any isolates.
- Identification of Shiga-toxin

Imaging

- Plain film of the abdomen often demonstrates colonic distension or evidence of bowel perforation.
- Barium enema may show “thumb-printing,” secondary to bowel wall edema and submucosal bleeding.

Pathological Findings

The lesions are usually limited to the kidneys and involve the glomerular capillaries and the afferent arterioles. Renal biopsy findings usually comprise diffuse thickening of the glomerular capillary wall and swelling of endothelial cells. Thrombi containing platelets and small amounts of fibrin are visible in the capillary lumina.

DIFFERENTIAL DIAGNOSIS

- Severe hemolytic anemia
- Malaria

TREATMENT

MEDICATION (DRUGS)

- Antihypertensives: Vasodilators, such as calcium-channel blockers or hydralazine, are useful in the acute phase. After recovery, if a patient persists with hypertension and/or proteinuria, then ACE inhibitors are indicated.
- In patients with seizures, diazepam or lorazepam are of choice. In patients with recurrent seizures or cerebral infarcts, long-term anticonvulsant therapy is indicated.
- Treatment with insulin may be needed in patients with pancreatic necrosis.
- Patients with invasive bacterial infections or abscesses should be treated with appropriate antibiotic coverage.

ADDITIONAL TREATMENT

General Measures

- Treatment of HUS is generally supportive.
- The mainstay of therapy involves:
 - Strict fluid balance
 - Nutritional support
 - Control of hypertension
 - Treatment of seizures
- In patients with GI illness secondary to STEC, it's advisable to avoid administration of antibiotics unless there is sepsis, to prevent antibiotic-induced damage to the bacterial membranes, which can result in release of large amounts of toxin.

- Renal replacement therapy for severe acidosis, fluid overload, electrolyte imbalance or uremia
- Treatment of severe anemia: Packed RBCs are transfused slowly if the hemoglobin decreases below 6 g/dL (BP can increase during transfusion)
- Platelet transfusion: Indicated if there is active bleeding and severe thrombocytopenia, or the patient needs surgery or invasive procedure

Additional Therapies

- Renal replacement therapy:
 - Unless contraindicated, peritoneal dialysis is the treatment of choice.
 - It should be started in patients with anuria >24 hours.
 - Kidney transplant should be considered in patients who progress to end-stage renal disease.
- Plasmapheresis or fresh frozen plasma infusion may be beneficial in idiopathic (atypical) forms of HUS.

SURGERY/OTHER PROCEDURES

Some patients can have extensive bowel necrosis requiring resection.

IN-PATIENT CONSIDERATIONS

IV Fluids

Any fluid deficit should be corrected, and composition of additional fluid should be limited to ongoing losses (insensible water loss plus urine and/or GI losses).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Resolution is usually heralded by a rise in platelet count and a gradual decrease in the frequency of blood transfusions.
- Pancreatic insufficiency may persist, requiring long-term insulin therapy beyond resolution of acute illness.
- If a patient who attends a daycare center has Stx HUS, contacts should be informed that any episodes of gastroenteritis merit close follow-up for evidence of anemia, thrombocytopenia, and renal failure. No prophylaxis is indicated. Ill children should not be permitted to reenter the child care center until diarrhea has resolved and 2 stool cultures obtained 48 hours after antimicrobial therapy has been discontinued are negative for *E. coli* O157:H7.

DIET

- Aggressive nutritional support is important due to the hypercatabolic state of these patients.
- Enteral feeding can be tried if diarrhea is resolved.
- Total parenteral nutrition can be used in patients with severe GI involvement and dialysis.
- Avoid antiperistaltic agents for treatment of colitis.
- Some patients can have pancreatic involvement with subsequent exocrine or endocrine pancreatic insufficiency.

PROGNOSIS

- Factors associated with poor prognosis are:
 - Anuria lasting >2 weeks
 - WBC count >20,000/mm³
 - Coma
 - Atypical HUS
 - Renal cortical necrosis
 - Prolonged diarrhea
- Patients with D+HUS can be mildly or severely affected. ~25% of survivors demonstrate long-term sequelae such as proteinuria and hypertension.
 - Mildly affected patients never develop anuria, almost never have seizures, are rarely hypertensive, do not require dialysis, and have an excellent outcome
 - Severely affected patients develop anuria and require dialysis, develop hypertension, and may have seizures. They can also progress to end-stage renal disease. Recurrence after renal transplantation is very uncommon.

COMPLICATIONS

- GI:
 - Acute colitis is usually transient.
 - Rectal prolapse, toxic megacolon, bowel wall necrosis, intussusception, perforation, and stricture
 - Pancreatic involvement may result in pancreatitis or insulin-dependent diabetes mellitus.
- CNS:
 - Most patients have mild CNS symptoms that include irritability, lethargy, and behavioral changes.
 - Major symptoms such as stupor, coma, seizures, cortical blindness, posturing, and hallucinations occur in 20–40% of patients.
 - Thrombotic or hemorrhagic stroke may occur.
 - The risk of seizures is associated with hyponatremia.

D59.3 Hemolytic-uremic syndrome

FAQ

- Q: What are some predictors of the severity of enteropathic HUS?
- A: Predictors include an elevated white cell count, a severe GI prodrome, anuria early in the course of illness, and age <2 years.
- Q: In a patient with nonenteropathic HUS, what is the chance other siblings will be affected?
- A: Familial HUS due to factor H deficiency may be autosomal dominant or recessive.
- Q: How many patients with gastroenteritis from *E. coli* O157:H7 will develop HUS?
- A: 10–20%
- Q: What should the family tell the daycare staff and neighbors?
- A: If the patient has enteropathic HUS, contacts should be informed that any episodes of gastroenteritis merit close follow-up for evidence of anemia, thrombocytopenia, and renal insufficiency. No prophylaxis is indicated. Exclusion of infected children from daycare centers until 2 consecutive stool cultures are negative for *E. coli* O157:H7 has been shown to prevent additional transmission.

HEMOPHILIA

Char Witmer

BASICS

DESCRIPTION

- Hemophilia A is factor VIII deficiency, and hemophilia B is factor IX deficiency. Both are inherited in an X-linked recessive manner.
- Deficiency or absence of FVIII or FIX leads to a delay and disruption of blood clotting that results in prolonged bleeding.
- The severity of bleeding depends on the percentage of clotting activity. No activity (<1%) results in severe disease; 1–5% is moderate, and 6–30% is mild hemophilia.

EPIDEMIOLOGY

- Most common severe inherited bleeding disorder
- Distribution:
 - Hemophilia A: 80–85%
 - Hemophilia B: 10–15%
- No geographic or ethnic associations
- 30% of cases are sporadic (no family history)

Incidence

- Hemophilia A: 1 per 5,000 male births
- Hemophilia B: 1 per 30,000 male births

RISK FACTORS

Genetics

- X-linked recessive disorder
- Daughters of fathers with hemophilia are obligate carriers for the hemophilia gene mutation. An obligate carrier has a 50% chance of passing the hemophilia gene mutations to her offspring.
- Carrier status and prenatal testing available
- Hemophilia A:
 - The intron 22 inversion mutation in the factor VIII gene is found in ~40–50% of patients with severe hemophilia A; detectable by direct gene mutation analysis.
- Hemophilia B:
 - Most factor IX gene defects are single-base pair changes that result in missense, frameshift, or nonsense mutations. Mutations have been detected in all regions of the factor IX gene.

GENERAL PREVENTION

- Prophylaxis: The regularly scheduled infusion of clotting factor concentrate with the goal of preventing bleeding episodes; primarily used in patients with severe disease.
 - Primary prophylaxis: Regularly scheduled infusion of clotting factor before joint bleeding is typically initiated before 1 year of age.
 - Secondary prophylaxis: Regularly scheduled infusion of clotting factor after joint bleeding has occurred
- Anticipatory guidance and prevention:
 - Good dental hygiene
 - Immunizations: No intramuscular injections; give subcutaneously with a small-gauge needle and apply direct pressure for several minutes.
 - Rapid treatment of hemarthrosis to avoid chronic joint damage
 - Avoidance of contact sports (e.g., football, hockey, rugby)
 - Encourage physical fitness to ensure strong muscles to maintain joint health and prevent joint bleeding. Some recommended activities include swimming, bicycle riding, and walking/hiking. Other sports that can be considered include soccer, tennis, and track.

- Home infusion therapy for prophylaxis as appropriate
- Self-infusion training: Usually starts in adolescence

PATHOPHYSIOLOGY

- Both factors VIII and IX are crucial for normal thrombin generation via the intrinsic pathway. The absence or decrease in activity of either protein severely impairs the ability to generate thrombin and fibrin.
- Hemophilia patients do not bleed more rapidly; rather, there is delayed formation of an abnormal clot resulting in prolonged bleeding.
- The friable clot formed has a tendency to ooze and rebleed.
- In closed spaces (e.g., joint), bleeding stops by tamponade; in open spaces (e.g., iliopsoas muscle, open wounds), significant amounts of blood may be lost.
- Repeated joint hemorrhages lead to synovial thickening and joint cartilage erosion. Joint space becomes narrowed and eventually fuses.

DIAGNOSIS

HISTORY

- Family history:
 - Familial history of hemophilia in male offspring of female blood relatives is present in only 70% of cases. 30% of the time there is no family history of hemophilia.
- Excessive bleeding in a male neonate:
 - Excessive bleeding with circumcision may be an initial presentation of hemophilia, although only 50% of patients with hemophilia will have excessive bleeding with circumcision.
 - Muscle bleeding from intramuscular injections (e.g., vitamin K or immunizations); presents as increasing swelling at the site of injection
 - Prolonged oral bleeding from a torn frenulum or prolonged bleeding from venipuncture or heel puncture can be seen.
 - 3.5–4% of neonates with hemophilia may present with an intracranial hemorrhage.
- Pattern of bleeding in severe hemophilia:
 - Characterized by easy, excessive, and palpable bruising with normal activity, spontaneous joint and muscle hemorrhages, and prolonged and potentially fatal hemorrhage after trauma or surgery
- Age of onset of bleeding:
 - Bleeding events occur frequently when the child begins to crawl and walk or with the eruption of teeth.
 - Patients with mild hemophilia may not present until they are older.
- Location of hemarthroses:
 - Large weight-bearing joints are most often involved: Knees, ankles, and hips. Other nonweight-bearing joints can be involved including elbows and shoulders.
- Early symptoms of a hemarthroses:
 - Aura of tingling or warmth, visible swelling, followed by increasing pain and decreasing range of motion (ROM), and inability to bear weight

PHYSICAL EXAM

Joint exam:

- Acute hemarthrosis: Limitation and pain with ROM, warmth, swelling, tenderness
- Chronic joint changes: Crepitus, decreased ROM, synovial hypertrophy, bony abnormalities, and proximal muscle weakness
- Intramuscular hematomas: May not have external bruising; there will be pain with motion and swelling. With larger bleeds there will be a discrepancy in limb circumference.
- Distal extremity neurovascular compromise can be a sign of compartment syndrome from bleeding into the forearm.

DIAGNOSTIC TESTS & INTERPRETATION

ALERT

- Neonates have a normal physiologic reduction in the vitamin K–dependent factors, including factor IX, making a determination of the degree of factor IX deficiency difficult in the neonatal period. The factor IX level must be confirmed after 6 months of age.
- When interpreting coagulation testing in a neonate, neonatal normal values for the PT and aPTT are different from those in adults.

Lab

- Patients with hemophilia either A or B will have a normal PT and a prolonged aPTT. Assay for factor VIII and factor IX levels:
- <1%: Severe hemophilia, characterized by spontaneous bleeding; hemarthroses and deep-tissue hemorrhages; will need frequent factor replacement therapy
 - 1–5%: Moderate hemophilia. Bleeding following mild to moderate trauma; hemarthrosis and muscle bleeding, seldom spontaneous hemorrhage
 - 5–30%: Mild hemophilia. Bleeding from trauma only, no spontaneous hemorrhages; patients require factor replacement only with significant trauma or prior to surgery or dental extraction

DIFFERENTIAL DIAGNOSIS

- Isolated prolonged aPTT associated with increased bleeding tendency:
 - von Willebrand disease
 - “Acquired hemophilia” owing to development of an inhibitory antibody to factor VIII or IX (extremely rare in children)
 - Hereditary factor deficiency of either VIII, IX, or XI
 - Afibrinogenemia
- Prolonged aPTT without increased bleeding tendency:
 - Factor XII deficiency
 - High-molecular-weight kininogen deficiency
 - Prekallikrein deficiency
 - Antiphospholipid antibody (lupus anticoagulant)
 - Heparin artifact
 - Underfilling of the specimen tube
 - Polycythemia

TREATMENT

MEDICATION (DRUGS)

Acute bleeding episodes:

- Factor replacement:
 - Factor VIII replacement products:
 - Recombinant, non–plasma-derived factor VIII
 - Plasma-derived, monoclonal antibody–purified factor VIII concentrate; heat or solvent detergent treated for viral inactivation
 - Cryoprecipitate (rarely used)
 - Factor IX replacement products:
 - Recombinant, non–plasma-derived factor IX
 - Plasma-derived, immunoaffinity-purified factor IX concentrate; heat or solvent detergent treated for viral inactivation
 - Prothrombin complex concentrate (PCC): Crude plasma fraction that contains variable amounts of activated factors II, VII, IX, and X; heat-treated for viral inactivation
 - Fresh frozen plasma (rarely used)
- Calculation of dose for pediatrics:
 - Recombinant factor VIII dosing (units) = % desired rise in plasma factor VIII \times body weight (kg) \times 0.5
 - Recombinant factor IX dosing (units) = % desired rise in plasma factor IX level \times body weight (kg) \times 1.4
- Target factor levels:
 - Joint bleed: 30–50% for 24–48 hours
 - Large muscle bleed: 70–100% repeated over 12–48 hours for large muscle bleeds
- CNS bleeding: 80–100% maintained for 10–14 days
- Desmopressin (DDAVP):
 - Synthetic vasopressin analog that stimulates release of endogenous factor VIII and von Willebrand factor
 - Only suitable for patients with mild or moderate factor VIII deficiency who have shown a response to DDAVP in a trial
 - Tachyphylaxis (unresponsiveness) may occur with repeated dosing.
 - Hyponatremia may also occur. Fluid restriction is recommended after each dose. Should not be used in neonates.
- Antifibrinolytic therapy:
 - Antifibrinolytic therapy is used to stabilize a clot by inhibiting the normal process of clot lysis by the fibrinolytic system.
 - Agents used for the treatment of oral hemorrhages and to minimize bleeding from dental and some surgical procedures: Aminocaproic acid, 100 mg/kg PO q6h (maximum, 6 g/dose), or tranexamic acid, 10 mg/kg PO q6–8h (maximum, 1.5 g/dose)

ADDITIONAL TREATMENT

General Measures

- Immobilization:
 - Splints, casts, crutches, and/or bed rest (24–48 hours)
 - Prolonged immobilization may reduce recovery of joint ROM
 - Initiation of physical therapy with factor coverage may be recommended, particularly after joint surgery.
- Special bleeding situations:
 - Intracranial hemorrhage:
 - Significant bleeding can occur despite a minor mechanism of head injury and the absence of external bruising. In severe hemophilia spontaneous intracranial bleeding can occur.

- Factor replacement to 100% should be administered immediately followed by the diagnostic evaluation.
- Major surgery:
 - Factor replacement to 100% preoperatively and postoperatively
 - Regular dosing of factor for a minimum of 1 week postoperatively, even in mild hemophilia
- Compartment syndrome:
 - Bleeding within the fascial compartments of muscles
 - Most often occurs in the forearm
 - Neurovascular compromise can lead to Volkmann contracture.
- Iliopsoas bleed:
 - Lower abdominal or upper thigh pain may be the 1st symptom.
 - Exam is notable for inability to extend hip with preservation of internal and external rotation (allows distinction from hemarthrosis of hip joint).
 - Diagnosis confirmed by ultrasound or CT scan
- Oral bleeding/epistaxis:
 - Constant pressure for 15–20 minutes
 - Aminocaproic acid or tranexamic acid
 - Topical thrombin directly to the site of bleeding
- Dental care:
 - Factor replacement is required for significant dental procedures like tooth extraction or procedures that require a mandibular block injection.
 - Preferably done in a hospital setting where hematology consultation is available.
 - Factor replacement is not required for routine teeth cleaning.
- Lacerations:
 - Factor replacement is necessary at time of placement and removal of the sutures.
- Hematuria:
 - Increased fluid intake and bed rest as initial treatment
 - If hematuria persists 24–48 hours, 30–40% factor replacement
 - Antifibrinolytics are contraindicated in the setting of hematuria because of the concern of obstructive uropathy from excessive clot formation.
- Patients should be followed regularly at a comprehensive hemophilia treatment center.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Life-threatening hemorrhages:

- CNS bleeding
- Bleeding into and around the airway
- Exsanguinating hemorrhage
- Prompt therapy with clotting factor concentrate should start immediately and prior to any diagnostic procedures.

ONGOING CARE

COMPLICATIONS

- Complications of disease:
 - Hemophilic arthropathy: Joint contractures, limited ROM, and chronic pain
 - Intracranial bleeding (can occur without known trauma in severe hemophilia)
 - Compartment syndrome
 - Airway compromise owing to bleeds in the pharynx, tongue, or neck
 - Life-threatening hemorrhage owing to GI, posttraumatic, or perioperative bleeds

- Complications of therapy:
 - Inhibitors: Antibodies against factor VIII or IX, which can inactivate infused factor
 - Viral transmission (HIV, hepatitis B and C) through clotting factor concentrates derived from pooled plasma preparations. This risk is now minimized through the creation of recombinant factor products.
 - Anaphylaxis: Seen primarily with infusions of factor IX
- Thromboembolic disease: The use of central lines in pediatric patients with hemophilia for factor infusions has been associated with thrombotic complications. Bypassing agents including activated prothrombin complex concentrates or activated recombinant factor VIIa have also been linked with thrombosis.

CODES

ICD9

- 286.0 Congenital factor VIII disorder
- 286.1 Congenital factor IX disorder

ICD10

- D66 Hereditary factor VIII deficiency
- D67 Hereditary factor IX deficiency

FAQ

- Q: Are there any medications contraindicated in a child with hemophilia?
- A: Aspirin should not be given, as it interferes with platelet function. NSAIDs cause a milder effect on platelets and should also be avoided when possible. Patients with hemophilia should use acetaminophen for fever or pain.
- Q: Can immunizations be given to a child with hemophilia?
- A: To prevent bleeding from immunizations, they should be given SQ (instead of IM) with the smallest gauge needle available. Ice or cold packs should be applied to the area to minimize hematoma formation.

HEMOPTYSIS

Suzanne E. Beck

BASICS

DESCRIPTION

Hemoptysis is the coughing up of blood from the respiratory tract. The term comes from the Greek words *haima*, meaning blood, and *ptysis*, meaning spitting. The amount and nature of bleeding should be characterized by taking a careful history. Bleeding from the respiratory tract can range from blood-streaked sputum to massive hemoptysis from the lung. The source of bleeding can be anywhere in the respiratory tract, from the nose to the alveolus. Associated symptoms vary and may include cough, chest pain, rhinorrhea, or dyspnea, or there may be none. Consequences of hemoptysis may include exsanguination, hypoxemia, and anemia, or there may be none.

EPIDEMIOLOGY

Large series of pediatric patients with massive hemoptysis have not been described. Most instances of massive hemoptysis take place in older children, usually with underlying cardiac or pulmonary conditions.

PATHOPHYSIOLOGY

- Related to the underlying pulmonary or cardiac disease
- Vascular origin of hemoptysis is from 2 sites: Pulmonary arteries or bronchial arteries

ETIOLOGY

- Aspiration
- Bronchiectasis
- Bronchitis
- Cavitory infections (e.g., tuberculosis, abscess, histoplasmosis)
- Cystic fibrosis
- Congenital vascular or airway lesions (pulmonary arteriovenous malformation, hemangioma, bronchogenic cyst)
- Congenital heart disease with collateral vessels or pulmonary hypertension
- Factitious hemoptysis

- Foreign body aspiration
- Hemorrhagic diathesis, including anticoagulant therapy
- H-type tracheoesophageal fistula
- Pneumonia
- Pulmonary embolism
- Pulmonary hemosiderosis
- Tracheostomy-related complications
- Trauma (pulmonary contusion, bronchoscopy, airway manipulation)
- Tumors (lymphomas)

DIAGNOSIS

HISTORY

- Distinguish the source of bleeding: Nose, mouth, gastrointestinal (GI) tract versus lungs:
 - Bleeding from the nose and mouth may be associated with recurrent episodes, recent trauma, or pain at the site and is usually self-limited.
 - Bleeding from the GI tract may be associated with vomiting, history of gastritis, or abdominal pain.
 - Bleeding from the lungs may be associated with chest discomfort or sensations, shortness of breath, or coughing.
 - Blood from the GI tract is often darker and acidic, whereas blood from the airway tends to be bright red and alkaline, or pink and frothy.
- Determine amount of bleeding (>1 cup in 24 hours is considered massive).
- Determine associated symptoms/conditions:
 - Familial history of pulmonary disease or bleeding disorder
 - Systemic symptoms (weight loss, may indicate tumor)
 - Exposure to environmental toxins (mold or flood-damaged homes)
 - Exposure to tuberculosis
 - Medication/drug use: Cocaine, marijuana, propylthiouracil
 - Recurrent episodes of cough associated with blood-tinged sputum or hemoptysis suggests underlying bronchiectasis or chronic pulmonary infection.
 - Acute pleuritic chest pain raises the possibility of pulmonary embolism with infarction or other pleural lesion.

PHYSICAL EXAM

- Respiratory distress or hypoxemia: Indicates significant ventilation–perfusion mismatch due to airspace disease, shunt due to pulmonary embolism, or acidosis due to hypovolemia and blood loss
- Paleness: Indicates anemia or poor perfusion
- Pleural friction rub: May be associated with pulmonary embolism
- Loud 2nd heart sound: Suggests primary pulmonary hypertension, mitral stenosis, or Eisenmenger syndrome
- Localized wheeze over a major lobar airway: Suggests an intramural lesion such as hemangioma, foreign body, or carcinoma
- Presence of a murmur over the lung fields: May suggest pulmonary arteriovenous malformation
- Clubbing: Indicates the presence of underlying pulmonary disease such as cystic fibrosis, congenital cardiovascular disease, or liver disease

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC, reticulocyte count, erythrocyte sedimentation rate, and coagulation profile: May indicate the volume of blood loss, chronicity of blood loss, inflammatory conditions, and evidence of bleeding diathesis
- Comprehensive metabolic panel: To determine hepatic and renal function, acid-base status
- Sputum for bacterial culture, Gram stain, and acid-fast bacilli
- Purified protein derivative (PPD) testing
- Drug screen: If appropriate
- ECG: Determine presence of right ventricular hypertrophy.
- ESR, CRP, other rheumatologic studies if suspected

Imaging

- Chest radiograph, both anteroposterior and lateral: May reveal pleural effusion, bronchiectasis, foreign bodies, or consolidation. Fleeting alveolar infiltrates suggest pulmonary hemorrhage.
- CT: Useful when chest radiographs and fiberoptic bronchoscopy are normal. High-resolution CT may identify an area of bleeding, especially if bronchiectasis and arteriovenous malformation are suspected.
- Angiogram or CT angiograms: Used to detect bleeding from a vascular malformation or pulmonary embolism
- Ventilation–perfusion scans: Important studies in patients suspected of having hemoptysis from pulmonary embolism or infarct

Diagnostic Procedures/Other

- Flexible fiberoptic bronchoscopy:
 - Usually performed to localize the site of bleeding. Preferred if bleeding is distal or if alveolar bleeding is suspected, such as in alveolar hemorrhage due to capillaritis or pulmonary hemosiderosis
 - Fiberoptic bronchoscopy performed acutely (during hemoptysis or within 48 hours of event) is more likely than delayed bronchoscopy to visualize and stop active bleeding.
- Rigid bronchoscopy has the advantage of providing a means of airway stabilization, ventilation, and oxygenation while identifying and treating the source of bleeding or airway obstruction (clot, hemangioma) if the lesion is proximal, or to perform a therapeutic intervention (e.g., foreign body removal).

DIFFERENTIAL DIAGNOSIS

- Infections: Pneumonia, pulmonary abscess, tuberculosis, bronchitis
- Pulmonary disease: Cystic fibrosis, bronchiectasis, foreign body aspiration, arteriovenous malformation, congenital lung malformation, pulmonary emboli, pulmonary hemosiderosis, alveolar capillaritis, aspiration, isolated unilateral pulmonary agenesis
- Cardiovascular disease: Congenital heart malformations, pulmonary hypertension
- Collagen vascular disease: Systemic lupus erythematosus, vasculitis, Goodpasture disease, Wegener granulomatosis
- Trauma
- Coagulation disorder
- Munchausen syndrome
- Bronchogenic cysts, neoplasms, hemangiomas

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Initial management should follow the lines of basic life support.
- Support IV volume with packed RBCs or fresh frozen plasma.
- Methods used to stop localized bleeding include tamponade with balloon-tipped catheters, ice water lavage, local instillation of epinephrine, catheter-directed umbilication, IV vasopressin, and surgical resection. Surgical resection is usually reserved for the most difficult cases, such as extensive collateralization of bronchial arteries or arteriovenous malformations unresponsive to embolization. The most effective nonsurgical treatment is bronchial artery embolization. Some newer techniques include endoscopic instillation of fibrinogen/thrombin and endobronchial argon plasma coagulation.

**ONGOING CARE****PROGNOSIS**

- Depends on the cause and nature of hemoptysis
- Immediate airway management decreases morbidity and mortality.

COMPLICATIONS

- Respiratory insufficiency
- Acute airway obstruction
- Hypovolemic shock
- Anemia
- Pneumonia
- Death

786.30 Hemoptysis, unspecified

ICD10

R04.2 Hemoptysis

HENOCH-SCHÖNLEIN PURPURA

Blaze Robert Gusic

BASICS

DESCRIPTION

Henoch-Schönlein purpura (HSP) is an immunologically mediated, nonthrombocytopenic, purpuric, and systemic vasculitis involving the small blood vessels of the skin, gastrointestinal (GI) tract, joints, and kidneys.

- Defined by the presence of 2 of the following:
 - Palpable purpura
 - Age of onset <20 years
 - Abdominal pain
 - Granulocytic infiltration of vessel walls
- In children, only palpable purpura with normal platelet count needs to be documented. Although most children do have purpura, colicky abdominal pain, and arthritis, up to 1/2 may present with symptoms other than purpura.

EPIDEMIOLOGY

Incidence

Incidence of 13.5 cases per 100,000 school-aged children per year (90% of patients are <10 years)

RISK FACTORS

Genetics

- There is only anecdotal evidence of genetic predisposition.
- Familial history of IgA-related disorders or inherited defects in complement (C2, C4 deficiency) may predispose to HSP.

PATHOPHYSIOLOGY

- Capillaries, arterioles, and venules are affected in HSP as opposed to polyarteritis nodosa, Wegener granulomatosis, and systemic lupus erythematosus (SLE), where small arteries are affected.
- Biopsy of the involved kidneys shows endocapillary proliferative glomerulonephritis involving endothelial and mesangial cells. Crescent formation may also be present. IgA, IgG, C3, and fibrin are commonly found in the mesangial regions.
- Considered to be an immune-mediated vasculitic disorder involving primarily IgA, specifically subclass IgA1. This is indirectly suggested by the elevation of serum IgA levels, circulating IgA immune complexes, IgA rheumatoid factor, IgA–fibronectin complexes, and immunoregulatory abnormalities involving IgA production.
- IgA from mucosal B cells interacts with IgG to form immune complexes that activate the alternate pathway of the complement system. Circulating IgA is deposited in the affected organs causing the inflammatory process.

ETIOLOGY

- No single etiologic agent has been identified.
- Most cases associated with preceding upper respiratory tract infections (URIs), usually group A *β*-hemolytic streptococci. A recent study shows a significant association with *Bartonella henselae*. Also reported following infections with parvovirus, adenovirus, hepatitis A virus, *Helicobacter pylori*, and *Mycoplasma pneumoniae*. Parvovirus B19 previously proposed, but evidence is inconclusive
- Also reported after drug ingestion (e.g., thiazides) and insect bites

DIAGNOSIS

HISTORY

- Previous disease: Especially infections such as hepatitis, URI, and streptococcal infections
- Abdominal pain: Pain is the most common GI tract symptom. 2/3 of children have GI tract symptoms. Emesis and melena are also reported.
- Transient, nondeforming, nonmigratory arthritis of knees, ankles, wrists, elbows, and digits is a frequent problem, and most common in knees and ankles.
- Presence of testicular pain or scrotal swelling, headache, cough, edema of the ankles or periorbital region, and hematuria suggests vasculitic lesions in the associated system.

PHYSICAL EXAM

- Particular attention to BP: Hypertension is common.
- Low-grade fever is present in 50% of the cases.
- Rash that is petechial or purpuric in a pressure-dependent, symmetric distribution, usually around the lateral malleoli of the ankles, on the ventral surfaces of the feet, and on the buttocks:
 - Purpura may be briefly preceded by maculopapular or urticarial lesions.
 - Lesions may ulcerate or present as hemorrhagic bullae.
- Joints should be examined for swelling and limitation of motion: Redness and warmth are not common. Symptoms precede the rash by up to 2 weeks in 25% of patients.
- Nonpitting subcutaneous edema of the scalp, periorbital region, hands, and feet is often noted:
 - Generalized edema is more common in children <3 years. The edema may lead to acute hemorrhagic edema, now considered to be a variant of HSP.
- Abdomen is often tender to palpation, but without rebound tenderness. Hepatosplenomegaly may be found. Because intussusception and appendicitis are possible complications, serial examinations may be necessary to determine if radiographic studies are indicated:
 - Abdominal symptoms may precede the rash by up to 2 weeks.
 - Symptoms of pancreatitis may appear after the onset of the rash, but pancreatitis has been reported as a rare presenting symptom.
- Orchitis, where affected testicle may be tender and swollen:
 - Swelling and bruising may be noted on the scrotum.
 - Testicular torsion has also been reported in HSP and may mimic orchitis.
- Neurologic changes:
 - CNS involvement may present with headaches, seizures, or behavioral changes.
 - Guillain-Barré syndrome has been reported.

DIAGNOSTIC TESTS & INTERPRETATION

There are no definitive diagnostic tests.

Lab

- CBC:
 - Normal platelet count differentiates from thrombocytopenic purpura. Hemoglobin is usually normal; leukocytosis; (especially eosinophilia), may be present.
- ESR: Normal or elevated
- Prothrombin (PT) and partial thromboplastin time (PTT): Normal
- IgA: Often elevated in the acute phase of illness, with normal or increased IgG and IgM
- C3: Normal (decreased in poststreptococcal glomerulonephritis and SLE)
- Antinuclear antibody: Negative (elevated in SLE)
- Von Willebrand factor antigen elevated with active HSP due to endothelial damage
- Throat swab for group A *β*-hemolytic streptococci: Positive in up to 75% of cases
- Serum basic/comprehensive chemistries: Elevated BUN and creatinine levels and decreased protein and albumin are seen with renal involvement.
- Urinalysis: Gross hematuria and proteinuria are present in many patients. Proteinuria alone is rare. Microscopic blood, RBCs, WBCs, and casts suggest glomerulonephritis.
- Stool guaiac: GI tract involvement may present as guaiac-positive stools, bloody stools, or melena. Important to have a low suspicion for intussusception, which is a known complication of HSP

Imaging

- Chest radiograph: May show interstitial lung disease
- Abdominal ultrasound: May be helpful if intussusception or appendicitis suspected
- Barium enemas are *not* indicated for suspected intussusception:
 - They will not reduce the ileoileal intussusception common to HSP (idiopathic intussusception is usually ileocolic in location) and may damage or perforate the inflamed bowel.
- Testicular ultrasound if torsion of the testes or appendix testes, known complications of HSP, suspected on clinical exam

Diagnostic Procedures/Other

- Renal biopsy: With severe renal failure, a biopsy should be performed to determine the extent of disease.
- Skin biopsy (optional): Direct immunofluorescence for IgA helpful in confirming the diagnosis

DIFFERENTIAL DIAGNOSIS

- Petechial and purpuric rashes seen in thrombocytopenia from:
 - Idiopathic thrombocytopenic purpura (ITP)
 - Sepsis/infection: Meningococcemia, Rocky Mountain spotted fever
 - Leukemia
 - Hemolytic uremic syndrome (HUS)
 - Coagulopathies

- Vasculitic rashes may result from primary and secondary vasculitides:
 - Polyarteritis nodosa
 - Wegener granulomatosis
 - Infection related
 - Connective tissue diseases (e.g., SLE), Berger disease (IgA nephropathy): Glomerulonephritis similar to HSP both clinically and immunologically, but not associated with the skin, GI tract, or joint manifestations of HSP streptococcal glomerulonephritis
 - Infantile acute hemorrhagic edema: Vasculitis that presents with urticarial or maculopapular rash, which then becomes purpuric. It is differentiated from HSP in that it usually affects children from 4 months to 2 years of age, is more common in the winter, and is not associated with systemic symptoms. On biopsy, IgA deposits are not as consistent a finding as they are with HSP.
- Rheumatoid arthritis
- Rheumatic fever

TREATMENT

ADDITIONAL TREATMENT

General Measures

HSP usually resolves spontaneously without specific therapy:

- Analgesics and NSAIDs may be used for control of joint pain and inflammation, but salicylates and other agents that affect platelet function should be avoided if GI tract bleeding is present.
- Steroids are used for painful cutaneous edema, arthritis, and abdominal pain (2 mg/kg/d of prednisone until clinical resolution); however, steroids have not been shown to affect purpura or to decrease duration of disease or frequency of recurrences:
 - No consensus on management of GI and renal involvement. Oral prednisone at 2 mg/kg/d has shown faster resolution of abdominal pain, whereas other studies indicate that the symptoms will resolve similarly without intervention.
 - Steroids may mask associated problems such as intussusception and bowel perforation.
 - In nephritis, immediate treatment with steroids may prevent more serious renal disease; however, most will improve spontaneously. Treatment should be considered for children at high risk for chronic renal insufficiency or failure (those presenting with nephrotic syndrome or renal insufficiency).
- > 50% crescentic glomerulonephritis on renal biopsy has a greater risk of future renal failure. Such cases should be considered for aggressive therapy with pulse or oral steroids and/or immunosuppressants (azathioprine, cyclophosphamide, cyclosporine) or plasmapheresis, intravenous immunoglobulin (IVIG), danazol, or fish oil.
- Treatment of hypertension may delay or prevent progression of renal disease in patients with glomerulonephritis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients should be seen weekly during the acute illness. Visits should include history and physical exam, along with BP measurement and urinalysis.
- All patients, even those who did not present with renal involvement, should have urine checked for blood weekly for 6 months and then monthly for 3 years because deterioration of renal function has been observed years after presentation in some patients.
- Women with a history of HSP should be monitored for proteinuria and hypertension during pregnancy.

PROGNOSIS

- Generally excellent: Most (>60%) children are better within 4 weeks of the onset.
- Better prognosis associated with younger age
- Recurrence within the 1st 6 weeks in up to 40%, usually as rash and abdominal pain
- No laboratory or clinical findings have been found to be predictive of recurrence.
- Most have only 1–3 episodes of purpura; however, a few will continue to experience symptoms for months or years. These patients have a poor prognosis and are more likely to develop severe nephritis.
- GI tract disease accounts for the most significant morbidity in the short term.
- Renal involvement is the cause of the most serious long-term morbidity. Microscopic hematuria alone or with mild proteinuria generally has a good outcome. A nephritic and nephrotic combination is more guarded, and those patients with a high percentage of crescent formation have worse outcomes.

COMPLICATIONS

- Persistent hypertension
- End-stage kidney disease (acute or as a late sequela)
- Intussusception (most common GI tract complication; affecting 1–5% of patients)
- Protein-losing enteropathy
- Hemorrhagic pancreatitis
- Hydrops of the gallbladder
- Strictures of the esophagus and ileus
- Bowel perforations, ischemia, and infarctions
- Pseudomembranous colitis
- Appendicitis
- Skin necrosis
- Subarachnoid, subdural, and cortical hemorrhage and infarction
- Peripheral mononeuropathies and polyneuropathies (Guillain-Barré syndrome)
- Pulmonary hemorrhage (uncommon, but may result in death)
- Torsion of the testis and appendix testes, and priapism
- Renal failure and hypertension, which can develop up to 10 years after onset of disease
- Scrotal swelling and pain

FAQ

- Q: When should I consider hospitalization for HSP?
- A: Often it is not necessary. Severe complications may require admission. These include GI hemorrhage, protein-losing enteropathy requiring total parenteral nutrition (TPN), decreased glomerular filtration rate (GFR) or hypertension, and pulmonary hemorrhage.
- Q: Is there a role for prophylactic penicillin?
- A: In patients with frequent relapses in whom group A β -hemolytic streptococci is often the inciting agent, administration of penicillin may be helpful.
- Q: Who are Henoch and Schönlein?
- A: The clinical finding of joint pain associated with purpura was named “purpura rheumatica” in 1837 by Schönlein. Henoch, a student of Schönlein’s, later described the association of GI tract and renal involvement. However, the 1st report was by Heberden in 1801. Of note, it has been speculated that Mozart—whose symptoms included fever, vomiting, exanthem, arthritis, anasarca, and coma—died of HSP.

HEPATIC FAILURE

Charles Vanderpool

Lynette A. Gillis

BASICS

DESCRIPTION

- A set of criteria has been proposed to diagnose acute hepatic failure in the pediatric population:
 - Biochemical evidence of liver injury
 - No previous history of chronic liver disease
 - Coagulopathy not responsive to vitamin K administration
 - International normalized ratio (INR) > 1.5 in presence of encephalopathy or INR > 2 without encephalopathy
- In older children and adolescents, in whom hepatic encephalopathy can be more easily assessed, acute hepatic failure may more simply be defined as:
 - Onset of encephalopathy < 8 weeks after the onset of symptoms referable to liver dysfunction in a patient without preexisting liver disease

EPIDEMIOLOGY

- Prevalence of specific causes is often age-dependent and may vary based on geographic region.
- In infants and children < 3 years of age, indeterminate and metabolic etiologies predominate.
- In older children and adolescents, drug-induced toxicity, especially acetaminophen, becomes more common.
- Infectious etiologies, especially viral hepatitis, vary in prevalence based on geographic region.

PATHOPHYSIOLOGY

Hepatocellular necrosis leads to release of growth factors that promote hepatic regeneration:

- Hepatic failure may become irreversible if:
 - The initial insult overcomes the liver's regenerative capacity.
 - The offending agent or derangement is not eliminated or corrected.
 - Secondary complications, such as shock or disseminated intravascular coagulation (DIC), lead to further injury.

ETIOLOGY

The major causes of acute liver failure can be grouped into the following broad categories:

- Indeterminate
- Drug Induced/Toxin: Acetaminophen, nonacetaminophen drug toxicity
- Metabolic/Genetic
- Infectious
- Vascular/Ischemic
- Malignancy
- Autoimmune

DIAGNOSIS

HISTORY

- Age: May suggest possible etiologic subgroup
- Toxin exposure: Prescription, over-the-counter, herbal, or supplemental medications
- Symptoms of viral prodrome
- Travel history, exposure history
- Length of symptoms, acuity of onset
- Associated symptoms/ROS:
 - Bleeding, bruising
 - Weakness, fatigue
 - Abdominal distension, pain, diarrhea
 - Pruritus secondary to cholestasis

PHYSICAL EXAM

- Skin: Jaundice, bruising
- Eyes: Scleral icterus
- Abdomen: Hepatomegaly, ascites with dullness to percussion or fluid wave, splenomegaly
- Neurologic:
 - Sequential mental status exams are paramount to monitor for change and should include age-appropriate questions.
 - Assess for presence of encephalopathy:
 - Grade I: Confused, altered sleep habits; reflexes normal, may have tremor or apraxia
 - Grade II: Drowsy, inappropriate behavior; hyperreflexic or asterixis; dysarthria or ataxia
 - Grade III: Stupor but may obey simple commands, sleepy; hyperreflexic, asterixis, Babinski positive; increased general tone
 - Grade IV: Comatose; reflexes absent; decerebrate or decorticate posturing

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Abdominal ultrasound with Doppler: Visualization of both hepatic parenchyma and vasculature (direction of portal flow, presence of thrombosis)
- Abdomen/Pelvic CT with or without contrast depending on renal function
- Head CT scan without IV contrast in presence of encephalopathy or neurologic signs to rule out intracranial hemorrhage or cerebral edema

Diagnostic Procedures/Other

- Comprehensive metabolic panel:
 - Hepatocellular injury: Aminotransferases (AST, ALT) often are markedly elevated, degree of elevation may depend upon mechanism and time frame of injury
 - Biliary injury/obstruction: Elevated alkaline phosphatase, gamma glutamyl transpeptidase (GGT), total/direct bilirubin
- Assessment of hepatocellular synthetic function:
 - Prolonged PT/INR (with adequate supply of vitamin K)
 - Depressed factor V, VII levels
 - Hypoalbuminemia
 - Hypoglycemia: Frequent glucose measurements should be followed during initial evaluation and should be checked with any mental status or neurologic change.

- Encephalopathy: Ammonia level (has not been proven to correlate directly to presence or grade of encephalopathy)
- Tests to determine etiology:
 - Toxin: Urine or serum drug screen, serum acetaminophen and aspirin level
 - Infectious: Hepatitis virus serologic testing, comprehensive viral cultures; PCR testing for EBV, CMV, HSV and other viruses; antibody tests
 - Autoimmune hepatitis: Antinuclear, anti-smooth muscle, anti-f-actin and anti-LKM antibodies
 - Wilson disease: Decreased serum ceruloplasmin (may not be reliable in setting of acute liver failure), increased serum or urinary copper, evidence of hemolysis (oxidative stress from serum copper)
- Liver biopsy: Timing and approach depends on clinical stability, platelet level, presence of coagulopathy or ascites.

DIFFERENTIAL DIAGNOSIS

The cause of hepatic failure can be indeterminate in up to 50% of cases. Etiologic subgroups include:

- Drug-induced/Toxin:
 - Acetaminophen: Most common in older children and adolescents
 - Salicylates
 - Iron compounds
 - Anticonvulsants
 - Isoniazid
 - Ethanol
 - Antibiotics
 - *Amanita* species (mushrooms)
- Metabolic/Genetic/Miscellaneous: Early infancy:
 - Galactosemia
 - Tyrosinemia
 - Neonatal hemochromatosis
 - Storage diseases
 - Mitochondrial disorders
 - Fatty acid oxidation disorders
 - Hereditary fructose intolerance
- Metabolic/Genetic/Miscellaneous: Childhood/Adolescence:
 - Autoimmune hepatitis
 - Wilson disease
 - Pregnancy (HELLP syndrome, acute fatty liver)
 - Reye syndrome
- Infectious:
 - Hepatitis virus: A, B, E; less commonly C
 - Herpes Virus: HSV, EBV, CMV, VZV, HHV6
 - Echovirus, especially in neonates
 - Parvovirus
 - Adenovirus
- Vascular/Ischemic:
 - Congestive heart failure
 - Hypotensive shock
 - Budd-Chiari syndrome: Hepatic venous outflow obstruction
 - Veno-occlusive disease: Nonthrombotic occlusion of hepatic venules, typically occurs following stem cell transplantation
- Malignancy:
 - Primary: Hepatoblastoma, hepatocellular carcinoma
 - Other: Leukemia, lymphoma, hemophagocytic lymphohistiocytosis
- Heatstroke, hyperthermia, rhabdomyolysis

TREATMENT

MEDICATION (DRUGS)

- Medications should be mixed in fluids without sodium, such as D5 or D10W, whenever possible.
- Hematologic:
 - Coagulopathy should be corrected conservatively in the absence of active bleeding.
 - Vitamin K: Administer IV or SQ/IM for prolonged PT/INR and monitor response with repeat PT/INR 4–6 hours following vitamin K administration.
 - FFP and cryoprecipitate should be reserved for acute severe bleeding; their use prohibits subsequent monitoring of PT/INR or specific factor levels.
 - Recombinant factor VIIa can be used in cases of acute severe bleeding.
- Infectious disease:
 - Prophylactic antibiotics and antifungal medications if febrile, following obtaining cultures from any central venous access or catheterization.
- Renal:
 - Nephrotoxic drugs should be avoided when possible.
 - Renal dose medications if renal compromise present.
 - Renal replacement therapy as indicated, as per nephrology team.
- Neurologic/Hepatic encephalopathy:
 - Sedatives, especially benzodiazepines, should be avoided if possible as they may worsen encephalopathy.
 - Lactulose (oral, enema forms) should be used if encephalopathy present; goal is to acidify stool (pH <6) and increase frequency of stool, but not cause profuse diarrhea.
 - Oral or rectal administration of antibiotics (neomycin, rifaximin) may be effective in treatment of hepatic encephalopathy by reducing ammonia production in the gut. Antibiotic administration has also been studied in prevention of hepatic encephalopathy.
- Other:
 - N-acetylcysteine is the cornerstone of treatment for acetaminophen-induced hepatic toxicity.
 - IV acid suppression should be considered

ADDITIONAL TREATMENT

General Measures

- Patients with acute liver failure should be closely monitored, preferably in an ICU setting at a tertiary-care center with a liver transplant program.
- Therapy should be directed at the underlying cause if a cause can be determined.
- General supportive care:
 - Fluid restriction: Total fluids should remain at or just below maintenance requirements, including all drips, medications, blood products.
 - Sodium restriction: Patients should typically not receive >0.25 NS as maintenance fluids. A total sodium intake of 1.0 mEq/kg/d is usually adequate. Hyponatremia should not be corrected with hypertonic saline as this can worsen fluid overload and encephalopathy.
 - Glucose infusion: Maintenance fluid typically should include 10% dextrose; glucose infusion may need to be increased as patients are at risk for hypoglycemia

- General system-based care:
 - Hematologic: Blood products should be given slowly to avoid rapid expansion of intravascular space.
 - Infectious disease: Minimize invasive catheterization when possible due to infection risk.

SURGERY/OTHER PROCEDURES

- Those likely to require liver transplantation include children with acute liver failure secondary to indeterminate cause, idiosyncratic drug toxicity, or Wilson disease.
- Those likely to have spontaneous recovery include children with autoimmune hepatitis, acetaminophen toxicity without severe acidosis, or ischemic shock.
- 1-year patient and graft survival is excellent, often >90%. Long-term survival >1 year is also typically excellent, from 70–85% or higher 4-year survival.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Initial evaluation should include assessment of neurologic status.
- Elective intubation should be considered in grades III or IV encephalopathy with somnolence.
- Aggressive initial fluid resuscitation should be avoided unless there is evidence of hemodynamic compromise.
- Secure venous access should be obtained immediately; central venous access should be considered to allow for higher glucose infusion rates if needed.

ONGOING CARE

PROGNOSIS

- King's College Criteria have been used to predict a poor prognosis in patients with acetaminophen-induced acute liver failure:
 - pH <7.3 regardless of encephalopathy grade OR
 - All of: PT >100 sec (INR >6.5), serum creatinine >3.4 g/dL, stage III or IV encephalopathy
- There is no consensus regarding prognostic criteria in patients in non-acetaminophen-induced liver failure. Factors associated with a poor prognosis include:
 - Factor V levels <10%
 - PT >50 sec (INR >3.5), especially if unresponsive to vitamin K
 - Grade III or IV encephalopathy
 - Duration of jaundice to encephalopathy >7 days
 - Ratio of total to direct bilirubin >2

COMPLICATIONS

- Complications are a direct consequence of loss of hepatic metabolic function:
 - Hepatic encephalopathy: Decreased elimination of neurotoxins or depressants
 - Cerebral edema: Pathogenesis incompletely understood
 - Coagulopathy: Failure of hepatic synthesis of clotting and fibrinolytic factors
 - Hypoglycemia: Impaired glucose synthesis and release, decreased degradation of insulin
 - Acidosis: Failure to eliminate lactic acid or free fatty acids

- In cases of suspected hepatic encephalopathy, consider other etiologies of neurologic change including hypoglycemia, intracranial hemorrhage, acute infection, or sepsis
- There is often rapid progression through the stages of encephalopathy. Increased intracranial pressure can develop quickly and can lead to irreversible neurologic sequelae.

- K72.90 Hepatic failure, unspecified without coma
- K72.91 Hepatic failure, unspecified with coma

HEPATOMEGALY

John M. Good

BASICS

DEFINITION

Liver enlargement beyond age-adjusted normal values; can be a common component of many diverse disease processes seen in infants and children.

- In children <2 years of age, the liver edge can extend 1–3 cm below the right costal margin in the midclavicular line.
- In older children, the liver edge rarely extends beyond 2 cm.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Congenital/anatomic

- Alagille syndrome
- Biliary atresia
- Choledochal cyst
- Congenital hepatic fibrosis
- Obstruction of the common bile duct due to stones, strictures, or tumors

• Infections

- Viral infections:
 - Hepatitis types A–E
 - Cytomegalovirus
 - Epstein–Barr virus
 - Coxsackievirus
- Congenital infections:
 - Toxoplasmosis
 - Rubella
 - Cytomegalovirus
 - Herpes
 - HIV
- Parasitic infections:
 - Amebiasis
 - Flukes
 - Schistosomiasis
 - Malaria
- Fungal diseases:
 - Candidiasis
 - Histoplasmosis
- STDs:
 - Gonococcal perihepatitis
 - Syphilis
 - HIV
- Zoonotic diseases: Brucellosis
- Leptospirosis
- Hepatic abscess
- *Bartonella henselae*
- *Pasteurella multocida*
- Tuberculosis
- Septicemia

• Toxic, metabolic, drugs

- Drug-induced hepatitis:
 - Acetaminophen
 - Alcohol
 - Corticosteroids
 - Erythromycin
 - Hypervitaminosis A
 - Iron
 - Isoniazid
 - Nitrofurantoin
 - Oral contraceptives
 - Phenobarbital
 - Valproate

• Trauma

- Hemorrhage
- Subcapsular hematoma
- Traumatic cyst

• Tumor

- Benign tumors:
 - Hemangioma
 - Hemangioendothelioma
 - Mesenchymal hamartoma
 - Focal nodular hyperplasia
 - Adenoma
- Malignant tumors:
 - Hepatoblastoma
 - Hepatocellular carcinoma
- Metastatic tumors
- Histiocytic disease

• Genetic/metabolic

- α -1-Antitrypsin deficiency
- Amyloidosis
- Beckwith–Wiedemann syndrome
- Chédiak–Higashi syndrome
- Crigler–Najjar syndrome
- Cystic fibrosis
- Diabetes mellitus
- Galactosemia
- GM1 gangliosidosis
- Glycogen storage diseases
- Hemochromatosis
- Hereditary fructose intolerance
- Homocystinuria
- Lipidoses
- Mucopolysaccharidoses
- Urea cycle defects
- Wilson disease
- Zellweger syndrome

• Allergic/inflammatory

- Chronic active hepatitis
- Sclerosing cholangitis
- Sarcoidosis
- Systemic inflammatory disease:
 - Juvenile rheumatoid arthritis
 - Systemic lupus erythematosus
 - Inflammatory bowel disease

• Miscellaneous

- Congestive heart failure (CHF)
- Extramedullary hematopoiesis
- Pulmonary hyperinflation
- Restrictive pericarditis
- Veno-occlusive disease
- Malnutrition
- Reye syndrome
- Total parenteral nutrition

ALERT

Indications for immediate hospitalization include:

- Persistent anorexia and vomiting
- Mental status changes
- Worsening jaundice
- Relapse of symptoms after initial improvement
- Known exposure to a liver toxin
- Rising PT
- Rising ammonia level
- Bilirubin >20 mg/dL
- Aspartate aminotransferase >2,000
- Development of new ascites
- Hypoglycemia
- Leukocytosis and thrombocytopenia

ETIOLOGY

- Most cases of hepatic failure in children are due to acute viral hepatitis.
- Toxic exposure accounts for 25% of cases, with the most common drug being acetaminophen.

HISTORY

A detailed history and physical exam will direct the practitioner to any additional laboratory testing or appropriate radiologic evaluation.

- **Question:** Prenatal history suggesting possible toxoplasmosis, other, rubella, cytomegalovirus, or herpes (TORCH) infection or HIV infection?
- **Significance:**
 - TORCH infections and HIV may cause hepatomegaly.
 - Liver involvement with HIV is usually secondary to disseminated opportunistic infections or neoplastic processes, rather than from the primary infection itself.
- **Question:** Any transfusions received before 1990?
- **Significance:** Hepatitis C is the most common cause of transfusion-associated hepatitis.
- **Question:** History of sexual activity or IV drug use?
- **Significance:** Consider not only hepatitis B and HIV, but also gonococcal perihepatitis (Fitz-Hugh–Curtis syndrome) and syphilis
- **Question:** Foreign travel?
- **Significance:** Suggests increased risk for parasitic infections or liver abscess
- **Question:** Contaminated shellfish?
- **Significance:** Has been the source of several large outbreaks of hepatitis A
- **Question:** Nonprescription and recreational drug use?
- **Significance:** Many pharmaceuticals have hepatotoxic side effects; ask about vitamin A, alcohol, and certain mushroom species, which can be hepatotoxic.

- **Question:** Other chronic illnesses?
- **Significance:**
 - Patients with heart disease may have liver enlargement due to CHF failure.
 - Patients with cystic fibrosis can have focal biliary cirrhosis.
 - Patients with diabetes mellitus often have hepatomegaly secondary to increased glycogen secretion.
 - Severely anemic patients have hepatomegaly because of extramedullary hematopoiesis.
- **Question:** Total parenteral nutrition?
- **Significance:** Cholestasis, bile duct proliferation, fatty infiltration, and early cirrhosis are all well-described complications.
- **Question:** Pruritus?
- **Significance:** Can be a subtle sign of cholestasis

PHYSICAL EXAM

- **Finding:** Liver edge?
 - **Significance:**
 - In children <2 years of age, the liver edge can extend 1–3 cm below the right costal margin in the midclavicular line.
 - In older children, the liver edge rarely extends beyond 2 cm.
 - Verify all suspected cases of hepatomegaly by checking the liver span.
- **Finding:** Signs of chronic liver disease?
 - **Significance:**
 - Liver is usually firm and enlarged, although actually may decrease in size eventually with advanced disease.
 - Splenomegaly, caput medusae, spider angiomas, esophageal varices, and hemorrhoids suggest portal hypertension.
 - Ascites may develop as a result of elevated hydrostatic pressures and decreased oncotic pressures secondary to hypoalbuminemia.
 - Also look for signs of occult bleeding or bruising due to impaired vitamin K production.
- **Finding:** Splenomegaly?
 - **Significance:**
 - In the context of chronic liver disease, implies portal hypertension
 - In the context of other signs of viral illness, such as adenopathy, fever, malaise, and pharyngitis, suggests acute viral hepatitis
 - In the absence of these signs, suggests storage disease or hematologic malignancy
- **Finding:** Conditions that may mimic hepatomegaly by downwardly displacing a normal-sized liver?
 - **Significance:**
 - Pulmonary hyperinflation
 - Subdiaphragmatic abscesses
 - Retroperitoneal mass lesions
 - Rib cage anomalies
- **Finding:** Clinical pearls?
 - **Significance:**
 - Until age 2, girls have a slightly larger liver span than boys.
 - A Reidel lobe is a normal variant in which the right lobe of the liver appears elongated due to its adhesion to the mesocolon.
 - Administration of vitamin K in an attempt to correct PT can be a valuable assessment of the liver's synthetic function.
 - Fetus hepaticus is a sweetish odor that can be detected on the breath and urine of patients with liver failure.
 - Asterix or liver flap is rare in children.

DIAGNOSTIC TESTS & INTERPRETATION

All patients with hepatomegaly should have a laboratory evaluation, including CBC with differential, comprehensive metabolic panel (including liver function tests, total protein and albumin, total and direct bilirubin, basic electrolytes and glucose), a PT, and a PPT.

- **Test:** CBC with differential
- **Test:** Aminotransferase and alanine aminotransferase
 - **Significance:**
 - Elevations reflect the amount of damage to hepatocytes.
 - Elevations > 1,000 indicate severe damage.
- **Test:** PT and PTT
 - **Significance:**
 - Good indicators of the liver's synthetic function
 - Elevations can occur with an acute injury or illness.
 - Combined with albumin level, this test can be a sensitive indicator of chronic liver disease as well.
- **Test:** γ -Glutamyltransferase and alkaline phosphatase
 - **Significance:**
 - Elevations of γ -glutamyltransferase out of proportion to elevations in aminotransferase and alanine aminotransferase can indicate an obstructive or infiltrative abnormality.
 - If an elevated γ -glutamyltransferase is associated with elevations in bilirubin, cholesterol, and alkaline phosphatase, an obstructive process is more likely.
- **Test:** Ammonia level
 - **Significance:** Rising ammonia levels with a prolongation of the PT and PTT suggest liver failure.
- **Test:** Hepatitis profile
 - **Significance:** Should be obtained in all patients with appropriate prodromal illness
- **Test:** Mono spot
 - **Significance:**
 - Although this is a nonspecific heterophile antibody test for Epstein–Barr virus infection, it can be predictive in association with an elevation of the atypical lymphocyte count.
 - High false-negative rate in children <4 years of age
 - Epstein–Barr virus titer is the only confirmatory test.
- **Test:** α -Fetoprotein and carcinoembryonic antigen
 - **Significance:** Tumor markers for hepatoblastoma and hepatocellular carcinoma, respectively
- **Test:** TORCH titers
 - **Significance:** Consider in newborns with hepatomegaly
- **Test:** Serum immunoglobulins, antinuclear antibody, smooth muscle antibody, antimicrosomal antibody
 - **Significance:** Additional autoimmune evaluation is indicated for those patients with chronic active hepatitis.
- **Test:** Serum ceruloplasmin level and urinary excretion of copper
 - **Significance:**
 - Decreased ceruloplasmin levels and increased urinary excretion of copper characterize Wilson disease, especially after the administration of oral d-penicillamine.
 - Consider the diagnosis for patients with unexplained liver disease

Imaging

Abdominal ultrasound should be performed on all patients with acholic stools, asymmetric liver enlargement, or abdominal mass.

- 789.1 Hepatomegaly

ICD10

- R16.0 Hepatomegaly, not elsewhere classified
- Q44.7 Other congenital malformations of liver

FAQ

- Q: Why does cholestasis cause pruritus?
- A: This probably reflects an abnormal accumulation of bile acids in the skin.
- Q: Do patients with chronic liver disease have any different nutritional needs?
- A: Patients may have impaired fat absorption, and therefore may have deficiencies of fat-soluble vitamins A, D, E, and K, which may become evident as anemia, neuropathy, rickets, pathologic fractures, visual disturbances, or skin changes. Also consider supplementing the diet with medium-chain triglycerides, which are more easily absorbed. There may also be higher than normal requirements of trace minerals.
- Q: What is the etiology of cholestasis caused by total parenteral nutrition?
- A: Certain amino acids present in total parenteral nutrition have been shown to increase the serum levels of bile acids, which may in turn affect peristalsis in the gallbladder. Fasting may also decrease the normal hormonal stimulation of bile secretion.

HEREDITARY ANGIOEDEMA

Mathew Fogg

BASICS

DESCRIPTION

Hereditary angioedema is an autosomal-dominant disorder in which mutations in the *C1-INH* (C1 esterase inhibitor) gene results in a deficiency or an inactive form of plasma C1-INH. This permits unregulated activation of the complement and plasma kinin-forming pathways, leading to angioedema.

RISK FACTORS

Genetics

- Autosomal dominant
- Mutations may be present in either of 2 genes for C1-INH, located on chromosome 11.
- Acquired forms lack a genetic predisposition (there is no mutation in the *C1-INH* gene).

PATHOPHYSIOLOGY

- Deficiency of C1-INH leads to unopposed activation of the first complement component, resulting in the formation of bradykinin, which produces angioedema.
- Angioedema may occur in the upper airway, gastrointestinal tract, and extremities.
- Life-threatening upper airway obstruction may develop.

ETIOLOGY

- Classic hereditary form: Defect in 1 of 2 genes on chromosome 11 that code for C1-INH
- Acquired forms:
 - In 1 form, normal amount and functionally normal C1-INH is secreted into the plasma, but it is bound to circulating antibodies that inactivate it (associated with benign and malignant monoclonal B-cell lymphoproliferative disorders).
 - In the other form, an autoantibody not associated with lymphoproliferative disorders binds to C1-INH, resulting in increased degradation of C1-INH.
 - Third form (rare) found exclusively in women of childbearing age, may have normal plasma C1 inhibitor levels and function.

DIAGNOSIS

SIGNS AND SYMPTOMS

Decide if the patient's symptoms are consistent with hereditary angioedema (recurrent angioedema after minor trauma, family history, onset at puberty, lack of hives, poor response to epinephrine).

HISTORY

- Age at onset of recurrent episodes of subcutaneous and submucosal edema (recurrent episodes of angioedema usually begin at puberty)
- Characterize episodes of angioedema. Angioedema episodes are characterized by edema of the upper airway, extremities, or bowels (can cause severe abdominal pain).
- Determine whether angioedema episodes are associated with hives. Episodes of hereditary angioedema are not associated with hives; however, patients may have a nonpruritic erythema marginatum rash.
- Duration of angioedema episodes usually last 1–4 days.
- Triggers:
 - Emotional stress
 - Physical trauma such as surgery or dental procedures
 - Infection
 - Menstruation
 - Pregnancy
 - Estrogen-containing oral contraceptives
- Family history:
 - Angioedema can be inherited in an autosomal-dominant fashion.
 - There may be other affected family members.
- Response to epinephrine, antihistamines, or corticosteroids: Angioedema related to hereditary angioedema responds poorly to epinephrine, antihistamines, and corticosteroids.

PHYSICAL EXAM

Besides angioedema, the physical examination is normal. Erythema marginatum, a nonpruritic eruption, may also be present in patients with hereditary angioedema.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- C1 esterase inhibitor level and function:
 - If C1 esterase inhibitor level is normal and an acquired deficiency is suspected, order a functional assay of C1 esterase inhibitor.
 - Samples for complement assays must be placed on ice immediately; otherwise, the results may be falsely low.

- Direct measurement of C1-INH level and function (study of choice to identify the hereditary form of C1-INH deficiency):
 - This is an antigenic assay.
 - Affected patients may have a minimal quantity of C1-INH detected, and heterozygotes (carriers) have ~1/2 of normal levels detected.
 - Some patients may have normal levels of protein with reduced function.
- C1q level:
 - In acquired C1-INH deficiency, levels of C1q will be reduced.
 - In the hereditary form, C1q will be normal.
- CH50 level:
 - A general screen of the complement system
 - If abnormal, can indicate a deficiency of any of the complement components

DIFFERENTIAL DIAGNOSIS

- Toxic, environmental, drugs (patients on ACE inhibitors)
- Allergic inflammatory:
 - IgE-mediated allergic reactions: Drug, food, and contact allergies
 - Transfusion reaction
- Tumor (associated with neoplasms via unknown mechanism)
- Genetic/metabolic:
 - Urticaria pigmentosa/mastocytosis
 - Familial cold urticaria
 - C3b-inactivator deficiency
 - Amyloidosis with deafness and urticaria
 - Hereditary vibratory angioedema
- Physical/environmental
 - Urticarials: Cold urticaria, cholinergic urticaria, pressure urticaria (angioedema), vibratory angioedema, solar urticaria, aquagenic urticaria
 - Exercise-induced anaphylaxis
- Rheumatologic (collagen vascular disease)
- Psychologic:
 - Panic attacks
 - Globus hystericus
 - Vocal cord dysfunction
- Miscellaneous: Idiopathic angioedema

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Prophylaxis:
 - Anabolic steroids (danazol or stanozolol) cause increased production of C1-INH, resulting in near-normal C2 and C4 levels (decreased degradation by activated C1) and a significantly decreased episode frequency. This therapy is indicated in patients with frequent or life-threatening episodes.
 - Plasmin inhibitors (β -aminocaproic acid or tranexamic acid) do not correct C2 and C4 levels, but are clinically effective.
 - Recombinant C1-INH concentrate is available outside the US and is highly effective. Prior to dental and surgical procedures, doses of androgen should be increased for 1–2 weeks. In addition, some experts recommend treatment with fresh frozen plasma shortly before and immediately after surgery, as this product contains C1-INH.
- Acute attacks:
 - Recombinant C1-INH concentrate is now available in the USA
 - Increase dose of androgen at first symptoms of an attack.
 - Immediately seek medical care; airway should be protected if any compromise is imminent.
 - Intermittent administration of subcutaneous epinephrine (This type of angioedema is usually poorly responsive, but in an emergency situation this may be considered.)
- Medical management: Treatment of the underlying condition often results in resolution of the angioedema.

ISSUES FOR REFERRAL

- Any patient with angioedema: An allergist/immunologist can help evaluate these patients for possible androgen prophylaxis therapy. In addition, they can assist in the creation of an emergency plan for management of acute attacks.
- Patients with difficult-to-control angioedema without an identified trigger: An allergist immunologist can assist with the appropriate evaluation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients should be seen at least annually.
- Follow-up should include the following:
 - Review of triggers
 - Prospective genetic counseling
 - Reinforcement of the need for prophylaxis
 - Review of attacks during the previous year
 - Creation of an emergency plan for the administration of recombinant C1 esterase inhibitor during severe attacks
- Regular follow-up with an endocrinologist is indicated for patients requiring androgen steroid therapy.

PATIENT EDUCATION

Education regarding:

- Role of triggers
- Prospective genetic counseling
- Need for prophylaxis
- Need for regular follow-up with an endocrinologist is indicated for patients who require androgen steroid therapy.

PROGNOSIS

Good with prophylactic and recombinant C1-INH therapies; recombinant C1-INH is not available in the US despite its proven clinical efficacy for treatment of acute attacks.

COMPLICATIONS

- Life-threatening upper airway obstruction
- Severe abdominal pain, often mistaken for a surgical abdomen

CODES

ICD9

- 277.6 Other deficiencies of circulating enzymes
- 279.8 Other specified disorders involving the immune mechanism

ICD10

- D84.1 Defects in the complement system

FAQ

- Q: What is a good screening test for angioedema?
- A: C1 inhibitor functional and quantitative assays are readily available from commercial labs and are the test of choice for hereditary angioedema.
- Q: What are the side effects of prophylactic androgen therapy?
- A: Side effects include masculinization, menstrual irregularities, enhanced epiphyseal growth-plate closure, water retention, hypertension, cholestatic hepatitis, hepatic carcinoma, decreased spermatogenesis, and gynecomastia.

HEREDITARY SPHEROCYTOSIS

Michele P. Lambert

BASICS

DESCRIPTION

Hemolytic anemia with shortened RBC survival owing to selective destruction of RBCs in the spleen secondary to an inherent defect of the RBC membrane. Membrane loss is gradual; it results in spherocytosis, which results in increased osmotic fragility. Pathophysiologically related to Hereditary Elliptocytosis and hereditary ovalocytosis)

EPIDEMIOLOGY

Most common in people of Northern European extraction (~1:3,000)

RISK FACTORS

Genetics

- ~75% of cases are inherited in an autosomal dominant pattern.
- The other 25% are autosomal recessive forms, dominant disease with reduced penetrance, or new mutations.
- Severity related to degree of membrane loss
 - Mild (20% of patients): Hemoglobin near normal, slight reticulocytosis (<6%), compensated hemolysis, mild splenomegaly. Often not diagnosed until adulthood due to gallstones
 - Moderate (60% of patients): hgb 8–10 mg/dL and reticulocytes generally >8%; >50% patients have splenomegaly
 - Moderately severe (10%): hemoglobin 6–8 mg/dL, retic >15%, intermittent transfusions
 - Severe (3–5%): life-threatening anemia requiring regular transfusions. Almost always recessive.

PATHOPHYSIOLOGY

The most common abnormality is a deficiency of ankyrin and subsequent decrease in spectrin, 2 major proteins of the erythrocyte membrane skeleton (50–60% Northern European decent; 5–10% Japan). Spectrin deficiency alone accounts for 20% of HS. Mutations in other erythrocyte surface proteins including beta-spectrin (typically mild to moderately severe), alpha-spectrin (sever HS), Band 3 (15–20% generally mild to moderately severe) and protein 4.2 (<5% HS, recessive and results in almost complete absence) and Rh antigen (<10% mild to moderate hemolytic anemia) also occur. The membrane skeletal defect causes RBC membrane fragility resulting in membrane loss. The sequelae are as follows:

- Loss of cell surface area relative to volume (spherocytosis) causes a decrease in cellular deformability.
- The spleen detains and “conditions” the nondeformable spherocytic RBC.
- Conditioning of cells involves depletion of adenosine 5'-triphosphate (ATP), increased glycolysis, increased influx and efflux of sodium, and loss of membrane lipid.
- Ultimately, these events lead to premature RBC destruction.

DIAGNOSIS

HISTORY

- Fatigue (a sign of anemia)
- Jaundice, scleral icterus, dark urine (signs of hemolysis)
- Phototherapy required in newborn period (50% of cases): Hyperbilirubinemia owing to hemolysis
- Positive familial history (for disease, gallstones, or splenectomy) is significant because of autosomal dominant inheritance.

PHYSICAL EXAM

- Splenomegaly is present in most older patients and may worsen with intercurrent illness.
- Icterus/Jaundice and pallor are present with increased hemolysis.
- Linear growth, weight gain, and sexual development may be delayed. Delayed growth is indication for splenectomy.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC:
 - Mild to moderate anemia
 - Mean corpuscular volume usually normal
 - Mean corpuscular hemoglobin concentration (MCHC) elevated (useful screening test with high specificity)
 - Reticulocyte count: May be only slightly elevated
 - Often accompanied by elevated RBC distribution width
 - Indirect hyperbilirubinemia: Present in 50–60% of cases
 - Peripheral smear: Microspherocytes, polychromasia
- Coombs test: Negative
 - Important differential test in a patient with hemolytic anemia and spherocytes
- Urinalysis:
 - Hemoglobinuria
 - Increased urobilinogen

Special tests:

- Osmotic fragility (most useful test in diagnosis, but can be normal in 10–20% of patients):
 - Spherocytes are more fragile; less resistant to osmotic stress and therefore lyse in higher concentrations of saline than normal RBCs.
 - Test can result in a false-negative, especially in newborns whose RBCs may be more dehydrated and with high fetal hemoglobin
 - Important to use an age-matched control if possible
 - Any anemia that results in spherocytes will give increased osmotic fragility (especially autoimmune hemolytic anemia) and must be excluded.
- Eosin-5-maleimide (EMA) binding: Flow cytometric analysis of RBCs with much higher sensitivity and specificity for HS, but not available at all centers.

DIFFERENTIAL DIAGNOSIS

- Hemolysis secondary to intrinsic RBC defects:
 - Membrane defects secondary to inherited disorders of membrane skeleton (HS and elliptocytosis) and RBC cation permeability and volume (stomatocytosis and xerocytosis)
 - Enzyme defects: Embden-Meyerhof pathway (i.e., pyruvate kinase deficiency) and hexose monophosphate pathway (i.e., glucose-6-phosphate dehydrogenase deficiency)
 - Hemoglobin defects:
 - Congenital erythropoietic porphyria;
 - Qualitative Hemoglobin S (Sickle cell), Hgb C, Hgb H, Hgb M
 - Quantitative: Thalassemias
 - Congenital dyserythropoietic anemias
- Hemolysis secondary to extracorporeal RBC defects:
 - Immune-mediated (important in differential because spherocytes are present on smear and can give increased osmotic fragility if sent): isoimmune (e.g., hemolytic disease of the newborn, blood group incompatibility) and autoimmune (e.g., cold agglutinin disease, warm autoimmune hemolytic anemia)
 - Non-immune-mediated: Idiopathic and secondary to underlying disorder (e.g., hemolytic uremic syndrome, thrombotic thrombocytopenic purpura)

ALERT

- A patient with HS may become extremely anemic during an aplastic crisis, hyperhemolysis episode, or folic acid deficiency, requiring transfusion.
- False-negative osmotic fragility tests can occur in several situations; therefore, index of suspicion must be high to follow the clinical course and repeat test (e.g., in neonatal period, during megaloblastic crisis, and recovery from aplastic crisis after transfusion when cells are youngest and least spherocytic).
- 20–25% of HS patients have normal unincubated osmotic fragility (incubated test almost always positive; therefore, may need both)
- Spherocytes are often present in immune-mediated hemolysis.

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Folic acid supplement
- Penicillin prophylaxis (if splenectomized)
- Pneumococcal, meningococcal, and *Haemophilus influenzae* B vaccines (prior to splenectomy)

SURGERY/OTHER PROCEDURES

Splenectomy: High response rate (most patients normalize their blood counts):

- Indications: Moderate-to-severe anemia with significant hemolysis resulting in transfusion dependence, decreased exercise tolerance, skeletal deformities, or delayed growth
- Complications: Risk of postsplenectomy sepsis, emerging data on increased risk of later pulmonary hypertension and increased risk of thrombosis
 - Cholecystectomy indications: Symptomatic gallbladder disease. Sometimes done simultaneous with splenectomy if gallstones evident by ultrasound
- Complications: Morbidity of surgical procedure and postoperative period

**ONGOING CARE**

Physical exam: Splenomegaly, follow growth curves closely:

- CBC with reticulocyte count as needed: If patient develops fatigue, pallor, increased jaundice
- Penicillin prophylaxis after splenectomy

PROGNOSIS

Severity of disease is extremely variable, ranging from an incidental diagnosis in adulthood to severe anemia requiring transfusions.

COMPLICATIONS

- Gallstones: Most common complication of HS; pigment stones can lead to cholecystitis and/or biliary obstruction.
- Cholelithiasis in HS manifests in second and third decades of life.
- Aplastic crises: Can result in severe life-threatening anemia; often caused by parvovirus B₁₉ infection. Epstein–Barr virus (EBV), influenza, cytomegalovirus (CMV) can also cause worsening anemia and reticulocytopenia
- Hyperhemolysis: Increased RBC destruction, often precipitated by infection
- Postsplenectomy sepsis: Lower risk of infection if postponed until 4–5 years of age and immunized with pneumococcal vaccine (50–70% sepsis caused by *Streptococcus pneumoniae*)
- Folate deficiency: Caused by insufficient dietary intake of folic acid for increased bone marrow requirement. Can result in megaloblastic crisis.
- Pulmonary hypertension: Long-term complication of splenectomy due to recurrent small vessel thrombosis in the lungs (either local clot or thromboembolic events). Long-term risk that weighs against splenectomy in patients with mild or well-compensated disease
- Other rare complications: Gout, indolent leg ulcers, or chronic erythematous dermatitis on legs

FAQ

- Q: Will my child require blood transfusions?
- A: It depends on the clinical severity of your child's disease.
- Q: If a parent has HS, how should the newborn be followed?
- A: The infant has a 50% chance of having HS. In infants with HS, the CBC is usually normal in the first 72 hours of life, but then drops because of an inability to mount an appropriate erythropoietic response to increased destruction. Therefore, infants at risk should have a CBC with reticulocyte count after 72 hours. These infants also need to be monitored closely for hyperbilirubinemia.
- Q: What are the risks and benefits of splenectomy?
- A: Splenectomy is almost always successful in ameliorating anemia, but adds the risk of postsplenectomy infections and later risks for pulmonary hypertension and maybe increased risk of thrombosis and/or cardiovascular disease. The risks and benefits need to be carefully weighed and, in patients with mild, well-compensated hemolysis, splenectomy is not indicated.

HEROIN INTOXICATION

Fran Balamuth

Cynthia J. Mollen (5th edition)

Thomas J. Mollen (5th edition)

BASICS

DESCRIPTION

Heroin is a semisynthetic derivative of opium. The opioid family includes the following:

- Drugs that occur naturally in opium (from the poppy plant)
- Codeine
- Morphine
- Semisynthetic derivatives (e.g., hydromorphone, oxycodone)
- Synthetic compounds (e.g., meperidine, methadone)

EPIDEMIOLOGY

- Neonatal:
 - Fetal exposure commonly involves polysubstance abuse.
 - 60–80% of heroin-exposed infants develop withdrawal: Depends on maternal dosing and length of use.
- Adolescents:
 - Use peaked among U.S. adolescents in the 1970s and then declined.
 - Use is increasing again because a purer product allows for smoking or snorting as well as injecting.
 - Most use experimentally or intermittently; few become addicted and use daily.
 - There have been case reports of adolescents as heroin body packers.
 - Use of opioid analgesics has increased dramatically over the last 10 years, and has become more common than heroin use.
 - ED visits for opioid analgesics increased 111% from 2004–2008: Most common substances were oxycodone, hydrocodone, and methadone.
- Overdose:
 - Up to 1/3 of heroin users experience nonfatal overdose.
 - Most occur in the home and with other people present.
 - Risk factors include length of injecting history and concurrent use of CNS depressants.
- Deaths:
 - Most heroin deaths occur when drug is administered IV.
 - Most deaths occur in patients in their late 20s or 30s, with significant drug dependence.
 - Multiple drug use is common in heroin-related death.
 - Many deaths occur in people with a history of a nonfatal overdose.

Incidence

- Statistically significant increase in new heroin use since 1992
- 114,000 new users in 2008
- Mean age of 1st use in 2001 = 23.3

Prevalence

- Precise estimates of prevalence of use difficult
- ~2.9 million people used at least once
- ~213,000 used in 2008
- Prevalence of fetal exposure <1–3.7%
- Heroin users are more likely to visit EDs than users of other illicit substances.

PATHOPHYSIOLOGY

- Well-absorbed from GI tract, nasal mucosa, pulmonary capillaries, and SC and IM injection sites
- Oral dose less potent than parenteral because of 1st-pass hepatic metabolism
- IV heroin peaks in <1 minute; intranasal and IM heroin peak in 3–5 minutes.
- Very lipid soluble; crosses blood–brain barrier within 15–20 seconds
- Extensive distribution into skeletal muscle, kidneys, liver, intestine, lungs, spleen, brain, and placenta
- Rapidly crosses the placenta, entering fetal tissues within 1 hour
- Crosses into breast milk in quantities sufficient to cause addiction
- Excreted in urine as morphine
- Receptor types:
 - μ (mu or OP3):
 - Located in CNS, GI tract, and sensory nerve endings
 - Effect: Analgesia, euphoria, respiratory depression, physical dependence, GI dysmotility, miosis, pruritus, bradycardia
 - κ (kappa or OP2):
 - Located in CNS
 - Effect: Analgesia, miosis, diuresis, dysphoria
 - δ (delta or OP1):
 - Located in CNS
 - Effect: Spinal analgesia, modulation of mu receptors/dopaminergic neurons

DIAGNOSIS

HISTORY

- Neonate:
 - Maternal history of heroin or other drug use
 - Extent of prenatal care
 - Time from most recent use to delivery
 - Breastfeeding
- Older child/Adolescent:
 - History of heroin use
 - Observed overdose
 - Found in setting consistent with possible drug use

PHYSICAL EXAM

- Neonate with in utero exposure:
 - Prematurity
 - Low birth weight
 - Perinatal depression with 5-minute Apgar <5
 - Hypotonia
- Intoxication/Overdose:
 - Classic toxidrome: Depressed level of consciousness, very decreased respiratory effort, miotic pupils, with or without diminished bowel sounds
 - More severe overdose: Bradycardia, hypotension, noncardiogenic pulmonary edema
- Withdrawal:
 - Early signs (8–24 hours): Anxiety, restlessness, insomnia, yawning, rhinorrhea, lacrimation, diaphoresis, stomach cramps, mydriasis
 - Late signs (up to 3 days): Tremor, muscle spasms, vomiting, diarrhea, hypertension, tachycardia, fever, chills, piloerection, seizures

- Additional neonatal withdrawal signs and symptoms:
 - Hyperirritability
 - Hypertonicity
 - Posturing
 - Exaggerated startle
 - Tachypnea
 - Hyperpyrexia
 - Poor suck/swallow coordination
 - High-pitched cry
 - Poor weight gain
- Timing of neonatal symptoms depends on maternal substance used: Withdrawal from heroin within 48 hours, can be longer for methadone. Delayed withdrawal possible up to 4 weeks with both drugs

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Therapy should not be withheld pending laboratory results.
- Urine toxicology screen (heroin easily detected; synthetic opioids are not)
- Serum toxicology screen for acetaminophen level, etc., if suspect polydrug use
- Serum tests to rule out other causes, if needed (e.g., glucose)
- Meconium testing in neonates

DIFFERENTIAL DIAGNOSIS

- Neonatal exposure:
 - Sepsis
 - Hypoglycemia
 - CNS abnormality
 - Metabolic disorder
 - Withdrawal from other maternal drug use
- Intoxication/Overdose
- Other pharmacologic agents:
 - Clonidine, sedative hypnotics, barbiturates, antipsychotics, γ -hydroxy butyrate
- Hypoglycemia
- Hypothermia
- Hypoxia
- Heatstroke
- Pontine or subarachnoid hemorrhage

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Intoxication/Overdose:
 - Start with the ABCs (airway, breathing, circulation).
 - Antidote is naloxone (Narcan).
 - Assessment of respiratory status/adequacy of ventilation
 - If adequate respiratory effort, observe until normal level of consciousness:
 - Consider naloxone as diagnostic challenge.
 - If inadequate respiratory effort:
 - Bag-valve-mask ventilation
 - IV naloxone (or SC, IM, endotracheal)
 - If <20 kg, 0.1 mg/kg; 2 mg if >20 kg. Can repeat to 10 mg total dose

- If suspect dependence, start with lower dose (0.4 mg ampule)
- If no response to large dose, question diagnosis of heroin toxicity: Heroin is exquisitely sensitive to naloxone
- Naloxone loses efficacy in 20–40 minutes; may need repeat dosing
- Can give as continuous infusion if necessary; dosing recommendations vary
- One method: 2/3 of effective dose given over 1 hour with gradual wean
- Consider low-dose naloxone (0.01 mg/kg) in apneic infants exposed to opiates in utero
- Endotracheal intubation if no response to naloxone in 5–10 minutes, or other reason for invasive airway management
- Observe in ED for a minimum of 2–3 hours for respiratory status stabilization.
- Consider chest radiograph to evaluate for pulmonary edema.
- Consider glucose testing to evaluate for hypoglycemia.
- Consider whole bowel irrigation with Go-Lytely for symptomatic body packers, and consult local poison control center.
- **Withdrawal:**
 - Standard treatment methadone maintenance (adolescents/adults):
 - Blocks euphoria and prevents withdrawal symptoms
 - Patients generally treated in established methadone maintenance programs
 - Buprenorphine is also an option.
 - Stabilize with 20–40 mg/d; wean by 2–5 mg/wk over several months.
 - Adjust wean if signs of withdrawal appear.
 - Some programs utilize heroin maintenance when methadone fails; research ongoing
 - Clonidine (0.2 mg q4–6h for 7–10 days) can control acute withdrawal symptoms.
 - Diazepam (10–15 mg q4–6h for 3–4 days), an alternative to clonidine
 - Rapid and ultra-rapid detoxification (using opioid antagonist with or without general anesthesia) is a possibility in selected patients; recent review suggests high-rate adverse events:
 - Should be used only by experienced team with appropriate resources
- In neonates:
 - Paregoric (0.4 mg/mL) not recommended owing to high alcohol content (45%) and toxic compounds such as camphor, anise oil, benzoic acid, and glycerin
 - Tincture of opium (10 mg/mL) best diluted 25-fold to a concentration equal to paregoric (0.4 mg/mL)
 - 0.1 mL/kg (2 drops/kg) q4h; increase 0.1 mL/kg q4h as needed to control symptoms. After 3–5 days, wean dose by 0.1 mL/kg/d. Observe infant for 3–5 days after stopping therapy.
 - May need IV morphine in severe cases
 - Methadone and buprenorphine have also been shown to be effective
 - Clonidine gaining favor for use in infants; pharmacokinetic data not available; although use is currently recommended only in the context of a randomized clinical trial
 - Phenobarbital not a 1st-choice agent owing to long half-life, CNS depression, induction of drug metabolism, and rapid tolerance to sedative effect; however, has been shown to be effective in conjunction with diluted tincture of opium.

- Infants with opioid withdrawal have elevated metabolic demands: Consider higher-calorie (24 kcal/oz) feeds.
- Breastfeeding is not recommended in mothers using heroin, but can be considered for mothers on methadone treatment.

ISSUES FOR REFERRAL

- Social services and referral to substance abuse program
- Consider referral for testing for HIV and hepatitis B and C.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Most patients with overdose warrant hospitalization.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Developmental follow-up for exposed neonates

PROGNOSIS

- Neonatal:
 - Long-term morbidity from neonatal heroin dependence unclear owing to confounding variables (e.g., developmental environment)
- Intoxication/Overdose:
 - With adequate early treatment, patients with uncomplicated overdoses do well: Key is to prevent respiratory arrest.
- Addiction:
 - Dependent on involvement in other risky behaviors (polydrug use, high-risk sexual practices, school failure, delinquency, etc.)
 - Longer treatment likely produces a better outcome.
 - Most relapses require lifetime of therapy

COMPLICATIONS

- Intoxication/Overdose:
 - Respiratory arrest
 - Noncardiogenic pulmonary edema
 - CNS depression/coma
 - Hypotension
 - Aspiration pneumonia
- Pregnancy:
 - No known teratogenic effects
 - Poor prenatal care
 - Preterm labor
 - Premature rupture of membranes
 - Breech presentation
 - Antepartum hemorrhage
 - Toxemia
 - Anemia
 - Uterine irritability
 - Infection (e.g., HIV, hepatitis B)
 - Infantile dependence
- Naloxone use:
 - May precipitate withdrawal syndrome in opioid-dependent patients
 - Symptoms: Agitation, hypertension, tachycardia, emesis
 - See dosing recommendations.
 - May cause acute severe withdrawal in infants born to addicted mothers

CODES

ICD9

- 304.00 Opioid type dependence, unspecified
- 779.5 Drug withdrawal syndrome in newborn
- E935.0 Heroin causing adverse effects in therapeutic use

ICD10

- F11.23 Opioid dependence with withdrawal
- F11.929 Opioid use, unspecified with intoxication, unspecified
- P96.1 Neonatal withdrawal symptoms from maternal use of drugs of addiction

FAQ

- Q: Is nalmefene an appropriate substitute for naloxone in a heroin overdose?
- A: Nalmefene, a long-acting specific narcotic antagonist, has not proved to be as effective as naloxone in a randomized, double-blind trial. It also may result in prolonged, dangerous withdrawal. It therefore has limited usefulness in this setting.

HERPES SIMPLEX VIRUS

Ross Newman
Jason Newland
Louis M. Bell (5th edition)

BASICS

DESCRIPTION

Herpes simplex virus (HSV) is a moderately large, double-stranded DNA virus. There are 2 serologically distinguishable subtypes: HSV-1 and HSV-2. HSV produces a wide spectrum of illness ranging from fever blisters to fatal viral encephalitis.

GENERAL PREVENTION

- Neonatal infection:
 - The risk of HSV infection in an infant born vaginally to a mother with a first-episode primary genital infection is high (25–60%). The risk to an infant born to a mother with recurrent HSV infection at delivery is much lower (2–5%).
 - Cesarean delivery in a mother with active genital herpes at the time of delivery is the main way to prevent neonatal infection. However, this does not prevent all cases because 60–80% of mothers of infected infants are asymptomatic or have unrecognized infection.
 - A cesarean delivery is not indicated for a mother with a history of genital HSV and absence of lesions at time of delivery
 - Fetal scalp monitors should be avoided in women suspected of genital HSV.
- Postnatal infection:
 - Universal body-substance precaution policies
 - Adults with oral herpes must be particularly careful to use appropriate hygiene.
 - Wrestlers with skin lesions suggestive of herpes
 - Patients with genital lesions from HSV should not have intercourse until the lesions heal.
 - Condoms can prevent the spread of virus.

EPIDEMIOLOGY

- Neonatal infection is usually acquired from the maternal genitourinary tract and causes serious disease with high mortality and morbidity.
- HSV-1 usually causes infections of the upper torso, head, and neck.
- HSV-2 usually causes genital infection. However, both forms can infect oral or genital cells, thus the virus type is not a reliable indicator of the anatomic site of infection.
- Route of spread is usually by close bodily contact or trauma such as teething or a break in the skin.
- Incubation period is 2–12 days (~6 days).
- Neonatal HSV infections are acquired from maternal strains, and 75–85% are caused by HSV-2.
- After the neonatal period, HSV-1 infections predominate, and 40–60% of children are seropositive for HSV-1 by the age of 5 years.

Prevalence

During puberty and early adolescence, the prevalence of HSV-2 increases, and 20–35% of adults are seropositive for HSV-2.

PATHOPHYSIOLOGY

- Initial viral replication occurs at the portal of entry.
- Vesicular fluid contains infected epithelial cells.
- After primary HSV infection, the virus remains latent in sensory neural ganglia innervating portions of the skin or mucous membranes originally involved. The virus can be reactivated by an appropriate stimulus such as sunlight or immune suppression.
- HSV can be replicated easily in the laboratory in tissue cultures.

COMMONLY ASSOCIATED CONDITIONS

- Gingivostomatitis is the most common form of HSV primary infection in children.
- Encephalitis due to HSV accounts for 2–5% of all encephalitis in the USA.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Neonatal infection:
 - HSV-2, the most common cause of neonatal infection, is usually acquired from maternal labial lesions, but a history of previous or current genital HSV infection is present in only 20–30% of mothers who deliver infected infants. HSV-2 can be transmitted to the infant without rupture of the amniotic membranes or after delivery by cesarean section:
 - HSV-1 can be transmitted to a neonate by any adult with active herpes labialis.
 - Neonates can have nonspecific presentations with up to 75% presenting with fever alone.
 - A vesicular rash or bullae are clues to diagnosis and present in 60% of patients with disseminated infection and 80–85% of patients with skin, eye, or mouth disease. Diagnosis without skin lesions is challenging.
 - Disseminated infection (20% of cases) involves the liver, lungs, adrenals, and sometimes the CNS and classically presents in the first to second week of life.
 - Localized CNS infection (33% of cases) presents with irritability, bulging fontanelle, or seizures and classically presents in the second to third week of life.
 - Localized skin, eye, or mouth infection (40–45% of cases) presents with rash alone, keratitis, or chorioretinitis and classically presents in the first to second week of life.
- Gingivostomatitis:
 - Most common presentation during childhood.
 - Fever and irritability precede the development of vesicular lesions on the lips, gingiva, and tongue. The vesicles then break down and become gray ulcers that are friable and bleed easily.
 - Children refuse to drink because of the mouth pain and are at risk of dehydration.
 - The child usually starts to improve in 3–5 days and recovers in 14 days.
 - Latent virus causes recurrent stomatitis or labiitis.

- Encephalitis:
 - The illness begins with fever, malaise, and irritability that last 1–7 days and progress to mental status changes, seizures, and coma. Meningeal signs are not common.
 - Patients can develop hemiparesis, cranial nerve palsy, and visual field defects.
 - No presence of oral or genital lesions
 - It is the result of a primary infection in 30% of cases and recurrent in 70%.
- Vulvovaginitis:
 - 35–50% of patients with the 1st episode of genital herpes will be able to give a history of genital HSV infection in their contact.
 - The primary illness is characterized by fever, headache, malaise, and myalgias. Local genital symptoms include severe pain, itching, dysuria, vaginal or urethral discharge, and tender inguinal adenopathy. The genital lesions begin as vesicles and progress to ulcers before they crust over. Lesions last for 2–3 weeks.
 - An aseptic meningitis syndrome occurs in 1–35% of cases. Patients will have fever, headache, meningismus, and photophobia.
 - Latent virus causes recurrent episodes, which are painful but less severe than in primary infections.

HISTORY

- Neonatal period exposures:
 - History of herpes in mother
 - Active vulvar lesions at time of delivery
 - Skin lesions
 - Oral lesion
- General questions re: Contagious disease:
 - Contact with people with herpes
 - Unprotected sex
 - Drinking from common straws, glasses
 - Use of lipstick samples at cosmetic counters

PHYSICAL EXAM

See “Signs and Symptoms.”

DIAGNOSTIC TESTS & INTERPRETATION

- Neonatal infection:
 - Samples for viral culture should be obtained from the eyes, oropharynx, and rectum.
 - Polymerase chain reaction (PCR) testing of the CSF is the test of choice for diagnosing CNS disease.
 - Cells from the base of freshly unroofed vesicles can be smeared on a slide for monoclonal antibody immunofluorescence.
 - Serologic tests are not useful for diagnosis of maternal or neonatal herpes during the acute phase of the disease.
- Encephalitis:
 - CSF reveals a pleocytosis with up to 2,000 WBCs/mm³, and usually >60% of the cells are lymphocytes.
 - CSF protein is elevated (median, 80 mg/dL).
 - HSV PCR is the diagnostic test of choice.
 - EEG can reveal a typical pattern of unilateral or bilateral focal spikes.
 - CT or MRI may show enhancement in the temporal areas.

- **Gingivostomatitis:**
 - Physicians usually make this diagnosis clinically because it is so common in young children.
- **Vulvovaginitis:**
 - A viral culture of the vesicle is the gold standard. Sensitivity is 94% for early lesions and decreases to 27% for crusted lesions.
 - Immunofluorescence of infected cells is a more rapid diagnostic test and has a sensitivity of 78–88%.

DIFFERENTIAL DIAGNOSIS

- Neonatal HSV infection must be distinguished from severe neonatal enterovirus disease or bacterial sepsis, especially in the first 4 weeks of life.
- HSV infection should be considered in all neonates with vesicular rash, chorioretinitis, microcephaly, or hepatosplenomegaly. It must be distinguished from other congenital viral infections such as rubella or cytomegalovirus (CMV).
- Herpes gingivostomatitis must be distinguished from herpangina, an enteroviral infection usually presenting as posterior pharyngeal ulcers and, sometimes, as hand, foot, and mouth disease.
- HSV encephalitis must be distinguished from other viral encephalitis and from the HSV-induced aseptic meningitis syndrome, which is a complication of primary genital infection.
- HSV vulvovaginitis must be distinguished from chancroid and syphilis. Syphilis lesions are usually nonpainful, hard ulcers. Chancroid lesions are multiple purulent ulcers from which *Haemophilus ducreyi* can be cultured.

TREATMENT

MEDICATION (DRUGS)

- **Neonatal infection:**
 - IV acyclovir (60 mg/kg/d in 3 divided doses) is the drug of choice. The recommended minimal duration of therapy is 14 days (if the disease is limited to the skin, eye, and mouth) and 21 days if disease is disseminated or involves the CNS. Infants with ocular involvement due to HSV infection should receive a topical ophthalmic drug (1–2% trifluridine, 1% iododeoxyuridine, or 3% vidarabine) in addition to parenteral antiviral therapy.
- **Encephalitis:**
 - IV acyclovir (30 mg/kg/d in 3 divided doses) for 21 days is appropriate therapy for HSV encephalitis beyond the neonatal period. In addition to parenteral antiviral therapy, appropriate management of fluids, intracranial pressure, and seizures is essential.
- **Gingivostomatitis:**
 - Most patients are managed with symptomatic therapy including antipyretics and oral fluids like popsicles. Oral anesthetics can be harmful and result in self-injury when children chew on anesthetized lips. Oral acyclovir has limited therapeutic benefit. If treatment is initiated, dosing is recommended at 80 mg/kg divided 4 times a day. Topical therapy is not recommended. Patients with frequent or severe recurrences may benefit from oral acyclovir at onset of symptoms.

- **Vulvovaginitis:**
 - Acyclovir (Zovirax) is the appropriate therapy for genital herpes infection. Oral acyclovir is used for patients with primary genital HSV infection and can decrease duration of illness and length of viral shedding. IV acyclovir is used for patients with severe local or systemic symptoms or complications like aseptic meningitis syndrome. Valacyclovir and famciclovir have not been shown to be more effective than acyclovir, however may lead to improved compliance with less frequent dosing. Topical therapy for primary genital lesions is not recommended.

ONGOING CARE

PROGNOSIS

Neonatal infection:

- Overall mortality from untreated neonatal HSV infection is 50%, and only 26% of survivors are normal.
- Infants with disseminated disease or localized CNS disease have the worst prognosis with mortality up to 20% despite antiviral therapy.

COMPLICATIONS

The major sequelae in survivors are brain damage, seizures, and blindness.

- B00.9 Herpesviral infection, unspecified
- P35.2 Congenital herpesviral [herpes simplex] infection

FAQ

- Q: What about recurrent cutaneous eruptions in a neonate? Should they be treated?
- A: The need for retreatment of infants with recurrent skin lesions is undetermined and under study. Because of concerns about silent CNS recurrent infection, some experts recommend acyclovir, 300 mg/m²/dose in 3 doses for 6–12 months.
- Q: Is prophylactic therapy for recurrent herpes genitalia helpful? When is it indicated?
- A: Antiviral therapy has minimal effect on recurrent genital herpes. Oral acyclovir initiated within 2 days of onset of symptoms shortens the course. Topical acyclovir is not helpful.
- Q: What steps should be taken in the nursery for an infant born to an HSV-positive mother?
- A: Neonates with documented perinatal exposure to HSV may be in the incubation phase of infection and should be observed carefully. Infants of mothers with active HSV should be isolated if they have been delivered vaginally or by cesarean delivery after membranes were ruptured for more than 4–6 hours. The risk of HSV infection in possibly exposed infants (e.g., those born to a mother with a history of recurrent genital herpes) is low, and isolation is not necessary.
- Q: Is a repeated lumbar puncture necessary at the end of therapy for neonates or for children with HSV encephalitis?
- A: Experts recommend repeating the lumbar puncture at the end of the planned course of therapy to determine whether the virus is still present by PCR assay. If there is a positive test, therapy should be prolonged.

HICCUPS

Blaze Robert Gusic

BASICS

DESCRIPTION

- Known medically as singultus, from the Latin *singult* (a sob or speech punctuated by sobs)
- Result of involuntary spasm of the diaphragm and intercostal muscles, leading to inspiration and abrupt closure of the glottis
- Affects nearly everyone at one time or another
- Hiccups serve no physiologic function and are often simply a benign affliction.

EPIDEMIOLOGY

- No male or female predominance for hiccup bouts; however, persistent and intractable hiccups are more frequent in males and are seen predominantly in adults.
- No racial, geographic, seasonal, or socioeconomic variability

Pregnancy Considerations

Fetal hiccups are common in the 3rd trimester of pregnancy.

GENERAL PREVENTION

Avoid precipitating factors.

PATHOPHYSIOLOGY

- A hiccup reflex arc has been postulated, although the exact anatomic mechanism remains unknown. The arc consists of:
 - The afferent limb: Phrenic and vagus nerves, the pharyngeal plexus from C2 to C4, and the thoracic sympathetic chain from T6 to T12
 - The efferent limb: Phrenic nerve to the diaphragm and the external intercostal nerves to the intercostal muscles
 - A central connection: A nonspecific location incorporating the medulla but independent of the respiratory center, the hypothalamus, and the phrenic nerve nuclei
- Hiccups have negligible effect on ventilation and usually involve only unilateral diaphragmatic contraction, most frequently on the left.
- Hiccups serve no respiratory function, despite activation of inspiratory musculature far more than during normal respiration.

ETIOLOGY

- Bouts may be precipitated by a number of benign causes including:
 - Gastric distention:
 - Aerophagia
 - Ingestion of excessive food, carbonated beverages, or alcohol
 - Gastric insufflation during endoscopy
 - Changes in the ambient or gastrointestinal temperature:
 - Cold showers
 - Ingestion of hot or cold beverages
 - Moving from cold to hot environment, or vice versa
 - Sudden excitement or stress
 - Tobacco use
- Persistent and intractable hiccups have many causes, which can be characterized as psychogenic, organic, or idiopathic:
 - Psychogenic:
 - Stress
 - Conversion reactions
 - Anorexia nervosa
 - Malingering
 - Personality disorders
 - Organic:
 - CNS disorders: Ventriculoperitoneal shunts, hydrocephalus, arteriovenous malformations, stroke, temporal arteritis, CNS trauma, encephalitis, meningitis, brain abscess
 - Peripheral nervous system disturbances: Irritation of the phrenic or vagus nerve from a variety of causes, including goiter, tumors or cysts of the neck, hiatal hernia, esophagitis, pneumonia, bronchitis, asthma, mediastinal lymphadenopathy, pericarditis, myocardial infarction, peptic ulcer disease, pancreatitis, inflammatory bowel disease, appendicitis, cholecystitis, and renal and hepatic disorders (stones or infections)
 - Infectious causes: Sepsis, influenza, herpes zoster, malaria, and tuberculosis
 - Metabolic or pharmacologic causes: Anesthesia, methylprednisolone, barbiturates, diazepam, methyldopa, uremia, hypocalcemia, and hyponatremia

DIAGNOSIS

HISTORY

- Severity, duration, and characteristics of hiccups
- Medication and alcohol use
- Hiccups persisting during sleep suggest an organic cause.

PHYSICAL EXAM

- Head and neck exam may reveal evidence of trauma, foreign body in the ear, nuchal rigidity, masses, cervical lymphadenopathy, or an enlarged thyroid.
- Assess the chest for evidence of pneumonia, bronchitis, or pericarditis.
- Assess the abdomen for evidence of appendicitis, intestinal obstruction, ruptured viscus, pancreatitis, or hepatobiliary disease.
- Neurologic exam may provide evidence of trauma, meningitis, encephalitis, ventriculoperitoneal shunt malfunction, or neoplasm.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Tests should be chosen based on historic and physical findings:

- CBC
- Renal function and electrolytes
- Liver function tests and calcium
- Toxicology screen and blood gas

Imaging

Chest radiograph may rule out phrenic, vagal, and diaphragmatic irritation by pulmonary, cardiac, and mediastinal abnormalities.

DIFFERENTIAL DIAGNOSIS

Hiccups are not often mistaken for any other entity.

TREATMENT

MEDICATION (DRUGS)

- Studies confined to adult populations. Pharmaceuticals are rarely recommended for children.
- Chlorpromazine is widely used in adults in IV preparations. Intramuscular haloperidol has also been effective in adults.
- Anticonvulsants, including diphenylhydantoin, valproic acid, and carbamazepine, are reported effective.
- Combination of cisapride, omeprazole, and baclofen has been reported to be effective and is considered the mainstay for idiopathic chronic hiccups.
- Gabapentin has been shown to be effective as a substitute for baclofen or as an additional agent in the above regimen.
- Amantadine has been used with potential therapeutic response.

ADDITIONAL TREATMENT

General Measures

- Directed at the underlying disease
- If cause is unknown, empiric therapy may be necessary.
- Nonpharmacologic modalities:
 - Interruption of respiratory function: Sneezing, coughing, breath holding, hyperventilation, sudden pain or fright, and even positive airway pressure ventilation
 - Disruption of phrenic nerve transmission: Tapping over the 5th cervical vertebra, ice applied to the skin over the area of the phrenic nerve, and even transecting the phrenic nerve
 - Behavioral modification and hypnosis
 - Acupuncture: Reported to be successful in the treatment of persistent hiccups
 - Nasopharyngeal stimulation: Traction of the tongue, stimulation of the pharynx with a cotton swab, lifting the uvula with a spoon
 - Old-fashioned home remedies such as sipping ice water, swallowing granulated sugar, drinking water from the far side of a glass or through a paper towel, and biting on a lemon

SURGERY/OTHER PROCEDURES

Surgical treatment is rarely performed. Cases of phrenic nerve blockade, percutaneous phrenic nerve pacing, and crush injury have been cited, but mostly in adults and in those with underlying chronic illnesses.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

No specific follow-up is indicated unless a specific organic cause has been identified.

PROGNOSIS

- Self-limited and resolve without complications
- Usually terminate within hours
- Hiccup bouts may last up to 48 hours. Persistent hiccups last from 48 hours up to 1 month, and intractable hiccups last for >1 month.

COMPLICATIONS

- Adverse effects that have been associated with intractable hiccups:
 - Malnutrition and dehydration
 - Weight loss
 - Insomnia
 - Fatigue
 - Psychological stress
- Rare complications:
 - Cardiac dysrhythmia
 - Reflux esophagitis
 - Wound dehiscence
 - Pulmonary edema from the negative pressure
 - Death

CODES

ICD9

- 306.8 Other specified psychophysiological malfunction
- 786.8 Hiccough

ICD10

- F45.8 Other somatoform disorders
- R06.6 Hiccough

FAQ

- Q: Does rebreathing into a paper bag really work?
- A: As a fall in pCO₂ may increase the frequency of hiccups, rebreathing air will increase pCO₂ and thus terminate hiccups.
- Q: Will hiccups harm my baby?
- A: Hiccups alone are harmless. If they are truly persistent, are intractable, or disrupt sleep, they may have the side effects as mentioned. Premature babies have been observed to spend 2.5% of their time having hiccups.
- Q: Is there an association between gastroesophageal reflux and hiccups?
- A: Hiccups can be caused by esophageal irritation from gastroesophageal reflux disease, and chronic hiccups have been linked to reflux esophagitis.

HIRSCHSPRUNG DISEASE

Joy L. Collins

BASICS

DESCRIPTION

- Characterized by aganglionosis of the distal bowel beginning at the anus and extending proximally for a variable distance, leading to abnormal intestinal motility and an abnormal or absent relaxation of the internal anal sphincter
- 1st description of congenital megacolon by Harald Hirschsprung in 1888
- May present as delayed passage of meconium, chronic constipation, partial or complete intestinal obstruction, or enterocolitis

EPIDEMIOLOGY

Incidence

- Most common cause of lower intestinal obstruction in neonates: 1 in 5,000 births
- Familial incidence in colonic aganglionosis: 75% of cases, rectosigmoid involved; 14%, descending colon involved; 8%, colon involved; 3%, small bowel affected

Prevalence

- Overall rate of male/female patients is 2.8:1; in long-segment disease, it is 2.8:1, and in total colonic aganglionosis, it is 2.2:1.
- Syndromic and nonsyndromic Hirschsprung disease: In the former there are other congenital anomalies (30% of cases), whereas in the latter it occurs as an isolated trait.

RISK FACTORS

Genetics

- Loci implicated include those at chromosomes 3p21, 10q11, 5p13, 22q13, 1p36, and 19q12
- Associated with mutations in the RET proto-oncogene
- ~5% of patients with Hirschsprung disease have mutations in the endothelin signaling pathway.

PATHOPHYSIOLOGY

- Basic histologic finding is the absence of Meissner and Auerbach plexuses and hypertrophied nerve bundles between the circular and the longitudinal muscles and in the submucosa.
- Defect is considered as a failure of caudal migration of the neural crest cells.

COMMONLY ASSOCIATED CONDITIONS

- In 3% of the patients, an association with Down syndrome, cardiac anomalies, and coexistent multiple neuroblastomas
- More recently, case reports of neurologic disorders associated in children with Hirschsprung disease
- May be familial and associated with disorders of the urogenital tract, cardiovascular defects, other GI system disorders, cleft palate, and extremity defects.
- Another study reveals upper gut dysmotility in patients with Hirschsprung disease and its allied disorders in adults.

DIAGNOSIS

HISTORY

- 80% of patients present in the neonatal period.
- Typical symptoms: Failure to pass meconium by 48 hours of life; delayed passage of meconium after 24 hours of life; history of constipation; history of chronic laxative use, abdominal distention, bilious vomiting, diarrhea in 22% of patients
- Neonates usually have normal weight, but growth retardation may occur when the disease is severe.
- Children with Hirschsprung disease may have small-volume and small-diameter stools. Some may have overflow diarrhea as well.

PHYSICAL EXAM

- On rectal exam, the sphincter tone is usually normal or increased. Removal of the finger may be followed by explosive diarrhea. In most instances, especially in older children, the rectum is empty.
- Patients may be anemic owing to chronic blood loss from the large bowel secondary to infection.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

CBC: Anemia, leukocytosis in the presence of enterocolitis

Imaging

- Plain film of abdomen:
 - May show distended intestinal loops
 - Diffuse intestinal pneumatosis has been reported as a rare presentation.
- Barium enema:
 - May be useful but not always diagnostic
 - Transition zone is a funnel-shaped area of intestine with normal distal area and dilated proximal area.
 - Reveals large intestinal mucosal pattern, prominently thickened folds, and irregular margins secondary to ulceration
 - Significant delay in excretion of barium should also raise one's suspicion for Hirschsprung disease.

Diagnostic Procedures/Other

- Anorectal manometry: May be diagnostic, but usually reserved for those cases causing diagnostic difficulties, as in the ultra-short-segment disease.
- Suction biopsy:
 - Should be done ~2–4 cm from the anal verge depending on the age of the patient
 - Biopsies must have adequate submucosa to demonstrate neurofibrils detected using acetylcholinesterase as a stain.
 - With the absence of ganglion cells, biopsy is diagnostic.
 - If the suction biopsies are not conclusive, a full-thickness biopsy is mandatory.

Pathological Findings

- Aganglionic segment
- Zone of hypoganglionosis proximal to the aganglionic segment
- Incomplete maturation of enteric nerve plexus
- Hypertrophy of nonmyelinated nerve fibers within bowel wall

DIFFERENTIAL DIAGNOSIS

- Mechanical obstruction
- Meconium ileus
- Meconium plug syndrome
- Neonatal small left colon syndrome
- Malrotation with volvulus
- Intestinal atresia
- Intussusception
- Necrotizing enterocolitis
- Functional obstruction
- Intestinal neuronal dysplasia
- Sepsis
- Metabolic disorders (e.g., uremia, hypothyroidism)
- Disorders of intrinsic enteric nerves (diabetes or dysautonomia)
- Disorders of smooth muscle function
- Electrolyte disturbances
- Chronic constipation

ALERT

Early recognition is of utmost importance in reducing the morbidity and mortality of Hirschsprung disease.

TREATMENT

MEDICATION (DRUGS)

- 1st line:
 - For constipation: Rhubarb, prune or pear juice, bran
 - For diarrhea: Bananas, carrots, blueberries
- 2nd line:
 - For constipation: Senna extract
- For diarrhea: Cholestyramine, loperamide (must make sure diarrhea is not due to enterocolitis or overflow)

ADDITIONAL TREATMENT

General Measures

Stabilizing treatment if child presents with suspected enterocolitis or obstruction:

- Fluid resuscitation
- Nasogastric decompression
- Broad-spectrum antibiotics
- Saline enemas for decompression

SURGERY/OTHER PROCEDURES

- Initial operation:
 - Defunctionalizing colostomy or ileostomy for total colonic aganglionosis or if child presents with obstruction not relieved by rectal irrigations:
 - Performed to avoid the hazards of enterocolitis
- Definitive surgery:
 - Performed 6 months to 1 year after the initial colostomy
 - May be performed as initial procedure in stable, nonobstructed child
- A multitude of surgical techniques have been described, including modifications on the traditional Swenson, Soave, and Duhamel procedures.
- Recent advances include:
 - The introduction of entirely transanal techniques
 - Increasing use of laparoscopic assistance with various procedures
 - Transition away from multistaged procedures to a variety of definitive single-stage operations
- In total colonic aganglionosis, the modified Lester Martin technique may be performed: Involves the anastomosis of the cecum and ascending colon as an onlay patch graft in the more distal normal small bowel, which is then pulled through the amputated rectum (which has been stripped of its mucosa), with a primary anastomosis.
- A Duhamel or modification thereof is also an option for total colonic aganglionosis; this involves total resection of the aganglionic colon with retrorectal pull-through of the ganglionated bowel and anastomosis in which a portion of aganglionic rectum is left in situ.

ALERT

- Clinicians must have *high* suspicion for enterocolitis both before and after definitive pull-through.
- Fecal incontinence could occur after surgery.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

Most children are followed on a regular basis for the 1st decade after surgery.

COMPLICATIONS

- Early (<4 weeks postoperation, usually related to technical issues):
 - Anastomotic leak
 - Cuff abscess and retraction of pull-through segment
 - Disturbance of micturition
 - Wound infection, intra-abdominal adhesions
- Late:
 - Chronic constipation
 - Long-term voiding dysfunction
 - Sexual dysfunction due to dissection around pelvic nerve plexus
 - Enterocolitis
- Enterocolitis is the most important complication:
 - Secondary to obstruction causing an increase in intraluminal pressure and decreased intramural capillary blood flow
 - Affects the protective mucosal barrier, enabling fecal breakdown products, bacteria, and toxins to enter the bloodstream
 - Usually presents with fever, diarrhea, and bilious vomiting
 - Can occur both before and after definitive pull-through
 - Clinicians must have *high* suspicion; can be rapidly progressive and FATAL

**CODES****ICD9**

751.3 Hirschsprung's disease and other congenital functional disorders of colon

ICD10

Q43.1 Hirschsprung's disease

FAQ

- Q: Will the bowel movements be normal after surgery?
- A: Studies have shown that 83% of children have ≤ 3 stools per day at a mean follow-up of 4.1 ± 2.5 years.
- Q: Are laxatives required after surgery?
- A: In $\sim 20\%$ of children, some sort of laxative therapy or rectal irrigation may be required.

HISTIOCYTOSIS

Charles Bailey

BASICS

DESCRIPTION

- Langerhans cell histiocytosis (LCH): Clinical condition associated with proliferation or inappropriate localization of Langerhans cells (dendritic cells, histiocytes, mononuclear phagocytes)
- Related disorders:
 - Macrophage hyperactivation syndromes (e.g., hemophagocytic lymphohistiocytosis [HLH], macrophage activation syndrome)
 - Malignant histiocytosis (lymphoma subtype)
- Disorder of unknown cause involving cells similar to Langerhans cells of the skin
- Other names include:
 - Histiocytosis X (superseded)
 - Eosinophilic granuloma: Refers to single lesion, usually of bone
 - Hand-Schüller-Christian syndrome: Chronic multifocal bone (especially cranial) and skin, diabetes insipidus, possibly with other organ involvement
 - Letterer-Siwe disease: Multisystem visceral LCH, often including hepatic and marrow involvement
 - Hashimoto-Pritzker syndrome: Infant dermatologic involvement, often self-limited

EPIDEMIOLOGY

- May occur at any age. Peak incidence in infancy, especially for multisystem disease
- Variable reports of mild male predominance

Incidence

2.5–9 cases per million

RISK FACTORS

Genetics

- Rare reports of recurrence within families
- Specific HLA alleles associated with disease phenotype in case series

PATHOPHYSIOLOGY

- Bone and skin lesions are most common in children, especially >1 year old
- Involvement of liver, spleen, marrow, and lung (rare in children) associated with more severe morbidity and mortality (“risk organs”)
- Involvement of CNS, gut, other “nonrisk” organs less common than skin/bone, and not associated with mortality
- Clonal histiocytes have been detected in all forms of disease, but do not have malignant behavior, and may represent normal LC development.

ETIOLOGY

LCH cells differ structurally from normal Langerhans cells, but critical factors leading to disease remain largely uncharacterized.

DIAGNOSIS

HISTORY

- Swelling, pain, or pathologic fracture from soft tissue or bone lesion
- Erythematous or brown papular rash
- Persistent otorrhea
- Proptosis
- Gait disturbance
- Early loss of teeth
- Failure to thrive
- Diarrhea, possibly bloody
- Fever of unknown origin
- Headache
- Abdominal pain
- Jaundice
- Polydipsia or polyuria (diabetes insipidus)
- School/cognitive problems
- Dyspnea or persistent cough
- History of spontaneous pneumothorax
- Signs and symptoms:
 - Wide variation in presenting signs and symptoms depending on affected organ systems
 - Single-system skeletal disease may be asymptomatic, with incidental discovery of lesions on radiographs obtained for other reasons (e.g., trauma).

PHYSICAL EXAM

- Growth or pubertal delay
- Skin: Brownish-red papules often involving intertriginous areas, seborrheic dermatitis (cradle cap), purpura, petechial rash especially at areas of skin contact (e.g., top of diaper); rash may become ulcerated, crusted, or scaly.
- Ears: Otorrhea, hearing loss
- Skeleton: Swelling or mass; may be painless or very tender to palpation; skull, axial skeleton, long bones more often affected than hands or feet
- Teeth: Gingivitis, “floating teeth”
- Eyes: Orbital swelling, cranial nerve palsies
- Lungs: Tachypnea, intercostal retractions
- GI: Hepatosplenomegaly, ascites, edema, jaundice; stool with blood or mucus
- Neurologic: Ataxia, cognitive difficulties

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Routine diagnostic evaluation:
 - CBC with differential to evaluate for marrow involvement
 - Liver function tests (LFTs), prothrombin time (PT), partial thromboplastin time (PTT) to evaluate liver function
 - Morning urine specific gravity/osmolality
- Other investigations:
 - Pulmonary involvement: Pulmonary function tests
 - Polyuria/suspected diabetes insipidus: Endocrine evaluation including water deprivation test and evaluation of anterior pituitary hormone production
 - Auricular involvement: Audiogram; ear, nose, and throat evaluation
- Bone involvement: Biopsy of lesions unless diagnosis of LCH already established

Imaging

- Chest radiograph and skeletal survey (bone scan not as sensitive in most patients, but may be better for infants)
- Liver/spleen ultrasound
- High-resolution chest CT if pulmonary involvement suspected
- MRI of brain with contrast, including detailed evaluation of sella turcica, if neurologic involvement or signs of diabetes insipidus
- Dental radiographs if teeth are involved
- CT/MRI imaging of lytic-appearing lesions often obtained prior to diagnosis to evaluate potential malignancy; classic “punched out” lesions may not require imaging beyond plain films.

Diagnostic Procedures/Other

- Biopsy of lesion to establish diagnosis
- Cytopenias or other high-risk organ involvement: Bone marrow aspirate and biopsy
- Liver dysfunction: Liver biopsy to evaluate for sclerosing cholangitis
- GI involvement: Endoscopic biopsy of small and large intestine
- Pulmonary involvement: Consider bronchoalveolar lavage (BAL) or lung biopsy to evaluate for infection if diagnosis of LCH not already established from more accessible tissue or if appearance on CT is atypical.

Pathological Findings

- Lesions show proliferation of Langerhans-like cells in places where they are not typically found.
- Langerhans cells are characterized by the presence of tennis racquet-shaped inclusions (Birbeck granules) on electron microscopy or by staining with anti-CD1a or -CD207 (langerin).

DIFFERENTIAL DIAGNOSIS

- Broad differential, depending on constellation of presenting symptoms
- Bone/soft tissue lesions:
 - Sarcoma (especially osteogenic sarcoma, Ewing sarcoma, or rhabdomyosarcoma)
 - Benign bone lesion (e.g., osteoma, bone cyst)
 - Infection
 - Metastatic tumor (e.g., neuroblastoma, leukemia/lymphoma)
- Skin lesions:
 - Seborrheic dermatitis
 - Otitis externa
 - Tinea infection
 - Viral exanthem (especially herpes simplex virus [HSV] in neonates)
- CNS lesions:
 - Teratoma or malignant germ cell tumor
 - Craniopharyngioma
 - Primary CNS tumor
- Pulmonary involvement:
 - Infection
 - Emphysema (e.g., α_1 -antitrypsin deficiency)

- Fever, lymphadenopathy (nontender, nonerythematous):
 - Lymphoma
 - Lymphadenitis (especially large DNA viruses)
 - Granulomatous (e.g., fungal, cat-scratch disease) infections
 - Rosai-Dorfman or Castleman disease
 - Rheumatologic disease
 - HLH
- Hepatic involvement:
 - Infections
 - Congenital hepatic and storage diseases
 - HLH
 - Tumor infiltration (e.g., leukemia)
 - Primary sclerosing cholangitis
- Cytopenias:
 - Leukemia or other tumor infiltration
 - Aplastic anemia
 - HLH
 - Myelofibrosis or storage diseases

TREATMENT

MEDICATION (DRUGS)

First Line

- Corticosteroids
- Vinblastine
- Antimetabolites (6-mercaptopurine [6-MP], methotrexate)

Second Line

- 2-Chlorodeoxyadenosine ± cytarabine
- Etoposide also has activity; used in early LCH treatment trials
- Thalidomide has shown some efficacy for persistent disease not involving high-risk organs.
- Cyclosporin A or antithymocyte globulin used less often for immunomodulation in refractory disease

ADDITIONAL TREATMENT

General Measures

- Type of therapy depends primarily on:
 - Number of organ systems affected
 - Number of bone lesions, if sole system involved
 - Involvement of “risk organs” associated with morbidity or mortality: Liver, spleen, bone marrow, and possibly lung
- Single system (most often bone, skin):
 - Observation of isolated lesions; often remain stable or spontaneously resolve
 - Local therapy:
 - Excision or biopsy/disruption often curative for bone or lymph node lesion
 - Steroids for confirmed LCH of skin or multiple nodes
 - Topical nitrogen mustard or tacrolimus used for refractory skin lesions
 - Systemic therapy used for multiple/refractory lesions
 - Systemic therapy:
 - Low-dose chemotherapy for some multifocal bone disease or multiple recurrent single bone lesions; superior results with multiagent regimens
 - Reduces risk of later DI in patients with skull, vertebral, or CNS lesions
 - Cotrimoxazole effective for some patients with cutaneous involvement.

- Multisystem:
 - Chemotherapy:
 - Typically 6–12-month course
 - Steroid, vinblastine, plus antimetabolites depending on extent of disease and risk organ involvement
 - Limited response by 6 weeks merits intensification (e.g., 2-CdA + AraC)
 - Less common: Immunotherapy or radiation
 - Limited experience with allogeneic stem cell transplantation for very high-risk refractory disease
 - Most patients treated at pediatric oncology centers
 - International clinical trials in progress
- Treatment of disease-related morbidity:
 - Lifelong intranasal desmopressin acetate often needed for the management of diabetes insipidus; posterior pituitary dysfunction is rarely reversible.
 - Organ transplantation may be necessary for high-risk patients with organ dysfunction.

Additional Therapies

Radiotherapy

Rarely used; reserved for refractory or critical bone lesions (e.g., spinal cord compression)

ISSUES FOR REFERRAL

Multidisciplinary care involving several specialties may be required for management of orthopedic, endocrinologic, hepatic, hematologic, or pulmonary complications.

SURGERY/OTHER PROCEDURES

- Initial biopsy for diagnosis: Often curative for solitary bone lesions
- Excision of isolated bone or lymph node lesions

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Evaluation at regular intervals for recurrence of lesions or new high-risk organ involvement, depending on extent of prior disease
- Because the course is quite variable, patients need to be followed closely at a center experienced in the management of histiocytosis.

Patient Monitoring

- Laboratory and imaging follow-up as described for initial evaluation, with focus on previously affected and high-risk organ systems
- Routine follow-up typically includes history, physical exam, CBC, LFTs, and skeletal imaging.

DIET

Maintain fluid and electrolyte intake if diabetes insipidus is present.

PROGNOSIS

- Single-system or bone/skin disease carries low risk of morbidity.
- <20% of patients with single-system disease, but up to 75% of patients with multifocal bone disease will have a remitting and relapsing course. Mortality is <5%.
- Often disease will “burn out” by the end of childhood. ~5% of patients will continue to have exacerbations as adults.

- 45% of patients with multisystem disease who reach CR will have reactivation; most do not involve risk organs.
- For patients with liver, spleen, bone marrow, or lung (“risk organ”) involvement who have not responded to initial 6 weeks of therapy, the risk for mortality is >66%. For good responders, mortality is ~10%.

COMPLICATIONS

- Most common long-term morbidities include orthopedic problems, diabetes insipidus, and neurologic dysfunction.
- Some patients with single-system bone involvement will have a chronic remitting and relapsing course.
- Craniofacial and vertebral involvement is associated with a higher risk of diabetes insipidus; risk improves with multidrug therapy.
- Smoking strongly associated with development of pulmonary disease in LCH patients
- Chronic disabilities with multisystem disease include pulmonary fibrosis, hepatic fibrosis, deafness, orthopedic problems, short stature, permanent ataxia, neurocognitive deficits, and poor dentition.

- C96.6 Unifocal Langerhans-cell histiocytosis
- C96.9 Malignant neoplasm of lymphoid, hematopoietic and related tissue, unspecified

HISTOPLASMOSIS

Marleine Ishak
Sumit Bhargava
Julian L. Allen (5th edition)

BASICS

DESCRIPTION

- Spectrum of illness, ranging from primary pulmonary to disseminated infection:
 - Pulmonary
 - Extrapulmonary
 - Disseminated
- Caused by the dimorphic fungus *Histoplasma capsulatum*
- Acute or chronic
- Primary or reactivation

EPIDEMIOLOGY

- Most common systemic fungal infection in U.S.
- Organism found in nitrogen-rich soil and high-carbon content, lower pH soil contaminated by animal droppings, especially those of bats and birds
- Outbreaks reported in pigeon breeders or cleaners of chicken coops, explorers of caves with bats, and populations living close to construction
- Endemic in eastern and central U.S., specifically in the St. Lawrence, Mississippi, and Ohio River valleys, the Rio Grande, Texas, Oklahoma, Kansas, Pennsylvania, Maryland, and Virginia
- No human-to-human or animal-to-human transmission
- Incubation period variable, 1–3 weeks

Incidence

Severity of symptoms depends on immunologic status of the host and size of inoculum:

- Asymptomatic in up to 95% of cases
- With heavy inoculum, 50–100% develop symptoms. Of these, 80% develop flu-like symptoms, lasting about a week; 10–20% develop pericarditis, arthritis, or erythema nodosum, resolving after a few weeks

Prevalence

80–90% of adults in endemic areas are skin-test positive.

RISK FACTORS

Risk factors for severe disease (progressive disseminated histoplasmosis) include very old and very young (<2 years) and cellular immunocompromise.

GENERAL PREVENTION

- Investigate common source of infection in outbreaks. Limit exposure to soil and dust from areas contaminated with bat and bird droppings.
- For occupational exposure to *H. capsulatum*-contaminated soil:
 - Wetting agents to prevent aerosolization of contaminated dust
 - National Institute for Occupational Safety and Health (NIOSH)-approved respirators; e.g., N95, gloves, and dispensable clothing (see NIOSH website in Bibliography)
- Isolation of the hospitalized patient: Standard precautions recommended

ETIOLOGY

- Inhalation of *H. capsulatum* spores
- The dimorphic fungus exists in mycelial form in the environment at 25°C and in yeast form in tissues at 37°C.

DIAGNOSIS

HISTORY

- Environmental exposures (pigeon breeding, construction, cave exploration, travel in endemic areas): Epidemiologically suggestive of histoplasmosis
- Upper respiratory symptoms, low-grade fever, cough, pleuritic chest pain: Suggestive of mild disease lasting 1–5 days
- Arthritis, more severe chest pain, skin lesions, pericarditis, or pleural effusion: Suggestive of moderate disease lasting ~15 days
- High fever, night sweats, weight loss, cough, chest pain, shortness of breath, hoarseness lasting >2–3 weeks: Suggestive of disseminated disease and underlying immune suppression
- Chronic cough, dyspnea, disabling respiratory dysfunction: Suggestive of chronic cavitary pulmonary disease

PHYSICAL EXAM

- Flu-like signs and symptoms are common in mild disease; physical exam may be normal.
- Less usual manifestations suggest moderate or disseminated disease:
 - Hepatosplenomegaly
 - Adenopathy
 - Pneumonitis
 - Skin lesions (erythema nodosum)
 - Pericardial friction rub
 - Pallor, petechiae
 - CNS findings
 - Severe disease can present as sepsis syndrome with hypotension, DIC, renal failure, and acute respiratory distress

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Culture of the organism in sputum, tissue specimens, peripheral blood, or bone marrow:
 - Definitive, but requires 2–6 weeks
 - Sputum cultures are negative in most patients with mild disease.
 - Cultures are positive in 2/3 of patients with cavitary disease and 1/3 of patients with noncavitary disease.
 - In progressive disseminated histoplasmosis in patients with AIDS, bone marrow, and blood cultures are positive in 80–90% of patients, and bronchoscopic cultures are positive in 80–90% of patients with abnormal chest radiographs.
- Identification of organism by microscopy:
 - Histologic identification in sputum, blood, bone marrow, biopsy specimens, and/or CSF
 - Staining methods: Hematoxylin and eosin, Wright, Giemsa, periodic acid-Schiff; Gomori methenamine silver more likely to detect sparse organisms
 - Histopathology is a valuable diagnostic tool and can demonstrate noncaseating granulomas in histoplasmosis.

- Radioimmune and hemagglutinin assays for *H. capsulatum* antigen:
 - Radioimmunoassay: Specific, sensitive, and rapid for diagnosing progressive disseminated histoplasmosis, but low sensitivity for acute pulmonary histoplasmosis in immunocompetent patients
 - May cross-react with coccidiomycosis and blastomycosis antigens
 - Hemagglutinin found in urine or blood in 50–90% of patients with progressive disseminated histoplasmosis (urine more sensitive) and in bronchoalveolar lavage fluid in 70% of AIDS patients with pulmonary histoplasmosis
 - Antigenuria is detected in 75% of patients with severe acute pulmonary histoplasmosis. Only 10–20% of patients with less severe acute pulmonary histoplasmosis or chronic cavitary pulmonary histoplasmosis will have antigenuria.
 - Antigen tests are generally useful only in 1st month of infection, but can persist for much longer in AIDS patients.
 - Antigen levels decrease with treatment and can increase again with relapse.
 - DNA probes increasingly used
- Serologic studies for antibodies:
 - Titers become positive 4–6 weeks after infection, peak at 2–3 months, and decline over a period of 2–5 years.
 - Positive titers in 90% of patients with symptomatic disease
 - False positives occur in patients with coccidiomycosis, blastomycosis, tuberculosis, or paracoccidiomycosis.
 - False negatives occur in immunocompromised patients with progressive disseminated histoplasmosis.
- Complement fixation:
 - Single titer 1:32 (1:8 in nonendemic areas) is diagnostic; 4-fold increase in titers is diagnostic.
 - More sensitive than immunodiffusion test, which is more specific
- Precipitating antibodies by immunodiffusion:
 - H band suggests active infection.
 - M band is less specific.
 - Presence of H and M bands is highly diagnostic.
- Evaluation for meningitis:
- Relative sensitivities:
 - Stain of CSF <10%
 - Culture CSF 20–60%
 - Antigen CSF 40–70%
 - Antibody CSF 60–80%
 - Meningeal or brain biopsy 50–80%

Imaging

Chest radiograph:

- Normal in 75% of patients with histoplasmosis, 25–50% of immunocompromised patients with disseminated disease
- Most common radiologic changes include:
 - Small 2–5-mm infiltrates in lung bases
 - Lobar or diffuse infiltrates
 - Enlarged or calcified hilar nodes
 - Buckshot calcifications seen in patients with large inoculum

- Cavitory lesions
- Pleural effusions in 10% of chest radiographs in adults
- Calcified nodules in liver and spleen

DIFFERENTIAL DIAGNOSIS

- Infections:
 - Pneumonia (viral, bacterial)
 - Influenza and other viral syndromes
 - Tuberculosis
 - Other fungal diseases:
 - Aspergillosis
 - Blastomycosis
 - Coccidiomycosis
 - Sarcoidosis
- Malignancy

ALERT

- Can be difficult to distinguish between active disease and previous exposure in patients from endemic regions
- May be confused with tuberculosis and other fungal diseases
- Isolated pulmonary nodule on chest radiograph may be difficult to distinguish from malignancy.

TREATMENT

MEDICATION (DRUGS)

- Uncomplicated cases of primary histoplasmosis of the lungs may not require drug therapy.
- Treatment should be considered for patients with pulmonary symptoms lasting >4 weeks or with obstructing granulomatous adenitis.
- Patients with more severe or disseminated disease or the immunocompromised require treatment with antifungal agents. Treatment regimens vary. Amphotericin B, 0.5–1.0 mg/kg/d IV for 4–6 weeks (or 35 mg/kg total). Recommended for disseminated disease or patients with respiratory compromise and hypoxemia. Alternative treatment in children: Amphotericin B for 2–3 weeks, followed by oral itraconazole for 3–6 months.
- Milder disease: For the following drugs, interactions with other drugs are common; consult drug interaction database or reference before prescribing. Limited or no information about use in newborn infants, and, in the case of ketoconazole, children <2 years:
 - Ketoconazole:
 - 3.3–6.6 mg/kg/d PO (400 mg/d initially, then 200 mg/d is maximum dose) for 3–6 months
 - Should be used with caution in patients receiving H₂ blockers; absorption is decreased in achlorhydric state
 - Levels can also be reduced by rifampin and phenytoin.
 - Fluconazole or itraconazole are generally preferred due to fewer side effects (hepatotoxicity, anaphylaxis, thrombocytopenia, hemolytic anemia, other GI side effects).

- Fluconazole:
 - 6–12 mg/kg/d PO (400–800 mg/d is maximum dose) for 3–6 months
 - Reduced dose may also be given IV.
 - Achieves levels in CSF
- Itraconazole:
 - 5–10 mg/kg/d PO (400 mg/d is maximum dose) for 3–6 months
 - May also be given IV
 - Although not approved for use in children, effective in the treatment of HIV patients with histoplasmosis
 - Does not achieve levels in CSF
- In patients with AIDS, lifelong suppressive therapy is recommended.
- Adjunct therapy with corticosteroids may be added in patients with life-threatening airway obstruction secondary to hilar adenopathy.
- Prophylaxis: Considered for patients with AIDS, low CD4 counts, and who live in endemic areas
- Pericarditis and mediastinal fibrosis: Treat with indomethacin.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

When to expect improvement:

- In mild-to-moderate cases not requiring drug therapy, usually 1–2 weeks
- In cases requiring therapy, improvement usually noted within 2 weeks
- Response to therapy more variable in AIDS patients

PROGNOSIS

- In most cases, prognosis is excellent.
- 90% mortality within 3 months in patients with acute disseminated histoplasmosis if left untreated
- High relapse in AIDS patients if not treated with chronic suppressive therapy

COMPLICATIONS

- In general, complications rare; usually indicate disseminated disease
- Symptoms include:
 - Prolonged fever, malaise, cough, weight loss, hepatosplenomegaly, diarrhea
 - Patients may also develop disseminated intravascular coagulopathy, adult respiratory distress syndrome, renal failure, endocarditis, or Addison disease.
- Disseminated disease can involve:
 - Skin
 - Eyes (uveitis)
 - Liver
 - Spleen
 - Adrenal glands (adrenal insufficiency)
 - Bone marrow
 - Heart
 - CNS (meningitis)

- Other complications include:
 - Tracheobronchial compression
 - Mediastinal granuloma formation or fibrosing mediastinitis
 - Fistula formation
 - Pericarditis can be severe enough to cause cardiac tamponade.
 - Obstruction of superior vena cava, esophagus, or pulmonary arteries
- Chronic cavitory pulmonary disease very similar to tuberculosis

CODES

ICD9

- 115.00 Infection by *Histoplasma capsulatum*, without mention of manifestation
- 115.05 Infection by *Histoplasma capsulatum*, pneumonia
- 115.90 Histoplasmosis, unspecified, without mention of manifestation

ICD10

- B39.2 Pulmonary histoplasmosis capsulati, unspecified
- B39.3 Disseminated histoplasmosis capsulati
- B39.9 Histoplasmosis, unspecified

FAQ

- Q: What are the most common clinical presentations of histoplasmosis?
- A: Asymptomatic, mild primary pulmonary (1–2 weeks), moderate (2–3 weeks), disseminated, and cavitory are common.
- Q: How is histoplasmosis best diagnosed?
- A: Skin test generally is not useful; culture and serologic testing is recommended.
- Q: Does histoplasmosis need to be treated with antifungal therapy?
- A: Mild primary disease—no; more severe or disseminated disease—yes.
- Q: How can histoplasmosis be prevented?
- A: Prevention can be achieved only by controlling the environmental factors in the affected areas; there are no vaccines for the prevention of histoplasmosis.
- Q: Do patients with histoplasmosis need to be isolated?
- A: No isolation of infected patients is required.

HODGKIN LYMPHOMA

Leslie S. Kersun

BASICS

DESCRIPTION

Malignant enlargement of lymph nodes characterized by a pleomorphic cellular infiltrate with multinucleated giant cells (Reed-Sternberg cells)

EPIDEMIOLOGY

Incidence

- Male > female
- Incidence shows bimodal age distribution:
 - Early peak, before adolescence in developing countries, mid- to late 20s in US
 - 2nd peak, late adulthood > 50 years of age
 - Childhood cases rare before 5 years of age
 - Most common in whites > 15 years of age

RISK FACTORS

Risk groups: Definitions vary in different countries and cooperative groups. For the largest cooperative group in the US:

- Low risk: IA–IIA, without bulk disease
- Intermediate risk:
 - IA–IIA with bulk disease (defined by nodal aggregate > 6 cm or mediastinal mass > 1/3 the thoracic diameter)
 - IAE, IIAE: IB–IIB
 - IIIA, IVA
- High risk: IIIB, IVB
- Prognostic factors:
 - Disease stage
 - Presence of “B symptoms” (see “History”)
 - Bulk disease or mediastinal mass
 - Laboratory abnormalities including hemoglobin (Hb) < 11 g/dL, WBC > 13.5 thousand/uL, elevated ESR
 - Timing of response to treatment

Genetics

Familial clustering suggests both genetic and environmental factors in pathogenesis:

- 3–7-fold increased risk of disease among siblings in families where twins are concordant
- Reports of parent–child pairs

PATHOPHYSIOLOGY

Reed-Sternberg cells are the malignant cells of Hodgkin lymphoma. They are monoclonal and derived from germinal center B cells.

- WHO classification divides disease into histologic categories:
 - Nodular lymphocyte–predominant Hodgkin lymphoma
 - Classical Hodgkin lymphoma (90%)
 - Nodular sclerosis: Most common subtype in children
 - Mixed cellularity
 - Lymphocyte depletion
 - Lymphocyte rich

ETIOLOGY

- Exact cause unknown
- Infections with Epstein-Barr virus may play role in transmission of disease.

DIAGNOSIS

HISTORY

- Stage B symptoms occur in 20–30% and include 1 of the following:
 - Unexplained fever > 38°C for ≥ 3 days
 - Unexplained weight loss > 10% of body weight in previous 6 months
 - Drenching night sweats
- Stage A disease signifies absence of B symptoms or asymptomatic.
- Other systemic symptoms can include fatigue, anorexia, pruritus, chest pain, and orthopnea
- History relative to possible immunodeficiency, Epstein-Barr virus, or HIV infection should be recorded.

PHYSICAL EXAM

Painless lymphadenopathy most common:

- Nodes usually firmer, rubbery in texture, and less mobile than inflammatory nodes. Cervical chain involved in 80% of patients
- Mediastinal mass in 2/3 of patients that may cause nonproductive cough or difficulty breathing
- Hepatosplenomegaly and bone tenderness in advanced stages
- If bone marrow involvement, can see pallor, bruising, or petechiae
- Rare cases present with autoimmune hemolytic anemia (AIHA) or idiopathic thrombocytopenic purpura (ITP) and can have jaundice, petechiae, or bleeding as a result.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC, ESR
- Liver and renal function studies
- Baseline thyroid function (pre-radiotherapy)
- Baseline electrocardiogram, echocardiogram
- Baseline pulmonary function tests (pre-radiotherapy and/or bleomycin)
- Bone marrow biopsy in selected cases

Imaging

- Chest radiograph (posterior-anterior and lateral) for mediastinal mass
- CT scan (neck, chest, abdomen, pelvis) to rule out disseminated disease
- PET scan is now standard in children and young adults.

Diagnostic Procedures/Other

Excisional lymph node biopsy for definitive diagnosis
Ann Arbor Staging System:

- I: Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (IE) by direct extension
- II: Involvement of 2 or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and 1 or more lymph node regions on the same side of the diaphragm (IIE)
- III: Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE) or both (IIIES)
- IV: Diffuse or disseminated involvement of 1 or more extralymphatic organs or tissues with or without associated lymph node involvement
- Staging further subclassified A or B according to absence or presence of symptoms (listed above), respectively

DIFFERENTIAL DIAGNOSIS

- Infection is most common cause for acute lymphadenopathy:
 - Bacterial (*Staphylococcus aureus*, hemolytic streptococcus, tuberculosis, atypical mycobacterium)
 - Other (Epstein-Barr virus, cytomegalovirus, cat-scratch disease, toxoplasmosis, HIV, histoplasmosis)
- Malignancy more common with chronic adenopathy:
 - Non-Hodgkin lymphoma
 - Neuroblastoma
 - Leukemia
 - Rhabdomyosarcoma
- Mediastinal masses divided anatomically:
 - Anterior: Lymphoid and thyroid tumors, bronchogenic cysts, aneurysms, lipomas
 - Middle: Lymphoid tumors, angiomas, pericardial cysts, teratomas, esophageal lesions, hernias
 - Posterior: Neurogenic tumors, cysts, thoracic meningocele, sarcomas

TREATMENT

MEDICATION (DRUGS)

Chemotherapy:

- Multiple agents allow different mechanisms of action (to circumvent resistance) and nonoverlapping toxicities so that full doses can be given. Some common combinations used in initial therapy include:
 - COPP: Cyclophosphamide, vincristine (Oncovin), procarbazine, prednisone. Often used in combination with ABV below.
 - ABV: Doxorubicin (Adriamycin), bleomycin, vinblastine
 - ABVD: ABV (as above) + dacarbazine
 - ABVE: Doxorubicin + bleomycin + vincristine + etoposide
 - ABVE-PC: ABVE (as above) + prednisone and cyclophosphamide
 - VAMP: Vinblastine, Adriamycin, methotrexate, prednisone
 - BEACOPP: Bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, prednisone

ALERT

For patients with lymphocyte-predominant histology: Excision alone has been used for patients with low-stage disease.

ADDITIONAL TREATMENT

General Measures

Radiotherapy

Exquisitely responsive to radiotherapy: In pediatric setting, radiotherapy used in conjunction with chemotherapy and not used as sole treatment modality. Some combinations of chemotherapy have only been studied with radiation as additional treatment modality. Often recommended if patient has slow or incomplete response to chemotherapy. Some chemotherapy regimens have been used in the setting of a clinical trial without radiation therapy if rapid and complete response to chemotherapy alone.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Once therapy is complete, office visits at decreasing frequency over time for:

- Laboratory evaluation including CBC, ESR
- Imaging of involved areas every 3 months for 1st year, every 3–4 months for years 2–3, then every 6 months for years 4–5 after therapy
- Relapse of disease usually occurs within 1st 3 years. Some may relapse as late as 10 years after initial diagnosis.
- Special studies as needed for toxicity-related complications. For example:
 - Yearly thyroid function tests if history of irradiation
 - Regular self-breast exam for females treated with chest radiation

- Mammograms beginning by the age of 25 or 7 years post–chest radiation (whichever is later in females)
- Periodic ECGs and Holter monitors if treated with radiation and/or anthracyclines
- Periodic pulmonary function tests if treated with radiation and/or bleomycin
- Refer to survivorship clinic at 5 years after completion of therapy
- Late effects secondary to chemotherapy and/or radiation
 - Pulmonary: Pneumonitis, pulmonary fibrosis, decreased pulmonary function, pneumothorax
 - Cardiac/vascular: Cardiomyopathy resulting in congestive heart failure, pericarditis, valvular damage, coronary heart disease, arrhythmias, myocardial infarction, and stroke
 - Gonadal dysfunction: Ovarian damage can be avoided by performing temporary oophorectomy prior to involved field radiotherapy (IFRT). Azoospermia secondary to alkylating agents is almost always permanent in postpubertal boys. Sperm banking recommended for boys with development of Tanner III or higher
 - Thyroid: Hypothyroidism, hyperthyroidism, thyroid nodules, thyroid cancer
 - Growth/musculoskeletal: Growth retardation more common in past when prepubertal patients received high doses of radiotherapy
 - Secondary malignant neoplasms: A major concern in selecting therapy:
 - Breast cancer most common solid tumor
 - Other secondary neoplasms: Thyroid and skin carcinomas, bone, colorectal, gastric, leukemia

PROGNOSIS

With current therapy including chemotherapy and/or radiation, 5-year disease-free survival:

- Low-risk disease: >90%
- Advanced disease: 60–95% depending on regimen used

COMPLICATIONS

Acute toxicity of treatment:

- Radiation: Include erythema, nausea, fatigue, possibly myelosuppression
- Chemotherapy: The general side effects include:
 - Hair loss
 - GI toxicity including nausea, vomiting, diarrhea, mucositis, risk for typhlitis
 - Myelosuppression (most common dose-limiting toxicity)
 - Transfusions may be required.
 - Febrile neutropenia and infection
 - All patients take prophylaxis for *Pneumocystis*.
 - Each chemotherapeutic agent has its own specific potential side effects, which are not reviewed here.

CODES

ICD9

- 201.50 Hodgkin’s disease, nodular sclerosis, unspecified site, extranodal and solid organ sites
- 201.60 Hodgkin’s disease, mixed cellularity, unspecified site, extranodal and solid organ sites
- 201.90 Hodgkin’s disease, unspecified type, unspecified site, extranodal and solid organ sites

ICD10

- C81.10 Nodular sclerosis classical Hodgkin lymphoma, unspecified site
- C81.20 Mixed cellularity classical Hodgkin lymphoma, unspecified site
- C81.90 Hodgkin lymphoma, unspecified, unspecified site

FAQ

- Q: Is my child at risk for other cancers?
- A: Yes. Although the incidence is low, children with Hodgkin lymphoma are primarily at risk for cancers resulting from their treatment. Breast cancer is the most common solid tumor and can occur decades after therapy. Therefore, long-term follow-up is essential.
- Q: Will my child be infertile following treatment?
- A: It depends on the therapy received. Certain chemotherapy agents are associated with a higher risk of infertility (alkylating agents), and boys are more sensitive than girls. Radiation to the gonads is also associated with infertility.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Richard M. Rutstein

BASICS

DESCRIPTION

- HIV-1 and HIV-2 are the etiologic agents of HIV infection and AIDS.
- HIV infection is lifelong.
- For most infected individuals, a long clinically asymptomatic period (5–15 years in adults, frequently shorter in children) is followed by the development of generalized nonspecific signs and symptoms (weight loss, adenopathy, hepatosplenomegaly) and mild clinical immunodeficiency.
- Eventually, after progressive immunologic deterioration, patients are susceptible to a wide variety of opportunistic infections and cancers, which represent the clinical syndrome known as AIDS.

GENERAL PREVENTION

- HIV infection is almost completely preventable.
- It is now possible to significantly decrease the risk to newborns of HIV-infected women:
 - With prenatal 3-drug regimens, delivery via elective cesarean section for selected cases, and 6 weeks of postnatal zidovudine, perinatal transmission rates are now 2% or less in HIV specialty care sites.
 - All pregnant women should be offered HIV testing at the first prenatal visit. In areas of high incidence, repeat testing should be done at 36 weeks of gestation.

EPIDEMIOLOGY

HIV infection is transmitted via:

- Sexual contact:
 - Male-to-female transmission more efficient than female to male
 - Anal receptive sex more likely to transmit than vaginal sex
- Exposure to infected blood:
 - Almost always involves parenteral exposure to infected blood (via transfusions or sharing needles)
 - In occupational exposure, risk of transmission from percutaneous exposure to a needle contaminated with HIV-infected blood is 1/300.
- Breast milk:
 - Overall risk of breast-feeding is ~15%.
 - In countries where breast-feeding is the norm, up to 30% of perinatally acquired HIV infections occur through breast-feeding.
- Perinatally, either *in utero* or during labor and delivery:
 - Of perinatally infected infants, 5–10% are believed infected *in utero*; the rest acquire the infection around the time of birth.
 - Risk of an HIV-infected mother (not on treatment) giving birth to an infected infant is ~20%, (in the absence of breastfeeding) with increased rate of transmission for women with low CD4 counts or higher viral titers. Vaginal delivery, especially with rupture of membranes >8 hours, appears to increase the risk of infant infection.
 - Presence of untreated STDs, chorioamnionitis, and prematurity all increase the risk of mother-to-child transmission of HIV.

- HIV is not believed to be transmitted by:
 - Bites
 - Sharing utensils, bathrooms, bathtubs
 - Exposure to urine, feces, vomitus (except where these fluids may be grossly contaminated with blood, and even then transmission is rare, if it happens at all)
 - Casual contact in the home, school, or daycare center

DIAGNOSIS

SIGNS AND SYMPTOMS

Indications for HIV testing:

- Infants whose maternal HIV status is unknown
- Infants of HIV+ mothers
- IV drug use
- Noninjectable drug use
- STDs, especially syphilis
- All sexually active adolescents, at least annually
- Transfusions before 1986
- Frequent infections
- Sinopulmonary infections
- Recurrent pneumonia/invasive bacterial disease
- Severe acute pneumonia (*Pneumocystis*)
- Recurrent or resistant thrush, especially after 12 months of age
- Congenital syphilis
- Acquired microcephaly
- Progressive encephalopathy, loss of developmental milestones
- History of idiopathic thrombocytopenic purpura/thrombocytopenia
- Failure to thrive
- Recurrent/chronic diarrhea
- Recurrent/chronic enlargement of parotid gland

PHYSICAL EXAM

- May be entirely normal in the 1st few months of life
- 90% will have some physical findings by age 2 years
- Most common findings are:
 - Adenopathy, generalized
 - Hepatosplenomegaly
 - Failure to thrive
 - Recurrent/Resistant thrush, especially after 1 year of age
 - Recurrent or chronic parotitis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Enzyme-linked immunosorbent assay (ELISA) antibody screen:
 - For children > 18 months of age, repeatedly reactive ELISA antibody screen, followed by confirmation with Western blot analysis, is diagnostic of HIV infection.
 - Any positive test should always be repeated before a definitive diagnosis is discussed with family.
 - In first year of life, positive HIV ELISA and Western blot antibody tests simply confirm maternal infection, because the antibody test is IgG based and maternal anti-HIV antibodies readily cross placenta. Maternal antibodies may remain detectable in the infant until 15 months of age.

- HIV RNA or DNA polymerase chain reaction (PCR) DNA testing:
 - Most reliable way of diagnosing HIV infection in infancy
 - Both tests have sensitivities and specificities >95% when done after 2 weeks of age.
- Elevated IgG levels: First observed immune abnormality noted in HIV-infected infants, generally reaching twice the normal values by 9 months of age
- CD4 counts:
 - Obtained at diagnosis and every 1–3 months
 - Results need to be evaluated on the basis of age-adjusted normal values. Absolute CD4 counts are elevated in childhood, with normal median values >3,000/mm³ in the first year of life, which then gradually decline with age, reaching values comparable with adult levels (800–1,000/mm³) by age 7.
- Quantitative viral RNA PCR assays:
 - Termed “viral loads,” results are reported in a range from undetectable, usually <50 copies/mL, to upper values of > 10 million cpm
 - Long-term prognosis is closely related to viral loads.
 - Viral loads that remain >100,000 are associated with poor short-term (2- to 5-year) outcomes.
 - Also used as a marker of efficacy of treatment; goal is to suppress viral replication to the undetectable range for as long as possible. 50–65% of pediatric patients presently followed at tertiary sites have an undetectable viral load.
 - Test is done at time of diagnosis (twice) to establish baseline, 1 month after initiating or changing therapies, and every 1–3 months thereafter.
- Neurologic evaluation, with consideration of psychometric testing, at entry, and annually. Neuroimaging is indicated in those with abnormal results. Postimmunization antibody levels to assess B cell function
- Other frequent lab abnormalities include thrombocytopenia, anemia, and elevated liver enzymes.

DIFFERENTIAL DIAGNOSIS

- Neoplastic disease:
 - Lymphoma
 - Leukemia
 - Histiocytosis X
- Infectious:
 - Congenital/perinatal cytomegalovirus
 - Toxoplasmosis
 - Congenital syphilis
 - Acquired Epstein–Barr virus
- Congenital immunodeficiency syndromes:
 - Wiskott–Aldrich syndrome
 - Chronic granulomatous disease

ALERT

The result of failing to screen for HIV infection is the inability to offer antiretroviral therapy for pregnant women, therefore, possibly preventing infant infection, and also the inability to prescribe *Pneumocystis carinii* pneumonia prophylaxis to infected newborns.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Immunizations:
 - All infected children receive standard childhood immunizations, including the recently approved pneumococcal conjugate vaccine.
 - Infected children should receive yearly influenza A/B immunizations and the 23 valent pneumococcal vaccine at age 2 years.
 - Symptomatic children should not receive the varicella vaccine, and those with severely low CD4 counts should not receive measles–mumps–rubella vaccination.
- Immune enhancement:
 - Passive: Studies done before the present era of antiretroviral therapy indicate that monthly gamma globulin infusions somewhat decreased febrile episodes and pneumococcal bacteremia. The children who benefit the most are those not on antibiotic prophylaxis for *P. carinii* pneumonia and/or who have had at least 2 episodes of invasive bacterial infections.
- Prophylaxis: One of the major advances in the care of HIV-infected children and adults has been the ability to offer prophylaxis against the most common opportunistic infections.

MEDICATION (DRUGS)

- Antiretroviral therapy:
 - Specific combination antiretroviral therapy prolongs life, delays progression of illness, promotes improved growth, and improves neurologic outcome.
 - Standard of care now involves the administration of combination therapy (usually 3 or more drugs), termed highly active antiretroviral therapy (HAART). There are now more than 25 approved antiretroviral agents, of 5 different drug classes.
 - Given the complexities of therapy, and the rapid changes in available therapies, antiretroviral therapy should always be prescribed in consultation with a specialist in pediatric/adolescent HIV infection.
 - Adherence to prescribed schedules is critical: When patients miss even 10–20% of doses, the durability of response is short.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Psychosocial support for the family is critical.
- Because of the complex, rapidly changing therapies available to treat pediatric HIV infection, all infected patients should be co-managed with an HIV specialty care site.
- Patients should be seen every 1–3 months to monitor immune status (CD4 counts) and virologic suppression (quantitative plasma viral RNA).

PROGNOSIS

Because the use of HAART has become standard, morbidity and mortality have both greatly decreased:

- Median survival is now clearly into adulthood.
- Incidence of new opportunistic infections (AIDS signal illnesses) has decreased greatly, as have hospital admissions.

COMPLICATIONS

- *P. carinii* pneumonia:
 - Most common early fatal illness in HIV-infected children (peak age 3–9 months) mortality is 30–50%. A high index of suspicion is necessary for prompt diagnosis (by lavage) and initiation of therapy.
 - 40% of new cases of HIV-related pediatric *P. carinii* pneumonia involve infants not previously recognized as HIV infected.
- Lymphocytic interstitial pneumonitis:
 - Frequently asymptomatic; can lead to slow onset of chronic respiratory symptoms
 - Causes a distinctive diffuse reticulonodular pattern on chest radiographs
 - Usually diagnosed between 2 and 4 years of age; related to dysfunctional immune response to Epstein–Barr virus infection
 - Definitive diagnosis is made by lung biopsy.
 - For symptomatic patients, prednisone is effective.
- Recurrent invasive bacterial infections:
 - Prior to the use of pneumococcal conjugate vaccines and HAART, the risk of bacteremia/pneumonia was ~10%/year in HIV-infected children.
 - Pneumococcal bacteremia is the most common invasive bacterial disease.
 - Bacterial pneumonia, sinusitis, and otitis media are common among infected children.
- Progressive encephalopathy:
 - Diagnosed between 9 and 18 months of age, the hallmark is progressive loss of developmental milestones or neurologic dysfunction.
 - Cerebral atrophy, with or without basal ganglion calcifications, on neuroimaging
- Disseminated *Mycobacterium avium* intracellulare:
 - Older children, usually >5 years of age, with severe immunodeficiency (CD4 ≤100)
 - Symptoms include prolonged fevers, abdominal pain, anorexia, and diarrhea.
- *Candida* esophagitis: Older children with severe immunodeficiency usually present with dysphagia or chest pain and oral thrush. Diagnosis indicated by findings on barium swallow, but definitive diagnosis made by biopsy
- Disseminated cytomegalovirus disease:
 - Retinitis less common in HIV-infected children than in adults
 - Cytomegalovirus may also cause pulmonary disease, colitis, and hepatitis.

- HIV-related cancers: Non-Hodgkin lymphoma most common cancer, with primary site usually located in the CNS
- Other organ dysfunction associated with HIV-infection in children:
 - Cardiomyopathy
 - Hepatitis
 - Renal disease
 - Thrombocytopenia/idiopathic thrombocytopenic purpura

CODES

ICD9

- 042 Human immunodeficiency virus [HIV] disease
- 795.71 Nonspecific serologic evidence of human immunodeficiency virus [HIV]
- V08 Asymptomatic human immunodeficiency virus [HIV] infection status

ICD10

- B20 Human immunodeficiency virus [HIV] disease
- R75 Inconclusive laboratory evidence of human immunodef virus
- Z21 Asymptomatic human immunodeficiency virus infection status

FAQ

- Q: When the HIV-exposed infant has seroreverted to antibody-negative status, how sure are we that he or she is uninfected?
- A: With today’s technology, if the child has also been RNA or DNA PCR negative at least twice, and is clinically well, the chance that the child still harbors HIV is very low and appears to be <1/5,000. The CDC considers any child with 2 negative HIV PCRs as definitively uninfected, provided one of the PCRs was done after 4 months of age.

HUMAN PAPILLOMA VIRUS

Sarah E. Winters

Elizabeth M. Wallis

Kristen Feemster (5th edition)

Jane Lavelle (5th edition)

BASICS

DESCRIPTION

- Members of the Papovaviridae family, the human papillomaviruses (HPV) cause warts of the skin and mucous membranes. Exophytic venereal warts or condylomata acuminata are caused by HPV types 6 and 11.
- Warts can be found on the external genitalia and the urethra, vagina, cervix, anus, and mouth. HPV types 6 and 11 are also associated with squamous cell carcinoma of the external genitalia.
- Virus types 16, 18, 31, 33, and 35 typically cause subclinical infection in the anogenital region and have been associated with intraepithelial genital carcinomas.
- HPV can also cause recurrent respiratory papillomatosis (RRP) in infants and young children. RRP primarily impacts the larynx but can also cause lesions anywhere along the respiratory tract.

EPIDEMIOLOGY

- General:
 - HPV is the most common viral STI.
 - Genital warts and HPV infection are diseases of young adults 16–25 years of age.
 - Cervical cancer is the leading cause of female malignancy in the developing world.
- Genital HPV:
 - Peak prevalence among women 18–24 years
 - 40% of sexually active adolescents are infected with HPV
 - <1% of adolescents develop genital warts.
 - 21% of HPV positive women have low-grade squamous intraepithelial lesions (LSIL) on Pap smear.
 - 500,000 new cases of cervical cancer diagnosed each year internationally
- RRP:
 - RRP impacts 4.3 per 100,000 children, mostly those age 2–3 years.
 - 67% of children with RRP are born to mothers who had condyloma during pregnancy.

RISK FACTORS

- Infants:
 - Primarily vertical transmission at birth
- Adolescents:
 - Behavioral risks, including young age at 1st coitus, multiple partners, cigarette use, and having older male partners
 - Biologic risk in adolescent girls secondary to cervical anatomy

GENERAL PREVENTION

- Condom use may diminish transmission.
- Examine partners; treat those infected.
- Pap smear to assess for cervical dysplasia
- Vaccination to prevent HPV types 6, 11, 16, and 18. Vaccination is recommended for female and male patients starting at age 11 and is approved for use for persons aged 9–26
- HPV infection is not a reportable disease.

PATHOPHYSIOLOGY

- Transmission is primarily through sexual contact.
- It can also be acquired during the birth process.
- Transmission from nongenital sites occurs rarely.
- The incubation period is variable and ranges from 3 months to several years.
- The virus is trophic for epithelial cells and infects the basal layer of actively dividing cells.
- Infection results in koilocytosis and nuclear atypia. Genital infections may progress to severe dysplasia and carcinoma in situ (CIS).
- Spontaneous regression of clinical disease occurs in 90% of low-risk types and 75% of high-risk types
- Recurrence is common.

COMMONLY ASSOCIATED CONDITIONS

- Epidermodysplasia verruciformis
- Other STIs

DIAGNOSIS

HISTORY

- Genital HPV:
 - Most patients have no symptoms.
 - Presence of warts, often painless
 - Vaginal, urethral, or anal discharge, bleeding, local pain
 - Dysuria
 - Pruritus
- RRP:
 - Infants have hoarse or weak cry, stridor, and failure to thrive.
 - Older children have hoarseness, stridor, dysphonia, and obstructive sleep apnea.

PHYSICAL EXAM

- Genital HPV:
 - Warts appear as soft, sessile tumors with surfaces ranging from smooth to rough with many fingerlike projections.
 - HPV may also cause flat keratotic plaques that project only slightly with a hyperpigmented surface and are difficult to identify without the addition of acetic acid.

- Subclinical infection is common, causing many foci of epithelial hyperplasia invisible to the examiner.
- In males, infection is found on the penis, urethra, scrotum, and perianal areas.
- In females, infection involves the urethra, vagina, cervix, and perianal area.
- Diagnosis is made by visual inspection of the anogenital region. Cervical dysplasia is clinically inapparent on exam.

- RRP:
 - Often normal exam, but may be evident on respiratory exam

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Application of 3–5% acetic acid for 5 minutes causes lesions to appear white and thus more readily apparent and can help with the detection of cervical disease.
- Tissue specimens may show koilocytosis typical for HPV infection.
- Pap smear with liquid cytology to assess for evidence of cervical dysplasia resulting from HPV infection
- Colposcopy aids the diagnosis of cervical lesions.
- Polymerase chain reaction is commercially available for HPV typing and is used in patients >21 with abnormal Pap smears.

Diagnostic Procedures/Other

- Genital HPV:
 - Pap smear or colposcopy to screen for cervical dysplasia
- RRP:
 - Direct visualization of the airway through laryngoscopy

DIFFERENTIAL DIAGNOSIS

- Genital HPV:
 - Condyloma lata
 - Molluscum contagiosum
 - Pink pearly papules or hypertrophic papillae of the penis
 - Lipomas
 - Fibromas
 - Adenomas
- RRP:
 - Croup
 - Vocal cord paralysis
 - Other forms of nasal, laryngeal, pharyngeal or tracheal obstruction

TREATMENT

MEDICATION (DRUGS)

Table 1. Treatment for external warts

Medication	Procedure	Side effect
Podofilox 0.5%	Patient applies medicine with a cotton swab b.i.d. for 3 days. After 4 days, it is repeated as necessary for 4 cycles. The area for treatment should not exceed 10 cm ² , and total drug should not exceed 0.5 mL/d.	Local
Imiquimod 5% cream	Patient applies cream at bedtime 3 times per week for up to 16 weeks. It is washed off after 6–10 hours.	Local
Podophyllin 10–25%	A practitioner applies a small amount to each wart and allows it to air dry. It is washed off 1–4 hours later. Dose is limited to 0.5 mL per treatment to avoid systemic toxicity.	Local
Trichloroacetic acid (TCA) 80–90%	The practitioner applies this sparingly to each wart directly. Talc is applied to remove unreacted acid. It is washed off after 4 hours.	Local
Laser surgical excision	Requires special equipment and training; often requires general anesthesia; controlled tissue destruction	Local
Cryotherapy	Liquid nitrogen or cryoprobe is used every 1–2 weeks by a specially trained provider.	Local

ADDITIONAL TREATMENT

General Measures

- To date, no therapy exists that eradicates the virus. Recurrences are likely due to reinfection.
- Most patients require a course of therapy rather than a single treatment.
- Genital HPV:
 - Lesions on mucosal surfaces respond better to topical treatments.
 - All available therapies have equal efficacy in eradicating warts, ranging from 22–94%, with the significant rate of relapse of 25% within 3 months (see table in “Medication”):
 - Consider size, location, number of warts, previous treatment, and patient preference.
 - Also consider patient preference, expense, and side effects.
 - Patients with extensive lesions should be referred to physicians who routinely treat these lesions.
 - Treatment:
 - External: See table in “Medication.”
 - Meatal: Cryotherapy or podophyllin
 - Anal: Cryotherapy or trichloroacetic acid
 - Vaginal: Trichloroacetic acid
 - Cervical: Refer to an expert.
- RRP:
 - Surgical excision

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow-up should continue until the warts have disappeared.
- Patients should return for recurrent disease.
- Latent infection and recurrent disease are common.
- USTPTF and American College of Obstetrics and Gynecology (ACOG) recommend initial Pap smear at age 21, while the American Cancer Society (ACS) recommends initial Pap smear after 3 years of initiating sexual activity, but no later than age 21.

PROGNOSIS

Therapy will not eradicate the virus; thus, HPV causes recurrent disease.

FAQ

- Q: What treatment is indicated during pregnancy?
- A: Most experts recommend surgical removal if necessary. Podophyllin is absolutely contraindicated.
- Q: Should partners of patients with genital warts be referred for examination?
- A: Recurrence is due to reactivation of the virus; reinfection plays no role. Partner may benefit from an examination to evaluate for the presence of warts, and for education and counseling. There is no information regarding prophylaxis to prevent infection, so treatment for this is not indicated. Most partners have subclinical infection. Female partners/patients should follow the routine recommendations for Pap smear screening.
- Q: Are genital warts in children always indicative of sexual abuse?
- A: No. The HPV virus has an incubation period of many months. Thus, warts transmitted to infants at the time of birth may not become clinically apparent for 1–2 years. Whether the incubation period can be longer than this remains unknown. Thus, maternal history and, potentially, examination are both important factors. However, all children with anogenital warts should be carefully evaluated by experienced clinicians for child abuse. It is possible that caregivers may transmit the virus to children through close but nonsexual contact; thus, this history is also important in older children.
- Q: Will young women still need to get Pap smears if they have received the HPV vaccine?
- A: Yes. The vaccine does offer good protection against the strains most commonly associated with genital warts and cervical cancer, 6, 11, 16, and 18. However, these strains are not the only ones that can cause infection or lead to cervical cancer. It is important to continue regular screening to ensure that one has not been exposed to other strains that may cause cervical dysplasia.

HYDROCEPHALUS

Jennifer A. Markowitz

BASICS

DESCRIPTION

- Accumulation of CSF in the ventricles and subarachnoid spaces, leading to their enlargement
- Overall head size may enlarge in response, depending on age and cause.

PATHOPHYSIOLOGY

- Normal pathway of CSF: Choroid plexus and interstitial fluid (sources), lateral ventricles, foramina of Monro, 3rd ventricle, aqueduct of Sylvius, 4th ventricle, foramina of Luschka and Magendie, subarachnoid space, arachnoid villi, and venous circulation
- Hydrocephalus results from obstruction to CSF flow, impaired reabsorption, or overproduction of CSF.
- Noncommunicating (obstructive) hydrocephalus results from obstruction within the ventricular system.
- Communicating hydrocephalus usually results from impaired CSF reabsorption or (rarely) overproduction (e.g., due to a choroid plexus papilloma).
- The noncommunicating/communicating distinction has no prognostic significance, but has implications for etiology and choice of therapeutic intervention.

ETIOLOGY

- Intraventricular hemorrhage is most commonly due to prematurity, but may also occur with trauma. It results in impaired CSF absorption due to meningeal adhesions, granular ependymitis, and clots. Posthemorrhagic hydrocephalus (PHH) occurs in 35% of all neonates surviving intraventricular hemorrhage; its incidence increases with increasing severity of hemorrhage.
- Tumors or cysts near the foramina or the aqueduct, or within the ventricular system
- Infection (meningitis, intrauterine infection) can lead to leptomeningeal adhesions and granulations that block reabsorption of CSF.
- Developmental:
 - Chiari malformation, type II (associated with myelomeningocele, brain migrational disorders, small posterior fossa, inferior displacement of medulla and cerebellar vermis, kinking of the brainstem, aqueductal stenosis, beaking of the tectum)
 - Dandy-Walker malformation (absence of cerebellar vermis, small cerebellar hemispheres, enlarged posterior fossa, often with cystic 4th ventricle)
 - X-linked and autosomal dominant hydrocephalus; the former is often associated with aqueductal stenosis and mutations in L1CAM on Xq28.
 - Sporadic primary aqueductal stenosis
 - Dysmorphic syndromes (e.g., Apert syndrome, Cockayne syndrome, Crouzon syndrome, Pfeiffer syndrome, trisomy 13, trisomy 18, trisomy 21, triploidy)
 - Alexander disease
 - Mucopolysaccharidoses (e.g., type II [Hunter], type VI [Maroteaux-Lamy])

- Migrational disorders/congenital muscular dystrophies (e.g., Miller-Dieker, muscle-eye-brain disease, Fukuyama congenital muscular dystrophy, Walker-Warburg syndrome)
- Achondroplasia
- Neurocutaneous syndromes (e.g., neurofibromatosis type 1, rare)
- Idiopathic

DIAGNOSIS

HISTORY

Presenting concerns:

- Infants: Enlarging head, irritability, vomiting, somnolence, poor feeding
- Older children: Headache, vomiting, double vision, somnolence

PHYSICAL EXAM

- Vital signs: In advanced acute hydrocephalus, Cushing triad (hypertension, reflex bradycardia, respiratory irregularities): This is not generally seen in infants prior to fusion of the sutures.
- Rapidly increasing head circumference in infants. Fullness of the anterior fontanelle neither sensitive nor specific, but should be noted. May observe splaying of the sutures
- Mental status: Irritability or somnolence in infants, behavioral changes in children (acute or chronic)
- Cranial nerves: “Setting sun” sign due to paralysis of upgaze, disconjugate gaze, papilledema, optic atrophy, and visual changes in the chronic setting
- Motor: Gait ataxia; spastic paraparesis in chronic hydrocephalus related to pressure on white matter tracts surrounding the ventricles
- Reflexes: Increased in chronic hydrocephalus

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Head ultrasound:
 - Standard screening test for neonates with suspected hydrocephalus or intraventricular hemorrhage
 - Anterior fontanelle must be patent for this test.
 - Demonstrates ventricular size, presence or absence of blood, associated structures, and anomalies
- Unenhanced CT of the brain:
 - Mainly used in infants and children whose anterior fontanelles have closed and following shunt procedures
 - Better visualization of 4th ventricle/brainstem and calcifications than with ultrasound; standardized technique that is less operator dependent; better availability in the emergency room setting
- MRI:
 - Definitive test for analyzing brain anatomy
 - Can identify posterior fossa developmental malformations such as Chiari and Dandy-Walker
 - Not indicated in acute hydrocephalus, especially when patient is unstable

- Techniques such as diffusion tensor imaging may help to estimate local pressure on white matter adjacent to ventricles, as a correlate of increased intracranial pressure. This may help identify increased intracranial pressure in patients with unchanged ventricular size and aid in the assessment of postsurgical outcome.

Note: When imaging to diagnose shunt malfunction, it is important to consider the lifetime cumulative radiation exposure for each child; fast-sequence shunt MRI series may be able to replace CT for certain patients, if available.

ALERT

Head CT often will not show developmental malformations that may accompany hydrocephalus. MRI is the imaging procedure of choice for elective study.

DIFFERENTIAL DIAGNOSIS

- Other causes of macrocephaly:
 - Familial macrocephaly/“benign external hydrocephalus”
 - Pericerebral effusions
 - Congenital anomalies of intracerebral or extracerebral veins
 - Tumors, intracranial cysts
 - Primary megalencephaly, hemimegalencephaly
 - GM2 gangliosidosis
 - Some leukodystrophies (e.g., Alexander disease, Canavan disease)
 - Head-sparing intrauterine growth retardation (relative macrocephaly)
 - Rapid catch-up growth following prolonged malnutrition
- Other causes of ventriculomegaly, typically with normal head circumference: Brain atrophy and chronic ethanol or corticosteroid exposure (reversible)
- Enlargement of the subarachnoid spaces: Usually bifrontal, normal to mildly enlarged ventricles. May be seen in children with macrocephaly, who if otherwise normal are diagnosed with “benign external hydrocephalus.” Recognize that metabolic and genetic disorders can also present with enlarged subarachnoid spaces (e.g., glutaric aciduria type I, others listed above).

TREATMENT

SURGERY/OTHER PROCEDURES

Acute interventions:

- Ventricular shunt:
 - Indication: Progressive or acute symptomatic hydrocephalus
 - Contraindications: Active central nervous system infection, active intraventricular hemorrhage, and poor overall prognosis
 - Components: Ventricular catheter, reservoir (target of shunt taps), valve, distal catheter
 - Distal sites: Peritoneum is the most common choice; pleura, ureter, venous system, gallbladder, and right atrium are other options.
 - Approach: Usually performed as an open procedure; endoscopic procedures available in some centers

- Complications:
 - Shunt failure occurs in 40% of shunts within the 1st year after placement, and 50% within the 1st 2 years. Causes are obstruction, infection, disconnection, or fracture of components; migration of shunt components; overdrainage; erosion into an abdominal viscus. Presents with symptoms similar to those of acute hydrocephalus
 - Infections occur at a rate of ~8–10% per shunt manipulation, usually during the 1st 6 months after surgery. Present with low-grade persistent fever, and less commonly with erythema of overlying skin. Most common organism is *Staphylococcus epidermidis*; reinfection occurs in 30% of patients harboring this organism.
 - Siphon effect: Drop in ventricular pressure on sitting or standing causing headache; newer shunt systems with antisiphon mechanisms are available.
 - Newer shunts have programmable valve mechanisms; one must be cautious when obtaining an MRI in patients with this type of shunt in place as the magnet may affect valve settings.

ALERT

- Timing of shunt placement is critical and problematic: Sometimes watchful waiting can obviate the procedure, whereas waiting too long may result in brain damage.
- Don't assume hydrocephalus is "cured." Late shunt failure may occur years after placement, often due to fracture of tubing, and can result in death from acute hydrocephalus causing herniation.
- Posthemorrhagic hydrocephalus (PHH) in the neonate may be managed initially with serial lumbar puncture; this has been shown to improve cerebral perfusion in these patients. Most do not require shunt placement. Ultimately some may require ventriculosubgaleal or ventriculoperitoneal shunts.
- 3rd ventricle fenestration (endoscopic 3rd ventriculostomy):
 - Indications: Most effective for obstructive hydrocephalus due to aqueductal stenosis or space-occupying lesions
 - Complications: Overall rate of serious complications 9.4%; these include infection, CSF leak, neurologic deficits, extraparenchymal hemorrhage; rare risk of damage to the basilar artery

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- When the etiology or need for shunt placement is unclear, it is important to follow clinical status, head circumference, and ventricular size (by head ultrasound or CT).
- Chronic hydrocephalus is often accompanied by spastic paraparesis, visual problems, and learning problems.

- Most interventions are supportive:
 - Physical therapy, occupational therapy, and orthopedic therapies for spasticity; interdisciplinary cerebral palsy clinics can be critical in providing easy access to these resources.
 - Special education programs may be appropriate for children with severe developmental delay.

ALERT

- It is important for long-term patients in intensive care nurseries to have head circumferences recorded at least twice weekly. Macrocephaly is not always obvious on visual inspection.
- Absence of papilledema does not exclude chronic increased intracranial pressure.

PATIENT EDUCATION

Parent Internet Information: National Hydrocephalus Foundation, <http://www.nhfonline.org>

PROGNOSIS

Depending on the severity and cause of hydrocephalus, efficacy of treatment, and presence or absence of concomitant neurologic disorders, outcome may vary widely from normal neurologic development to severe impairment or death.

COMPLICATIONS

- Acute hydrocephalus: Herniation syndromes may be fatal.
- Chronic hydrocephalus:
 - Macrocephaly
 - Spastic paraparesis may lead to gait and motor problems.
 - Vision loss
 - Developmental delay
 - Precocious puberty due to pressure on the hypothalamus

FAQ

- Q: When does an infant need a head ultrasound?
- A: Any infant whose head circumference increases by more than a quartile on the growth chart needs a head ultrasound. Preterm infants below a certain gestational age or birth weight (varies from hospital to hospital) should all receive screening head ultrasounds while in the intensive care nursery.
- Q: When should an infant or child receive an MRI rather than an ultrasound or CT?
- A: Although MRI may be superior in many cases, the logistics of ordering the proper sequences and the need for sedation or anesthesia for long studies must be strongly considered. Consultation with a neurologist or neurosurgeon is generally advised.
- Q: What is the workup for shunt obstruction and shunt infection?
- A: Symptoms and signs of increased intracranial pressure should lead to a neurosurgical evaluation; the most useful studies include head CT (to assess ventricular size and placement of ventricular catheter) and shunt series (plain films of the entire shunt system to check for disruptions). "Pumping" the shunt reservoir is a procedure with a low positive predictive value for shunt failure. Tapping the shunt to assess pressure must be done with discretion, as repeated taps may disrupt the valve mechanism. Fever is the most important indication for a shunt infection evaluation (shunt tap with CSF cell count, protein, glucose, Gram stain, and culture). Often patients will be evaluated for both complications.

HYDRONEPHROSIS

J. Christopher Austin
Michael C. Carr

BASICS

DESCRIPTION

- Hydronephrosis: Dilation of the renal pelvis (pelviectasis) and calyces (caliectasis) due to excess urine in the collecting system of the kidney
- Hydroureteronephrosis: Dilation of the renal collecting system and the ureter to the level of the bladder

EPIDEMIOLOGY

- Incidence of genitourinary abnormalities noted on routine prenatal ultrasound is 0.2%.
- 87% of these are antenatally detected hydronephrosis/hydroureteronephrosis.
- 5% of fetuses with hydronephrosis are due to ureteropelvic junction obstruction.
- Perinatal mortality associated with hydronephrosis has ranged from 13–72%, but is most strongly correlated with the presence of chromosomal abnormalities, multiple system abnormalities, detection earlier in gestation, oligohydramnios, and evidence of infravesical obstruction.
- Posterior urethral valves and triad syndrome account for 6% of cases.

ETIOLOGY

- Ureteropelvic junction obstruction:
 - Intrinsic narrowing or an aperistaltic segment of distal ureter. These are also called megaureters.
- Vesicoureteral reflux:
 - In primary reflux (grades I to V depending on the severity), it is due to an insufficient flap valve-type mechanism at the ureterovesical junction.
 - Hydroureteronephrosis is usually seen only with higher grades of reflux (grades III to V) or secondary reflux (reflux in the presence of an abnormal bladder, in which the reflux is often due to high storage or voiding pressures within the bladder). Secondary reflux is not graded.
- Ureterocele:
 - Hydroureteronephrosis secondary to obstruction of the ureter from a cystic dilation of the intravesical portion of the distal ureter
 - Most often associated with the upper pole ureter in a duplicated collecting system; less frequently associated with a single system
 - Ureterocele is further classified as intravesical (contained completely within the bladder) or ectopic (extending down the bladder neck and often into the urethra).
- Ectopic ureter:
 - A ureter that drains into an abnormal location away from the trigone
 - The hydroureteronephrosis can be the upper pole ureter of a duplicated collecting system or a single system.
 - Ectopic ureters can drain at various sites along the lower urinary tract depending on the sex of the child. In boys, they can drain into the bladder neck, prostatic urethra, vas deferens, seminal vesicle, or epididymis. In girls, they can drain into the bladder neck, urethra, introitus, and vagina.
 - The ectopic locations often require passage through the bladder neck or urogenital diaphragm, which produces obstruction of the distal ureter.

- Urolithiasis:
 - Obstructing calculi often produce dilation of the urinary tract proximal to its location.
 - Stone disease is rare in infancy except in preterm infants who receive furosemide.
 - The hydronephrosis is usually associated with renal colic.
- Posterior urethral valves:
 - Hydroureteronephrosis, nearly always bilateral, produced by outflow obstruction of the bladder from valve leaflets in the prostatic urethra
 - Because both kidneys are affected, there is a significant risk of chronic renal insufficiency and development of end-stage renal disease.
- Triad syndrome:
 - Hydroureteronephrosis, often with massively dilated ureters, and a large bladder
 - Also known as prune belly syndrome or Eagle-Barrett syndrome
 - These boys have a triad of hypoplastic abdominal wall musculature (leading to a prunelike appearance), bilateral undescended testes, and a dilated urinary tract.
 - Many have associated urethral atresia, which imparts a worse prognosis for renal function.
 - Exact cause of triad syndrome remains elusive.
 - Significant risk of renal insufficiency in these patients
 - A similar syndrome may occur in girls with a prunelike appearance to the abdomen and anomalies of the urogenital tract; however, it is very rare.

DIAGNOSIS

HISTORY

- Newborns:
 - Antenatal hydronephrosis: Presence of hydronephrosis or hydroureteronephrosis
 - If unilateral, severity of hydronephrosis and the status of contralateral kidney
 - If bilateral, presence of bladder wall thickening, bladder enlargement, bladder emptying, or a dilated posterior urethra (keyhole sign) may indicate posterior urethral valves or triad syndrome.
 - If oligohydramnios is present, pulmonary hypoplasia is a concern. The presence of oligohydramnios, increased renal echogenicity, and cystic changes in the kidneys are indicators of poor renal function and dysplasia.
- Older children:
 - History of urinary tract infections or gross hematuria
 - General health and growth (poor growth with chronic renal insufficiency or acidosis)
 - Daytime incontinence, poor urinary stream, or symptoms of voiding dysfunction may be an indicator of bladder dysfunction due to posterior urethral valves.
 - History of episodic abdominal (which may not lateralize well), flank, or back pain in the presence of hydronephrosis is often due to symptomatic ureteropelvic junction obstruction (see topic “Ureteropelvic Junction Obstruction”).

PHYSICAL EXAM

- Neonate:
 - Signs of oligohydramnios (Potter facies, lateral patellar dimples, clubfeet, and other limb deformities) and respiratory distress
 - Palpable abdominal mass
 - Palpable walnut-sized bladder (posterior urethral valves)
 - Patent urachus
 - Ascites
 - Development of abdominal wall musculature (wrinkled prunelike appearance in triad syndrome)
- Older children:
 - Presence of abdominal mass
 - Abdominal or flank tenderness

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Newborn:
 - Hydronephrosis or hydroureteronephrosis with a normal contralateral kidney does not require any immediate laboratory testing.
 - If both kidneys are affected or a solitary kidney is affected, there is a need for serial assessments of renal function (serum electrolytes and creatinine).
- Older children:
 - Urinalysis to detect hematuria or pyuria. Culture if infection suspected
 - In cases where both kidneys are affected or there is a solitary kidney, renal function should be evaluated.

Imaging

- Infants with antenatally detected hydronephrosis typically are evaluated with 3 imaging studies:
 - Renal/bladder ultrasound
 - Voiding cystourethrogram
 - Renal scan
- The timing can be elective for a unilateral lesion with a normal contralateral kidney, but if both kidneys are affected or a solitary kidney is involved, prompt evaluation of the newborn should be undertaken.
- Renal/bladder ultrasound:
 - Because of a period of relative oliguria of a newborn in the first 24–48 hours of life, an ultrasound may underestimate the degree of hydronephrosis during this time and thus should be postponed until the infant is at least 48 hours old.
 - This should not preclude evaluating an infant during this time as long as a study is repeated in 4–6 weeks.
 - In cases where both kidneys were affected or there is a solitary affected kidney, the evaluation should not be delayed.
 - Ultrasound of the kidneys should reveal the severity of dilation of the renal pelvis and calyces, changes in the amount and echogenicity of the parenchyma, and presence of cortical cysts.
 - Evaluation of the full bladder is important as well. It will show dilated distal ureters, which may indicate a ureterovesical junction obstruction, vesicoureteral reflux, or hydroureteronephrosis from posterior urethral valves or triad syndrome.

- Voiding cystourethrogram:
 - Evaluates for the presence of vesicoureteral reflux
 - Allows for the grading of the severity of reflux as well
 - The shape of the bladder, presence of diverticulum, and trabeculations may indicate hypertrophy from posterior urethral valves, neurogenic bladder dysfunction, or voiding dysfunction (in older children).
 - Test can be delayed until after discharge from the nursery unless there is concern about posterior urethral valves, in which case it should be done in the early postnatal period.
- Renal scan:
 - Can quantify the differential renal function or the amount each kidney contributes to overall renal function (the normal differential function is 50% ± 5% for each kidney)
 - The 2 most commonly used radionuclides are 3-mercaptoacetyl triglycine (MAG-3) and diethylenetriamine penta-acetic acid (DTPA). MAG-3 is the best choice for infants and babies.
 - In addition to the ability to detect diminished function, if there is poor drainage of the affected kidney, furosemide is given to wash out the radiotracer. The duration for washing out 1/2 of the accumulated radiotracer ($T_{1/2}$) is often given in the report. A prompt $T_{1/2}$ (< 10 min) is indicative of a nonobstructed kidney. A slower $T_{1/2}$ may be indicative of obstruction when it is > 20 minutes. An intermediate $T_{1/2}$ (10–20 minutes) is indeterminate for obstruction. Many factors affect the $T_{1/2}$ making it less reliable for indicating obstruction. These factors include the hydration status, presence of vesicoureteral reflux, and the overall function of the kidney (very poorly functioning kidneys have a poor response to diuretics).
- IV pyelogram:
 - Most useful for evaluating the anatomy of the kidney and the ureters
 - Also a useful test for evaluating an older child with intermittent symptoms of abdominal or flank pain
 - Can be diagnostic of an intermittent ureteropelvic junction obstruction as the cause of the child's pain
- CT scan:
 - Most commonly done in cases where the hydronephrosis is symptomatic
 - Noncontrast spiral CT is the most sensitive way to detect stones, as even stones radiolucent on plain films (uric acid) will be detected by CT.
- MRI: Currently has a limited role in evaluating hydronephrosis, but contrast-enhanced MRI is currently being studied as an alternative to renal scans and ultrasound in the evaluation of hydronephrosis.

DIFFERENTIAL DIAGNOSIS

- Cystic renal tumor:
 - Most commonly Wilms tumor
 - Should be distinguished from hydronephrosis by ultrasound or CT scanning
- Multicystic dysplastic kidney:
 - Can be difficult to distinguish from severe hydronephrosis with marked parenchymal thinning
 - Renal scan will show no function or perfusion with a multicystic dysplastic kidney

TREATMENT

ADDITIONAL TREATMENT

General Measures

Neonates with hydronephrosis are started on prophylactic antibiotics (1/4 the therapeutic dose given once a day) of amoxicillin. When the baby is 2 months old, the antibiotic can be changed to trimethoprim, trimethoprim/sulfamethoxazole or nitrofurantoin.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Ureteropelvic junction obstruction:
 - After initial evaluation, the infants are usually followed with serial studies, either ultrasound or renal scans, depending on the degree of functional impairment, the severity of the hydronephrosis, and the pattern of drainage on the renal scan.
 - From more information, see topic "Ureteropelvic Junction Obstruction."
- Ureterovesical junction obstruction:
 - After initial evaluation, these children are followed with serial studies as with ureteropelvic junction obstruction.
 - These lesions are much less common than ureteropelvic junction obstruction, and most of the time, the affected kidneys have normal function and can be followed conservatively.
 - If the function of the kidney is significantly diminished (differential function of 35–40%), surgical treatment of the obstruction is indicated.
- Vesicoureteral reflux:
 - Infants with reflux are kept on prophylactic antibiotics.
 - In the absence of breakthrough infections, they are re-evaluated annually.
 - If persistent high-grade reflux continues or breakthrough infections are a problem, surgical correction is carried out.
 - For more information, see topic "Vesicoureteral Reflux."
- Ureterocele/ectopic ureter: Because these are obstructive lesions, they are generally treated surgically early in life at the time of diagnosis.

- Posterior urethral valves:
 - Full-term infants undergo cystoscopic valve ablation, whereas preterm infants may require a temporary vesicostomy until endoscopic treatment is feasible.
 - These boys require careful follow-up from a pediatric urologist and nephrologist as they grow up.
 - For more information, see topic "Posterior Urethral Valves."
- Triad syndrome: Typically these boys will undergo bilateral orchiopexy with or without an abdominoplasty depending on the severity of the hypoplasia of the abdominal wall during the first 6–12 months of life.

CODES

ICD9

- 591 Hydronephrosis
- 753.21 Congenital obstruction of ureteropelvic junction

ICD10

- N13.1 Hydronephrosis w ureteral stricture, NEC
- N13.30 Unspecified hydronephrosis

FAQ

- Q: If my baby has hydronephrosis affecting only 1 kidney, will he need a kidney transplant?
- A: In the absence of oligohydramnios and bilateral hydroureteronephrosis, it would be a very rare event that a child would develop renal failure requiring transplantation.
- Q: My unborn baby has hydronephrosis in only one kidney, and the other kidney is normal. What are the chances that it is a ureteropelvic junction obstruction?
- A: The chances are ~45% that isolated hydronephrosis will be due to a ureteropelvic junction obstruction.
- Q: My male unborn baby has bilateral hydronephrosis but a "normal" bladder. Is there still a chance that he has posterior urethral valves?
- A: Yes. Although it is less likely to be due to posterior urethral valves than if a thick-walled, enlarged, poorly emptying bladder were seen, prenatal ultrasonography is operator dependent and can miss dilated ureters or bladder abnormalities.

HYPERIMMUNOGLOBULINEMIA E SYNDROME

Erin E. McGintee

BASICS

DEFINITION

Rare disorder characterized by markedly elevated serum IgE levels, chronic eczematoid dermatitis, skeletal abnormalities, and recurrent staphylococcal infections

RISK FACTORS

Genetics

- Most cases sporadic, but both autosomal-dominant (AD-HIES) and autosomal-recessive forms (AR-HIES) have been reported.
- AD-HIES is caused by mutations in STAT3, a transcriptional regulator.
- Mutations in DOCK8 and Tyk2 have been identified in AR-HIES.

PATHOPHYSIOLOGY

- Impaired cytokine signaling (IFN- γ , IL-6, and IL-10 defects have been identified) leads to a variety of immunologic impairments.
- Phagocytic: Impaired chemotaxis
- T cell: Impaired proliferative response to antigens
- B cell: Variable heterogeneity of ability to form antibodies to antigens

DIAGNOSIS

HISTORY

- Recurrent infection: "Cold" abscesses, pneumonia, pneumatoceles, otitis media, sinusitis
- Organisms that cause infection: *Staphylococcus aureus*, *Candida*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, group A *Streptococcus*
- Superinfection with fungal and opportunistic organisms.
- AR-HIES may present with severe viral infection or molluscum.
- Severe eczematoid dermatitis as early as 1 week of age.
- Delayed shedding of primary teeth (AD-HIES)

PHYSICAL EXAM

- Coarse facial features, prominent forehead, broad nasal bridge, prominent nose
- Growth retardation can occur with recurrent illnesses.
- Osteoporosis complicated by recurrent fractures
- Eczematoid dermatitis
- Hyperextensible joints

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Eosinophilia: Peripheral eosinophils, >700 cells/mL
- Quantitative immunoglobulins: IgG, IgA, IgM usually normal, but IgE elevated, usually $>10,000$ IU/mL
- IgE antibodies against *S. aureus*
- Functional antibodies to diphtheria, tetanus, *Haemophilus influenzae* Type b, and *Pneumococcus* results are variable, but there is a subgroup of patients who are unable to mount an appropriate antibody response to these antigens.
- Some patients demonstrate impaired polymorphonucleocyte (PMN) chemotaxis.
- Pulmonary function tests to evaluate extent of lung disease from infections such as pneumatoceles

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis
- Wiskott-Aldrich syndrome
- Omenn syndrome
- IPEX
- Chronic granulomatous disease

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Supportive, based on clinical and laboratory findings
- Lifelong use of antistaphylococcal therapy: Dicloxacillin or amoxicillin/clavulanate potassium (Augmentin) at therapeutic doses
- Surgical intervention for management of pneumatoceles for drainage or secondary to compression of nearby parenchyma
- IV immunoglobulin as replacement therapy for abnormal functional antibodies is usually given at starting dose of 400 mg/kg monthly.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Long-term outcome is unknown; it depends on a timely diagnosis that allows for close monitoring and aggressive treatment of infections.
- Sequelae from recurrent infections, such as pneumonias and pneumatoceles, can result in a debilitating course.
- Increased chance of malignancy has been reported in some cases.

- 279.3 Unspecified immunity deficiency
- 288.1 Functional disorders of polymorphonuclear neutrophils

ICD10

D82.4 Hyperimmunoglobulin E [IgE] syndrome

FAQ

- Q: Is this disease also referred to as Job syndrome?
- A: Yes, because Job suffered from difficulties with boils and other skin manifestations.

HYPERINSULINISM

Vaneeta Bamba

Diva D. De León

BASICS

DESCRIPTION

Hyperinsulinism (HI) is a disorder of dysregulated insulin secretion characterized by excessive and/or inappropriate insulin secretion resulting in severe hypoglycemia. Hyperinsulinism can occur transiently but congenital HI refers to a permanent inborn condition.

EPIDEMIOLOGY

Most common cause of persistent or recurrent hypoglycemia in children beyond the immediate neonatal period.

Incidence

- Annual incidence estimated at ~1:40,000–50,000 live births in the USA.
- May be as high as 1:2,500 in select populations (Saudi Arabians, Ashkenazi Jews)

Prevalence

- Estimated prevalence of hypoglycemia due to hyperinsulinism in the USA is 0.0008%.

Genetics

- Autosomal recessive mutations of K_{ATP} channel genes (*ABCC8* and *KCNJ11*) at chromosomal locus 11p14-15.1 resulting in diffuse involvement throughout the pancreas (diffuse HI)
- Autosomal dominant mutations of K_{ATP} channel genes
- A nonmendelian mode of inheritance with reduction to homozygosity (or hemizyosity) of paternally inherited mutation of K_{ATP} channel gene, and a specific loss of maternal alleles of the imprinted chromosome region 11p15 (focal HI).
- Autosomal dominant mutations of glucokinase (*GCK*): Activating mutations in the glucokinase gene
- Autosomal dominant mutations of glutamate dehydrogenase (*GLUD-1*): Known as hyperinsulinism/hyperammonemia syndrome due to activating mutations of glutamate dehydrogenase (GDH) enzyme
- Autosomal recessive mutations of the mitochondrial enzyme short-chain-3-dihydroxyacyl-CoA dehydrogenase (*SCHAD*; encoded by *HADHSC*)
- Autosomal dominant mutations in *HNF4A*, mutations known to cause a familial form of monogenic diabetes can present with neonatal hyperinsulinism
- Autosomal dominant promoter activating mutations in *SLC16A1* encoding monocarboxylate transporter 1 (MCT1): Causes exercise-induced HI

PATHOPHYSIOLOGY

- These mutations result in uncoupling of insulin secretion from the glucose-sensing machinery of the pancreatic β -cell and inappropriate insulin secretion even in the face of low blood glucose.
- The most common and severe forms of HI arise from mutations in the K_{ATP} channel, which can manifest in focal or diffuse disease.
- In the focal form of the disease, only a cluster of pancreatic β -cells are affected, whereas in diffuse disease, all pancreatic β -cells are abnormal.
- In hyperinsulinism/hyperammonemia syndrome, activating mutations of glutamate dehydrogenase result in protein-induced insulin secretion and cause persistently elevated ammonia level.
- *HNF4A* mutations known to cause a familial form of monogenic diabetes, can present with neonatal hypoglycemia due to HI.
- In the case of exercise-induced HI, ectopic expression of MCT1, allows transport of lactate and pyruvate across the β -cell membrane, particularly during anerobic exercise. Pyruvate is metabolized and there is an increase in ATP to ADP ratio, thus stimulating insulin secretion. Hypoglycemia occurs 30–45 minutes after intense anerobic exercise.

ETIOLOGY

- Mutations in 7 genes have been associated with congenital HI: Genes coding for either of the two subunits of the beta cell K_{ATP} channel [*SUR1*, sulfonyleurea receptor (*ABCC8*); *Kir6.2*, inwardly rectifying potassium channel (*KCNJ11*)], glucokinase (*GCK*), glutamate dehydrogenase (*GLUD-1*), *SCHAD* (*HADHSC*), monocarboxylate transporter-1 (*SLC16A1*), and *HNF4A*.
- A transient form of HI has been associated with perinatal stress [small for gestational age (SGA) birth weight, maternal hypertension, precipitous delivery, or hypoxia], but the mechanism has not been elucidated.

COMMONLY ASSOCIATED CONDITIONS

Hyperinsulinism can be associated with Beckwith–Wiedemann syndrome and congenital disorders of glycosylation. The underlying mechanism of hyperinsulinism in these disorders is not clear.

DIAGNOSIS

HISTORY

Symptoms of hypoglycemia in the infant:

- Poor feeding
- Hypotonia
- Lethargy
- Cyanosis
- Tachypnea
- Tremors
- Seizures
- Early-morning irritability that responds to feeding

PHYSICAL EXAM

- Macrosomia:
 - Indicates congenital HI due to mutations in the K_{ATP} channel
- Small for gestational age:
 - Indicates transient HI
- Macroglossia, umbilical hernia, visceromegaly:
 - Indicates Beckwith Wiedeman syndrome
- No midline defects, including normal palate and genitalia
 - Midline defects indicate hypopituitarism.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Plasma insulin levels are rarely dramatically elevated in HI; rather there is inadequate suppression of insulin ($>2 \mu\text{U/mL}$) at time of hypoglycemia.
- Suppressed levels of plasma free fatty acids ($<1.5 \text{ mmol/L}$) and ketones (β -hydroxybutyrate level $<2.0 \text{ mmol/L}$) at time of hypoglycemia
 - Indirect signs of excessive insulin action
- Glycemic response to glucagon (blood sugar rise $>30 \text{ mg/dL}$) at time of hypoglycemia:
 - Indicates inappropriately stored glycogen at time of hypoglycemia (sign of excessive insulin action)
- Suppressed insulin-like growth factor binding protein-1 (IGFBP-1) level:
 - IGFBP-1 production is inhibited by insulin (sign of excessive insulin action).
- Elevated plasma ammonia levels:
 - Indicate hyperinsulinism/hyperammonemia syndrome
- Elevated plasma 3-hydroxybutyryl-carnitine and urinary 3-hydroxyglutarate
 - Indicates *SCHAD*
- Normal growth hormone, cortisol, and thyroxine levels:
 - Exclude hypopituitarism

Imaging

- PET scans at specialized hyperinsulinism centers using 18-fluoro-DOPA may identify and localize focal lesions.
- Traditional imaging studies such as ultrasound, CT scan and MRI are not helpful in identifying focal HI lesions.

Pathological Findings

- Pancreatic histology in children with HI due to K_{ATP} channel mutations can be subdivided into 2 major forms:
 - Diffuse HI: Abnormally enlarged islet cell nuclei found diffusely throughout the pancreas
 - Focal HI (40–60% of cases): Discrete region of adenomatous hyperplasia surrounded by normal-appearing pancreas
- Normal histology can also be seen in HI.

DIFFERENTIAL DIAGNOSIS

- Sepsis
- Congenital heart disease
- Infant of diabetic mother (IDM)
- Beckwith–Wiedemann syndrome (BWS)
- Panhypopituitarism
- Congenital disorders of glycosylation
- Respiratory distress syndrome
- Erythroblastosis fetalis
- Other inborn errors of metabolism
- Children with dumping syndrome after fundoplasty can have severe post-meal hypoglycemia due to excessive insulin secretion after a meal.

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

The major goal is prevention of brain damage by controlling blood glucose:

- Parenteral dextrose infusions to stabilize blood sugar acutely: For an acute hypoglycemic event, give a bolus of 2–3 mL/kg of 10% dextrose (0.2–0.3g/kg). For maintenance, use glucose infusion rates of 8–10 mg/kg/min to maintain BG > 70 mg/dL (some HI patients may need up to 25 mg/kg/min).
- Supplemental oral or nasogastric/G tube feeds

MEDICATION (DRUGS)

- Diazoxide, a suppressant of insulin secretion, at 5–15 mg/kg/d divided q12h (most patients with KATP HI do not respond to diazoxide). Most patients with transient HI who require medical therapy respond well to diazoxide and resolve spontaneously.
- Octreotide, a long-acting somatostatin analog, at 5–20 μ g/kg/d divided q6h or given by continuous SQ infusion. Octreotide may increase the risk of necrotizing enterocolitis in neonates.
- Glucagon, at 1 mg/d by continuous intravenous infusion, may stabilize blood glucose levels in preparation for surgery.

SURGERY/OTHER PROCEDURES

- Subtotal pancreatectomy in children refractory to medical therapy or in those with focal lesions
- For focal HI, surgery can be curative.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Up to 30–44% of patients can have neurodevelopmental retardation due to hypoglycemia
- Diabetes may develop later in life, especially after pancreatectomy

Patient Monitoring

- Home blood glucose monitoring, especially with longer fasts or intercurrent illnesses
- Hospitalizations for IV glucose infusions may be necessary during intercurrent illnesses with vomiting.
- Follow-up fasting studies may be needed to evaluate safety and/or disease regression.
- Diazoxide may cause fluid retention and hypertrichosis.
- Neonates treated with octreotide should be closely monitoring for evidence of necrotizing enterocolitis.
- Tachyphylaxis and hyperglycemia may occur with octreotide.
- Close observation of linear growth is necessary, because octreotide can suppress GH secretion.

DIET

- Frequent feedings and avoidance of long fasts
- Avoidance of protein loads in those with hyperinsulinism/hyperammonemia, as high-protein diets may stimulate insulin secretion

COMPLICATIONS

- Severe refractory hypoglycemia
- Cognitive deficits, especially of short-term memory, visual–motor integration, and arithmetic skills
- Seizures
- Coma
- Permanent brain damage
- Glucose intolerance or frank diabetes mellitus

**CODES****ICD9**

251.1 Other specified hypoglycemia

ICD10

E16.1 Other hypoglycemia

FAQ

- Q: What is the chance of hyperinsulinism in the sibling of an affected child?
- A: 25% in the autosomal-recessive type; 50% in the autosomal-dominant type; <1% for siblings of children with focal hyperinsulinism
- Q: How low and for how long can glucose go before brain damage occurs?
- A: The definition of hypoglycemia has been the subject of controversy in pediatrics, but activation of glucose counterregulatory systems occurs when blood glucose levels reach the 65–70 mg/dL range; symptoms of hypoglycemia present at the 50–55 mg/dL level, and cognitive dysfunction occurs when blood glucose levels are in the 45–50 mg/dL range. Taking these data into account, blood glucose concentration should be maintained > 70 mg/dL. The duration of hypoglycemia necessary for brain damage to occur is unknown.
- Q: What is the chance that HI will eventually resolve without surgery?
- A: Only ~40–50% of cases are controlled with medication alone. Patients with mutations in KATP channel may be more likely to require surgery, and in those patients with focal disease, surgery may be curative. Perinatal-stress induced hyperinsulinism usually resolves within the first 3 months of life.

HYPERLIPIDEMIA

Dale Y. Lee

Ruben W. Cerri (5th edition)

BASICS

DESCRIPTION

Hyperlipidemia is an elevation of serum lipids. These lipids include cholesterol, cholesterol esters (compounds), phospholipids, and triglycerides. Lipids are transported as part of large molecules called lipoproteins.

- 5 major families of lipoproteins:
 - Chylomicrons
 - Very low-density lipoproteins (VLDL)
 - Intermediate-density lipoproteins (IDL)
 - Low-density lipoproteins (LDL)
 - High-density lipoproteins (HDL)
- Normal serum lipid concentrations: Total cholesterol: 170 mg/dL (borderline, 170–199 mg/dL)
 - LDL cholesterol: < 110 mg/dL (borderline, 110–129 mg/dL)
 - HDL cholesterol: ≥ 35 mg/dL
 - Total triglycerides: 100 mg/dL (borderline, 100–140 mg/dL)
- More detailed age and gender specific values are available (refer to Table 2 of 2008 *Clinical Report: Lipid Screening and Cardiovascular Health in Childhood*)
- Primary hypercholesterolemia or hypertriglyceridemia (hyperlipidemia): Elevation in serum cholesterol as a result of an inherited disorder of lipid metabolism (i.e., familial hypercholesterolemia)
- Secondary hypercholesterolemia or hypertriglyceridemia: Elevation in serum cholesterol as a result of another disease process (e.g., nephrotic syndrome)

EPIDEMIOLOGY

Incidence

The incidence of homozygous familial hypercholesterolemia is 1 in 1,000,000; the incidence of the heterozygous state is 1 in 500. Unknown causes result in hypercholesterolemia and/or hypertriglyceridemia occurring in 2% of the population.

Prevalence

- National Health and Nutrition Exam Surveys (NHANES I-III) have provided information about the serum cholesterol levels in children.
- For all children 4–17 years, the 95th percentile for serum total cholesterol is 216 mg/dL and the 75th percentile is 181 mg/dL.
- The average total and LDL cholesterol levels are, before puberty, significantly higher in girls than they are in boys.
- The mean total cholesterol level for all children from 4–11 years old peaks at age 9–11 and then gradually decreases until mid to late adolescence.

RISK FACTORS

Genetics

- Familial hypertriglyceridemia (FHTG): Dominantly inherited disorder
- Familial hypercholesterolemia (FH): Dominantly inherited defect of LDL receptor
- Familial combined hyperlipidemia (FCHL): Dominantly inherited lipid disorder

GENERAL PREVENTION

- Fat intake is generally unrestricted prior to 2 years of age. After age 2, 2 complementary approaches are recommended.
- Diet and lifestyle guidelines are to promote:
 - Consumption of an overall healthy diet
- A healthy body weight (BMI: 18.5–24.9 kg/m²)
- Recommended lipid levels:
 - LDL cholesterol < 110 mg/dL
 - HDL cholesterol > 50 mg/dL in women, > 40 mg/dL in men
 - Triglycerides < 150 mg/dL
- Normal BP (age appropriate)
- Normal blood glucose level (fasting blood glucose ≤ 100 mg/dL)
- Being physically active
- Avoiding use of and exposure to tobacco products
- Screen children and adolescents who have:
 - Positive family history of dyslipidemia or premature CVD (≤ 55 years old for men, ≤ 65 years old for women), such as coronary atherosclerosis, documented MI.
 - Unknown family history
 - Obesity (BMI ≥ 95 th percentile), or are overweight (BMI ≥ 85 th–<95th percentile)
 - Cigarette smoking exposure
 - Diabetes mellitus

DIAGNOSIS

HISTORY

- Family history of premature heart disease or dyslipidemia:
 - Almost all cases of primary hyperlipidemia are of dominant inheritance.
- Smoking:
 - Smoking reduces HDL cholesterol levels and increases the risk of vascular disease.
- Use of oral contraceptives:
 - Birth control pills have been shown to cause elevations in lipoprotein levels and, when coupled with already elevated lipid levels, can increase the risk of atherosclerosis.
- Regular exercise
- Diet:
 - Children with increased intake of fat, carbohydrates, sugar added drinks, and fast foods are likely to be overweight/obese
- Obesity:
 - Obese children are more likely to have abnormal serum lipids.

PHYSICAL EXAM

- Eye exam:
 - Arcus corneae: Deposits of cholesterol, resulting in a thin, white circular ring located on the outer edge of the iris
- Skin exam:
 - Tendon xanthomas: Thickened tissue surrounding the Achilles and extensor tendons
 - Xanthelasma: Yellowish deposits of cholesterol surrounding the eye
 - Palmar xanthomas: Pale lines in creases of palms
 - Eruptive xanthomas: Characteristic of hypertriglyceridemia; papular yellowish lesions with a red base that occur on the buttocks, elbows, and knees
 - Enlarged tender liver may present in association with fatty liver.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Screening for patients with:
 - A parental history of elevated total cholesterol levels (> 240 mg/dL) or other dyslipidemia
 - A family history of premature coronary heart disease
 - Incomplete or unavailable family histories
 - Other risk factors for CVD (obese or overweight, cigarette smoking, hypertension, diabetes, inactivity)
- Fasting lipid profile: Total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides:
 - Determine the type of hyperlipidemia.
- First screening should take place after 2 years of age, but no later than 10 years of age
- If fasting lipid profile is within normal range, repeat test in 3–5 years
- Chemistry panel (ALT, AST, bilirubin, BUN, creatinine, urinalysis):
 - Screening test for liver and kidney disease
- Thyroid evaluation (thyroxine, thyroid stimulating hormone):
 - Determines the presence of hypothyroidism

ALERT

- Serum total cholesterol is inaccurate when serum triglycerides are > 400 mg/dL.
- Hypertriglyceridemia is associated with falsely lowered serum Na.

DIFFERENTIAL DIAGNOSIS

- Hypercholesterolemia:
 - Primary hypercholesterolemia (see above)
 - Hypothyroidism
 - Nephrotic syndrome
 - Liver disease (cholestatic)
 - Renal failure
 - Anorexia nervosa
 - Acute porphyria
 - Medications (antihypertensives, estrogens, steroids, microsomal enzyme inducers, cyclosporine, diuretics)
 - Pregnancy
 - Dietary: Excessive dietary intake of fat, cholesterol, and/or calories

- Hypertriglyceridemia:
 - Primary hypertriglyceridemia (see above)
 - Acute hepatitis
 - Nephrotic syndrome
 - Chronic renal failure
 - Medications (diuretics, retinoids, oral contraceptives)
 - Diabetes mellitus
 - Alcohol abuse
 - Lipodystrophy
 - Myelomatosis
 - Glycogen storage disease
 - Dietary: Excessive dietary intake of fat and/or calories

TREATMENT

MEDICATION (DRUGS)

- Drug therapy should be considered only for children ≥ 8 years of age after an adequate trial of diet therapy (for 6–12 months) and if they have one of the following:
 - LDL cholesterol level remains > 190 mg/dL
 - LDL cholesterol level remains > 160 mg/dL and there is a family history of premature cardiovascular disease (≤ 55 years of age for men, ≤ 65 for women) or ≥ 2 other risk factors are present (obesity, hypertension, cigarette smoking).
 - LDL ≥ 130 mg/dL and have diabetes mellitus
- Physicians caring for overweight and obese children who have lipid disorders should emphasize the importance of diet and exercise rather than drug therapy for most of their patients.
- Statins (1st-line drug therapy): Decrease endogenous synthesis of cholesterol and increase clearance of LDL from circulation
 - Similar safety and efficacy in the treatment of lipid disorders in children as in adults
 - Side effects include hepatitis and myositis
- Bile-acid-binding resins: Bind cholesterol in bile acids in intestine and prevent reuptake into enterohepatic circulation
 - Associated with GI discomfort
 - Very poor compliance in children
- Niacin: Lowers LDL and triglycerides while increasing HDL; however, poorly tolerated in children due to side effects occur in $> 50\%$, including flushing, itching, and elevated hepatic transaminases
 - Drugs needing further pediatric studies: Cholesterol absorption inhibitors and fibrates

ADDITIONAL TREATMENT

General Measures

- Outpatient management unless secondary hyperlipidemia caused by liver or renal failure, which would necessitate inpatient management of primary illness. Note: The cause of secondary hyperlipidemia should be treated with disease-specific therapy to reduce elevated lipid levels.
- For primary hyperlipidemia: It is recommended that once a lipoprotein analysis is obtained, it should be repeated so that an average LDL cholesterol level can be calculated.

- Risk assessment and treatment:
 - Population approach: General emphasis on healthy lifestyle to prevent development of dyslipidemias. Recommendations include increasing intake of fruits, vegetables, fish, whole grains, and low-fat dairy products; reducing intake of fruit juice, sugar-sweetened beverages and food.
 - Individual approach: Focuses on patients who are high risk. Initial intervention is focused on changing diet, but patients often require pharmacologic intervention.

Additional Therapies

Activity:

- 60 minutes of moderate to vigorous play or physical activity daily
- Reduce sedentary behaviors (e.g., watching TV, playing videogames, using computers)
- Participation in organized sports.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- For patients with primary hyperlipidemia who are off medication, follow-up should be performed every 1–2 years with lipoprotein profile evaluation. For those patients on medication, follow-up should be conducted every 3–6 months.
- For all other patients with risks factors and normal lipid profile a monitored lifestyle and diet changes should be strongly recommended at every office visit.

DIET

- Dietary modification is safe in the treatment of hyperlipidemia in children > 2 years of age:
 - Restrict saturated fat to $< 7\%$ daily calories
 - Restrict dietary cholesterol to 200 mg/d
 - Limit trans fatty acids to $< 1\%$ daily calories
 - Supplemental fiber at goal dose of child's age + 5 g/d (up to 20 g/d)
- For children between 12 months and 2 years who are overweight, obese, or have a family history of dyslipidemia or CVD, the use of reduced fat milk can be considered.

PROGNOSIS

- Familial hypercholesterolemia:
 - Homozygotes: Coronary artery disease in 1st or 2nd decade of life
 - Heterozygotes: 50% of males develop premature heart disease by age 50 (females, age 60)
- Familial combined hyperlipidemia: Occurs in 1–2% of the population and accounts for 10% of all premature heart disease. A reduction of LDL cholesterol by 1% reduces risk by 2%.
- Children and adolescents with high cholesterol levels are more likely than the general population to have high levels as adults.

COMPLICATIONS

- Hypercholesterolemia has been linked to premature coronary artery disease and vascular disease.
- Severe hypertriglyceridemia can cause pancreatitis.
- Hypercholesterolemia:
 - Premature heart disease
 - Stroke
 - Carotid artery disease
- Hypertriglyceridemia:
 - Pancreatitis

- E78.1 Pure hyperglyceridemia
- E78.5 Hyperlipidemia, unspecified

HYPERTENSION

Christine B. Sethna

Kevin E. C. Meyers

BASICS

DESCRIPTION

- Hypertension: Average systolic and/or diastolic BPs above the 95th percentile for age, gender, and height percentile on at least 3 separate occasions as defined by the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents.
- Prehypertension: BP between the 90th percentile and 95th percentile or BP >120/80 in adolescents.
- Stage 1 hypertension: BP 95–99% plus 5 mm Hg.
- Stage 2 hypertension: BP >99th% plus 5 mm Hg.
- Primary (essential) hypertension: Hypertension for which there is no underlying cause
- Secondary hypertension: Hypertension for which an underlying cause can be identified
- White coat hypertension: Elevated BP readings in a medical setting with normal actual blood pressures
- Masked hypertension: Normal BP readings in a medical setting with elevated actual blood pressures

EPIDEMIOLOGY

- Secondary hypertension is more common in children than in adults.
- Primary hypertension is now identifiable in children and adolescents, and is associated with overweight, the metabolic syndrome, and family history of hypertension.

Prevalence

- The prevalence of hypertension is increasing due to the epidemic of youth obesity and the metabolic syndrome.
- Hypertension in the pediatric population is estimated between 1% and 23%.
- 30% of children with BMI >95% have hypertension.
- Primary hypertension in blacks is twice that of whites.

RISK FACTORS

- Primary hypertension: Obesity, sedentary lifestyle, low birth weight, smoking, alcohol use, hyperlipidemia, family history, stress, sodium intake, sleep apnea
- Secondary hypertension: Umbilical artery catheterization, UTI, genetic disease
- The younger the child and the more elevated BP, the greater likelihood of a secondary cause.

Genetics

- The genetic basis of primary hypertension is polygenic, but more likely to develop in individuals when there is a strong family history.
- The genetics of secondary causes depend on the condition:
 - Polycystic kidney disease: Autosomal dominant, autosomal recessive
 - Neurofibromatosis: Autosomal dominant
 - Glucocorticoid-remediable aldosteronism: Autosomal dominant

GENERAL PREVENTION

Avoidance of excess weight gain and regular physical activity can prevent obesity-related hypertension.

PATHOPHYSIOLOGY

- Many different mechanisms play a role in primary hypertension: Volume overload (sodium retention, excess sodium intake), volume distribution (sympathetic and renin overactivity, stress), and increased peripheral resistance (renin and sympathetic activity, insulin, endothelin)
- Secondary causes, with examples, include:
 - Renal: Acute glomerulonephritis, chronic renal failure, polycystic kidney disease, reflux nephropathy
 - Renovascular: Fibromuscular dysplasia, neurofibromatosis, vasculitis
 - Cardiac: Coarctation of the aorta
 - Endocrine: Pheochromocytoma, hypo/hyperthyroid, neuroblastoma, glucocorticoid-remediable aldosteronism, Conn syndrome, apparent mineralocorticoid excess, congenital adrenal hyperplasia, Liddle syndrome, Gordon syndrome
 - Neurologic: Increased intracranial pressure
 - Drugs: Corticosteroids, oral contraceptives, sympathomimetics, illicit drugs (cocaine, phencyclidine)
 - Other: Pain, burns, traction

DIAGNOSIS

- Hypertensive emergency: Severely elevated BP with evidence of target organ injury (encephalopathy, seizures, renal damage)
- Hypertensive urgency: Severely elevated BP with no evidence of secondary organ damage

HISTORY

- Headache, blurry vision, epistaxis, unusual weight gain or loss, chest pain, flushing, fatigue
- UTIs can be associated with reflux nephropathy and hypertension.
- Gross hematuria, edema, fatigue may suggest renal disease.
- Birth history: Umbilical artery catheterization
- Medications: Corticosteroids, cold preparations, oral contraceptives, illicit drugs
- Family history: Hypertension, diabetes, obesity, familial endocrinopathies, renal disease
- Trauma: Arteriovenous (AV) fistula, traction
- Review of symptoms: Sleep apnea, obesity

PHYSICAL EXAM

- BP:
 - Children >3 years should have their BP measured during a health care episode
 - Child should be seated quietly for 5 minutes, feet on the floor with the right arm supported at the level of the heart. Routine BPs pressures are measured in the arm.
 - Use the proper cuff size. The inflatable bladder should completely encircle the arm and cover ~80–100% of the upper arm. A cuff that is inappropriately small will artificially increase the measurement.
 - Elevated BPs obtained by oscillometric devices should be repeated by auscultation.
 - When hypertension is confirmed, BP should be measured in both arms and in a leg. Normally, BP is 10–20 mm Hg higher in the legs. If leg BP is lower than arm, consider coarctation of the aorta.
- Tachycardia in hyperthyroidism, pheochromocytoma
- Body habitus: Thin, obese, growth failure, virilized, stigmata of Turner or Williams syndromes
- Skin: Café au lait spots, neurofibromas, rashes, acanthosis, malar rash
- Head/Neck: Moon facies, thyromegaly
- Eyes: Funduscopic changes, proptosis
- Lungs: Rales
- Heart: Rub, gallop, murmur
- Abdomen: Mass, hepatosplenomegaly, bruit
- Genitalia: Ambiguous, virilized, femoral pulses
- Neurologic: Bell's palsy

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The laboratory evaluation to determine the cause of hypertension should proceed in a stepwise fashion.
- Patients should have the following: Urinalysis, urine culture; serum electrolytes, blood urea nitrogen, creatinine, calcium, cholesterol; CBC; ECG, echocardiogram (the most sensitive study to monitor end-organ changes); renal ultrasound; retinal exam
- Further evaluation is based on history, physical exam, and/or to prove secondary causes: Voiding cystourethrogram, DMSA renal scan, 3D CT angiogram, MRA, urine or plasma for catecholamines and metanephrines, plasma renin activity, aldosterone levels
- More invasive studies include renal angiogram; renal vein renin concentrations; MIBG scan; renal biopsy; genetic studies to identify rare causes of hypertension

Diagnostic Procedures/Other

Ambulatory BP monitoring refers to a procedure in which a portable BP device, worn by the patient, records BP over a specified period, usually 24 hours. Ambulatory BP monitoring may be helpful in cases assessing in which the diagnosis of hypertension is uncertain (white coat hypertension and masked hypertension, labile hypertension, effectiveness of antihypertensive agents and children at high risk of cardiovascular disease; e.g., diabetes mellitus, chronic kidney disease, labile hypertension).

DIFFERENTIAL DIAGNOSIS

The initial objective after diagnosing hypertension in children is distinguishing primary from secondary causes. Generally, the younger the child and more elevated the BP measurements, the more likely the cause of hypertension is secondary.

TREATMENT

MEDICATION (DRUGS)

- Classes of antihypertensive agents include α - and β -blockers, diuretics, vasodilators (direct and calcium channel blockers), ACE inhibitors, and angiotensin receptor blockers (ARB).
- Therapy should be initiated with a single drug.
- Avoid multiple medications with the same mechanism of action.
- Elicit a history of adverse effects and adjust medications accordingly.
- Specific classes should be used with concurrent medical conditions: ACE inhibitors or ARBs in children with diabetes and microalbuminuria or proteinuric renal diseases; β -blockers or calcium channel blockers with migraine headaches.
- Certain classes of medication should be avoided in patients with specific conditions, such as asthma and diabetes (β -blockers) and bilateral renal artery stenosis (ACE inhibitors).
- ACE inhibitors are associated with congenital malformations and are contraindicated during pregnancy; calcium channel blockers and β -blockers are alternatives.

ADDITIONAL TREATMENT

General Measures

- If BP is >95th percentile, it should be repeated on 2 more occasions.
- If BP is >99th percentile plus 5 mm Hg, prompt referral for evaluation and therapy should be made.
- If the patient is symptomatic, immediate referral and treatment are indicated.
- Mild primary hypertension may be managed with nonpharmacologic treatment: Weight reduction, exercise, sodium restriction, avoidance of certain medications such as pseudoephedrine.
- Pharmacologic therapy should be directed to the cause of secondary hypertension when this is known or for severe, sustained hypertension.
- Medications may be needed in children with mild-to-moderate hypertension if nonpharmacologic therapy has failed, or if end-organ changes are present or diabetes is present.

Additional Therapies

- Regular aerobic physical activity (30–60 minutes several days a week)
- Limitation of sedentary activities to <2 hours per day
- Patients with uncontrolled stage 2 hypertension should be restricted from high-static competitive sports until the BP is in normal range.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Dialysis may be needed for hypertension in chronic renal failure.

SURGERY/OTHER PROCEDURES

Surgical correction of renovascular hypertension and coarctation of the aorta. Percutaneous transluminal angioplasty has been used for renal artery stenosis.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Hypertensive emergencies should be treated with IV blood pressure medications, aiming to decrease the BP by 25% over the 1st 8 hours and gradually normalizing BP over 24–48 hours.
- Hypertensive urgencies can be treated by either IV or PO antihypertensives depending on symptomatology.

Admission Criteria

- Hypertensive emergencies should be admitted to the ICU if indicated.
- Hypertensive urgencies should be admitted to the hospital.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

The reduction of BP with medication should be gradual to avoid side effects. The medications themselves cause adverse effects, such as exercise intolerance (β -blockers), headaches (vasodilators), renal insufficiency or hyperkalemia (ACE inhibitors), or hypokalemia (diuretics).

DIET

- Dietary increase in fresh vegetables, fresh fruits, potassium, fiber, and nonfat dairy
- Restriction of sodium, calories, saturated fat, and refined sugar

PATIENT EDUCATION

- Diet:
 - Increase in fresh vegetables, fresh fruits, fiber, and nonfat dairy
 - Restriction of sodium and calories
- Activity:
 - Regular aerobic physical activity (30–60 minutes several days a week)
 - Limitation of sedentary activities to <2 hours per day
- Prevention:
 - Avoidance of excess weight gain, smoking, and alcohol use; regular physical activity

PROGNOSIS

The patient's prognosis depends on the underlying cause of the hypertension. It is excellent if the BP is well controlled.

COMPLICATIONS

- CHF
- Renal failure
- Encephalopathy
- Retinopathy

CODES

ICD9

- 401.9 Essential hypertension (unspecified)
- 405.99 Other unspecified secondary hypertension

ICD10

- I10 Essential (primary) hypertension
- I15.9 Secondary hypertension, unspecified

FAQ

- Q: What is the value of ambulatory BP monitoring?
- A: This device is similar to a Holter monitor and measures BPs over a 24-hour period while the patient is awake and asleep. By reviewing the BPs, one can determine if a significant proportion of readings are elevated and whether or not the normal dip in pressures during sleep is seen. Thus, conditions such as white coat hypertension can be verified or discounted.
- Q: What are the indications for invasive studies, such as angiography?
- A: This decision should be individualized and based on the severity of the hypertension, response to medication, the clinical presentation (e.g., neurofibromatosis), and results of other studies. In general, young children and all children with severe, unexplained hypertension should be completely evaluated.
- Q: Can adolescents with elevated BP compete in sports?
- A: Adolescents with hypertension should be encouraged to participate in athletics if their BP is well controlled. The use of stress testing in this population is controversial.
- Q: Do I need to worry about isolated systolic hypertension?
- A: Studies in adults have shown that sustained systolic hypertension may be just as important as diastolic hypertension.

HYPOGAMMAGLOBULINEMIA

Timothy Andrews

BASICS

DEFINITION

Humoral immunodeficiency signified by low or absent immunoglobulin levels, as compared with age-matched controls, and defective specific antibody production

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Selective IgA deficiency**
 - For details, refer to the topics “Common Variable Immunodeficiency (CVID)” and “Immunoglobulin A Deficiency.”
- **X-linked agammaglobulinemia (Bruton agammaglobulinemia)**
 - Intrinsic defect in B-cell maturation due to mutations in the gene on the X chromosome encoding a B-cell-associated tyrosine kinase is involved in cytoplasmic signal transduction.
 - All immunoglobulin isotypes significantly decreased or absent
 - Significant reduction or absence of B cells
 - Bacterial infections caused by pyogenic encapsulated organisms such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Pseudomonas* species
 - Recurrent respiratory tract infections including otitis, sinusitis, bronchitis, and pneumonia
 - Associated complications include arthritis of the large joints, chronic meningoencephalitis due to echoviruses, chronic diarrhea due to *Giardia lamblia*, inflammatory bowel disease, neutropenia, autoimmune hemolytic anemia, dermatomyositis, and an increased incidence of lymphoreticular malignancies.
 - Patients are also susceptible to viral infections, particularly enterovirus; live viral vaccines are contraindicated in these patients because some patients have vaccine-associated poliomyelitis.
 - Autosomal recessive agammaglobulinemia
 - Similar phenotype to X-linked agammaglobulinemia
 - Hyper-IgM syndrome
- **X-linked hyper IgM: Hyper IgM syndrome type**
 - Defect is caused by mutations in the gene encoding the CD40 ligand surface molecule on T cells. This leads to defective T-cell signaling for B-cell immunoglobulin class switching.
 - Normal to elevated IgM levels with low to absent IgG, IgA, and IgE
 - Recurrent upper respiratory tract infections, otitis, pneumonia, sinusitis
 - Associated complications include autoimmune hemolytic anemia/thrombocytopenia/neutropenia, opportunistic infections with *Pneumocystis carinii*, and lymphoproliferative disease.
- **CD40 mutation: Hyper IgM syndrome type 3**
 - Type I integral membrane glycoprotein encoded by gene chromosome 20 defect results in defective B-cell class switching.
 - Autosomal recessive form of hyper IgM clinically similar to X-linked hyper IgM

- **Activation-dependent cytidine deaminase mutation: Hyper IgM syndrome type 2**
 - Activation-dependent cytidine deaminase is an RNA-editing enzyme encoded by a gene on chromosome 12p13 expressed in germinal center B cells.
 - Deficiency causes impaired terminal differentiation of B cells and failure of isotype switching.
 - Extreme elevation of IgM with low to absent IgG, IgA, and IgE
 - Lymphoid hyperplasia, unlike X-linked hyper IgM in which there is minimal lymphoid tissue
 - Older at age of onset
 - No susceptibility to *P. carinii*
- **Transient hypogammaglobulinemia of infancy**
 - Difficult to differentiate this from the normal physiologic nadir of IgG that occurs between 3 and 6 months of age owing to the loss of maternally derived immunoglobulin. This nadir is normally short-lived.
 - Affected infants have abnormally prolonged delay in the onset of their own immunoglobulin production to compensate for this nadir.
 - Cause is unknown.
 - Self-limited; most infants recover by 18–36 months
 - Clinical course is typically benign. Therapy with IV immunoglobulin should be considered only in infants with severe recurrent infections.
 - This syndrome is frequently seen in infants with a familial history of severe combined immunodeficiency or other immunodeficiencies.
- **Selective IgG subclass deficiency (the 4 subclasses of IgG, in decreasing order of serum levels: IgG1, IgG2, IgG3, and IgG4)**
 - Total serum IgG levels can be normal even when 1 subclass is low or absent.
 - Deficiency of IgG3 is most common in adults, whereas deficiency of IgG2 is seen more frequently in children.
 - IgG2 deficiency has been associated with an inability to respond to polysaccharide antigens.
 - Clinical significance of IgG subclass deficiency has not been fully defined. Many patients have an increased frequency of upper and lower respiratory tract infections, whereas others are asymptomatic.
 - No consensus on standard therapy for these patients in regard to replacement IV immunoglobulin
- **Kappa-chain deficiency**
 - Absence of the kappa subtype of light chains in immunoglobulin molecules
 - Described in 2 families
 - Associated with variable defects in specific antibody formation
- **Immunodeficiency with thymoma**
 - Seen in adults, typically between 40 and 70 years
 - Associated with significantly decreased to absent IgG, IgA, and IgM
 - Secondary causes of hypogammaglobulinemia

Viruses

- Epstein–Barr virus
 - Cytomegalovirus
 - Congenital rubella
 - Mechanism by which antibody responses and immunoglobulin production are altered in infected patients is not clearly defined.
- **Infectious mononucleosis**
 - Has been associated with defective specific antibody responses to neoantigens and impaired in vitro B-cell function in normal individuals. These defects are transient and resolve within 6–8 weeks after the onset of the disease.
 - A disastrous response to Epstein–Barr virus infection is seen in X-linked lymphoproliferative syndrome. These patients develop fatal infectious mononucleosis, marrow aplasia, B-cell lymphoma, and agammaglobulinemia.
 - HIV, cytomegalovirus, and rubella infections have been associated with abnormal specific antibody responses.
 - **Drugs**
 - Immunosuppressive/chemotherapeutic agents, phenytoin-associated defects in immune function and antibody production usually resolve after therapy is discontinued.
 - **Other**
 - Protein-losing enteropathy
 - Intestinal lymphangiectasia
 - Nephrotic syndrome
 - The hypogammaglobulinemia is due to direct loss through the GI tract or kidneys.
 - Lymphoreticular malignancies have been associated with various immune defects and decreased immunoglobulin production.

HISTORY

Detailed history for recurrent infection is key to evaluating suspected humoral immunodeficiency.

- **Question:** Humoral immunodeficiencies?
- **Significance:** Usually present with recurrent infections caused by encapsulated bacteria such as *H. influenzae* type B and *S. pneumoniae*
- **Question:** It is important to rule out hypogammaglobulinemia in patients with recurrent infections because replacement therapy with IV IgG is readily available.
- **Significance:**
 - Patients with hypogammaglobulinemia usually present after 3–6 months of age.
 - Late onset of infections may be more consistent with common variable immunodeficiency.
- **Question:** Recurrent severe infections such as meningitis, sepsis, and osteomyelitis?
- **Significance:** Some of the congenital immunodeficiency syndromes are signified by specific infections such as chronic meningoencephalitis with echoviruses, vaccine-associated poliomyelitis, and *P. carinii* pneumonia.
- **Question:** Familial history of immunodeficiencies?
- **Significance:** Previously affected males suggest an X-linked inheritance pattern.

- **Question:** Early infant deaths due to overwhelming infection?
- **Significance:** May indicate a previously undiagnosed congenital immunodeficiency. Many of the congenital immunodeficiencies have associated arthritis, autoimmune disease, chronic lung disease, and GI manifestations.

PHYSICAL EXAM

Patients should be examined for signs of acute and chronic infections.

- **Finding:** Growth parameters?
- **Significance:** Children with significant, recurrent infections and GI disease related to immunodeficiency may present with failure to thrive.
- **Finding:** Signs of chronic otitis media or conjunctival recurrent disease?
- **Significance:** Patients with X-linked agammaglobulinemia frequently have signs of chronic conjunctivitis.
- **Finding:** Gingivitis and stomatitis?
- **Significance:** May occur with the neutropenia-associated hypogammaglobulinemia syndromes
- **Finding:** Lymphoid tissue?
- **Significance:** Absence of tonsillar tissue and palpable lymph nodes is suggestive of X-linked agammaglobulinemia.
- **Finding:** Lymphadenopathy and tonsillar hypertrophy?
- **Significance:**
 - Can be seen in hyper-IgM syndrome and common variable immunodeficiency
 - Persistently enlarged nodes should be investigated.
- **Finding:** Wheezes, rales?
- **Significance:** May signify acute pneumonia or chronic lung disease
- **Finding:** Hepatosplenomegaly or masses?
- **Significance:**
 - May be seen in hyper-IgM syndrome and common variable immunodeficiency
 - Abdominal masses should be investigated promptly to rule out malignancy.
- **Finding:** Arthritis, clubbing?
- **Significance:**
 - Arthritis can be seen in patients with X-linked agammaglobulinemia and common variable immunodeficiency.
 - Clubbing can be seen in the presence of chronic lung disease or bronchiectasis.

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** CBC with differential
- **Significance:** Autoimmune hemolytic anemia, neutropenia, and thrombocytopenia can be seen in X-linked agammaglobulinemia, hyper-IgM, and common variable immunodeficiency.
- **Test:** Quantitative immunoglobulin levels
- **Significance:**
 - Each isotype should be measured (IgG, IgA, IgM, IgE).
 - Normal or elevated IgM level in face of low to absent IgG, IgA is characteristic of hyper-IgM syndrome.

- **Test:** Serial testing of immunoglobulins
- **Significance:** Should be done in infants suspected of transient hypogammaglobulinemia to document subsequent normalization of immunoglobulin levels
- **Test:** Qualitative antibody levels
- **Significance:**
 - Isohemagglutinins are primarily IgM antibodies to the main blood groups.
 - Should be present in normal patients, but will be absent in patients with AB blood type
 - Presence is inconstant in children < 1 year of age.
- **Test:** Antibody titers to tetanus, diphtheria, *S. pneumoniae*, and *H. influenzae* type B measured postvaccination
- **Significance:** Ability to mount a protective antibody response to childhood vaccinations may indicate a less severe clinical course in hypogammaglobulinemia.
- **Test:** B-cell enumeration
- **Significance:**
 - Number of peripheral B cells will be decreased to absent in X-linked agammaglobulinemia and in autosomal-recessive agammaglobulinemia.
 - Usually normal in other hypogammaglobulinemia syndromes
- **Test:** Total lymphocyte count
- **Significance:** T-lymphocyte number and function are normal.

Imaging

Chest and sinus radiography and CT scans:

- May be helpful in evaluating for acute and chronic disease
- Bronchiectasis can be a long-term sequela of chronic pulmonary infection.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Prompt and appropriate antibiotic therapy is an important part of routine treatment.
- May be a role for prophylactic antibiotics in patients with persistent recurrent infections
- Replacement therapy with IV immunoglobulin is the primary therapeutic modality for X-linked agammaglobulinemia, hyper-IgM syndrome, and common variable immunodeficiency.
 - Usual initiating doses are 200–400 mg/kg every 3–4 weeks.
 - Nadir IgG levels should be >300 mg/dL.

ONGOING CARE

PROGNOSIS

Therapy is usually lifelong in patients with documented humoral immunodeficiency.

ALERT

Patients receiving IV immunoglobulin therapy should not receive routine vaccinations; they are passively immunized with the therapy.

- D80.0 Hereditary hypogammaglobulinemia
- D80.1 Nonfamilial hypogammaglobulinemia
- D80.2 Selective deficiency of immunoglobulin A [IgA]

FAQ

- Q: When should I make a referral?
- A: Refer any patient suspected of having a primary humoral immunodeficiency to a specialist in allergy and immunology. These are patients with chronic disease who require prolonged follow-up and good communication between the referring physician and specialist.

HYPOPARATHYROIDISM

Adda Grimberg

BASICS

DESCRIPTION

Hypoparathyroidism is decreased parathyroid hormone (PTH) effect.

EPIDEMIOLOGY

- Many normal neonates can have hypocalcemia (serum calcium >8 mg/dL) during the 1st 3 weeks of life owing to physiologic transient hypoparathyroidism.
- Parathyroid gland immaturity can lead to deficient PTH release and exaggerated normal fall in serum calcium concentration during the 1st 3 days of life.
- Relative immaturity of renal phosphorus handling and response to PTH can lead to late neonatal hypocalcemia precipitated by a high-phosphate diet (cow's milk-based formulas).
- Following total thyroidectomy, 10% of patients develop transient hypoparathyroidism, and of these, less than half remain with permanent hypoparathyroidism.

RISK FACTORS

Genetics

- X-linked recessive: Neonatal onset
- Autosomal dominant and autosomal recessive forms:
 - Chromosome 3q13: Activating mutations in the calcium-sensing receptor (CaSR) gene
 - Chromosome 6p23-24: Homozygous loss of function of GCMB gene (transcription factor required for parathyroid gland embryology)
 - Chromosome 10p15: GATA3 gene mutations cause dominantly inherited familial hypoparathyroidism, sensorineural deafness, and renal anomaly ([HDR] syndrome).
 - Chromosome 11p: Mutations in the PTH gene
 - Chromosome 22q11: DiGeorge syndrome
 - Chromosome 21q22 (AIRE gene): Type 1 polyglandular autoimmune disease; some cases of chronic hypoparathyroidism without associated Addison disease or chronic candidiasis
 - Chromosome 20q13: Albright hereditary osteodystrophy
- Mitochondria diseases: Kearns-Sayre syndrome (progressive external ophthalmoplegia before age 20 years and pigmentary retinal degeneration, frequently with other organ system involvement including cardiac, neurologic, and hypoparathyroidism)

PATHOPHYSIOLOGY

Diminished or absent PTH activity results in:

- Hypocalcemia and hyperphosphatemia
- Reduced vitamin D activation to 1,25(OH)₂-vitamin D
- Hypocalcemia leads to increased neural excitability.

COMMONLY ASSOCIATED CONDITIONS

- Transient:
 - Fetal parathyroid suppression: Maternal hypercalcemia, diabetic mother
 - Hypomagnesemia: Direct effects (suppressed PTH secretion, increased PTH resistance)
 - Alcohol intoxication
 - Congenital
 - Familial: X-linked recessive, autosomal dominant, autosomal recessive
 - Sporadic and isolated
 - DiGeorge syndrome: Parathyroid gland hypoplasia, thymic hypoplasia/aplasia, facial abnormalities, aortic arch and cardiac defects, and neuropsychiatric disorders including speech difficulties, learning disabilities, and high risk for developing psychotic disorders including schizophrenia
- Acquired:
 - Postsurgical
 - Postirradiation
 - Following severe burns
 - Type 1 polyglandular autoimmune disease (Blizzard syndrome): Hypoparathyroidism associated with chronic mucocutaneous candidiasis and autoimmune adrenal insufficiency; can also have diabetes mellitus, lymphocytic thyroiditis, hypogonadism, pernicious anemia, chronic hepatitis
 - Iron deposition: Thalassemia, hemochromatosis
 - Copper deposition: Wilson disease
 - Metastatic carcinoma
 - Miliary tuberculosis
- Pseudohypoparathyroidism: Resistance to PTH:
 - Albright hereditary osteodystrophy: G-protein mutation

DIAGNOSIS

HISTORY

- In neonates: Maternal calcium and magnesium abnormalities, maternal diabetes
- Family history of calcium disorders
- Medications
- Recurrent infections
- Recurrent muscle cramps
- Paresthesias

PHYSICAL EXAM

- Chvostek sign: Facial nerve stimulation (tapping anterior of external auditory meatus) causes contraction of orbicularis oris, producing upper lip or mouth twitch.
- Trousseau sign: Inflation of BP cuff reduces the blood flow to peripheral motor nerves and thereby can elicit carpopedal spasm in latent tetany.
- Carpopedal spasm
- Laryngeal stridor
- Mental status changes
- Irritability
- Papilledema

- Cataracts
- Bradycardia, hypotension
- Dry skin, coarse hair, brittle nails
- Albright hereditary osteodystrophy (pseudohypoparathyroidism type Ia): Short stature, round face, thick neck, barrel chest, obesity, subcutaneous calcifications, brachydactyly (short 4th metacarpal bones)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total and ionized serum calcium concentrations: Low
 - False positives: Hypomagnesemia
- Serum phosphorus concentration: Elevated in hypoparathyroidism; low in rickets
- Serum magnesium concentration: Rule out hypomagnesemia.
- Albumin: Assess calcium binding (if cannot get ionized calcium).
- Intact PTH levels
- 25-OH- and 1,25(OH)₂-vitamin D levels: Distinguish hypoparathyroidism from rickets.
- Urinary calcium/creatinine ratio: Low in idiopathic hypoparathyroidism, higher (almost equal to normocalcemic controls) in calcium ion-sensing receptor gain-of-function mutations
- Urinary cyclic AMP response to PTH: Diagnostic test if concerned about pseudohypoparathyroidism; otherwise, not routinely done

Imaging

- Chest radiograph: Rachitic rosary (rickets), absence of thymus (DiGeorge syndrome)
- Head CT: Intracranial calcifications are associated with chronic hypoparathyroidism and pseudohypoparathyroidism.

DIFFERENTIAL DIAGNOSIS

Hypocalcemia:

- Vitamin D deficiency
- Vitamin D-dependent rickets type I and II
- Hyperphosphatemia
- Prematurity
- Acute pancreatitis
- Malignancy: Osteoblastic metastases, tumor lysis syndrome
- Medication: Citrated blood products, phenobarbital, Dilantin, phosphate

TREATMENT

MEDICATION (DRUGS)

- Titer therapy to maintain serum calcium concentrations >8.0 mg/dL. In cases requiring lifelong therapy, compromise for serum calciums in the 8–9-mg/dL range to decrease the long-term risk for developing nephrocalcinosis:
 - 1,25(OH)₂-vitamin D: <1 year: 0.04–0.08 mcg/kg/d; 1–5 years: 0.25–0.75 mcg/d; >6 years and adults: 0.5–2 mcg/d
 - Calcium: Dose depends on preparation and on patient needs.
 - A recent 3-year randomized trial comparing twice-daily calcitriol (plus calcium and cholecalciferol in four daily doses) versus subcutaneous synthetic human PTH-(1–34) treatment in 12 children with chronic hypoparathyroidism (and without severe renal or hepatic insufficiency) showed stable calcium homeostasis and normal bone mineral accrual, linear growth, and weight gain with both treatments.
 - Duration: For life
- Activating mutations in the calcium sensor are treated with thiazide diuretics and hydration.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Regularly with the endocrinologist
- When to expect improvement: Immediately
- Signs to watch for:
 - Patients with acute, severe hypocalcemia should be placed on telemetry to monitor for cardiac arrhythmias (especially prolonged QTc)
 - Muscle cramps
 - Carpopedal spasms
 - Seizures

DIET

Unrestricted

PROGNOSIS

Fair; long-term outcome: Development of nephrocalcinosis resulting in renal insufficiency

COMPLICATIONS

- Hypocalcemia can cause tetany, arrhythmias, seizures, and respiratory arrest.
- Long-standing untreated hypoparathyroidism and pseudohypoparathyroidism can lead to intracranial calcifications, especially in the basal ganglia. These may cause extrapyramidal signs (e.g., choreoathetosis, dystonic spasms, parkinsonism). Cognitive impairment and psychiatric disturbances can also be seen.
- Untreated hypoparathyroidism can also lead to dilated cardiomyopathy, which improves with restoration of normocalcemia.

CODES

ICD9

- 252.1 Hypoparathyroidism
- 775.4 Hypocalcemia and hypomagnesemia of newborn

ICD10

- E20.9 Hypoparathyroidism, unspecified
- E89.2 Postprocedural hypoparathyroidism
- P71.4 Transitory neonatal hypoparathyroidism

FAQ

- Q: Is the thyroid also involved?
- A: No
- Q: Are seizures common?
- A: Yes. Seizures are a common presentation of hypoparathyroidism in childhood, and physiologic transient hypoparathyroidism is the most common cause of neonatal seizures.
- Q: Can hypoparathyroidism be associated with other abnormalities?
- A: Yes. Investigate neonates at the time of diagnosis for cardiac defects and thymic aplasia (DiGeorge syndrome), and monitor patients with hypoparathyroidism for development of other autoimmune endocrinopathies and chronic mucocutaneous candidiasis (type 1 polyglandular autoimmune disease).
- Q: When should IV versus oral calcium supplementation be used?
- A: IV calcium supplementation provides the quickest correction of hypocalcemia and is therefore useful in severe cases (seizures, stridor, tetany, cardiac arrhythmias) or in the initiation of therapy (as you await establishment of adequate vitamin D levels, which are necessary for enteral calcium absorption). Switch to oral calcium supplementation as soon as possible to reduce the risk of potential IV calcium-mediated venous sclerosis and tissue extravasation.

HYPOPLASTIC LEFT HEART SYNDROME

Javier J. Lasa (5th edition)

Laura Mercer-Rosa

BASICS

DESCRIPTION

Hypoplastic left heart syndrome (HLHS) is a continuum of congenital cardiac defects resulting from severe underdevelopment of the structures on the left side of the heart (left atrium, mitral valve, left ventricle, aortic valve, and ascending aorta).

EPIDEMIOLOGY

Incidence

- 0.16–0.36 per 1,000 live births
- 8% of congenital heart disease (CHD); third most common cause of critical CHD in the newborn
- 23% of all neonatal mortality from CHD
- Familial inheritance: Sibling recurrence risk ranges from 8% to 21% with higher recurrence observed when cardiovascular malformations are present in either parent. In addition, rare kinships have a frequency approaching autosomal-dominant transmission.
- Comorbid forms of CHD (13.5%)
- Male predominance (67%)
- Increased mortality when associated with definable genetic disorders, which comprise 10–28% of HLHS patients:
 - Turner syndrome, Noonan syndrome, Smith-Lemli-Opitz syndrome, Holt-Oram syndrome
 - Trisomy 13, 18, 21, or other microdeletion syndromes
- Major extracardiac anomalies (diaphragmatic hernia, omphalocele)

PATHOPHYSIOLOGY

- The etiology of HLHS appears multifactorial, most likely resulting from an in utero reduction of left ventricular inflow or outflow (mechanisms postulated include premature closure of the foramen ovale and fetal cardiomyopathy).
- As a result, the right ventricle (RV) must supply both the pulmonary and systemic circulations (via the ductus arteriosus) before and after birth.
- The reduction in pulmonary vascular resistance that occurs with lung expansion at birth reduces the proportion of RV output to the systemic circulation. If the ductus arteriosus closes, shock occurs.

DIAGNOSIS

HISTORY

- Respiratory distress (tachypnea, grunting, flaring, retractions)
- Cyanosis
- Cardiovascular collapse and profound metabolic acidosis when the ductus arteriosus closes

PHYSICAL EXAM

- CHF secondary to pulmonary overcirculation (e.g., tachycardia, hepatomegaly, gallop)
- Normal S1 and single S2 (A2 absent); a murmur of tricuspid regurgitation may be auscultated.
- Varying degrees of cyanosis
- Decreased perfusion and weak peripheral pulses

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Chest radiograph: Varying degree of cardiomegaly with increased pulmonary vascular markings (if the atrial septum is intact or highly restrictive, lungs will appear hazy with a pulmonary venous obstructive pattern)
- EKG: Right axis deviation (+90 to +210 degrees), RV hypertrophy with a qR pattern in the right precordial leads, decreased left ventricular forces with an rS pattern in the left precordial leads
- Echocardiogram: Varying degrees of hypoplasia or atresia of the mitral valve, left ventricle, aortic valve, ascending aorta, and aortic arch; patent ductus arteriosus with right-to-left shunt in systole and diastolic flow reversal; atrial septal defect with left-to-right flow
- Cardiac catheterization: No longer routinely performed; similar findings as with echocardiography

DIFFERENTIAL DIAGNOSIS

- Cardiac: Other causes of circulatory collapse in the neonate include critical aortic stenosis and coarctation of the aorta, cardiomyopathy (infectious, metabolic, or hypoxic), persistent supraventricular tachycardia, obstructive cardiac neoplasms, and large arteriovenous fistulae.
- Noncardiac: Neonatal septicemia, respiratory distress syndrome, inborn errors of metabolism

TREATMENT

ADDITIONAL TREATMENT

General Measures

Supportive:

- Although surgical intervention has become the medical standard, supportive measures are sometimes offered, especially when multiple noncardiac congenital anomalies exist or when severe multiorgan system damage is present.
- The preoperative goal is to balance the systemic and pulmonary circulations provided by the RV to a Qp/Qs (ratio of pulmonary to systemic blood flow) of ~1:1, usually achieved with a pulse oximetry measurement of 75%.
- Prostaglandin E1 infusion: 0.05–0.1 mcg/kg/min.
- Aggressive treatment of metabolic acidosis with fluid boluses, bicarbonate, and/or tromethamine (THAM)
- 0.21 FiO₂, goal PaO₂ of 35–40 mm Hg.
- Careful use of small amounts of inotropic agents (in cases of sepsis or RV failure). Aggressive use of inotropic agents (alpha effect) may worsen systemic perfusion.

SURGERY/OTHER PROCEDURES

- Palliative surgery is generally performed in 3 stages:
 - Stage I (Norwood) palliation (performed in the first few days of life or soon after presentation): Involves transection of the main pulmonary artery with anastomosis of the augmented aortic arch to the pulmonary valve stump to form a neo-aortic valve and arch, placement of an aorta-to-pulmonary artery shunt (modified Blalock-Taussig shunt), and often an atrial septectomy. The RV provides both systemic and pulmonary blood flows with post-operative saturations of ~75%.
 - Stage I Sano modification: Developed in 2003 as an alternative to the Norwood procedure, the Sano modification replaces the modified Blalock-Taussig shunt with an RV to pulmonary artery conduit with the RV continuing to supply both pulmonary and systemic circulations.
 - Hybrid Procedure: This recent alternative to the Norwood procedure utilizes both median sternotomy (pulmonary artery banding) and interventional cardiac catheterization (PDA stenting) to provide both systemic and pulmonary blood flow while avoiding cardiopulmonary bypass.
 - Stage II/Hemi-Fontan or bidirectional Glenn procedure: Involves anastomosis of the superior vena cava to the pulmonary artery, resulting in volume unloading of the RV. All prior shunts are usually removed. The oxygen saturations after this procedure are usually 85–90%.
 - Stage III/Modified Fontan procedure: Baffling the inferior vena cava to the pulmonary artery with placement of a small fenestration in the baffle, permitting a small residual right-to-left shunt. The RV is now supplying only systemic blood flow. The oxygen saturations after this procedure are usually 90–95%.

- There are many surgical modifications to these 3 procedures. In addition, these procedures may be performed at different ages based on an institution's experience. Our approach has been to perform the hemi-Fontan operation at 4–6 months of age and the Fontan operation at 18 months to 2 years of age.
- Orthotopic heart transplantation may be performed either as an initial approach or after a stage I palliation.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

During initial resuscitation and stabilization of a newly diagnosed infant:

- Prostaglandin E1 therapy should be initiated as soon as possible to maintain ductal patency.
- Avoid using oxygen despite low pulse oximetry saturation. Increasing FiO₂ will lower pulmonary vascular resistance preferentially shunting cardiac output away from the systemic circulation towards the lungs, thereby worsening systemic perfusion.
- Should invasive ventilation be required, avoid hyper-ventilation. Permissive hypercapnia is preferred due to the secondary increase in pulmonary vascular resistance, and subsequent improvement in systemic perfusion. Maintain mildly elevated PaCO₂ levels (40–50 mm Hg).

Admission Criteria

The admission for the first operation usually lasts for about 3–4 weeks after birth. Patients are watched to ensure stable oxygen saturation and weight gain. Nutritional needs often require nasogastric tube feed supplementation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Interval pediatric evaluations should include careful consideration of growth parameters, cardiovascular symptoms, and developmental milestones. Examinations should focus on the presence or absence of cyanosis, edema, pleural effusions, diarrhea, ascites, and arrhythmias.

- For patients after staged palliation, frequent echocardiograms and intermittent cardiac catheterizations may be needed to assess for:
 - RV dysfunction
 - Residual or recurrent aortic arch obstruction
 - Branch pulmonary artery narrowing
 - Venous collateral formation causing increased cyanosis
 - Protein-losing enteropathy
 - Sinus node dysfunction
 - Atrial arrhythmias
- For patients treated alternatively with heart transplantation, other lifelong issues should be addressed:
 - Graft rejection and/or coronary vasculopathy
 - Infection
 - Hypertension
 - Lymphoproliferative disease

- Follow-up medications:
 - Lifelong subacute bacterial endocarditis (SBE) prophylaxis (high-risk category)
 - Furosemide is generally administered until the hemi-Fontan.
 - Afterload reduction (i.e., angiotensin-converting enzyme inhibitors) may be used to reduce the workload on the heart at any stage.
 - Antiplatelet (aspirin) and anticoagulant (Coumadin) therapies are used by most physicians after stage I and later in the setting of the low-flow state of the cavopulmonary connection.
- For transplant patients, immunosuppressive regimens are managed differently according to institution preferences.

PROGNOSIS

- Fatal if untreated (95% mortality within the 1st month of life)
- In the current era, HLHS is often diagnosed prenatally, and improved outcomes may result from early diagnosis and prevention of the presentation as neonatal shock.
- 90% early survival after stage I palliation if treated in a timely fashion at experienced institutions
- 5% mortality at stage II hemi-Fontan (bidirectional cavopulmonary anastomosis) procedure
- Recently, 1% mortality at Fontan operation (with the addition of a fenestration to allow right-to-left shunting)
- Excluding infants who die waiting for a donor organ, the 5-year actuarial survival for either staged palliation (Fontan) or heart transplantation is similar, ~75%.

COMPLICATIONS

Neonatal presentation:

- Circulatory collapse with resultant metabolic acidosis
- Multiorgan system failure (i.e., necrotizing enterocolitis, renal failure, liver failure, CNS injury)

ICD9

746.7 Hypoplastic left heart syndrome

ICD10

Q23.4 Hypoplastic left heart syndrome

FAQ

- Q: What should the differential diagnosis include when an infant with hypoplastic left heart syndrome (HLHS) who has undergone stage I palliation presents with cyanosis and respiratory distress?
- A: Modified Blalock-Taussig shunt thrombosis, anemia, intercurrent lower respiratory tract infection leading to V/Q mismatch, low cardiac output state, sepsis.
 - Infants with HLHS status post stage I palliation are solely dependent on the modified Blalock-Taussig shunt for pulmonary blood flow. This synthetic tube graft ranges from 3.5 to 4 mm in diameter and is prone to thrombosis, especially during periods of illness, which leads to dehydration (gastroenteritis), poor nutrition, or systemic inflammation.
- Q: Should there be a specific concern if a patient with HLHS who has completed the 3-stage palliation with Fontan procedure presents with complaints of unremitting diarrhea, crampy abdominal pain, ascites, and peripheral edema?
- A: Yes, protein-losing enteropathy (PLE) is a poorly understood disease process affecting patients with single ventricle after Fontan operation associated with significant morbidity and mortality. PLE is defined as the abnormal loss of serum proteins into the lumen of the GI tract and occurs in up to 11% of patients after Fontan palliation. Diuretic therapy and nutritional supplementation are often insufficient management strategies, frequently requiring the addition of somatostatic analogs (octreotide), sildenafil, and/or the creation of a fenestration in the Fontan circuit to palliate potentially elevated Fontan pressures.

HYPOSPADIAS

Douglas Canning
Matt Christman

BASICS

DESCRIPTION

Hypospadias is the incomplete development of the anterior urethra due to the failure of the urethral folds to unite over and cover the urethral groove. Minor glanular hypospadias form from abnormal ingrowth of ectoderm from the glans to the corona.

EPIDEMIOLOGY

Incidence

- 1/250–1/300 live male births
- With affected father: 8%
- With affected brother: 14%
- With 2 or more affected family members: 21%
- Unexplained increase in incidence since the 1970s may be due to more diagnostic precision and awareness

RISK FACTORS

Genetics

- Increased incidence in monozygotic twins (8.5-fold greater than in singletons)
- Reported mutations include defects in the androgen receptor, 5α -reductase enzyme defects, alterations in homeobox genes, and variants of fibroblast growth factor, although these are found only in a minority of patients.

ETIOLOGY

- Polygenic/multifactorial
- Higher familial incidence
- Proposed theories include:
 - Estrogenic environmental contamination
 - Pressure of the fetal limbs on developing penis
 - Insufficient human chorionic gonadotropin (HCG) in placenta
 - Abnormality in androgen metabolism as a local manifestation of a systemic endocrinopathy

DIAGNOSIS

HISTORY

- Important to inquire about:
 - Other affected family members
 - Other congenital anomalies
- Increased incidence of cryptorchidism
- Consider workup for disorders of sexual differentiation (DSD) if cryptorchidism is found along with severe hypospadias
 - May be associated with an enlarged utricle, complicating urethral catheter placement
 - Severe hypospadias (perineal and penoscrotal) may have associated vesicoureteral reflux (VUR). No need to screen for VUR even in severe hypospadias.

PHYSICAL EXAM

- Incomplete foreskin
- Distal urethral pit on glans
- Ventral curvature of penis:
 - Localize meatal position by pulling outward on ventral penile shaft skin
 - Record position as glanular; coronal; distal, middle, or proximal shaft; penoscrotal; or perineal
 - Important to document position of testes
 - If testes impalpable, consider workup for disorder of sexual differentiation

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Karyotype in patients with bilateral undescended testes and hypospadias; may also be obtained in cases of unilateral undescended testis and hypospadias.

Imaging

- If there is a question of ambiguous genitalia, pelvic ultrasound or cystography may be indicated.
- There is no need for imaging in cases of routine, isolated hypospadias.

DIFFERENTIAL DIAGNOSIS

Ambiguous genitalia, namely, XX disorder of sexual differentiation

TREATMENT

ADDITIONAL TREATMENT

General Measures

If the patient has a very small penis, he may benefit from hormonal stimulation with testosterone preoperatively.

ALERT

- Newborn circumcision is absolutely contraindicated.
- Bilateral impalpable testes and hypospadias must be worked up to rule out salt-losing adrenogenital syndrome.

SURGERY/OTHER PROCEDURES

- Surgical repair:
 - Surgical repair is usually performed in the first 3–6 months of life.
 - Mild glanular hypospadias may not need surgery.
- Type of repair depends on position of meatus and degree of chordee:
 - Tubularized incised plate
 - Meatal advancement
 - Onlay island flap
 - Tubularized island flap
 - 90% success rate for distal repairs
 - Success rate may be less for proximal repairs.
- Potential complications include:
 - Urethrocutaneous fistula
 - Urethral diverticulum
 - Urethral stricture
 - Unacceptable cosmetic outcome

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

- Compressive dressing for 2 days, removed by parents at home
- Indwelling urethral catheter/stent remains for about 2 weeks
- Postoperative visit at 2 weeks to remove catheter
- Longer term follow-up includes witness of urinary stream as toddler to identify fistula or recurrent curvature if present.

**CODES****ICD9**

- 752.61 Hypospadias

ICD10

- Q54.8 Other hypospadias
- Q54.9 Hypospadias, unspecified

FAQ

- Q: Does the patient with hypospadias routinely have other anatomic problems?
- A: No. The majority of patients with hypospadias have no other problems.
- Q: Why is there no need for routine imaging?
- A: Studies have been done and show that without symptoms or problems, patients with hypospadias have no other congenital problems.

IDIOPATHIC INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)

Sabrina E. Smith

Dennis J. Dlugos

BASICS

DESCRIPTION

Diagnostic criteria of idiopathic intracranial hypertension (IIH) include:

- Signs and symptoms of increased intracranial pressure (e.g., headache, vomiting, ocular manifestations, and papilledema)
- Elevated cerebrocranial fluid pressure but otherwise normal CSF
- Normal neurologic exam except for papilledema (occasional abducens or other motor cranial neuropathy)
- Normal neuroimaging study (or incidental findings only)

EPIDEMIOLOGY

- Boys and girls are affected equally in childhood; in adulthood, more women than men are affected.
- IIH has been reported in patients as young as 4 months of age, with a median age of 9 years.

Incidence

Incidence in children is unknown.

RISK FACTORS

Genetics

Sporadic, no clear genetic predisposition, unless related to an underlying hormonal, toxic, or inflammatory condition; no data are available in children.

PATHOPHYSIOLOGY

Pathogenesis unknown, but may involve decreased CSF absorption owing to arachnoid villi dysfunction or elevated intracranial venous pressure. For example, obesity may lead to increased intra-abdominal, intrathoracic, and cardiac filling pressure, leading to elevated intracranial venous pressure.

ETIOLOGY

- Numerous precipitants of IIH have been reported. In adolescents, it is clearly associated with obesity and weight gain, but not clearly linked to obesity in children <11 years. Many weaker associations may be due to chance.
- IIH is often linked to minocycline, tetracycline, sulfonamides, isotretinoin, and thyroid replacements, and to corticosteroid withdrawal. It is also linked to vitamin A deficiency or intoxication, chronic anemia, and hypothyroidism.

COMMONLY ASSOCIATED CONDITIONS

- Visual loss due to optic nerve pressure
- Endocrinopathies, exogenous steroids, lead exposure, and therapy involving tetracycline and several other antibiotics may be associated with IIH.

DIAGNOSIS

HISTORY

- Headache
- Blurred vision
- Transient visual darkening
- Stiff neck
- Pulsatile tinnitus
- Dizziness
- Infants and young children may present with irritability, somnolence, or ataxia.
- IIH should be considered in any child with chronic headache or unexplained visual changes.
- Directed history for signs of associated endocrinopathy, exposure to antibiotics or steroids, sinus infection, abnormal clotting, or familial tendency to thrombosis or visual disturbance

PHYSICAL EXAM

- Examination of the fundi is essential.
- Recording baseline visual acuity and visual fields in older children is essential.
- Papilledema is almost always present in older children with IIH.
- Most infants have some degree of papilledema, even with open fontanelles and split sutures.
- 6th cranial nerve (abducens) palsies are common in children with IIH; they were found in 29 of 68 patients in 1 series.
- Facial or other cranial nerve deficits rare

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CSF exam including opening pressure; cell count, glucose, and protein are essential and should be normal in IIH.
- CBC and thyroid function tests should be obtained because anemia, hypothyroidism, and hyperthyroidism have rarely been associated with IIH.
- The following may be useful in selected cases:
 - ANA test
 - ESR
 - Urine cortisol
 - Serum lead level
 - Serologic testing for Lyme disease

Imaging

Cranial CT or MRI should be normal. MRI is recommended because of superior imaging of brainstem, posterior fossa, and venous sinuses. Magnetic resonance venography is strongly suggested to evaluate for venous sinus thrombosis, which can be difficult to distinguish from IIH.

Diagnostic Procedures/Other

- Lumbar puncture manometry, with the patient in a relaxed lateral decubitus position, should show an opening pressure >280 mm H₂O.
- Goldmann perimeter visual field testing or computerized visual fields are useful in children >5 years to document field deficits and monitor response to therapy.

DIFFERENTIAL DIAGNOSIS

Some conditions may be confused with IIH, but the clinical picture and CSF analysis usually permit their distinction:

- Chronic meningitis (e.g., CNS, Lyme disease), encephalitis, or cerebral edema (may show minimal changes on neuroimaging with elevated CSF protein levels and little evidence of pleocytosis)
- Cerebral venous sinus thrombosis
- Chronic headache (common) with pseudopapilledema (optic nerve disc drusen)

TREATMENT

MEDICATION (DRUGS)

First Line

- For patients with mild to moderate visual loss, acetazolamide, a carbonic anhydrase inhibitor that decreases CSF production, is the drug of choice:
 - The pediatric dosage is 60 mg/kg/d divided q.i.d. for the standard form and b.i.d. for the long-acting form (Diamox sequels).
 - The initial adult dose is 250 mg q.i.d. or 500 mg b.i.d., increased to 750 mg q.i.d. or 1,500 mg b.i.d. if tolerated.
- If visual loss, papilledema, and symptoms of pressure resolve, acetazolamide dosage can be tapered after 2 months of therapy.

Second Line

Furosemide can be used if acetazolamide is ineffective or has intolerable adverse effects.

ISSUES FOR REFERRAL

Follow-up and tapering of acetazolamide should be done in conjunction with a neurologist or neuro-ophthalmologist.

SURGERY/OTHER PROCEDURES

- Serial lumbar punctures are not recommended as standard therapy, although the initial puncture can be useful to relieve symptoms quickly.
- Surgical therapy (e.g., optic nerve sheath fenestration, lumboperitoneal shunt) is indicated for progressive visual loss despite medical therapy and may also be considered as an urgent intervention at presentation depending on degree of visual loss. Optic nerve sheath fenestration may be the preferred surgical treatment, especially in children, because of the high failure rates of lumboperitoneal shunting. High-dose IV steroids and acetazolamide therapy may be used while awaiting surgical therapy.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- The urgency of diagnosis and treatment depends on the severity of visual loss. Recent reports suggest that severe visual loss may progress rapidly, warranting close initial (weekly) tracking of vision and prompt consideration of surgical treatment (see below).
- For patients with no visual loss, removal of possible causative agents may be the only intervention needed, along with treatment of associated conditions (e.g., obesity, anemia, thyroid disease). Consider treatment with acetazolamide (Diamox; see later comment). Headache can be treated symptomatically if needed.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Initially, patients should have visual acuity, visual fields, and fundi evaluated weekly or biweekly.
- If vision is stable, monthly visits may be adequate for 3–6 months.
- More frequent follow-up is required for any signs of progressive visual loss.
- IIH can recur. In one pediatric series, nearly 1/4 of patients had recurrence.
- Pitfalls: Children are not exempt from permanent visual loss as a consequence of IIH. Ophthalmologic follow-up is important. Occasional patients, especially adolescents, may experience headache weeks or months after resolution of objective signs of IIH (i.e., even though intracranial pressure has returned to normal).
- IIH may be diagnosed erroneously if:
 - Pseudopapilledema is mistaken for papilledema. (Pseudopapilledema is apparent optic disc swelling that simulates papilledema, but is usually secondary to an underlying benign process. It can be differentiated by an experienced ophthalmologist or neurologist.)
 - CSF abnormalities (i.e., isolated increase in protein) are overlooked.
 - Clinician fails to identify underlying cerebral venous sinus thrombosis.

FAQ

- Q: What are the side effects of acetazolamide?
- A: Side effects of acetazolamide include GI upset, paresthesias, loss of appetite, drowsiness, metabolic acidosis, and renal stones. An alternative is furosemide.
- Q: If IIH occurs on tetracycline, can the patient take penicillin?
- A: Penicillins/cephalosporins have not been reported as a significant cause of IIH.
- Q: Are there any limitations on physical activity?
- A: Activity can be graded entirely according to the child's symptoms.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Charles Bailey

BASICS

DESCRIPTION

- Idiopathic thrombocytopenic purpura (ITP) is an autoimmune syndrome characterized by:
 - Isolated thrombocytopenia (platelet count $<100,000/\text{mm}^3$)
 - Shortened platelet survival
 - Presence of circulating platelet autoantibodies
 - Increased number of megakaryocytes in the bone marrow
- There are 3 types of ITP:
 - Acute ITP resolves (platelet count normal) within 6 months after diagnosis, without relapse.
 - Chronic ITP is defined by persistent thrombocytopenia >6 months after initial presentation.
 - Recurrent ITP exhibits an intermittent pattern of thrombocytopenia after an initial recovery to normal count.

EPIDEMIOLOGY

- Most common acquired platelet disorder in childhood
- Males and females are equally affected in childhood ITP (mild male predominance in younger children; female/male ratio is 3:1 in adult and chronic ITP).
- Median age at diagnosis is 4 years. Children <1 year or >10 years more likely to develop chronic ITP
- $>70\%$ of childhood ITP is acute (i.e., resolves within 6–12 months).
- Risk of severe bleeding is $<5\%$.

Incidence

Incidence is 2–5/100,000 children per year (<15 years of age).

PATHOPHYSIOLOGY

- Thrombocytopenia results from increased destruction of antibody-coated platelets by phagocytic cells in the reticuloendothelial system, particularly the spleen.
- It is hypothesized that antibodies generated in response to foreign antigen or drug cross-react with platelet membrane glycoproteins (most commonly IIb/IIIa and Ib/IX). Multiple mechanisms of immune dysregulation have been implicated.
- Typical bone marrow aspirate shows increased numbers of immature megakaryocytes. However, some studies suggest that inhibition of thrombocytopoiesis limits ability to compensate for destruction.

COMMONLY ASSOCIATED CONDITIONS

- Autoimmune disorders (e.g., systemic lupus erythematosus [SLE], autoimmune lymphoproliferative syndrome [ALPS])
- HIV

DIAGNOSIS

HISTORY

- Unusual bruising (with minor or no trauma, or in uncommon locations such as torso, neck, face), petechiae, epistaxis, or prolonged bleeding with minor trauma, gingival bleeding, hematuria, or hematochezia
- Ask about headache, abdominal or back pain, and any change in neurologic status.
- Onset is acute in an otherwise well child.
- Not associated with pallor, fatigue, weight loss, or persistent fevers
- 50% of cases are preceded by a viral infection 1–3 weeks before onset (particularly varicella; also Epstein-Barr virus, cytomegalovirus).
- Recent vaccination, especially live virus
- Drug history, focusing on drugs with antiplatelet effects (e.g., aspirin, seizure medications, heparin)
- Evidence of other autoimmune diseases (e.g., rheumatoid or collagen vascular symptoms, thyroid disease, hemolytic anemia)
- Family history is usually negative for bleeding disorders. Ask about family autoimmune disease.
- Risk factors for HIV should be elicited, because ITP-like thrombocytopenia may be a presentation of HIV in children.

PHYSICAL EXAM

- Clusters of petechiae or large or purple bruises readily apparent on skin or oropharynx
- Dried blood or clots in the nares
- Persistent slow bleeding from nares, gums, or wounds
- A funduscopic exam should be performed on all patients (retinal hemorrhage).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Thrombocytopenia (typically $<20,000/\text{mm}^3$) with a normal WBC count and hemoglobin (mild anemia in proportion to amount of blood loss)
- Mean platelet volume may be increased.
- Peripheral blood smear should always be reviewed to differentiate platelet clumps from true thrombocytopenia. Smear will be otherwise normal, with no red cell fragmentation, no spherocytes, and no blasts.
- Prothrombin time and partial thromboplastin time are normal. Bleeding time will be prolonged, but testing is unnecessary.
- Direct antiglobulin test to exclude coexisting autoimmune RBC hemolysis (Evans syndrome)
- Antinuclear antibody (ANA) in subset of patients for whom causes of thrombocytopenia other than acute childhood ITP must be ruled out, including adolescents, especially girls, patients with chronic ITP, and those with suspicion of autoimmune disease

- HIV testing if risk factors are identified
- Bone marrow aspirate if anemia, abnormal WBC, leukemic blasts on peripheral smear, organomegaly, jaundice, or lymphadenopathy is present; otherwise controversial. It is safe to perform with a low platelet count.
- Most hematologists examine bone marrow before initiating corticosteroids.
- Marrow shows normal to increased numbers of megakaryocytes with otherwise normal morphology and cellularity.
- Assays for platelet-associated antibodies (either direct or indirect) are not routinely indicated.
- Demonstration of platelet-associated IgG may be useful in more complicated patients in whom chronic ITP is a possible diagnosis.
- *Helicobacter pylori* testing and treatment of infection may improve platelet recovery.

Imaging

As indicated by symptoms, particularly abdominal pain, headache, vision or focal neurologic change

DIFFERENTIAL DIAGNOSIS

- Consider other diagnoses if there is pallor, jaundice, adenopathy, bone pain, arthritis, or organomegaly (mild splenomegaly may occur in 5–10%).
- Destructive thrombocytopenias (normal or increased megakaryocytes in marrow):
 - Immunologic: ITP, infection (HIV, cytomegalovirus, Epstein-Barr virus, varicella zoster virus, parvovirus B19), drug induced, posttransfusion purpura, autoimmune hemolytic anemia (Evans syndrome), lymphoproliferative disorders, SLE, hyperthyroidism
 - Nonimmunologic: Microangiopathic hemolytic anemia, hemolytic uremic syndrome, disseminated intravascular coagulopathy (DIC), thrombotic thrombocytopenic purpura, Kasabach-Merritt syndrome (giant hemangioma), cardiac defects (left ventricular outflow obstruction, prosthetic heart valves, repaired intracardiac defects), malignant hypertension
- Impaired or ineffective production (decreased or absent megakaryocytes in marrow):
 - Marrow-infiltrative processes (leukemias, myelofibrosis, lymphomas, neuroblastoma, other solid tumor metastases, osteopetrosis, storage diseases)
 - Drug- or radiation-induced aplastic anemia, nutritional deficiency states (iron, folate, vitamin B₁₂)
 - Infection-associated suppression: Typically viral (e.g., hepatitis, Epstein-Barr virus, HIV, parvovirus B19), also severe or neonatal sepsis
 - Congenital disorders: Thrombocytopenia absent radii (TAR) syndrome, Fanconi anemia, trisomy 13 and 18, Bernard-Soulier syndrome, Wiskott-Aldrich syndrome, May-Hegglin anomaly, other inherited thrombocytopenias (X linked or autosomal dominant), metabolic disorders (e.g., methylmalonic acidemia)

TREATMENT

MEDICATION (DRUGS)

First Line

- IVIG: 94–97% will have an increase in platelet count >20,000/mm³ by 72 hours. The usual dose is 0.8–1 g/kg over 6–8 hours. Response typically peaks after 1 week and lasts 3–4 weeks:
 - Advantages: Faster time to platelet count >20,000/mm³ (24 hours), marrow aspirate may be deferred, helps confirm diagnosis
 - Disadvantages: High cost, long infusion time, allergic reactions, 10–30% have evidence of aseptic meningitis with severe headache and stiff neck, 50–75% have headache, nausea, vomiting, or fever
 - Routine acetaminophen and diphenhydramine prior to and for 24 hours after infusion may reduce acute side effects.
 - Subcutaneous administration has been used successfully as an alternative to IV infusion.
- Corticosteroids: 80% respond with platelet counts >20,000/mm³ by 72 hours (faster with high-dose pulse therapy). Oral prednisone at 2 mg/kg/d tapered over 2–4 weeks is typical:
 - Advantages: Ease of dosing (oral, outpatient), low cost, often longer duration of response
 - Disadvantages: Most pediatric hematologists require a bone marrow aspirate before steroid therapy is begun, to exclude leukemia. Short-term side effects: Mood changes, increased appetite and weight gain, hypertension, insulin resistance. Long-term side effects with chronic use: Adrenal suppression, osteopenia, growth delay
- Anti-Rh D immunoglobulin (patient must be Rh[+] and nonsplenectomized): 80% respond with platelet counts >20,000/mm³ after 72 hours. Dose is 50–75 mcg/kg IV over 3–5 minutes. Response lasts ~5 weeks:
 - Advantages: Less expensive than IVIG but more costly than steroids. Lower rate of allergic side effects (10%) than with IVIG and does not cause aseptic meningitis. Amenable to outpatient administration.
 - Disadvantages: Fever/chills, mild hemolysis (Hb decrease of 1–3 g/dL) in all patients. Rare reports of catastrophic hemolysis; subcutaneous route may ameliorate risk.
- Any of these therapies may be repeated if responsive patient later develops recurrent thrombocytopenia.

Second Line

- Rituximab (anti-CD20 monoclonal antibody) induces response in many refractory patients (after median 5 weeks), but duration is often limited (median <12 months).
- Thrombopoietin receptor agonists (e.g., eltrombopag, romiplostim) have been shown in trials to improve platelet counts and bleeding risk in patients with chronic ITP. Cost, concerns about adverse effects including myelofibrosis and thrombosis, and paucity of long-term follow-up data limit use of these agents.
- Cytotoxic chemotherapy (vincristine or low-dose cyclophosphamide) or immunosuppression (CsA or MMF) is effective in some patients refractory to other therapy and splenectomy.

ADDITIONAL TREATMENT

General Measures

- Platelet transfusions are generally ineffective, because transfused platelets are rapidly destroyed. Role is limited to emergent support for critical hemorrhage.
- Medical treatment slows antibody-mediated platelet clearance and raises platelet counts acutely, but does not alter the long-term course.
- Because severe hemorrhage is rare and ITP resolves spontaneously in 90% of pediatric cases, most patients will not require treatment.
- Guidelines put forth by the American Society of Hematology recommend treatment for:
 - Patients with severe or life-threatening bleeding
 - Patients with moderate bleeding, overt mucosal bleeding, or developmental or psychosocial risk for injury
 - Patients with a platelet count <10,000/mm³ are at higher risk for bleeding, but platelet count alone is not an indication for treatment.
- Active toddlers or children at risk for trauma may require treatment when platelet count is <20,000–30,000/mm³.
- Observation alone is acceptable for older children without serious bleeding, and with adequate supervision and assured follow-up. May be preferable to repeated courses of treatment in clinically well children with chronic ITP
- Avoid medications that affect platelet function, such as aspirin, ibuprofen, most other NSAIDs, and anticoagulants.
- Educate parents about signs and symptoms of intracranial hemorrhage (ICH), elevated intracranial pressure (ICP), and GI bleeding.
- Avoid activities with significant fall, collision, or other trauma risk while thrombocytopenic.

SURGERY/OTHER PROCEDURES

Splenectomy: 60–80% respond with complete remission. No reliable presurgical predictors of response have been found.

- Advantages: Response in patients refractory to medical therapy
- Disadvantages: Surgical morbidity; risk of sepsis with encapsulated organisms (Immunize preoperatively against *Haemophilus influenzae*, pneumococcus, and meningococcus, and consider lifelong penicillin prophylaxis.)

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Life-threatening hemorrhage: The goal is to stop bleeding rapidly. Platelet transfusion, IVIG, and steroids (after emergent marrow exam, if possible) should be given concomitantly. Emergent splenectomy is necessary in rare cases.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Platelet count biweekly when <20,000/mm³, weekly when <50,000/mm³ or after treatment, except in stable chronic ITP. Increase interval if no symptoms and platelet count >50,000/mm³.
- Platelet counts may fall transiently with intercurrent illnesses prior to resolution of ITP.
- Discontinue monitoring when no symptoms and normal platelet count for >3 months.

PROGNOSIS

- Acute ITP: In 3 months, 60% of children will have a normal platelet count; at 1 year from diagnosis, 90%. Recurrence with future infections/illnesses is rare.
- Chronic ITP: Platelet count tends to be higher, at 40,000–80,000/mm³. Remissions can occur many years after diagnosis (predicted spontaneous remission rate 61% after 15 years).
- Not yet possible to prospectively distinguish patients with acute ITP from those who will persist with chronic ITP
- Patients with chronic ITP should be periodically re-evaluated for secondary ITP associated with underlying diseases such as systemic lupus erythematosus, HIV infection, ALPS, or Evans syndrome.
- Of patients with chronic ITP, 50–60% eventually stabilize without need for ongoing therapy or need for splenectomy.
- Spontaneous resolution of thrombocytopenia can occur as long as 10–20 years after diagnosis.

COMPLICATIONS

- The incidence of significant bleeding-related morbidity and mortality is low (<5%):
 - ICH is a rare (0.1%) but potentially fatal event in acute ITP.
 - Platelet count always <20,000/mm³ in published literature (80% of cases <10,000/mm³)
 - May occur any time and without prior trauma
- Mucosal bleeding from nose, gums, lower GI tract, or kidneys is not uncommon. Hematemesis and melena are rare.
- Menorrhagia may be severe.
- Retinal hemorrhage is rare.

IMMUNE DEFICIENCY

Kathleen E. Sullivan

BASICS

DEFINITION

Immunodeficiencies generally represent a defect in host defense.

- Congenital and acquired forms exist.
- Defects in antibody production: Most often characterized by frequent sinopulmonary infections with typical organisms
 - X-linked agammaglobulinemia: Onset of symptoms after 6 months of age; sinopulmonary infections with typical bacterial pathogens. Markedly decreased immunoglobulins and B cells are characteristic. Tonsils are absent.
 - Hyper-IgM syndromes: Several forms. Usually present with recurrent bacterial infections in infancy; *Pneumocystis jiroveci* is seen; intermittent neutropenia is common. Decreased IgG, IgE, IgA with normal or increased IgM.
 - Common variable immunodeficiency: Usually presents with recurrent bacterial infections; most commonly arises in the 2nd or 3rd decade of life (but is seen in all ages). Immunoglobulin levels and function gradually decline; autoimmunity is common.
 - IgG subclass deficiency: IgG2 subclass deficiency is seen as a transient developmental delay in the acquisition of humoral immunity. May also precede the development of common variable immunodeficiency and can rarely be seen as an isolated defect.
 - IgA deficiency: The most common congenital immunodeficiency (1:500); most are asymptomatic. Symptoms can be seen at any age; typically sinopulmonary infections; increased risk of allergy, autoimmune disease, and anaphylaxis from blood products.
 - Transient hypogammaglobulinemia of infancy: A developmental delay of immunoglobulin production; function is intact; typically resolves between 9 and 15 months of age.
- T-cell defects: Most often characterized by persistent viral infections or opportunistic infections.
 - Severe combined immunodeficiency (SCID): Most common presentation is a respiratory virus that fails to clear or chronic diarrhea. Failure to thrive, thrush, and *P. jiroveci* pneumonia are also common; see “Failure to Thrive” and “Pneumocystis Pneumonia.”
 - Chromosome 22q11.2 deletion syndrome (DiGeorge syndrome/velocardiofacial syndrome): See “DiGeorge Syndrome.”
 - Chronic mucocutaneous candidiasis: There are multiple forms of this disorder. One form is also called autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) and has a very strong association with polyendocrinopathies and ectodermal dysplasia. The other types are more likely to have an associated T-cell defect. Infants have extensive or recurrent *Candida*; predisposition to other infections is modest.
 - IPEX (immunodeficiency, polyendocrinopathy, enteropathy, X-linked syndrome): Diarrhea associated with villous atrophy and a T-cell infiltrate, progressive autoimmune destruction of endocrine organs. Infections can be severe but the autoimmune manifestations predominate.

- Neutrophil defects: *Staphylococcus*, *Pseudomonas*, unusual bacterial or fungal infections are characteristic.
 - Autoimmune neutropenia of infancy: Most common neutrophil defect of childhood; usually detected at ~6–12 months of age; often resolves by 2 years of age.
 - Congenital neutropenia: Infections may be skin infections or sinopulmonary; patients have either persistently absent or markedly low neutrophil counts. Some patients will have 21-day cycles of neutropenia—cyclic neutropenia.
 - Leukocyte adhesion deficiency: ~10% have delayed separation of the umbilical cord; most common presentations are recurrent skin ulcers and periodontitis. Spontaneous peritonitis occurs.
 - Chronic granulomatous disease: Recurrent skin abscesses common, deep hepatic abscesses, and pulmonary infections. Typical organisms are *Staphylococcus aureus*, *Burkholderia*, *Serratia*, *Nocardia*, mycobacteria, *Aspergillus*, and *Candida*; age of onset is usually 1–3 years.
- Innate defects in signaling: Typically present with severe bacterial or viral infections in early infancy
 - IRAK4 and MyD88 deficiencies are associated with staphylococcal, streptococcal, or pseudomonas sepsis/meningitis.
 - Unc93 and other defects are associated with neonatal herpes encephalitis.
- Macrophage activation defects: Universally associated with atypical mycobacteria. *Salmonella* is also seen. Biopsies may reveal poorly formed granulomas.
- Multiple genetic types have a broad range of severity: IFNGR1, IFNGR2, STAT1, IL12P40, IL12RB1.
 - Complement deficiency: Deficiencies of C5–C9 are associated with *Neisseria* infections; deficiencies of C1, C2, and C4 are associated with lupus and recurrent bacterial infections. C3 deficiency is associated with glomerulonephritis and severe recurrent infections. Defects in complement regulatory proteins are associated with atypical hemolytic uremic syndrome (HUS).
- Immunodeficiency syndromes
 - Ataxia telangiectasia: Progressive cerebellar ataxia beginning at ~2 years of age; ocular telangiectasias beginning at about 5–15 years of age; recurrent sinopulmonary infections; α -fetoprotein is elevated, IgA and IgG2 are diminished.
 - Wiskott–Aldrich syndrome: Clinical triad of eczema, thrombocytopenia, and recurrent infections. Immunoglobulin levels are variable but responses to vaccines are often poor; platelets range from 20,000 to 90,000 and are small.
 - Hyper-IgE syndrome: Recurrent infections of the skin and lungs; *S. aureus* is a major cause of infection, and pulmonary infections typically heal with pneumatoceles.
 - X-linked lymphoproliferative syndrome: 4 main types of presentation and 2 genetic types: Acute Epstein–Barr virus infection with hemophagocytosis, lymphoma, hypogammaglobulinemia, and aplastic anemia. Family history is key to diagnosis.

- Chédiak–Higashi syndrome: Pigmentary dilution, progressive neuropathy, and frequent infections; associated with a hemophagocytic process. Neutrophil counts are low and neutrophils have giant inclusions.
- Familial hemophagocytic lymphohistiocytosis: A defect in cytotoxic function; presents with fever, pancytopenia, and hepatosplenomegaly; usually <5 years of age.
- Ectodermal dysplasia with immune deficiency also known as NEMO (NF- κ B essential modulator) deficiency: Variable ectodermal dysplasia and variable immune deficiency. Immunoglobulin levels are variable as are responses to vaccines. Susceptibility to mycobacteria, *Pneumocystis*, and common bacterial pathogens.
- Secondary immunodeficiencies include:
 - HIV infection
 - Malignancy
 - Viral suppression
 - Nephrotic syndrome
 - Protein-losing enteropathy
 - Malnutrition
 - Medications
 - Splenectomy

EPIDEMIOLOGY

Primary immune deficiencies range from the common (1:600) to the very rare (1:1,000,000)

- 1:600 for IgA deficiency in Caucasians
- 1:3,000 for chromosome 22q11.2 deletion syndrome (DiGeorge syndrome)
- 1:20,000 for common variable immune deficiency
- 1:50,000 for SCID
- 1:200,000 for chronic granulomatous disease
- 1:1,000,000 for NEMO deficiency

RISK FACTORS

- The immunodeficiencies are generally autosomal recessive, although there are several important exceptions.
- X-linked (Properdin deficiency, X-linked agammaglobulinemia, X-linked hyper-IgM, X-linked SCID, X-linked chronic granulomatous disease, X-linked lymphoproliferative syndrome [2 types], IPEX, Wiskott–Aldrich syndrome, NEMO deficiency). All of these have autosomal-recessive phenocopies or may be seen in females with altered X inactivation.
- Autosomal dominant: Hyper-IgE syndrome, chromosome 22q11.2 deletion syndrome, some macrophage activation defects
- Polygenic: IgA deficiency and common variable immunodeficiency

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic inflammation of mucous membranes such as that due to reflux or allergies can lead to recurrent infections.
- Immunocompromise due to chemotherapy and immunosuppressive drugs
- Malnutrition
- Intercurrent viral infections such as Epstein–Barr virus and cytomegalovirus

- Medications such as Dilantin and gold can cause IgA deficiency or hypogammaglobulinemia
- Inborn errors of metabolism
- Chromosomal syndromes
- Protein loss can be associated with hypogammaglobulinemia.
- HIV infection

HISTORY

- **Question:** Family history?
- **Significance:** X-linked disorders are common.
- **Question:** Number and duration of infections?
- **Significance:** To determine whether the problem is one of clearance, or frequency
- **Question:** Types of infections?
- **Significance:** Infections of skin are frequently due to neutrophil problems, whereas recurrent infections of a single site imply an anatomic problem. Opportunistic infections are associated with both neutrophil defects (unusual bacteria and fungi) and T-cell defects (opportunistic viruses).
- HIV risk factors

PHYSICAL EXAM

The physical exam should be directed at defining organ damage as a result of infection, the presence of any current infections, the presence of any syndromic features, the presence of signs of autoimmune disease, and the characterization of accessible lymphoid organs.

- **Finding:** Examination of lymph nodes, tonsils, liver, and spleen?
- **Significance:** Hypoplasia or expansion

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** Laboratory evaluations should focus on the quantity and function of antibodies: IgG, IgA, IgM, IgE levels, and responses to vaccines such as diphtheria and tetanus.
- **Significance:** A patient with recurrent sinopulmonary infections with typical organisms could have a defect in antibody production.
- **Test:** Evaluation of T-cell production and function—T-cell enumeration and lymphocyte proliferation studies
- **Significance:** Chronic viral infections or opportunistic infections suggest a T-cell defect.
- **Test:** Evaluation of neutrophil numbers and function—a CBC with differential, morphologic examination of neutrophils, and a measure of respiratory burst
- **Significance:** Neutrophil disorders typically present with skin abscesses or ulcers or deep infections with *Staphylococcus* or fungi.
- **Test:** Special studies designed to test the function of the toll-like receptor signaling complex
- **Significance:** Innate defects, such as IRAK4, MyD88, and NEMO deficiencies, can be detected.
- **Test:** A CH50
- **Significance:** Complement deficiencies—a CH50 will detect most of the structural component deficiencies. Special studies are needed for defects of the alternative pathway and the regulatory proteins.
- **Test:** CBC with differential, IgG, IgA, IgM levels, and diphtheria and tetanus titers
- **Significance:** In certain patients it may be difficult to differentiate between viral processes and bacterial processes. In these cases, a CBC with differential, IgG, IgA, IgM levels, and diphtheria and tetanus titers are a useful screen to evaluate for the most common immunodeficiencies.

TREATMENT

- Prophylactic antimicrobials:
 - IgG subclass deficiency
 - Chronic mucocutaneous candidiasis
 - Ataxia telangiectasia
 - Hyper-IgE syndrome
 - Chronic granulomatous disease

ADDITIONAL TREATMENT

General Measures

- Suspected SCID requires isolation, cytomegalovirus negative/irradiated blood products, and a prompt evaluation for hematopoietic stem cell transplant.
- Immunoglobulin replacement (either IV or SC)
 - X-linked agammaglobulinemia
 - Hyper-IgM
 - Common variable immunodeficiency
 - IgG subclass deficiency (infrequently)
- Probiotics can be useful for patients exposed to frequent antibiotics.
- Hand washing and topical measures to prevent infections

SURGERY/OTHER PROCEDURES

- Hematopoietic stem cell transplantation:
 - SCID
 - Wiskott–Aldrich syndrome
 - X-linked lymphoproliferative syndrome
 - Chédiak–Higashi syndrome
 - Familial hemophagocytic lymphohistiocytosis
 - Selected cases of hyper-IgM, chronic granulomatous disease, macrophage activation defects, NEMO deficiency
- Thymus transplantation:
 - Severe chromosome 22q11.2 deletion syndrome (DiGeorge syndrome)

ONGOING CARE

PROGNOSIS

- Most antibody deficiencies have an excellent prognosis. Transient or developmental deficiencies of IgG or IgG subclasses typically resolve by 2 years of age.
- Some patients with common variable immunodeficiency can develop malignancy or autoimmune disease is this defines the prognosis.
- The treatment of neutrophil disorders remains problematic, and most children with chronic granulomatous disease will not have a full life expectancy.
- Patients with T-cell disorders for whom bone marrow transplantation is not performed can do well if the defect is mild and if they do not suffer from autoimmune disease, malignancy, or recurrent infections.

COMPLICATIONS

- Bronchiectasis
- Deafness
- Autoimmune disease
- Lymphoreticular malignancies occur in patients with T-cell disorders.
- Live viral vaccines administered to patients with significant T-cell dysfunction can result in unchecked viremia.
- Oral polio vaccine administered to patients with agammaglobulinemia can cause meningoencephalitis.

CODES

ICD9

- 279.3 Unspecified immunity deficiency
- 279.04 Congenital hypogammaglobulinemia
- 279.06 Common variable immunodeficiency

ICD10

- D80.0 Hereditary hypogammaglobulinemia
- D83.9 Common variable immunodeficiency, unspecified
- D84.9 Immunodeficiency, unspecified

FAQ

- Q: I have many patients with recurrent episodes of green rhinorrhea. Do these episodes all need to be treated with antibiotics, and should the child have an immunologic evaluation?
- A: Many viral infections cause green rhinorrhea and thus do not require antibiotics. Children with no other infections may be safely observed.
- Q: Does a child with thrush require evaluation?
- A: A child with severe thrush in the absence of risk factors should have an evaluation for T-cell dysfunction, HIV, and the possibility of chronic mucocutaneous candidiasis of childhood. Moderate thrush or recurrent simple thrush does not require evaluation unless it is occurring in an older child.
- Q: A newborn in my practice still has his umbilical cord attached at 6 weeks of age. Is that abnormal, and does it require an evaluation for leukocyte adhesion deficiency?
- A: A completely healthy-appearing cord at 6 weeks of age does not require any evaluation. If there is clinical suspicion of leukocyte adhesion deficiency, a CBC can be performed to identify neutrophilia.

CLINICAL PEARLS

- Boys with X-linked agammaglobulinemia and X-linked hyper-IgM do not have tonsils and adenoids.
- Children and adults with hyper-IgE syndrome develop abscesses that are not painful.
- Infections in patients with IRAK4 or MyD88 deficiency may not be accompanied by fever.

IMMUNOGLOBULIN A DEFICIENCY

Mathew Fogg

BASICS

DESCRIPTION

Serum IgA <5 mg/dL and a normal serum IgG and IgM, in patients >1 year

RISK FACTORS

Genetics

Most common autosomal dominant mode of inheritance with variable expressivity, but the following rare associations also occur:

- 18q syndrome
- Partial deletions in the long or short arm, and ring forms of chromosome 18
- Also associated with HLA-A1, HLA-A2, B8, and Dw3

PATHOPHYSIOLOGY

Increased incidence of the following:

- Atopy
- Sinopulmonary infections
- GI infections (especially *Giardia lamblia*)
- Crohn disease
- Ulcerative colitis
- Celiac disease
- Autoimmune illnesses:
 - Arthritis
 - Lupus
 - Immune endocrinopathies
 - Autoimmune hematologic conditions
 - Chronic active hepatitis

DIAGNOSIS

HISTORY

- Patients with IgA deficiency:
 - Can have frequent sinopulmonary infections
 - Can have frequent GI infections
 - Tend to be allergic
 - Have an increased incidence of autoimmune diseases
- ~30% of patients with IgA deficiency are completely healthy.

PHYSICAL EXAM

- Look for signs of recurrent infection and atopy.
- Allergies are associated with IgA deficiency. Signs include:
 - Cobblestoning of the conjunctiva caused by allergic inflammation in the eyes
 - Allergic shiners
- Serous otitis media may be the result of recurrent ear infections:
 - Increased ear infections can be seen in IgA deficiency.
 - Serous otitis media can be secondary to allergies, also associated with IgA deficiency.
- Pain on palpation of the sinuses: Recurrent sinus infections are associated with IgA deficiency.
- An increased frequency of pneumonia is associated with IgA deficiency.
- Swollen joints: An increased frequency of autoimmune diseases is associated with IgA deficiency.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

The general goal is to decide whether the patient's complaints are consistent with IgA deficiency (frequent upper respiratory and GI infections, or allergies).

- Measure serum IgA level:
 - If the patient is IgA deficient, exclude other conditions associated with IgA deficiency.
 - Serum IgA level: Patient is considered deficient if the serum IgA level is <5 mg/dL.
- Total immunoglobulins: If normal, helps rule out X-linked agammaglobulinemia (Bruton), common variable immunodeficiency, and severe combined immunodeficiency
- IgG subclasses: Study helps rule out an associated IgG2 subclass deficiency; clinical significance of IgG2 subclass deficiency is controversial.
- Lymphocyte mitogens:
 - A functional lymphocyte study
 - If normal, helps rule out common variable immunodeficiency, severe combined immunodeficiency, ataxia telangiectasia, DiGeorge syndrome, and Nezelof syndrome
- Lymphocyte *Candida* antigen stimulation: No response to *Candida* in vivo is consistent with chronic mucocutaneous candidiasis.

DIFFERENTIAL DIAGNOSIS

- Toxic, environmental, drugs: Penicillamine and anticonvulsants can induce IgA deficiency.
- Genetic/Metabolic:
 - X-linked agammaglobulinemia (Bruton)
 - Common variable immunodeficiency
 - Severe combined immunodeficiency
 - Ataxia telangiectasia
 - DiGeorge syndrome
 - Chronic mucocutaneous candidiasis
 - Nezelof syndrome
 - Selective IgG2 deficiency

- Miscellaneous: Patients may be completely healthy, and IgA deficiency may be an incidental finding.
- Common causes: May be the result of decreased synthesis or impaired differentiation of IgA B lymphocytes into IgA plasma cells

ALERT

Factors that may help alert you to make a referral include:

- Suggestion that IgA deficiency may be part of a more complex immune deficiency: An allergist/immunologist can assist with an appropriate immunologic evaluation.
- IgA deficiency associated with autoimmune disease: Evaluation and treatment by a rheumatologist would be indicated.
- Patient likely to need a blood transfusion: IgA-deficient patients show an increased incidence of anaphylaxis to IgA-containing blood products. The allergist can help select appropriate blood products for these patients.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- There is no specific drug therapy.
- Recurrent infections should be treated aggressively with broad-spectrum antibiotics.
- Antibiotic prophylaxis to prevent recurrent sinopulmonary infections is often indicated.
- IV γ -globulin is not indicated.

ALERT

Patients with IgA deficiency may develop antibodies against IgA in transfused blood products. These patients are at risk for anaphylactic (or anaphylactoid) transfusion reactions. To avoid these reactions, these patients may receive:

- Packed RBCs (only if these cells have been washed 3 times)
- Plasma products from IgA-deficient donors
- Autologous banked blood

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients should be observed for:
 - Sinopulmonary infections
 - GI infections
 - Autoimmune diseases
 - Inflammatory bowel disease
- It is important to manage infectious complications aggressively and to intervene promptly when the associated conditions present.

PATIENT EDUCATION

- Recurrence risk for a couple with an affected child depends on the mode of inheritance:
 - Most commonly, the mode of inheritance is autosomal dominant and the risk would be 50%.
 - However, expressivity is variable, and the patient's phenotype may not be that of an IgA-deficient person.
- IgA deficiency can be induced by some anticonvulsants and by penicillamine.
- IgA-deficient patients should wear medical alert bracelets. These patients can have anaphylaxis if administered blood products containing IgA. In an emergency situation, this is important information for the caregivers to have.

PROGNOSIS

Survival into the 7th decade is common.

COMPLICATIONS

Increased incidence of the following:

- Respiratory tract infections
- GI tract infections
- Atopy

FAQ

- Q: What is the recurrence risk for a couple with an affected child?
- A: It depends on the mode of inheritance. Most commonly, the mode of inheritance is autosomal dominant and the risk would be 50%. However, the expressivity is variable, and the patient's phenotype may not be that of an IgA-deficient person.
- Q: Does the patient take any medications?
- A: The IgA deficiency can be induced by some anticonvulsants and by penicillamine.
- Q: Should IgA-deficient patients wear medical alert bracelets?
- A: Yes. These patients can have anaphylaxis if they are given blood products containing IgA. In an emergency situation, this is important information for the caregivers to have.

IMPERFORATE ANUS

Judith Kelsen

BASICS

DESCRIPTION

Congenital abnormality in which the bowel fails to perforate or only partially perforates the pelvic muscular floor and/or the epidermal covering

EPIDEMIOLOGY

- Incidence is estimated to be in the range of 1:3,000–1:9,000.
- High lesions are more common in males (2:1).
- Low lesions occur with equal frequency in both sexes.

RISK FACTORS

Genetics

- Can be an isolated defect or part of a syndrome or association
- Can be part of omphalocele-exstrophy of the bladder-imperforate anus-spinal defects (OEIS) complex or cloacal exstrophy (EC)
- Syndromic disorders that contain imperforate anus are associated with defects on chromosomes 6, 7, 10, and 16.
- Can be associated with Trisomy 21

PATHOPHYSIOLOGY

- The hindgut comes in contact with the cloacal membrane during the 6th week of fetal development. At this time, the hindgut is divided into a ventral urogenital and dorsal rectal component. By the 8th week, the dorsal 1/2 perforates to the exterior. In imperforate anus, the process is arrested during this critical period.
- There are many anatomic variants of imperforate anus. From the prognostic point of view, the most important is classification and distinguishing the main types: Suprlevator (high) and translevator (low). In the low variant, the rectal termination is above the anal pit and not related to the urethra.
- A separate group is of cloacal malformation, in which the urinary genital and digestive systems drain to a common channel that communicates with the perineum.

- A fistula communicating from the gut to the urogenital system or to the external opening is present in 90% of cases. In females, most commonly the fistula leads to the opening in the posterior fourchette of the vagina (in low lesions) or to the upper vagina (in high lesions). In males, the fistula leads to the raphe of the scrotum (in low lesions) or to the urethra (in high lesions).

COMMONLY ASSOCIATED CONDITIONS

- Other anomalies are present in 1/3 of patients with an imperforated anus.
- Imperforate anus can be associated with vertebral and cardiac anomalies, tracheoesophageal fistula, and renal and limb anomalies (VACTERL).
- Other anomalies associated with imperforate anus include intestinal atresia, malrotation, omphalocele, annular pancreas, urologic anomalies, spinal anomalies, duplicate uterus, septate vagina, vaginal atresia, and absence of rectal muscles.

DIAGNOSIS

HISTORY

- Most children are diagnosed in the 1st days of life by abnormal findings on physical exam.
- Failure to pass meconium, a history of constipation, and signs of low intestinal obstruction (abdominal distention and vomiting) should mandate re-exam of perianal area.

PHYSICAL EXAM

- Lesion presents as no opening, an inadequate caliber of anus, or an anterior malposition of the opening.
- Attempt to localize the opening of the fistula and look for associated anomalies.
- Evaluate for lumbosacral neurologic function. Anal wink can usually be elicited, because a vertiginous external anal sphincter is present in most cases.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Invertogram: After sufficient time for a transit of gas (> 12 hours after birth), the child is placed in an upside-down position for 3 minutes, after which a lateral view of the pelvis is obtained.
- Lumbosacral films to evaluate for vertebral anomalies
- MRI of the spine should be considered to look for a tethered cord.
- Renal ultrasound, voiding cystoureterogram, and IV pyelogram can be used to evaluate for urinary tract anomalies.

DIFFERENTIAL DIAGNOSIS

- No disorders can mimic imperforate anus
- Task is to define the location of the termination of the bowel and the opening of the fistula.

TREATMENT

SURGERY/OTHER PROCEDURES

- Surgery should be performed by an experienced surgeon.
- High lesions require an emergent diverting colostomy and pull-through procedure with a Pena midsagittal anorectoplasty at 3–9 months of age. The colostomy is closed after the anoplasty has healed and any necessary secondary dilations have been completed.
- New techniques: While the above procedure has been the gold standard, a significant percentage of patients continue to have fecal disorders postoperatively.

- The use of the laparoscopically assisted anorectal pull-through using laparoscopy and muscle electrostimulation (LAARP) has been developed.
- Transanal anorectoplasty was recently shown to have sphincter sparing and results in accurate placement of anus in external canal with good neurological function.
- After surgery, follow-up with anal dilatation helps minimize the risk of stricture formation and helps the newly constructed canal to become functional.
- Complications of surgery include stricture of the anocutaneous anastomosis, rectourinary fistula, mucosal prolapse, constipation, and incontinence.

ONGOING CARE

PATIENT EDUCATION

- Imperforate anus can be associated with multiple other anomalies and not necessarily isolated.
- Renal and vertebral anomalies must be excluded.
- Genetic basis: Imperforate anus can be associated with chromosomal anomalies or can be an isolated problem.

PROGNOSIS

- Continence can be attained in 90% if patients have low lesions.
- <50% of patients with high lesions are continent before school age, but most continue to improve and achieve continence by adolescence.
- Highest incidence of incontinence occurs in males with rectobladder fistulae.

COMPLICATIONS

- Constipation is the most common problem following repair.
- A significant percentage will have incontinence.
- Many patients will need regular enemas for years to prevent or reduce constipation and fecal incontinence.
- Although some patients experience significant problems early in school years, overall studies have shown patients with imperforate anus did not experience psychosocial impairment despite significant functional problems.

CODES

ICD9

- 565.1 Anal fistula
- 751.2 Imperforate anus

ICD10

- Q42.2 Congenital absence, atresia and stenosis of anus with fistula
- Q42.3 Congenital absence, atresia and stenosis of anus without fistula

FAQ

- Q: Is this an isolated defect in my child?
- A: Often, imperforate anus can be associated with multiple other anomalies and not necessarily isolated. Renal and vertebral anomalies must be excluded.
- Q: What is the genetic basis for this defect?
- A: Imperforate anus can be associated with chromosomal anomalies or can be an isolated problem.

IMPETIGO

Michelle Terry

BASICS

DESCRIPTION

Impetigo is a superficial skin infection characterized by the eruption of shallow pustules that rupture and form thick yellow crusts.

- Impetigo occurs most commonly in children and is contagious.
- Pyoderma and impetigo contagiosa are synonyms for impetigo.

CLASSIFICATION:

- Primary impetigo is defined as direct bacterial invasion of previously normal skin.
- Secondary impetigo is defined as infection at sites of minor skin trauma such as abrasions, insect bites, or underlying conditions such as eczema.

TYPES OF IMPETIGO

- Non-bullous impetigo—the most common form of impetigo. Lesions begin as papules that progress to vesicles surrounded by erythema. Over the course of a week, they become pustules that enlarge and break down to form thick, adherent yellow crusts.
- Bullous impetigo—characterized by vesicles containing clear yellow fluid, that then becomes darker and more turbid; ruptured bullae leave a “honey”-colored crust.
- Ecthyma—an ulcerative form of impetigo in which the lesions extend through the epidermis and deep into the dermis.

MICROBIOLOGY

The predominant bacteria are:

Non-bullous impetigo

- Group A beta-hemolytic streptococcus (GABHS)
- *Staphylococcus aureus*
- Miscellaneous gram-negative and anaerobic bacteria have also been isolated from lesions.

Bullous impetigo

- *Staphylococcus aureus*

Ecthyma

- Group A beta-hemolytic streptococcus (GABHS)
- *Staphylococcus aureus*
- Miscellaneous gram-negative and anaerobic bacteria (including *Pseudomonas aeruginosa* in ecthyma gangrenosum)

EPIDEMIOLOGY

- Frequency: Impetigo accounts for approximately 10% of skin problems observed in pediatric clinics and is one of the more common dermatologic infections.
- Location: Impetigo occurs more frequently in warm, humid environments.
- Age: Impetigo is found most commonly in preschool-aged children and can spread rapidly through child care centers and schools.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Varicella
- Staph scalded skin syndrome
- Erythema multiforme
- Herpes simplex virus infection
- Burns (thermal and chemical)
- Nummular eczema
- Tinea corporis
- Insect bites
- Scabies
- Lice

HISTORY

- Patients with impetigo may report a history of minor trauma, insect bites, scabies, herpes simplex virus infection, varicella infection, or eczema before the development of the infection. Impetigo lesions are usually present for a few days to weeks before the patient seeks medical attention.
- Impetigo is usually painless, although patients may complain of that the lesions are itchy. Additional symptoms such as fever, respiratory distress, vomiting, or diarrhea are rare and perhaps indicative of another diagnosis besides impetigo.
- Outbreaks commonly occur in families and child care centers, as well as among sports team members.

PHYSICAL EXAM

- Nonbullous impetigo
 - Lesions first begin as thin-walled vesicles or pustules on an erythematous base. The lesions promptly rupture, releasing their serum, which dries and forms a light brown, “honey-colored” crust.
 - Multiple lesions generally occur at the same site, often coalescing.
 - As the lesions resolve with treatment, the crusts slough from the affected areas and usually heal without scarring.
- Bullous impetigo
 - Lesions may form on grossly normal or previously traumatized skin.
 - The vesicles do not rupture as easily or quickly as in nonbullous lesions, but they do enlarge into bullae that are usually 1–2 cm in diameter. The bullae initially contain a clear yellow fluid that subsequently turns cloudy and dark yellow.
 - After the lesions rupture, a thin, light brown, crust remains.

- Ecthyma
 - The lesion is a vesicle or pustule overlying an inflamed area of skin that deepens into a dermal ulceration with overlying crust.
 - The crust of ecthyma lesions is gray-yellow and is thicker and harder than the crust of impetigo.
 - A shallow, punched-out ulceration is apparent when adherent crust is removed and the deep dermal ulcer has a raised and indurated surrounding margin.
 - Ecthyma heals slowly and commonly produces a scar.
 - Regional lymphadenopathy is common in ecthyma, even with solitary lesions. Lymphadenopathy is less common in bullous impetigo and is rare in nonbullous impetigo.

Lab

- Usually, no lab evaluation is required, impetigo is a clinical diagnosis.
- Gram stain and wound culture is helpful, especially if MRSA is suspected.
- CBC with differential and blood cultures are helpful if systemic symptoms are present.
- A skin biopsy may be useful if the diagnosis is uncertain.

TREATMENT

Supportive

- Clipping the patient’s fingernails short to discourage scratching of the lesions is recommended.
- Cleansing and debriding the lesions are unnecessary.

MEDICATION (DRUGS)

Topical therapy:

- The preferred treatment when there are a limited number of lesions without bullae. Topical therapy has fewer side effects and lower risk for contributing to bacterial resistance compared with oral therapy.
- Mupirocin 2% ointment or cream, children >2 months old: Applied to affected areas three times daily for 5 days
- Retapamulin 1% ointment, children >9 months old: applied to affected area (up to 2% BSA) twice daily for 5 days
- Although the components of over-the-counter triple antibiotic ointments (consisting of bacitracin–neomycin–polymyxin B) do have some activity against the organisms causing impetigo, they are not considered effective for treatment.

Oral therapy

- Oral antibiotic therapy should be used for impetigo when the lesions are bullous, and when it is impractical to use topical therapy either due to the extent or location of lesions:
- Amoxicillin/clavulanic acid 40mg/kg/d in 2 divided doses × 10 days
- Cephalexin 25 mg/kg/d in 4 divided doses × 10 days
- Clindamycin 15–25 mg/kg/d in 3 divided doses × 10 days
- Erythromycin 40 mg/kg/d in 4 divided doses × 10 days
- When MRSA is suspected:
 - Please become familiar with resistance patterns in the community.
 - Clindamycin 15–25 mg/kg/d in 3 divided doses × 10 days
 - Trimethoprim–sulfamethoxazole: Trimethoprim 8 mg/kg and sulfamethoxazole 40 mg/kg daily in 2 divided doses × 10 days

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS****Duration of Therapy:**

The duration of antimicrobial therapy should be tailored to clinical improvement; 7–10 days of treatment is usually appropriate. The skin covered with the crusted lesions can be cleansed gently with soap and water. In addition, regular hand washing is important for reducing spread among children.

Signs of Incomplete Therapy:

- Recurrent infection may indicate incomplete therapy, reinfection, or an *S. aureus* carrier state.
- Development of fever is unusual, and may indicate a more serious infection and/or the presence of cellulitis or an abscess.

Pitfalls:

- Impetigo frequently spreads among close contacts and family members. Patients and family members should wash their hands frequently, keep clothes and bedding clean, and not share towels and other personal care items.
- Underlying skin conditions (e.g., eczema) and infestations (e.g., scabies) should be treated appropriately to decrease the likelihood of the development of impetigo.

COMPLICATIONS

Cellulitis, lymphangitis, suppurative lymphadenitis, and staphylococcal scalded skin syndrome occur in as many as 10% of patients with impetigo. In addition, acute post streptococcal glomerulonephritis, scarlet fever, osteomyelitis, septic arthritis, pneumonia, septicemia, and rheumatic fever have also been observed in patients with impetigo.

PROGNOSIS

The sores of impetigo usually heal; although there may be some post-inflammatory hyperpigmentation. Overall, the infection is highly curable, but the condition often recurs in young children.

**CODES****ICD9**

684 Impetigo

ICD10

- L01.00 Impetigo, unspecified
- L01.01 Non-bullous impetigo
- L01.03 Bullous impetigo

FAQ

- Q: Which is the more effective treatment for impetigo—oral or topical antibiotics?
- A: In general, if there are a few localized lesions, topical therapy with mupirocin is preferred. If there is more diffuse involvement, or systemic symptoms, a course of oral antibiotics is recommended.
- Q: Can a child with impetigo attend school or child care?
- A: After a child begins antibiotic therapy and the lesions begin to improve, the child may resume his or her activities without restrictions.
- Q: How does one help prevent impetigo from spreading?
- A: Gently wash the affected areas with mild soap and running water, use the antibiotics (topical or oral) as directed, and then cover lesions with bandages. Wear gloves when applying any antibiotic ointment to the patient's lesions and endorse thorough hand washing afterwards. Do not share clothes, linens, or towels used by the affected individual until the infection has cleared.

INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Sogol Mostoufi-Moab

Sheela N. Magge

Paul S. Thornton (5th edition)

BASICS

DESCRIPTION

Inappropriate secretion of antidiuretic hormone (ADH) or ADH-like peptide in the presence of low serum sodium, low serum osmolality, and high urine osmolality, and in the absence of renal, adrenal, or thyroid pathology

EPIDEMIOLOGY

Incidence

The syndrome of inappropriate antidiuretic hormone (SIADH) can occur at any age. Its incidence depends on the various possible etiologies.

RISK FACTORS

Genetics

Genetic causes of SIADH are exceedingly rare. However, 2 cases have been described with gain-of-function mutation in the vasopressin-2 receptor contributing to SIADH and undetectable serum ADH levels.

PATHOPHYSIOLOGY

- ADH is synthesized within the neurons of the hypothalamus, transported in conjunction with neurophysin down the supraopticohypophyseal tract, and stored in the posterior pituitary.
- ADH acts on the renal collecting ducts.
- Interaction of ADH with its receptors forms intracellular cyclic AMP (cAMP), which increases water permeability through insertion of aquaporins (water channels) in renal collecting ducts and consequently enhances reabsorption of free water.
- SIADH results when elevated levels of ADH or ADH-like peptides cause free water retention and hypervolemia leading to hyponatremia. Three possible mechanisms include:
 - Increased hypothalamic production of ADH (e.g., CNS disorders such as stroke or meningitis)
 - Independent production of ADH or ADH-like substances from ectopic sources (e.g., lung oat cell carcinoma or olfactory neuroblastoma)
 - Decreased venous return that stimulates atrial volume receptors and thereby leads to ADH release (e.g., heart failure, cirrhosis, pulmonary and intrathoracic diseases, such as tuberculosis)

ETIOLOGY

- Idiopathic
- CNS pathology, causing increased secretion of ADH or ADH-like peptides: Meningitis, head trauma, neurosurgical procedures, encephalitis, Guillain-Barré syndrome, brain tumor, brain abscess, hydrocephalus, hypoxia, subarachnoid hemorrhage, cerebral venous thrombosis
- Ectopic production of ADH or ADH-like peptides: Oat cell carcinoma of the lung, bronchogenic carcinoma, olfactory neuroblastoma, and pancreatic carcinoma
- Pulmonary disease (leading to secondary elevation in ADH secretion or ADH-like peptides): Tuberculosis, viral or bacterial pneumonia, asthma, cystic fibrosis, pneumothorax, positive pressure ventilation

- Drugs (which mimic ADH or stimulate its release): Vincristine, cyclophosphamide, carbamazepine, chlorpropamide, phenothiazines, clofibrate, nicotine, fluoxetine, sertraline
- Iatrogenic exogenous administration of ADH: Vasopressin infusion for treatment of diabetes insipidus, excess desmopressin (DDAVP) in conjunction with fluid intake
- Severe, prolonged nausea
- Postoperative patient (e.g., as part of triple-phase response after hypothalamic-pituitary surgery, after transsphenoidal pituitary surgery)
- Rocky Mountain spotted fever

DIAGNOSIS

HISTORY

- Unusual water intake (suspicious for psychogenic polydipsia)
- Review of intake and output for inpatients
- Decreased urine output
- Anorexia, lethargy
- Weight gain or weight loss
- Renal disease
- Vomiting
- Diarrhea
- Use of diuretics
- Burns
- Heart disease
- Liver disease
- Brain injury: Trauma, surgery, hypoxia, toxin

PHYSICAL EXAM

- A complete neurologic and physical exam must be performed. Classically, patients with SIADH manifest subtle signs of hypervolemia but without increased urine output.
- With or without edema
- No signs of dehydration
- Signs of fluid overload
- Absent hyperpigmentation of skin creases/gums (presence suggests Addison disease)
- Hyponatremia, may cause lethargy or irritability, and muscle cramps. In severe cases, patients may lose deep tendon reflexes, seize, or be comatose.

ALERT

- Pitfall: Failure to distinguish SIADH from other causes of hyponatremia such as adrenal insufficiency, hypothyroidism, or cerebral salt wasting (CSW) can result in erroneous medical management and lead to worsening hyponatremia.
- Patients with SIADH are still capable of making urine; basing the diagnosis on urine volume alone can be misleading.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Specific tests:
 - Simultaneous urinary osmolality, serum osmolality, and serum sodium (order a basic metabolic panel)
 - Urine sodium: Usually > 30 mmol/L
 - Serum uric acid: Usually low in SIADH
 - Presence of hyponatremia (serum sodium < 130 mEq/L), decreased serum osmolality (< 260 mOsm/kg), with an inappropriately elevated urinary osmolality (> 260 mOsm/L)
 - Plasma ADH concentration: Diagnostic but not helpful for rapid diagnosis
- Nonspecific tests:
 - Fractional renal excretion of sodium: Net sodium loss is normal or elevated and is dependent on sodium intake.
 - Urinary specific gravity: Helpful but not as specific as urine osmolality
 - Blood glucose: Hyperglycemia results in pseudohyponatremia.
 - Triglycerides: Hyperlipidemia causes pseudohyponatremia.

Imaging

Head MRI with special cuts of the pituitary and hypothalamus if indicated

DIFFERENTIAL DIAGNOSIS

- Hypovolemic hyponatremia (e.g., hyponatremic dehydration, seen after running a marathon)
- Euvolemic hyponatremia (e.g., hypothyroidism, adrenal insufficiency)
- Hypervolemic hyponatremia (e.g., CHF, cirrhosis, nephrotic syndrome)
- Diuretics
- Total body sodium loss through vomiting, nasogastric suction, diarrhea, or increased intestinal secretions
- Renal failure
- Severe potassium depletion
- Water intoxication
- Cerebral salt wasting: Excess production or effects of atrial and/or brain natriuretic peptide hormones
- Reset hypothalamic osmostat
- Rocky Mountain spotted fever
- Pseudohyponatremia with hyperglycemia (diabetic ketoacidosis), severe hyperlipidemia, or after administration of mannitol

TREATMENT

MEDICATION (DRUGS)

- For emergency use only: Hypertonic saline (1.5–3% NaCl)
- Diuretics should be avoided because they worsen hyponatremia.
- ADH antagonists, such as tolvaptan, have been shown to be effective for treatment of SIADH in research trials for adults.
- Demeclocycline (for chronic SIADH)

ADDITIONAL TREATMENT

General Measures

- The most important aspects of therapy for SIADH are diagnosis and treatment of the underlying cause.
- Hyponatremia may result in seizures, which will require immediate treatment with 3% hypertonic saline until the seizure activity stabilizes. Despite the urgent need for correction of hyponatremia to address the severe neurologic symptoms, the rate of sodium correction should not exceed 12 mEq/L in 24 hours.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Patients with severe hyponatremia and/or neurologic manifestations will need to be admitted for correction of hyponatremia under close medical supervision.

IV Fluids

- Fluid restriction is essential to treat and prevent worsening hyponatremia. Thus, IV fluid, in general, is not recommended for patients with SIADH. If IVF is clinically necessary, a rate comparable to insensible losses (1/3 daily maintenance) is recommended with close attention to the serum sodium levels.
- The hyponatremia in SIADH is due to free water retention and not due to decreased total body sodium content. For this reason, changing IV fluid from hypotonic solutions to hypertonic (normal saline) without restriction of rate will still result in worsening hyponatremia.

Discharge Criteria

- Depends on the primary etiology causing SIADH
- Generally, when the serum sodium is stabilized and the patient is neurologically stable

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- When to expect improvement: Usually during the 1st 48–72 hours
- Signs to watch for: Changes in neurologic status

DIET

Fluid restriction is the most important aspect in the treatment of SIADH. Generally, only fluids for insensible losses (1/3 daily maintenance) are recommended.

PROGNOSIS

Based on the primary cause

COMPLICATIONS

- Severe hyponatremia can cause seizures and, rarely, brain damage. Correcting hyponatremia too quickly can lead to central pontine myelinolysis (CPM), a devastating demyelinating disease, which impairs vital functions such as breathing.
- Susceptibility to CPM due to correction of hyponatremia is strongly influenced by the severity and preexisting duration of hyponatremia in the patient.
- Serum sodium should not be increased > 12 mEq/L in 24 hours.

FAQ

- Q: Is the use of diuretics beneficial in treating SIADH?
- A: No. Although diuretics may relieve the effects of volume overloading, they also worsen hyponatremia. Overall, diuretics usually cause more detriment than benefit.
- Q: What distinguishes SIADH from cerebral salt wasting?
- A: CSW occurs because of increased natriuresis from increased plasma and CSF levels of atrial natriuretic peptide (ANP) after neurologic insults (e.g., subarachnoid hemorrhage). Owing to the natriuresis, these patients become dehydrated with notable decreased plasma volume and elevated BUN. In contrast, patients with SIADH have free water overload, causing hyponatremia. CSW is associated with very high urine output, in contrast to SIADH, which has low urine output. However, patients with SIADH who are treated with excess solute (3% saline) may exhibit a natural natriuresis and a high urine output. Thus, polyuria alone should never be used to distinguish between CSW and SIADH. Net sodium loss is very high in CSW, but SIADH has normal to slightly elevated net sodium loss; thus, urinary sodium levels are often not very helpful in distinguishing CSW from SIADH. Laboratory features of CSW include suppressed plasma aldosterone and normal serum uric acid concentration. Note that plasma ADH concentration is high in SIADH, and initially in CSW as well. However, in CSW, after the intravascular volume has been restored, the ADH will decrease again, and patients may not exhibit elevated urine osmolality. In these patients, persistent hyponatremia with elevated urine osmolality is more suggestive of SIADH, which is far more common than CSW.
- Q: Why is it important to distinguish SIADH from CSW?
- A: Therapies differ dramatically for these conditions. Unlike the water restriction used to treat SIADH, treatment of dehydration, such as that seen in CSW, requires replacement of ongoing salt and water losses. However, CSW is much less common than SIADH and appropriate diagnosis of each condition is necessary to avoid worsening of hyponatremia by the treatment regimen.

INFANTILE SPASMS

Juliann Paolicchi

Amy R. Brooks-Kayal (5th edition)

Eric Marsh (5th edition)

BASICS

DESCRIPTION

- An epileptic encephalopathy of infancy or early childhood consisting of myoclonic seizures and electroencephalographic pattern: High-voltage slowing, asynchrony, disorganization, and multifocal spikes (hypsarrhythmia)
- Seizures can be flexor, extensor, mixed flexor/extensor, or arrest/akinetic. They occur in clusters, typically upon awakening or drowsiness, and can have focal features.
- The combination of infantile spasms, hypsarrhythmia, and developmental arrest is known as West syndrome.
- Infantile spasms (ISs) are symptomatic if the child has a coexistent neurologic condition or developmental delay at presentation, or if a specific etiology can be identified. They are cryptogenic if no underlying cause is found.

EPIDEMIOLOGY

90% have onset < 1 year of age, with the majority between 3 and 7 months. Onset after 18 months is rare.

Incidence

Incidence is 0.16–0.42/10,000 live births. In patients with tuberous sclerosis complex the incidence is 68%.

RISK FACTORS

Genetics

- Most cases are sporadic with a positive family history of IS present in 3–6%.
- Tuberous sclerosis complex may be sporadic or autosomal dominant.
- X-linked infantile spasm syndromes (ARX, CDKL-5), and chromosomal (STXBP-1) show variable penetrance.

ETIOLOGY

- Genetic syndromes:
 - Neurocutaneous disorders: Tuberous sclerosis complex, incontinentia pigmenti, neurofibromatosis type I (NF1)
 - Down syndrome
 - X-linked infantile spasm syndromes: ARX, CDKL5, Aicardi syndrome
 - Autosomal infantile spasm syndromes: Miller-Dieker syndrome (17p13.3), 18q and 7q duplication, partial 2p trisomy, and STXBP1 and MAGI2 deletions
- Metabolic disorders:
 - Congenital lactic acidosis and mitochondrial disorders
 - Phenylketonuria
 - Nonketotic hyperglycinemia
 - Pyridoxine and folinic acid deficiency syndromes
- Malformations of cortical development
- Almost any cause of prenatal, perinatal, or early infantile brain injury may lead to infantile spasms, including meningitis, encephalitis, hypoxic-ischemic injury, abusive head trauma, stroke, and congenital infection.
- ~40% of infantile spasms are cryptogenic, but that percentage may decrease with recent genetic discoveries.

COMMONLY ASSOCIATED CONDITIONS

- Intrauterine infection, CNS infections
- Cerebral malformations: Malformation of cortical development
- Hypoxic-ischemic encephalopathy, perinatal asphyxia, prenatal/perinatal stroke
- Abusive head trauma
- Intraventricular hemorrhage
- Kernicterus
- Genetic and neurocutaneous conditions noted above

DIAGNOSIS

HISTORY

- Prenatal and perinatal history, including maternal age, pregnancy complications, perinatal difficulties
- Family history of tuberous sclerosis, epilepsy, or previous children with infantile spasms or early infant demise
- Developmental history to establish any preexisting developmental delay
- Description of spells to differentiate spasms from nonepileptic seizures

PHYSICAL EXAM

- Check general growth parameters, especially head circumference.
- Microcephaly suggests preexisting brain abnormality, poorer prognosis.
- Dysmorphism (Down stigmata)
- Retinal defects as in Aicardi syndrome or metabolic diseases
- Hepatomegaly, suggesting inborn errors of metabolism or congenital infection
- Careful skin exam, including Wood lamp exam, should be performed for evidence of neurocutaneous disorders, especially the hypopigmented macules associated with tuberous sclerosis.
- Neurologic exam: Particular attention should be paid to level of alertness (visual attentiveness often impaired at presentation), developmental milestones, and motor tone.

DIAGNOSTIC TESTS & INTERPRETATION

- EEG: High-voltage, disorganized, multifocal spikes; asynchronous, hypsarrhythmia
- Infants with cutaneous signs of tuberous sclerosis should undergo cardiologic and ophthalmologic evaluation and renal ultrasound; genetic counseling for family; other family members should be evaluated.
- Pyridoxine or folinic acid challenge during electroencephalogram: Infantile spasms can present as pyridoxine or folinic acid–dependent seizures.

Lab

- Routine blood studies:
 - Electrolytes
 - Calcium
 - Glucose (although generally unrevealing)

- Chromosomal analysis:
 - Karyotype for Down phenotype
 - Tuberous sclerosis complex screening for clinical or radiologic evidence of tuberous sclerosis. Genetic testing available for other neurocutaneous disorders, if suspected
 - Chromosome microarray for suspected genetic or cryptogenic cases
 - Specific genetic panels available for infantile spasm–associated syndromes
- Metabolic screening, including blood lactate, pyruvate, and ammonia. Serum amino acids, cholesterol panel (pyridoxine disorders), urine organic acids. Review neonatal metabolic screening for phenylketonuria and biotinidase.
- TORCH titers, depending on level of suspicion for congenital infection or microcephaly

Imaging

- MRI is the single most useful laboratory test; intracranial calcifications associated with intrauterine infections and tuberous sclerosis are more apparent on CT, but CT rarely needed
- PET imaging for refractory infantile spasms and suspected cortical malformations

Diagnostic Procedures/Other

If no cause is found using other diagnostic modalities, consider lumbar puncture for lactic acid, amino acids, folate metabolites, glucose, glycine, and abnormalities of neurotransmitter levels.

Pathological Findings

Depends on etiology: May include gliosis, atrophy, remote stroke, malformation of cortical development, tubers, etc.

DIFFERENTIAL DIAGNOSIS

- Nonepileptic disorders:
 - Benign myoclonus
 - Benign sleep myoclonus
 - Paroxysmal torticollis
 - Posturing related to gastroesophageal reflux (Sandifer syndrome)
 - Shuddering spells
 - Exaggerated startle in children with cerebral palsy
- Myoclonic epilepsies of infancy:
 - Benign myoclonic epilepsy of infancy
 - Severe myoclonic epilepsy (early infantile epileptic encephalopathy)

TREATMENT

MEDICATION (DRUGS)

First Line

- Adrenocorticotropic hormone (ACTH) is the historical treatment option, and many different protocols are in use with variability between high- and low-dose protocols.
- Treatment is often initiated at 150 U/m²/d IM (high dose) or 20–30 U/d (low dose) for 1–2 weeks. If the low-dose protocol is not effective after 2 weeks, the patient receives high dose at 40 U/d. The dose in either case is gradually tapered over 1–3 months. A recent study showed no difference in the high- and low-dose protocols in terms of efficacy (50–58%), but the high-dose group had greater side effects. A recent consensus study recommended high dose for 2 weeks, followed by a taper.

- Side effects: Weight gain, irritability, sleep disturbance, hyperglycemia, hypertension, electrolyte abnormalities, cardiomyopathy, immunosuppression, gastritis/GI bleeding, osteoporosis, growth failure
- ACTH therapy has not been proven to affect outcome in infants whose spasms are caused by prenatal or perinatal brain abnormalities (symptomatic infantile spasms).
- Patients are typically admitted for initiation and education of ACTH therapy, and weekly monitoring of BP, glucose, electrolytes, BUN/creatinine, stool guaiac, and signs of infection is recommended. Stopping ACTH resolves its side effects.
- Vigabatrin is considered the 1st-line agent for infantile spasms secondary to tuberous sclerosis complex. Dosing is initiated at 50 mg/kg/d and increased to 100–200 mg/kg/d for efficacy. The duration of therapy is not established owing to potential visual field constriction that may be related to duration of therapy. Other side effects include hypotonia, drowsiness, irritability, and reversible MRI abnormalities. Comparison trials with ACTH suggest better tolerance, similar long-term outcomes in the symptomatic group, and potentially less short-term efficacy.

Second Line

- A trial of pyridoxine (100 mg IV) and folinic acid (2.5 mg IV) should be considered to rule out pyridoxine and folinic acid deficiency or dependency. Reports (primarily from Japan) exist of successful treatment of infantile spasms with daily high-dose pyridoxine (200–300 mg/d).
- Topiramate (at dosages up to 20–60 mg/kg/d)
- Zonisamide (5–15 mg/kg/d)
- Clonazepam (0.1–0.15 mg/kg/d) or nitrazepam (0.5–3.5 mg/kg/d)
- Ketogenic diet
- Prednisone (2 mg/kg/d)
- Less used alternatives:
 - Tiagabine (0.3–1.3 mg/kg/d)
 - Valproate used cautiously because of the increased rate of fatal hepatotoxicity in this age group

SURGERY/OTHER PROCEDURES

May be indicated in malformations of cortical development, particularly hemimegalencephaly and treatment-refractory infantile spasms, especially due to tuberous sclerosis. Referral to a pediatric epilepsy center is recommended.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- If patient appears ill (possible with metabolic disorders) tend to ABCs before treatment of spasms. (Infantile spasms themselves rarely threaten vital functions.)
- General:
 - The goal of treatment is cessation of spasms and resolution of electroencephalogram.
 - The primary options for treatment are ACTH and vigabatrin, approved for the treatment of IS; however, owing to the difficulty of placebo-controlled trials for IS and the variability of the many treatment protocols, a clear consensus on treatment has not been reached.

ONGOING CARE

PROGNOSIS

- Developmental retardation occurs in 85% of patients, and long-term outcome is dependent on underlying etiology. Patients with cryptogenic IS have an overall better prognosis than symptomatic IS.
- 10% of patients achieve normal cognitive, physical, and educational development.
- 50–90% of children develop other seizure types, most commonly in the symptomatic group. 27–50% develop severe epileptic encephalopathy (Lennox-Gastaut syndrome).

COMPLICATIONS

- Hypertension and hemorrhagic gastritis may occur during ACTH therapy and must be anticipated by weekly follow-up visits. Parents need to be educated about immunosuppression during therapy, and vaccinations are typically held for 3 months.
- Infantile spasm recurrence is common, as is the development of secondary epilepsy syndromes, and requires additional treatment.

CODES

ICD9

- 345.60 Infantile spasms, without mention of intractable epilepsy
- 345.61 Infantile spasms, with intractable epilepsy

ICD10

- G40.401 Other generalized epilepsy and epileptic syndromes, not intractable, with status epilepticus
- G40.409 Other generalized epilepsy and epileptic syndromes, not intractable, without status epilepticus

FAQ

- Q: Do infantile spasms ever remit spontaneously?
- A: Spontaneous remission of infantile spasms has been reported but appears to be rare.
- Q: What is the developmental prognosis in idiopathic infantile spasms?
- A: Guarded; periodic evaluation by a child neurologist or developmental pediatrician helps to detect delays in motor or cognitive development and involvement of early intervention services is recommended. Cessation of spasms and resolution of electroencephalogram are associated with the best outcome.

INFLUENZA

Kristen A. Feemster
Joel A. Fein (5th edition)

BASICS

DESCRIPTION

An acute febrile illness characterized by fever, malaise, and respiratory symptoms

EPIDEMIOLOGY

- Although influenza affects people of all ages, the highest morbidity and mortality occur in young children <2 years old and the geriatric population.
- Attack rates are highest among school-aged children and range from 10–40%. ~1% of infections result in hospitalization but infection and hospitalization rates vary significantly across seasons.
- 20% of hospitalized children develop severe outcomes, and complication rates increase in children <2 years and those with high-risk conditions (see “Complications”). Epidemics of influenza occur almost exclusively during winter months, peak ~2 weeks after the index case, and last 4–8 weeks. Up to 75% of school children in the epidemic region may be affected.
- Transmission of influenza virus occurs by aerosol droplets, as well as by direct or indirect contact.
- Viral shedding starts 24 hours before symptoms onset and usually continues for 7 days:
 - Prolonged shedding may occur in young children, immunocompromised individuals

RISK FACTORS

High-risk conditions for severe disease include: Chronic pulmonary disease (i.e., asthma), hemodynamically significant cardiac disease, HIV and other immunodeficiencies, chronic immunosuppressive therapy, hemoglobinopathies (i.e., sickle cell disease), long-term salicylate use, chronic renal dysfunction, chronic metabolic disease, morbid obesity, and neuromuscular disorders.

General Prevention

- Vaccination:
 - American Academy of Pediatrics recommends influenza vaccination for:
 - All children ≥6 months during influenza season (October–March)
 - Health care professionals
 - Out-of-home caregivers and household contacts of all children <5 years old *OR* children 5–18 years old who are at high risk for complications from influenza infection (see Risk Factors)
 - Pregnant women
 - Vaccine types:
 - Trivalent inactivated influenza vaccine (TIV) approved for children ≥6 months; administered as an intradermal injection.
 - Live-attenuated influenza vaccine (LAIV) approved for healthy nonpregnant 2- to 49-year-olds; administered as an intranasal spray; not recommended for high-risk persons, contacts of severely immunocompromised persons, or children receiving chronic aspirin therapy (because of the association between aspirin use, influenza infection, and Reye syndrome.)
- Children <10 years old receiving seasonal influenza vaccination for the 1st time should receive 2 doses of vaccine administered at least 1 month apart.

- LAIV can be given simultaneously with both live and inactivated vaccines. However, after administration of any live vaccine, a minimum of 4 weeks should pass before administering another live vaccine.
- People with a known anaphylactic hypersensitivity to eggs or a history of Guillain-Barré syndrome within 6 weeks of previous influenza vaccination should consult a physician before receiving the vaccine.
- Postexposure chemoprophylaxis:
 - Prophylactic administration of antiviral medications is indicated for: High-risk children who are unvaccinated or were vaccinated within 2 weeks of exposure, immunocompromised patients who have a poor response to vaccine, and high-risk patients who cannot receive the vaccine (anaphylactic reaction to chicken or eggs); also for control of outbreaks in institutions housing high-risk people
 - Chemoprophylaxis should begin within 48 hours of exposure to be most effective
 - The neuraminidase inhibitors zanamivir and oseltamivir are now approved for prophylaxis. Amantadine and rimantadine should not be used due to widespread resistance.

ETIOLOGY

- The orthomyxoviruses influenza types A, B, and C; influenza C virus has not been reported as a cause of influenza epidemics.
- Influenza A has subtypes defined by 2 surface antigens: Hemagglutinin and neuraminidase:
 - Currently circulating subtypes include novel 2009 H1N1 and H3N2
- Mild variation, or antigenic drift, for both A and B viruses results in seasonal epidemics; antigenic shift occurs only with A viruses and results in pandemics.

COMMONLY ASSOCIATED CONDITIONS

- Pharyngitis
- Laryngotracheitis (croup)
- Bronchitis/bronchiolitis
- Pneumonia
- Gastroenteritis
- Conjunctivitis
- Otitis media

DIAGNOSIS

- Illness is marked by acute onset of constitutional and respiratory symptoms.
- Infection with influenza causes distinct clinical pictures based on the affected individual's age:
 - Infants and young children are less likely to present with typical symptoms but may suffer higher fevers and more severe respiratory symptoms.
 - Many older children and adults infected with influenza are diagnosed with a “viral respiratory infection,” without specific reference to the viral etiologic agent.
- The diagnosis of influenza infection is more commonly made in light of previously identified index cases or specific findings, such as myositis.

HISTORY

- Abrupt onset of illness, beginning with chills, headache, malaise, and dry cough
- Subsequent increase in respiratory tract symptoms that can range from mild cough to severe respiratory distress (infants)
- Other symptoms: Fever, anorexia, myalgias, sore throat, irritability
- GI complaints in younger children may include vomiting, diarrhea, and severe abdominal pain.
- Children may also commonly present with otitis media.

PHYSICAL EXAM

- Cough is the predominant respiratory sign. Infants and small children may exhibit a “barky” cough (croup).
- Nasal congestion and conjunctival and pharyngeal infections are common.
- Cervical adenopathy is more common in children than in adults.
- Neonates may appear septic with apnea, circulatory collapse, or petechiae.
- A generalized macular or maculopapular rash is sometimes observed.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Culture is the traditional gold standard for diagnosis of influenza. Viral culture from nasopharyngeal secretions will be positive within 2–6 days:
 - Only culture isolates can be used to measure subtype and antiviral resistance of circulating strains.
- Direct immunofluorescent antibody (DFA) and indirect immunofluorescence antibody (IFA) tests have moderate sensitivity (6–70%) and excellent specificity (>95%), and are completed within 2–4 hours.
- Rapid antigen testing is available for diagnosing influenza A and influenza B. The tests can be completed within 10–15 minutes but have a wide range of sensitivities (22–77% in community settings), which may limit their usefulness. A negative test result should not guide management, especially when community prevalence is high.
- Reverse transcriptase-polymerase chain reaction (RT-PCR) is now the most accurate and sensitive testing modality. These tests are increasingly available but labor intensive.
- False positives:
 - The false-positive rate of DFA, IFA, and rapid antigen testing may be as high as 20% for influenza A and 40% for influenza B.
 - The use of nasopharyngeal aspirates rather than nasopharyngeal swabs may reduce this false-positive rate by 5–10%.

Imaging

Chest x-ray:

- May be normal despite significant respiratory involvement
- X-rays of patients with lower airway involvement are indistinguishable from those in patients with other viral lower respiratory infections.

DIFFERENTIAL DIAGNOSIS

- Viral infections including but not limited to respiratory syncytial virus, parainfluenza, adenovirus:
 - Difficult to distinguish infection from other respiratory pathogens based upon clinical presentation alone
- *Streptococcus pyogenes* infection
- Bacterial sepsis in young infants

TREATMENT

MEDICATION (DRUGS)

- Neuraminidase inhibitors (oseltamivir and zanamivir) are the recommended antiviral medications for both treatment of and chemoprophylaxis against influenza A and B:
 - Although amantadine hydrochloride and rimantadine are approved for treatment of influenza A in children > 1 year of age, the CDC has recommended against their use for both treatment and prophylaxis due to increasing resistance. Neither is effective against influenza B.
- Early treatment decreases duration of illness and can decrease symptom severity among patients at high risk of complications
- Antiviral treatment is recommended for any patient who is:
 - Hospitalized
 - Has severe or progressive illness
 - At high risk for complications
- Treatment is most effective when initiated <2 days after symptom onset but may still reduce morbidity and mortality for hospitalized patients or patients with severe disease if started after >2 days of symptoms.
- Treatment of healthy children with suspected or confirmed influenza in the outpatient setting is at the clinician’s discretion but should be initiated <2 days after symptom onset
- Dosage recommendations:
 - Zanamivir is approved for treatment in children ≥ 7 years and prophylaxis in children ≥ 5 years of age.
 - Treatment: Two 10 mg inhalations b.i.d. × 5 days
 - Prophylaxis: Two 10 mg inhalations once per day × 10 days
 - Can cause bronchospasm, so should not be used in patients with history of chronic pulmonary diseases such as asthma

- Oseltamivir is approved for treatment and prophylaxis in children ≥ 1 year of age:
 - Dose depends upon weight (<15 kg: 30 mg, 15–23 kg: 45 mg, >23–40 kg: 60 mg, >40 kg: 75 mg), b.i.d. × 5 days for treatment and once daily × 10 days for prophylaxis
 - Treatment guidelines for infants < 1 year were developed for 2009 pandemic influenza A (H1N1) under an Emergency Use Authorization (now expired)
 - May cause nausea and vomiting
- Investigational parenteral medications (peramivir and zanamivir):
 - For severely ill high risk patients with suspected or confirmed oseltamivir-resistant infection
 - Available through emergency Investigational New Drug protocol only
- Longer courses of therapy can be administered if patients remain severely ill after 5 days.
- Recommended duration of chemoprophylaxis is 10 days for household contacts and 7 days in other settings
- Preexposure prophylaxis can be considered for very-high-risk patients who cannot otherwise be protected against infection (i.e., cannot receive the vaccine) when there is high risk of exposure to influenza cases:
 - Duration depends upon expected duration of exposure, but 4–6 weeks has been well tolerated.
- Chemoprophylaxis should not be given within 14 days after LAIV receipt as the vaccine strains are susceptible to the antiviral medications.

ADDITIONAL TREATMENT

General Measures

Most patients with influenza infection require supportive oral hydration, antipyresis, and routine decongestant therapy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

When to expect improvement:

- Fever associated with influenza infection usually lasts up to 5 days. Recrudescence of fever does not necessarily signify the onset of a secondary bacterial infection.
- Cough may last up to 2 weeks.
- Lethargy or malaise may persist for up to 2 weeks.
- Influenza A infection usually lasts longer than influenza B or influenza C infection.

CODES

ICD9

- 487.1 Influenza with other respiratory manifestations
- 487.8 Influenza with other manifestations
- 488.12 Influenza due to identified 2009 H1N1 influenza virus with other respiratory manifestations

ICD10

- J10.1 Influenza due to other identified influenza virus with other respiratory manifestations
- J11.1 Influenza due to unidentified influenza virus with other respiratory manifestations
- J11.89 Influenza due to unidentified influenza virus with other manifestations

FAQ

- Q: When is it safe for a child with influenza to return to daycare or school?
- A: Older children with influenza may shed the virus in nasal secretions for up to 7 days from onset of symptoms, and younger children even longer. Therefore, older children with influenza may return to school 1 week after the onset of symptoms, and infants and toddlers should remain home for 10–14 days.
- Q: Can a child on chronic steroid therapy be immunized against influenza?
- A: In general, children who require maintenance steroid therapy for their underlying illness should still receive influenza immunization. If possible, immunize while the child is on the lowest possible dose of steroids and not during a period of high-dose therapy.
- Q: What are the chances of acquiring influenza despite annual vaccination?
- A: Vaccination against influenza is >70–90% effective in preventing disease and >90% effective in preventing death from the infection.
- Q: Is chemoprophylaxis an acceptable alternative for protecting children against influenza?
- A: In general, chemoprophylaxis should not be used as a substitute for vaccination; specific recommendations and indications for chemoprophylaxis can be found at: www.aapredbook.org/flu

INGUINAL HERNIA

Joy Collins

Eugene Schneider (5th edition)

BASICS

DESCRIPTION

A hernia is defined as the protrusion of an organ or its portion through the wall that normally contains it. Inguinal hernia is a protrusion of abdominal contents (intestine, omentum) through the inguinal canal outside the peritoneal cavity.

EPIDEMIOLOGY

- Extremely common; represents the most frequent problem requiring surgical intervention in the pediatric age group
- Much more common in boys (90% of cases) than girls, has a definite familial tendency, and presents more frequently on the right side, possibly as a result of later descent of the right testis and delayed obliteration of the right processus vaginalis
- Clinical presentation is on the right side in 60% of cases, on the left side in 30%, and bilateral in 10%.
- Incidence varies with age and ranges from 3–5% in full-term babies to 7–30% in preterm infants.

RISK FACTORS

- Prematurity
- Urologic conditions: Cryptorchidism, hypospadias, epispadias, bladder exstrophy
- Abdominal wall defects: Gastroschisis, omphalocele
- Conditions that increase intra-abdominal pressure: Ascites, peritoneal dialysis, ventriculoperitoneal shunt
- Meconium peritonitis
- Cystic fibrosis
- Congenital dislocation of the hip
- Connective tissue disease: Marfan syndrome, Ehlers-Danlos syndrome
- Mucopolysaccharidoses
- Family history

PATHOPHYSIOLOGY

- In boys, during the 7th month of gestation, the testes begin their descent from the peritoneal cavity, where they developed, through the inguinal canal and down into the scrotum.
- Between the 7th and 9th months of gestation, the testes reach the scrotum, at which point the processus vaginalis—an outpouching of the peritoneum attached to the testes—begins to obliterate spontaneously, leaving a small potential space adjacent to the testes, called tunica vaginalis.

- In girls, although the ovaries do not leave the abdomen, the round ligament (part of the gubernaculum) travels through the inguinal ring into labium majus. When the processus vaginalis remains open, it is called the canal of Nuck.
- Incomplete obliteration of the processus vaginalis leaves a sac of peritoneum extending all the way from the internal inguinal ring to the scrotum or labium majus, from which an inguinal hernia may develop.

DIAGNOSIS

HISTORY

- Location of the bulge:
 - Swelling or bulge in the inguinal area is the most common presenting sign of inguinal hernia.
- Does the bulge change in size, and if so, what activities bring about these changes? The usual history is of an intermittently appearing bulge, especially noted at times of increased intra-abdominal pressure, such as during crying or straining.
- Does the child appear to be bothered by the swelling (extreme fussiness during diaper changes in babies or complaints of pain/discomfort in older children)? Hernias are usually asymptomatic. The parents may perceive the bulge as being painful to the baby because it often is more pronounced when the baby is crying. However, if the parents provide definitive history of a painful bulge in the inguinal region, incarcerated inguinal hernia must be suspected.

PHYSICAL EXAM

- Examine the child in the supine and standing positions. Reduction of hernia contents through the inguinal ring is confirmatory.
- If the bulge is apparent in the standing position but disappears when the child is supine, presence of a hernia is strongly suggested.
- If the bulge is not readily apparent, perform maneuvers that increase intra-abdominal pressure (have the patient blow up balloons, gently press on his or her abdomen, or have him or her cough or strain).
- Transillumination of the scrotum may help in differentiating hernias, which usually do not transilluminate, from hydroceles, which typically do (unreliable sign).

- When the empty hernia sac is palpated over the cord structures, the sensation may be similar to that of rubbing 2 layers of silk together. This finding is known as “the silk sign” and when detected by an experienced practitioner is highly suggestive of an inguinal hernia.
- Always consider an incarcerated hernia, testicular torsion, epididymitis, orchitis, or trauma when exam reveals a tender scrotal mass.
- Try to reduce the hernia with the child in the supine or head-down position so that gravity assists the maneuver. Use a pacifier to calm the infant. Do not force a difficult incarcerated hernia.
- Sliding hernia occurs when 1 wall of the hernia is composed of viscera.
- Richter hernia results from the herniation of only a part of the bowel wall, which results in bowel ischemia without bowel obstruction (very rare).
- Hernia of Littre has Meckel diverticulum in the hernia sac.

DIAGNOSTIC TESTS & INTERPRETATION

Karyotyping should be considered when a testis is palpable in the inguinal canal or found at herniorrhaphy in phenotypic females, because there is an association between androgen insensitivity and inguinal hernia.

Imaging

The diagnosis of an inguinal hernia can usually be made on the basis of the clinical history and exam. However, in some cases, use of scrotal or inguinal ultrasonography may be indicated:

- Suggestion of torsion (use duplex ultrasound to evaluate blood flow)
- Suggestion of the spermatic cord or testicular tumor
- Scrotal trauma and concern about testicular rupture

Diagnostic Procedures/Other

Consult a pediatric surgeon when a diagnosis of inguinal hernia or hydrocele is suspected. In the event of incarceration and/or strangulation, request an urgent consultation.

DIFFERENTIAL DIAGNOSIS

- Lymphadenopathy
- Hydrocele
- Retractable testis
- Undescended testis
- Varicocele
- Testicular tumor

TREATMENT

SURGERY/OTHER PROCEDURES

Herniorrhaphy:

- Complication rate after an elective repair is low (1–2%) but increases dramatically (~20%) if the hernia becomes incarcerated. This excessive morbidity, along with a fairly high rate of incarceration in the 1st year of life, is responsible for the recommendation to repair pediatric inguinal hernias soon after they are diagnosed.
- ~10% of patients develop a contralateral hernia after a unilateral repair. Routine contralateral inguinal exploration in children with unilateral hernia has been a topic of debate for more than 50 years.
- Some surgeons perform diagnostic laparoscopy to evaluate for a contralateral patent processus vaginalis at the time of unilateral herniorrhaphy.
- Laparoscopic inguinal hernia repair has been performed in children of all ages, with a variety of techniques described in the literature. Currently, open repair remains the standard of care, but further study of laparoscopic repair is ongoing.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

An inguinal hernia will not resolve spontaneously; herniorrhaphy (an outpatient procedure) is accepted universally as the treatment of choice.

ONGOING CARE

PATIENT EDUCATION

Following operative repair, avoidance of major physical activity for 1 week is recommended.

COMPLICATIONS

- Incarceration (>50% of cases occur within the 1st 6 months of life)
- Strangulation
- Intestinal infarction leading to perforation and peritonitis
- Testicular/ovarian ischemia or infarction

CODES

ICD9

- 550.90 Inguinal hernia, without mention of obstruction or gangrene, unilateral or unspecified (not specified as recurrent)
- 550.91 Inguinal hernia, without mention of obstruction or gangrene, unilateral or unspecified, recurrent

ICD10

- K40.90 Unilateral inguinal hernia, without obstruction or gangrene, not specified as recurrent
- K40.91 Unilateral inguinal hernia, without obstruction or gangrene, recurrent

FAQ

- Q: Are trusses helpful to keep the hernia from incarcerating?
- A: No. Surgery is the accepted treatment.

INTESTINAL OBSTRUCTION

Vered Yehezkely Schildkraut
Raanan Shamir

BASICS

DESCRIPTION

- Pathologic blockage of progression of intestinal contents:
 - May be partial or complete
 - May arise from **intrinsic abnormalities** (e.g., meconium ileus, intestinal atresia) or **extrinsic abnormalities** (e.g., adhesions, bands or volvulus). May be of small bowel origin (most cases) or colon.
 - May be simple or strangulation obstruction (i.e., associated with bowel ischemia).
- May be mechanical or functional: **Paralytic ileus:** Failure of intestinal motor function without mechanical obstruction:
 - Common after abdominal operations.
 - Causes:
 - Infection (pneumonia, gastroenteritis, peritonitis, systemic sepsis).
 - Drugs (e.g., opiates, loperamide, vincristine).
 - Metabolic abnormalities (hypokalemia, uremia, myxedema, and diabetic ketoacidosis).
- **Chronic intestinal pseudo-obstruction (CIPO):** A severe intestinal motility disorder described in diverse conditions, including muscular, endocrine, metabolic and autoimmune disorders. CIPO is characterized by episodes of continuous symptoms and signs of bowel obstruction in the absence of a fixed lumen-occluding lesion. It may be congenital or acquired, primary or secondary. Examples include mitochondrial diseases (primary), fetal alcohol syndrome (intrauterine exposure) and post viral dysmotility (e.g., secondary to Epstein-Barr virus).

PATHOPHYSIOLOGY

- Mechanical obstruction:
 - Intestinal contents accumulate proximal to the site of obstruction.
 - The bowel distends with swallowed air, ingested food, secretions, and gases from intestinal reactions and bacterial fermentation.
 - Retrograde flow of intestinal contents and reflex gut distention results in vomiting.
 - Internal and external losses result in hypovolemia, oliguria, and azotemia.
 - Bacteria proliferate in the small bowel and its contents become feculent.
- Strangulation obstruction: Impaired blood flow to the intestine in addition to intestinal content obstruction
 - Loss of plasma into the bowel, leading to shock.
 - When strangulation progresses, gangrene, peritonitis, and perforation may ensue.
 - Damage to the normal gut barrier may enable bacteria, bacterial toxins, and inflammatory mediators to enter the circulation causing sepsis.

ETIOLOGY

May be **congenital** (e.g., atresia, duplication), **acquired** (e.g., neoplastic, inflammatory), or **iatrogenic** (e.g., adhesions, radiation stricture). Etiology varies according to age group:

- **Neonates:**
 - Intestinal atresia (the most common cause in the neonate, approximately one third of cases).
 - Meconium ileus primarily in cystic fibrosis) and meconium plug.
 - Duodenal atresia (associated with Down syndrome).
 - Anorectal malformation: Anal atresia and stenosis.
 - Necrotizing enterocolitis.
- **Hirschsprung disease.**
- **Infants:**
 - Pyloric stenosis (the most common cause).
 - Intussusception (the most common cause between 3 months and 6 years of age).
 - Postoperative adhesions.
 - Incarcerated inguinal hernia.
 - Hirschsprung disease.
 - Duplications.
 - Meckel diverticulum.
- **Older children:**
 - Postoperative or postinfectious intestinal adhesions.
 - Inflammatory bowel disease.
 - Cancer-related intestinal obstruction and radiotherapy-induced adhesions.
 - Malrotation.
 - Annular pancreas.
 - Meckel diverticulum.
 - Superior mesenteric artery syndrome.
 - Esophageal injury, corrosive injury, or foreign body ingestion.
 - Juvenile polyposis and related syndromes.
 - Distal intestinal obstruction syndrome (in cystic fibrosis).
 - Roundworm (*A. lumbricoides*).
 - Gastric and intestinal bezoars.
 - Colonic volvulus secondary to aerophagia and constipation in children with intellectual disability.

DIAGNOSIS

ALERT

There is no spontaneous resolution of inguinal hernia. Surgery should be scheduled before incarceration occurs. Inguinal hernias have 10–28% risk for incarceration.

SIGNS AND SYMPTOMS

- Presentation may be acute and obvious or chronic and subtle. The latter and partial obstruction could be difficult to diagnose.
- Careful history, physical examination, and consideration of age-related etiology most often will identify the specific cause.

HISTORY

- The classic symptoms of intestinal obstruction include vomiting (often bile stained), abdominal distention, colicky abdominal pain, and failure to pass stool.
- In neonates:
 - History of maternal polyhydramnios and aspiration of >20 mL gastric fluid after birth are suggestive of high intestinal obstruction.
 - Failure to pass meconium within 48 hours of birth.

- Older children:
 - Pain is one of the cardinal manifestations. It can be poorly localized, colicky visceral pain or sharp peritoneal pain.
 - Nausea and vomiting: High obstruction causes bilious emesis; distal obstruction may lead feculent emesis; in colonic obstruction, vomiting may be absent or late.
 - No passage of stool in low obstruction or bloody stool with mucus in strangulation (e.g., intussusception and volvulus).

ALERT

Neonates, more so than older children, with unrecognized intestinal obstruction deteriorate rapidly, with increased morbidity, mortality, and surgical complications.

PHYSICAL EXAM

- General assessment and vital signs, signs of dehydration, sepsis, or malnutrition.
- Palpation may reveal the presence of a hernia, a mass suggestive of feces, or intussusception. Tenderness and rigidity result from peritonitis.
- Bowel sounds may be initially increased, but later become decreased, occasional, or absent.
- Anal inspection excludes anal atresia and stenosis. Rectal examination reveals, at times, a palpable polyp or intussusceptum and blood (overt, occult, or “currant jelly”, typical of intussusception).
- Strangulation is suspected when there is fever, tachycardia, signs of peritonitis, and severe pain that persists after nasogastric decompression.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No laboratory studies are diagnostic.
- Full blood count, electrolytes, and blood gas should be taken.
- High obstruction may lead to hypochloremic hyperkalemic metabolic alkalosis.
- Bowel infarction may lead to marked leukocytosis, thrombocytopenia, and metabolic acidosis.
- Serum amylase and lipase should be determined to rule out pancreatitis, but they might be mildly elevated in intestinal obstruction.

Imaging

- **Plain abdominal X-rays** in the supine and erect or decubitus views will identify the classic features: Gasless abdomen, air–fluid levels and distended loops of intestine. High small bowel obstruction or strangulation obstruction may present with normal or nearly normal X-rays.
 - In small bowel obstruction: Dilated bowel, air–fluid levels without gas in the colon.
 - Paralytic ileus: Distended loops of bowel.
 - Duodenal obstruction: “Double-bubble” sign.

- Pneumoperitoneum in perforation.
- Peritoneal calcifications in meconium peritonitis.
- Right lower quadrant ground-glass appearance in meconium ileus.
- Obstruction with intraluminal calcifications in rectourinary fistula, colonic aganglionosis, or intestinal atresia.
- **Ultrasonography:** May identify a mass (e.g., perforated appendix), pyloric stenosis, malrotation, volvulus, intussusception (“target sign” or “Doughnut sign”) or pelvic pathology in adolescents.
- **CT or MRI:** Localize the obstruction, diagnosis of strangulation; helpful in postoperative obstruction, Crohn disease, and neoplasms.
- **Barium enema** to confirm intussusception or Hirschsprung disease and “microcolon” in neonatal small bowel obstruction.
 - Upper GI series for malrotation or volvulus.
 - Water-soluble, low osmolarity materials should be preferred (risk of perforation). Effort should be made to minimize radiation exposure.

ALERT

- Evaluation for associated congenital anomalies is mandatory, as some are life threatening. The most frequent are cardiac and renal abnormalities.
- **Manometry** is used in CIPO to assess neuromuscular function and can distinguish myopathy from neuropathy.

DIFFERENTIAL DIAGNOSIS

Other causes of abdominal pain and vomiting should be considered and ruled out by history and physical examination:

- Appendicitis.
- Torsion of testis or ovary.
- Lower lobe pneumonia.
- Pancreatitis.
- Sickle cell crisis.
- Henoch–Schönlein purpura.
- Biliary colic.
- Lead poisoning.
- Acute adrenal insufficiency.
- Diabetic ketoacidosis.
- Acute intermittent porphyria.

TREATMENT

Initial Stabilization

- Hold oral intake.
- Decompress the stomach by nasogastric tube.
- Administer IV fluids, correct electrolyte imbalance, and ensure adequate urine output.
- Identify etiology of obstruction and establish definitive repair.
- Cultures and broad-spectrum antibiotics (covering Gram-negative aerobes and anaerobes) according to patient’s age and status.

General Measures

- In intussusception, hydrostatic or air reduction is successful in 90% of cases.
- Nasogastric decompression or anti-inflammatory medication for adhesions or inflammatory strictures.

- Contrast-material enemas, manipulation, and direct enteral irrigation with *N*-acetylcysteine for uncomplicated meconium ileus.
- Manual reduction of incarcerated inguinal hernia.
- Colonic volvulus may be treated with endoscopic decompression followed by elective surgery.
- Endoscopic removal of foreign bodies.
- Paralytic ileus is usually self-limiting and resolves with supportive treatment.

SPECIAL THERAPY

- Conservative management with decompression by nasogastric tube and IV fluids is the first-line approach in:
 - Early postoperative, partial, and recurrent adhesive obstructions.
 - Necrotizing enterocolitis.
 - Meconium ileus.
 - Duodenal hematomas.
 - Superior mesenteric artery syndrome.
 - Crohn’s disease.

SURGERY/OTHER PROCEDURES

- Definitive treatment requires an urgent operation.
- Exceptions to this rule include the above mentioned conditions managed conservatively.
- In all situations: if no improvement within 12–24 hours, surgery is advisable.
- The surgical procedure is individualized according to the specific type, site, anatomy of the obstruction, and associated conditions.
- **Laparoscopy-assisted surgery** can be used for the diagnosis and repair of small bowel obstruction and for adhesiolysis.

ONGOING CARE

PROGNOSIS

- Varies with different causes of intestinal obstruction, age of the patient, presence of prematurity, and associated anomalies.
- Short bowel syndrome continues to be a major impediment to improved survival rate; permanent parenteral nutrition is associated with morbidity and mortality.

COMPLICATIONS

May result from delayed operation:

- Dehydration.
- Intestinal ischemia with sepsis and shock.
- Bowel perforation and peritonitis.
- Short-gut syndrome.

CODES

ICD9

- 751.1 Atresia and stenosis of small intestine
- 560.9 Unspecified intestinal obstruction
- 777.1 Meconium obstruction in fetus or newborn

ICD10

- K56.60 Unspecified intestinal obstruction
- P76.0 Meconium plug syndrome
- Q41.9 Congen absence, atresia and stenosis of sm int, part unsp

FAQ

- Q: Will my child need surgery for this problem?
- A: Most likely; It depends on the cause. Surgical treatment is necessary to correct intestinal obstruction, except in a few cases, such as intussusception, pseudo-obstruction, and paralytic ileus.
- Q: What is the most common cause of this problem in my 3-day-old son?
- A: In an infant, the most common causes are atresias of the intestine, which are absences of the normal amount of large or small intestine in the abdomen.
- Q: Is my child likely to have recurrent episodes of intestinal obstruction?
- A: It depends on the cause for the obstruction. Conditions associated with recurrence include intussusception, inflammatory conditions (e.g., Crohn’s disease) and postoperative adhesions.

INTOEING–TIBIAL TORSION

Ali Al-omari

John P. Dormans

BASICS

DESCRIPTION

- Tibial torsion: Twisting (internal or external) of the tibia (may be associated with femoral torsion)
- Medial or internal tibial torsion associated with intoeing (most common)
- Lateral or external tibial torsion associated with outtoeing
- Normal defined as within 2 standard deviations of mean

EPIDEMIOLOGY

- Common and usually normal (i.e., within 2 standard deviations of the mean).
- It is often associated with physiologic bowleg.

RISK FACTORS

Genetics

No strong evidence to suggest that this is an inherited condition (heredity-familial tendency)

PATHOPHYSIOLOGY

- Tibial torsion: Twisting the tibia; usually medial or internal; associated with intoeing
- If associated with increased femoral anteversion, may be associated with patellofemoral malalignment (kneecap subluxation)

ETIOLOGY

- Normal fetal development
- Intrauterine position
- Heredity-familial tendency
- Posturing (sitting position): Cause or effect?
- Associated pathology (e.g., spasticity, fracture malunion, or developmental dislocation of the hip [DDH])

DIAGNOSIS

HISTORY

- Birth history: Common in 1st-borns
- Pain or limping may indicate other diagnosis.
- Metatarsus adductus, torticollis, and DDH may be associated with other conditions that result from immobility in uterus.
- Functional limitations (i.e., child trips and falls frequently) may suggest other diagnosis, such as mild cerebral palsy, especially if abnormal birth history, abnormalities in developmental milestones, and physical findings consistent with cerebral palsy.

PHYSICAL EXAM

- If child is ambulatory, watch gait and assess for foot progression angle: The angle formed between the axis of the foot and the axis of forward progression of gait.
- Also assess other aspects of gait: Stride, heel-toe gait, cadence, limping, other abnormalities. Unilateral or bilateral torsion
- Leg-length discrepancy, hip abnormalities, contractures, spasticity, thigh-foot axis (TFA)
 - With the child prone, the knee flexed to 90°, and the ankle at neutral, measure the difference between the axis of the foot and the axis of the femur.
 - If the TFA is internal, this suggests internal tibial torsion; If external, external tibial torsion.
- Transmalleolar axis: With the child seated and the knee flexed to 90°, assess the malleolar axis in reference to the coronal plane (less reliable than TFA).

- Look for abnormalities of the feet: Metatarsus adductus or clubfoot may be a primary cause of intoeing. Significant calcaneovalgus may be a component of outtoeing.
- Careful neurologic exam: To see if intoeing is related to a mild neurologic abnormality, such as mild spastic diplegic cerebral palsy
- Physical exam tricks:
 - “Torsional profile” consists of foot-progression angle, medial hip rotation in extension (to assess femoral torsion), lateral hip rotation in extension (to assess femoral torsion), thigh-foot angle (to assess tibial torsion), transmalleolar axis (to assess tibial torsion), and configuration of the foot.
 - “Kissing patellae”: Occurs when bilateral increased femoral anteversion causes the patellae to face one another, giving the appearance of kissing patellae

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Usually not helpful (i.e., normal with tibial torsion)

Imaging

- Usually not needed; physical exam gives information needed.
- Hip radiograph: May be indicated if hip pathology (i.e., DDH) is suspected

- CT: An accurate way to measure tibial and femoral torsion, but there is radiation exposure. An occasional indication may be a patient who is being evaluated for surgery.
- MRI and ultrasound: Have been described to quantify torsion, but generally are less accurate than CT

DIFFERENTIAL DIAGNOSIS

Look for DDH, spasticity (e.g., mild cerebral palsy), metatarsus adductus, femoral anteversion

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Observation
- Activity: No restrictions

Additional Therapies

- Physical therapy
 - Will not change natural history (it may help with associated patellofemoral malalignment pain)
 - Devices (casts, shoe wedges, twister cables, splints, Denis-Brown bars): No proven benefit

SURGERY/OTHER PROCEDURES

- Rarely needed
- Tibial osteotomy is seldom, if ever, needed.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Observation and familial and patient reassurance (almost always the treatment of choice)
- Devices such as casts, shoe wedges, twister cables, splints, and Denis-Brown bars have no proven benefit (i.e., they will not change the natural history). Some of these may in fact cause problems such as ligamentous damage to hip, knee, ankle, and foot.
- Reassurance is usually enough. The condition improves spontaneously. Usually corrects enough by 8 years of age
- Surgery seldom needed
- Tibial osteotomy: When done, is usually a distal supramalleolar osteotomy

ONGOING CARE

PROGNOSIS

- Good; usually not painful, cosmetically unattractive, or dysfunctional
- Usually corrects enough by 8 years of age
- Should improve with growth and development. There is no substantial evidence that increased femoral anteversion will cause arthritis of the hip or knee.
- Overall, good prognosis for the majority of patients

COMPLICATIONS

Functional if severe; no long-term complications (osteoarthritis) proven. However, most of the complications are related to operative treatment.

CODES

ICD9

754.43 Congenital bowing of tibia and fibula

ICD10

Q68.4 Congenital bowing of tibia and fibula

FAQ

- Q: When are special shoes or braces indicated for tibial torsion?
- A: Almost never. The situation will improve without treatment in most patients. There is no convincing evidence that any of these treatments truly alter the natural history of the condition.
- Q: Why do patients with torsional pathology occasionally have knee pain?
- A: Children may have increased femoral anteversion with associated external tibial torsion (i.e., an external rotation of the tibia that matches and, in effect, balances the internal rotation of the femur). This can be diagnosed by observing the above rotational profile and by noting increased Q-angle. This situation is sometimes a “setup” for patellofemoral pain.

INTRACRANIAL HEMORRHAGE

Irfan Jafree

Peter Bingham (5th edition)

BASICS

DESCRIPTION

Extravasation of blood from intracranial vessels to the epidural, subdural, intraparenchymal (intracerebral), or intraventricular space within the cranial vault

EPIDEMIOLOGY

- Germinal matrix hemorrhage is the most common intracranial hemorrhage (ICH) in premature infants.
- Trauma: Common cause of ICH in children
- Arteriovenous malformations (AVMs): Most common cause of nontraumatic ICH in children
- Children with change in mental status or seizure at presentation have worse outcome.

Incidence

Stroke in children (birth to 14 years of age): 2.5–2.7 cases per 100,000 children; 55% are believed to be ischemic, others represent ICH.

RISK FACTORS

Genetics

Increased frequency with hereditary disorders of coagulation, congenital heart disease, and polycystic kidney disease associated with intracranial aneurysms

GENERAL PREVENTION

- Automobile seat belts
- Bicycle, skating, and skateboarding helmets
- Child abuse prevention
- Diving safety practices
- Preventing falls
- Maintaining safe driving speeds
- Keeping children away from firearms
- Hematologic monitoring for those at risk for hemorrhage due to blood disorders

PATHOPHYSIOLOGY

- Epidural hematoma (blood between the dura mater and the skull) is frequently arterial, related to skull fracture; typically middle meningeal artery bleeding following temporal bone fracture. 1/4 epidural hematomas in children are from dural venous laceration.
- Subdural hematoma (blood between the dura mater and the arachnoid membrane) is frequently venous from trauma causing stretching and tearing of bridging cortical veins or coagulopathy.
- Subarachnoid hemorrhage (blood between the arachnoid membrane and brain): Ruptured intracranial aneurysm, AVM, or trauma
- Blood within the brain parenchyma may be the result of trauma, hypertension, infections such as herpes simplex encephalitis, brain tumor, venous sinus thrombosis, or cerebral infarction (occurs mostly with rupture of medium or smaller branches of major cerebral arteries).
- Subependymal germinal matrix hemorrhage: Especially in premature infants born <34 weeks' gestation

- Intraventricular hemorrhage commonly with intraparenchymal or subependymal germinal matrix (in the subependymal layer of the lateral ventricle) hemorrhage extends into the ventricular system. 4 grades:
 - Grade I: Isolated to 1 or both germinal matrices
 - Grade II: Intraventricular hemorrhage without ventricular dilatation
 - Grade III: Intraventricular hemorrhage with ventricular dilatation (hydrocephalus)
 - Grade IV: Intraventricular hemorrhage with ventricular dilatation and extension into the adjacent hemispheric white matter

ETIOLOGY

- Vascular:
 - Congenital vascular anomalies: AVM, venous angioma, cavernous malformation, hereditary hemorrhagic telangiectasia, aneurysm, coarctation with intracranial aneurysm, vein of Galen malformation
 - Developmental/acquired vasculopathy: Ehlers-Danlos syndrome type IV, Moyamoya syndrome, pseudoxanthoma elasticum, sickle cell disease, hypertension, mycotic aneurysm, vasculitis (cocaine, inflammatory diseases)
- Trauma:
 - Child abuse
 - Angioplasty
 - Trauma (subdural, epidural, subarachnoid)
- Other contexts of ICH:
 - Prematurity
 - Neonatal asphyxia
 - Sinovenous thrombosis
 - Cerebral infarction, especially resulting from venous thrombosis
- Alcohol, cocaine, and other sympathomimetics are associated with ICH
- Hematologic disorders:
 - Immune thrombocytopenic purpura
 - Thrombotic thrombocytopenia
 - Purpura
 - Autosomal recessive afibrinogenemia
 - Disseminated intravascular coagulation
 - Hemolytic uremic syndrome
 - Iatrogenic (chemotherapy) thrombocytopenia
 - Congenital serum C2 deficiency
 - Kidney or liver dysfunction
 - Vitamin K deficiency
 - Factor deficiency (factor V, protein C, or S deficiency)
 - Leukemia, lymphoma

DIAGNOSIS

HISTORY

- Head trauma
- Delivery, circumstances during
- Headache severity, quality
- Abrupt, severe headache and stiff neck may suggest a “warning leak” from aneurysm.
- Change in level of consciousness, “lucid interval” with epidural hematoma

- Seizures, especially new onset
- Visual problems
- Focal neurologic deficits
- Epistaxis (may occur with leakage of cerebrospinal fluid if skull fracture is present)
- Meningeal symptoms
- Patient or family history of coagulopathy
- Risk factors for cerebral venous sinus thrombosis: Dehydration, coagulopathy, polycythemia, sepsis, and asphyxia (especially in newborns)
- Risk factors for arterial aneurysms: Polycystic kidney disease, coarctation of the aorta
- Failure to thrive, hydrocephalus with vein of Galen malformation
- Signs and symptoms:
 - Presentation may include change or decrease in consciousness, seizure, severe headaches, meningismus (because blood is an irritant), or sudden focal neurologic deficit.
 - With posterior fossa bleed: Disconjugate gaze, ataxia, and rapid deterioration to coma
 - Expeditious history, exam, and emergency CT
 - Increasing intracranial pressure from hemorrhage or hydrocephalus is life threatening.

PHYSICAL EXAM

- Signs of increased intracranial pressure or herniation, such as Cushing triad (hypertension, bradycardia, abnormal respiratory pattern), papilledema, pupils that do not constrict to light, ophthalmoparesis, decorticate or decerebrate posturing. Intraventricular blood may present with signs of increased intracranial pressure caused by communicating hydrocephalus. Increased intracranial pressure may result in a bulging fontanel and splayed sutures.
- Meningeal signs, low-grade fever
- In setting of trauma:
 - Leakage of CSF from the ear or nose
 - Battle sign: Bruising over the mastoid process suggestive of basilar skull fracture
 - Raccoon eyes: Periorbital ecchymosis suggestive of basilar skull fracture
 - Subhyaline retinal hemorrhages
- Herpes simplex type 1 encephalitis: Frequently presents with fever, cognitive impairment, seizures
- Germinal matrix hemorrhages often clinically silent but may present with apnea in the newborn
- ICH should be suspected in the septic-appearing neonate, especially if there are no obvious risk factors for sepsis.
- Subarachnoid hemorrhage frequently presents as worst headache ever experienced, subhyaloid hemorrhages, signs of meningeal irritation
- Unexplained subdural hemorrhage in infants, particularly bilateral: Inflicted trauma until proven otherwise

DIAGNOSTIC TESTS & INTERPRETATION

Immediate stroke evaluation (1st 24 hours):

Consider:

- Head CT
- Chest radiograph
- Electrocardiogram (ECG for evaluation of acute cardiac ischemia or old infarction)
- Urine toxicology screen
- CBC
- Metabolic profile (high creatinine and glucose associated with hematoma expansion)

- Prothrombin time/partial thromboplastin time (PT/PTT), international normalized ratio
- ESR/ANA
- Lumbar puncture: Lumbar puncture will show RBCs, reduced glucose, xanthochromia (best detected by spectrophotometry), and bloody CSF. Consider spinal fluid evaluation if CT negative.
- MRI/magnetic resonance angiogram/venography
- Transcranial/carotid ultrasound (for vasospasm)

Imaging

- CT of the head:
 - The most important study to obtain when considering ICH in the differential diagnosis, because of its relative convenience, speed, and low false-negative rate
- CT angiography and contrast-enhanced CT, based on the presence of contrast extravasation within the hematoma, may identify patients at high risk of ICH expansion:
 - Fresh intracerebral blood increased density; between 1 and 6 weeks, becomes isodense with adjacent brain parenchyma. Acute ICH may appear isodense if hemoglobin <8–10 g/dL.
 - “Biconvex and displacing gray–white interface”: Extradural hemorrhage
 - “Crescent shaped”: Subdural hemorrhage; bilateral subdural hemorrhage frequent in intentional injury
- MRI gradient echo and T2 susceptibility weighted MRI are helpful not only for acute hemorrhage, but also for old hemorrhage such as seen with amyloid angiopathy.
- CTA, CT venography, MRA/MRV: Helpful for evaluation of structural lesions, including vascular malformations, dissection, tumors, venous sinus thrombosis, etc.
- Head ultrasound: Hemorrhages in infants with gestational age of <32 weeks with birth weight <1,800 g; serial ultrasound exams are warranted.

DIFFERENTIAL DIAGNOSIS

- Stroke
- Brain tumor
- Migraine headache

ALERT

- Early subarachnoid hemorrhage may not be apparent on CT and may require lumbar puncture (if safe to perform) or serial CT evaluation while the patient is under clinical observation.
- ICH, especially in young infants and children without an obvious etiology, should raise the suspicion of nonaccidental trauma.
- Patients with concussion without ICH may still develop cerebral edema; observe for signs of increasing intracranial pressure.

TREATMENT

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Admission to neuro-ICU
- Institute acyclovir therapy if herpes simplex type 1 encephalitis is considered.
- Blood pressure management. Definite optimal values have not been established, but systolic BP <160 mm Hg are probably best, while avoiding compromised cerebral blood flow. This can be achieved by using IV agents including nicardipine (5 mg/hr with titration 2.5 mg/hr every 5 minutes up to maximum of 15 mg/hr), labetalol (10–20 mg IV over 2 minutes, then 40–80 mg IV every 10 minutes until either BP goal achieved or 300 mg has been given, then repeat effective every 6–8 hours), enalaprilat (0.625–1.2 mg every 6 hours).
- Glucose monitoring to achieve normoglycemia
- DVT prophylaxis: ICH is associated with a high risk of thromboembolic disease. Use combination of intermittent pneumatic compression and elastic stockings.
- Temperature management: Fever associated with worse neurologic outcome; maintain normothermia.
- Correction of coagulopathies (suggested by PT, PTT, platelet abnormalities), should be done promptly, may require hematology evaluation and include various therapies such as vitamin K, fresh frozen plasma, prothrombin complex concentrate, recombinant factor VII, or platelet infusion.
- ICP monitoring when elevated ICP is suspected
- Antiepileptic drugs: Only for clinical seizures or electrograph seizures (suspected when change in mental status is disproportionate to ICH or subtle signs including intermittent nystagmus, myoclonus, or marked blood pressure fluctuations and confirmed by continuous EEG monitoring)
- Neurosurgical intervention is frequently necessary for subdural and epidural hematomas. Serial neurologic exams on patients treated for ICH. Surgical treatment is suggested for cerebellar hemorrhage with brainstem compression or hydrocephalus from ventricular obstruction. It can also be considered for lobar clots >30 mL and within 1 cm of the surface.
- Intracranial aneurysms: Frequently amenable to neurosurgical intervention to decrease the likelihood of rebleeding. In addition, careful control of intracranial pressure and prompt attention to hydrocephalus may be necessary.
- Definitive treatment of AVMs consists of surgical resection or interventional neuroradiologic techniques, or proton beam irradiation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Long-term observation for signs of injury: Cognitive deficits, focal weakness, seizures

PROGNOSIS

Often, good neurologic recovery is possible.

COMPLICATIONS

- Increased intracranial pressure and brain herniation syndromes
- Hydrocephalus: Communicating/noncommunicating
- Vasospasm secondary to blood and breakdown products of erythrocytes
- Seizures, death
- Motor, visual, and cognitive deficits secondary to ischemic infarction

CODES

ICD9

- 432.9 Unspecified intracranial hemorrhage
- 853.00 Other and unspecified intracranial hemorrhage following injury without mention of open intracranial wound, unspecified state of consciousness

ICD10

- I62.9 Nontraumatic intracranial hemorrhage, unspecified
- S06.330A Contusion and laceration of cerebrum, unspecified, without loss of consciousness, initial encounter

FAQ

- Q: What is a lucid interval and how long will it last?
- A: Epidural hematoma may present in a delayed fashion after head trauma, may last 24 hours before change in consciousness, or other signs appear.
- Q: What is the role of CT in the diagnosis of subarachnoid bleeding?
- A: Early subarachnoid hemorrhage may not be apparent on CT initially but may require either a lumbar puncture or follow-up CT studies.

INTUSSUSCEPTION

Andrew B. Grossman

BASICS

DESCRIPTION

- The most common abdominal emergency of early childhood
- The telescoping of one part of the bowel into itself or adjacent bowel, causing abdominal pain, vomiting, and eventually bloody stools and lethargy
- Telescoping of the bowel causes diminished venous blood flow and bowel wall edema, which can result in ischemia and obstruction. Eventually, arterial blood flow is inhibited and infarction of the bowel wall occurs, which results in hemorrhage and, if untreated, possible perforation.
- Strangulation of the bowel rarely occurs in the first 24 hours but evolves afterward.
- Ileocolic type accounts for 80–90% of intussusceptions; ileoileal and colocolic types also occur.
- Typical triad of acute onset of colicky abdominal pain, right upper quadrant (RUQ) mass, and “currant jelly” stools, although clinical presentation can vary
- Increased incidence in children who received the RotaShield rotavirus vaccine. The currently available vaccine (RotaTeq) has not been shown to increase the risk.

EPIDEMIOLOGY

- Male/Female ratio: 3:2
- Generally occurs in patients 6 months to 3 years of age
- Peak age from 6–12 months

Incidence

1–4/1,000 live births

ETIOLOGY

- Children <3 years: Usually idiopathic or enlarged Peyer patch from viral infection
- Children ≥3 years: Often a pathologic lead point: Meckel diverticulum, hematoma from Henoch-Schönlein purpura or bleeding diatheses, tumors (polyps, lymphoma, sarcoma, lipoma, neurofibroma), adhesions, duplication, postsurgical anastomotic sutures or staples, cystic fibrosis

DIAGNOSIS

HISTORY

- The typical presentation is the sudden onset of severe intermittent (colicky) abdominal pain, with the child often drawing the legs up to the abdomen and crying. Can be asymptomatic between paroxysms of pain
- Lethargy out of proportion to the severity of dehydration
- Nonbilious emesis initially, becomes bilious with progressive obstruction
- “Currant-jelly” stools (sloughed mucosa, blood, and mucous) appear in 50% of cases: A sign of a longer course

PHYSICAL EXAM

- Lethargic with colicky pattern of abdominal pain
- Mass in the RUQ may be palpated (“RUQ sausage”)
- Absence of bowel contents in right lower quadrant (Dance sign)
- Abdominal distention
- Rectal exam: Blood-tinged mucous or currant jelly stool; occasionally the intussusception can be felt
- Peritoneal signs if intestinal perforation has occurred

DIAGNOSTIC TESTS & INTERPRETATION

Lab

CBC, electrolytes

Imaging

- Abdominal x-ray: Not sensitive or specific. Normal in early stages, later can have absence of gas in right lower quadrant (RLQ) and RUQ, as well as RUQ soft tissue mass; with obstruction, will have air-fluid levels, paucity of distal gas
- Abdominal ultrasound: If performed by experienced radiologist, highly sensitive and specific; “doughnut sign” with presence of several concentric rings

- Contrast enema: Diagnostic and therapeutic with reduction often achieved; air enema preferred because less perforation risk than barium; can miss a lead point

ALERT

- Only 30% present with the classical triad of abdominal pain, palpable abdominal mass, and currant-jelly stool, so high clinical suspicion is necessary
- Clinical status of hypovolemic patients may worsen with high-osmotic contrast agents.

DIFFERENTIAL DIAGNOSIS

- Infection: Gastroenteritis, enterocolitis, parasites
- Immunologic: Henoch-Schönlein purpura
- Miscellaneous:
 - Appendicitis
 - Meckel diverticulum: May act as a lead point in the absence of bleeding
 - Incarcerated hernia
 - Crohn disease
 - Celiac disease
 - Henoch Schönlein purpura
- Obstruction: Adhesions, hernia, volvulus, stricture, bezoar, foreign body, polyp, tumor

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Prompt reduction is imperative.
- Spontaneous reduction occurs in 5%.
- Obtain surgical consultation before contrast enema reduction attempt secondary to risk of perforation; failed reduction requires surgical correction.
- Absolute contraindications to reduction by enema: Peritonitis, shock, and perforation
- Relative contraindications to reduction by enema: Symptoms > 24 hours, evidence of obstruction (i.e., air fluid levels), sonographic evidence of ischemia
- Perforation during reduction occurs in 1% of cases, mostly in the transverse colon.

SURGERY/OTHER PROCEDURES

If perforation/peritonitis exists, patient is unstable, nonoperative reduction is unsuccessful, or lead point is identified, proceed to surgical reduction.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Nasogastric tube placement: Bowel decompression
- IV line placement: Correction of fluid and electrolyte losses

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Recurrence after nonoperative reduction has been reported in up to 10% of cases and usually is seen within 24 hours of the reduction.

PROGNOSIS

- Timely diagnosis results in a highly favorable prognosis.
- Hydrostatic reduction by contrast enema is therapeutic in 50–90% of cases.
- Risk of recurrence is ~10% after contrast enema reduction, 1% after manual reduction, and not reported after intestinal resection; the greatest risk is in the 24–72 hours after reduction.

COMPLICATIONS

- Bowel necrosis secondary to local ischemia
- GI bleeding
- Bowel perforation
- Sepsis, shock

CODES

ICD9

560.0 Intussusception

ICD10

- K38.8 Other specified diseases of appendix
- K56.1 Intussusception
- Q43.8 Other specified congenital malformations of intestine

FAQ

- Q: Can my child have a recurrent intussusception?
- A: Yes. The risk is very low, probably <10% if the child has had a nonsurgical reduction. If the lead point is removed surgically, recurrence is very unlikely. The greatest risk is in the 1st 72 hours after reduction.
- Q: What are the common ages for presentation?
- A: 6 months to 3 years is the age range associated with the greatest risk of intussusception, but it may occur at any age. The prevalence of pathologic conditions rises with the age of a child diagnosed with intussusception.

IRON DEFICIENCY ANEMIA

Peter de Blank

Janel L. Kwiatkowski (5th edition)

BASICS

DESCRIPTION

A reduction in hemoglobin production due to an insufficient supply of iron that results in a microcytic, hypochromic anemia

EPIDEMIOLOGY

- Iron deficiency is the most common nutritional deficiency of children
- Leading cause of anemia among infants and children in the US
- Most commonly seen in children ages 9 months to 3 years and in teenage girls

Prevalence

- Prevalence is variable depending on socioeconomic status, availability of iron-fortified formulas, prevalence and duration of breastfeeding, and the way that iron deficiency is defined.
- Prevalence of iron deficiency anemia in US is generally between 1% and 5% of children.

RISK FACTORS

- Low socioeconomic status
- Certain ethnic groups (e.g., Southeast Asian) may be at increased risk owing to dietary practices.

GENERAL PREVENTION

- Maintain breastfeeding for the 1st 5–6 months of life if possible. The iron concentration is lower in breast milk than formula, but iron in breast milk is more bioavailable (50% vs. 10%).
- Iron supplementation (1 mg/kg/d) for infants who are exclusively breastfed beyond 6 months
- Iron-fortified formula for the 1st 12 months of life for infants who are not breastfed
- Iron supplementation after 2 months of life for low-birth-weight and premature infants because of decreased iron stores and increased growth rate
- Encourage iron-enriched cereal when infants are started on solid food.
- Avoid whole cow's milk during the 1st year of life, to prevent occult GI bleeding.
- Screen hemoglobin level at periodic intervals. The American Academy of Pediatrics recommends 9 months, 5 years, and 14 years.

PATHOPHYSIOLOGY

- Iron is required for oxygen transport by hemoglobin.
- Iron absorption and distribution regulated by hepcidin, a peptide hormone secreted by liver, macrophages, and adipocytes
- Iron is absorbed primarily in the duodenum.
- Iron deficiency develops because of an inadequate supply or increased demand for iron, or a combination of these.
- Sequential stages of iron deficiency:
 - Depletion of iron stores: Reflected by low serum ferritin and absent bone marrow stores (Prussian blue staining)
 - Iron-deficient erythropoiesis: Near-normal number of red blood cells produced, but they have abnormal hemoglobin synthesis with wide distribution in RBC size
 - Iron deficiency anemia: Microcytosis evident

ETIOLOGY

- Causes of inadequate supply include dietary deficiency and malabsorption:
 - Dietary deficiency in infants and young children results from introduction of cow's milk prior to age 12 months, exclusive breastfeeding beyond age 6 months without iron supplementation, and excessive cow's milk intake (>24 oz/d).
 - Malabsorption results from surgical resection of intestine, celiac disease.
 - Certain foods impair iron absorption (tannins in tea and coffee, phytates).
- Causes of increased demand include rapid growth and blood loss:
 - Periods of rapid growth include infancy (especially low-birth-weight and premature infants) and adolescence.
 - GI blood loss is most common and includes cow's milk enteropathy (seen in infants), inflammatory bowel disease (IBD), and bleeding from Meckel diverticulum.
- Other etiologies of blood loss include perinatal loss, menorrhagia, pulmonary hemosiderosis, and hematuria.

DIAGNOSIS

HISTORY

- Evaluate dietary intake of iron, including breast- or formula feeding and type of formula (iron fortified or low iron).
- Age at introduction of cow's milk
- Daily intake of cow's milk
- Birth history for prematurity or blood loss
- Pica
- Lead exposure
- Blood loss from urine, stool, menorrhagia
- Iron deficiency anemia often develops slowly, and no symptoms may be present. When present, signs and symptoms include:
 - Irritability and behavioral disturbances
 - Fatigue, exercise intolerance
 - Pallor
 - Headache
 - Pica or pagophagia (chewing ice)

PHYSICAL EXAM

- Often normal
- Pallor, irritability
- Tachycardia, flow murmur if anemia is more severe
- Koilonychia (spoon nails)
- Glossitis or stomatitis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hemoglobin level <2 standard deviations below the age-specific mean defines anemia.
- Low MCV (red cell volume) and MCH (hemoglobin concentration) for age

- High RDW (red cell distribution width):
 - Measures the variation in red cell size
 - Normal is <14.5%.
 - Often increased before anemia is present
- Low serum ferritin (≤ 12 ng/mL) reflects reduced tissue iron stores:
 - Earliest laboratory abnormality
 - May be normal or increased with concurrent infection or inflammation
 - Higher cutoff improves sensitivity of the test: Ferritin ≤ 30 ng/mL has sensitivity of 92% and PPV of 83% for iron deficiency anemia, vs. sensitivity of 25% for ferritin ≤ 12 ng/mL.
- Low serum iron
- Increased total iron-binding capacity
- Low transferrin saturation; measures the iron available for hemoglobin synthesis
- Increased soluble transferrin receptor (sTfR):
 - Indicator of increased tissue iron demand
 - Also increased in thalassemia syndromes but not in anemia of chronic inflammation (ACI)
 - sTfR/log(ferritin) <1 suggests anemia of chronic inflammation.
 - sTfR/log(ferritin) >2 suggests iron deficiency anemia.
- Decreased reticulocyte hemoglobin content: This test is an early indicator of iron deficiency because reticulocytes have a short (1–2-day) life span before becoming mature red cells.
- Increased free erythrocyte protoporphyrin, a precursor molecule in hemoglobin synthesis. Also high in lead poisoning and chronic inflammation
- Thrombocytosis (can approach 1 million/dL)
- Peripheral blood smear with microcytosis, hypochromia, poikilocytosis (varying shapes), pencil forms, and anisocytosis (varying sizes)
- Test for occult blood in stool often positive with gastrointestinal blood loss:
 - However, the test can be positive with oral iron supplementation.
- Iron absorption test can assess adequacy of PO iron supplementation. 3 mg/kg elemental iron should increase serum iron more than 100 mcg/dL within 4 hours of ingestion.

Diagnostic Procedures/Other

Bone marrow examination: Shows decreased iron stores by Prussian blue staining; rarely needed to establish diagnosis

DIFFERENTIAL DIAGNOSIS

- Recent infection
- Lead poisoning
- Thalassemia trait
- Anemia of chronic inflammation (e.g., juvenile rheumatoid arthritis, IBD)
- Sideroblastic anemias

TREATMENT

- Iron supplementation (see below)
- Family education regarding age-appropriate diet and iron-containing foods
- Specific treatment if underlying condition causing blood loss is found (e.g., hormonal therapy for menorrhagia, medications for IBD)
- May require initial inpatient observation in cases of severe anemia
- Red cell transfusion only if evidence of cardiovascular compromise (rarely indicated)

MEDICATION (DRUGS)

First Line

- Oral replacement with ferrous iron, 3–6 mg/kg/d of elemental iron divided into 2 or 3 doses.
- Iron should be given on an empty stomach or with a vitamin C–containing juice to increase absorption. Ascorbic acid increases oral absorption of iron by ~30%.
 - Side effects (in 10–20%) include nausea, constipation, GI upset, and vomiting. Iron suspensions can stain teeth temporarily.

Second Line

Parenteral (IM or IV) iron formulations indicated only for severe noncompliance or malabsorption, or if ongoing loss exceeds absorption capacity. Administration may be associated with pain at injection site or anaphylaxis.

ISSUES FOR REFERRAL

- Evaluation for source of GI blood loss
- Unexplained recurrence after treatment
- Failure to improve with iron supplementation

IN-PATIENT CONSIDERATIONS

Admission Criteria

- Active bleeding
- Severe anemia (hemoglobin level <6 g/dL) especially if symptoms or ongoing blood loss
- Tachycardia, S₃ gallop, or other signs of CHF

Nursing

Family education: Teaching administration of iron and dietary counseling

Discharge Criteria

- No signs of CHF
- If blood loss, bleeding is controlled
- Stable hemoglobin level
- Parent demonstrates ability to administer oral iron therapy to young children and demonstrates adequate knowledge about dietary modifications.
- Adequate follow-up ensured

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Reticulocyte count increases in 3–4 days.
- Hemoglobin concentration should rise by at least 1 g/dL in 2–3 weeks.
- Continue iron for 2 months beyond correction of anemia to replenish body stores.
- Causes of poor response to oral iron supplementation include:
 - Noncompliance (most common)
 - Ongoing blood loss
 - Insufficient duration of therapy
 - High gastric pH
 - Concurrent lead intoxication
 - Other diagnosis: Thalassemia trait and anemia of chronic disease are not iron responsive

DIET

- Milk should be restricted to <24 oz daily or eliminated in those with milk protein enteropathy.
- Bottle should be discontinued after 12 months.
- Diet should include foods rich in iron: Meats, beans, iron-fortified cereal, strawberries, spinach

PATIENT EDUCATION

- Activity: Usually, no activity restriction is needed. Those with severe anemia resulting in CHF should have limited activity until the anemia is corrected.
- Diet: A diet containing iron-rich foods should be encouraged. Limit milk intake to <24 oz daily.
- Prevention: Prevention of iron deficiency is preferable. Anticipatory guidance about diet, prolonged bottle use, etc., should be given, and government-sponsored programs such as the Special Supplemental Nutrition Program for Women, Infants and Children (WIC) should be used.

PROGNOSIS

- Anemia is readily corrected with iron replacement.
- Developmental delay may be long lasting or irreversible.

COMPLICATIONS

- Impaired cognitive and motor development in infants and toddlers
- Impaired immunity
- Short-term memory impairment and poor exercise performance in adolescents

ICD10

D50.9 Iron deficiency anemia, unspecified

FAQ

- Q: What dietary changes can help prevent the recurrence of iron deficiency?
- A: Limit milk to 24 oz/day so that your child has a better appetite for iron-containing foods. Heme iron, found in meats, fish, and poultry, is absorbed better than nonheme iron and also enhances absorption of nonheme iron. Other foods that have iron are raisins, dried fruit, sweet potatoes, lima beans, chili beans, green peas, peanut butter, and enriched foods. Give iron on an empty stomach along with an ascorbic acid–containing juice to increase absorption. Foods that decrease absorption include bran, vegetable fiber, tannins found in tea, and phosphates. Antacids may also decrease iron absorption.
- Q: What are the side effects of iron therapy?
- A: Iron may cause temporary staining of the teeth, which can be decreased by diluting the iron with a small amount of juice. Iron will also change the color of bowel movements to greenish black and may be associated with constipation.
- Q: What are the most important tests to do to establish the diagnosis of iron deficiency?
- A: For patients with a history of dietary deficiency or known blood loss, a CBC that shows a low hemoglobin and MCV and an elevated RDW is very suggestive of iron deficiency. A therapeutic trial of iron without further laboratory testing is an appropriate next step. A rise in the hemoglobin concentration of ≥ 1 g/dL after 1 month of therapy confirms the diagnosis. If this does not occur, further laboratory testing is necessary and other diagnoses should be considered.
- Q: How does a concurrent infection affect the diagnosis of iron deficiency?
- A: Common childhood infections may be associated with a mild microcytic anemia that resembles iron deficiency. Laboratory tests to diagnose iron deficiency may be misleading while a child is acutely ill. Acute infection is associated with a shift of iron from serum to storage sites, causing a decrease in serum iron and an increase in ferritin. It is more helpful to test a child for iron deficiency 3–4 weeks after an acute infection.

IRON POISONING

Carla Campbell

Carl Tapia

BASICS

DESCRIPTION

- The nontherapeutic ingestion of an iron-containing preparation, which may be available in a number of iron salts
- Ingested doses of <20 mg/kg of elemental iron are generally nontoxic; of 20–60 mg/kg lead to moderate toxicity; and of >60 mg/kg lead to severe toxicity and can be potentially fatal

EPIDEMIOLOGY

- Most frequent cause of pediatric unintentional ingestion fatalities in the 1980–1990s, accounting for ~30% of fatalities in 1 series; incidence of fatalities and poison control center calls has been declining in recent years, perhaps due to changes in package labels
- Almost all iron-related injuries are in children <4 years of age, and are usually due to ingestion of adult iron formulations.
- Risk factors for iron poisoning include ready availability of iron preparations in homes with pregnant women and young children, and the similarity in appearance of some iron pills and vitamins to candy.

PATHOPHYSIOLOGY

- Direct corrosive effects of iron on GI mucosa may lead to abdominal pain, vomiting, hematemesis, diarrhea, hematochezia, and melena. These effects may cause intestinal ulceration, edema, and inflammation.
- Hepatotoxicity from free iron accumulation can lead to periportal necrosis and hepatic failure, as well as coagulopathy.
- GI fluid losses can lead to hypotension and tissue hypoperfusion.
- Decreased cardiac output from decreased venous filling pressures, decreased preload, relative bradycardia, and a possible direct negative inotropic effect of iron on the myocardium can lead to shock.
- Metabolic acidosis results from tissue hypoperfusion with lactate formation, unbuffered hydrogen ion as absorbed ferrous iron is converted to ferric iron, disruption of oxidative phosphorylation, and lipid peroxidation of mitochondrial membranes.
- Acute respiratory distress syndrome (ARDS) may present in severe cases, and may be caused by iron-induced alveolar membrane damage.

- Stages of the clinical effects of iron poisoning: Stage I (early acute): 0–6 hours postingestion: Characterized by GI, CNS, and cardiovascular (CV) signs and symptoms. Stage II (quiescent): 6–24 hours: Characterized by decrease in GI symptoms and relative improvement in overall clinical condition. Stage III (recurrent): 12–48 hours: Characterized by cyanosis, profound metabolic acidosis, shock, evidence of hepatic and renal failure, bowel ischemia, myocardial depression, and cerebral dysfunction sometimes causing seizures and coma. Stage IV (late): 2–8 weeks postingestion: Characterized by gastric scarring and pyloric stenosis, sometimes leading to obstruction

DIAGNOSIS

HISTORY

- Discovery of iron-containing pills, pill fragments, or other preparations in a young child's mouth or in opened containers in the home
- Detailed information on iron compound ingested such as iron salt type (determines percentage of elemental iron potentially ingested), number of pills ingested, and approximate ingestion time can be used to calculate estimated ingested iron dose in mg/kg of elemental iron.
- As a reference, the percentage of elemental iron in ferrous fumarate is 33%; in ferrous chloride is 28%; in ferrous sulfate is 20%; and in ferrous gluconate is 12%.

PHYSICAL EXAM

- A lethargic, hypotensive, vomiting toddler: The diagnosis of iron poisoning should be strongly considered for this scenario.
- Hypotension, decreased capillary refill, pallor, tachycardia, and CNS depression (lethargy or coma) suggest hypovolemic and/or hemorrhagic shock.
- Abdominal tenderness, vomiting, diarrhea, and occult or apparent GI bleeding may be seen as the direct corrosive effects of iron on gastric mucosa.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Iron level:
 - The serum iron level at 4–6 hours postingestion is most predictive of the clinical course, and is used in conjunction with the clinical assessment.
 - Iron levels 300–500 mcg/dL are usually associated with GI toxicity and moderate systemic toxicity.
 - Iron levels 500–1,000 mcg/dL are usually associated with significant systemic toxicity and shock.
 - Iron levels >1,000 mcg/dL are usually associated with significant morbidity and mortality:
 - Chemistries including hepatic profile: To assess for hepatic injury and/or metabolic acidosis (positive anion-gap acidosis)
 - CBC: To determine degree of anemia from blood loss
 - Coagulation studies: To monitor for coagulopathy
 - ABG: To monitor metabolic acidosis

- Pitfalls:
 - Total iron-binding capacity (TIBC) not recommended to assess degree of toxicity.
 - Lower iron levels do not necessarily preclude the possibility of serious iron toxicity.
 - Radiographic studies: Abdominal radiograph: May reveal iron pills, which can then guide approach to GI decontamination. Liquid iron preparations and multivitamins with iron are typically not radiopaque. Absence of pills on x-ray does not exclude potential iron ingestion and toxicity.

DIFFERENTIAL DIAGNOSIS

- Ingestions: Methanol, paraldehyde, ethanol, ethylene glycol, salicylate, theophylline, or digoxin ingestions.
- GI:
 - GI hemorrhage
 - GI trauma with perforation
 - Appendicitis with rupture
 - Intussusception
 - Hemolytic uremic syndrome
 - Gastritis
 - Esophagitis
 - Mallory-Weiss tear
 - Vascular malformation
- Other:
 - Reye syndrome
 - Fulminant sepsis
 - Meningitis
 - Diabetic ketoacidosis

TREATMENT

General Measures

- Asymptomatic patients with minimal or no GI involvement can be observed in the emergency department for a 6-hour period and discharged home.
- Symptomatic patients with GI or mild symptoms should be admitted for inpatient management.
- Symptomatic patients with significant toxicity should be treated in an intensive care setting by specialists skilled in management of this ingestion. Metabolic acidosis and radiopaque material on abdominal radiograph predict significant iron absorption and toxicity.

SPECIAL THERAPIES

- GI decontamination:
 - Goal is to decrease iron absorption and break up pill concretions, which may directly damage the GI mucosa.
 - Whole-bowel irrigation with a polyethylene glycol electrolyte solution until all pill remnants have passed in the stool is recommended for most cases.
 - Gastric lavage with normal saline or tap water may be attempted, but iron tablets are often too large to pass through nasogastric tube.
 - Activated charcoal: Iron does not bind well to it, so this method of decontamination is not effective.
 - Syrup of ipecac is not recommended.
 - Rarely, endoscopy or gastrotomy may need to be performed to remove embedded pills.
- Chelation with deferoxamine (DFO):
 - Given parenterally via continuous IV infusion at 5–15 mg/kg/h. (Consult specialist or guidelines for specific dosing instructions.) This is recommended for symptomatic or ill patients, patients with a positive abdominal radiograph or significant exposure history, and all patients with levels of ≥ 500 mcg/dL.
 - Chelation can be discontinued with clinical improvement, resolution of metabolic acidosis, resolution of radiograph radiopacities, and urine color normalization.
 - If renal failure develops, chelation can be continued and dialysis performed (the iron–DFO complex is dialyzable).
 - The most common side effect of chelation is hypotension; therefore, adequate fluid resuscitation is imperative.

IN-PATIENT CONSIDERATIONS**Initial Stabilization**

- Evaluate for presence of GI or systemic involvement, including acidosis, shock, or lethargy.
- Supportive care should include assessment of airway, supplemental oxygen, establishing IV access, and supporting BP with normal saline or Ringer's lactate.
- Endotracheal intubation and oro- or nasogastric tube placement should be considered in a lethargic patient to facilitate GI decontamination.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Abdominal x-ray should be followed until complete decontamination is documented.
- Patients should be monitored for possible late complications, such as strictures of the GI tract.

PATIENT EDUCATION

- Strategies include parental education, package-labeling warning of the potential pediatric ingestion hazard, regulatory change to require prescription status for preparations containing iron, and improved packaging of iron preparations.
- The Consumer Product Safety Commission (CPSC) requires child-resistant packaging for packages containing ≥ 250 mg of elemental iron. The FDA regulation that required individually packaged units for products containing ≥ 30 mg of elemental iron per dosage unit was repealed in 2003; still, most children's multivitamin preparations only contain up to 18 mg of elemental iron per tablet.

PROGNOSIS

- Manifestations of iron ingestion can range from asymptomatic to severe systemic toxicity and death.
- Prognosis can be estimated based on factors such as estimated ingestion dosage, serum iron level, clinical course, and presence of complications.

COMPLICATIONS

- Small bowel infarction and necrosis
- Gastric or intestinal scarring and strictures, which may present as gastric outlet or intestinal obstruction
- Hepatic failure
- Metabolic acidosis
- Hypovolemic and hemorrhagic shock
- Coagulopathy
- ARDS
- CNS effects including lethargy, seizures, and coma
- *Yersinia enterocolitica* infection or sepsis
- Death

**CODES****ICD9**

964.0 Poisoning by iron and its compounds

ICD10

- T45.4X4A Poisoning by iron and its compounds, undetermined, initial encounter
- T45.4X4D Poisoning by iron and its compounds, undetermined, subsequent encounter
- T45.4X4S Poisoning by iron and its compounds, undetermined, sequela

FAQ

- Q: Why isn't syrup of ipecac recommended to induce vomiting?
- A: Because the major early signs and symptoms involving the GI tract include vomiting, inducing vomiting may interfere with the clinical assessment. There is also the risk of aspiration in the patient with severe poisoning.
- Q: What is the recommendation regarding observation of a patient for development of symptoms with iron ingestion of an unknown quantity?
- A: Observe for 6 hours. Those who are asymptomatic 6 hours after ingestion are not likely to exhibit systemic illness.
- Q: What is the recommendation regarding nonintentional ingestion of children's vitamins with iron, carbonyl iron formulations, or polysaccharide iron complex formulations?
- A: These ingestions are generally deemed to contain low levels of iron, and the American Association of Poison Control Centers recommends against emergency room referral for nonacute patients with adequate home supervision. Even patients with mild diarrhea and emesis can be safely observed in the home following these ingestions, although consultation with a physician and Poison Control hotline is still advised.

IRRITABLE BOWEL SYNDROME

Edisio Semeao

BASICS

DESCRIPTION

- Irritable bowel syndrome (IBS) is the best known and one of the most common functional GI tract disorders.
- These disorders are characterized by chronic and/or recurrent GI tract symptoms not explained by structural abnormalities, infection, or neoplastic or metabolic changes on routine testing.
- Terms such as *spastic colon*, *nervous colon*, and *spastic colitis* have also been used to describe IBS. Spastic colitis, however, is inaccurate because these patients do not have evidence of inflammation of their colon (colitis) at colonoscopy.
- Patients with IBS have a constellation of symptoms that include:
 - Chronic abdominal pain, usually lower abdomen
 - Altered bowel pattern:
 - Constipation
 - Diarrhea
 - Alternating constipation and diarrhea

EPIDEMIOLOGY

- 60–70% of patients with IBS are women.
- More common in adolescents in the pediatric population
- Poses a significant health care burden, with a total cost of \$30 billion annually
- There is no known genetic predisposition for developing IBS.
- Women are 2 times more likely to be diagnosed with IBS than men.

Prevalence

- IBS is a prevalent disorder that occurs in 10–20% of the US population.
- It is more prevalent than hypertension, asthma, diabetes, and ischemic heart disease.
- Up to 28% of referrals for gastroenterology consults are for IBS.
- In adults, IBS is the 7th most common cause of visits to primary care physicians.
- 50% of patients present with symptoms before age 35, and 33% can trace their symptoms back into childhood.

PATHOPHYSIOLOGY

- Most commonly, IBS is thought to be a disorder of GI function relating to motility, sensation, and/or perception.
- The pathogenesis of IBS is believed to be multifactorial, with a variety of factors influencing the gut–brain axis at various levels.
- These factors interact to cause the symptoms of IBS and include:
 - Predisposing factors (social, cultural, environmental) include genetics, early life experiences, gender, and intergenerational illness behavior.
 - Precipitating factors (physiologic) may be associated with IBS but not directly a cause: Stress, infection/inflammation, bacterial flora, intestinal motility, and hormonal dysregulation.
 - Perpetuating factors (behavioral) further amplify the GI dysfunction in patients with IBS and include depression, anxiety, panic disorder, somatization, poor social support, and maladaptive behavior.
- There are no actual histologic, microbiologic, or biochemical abnormalities noted in patients with IBS.

DIAGNOSIS

- There are no specific diagnostic tests or pathognomonic signs or symptoms for the diagnosis of IBS.
- Over the past several years investigators have developed symptom-based, consensus diagnostic criteria for IBS, and the latest version (Rome III) has allowed for a confident diagnosis of this disorder based on a cluster of symptoms, minimal diagnostic evaluation, and the absence of “red flags.”
- Rome III criteria: The signs and symptoms for the diagnosis of IBS may occur on a recurrent basis and need not be continuous. At least 3 months, with onset at least 6 months previously of recurrent abdominal pain or discomfort associated with 2 or more of the following:
 - Improvement in the abdominal pain after a bowel movement
 - An increasing number of stools with the start of the pain
 - Change in the form and appearance of the stool with the onset of pain:
 - Based on type of symptoms, IBS can be further classified into 1 of 3 subtypes:
 1. Diarrhea predominant
 2. Constipation predominant
 3. Mixed
 - Female IBS patients are more likely to have constipation-predominant disease.

HISTORY

- Evaluation of these patients needs to include a careful and detailed history, including a description of the symptoms, with assessment if they recur on a regular basis.
- Detailed diet and travel history
- Inciting and exacerbating factors
- Characteristics of abdominal pain:
 - Sharp, dull, crampy, or burning
 - Usually periumbilical or lower abdominal in nature, but not necessarily
 - Starts after a meal and rarely awakens a patient from sleep
- Patients, especially children, describe associated symptoms, such as pallor, nausea, anorexia, and fatigue with the abdominal pain.
- Presence or absence of abdominal distention
- Presence of increased belching and/or flatulence
- Change in bowel habits: Presence of alternating diarrhea and constipation:
 - Patients tend to have one predominant form.
 - Most patients experience relief of pain after a bowel movement.
 - Patients with constipation may go several days to a week without any stool passage.
 - In some instances, mucus may be described in this group of patients. However, blood is a rare finding and is usually associated with local/anal irritation or fissure secondary to diarrhea or constipation.

- Red flags:
 - Prolonged, unexplained fevers
 - Significant, unexplained weight loss, anorexia
 - Family history of colorectal cancer or GI disorders
 - Onset in older patients
 - Joint complaints
 - Nocturnal symptoms that awaken a patient
 - Recent major change in the nature or severity of the symptoms

PHYSICAL EXAM

- Findings, including those from rectal exam, are usually completely normal.
- There is usually no evidence of weight loss or growth failure.
- Red flags: Abdominal mass or other abnormal finding

DIAGNOSTIC TESTS & INTERPRETATION

- There are no specific tests for the diagnosis of IBS. The use of various tests may be indicated to evaluate for organic disease based on the presence of “red flags” in the history or the physical exam.
- Confine testing to basic screening tests so that patients are not left with the impression that there is a significant organic disease present.
- Tests may include:
 - Lactose breath test: Presence of lactose intolerance
 - Stool cultures for routine specimen, *Clostridium difficile*, and ova and parasites: Exclude infectious etiologies for symptoms.
 - Gastric emptying, antral-duodenal, and anal-rectal manometry are special tests.

Lab

There are no laboratory tests that are diagnostic for IBS. Routine CBC, ESR, urinalysis, electrolytes, liver function tests, albumin, amylase, lipase, celiac antibodies, and thyroid studies are performed to exclude other diseases.

Imaging

Abdominal radiograph or CT scan may exclude an intra-abdominal process.

Diagnostic Procedures/Other

Upper endoscopy and/or colonoscopy: Indications include:

- Bleeding
- Profuse diarrhea
- Weight loss
- Iron deficiency anemia
- Abnormal laboratory or radiographic studies
- Extraintestinal manifestations of inflammatory bowel disease

Pathological Findings

Red flags from testing that would raise concern about the diagnosis of IBS include:

- Anemia
- Leukocytosis
- Elevated ESR or C-reactive protein
- Positive fecal occult blood
- Positive stool cultures
- Positive serology for celiac disease
- Abnormal histology on endoscopy/colonoscopy

DIFFERENTIAL DIAGNOSIS

- Common disorders that need to be considered are those that may present with recurrent abdominal pain and altered bowel patterns, including:
 - Chronic inflammatory conditions of the bowel (Crohn disease, ulcerative colitis, indeterminate colitis, celiac disease)
 - Infectious disorders (parasites, bacterial)
 - Lactose intolerance
 - Complications of constipation (megacolon, encopresis, intermittent sigmoid volvulus)
 - Drug-induced diarrhea or constipation
 - Gynecologic disorders
 - Neoplasms
 - Psychiatric disorders
- Patients fulfilling Rome III criteria for IBS rarely (<1% probability) have an underlying illness. In contrast, IBS is so prevalent that there may be a co-occurrence with other disorders that can modify and/or amplify the clinical features of IBS. Common disorders include celiac disease and lactose intolerance.

TREATMENT

MEDICATION (DRUGS)

First Line

Limited by marginal therapeutic benefits, side effects, and potential exacerbation of IBS

- Bulking agents: Fiber supplementation in the diet is a usual 1st step in therapy that prolongs stool transit time and absorption.
- Laxatives: Unproven benefits, no real trials, and frequent complications
- Antispasmodics: Dicyclomine (Bentyl) and hyoscyamine (Levsin) may aid in pain relief, but overall efficacy in global symptom control is not proven.
- Antidiarrheal agents: Unproven benefits and associated with some risks.

Antidepressants

- Tricyclic antidepressants: Play a role in pain relief. They have also been shown to decrease symptoms independent of their effect on anxiety and depression. May have unwanted side effects
- Selective serotonin reuptake inhibitors: Improvement in symptoms independent of their effect on anxiety and depression. The mechanism of action may be related to the effect of serotonin's role in motility, sensation, and secretion in the GI tract
 - Serotonin receptor medications
 - 5-HT₃ antagonist: Alosetron (Lotronex) inhibits cholinergic neurons and visceral sensory mechanisms. Presently, it is only available in limited, restricted use in females with severe diarrhea-predominant IBS who have failed other therapies. Complications of ischemic colitis (3:1,000) and severe constipation have been reported. A few cases of ischemic colitis resulted in either death or need for surgical resection.

- Probiotics
 - 25% of patients with IBS report start of symptoms after a GI intestinal infection. Recent studies have concluded that probiotics may be useful; however, dose, formulation, and type greatly affect the results.
- Antibiotics: Neomycin and rifaximin. Can be used to treat for possible bacterial overgrowth
- Dietary restrictions: Can be used as adjuvant therapy; however, have not been shown to be beneficial as a primary therapy
- Herbal medications
 - St John's wort: Has not been shown to have any positive effect in the treatment of IBS
 - Peppermint: Studies have shown that its use can decrease the symptoms of IBS. It is accepted as an adjunct therapy.
- Psychotherapy: Patients are taught a variety of techniques and exercises to use during the episodes of pain that allow them to focus on other subjects, not on the pain.
- Future therapies: Tachykinins—biologically active peptides that affect bowel function. They include substance P and neurokinin A and their clinical significance is unclear.
- Overall, the most effective intervention may be to combine therapies that will target specific symptoms and arms of the gut–brain axis to globally control the symptoms from IBS.

COMPLICATIONS

- A large number of the complications that arise from IBS include depression and anxiety, causing a decreased quality of life.
- Patients with IBS show a significant amount of absenteeism from both school and work.

ADDITIONAL TREATMENT

General Measures

- For patients with mild symptoms of IBS, reassurance, education, and lifestyle changes such as avoiding identified triggers may be adequate for management.
- In patients with more severe or complex symptoms, a multidisciplinary approach including pharmacotherapy and psychosocial intervention may be needed.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

There is no standard or specific follow-up needed for patients with IBS. They should continue with routine care, and one should ensure effective communication between the patient and physician to review the clinical symptoms and evaluate for any changes in the symptoms that may indicate another underlying problem.

564.1 Irritable bowel syndrome

ICD10

- K58.0 Irritable bowel syndrome with diarrhea
- K58.9 Irritable bowel syndrome without diarrhea

FAQ

- Q: Is evidence of microscopic colitis consistent with the diagnosis of IBS?
- A: There should be no histologic or laboratory abnormalities.
- Q: Will patients with IBS have a coexisting GI disorder?
- A: Frequently, patients may be diagnosed with lactose intolerance or celiac disease. In these instances, both disorders need to be treated to alleviate the symptoms.

JAUNDICE

Kathleen M. Loomes

BASICS

DEFINITION

- Jaundice is derived from the French word *jaune*, which means “yellow.”
- Jaundice: A yellow or green/yellow hue to the skin, sclerae, and mucous membranes which can be appreciated at serum bilirubin levels >2 mg/dL. Intensity of color is directly related to the serum bilirubin level.
- Unconjugated bilirubin: 80% is due to hemoglobin turnover and 20% is from degradation of hepatic and renal heme proteins. It is a hydrophobic compound that must be carried to the liver by albumin for processing.
- Conjugated bilirubin: Conjugated to glucuronic acid in the liver, a water-soluble derivative that helps lipid emulsification and absorption
- Conjugated hyperbilirubinemia (direct hyperbilirubinemia): A conjugated bilirubin of >2 mg/dL or $>20\%$ of the total bilirubin

EPIDEMIOLOGY

The most common causes of pathologic jaundice:

- Newborn period: Biliary atresia, idiopathic neonatal hepatitis, α -1-antitrypsin deficiency, infection
- Older child: Autoimmune hepatitis, viral hepatitis, Wilson disease, biliary obstruction

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Unconjugated hyperbilirubinemia**
 - Congenital/anatomic:
 - Placental dysfunction/insufficiency resulting in polycythemia (e.g., infants of diabetic mothers)
 - Upper GI tract obstruction (e.g., pyloric stenosis, duodenal web, atresia)
 - Congenital hypothyroidism
 - Infectious:
 - Sepsis
 - Trauma/delivery complications:
 - Cephalohematoma/bruising
 - Delayed cord clamping, twin–twin transfusion, maternal–fetal transfusion leading to polycythemia
 - Intrauterine hypoxia (secondary to cocaine abuse, high altitude) resulting in polycythemia
 - Induction of labor with oxytocin
 - Prematurity
 - Genetic/metabolic:
 - Inherited red cell enzyme, membrane defects (e.g., spherocytosis, glucose 6-phosphate-dehydrogenase deficiency, phosphokinase deficiency, elliptocytosis)
 - Red cell abnormalities (sickle cell anemia, thalassemia)
 - Defect in hepatic bilirubin conjugation (e.g., Crigler–Najjar types I and II, Gilbert)
 - Inborn errors of metabolism
 - Allergic/inflammatory/immunologic:
 - Isoimmunization (ABO, Rh, Kell, other incompatibility)
- Functional:
 - Physiologic jaundice—peaks during the day
 - Breastfeeding-associated jaundice
 - Swallowed maternal blood
 - Increased bilirubin load due to infant bleeding from a clotting disorder
 - Familial benign unconjugated hyperbilirubinemia in mother and neonate (Lucey–Driscoll syndrome)
- **Conjugated hyperbilirubinemia**
 - Extrahepatic:
 - Bacteriemia
 - Choledochal cysts and other abnormalities of the choledochopancreatic ductal junction
 - Spontaneous perforation of the bile duct
 - Bile or mucous plug or biliary sludge
 - Gallstones
 - Infectious etiologies:
 - Bacterial: Gram-negative sepsis, urinary tract infection
 - Viral: Cytomegalovirus; echovirus; herpes simplex virus; rubella; Epstein–Barr virus; HIV, hepatitis A, B, C, D, and E
 - Toxoplasmosis
 - *Pneumocystis carinii*
 - *Entamoeba histolytica*
 - *Mycobacterium tuberculosis*
 - *Mycobacterium avium*-intracellulare
 - Syphilis
 - Toxic, environmental, drugs:
 - Post-shock or post-asphyxia (ischemic injury to liver)
 - Drugs: Acetaminophen, valproate, chlorpromazine, Amanita toxin and others
 - Hyperalimentation (total parenteral nutrition)
 - Tumor:
 - Neuroblastoma, hepatic, biliary, pancreatic, duodenal, peritoneal
 - Portal hepatitis nodes
 - Genetic/metabolic:
 - Arteriohepatic dysplasia (Alagille syndrome)
 - Progressive familial intrahepatic cholestasis (including FIC1, BSEP, and MDR3 deficiency)
 - Benign recurrent intrahepatic cholestasis
 - Defects in bile acid metabolism
 - Defects in amino acid metabolism
 - Defects in lipid metabolism: Wolman disease, Niemann–Pick disease, Gaucher disease
 - Defects in carbohydrate metabolism: Galactosemia, hereditary fructose intolerance, glycogenesis type IV
 - Defects in fatty acid oxidation
 - Defects in mitochondrial DNA and respiratory chain defects
 - α -1-antitrypsin deficiency
 - Cystic fibrosis
 - Wilson disease (older children)
 - Inherited noncholestatic conjugated jaundice syndromes (e.g., Dubin–Johnson and Rotor syndrome)
 - Hereditary cholestasis with lymphedema (Aagaens syndrome)
 - Inflammatory/immunologic/endocrine:
 - Idiopathic neonatal hepatitis
 - Neonatal iron storage disease
 - Idiopathic panhypopituitarism
 - Autoimmune hepatitis (children and adolescents)
 - Sclerosing cholangitis (children and adolescents, unless neonatal form)

APPROACH TO THE PATIENT

- **Phase 1:** Determine if hyperbilirubinemia is unconjugated or conjugated.
- **Phase 2:** If unconjugated hyperbilirubinemia
 - Obtain CBC and indices
 - Reticulocyte count
 - Coombs test: If test is positive, the diagnosis is isoimmune; if test is negative, then consider polycythemia, extravascular bleed, or RBC structural or enzyme defects.
- **Phase 3:** If conjugated hyperbilirubinemia
 - Alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ -glutamyltranspeptidase (GGT)
 - PT/PTT/international normalized ratio (INR)
 - Ultrasound of the liver/pancreas/gallbladder and biliary tree
 - Rule out those etiologies of conjugated hyperbilirubinemia that may adversely affect the outcome if diagnosis is delayed (biliary atresia, tyrosinemia, galactosemia, inborn error of bile acid synthesis, hereditary fructose intolerance, panhypopituitarism and others).

HISTORY

- **Question:** Unexplained itching?
- **Significance:** Cholestatic liver disease (conjugated hyperbilirubinemia)
- **Question:** History of poor school performance, change in mental status, handwriting?
- **Significance:** Wilson disease
- **Question:** History of other family members having prolonged jaundice, hepatic failure, or sudden death in infancy?
- **Significance:** Suggests an underlying inborn error of metabolism such as tyrosinemia, galactosemia, or a fatty acid oxidation defect
- **Question:** History of IV drug abuse or exposure to blood or blood products, especially prior to 1992?
- **Significance:** The patient may have transfusion-associated hepatitis (e.g., hepatitis C).

PHYSICAL EXAM

- **Finding:** Scratch marks?
- **Significance:** Pruritus secondary to cholestasis
- **Finding:** Spider angioma, palmar erythema?
- **Significance:** Chronic liver disease
- **Finding:** Petechiae, purpura, microcephaly, thrombocytopenia?
- **Significance:** Congenital TORCH infection
- **Finding:** Heart murmur?
- **Significance:** Alagille syndrome (peripheral pulmonary stenosis)
- **Finding:** Splenomegaly?
- **Significance:** Suggests acute hemolysis (in unconjugated hyperbilirubinemia) or chronic liver disease and portal hypertension (conjugated hyperbilirubinemia)
- **Finding:** Ascites?
- **Significance:** Suggests portal hypertension
- **Finding:** Acholic stool?
- **Significance:** Severe cholestasis or biliary obstruction

DIAGNOSTIC TESTS & INTERPRETATION

- Percutaneous liver biopsies: Liver pathology—in infants with cholestasis, the most common patterns are giant cell hepatitis, bile duct proliferation, and bile duct paucity. A pattern of duct proliferation, bile plugs, portal expansion, and fibrosis suggests biliary obstruction.
- Intraoperative cholangiogram is indicated for infants with a liver biopsy suggestive of biliary obstruction and possible biliary atresia. If the cholangiogram is consistent with biliary atresia, the surgeon will perform the Kasai portoenterostomy.
- **Test:** Total bilirubin with fractionation into unconjugated, conjugated, and delta fractions
- **Significance:** Direct vs. indirect hyperbilirubinemia

If unconjugated hyperbilirubinemia, investigation is initiated with:

- **Test:** CBC with indices, reticulocyte count, and peripheral blood smear for RBC morphology
- **Significance:** Polycythemia in neonate, hemolysis, or other conditions associated with increased destruction of red cells
- **Test:** Coombs test
- **Significance:** Isoimmune and autoimmune hemolytic anemia
- **Test:** PT/PTT/INR, platelet count
- **Significance:** Coagulopathy associated with hemorrhage that causes an increased bilirubin load

If neonatal conjugated hyperbilirubinemia, investigation is initiated with:

- **Test:** Serum aminotransferases (ALT, AST)
- **Significance:** Ongoing liver inflammation
- **Test:** Alkaline phosphatase and GGT
- **Significance:** Biliary tree obstruction, bile duct injury, or cholestasis
- **Test:** PT/INR, PTT, serum albumin, fibrinogen
- **Significance:** Liver synthetic function
- **Test:** Sepsis evaluation (blood and urine, and spinal fluid)
- **Significance:** Sepsis can impair conjugation and excretion of bilirubin; results in poor feeding with bile sludging and subsequent formation of gallstones.
- **Test:** Free T3, T4, and thyroid-stimulating hormone
- **Significance:** Congenital hypothyroidism
- **Test:** α -1-antitrypsin serum levels and PI phenotype
- **Significance:** Serum α -1-antitrypsin levels will be low in inherited protease inhibitor deficiency. Levels can be falsely elevated due to the fact that α -1-antitrypsin is an acute-phase reactant.
- **Test:** Urine dipstick for glucose and reducing substances
- **Significance:** Positive reducing substances seen in galactosemia and hereditary fructose intolerance.

- **Test:** Urine for bile acid analysis
- **Significance:** Inborn error of bile acid metabolism
- Metabolic workup may be performed depending on clinical setting, including plasma amino acids, urine organic acids, succinylacetone, lactate, pyruvate, and other tests as indicated.
- In an older child presenting with conjugated hyperbilirubinemia, the most common causes are biliary obstruction due to gallstones, viral hepatitis, and autoimmune hepatitis.

Imaging

- **Ultrasound:**
 - A noninvasive method to examine the overall liver appearance, size, and density
 - Allows for examination of the biliary tree and gallbladder to rule out choledochal cysts, sludge/stones, and ductal dilatation indicating possible obstruction
 - Infants with biliary atresia/splenic malformation syndrome may have other findings including polysplenia, asplenia and pre-duodenal portal vein with azygous continuation.
- Hepatobiliary scintigraphy (HIDA scan): Tracer secretion into the duodenum excludes biliary atresia or extrahepatic biliary obstruction.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Treat Crigler–Najjar syndrome promptly with phototherapy and phenobarbital to prevent kernicterus
- Older children with Wilson disease may present with profound hemolysis and may have predominantly unconjugated hyperbilirubinemia with severe parenchymal liver disease and fulminant liver failure.

ISSUES FOR REFERRAL

- Any infant with jaundice beyond 10–14 days of age should have a fractionated bilirubin sent.
- Any infant with conjugated hyperbilirubinemia should be referred immediately to a pediatric gastroenterologist for further workup.

CODES

ICD9

- 774.6 Unspecified fetal and neonatal jaundice
- 782.4 Jaundice, unspecified, not of newborn

ICD10

- P59.9 Neonatal jaundice, unspecified
- R17 Unspecified jaundice

FAQ

- Q: Are there any characteristic findings in neonatal jaundice that are specifically concerning?
- A: These findings are concerning until proven otherwise:
 - Development of jaundice before 36 hours of life
 - Persistent jaundice beyond 10 days of life
 - Serum bilirubin concentration > 12 mg/dL
 - Elevation of direct bilirubin > 2 mg/dL or 20% of total bilirubin at any time
- Q: Are there any ethnic/social factors associated with higher bilirubin levels?
- A: Factors that have been associated with high serum bilirubin levels are low birth weight, certain ethnic groups (Asian, Native American, Greek), delayed meconium passage after birth, and breastfeeding. Factors that have been associated with lower serum levels in neonates include maternal smoking, black race, and certain drugs such as phenobarbital.

KAWASAKI DISEASE

Jeffrey S. Gerber

BASICS

DESCRIPTION

An idiopathic, multisystem disease of young children characterized by vasculitis of the small- and medium-sized blood vessels. The acute phase is self-limited; signs and symptoms evolve over the 1st 10 days, then resolve spontaneously. However, 20–25% of untreated patients will develop coronary artery aneurysms.

EPIDEMIOLOGY

Kawasaki disease (KD) has surpassed rheumatic fever as the leading cause of acquired heart disease in children in the U.S.

Incidence

- The annual U.S. hospitalization rate for children <5 years of age with KD is estimated at 20.815 per 100,000 children.
- Rates were highest among Asian and Pacific Islander children (30.3 per 100,000), followed by African American children.
- Kawasaki disease accounted for >4,200 hospitalizations in the U.S. in 2000, with hospital charges of ~\$35 million. No deaths were reported among hospitalized patients during the acute phase of illness.
- Median age of cases is 3 years. 76.82% of cases occurred in children <5; 95% in children <10. Slightly higher incidence in boys.
- Recurrence rate is <1–31%

ETIOLOGY

- Etiology is uncertain.
- Epidemiologic and clinical features (seasonal peak in winter/spring, peak in toddler age group, with sparing of young infants, and low recurrence rate) suggest an infectious cause trigger in a genetically susceptible child, although there is no convincing evidence linking a particular pathogen with KD.
- Controversial evidence suggests that KD may be associated with infection with superantigen-producing bacteria (either *Staphylococcus aureus* or group A streptococci).
- Association with recent carpet cleaning, humidifier use, or residence near water has not been substantiated.

COMMONLY ASSOCIATED CONDITIONS

- Diarrhea and abdominal pain may be seen.
- Patients may develop arthralgias or even frank arthritis.
- Pancarditis may present as myocardial dysfunction early in the course of disease, with signs of CHF.
- Infantile periarteritis nodosa:
 - A previously described entity in which the pathologic findings of coronary artery aneurysms are indistinguishable from those seen in KD.
 - Most patients with periarteritis nodosa do not have the other findings of KD.

DIAGNOSIS

- Diagnosis of KD requires fever for ≥ 45 days and ≥ 4 of the following criteria, which are not required to be present simultaneously:
 - Bilateral nonexudative conjunctival injection
 - Polymorphous, nonvesicular rash
 - Mucosal involvement of the upper respiratory tract that may include erythema, fissured lips, crusting of the lips and mouth, strawberry tongue, or injected, nonexudative pharyngitis.
 - Edema or erythema of the hands and feet
 - Cervical adenopathy (> 1.5 cm diameter), which is often unilateral
- Incomplete KD:
 - Patients may present with fever and <4 of the 5 diagnostic criteria and still develop aneurysms
 - Children with KD at the extremes of age (>9 or <1) are more likely to have incomplete disease, and coronary aneurysm is more common in children <1.

HISTORY

- Typical presentation proceeds through 3 recognizable phases:
 - Acute phase (1–2 weeks from onset):
 - Highly febrile (generally >39°C), irritable, toxic appearing
 - Occasionally toxic; rarely hypotensive
 - Fever generally >39°C
 - Oral changes usually quickly follow and also may last 1–2 weeks.
 - Rash prone to occur in perineal area
 - Edema and erythema of the feet are usually painful and limit ambulation.
 - Subacute phase (from 2–8 weeks after onset):
 - Without treatment, gradual improvement occurs; fever decreases and there is desquamation of the perineal area, palms, soles, and/or periungual areas.
 - Coronary artery aneurysms often appear during the early portion of this phase, and acute myocardial infarction (MI) may be seen rarely.
 - May have persistent arthritis or arthralgias
 - Convalescent phase (from months to years after):
 - Resolution of remaining symptoms
 - Laboratory values return to normal
 - Aneurysms may resolve or patients may have persistent aneurysms, persistent cardiac dysfunction, or even MI.

PHYSICAL EXAM

- High, unremitting fevers that last 1–2 weeks
- Rash is erythematous and polymorphous; not vesicular or bullous:
 - Often prominent on trunk, perineum; usually maculopapular, may coalesce and may be petechial
- Conjunctivitis: Bilateral and nonexudative
- Oral changes may be erythema, fissures, and crusting of lips, diffuse oropharyngeal erythema, or the presence of a strawberry tongue or any combination of these findings. Not exudative.

- Extremity changes may include erythema of the palms and soles and/or induration of the hands and feet:
 - Desquamation, especially periungual, usually occurs in the subacute phase.
 - Transverse grooves across the fingernails (Beau lines) may be seen 2–3 months after onset.
- Adenopathy is usually cervical and often unilateral:
 - Least often seen of the major criteria
 - May be fleeting and easily missed
- Aseptic meningitis: Common; patients are extremely irritable and may show signs of encephalopathy or ataxia.
- Pancarditis during the acute phase: May present with tachycardia, gallop rhythms, muffled heart sounds, signs of CHF, and murmurs consistent with aortic or mitral insufficiency
- Abdominal exam GI: Patients may have a right upper quadrant mass abdominal pain, diarrhea, (hydrops of gallbladder [$< 10\%$]), diarrhea, hepatosplenomegaly, or jaundice.
- Meatitis and vulvitis: May be seen in association with urethritis and sterile pyuria (70%)
- Arthralgias are common; frank arthritis is seen in up to 20% of patients.
- May involve large and small joints
- Is nondeforming
- Onset may be as late as 2nd or 3rd week
- Usually resolves in <1 month
- Uveitis (25–50%): During acute phase, slit-lamp exam may reveal anterior uveitis.

DIAGNOSTIC TESTS & INTERPRETATION

There is no diagnostic test for KD. However, a constellation of laboratory tests provides support for the diagnosis within the appropriate clinical context. Such data become most helpful in less definitive clinical scenarios, and most useful for aiding the diagnosis of incomplete KD. Exclusion of other diseases (adenovirus, scarlet fever, toxic shock syndrome, roseola, enterovirus, EBV) is paramount.

Lab

- CBC:
 - WBC usually increased with a left shift; >15,000 in 50% of cases
 - Anemia for age
 - Elevated ESR and C-reactive protein
- Platelet count:
 - Platelets may be low, normal, or high at presentation but increase rapidly after the 2nd week of illness; may be > 1 million/mm³
 - During subacute phase, platelet counts may increase to $1-2 \times 10^6$.
- Other laboratory abnormalities include:
 - Sterile pyuria (70%)
 - Mild increases in hepatic transaminases
 - A CSF pleocytosis with a normal protein and glucose
 - Mild hypoalbuminemia

Imaging

- Chest x-ray: May show dilated heart during acute phase
- Echocardiography:
 - During acute phase can show a decreased shortening fraction and effusion
 - Coronary ectasia, dilation, or aneurysms may be detected as early as 6 days into the illness; peak onset is between 3 and 4 weeks.

Diagnostic Procedures/Other

ECG: During acute phase may show prolonged PR interval, decreased QRS voltage, flat T waves, and ST changes

DIFFERENTIAL DIAGNOSIS

- Infections:
 - In 1 series, measles and group A -β-hemolytic streptococcal infections most closely resembled KD and accounted for 83% of patients referred who did not have KD.
 - Severe staphylococcal infections with toxin release (e.g., toxic shock syndrome) may also resemble KD, although there is usually renal involvement (extremely rare in KD) and low platelets.
 - Other infections that must be considered include adenovirus, Epstein-Barr virus EBV, roseola, enterovirus, Rocky Mountain spotted fever, and leptospirosis.
- Immunologic:
 - Juvenile idiopathic arthritis and unusual variants of acute rheumatic fever
 - Hypersensitivity reactions and Stevens-Johnson syndrome (SJS)
 - In SJS the conjunctivitis is more likely to be exudative, the rash is more likely to be vesicular with crusting, and there is often a history of drug ingestion.

TREATMENT

MEDICATION (DRUGS)

- IV immunoglobulin (IVIG):
 - Usual dose is 2 g/kg as a 1-time dose
 - Efficacy of IVIG after the 10th day of illness is unclear.
 - Patients who fail to respond to an initial dose of IVIG or who have a recrudescence of their symptoms should be retreated with IVIG (up to 2/3 may have a good response to repeat doses).
 - Side effects: Patients may develop signs of fluid overload and CHF. Aseptic meningitis may also be seen. This may be difficult to differentiate from the aseptic meningitis seen in patients as part of their KD.
- Aspirin:
 - High-dose aspirin (was the mainstay of therapy; still used in conjunction with IVIG, although no data look at IVIG with aspirin versus IVIG alone has been evaluated)
 - Usual initial dose is 80–100 mg/kg/d in divided doses.
- Corticosteroids:
 - A randomized controlled trial did not support the addition of steroids to IVIG for primary treatment.
 - The role of steroids for refractory disease remains unclear.
 - Cyclophosphamide, plasma exchange, TNF-α antagonists biologics (e.g., infliximab), and other salvage therapies have also been reported useful in patients who do not respond to repeated doses of IVIG.

- Duration:
 - Aspirin is continued at high dose until day 14 of the illness or when the child has been afebrile for 48 hours.
 - Aspirin dose is then decreased to 3–5 mg/kg/d for 6 weeks or until platelet count returns to normal.
 - If there are coronary artery abnormalities, additional antiplatelet/anticoagulation drugs therapy should be considered depending upon the severity of structural and clinical disease.

ADDITIONAL TREATMENT

General Measures

- The acute treatment of KD is aimed at reducing the inflammation of the coronary arteries to inhibit the development of aneurysm formation.
- If aneurysms are present, chronic imaging and therapy is directed at inhibiting coronary thrombosis and resultant MI.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The natural course is a gradual improvement during the subacute phase.
- With IVIG, children usually defervesce and show significant resolution of clinical symptoms within 2–3 days of treatment (70–80%).
- 2/3 of patients who receive a repeat dose of IVIG will respond to this dose.

Patient Monitoring

- WBC count, platelet count, and ESR should be followed weekly to biweekly until they return to normal.
- ECG and echo should be done performed to rule out the development of coronary artery aneurysms at diagnosis, at 2 weeks, and at 6–8 weeks from disease onset; more frequent imaging is recommended in patients with coronary abnormalities.
- If aneurysms are present, cardiology follow-up should include coronary artery catheterization and imaging at some time (usually 8–12 weeks after onset of illness).
- Symptoms of cardiac insufficiency (fatigue, chest pain, dyspnea on exertion) should be respected and an evaluation for myocardial dysfunction undertaken when these are present.

PROGNOSIS

- Without treatment with IVIG, 15–25% of patients develop coronary aneurysms.
- Use of IVIG decreases the incidence of coronary artery aneurysms to 4–8<5%.
- Death occurs secondary to cardiac disease in 0.13–0.2% of cases; ~10% is related to early myocarditis, and the remainder is due to MIs.
- MI can occur several years after the initial illness.
- Patients who are <1 year old, >98 years old, male, and whose fevers persist for >14 days are more likely to develop aneurysms.
- Mortality rates are much higher in males and patients who develop giant coronary artery aneurysms (diameter of >8 mm).
- Patients with a history of KD may have a worse cardiovascular risk profile in later life, indicative of an increased risk of atherosclerotic heart disease compared to the general population.

COMPLICATIONS

- Aneurysms are usually 1st noted 12–28 days after onset of the disease. They rarely appear >28 days after onset.
- Aneurysms may thrombose, leading to MI and death.
- Rarely, aneurysms may rupture acutely.
- A pancarditis is often present in the 1st 10 days of the illness. Pericardial effusions may accompany this.

CODES

ICD9

446.1 Acute febrile mucocutaneous lymph node syndrome [MCLS]

ICD10

M30.3 Mucocutaneous lymph node syndrome [Kawasaki]

FAQ

- Q: Do coronary artery aneurysms associated with KD ever resolve?
- A: Most coronary artery aneurysms do resolve. Even some giant aneurysms (those >8 mm in diameter) will resolve; there is concern, however, that even if aneurysms resolve, these patients may be at risk for the early development of atherosclerosis.

KNEE PAIN, ANTERIOR/PATELLOFEMORAL MALALIGNMENT SYNDROME

Theodore J. Ganley

BASICS

DESCRIPTION

- Condition characterized by discomfort at the anterior aspect of the knee that is generally associated with activities, especially those that involve running, jumping, and climbing stairs
- Has also been called “miserable malalignment syndrome”

PATHOPHYSIOLOGY

- Predisposing factors for patellofemoral malalignment syndrome include:
 - Femoral anteversion
 - Genu valgus
 - Pes planus
- These 3 anatomic features have been commonly referred to as a terrible triad contributing to anterior knee pain. Because the entire kinetic chain is linked in function, malalignment at 1 area can lead to secondary stresses at a distant location.
- Excess femoral anteversion, as well as marked pes planus, can contribute to the increase lateral pull on the patella and subsequent patellofemoral pain.
- Further contributing factors include a wider pelvis and more laterally positioned tibial tubercle, both of which also contribute to altered biomechanics at the knee.
- Tight hamstrings, heel cords, and quadriceps, as well as diminished quadriceps tone, can lead to increased forces across the patellofemoral joint.

DIAGNOSIS

HISTORY

- Pain under and around the kneecap with activities including squatting, sitting for prolonged periods with the knees bent, and going up or down stairs or hills: These activities increase patellofemoral contact stress.
- Recent history of direct trauma to the kneecap: A blunt trauma to the kneecap can cause soft tissue or subchondral contusion that may exacerbate this condition.

PHYSICAL EXAM

- Cracking noises from the front of the knee with flexion and extension:
 - Cracking can be a sign of softening of the undersurface of the patella
 - Chondromalacia is patellar articular cartilage pathologic changes, which range from mild cracking attributed to softening to locking and catching attributed to cartilage disruption.
- There is no single angulation or rotation profile that is universal for all anterior knee pain patients. Those with anterior knee pain however more commonly have femoral anteversion, genu valgus and pes planus. Low quadriceps tone and hamstring as well as quadriceps tightness may also be found.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Anterior and posterior, lateral, Merchant plain radiographs of the knee:
 - The Merchant kneecap view shows the shape of the patella within the trochlea.
 - Patients will frequently be found to have lateral patellar tilt, as well as an abnormally shaped patella with excessive elongation of the lateral portion of the patella/lateral patellar facet.
- MRI: Not a 1st-line study for patellofemoral syndrome; however, it may be performed to rule out associated pathology in patients with recalcitrant pain and unusual clinical presentations.

DIFFERENTIAL DIAGNOSIS

- Osgood-Schlatter disease:
 - Tenderness not at the patella but at the anterior tibial tubercle
 - A self-limiting inflammation of the apophysis that tends to occur in growing teenagers and pre-teens
 - Irregularity and fragmentation of the apophysis are seen on lateral radiographs.
- Meniscus tear:
 - Disruption of the crescent-shaped fibrocartilaginous tissue adjacent to the tibial and femoral articular surfaces
 - Most commonly presents as posteromedial or posterolateral hemijoint tenderness with knee hyperflexion and rotation

- Prepatellar bursitis:
 - An inflammation of the fluid-filled bursal sac beneath the SC tissue and immediately anterior to the patella
 - More common in patients who kneel for extended periods of time and has been called “carpet layer’s knee”
 - Swelling and tenderness immediately anterior to the patella; does not primarily present with deeper tenderness in the medial and lateral parapatellar regions found in patellofemoral syndrome

ALERT

Patients with a traumatic effusion, locking, catching, instability to ligamentous stress testing, multiple joint effusions, or night waking should be evaluated for other traumatic or medical conditions.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- A progressive exercise program is the main focus of treatment.
- Strength and flexibility exercises are needed to increase the strength and control the quadriceps muscle, as well as to stretch the quadriceps, hamstrings, and tendoachilles complex.
- Straight-leg-raising program can help to strengthen the quadriceps:
 - This can be performed several times each day as a home exercise program or formally with physical therapy in more recalcitrant cases.
 - Quadriceps, hamstrings, and tendoachilles stretches can be performed at the same time intervals as the strengthening program.

- Patients can be advanced from low-resistance exercises such as swimming, stationary bike, and elliptical trainers to higher-level running activities.
- Activity restriction in the initial acutely symptomatic stage is instituted to eliminate high-impact sports, including especially those that involve running and jumping.

CODES

ICD9

- 719.46 Knee pain
- 733.92 Chondromalacia

ICD10

- M22.40 Chondromalacia patellae, unspecified knee
- M25.569 Pain in unspecified knee
- M94.269 Chondromalacia, unspecified knee

FAQ

- Q: Is it acceptable to play sports, or is this condition too dangerous?
- A: Patients with a history of patellofemoral syndrome who have regained their strength and flexibility are permitted to return to their activities, provided that they do not have pain and limping during their activities. A history of catching, locking, or knee effusions may be a sign of further biomechanical intraarticular pathology that should be addressed.
- Q: Is bracing indicated?
- A: Some patients with anterior knee pain respond to neoprene sleeves, and those with a component of increased lateral translation may benefit from neoprene sleeves with lateral patellar supports. Bracing, however, is not a substitute for a strength and conditioning program.
- Q: Is chondromalacia patella the same as patellofemoral syndrome?
- A: No. Chondromalacia is a classification of the anatomic pathologic changes of the undersurface of the patella. Patellofemoral syndrome is the clinical condition encompassing the patient’s history, physical, and radiographic elements of anterior knee pain.

LACRIMAL DUCT OBSTRUCTION

Scott M. Goldstein
Femida Kherani (5th edition)

BASICS

DESCRIPTION

Congenital or acquired blockage of the distal portion of the tear drainage system extending from the lacrimal sac to the opening of the nasolacrimal duct in the inferior meatus in the nose. This results in chronic tearing.

EPIDEMIOLOGY

Incidence

~6% of newborns, most of which resolves spontaneously

PATHOPHYSIOLOGY

- Congenital obstruction occurs from incomplete canalization of the nasolacrimal duct during embryogenesis.
- Acquired obstructions result from scar tissue occluding the duct. This usually results secondarily from infection, inflammation, or trauma.

DIAGNOSIS

HISTORY

- Determine when the symptoms began.
- Clarify which eye is more symptomatic and whether frank epiphora is present.
- Congenital obstruction usually manifests itself within the 1st few months of life.
- Patients with acquired obstruction usually have a history of eye infection, dacryocystitis, or trauma to the drain system.
- Both present with symptoms including tearing, crusting of eyelashes particularly on awakening, and discharge from eye.

PHYSICAL EXAM

- Common symptoms:
 - Increased tear meniscus
 - Maceration of eyelid skin
 - Mucopurulent discharge
 - Crusted debris on the eyelashes
 - Occasionally conjunctival hyperemia
- Palpation of lacrimal sac with expression of mucoid discharge: Distal obstruction in the lacrimal system allowing accumulation of mucopurulent material in the sac, which can be expressed through the puncta with pressure on the lacrimal sac

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Lacrimal scintigraphy can be performed on occasion to evaluate drainage from the eye into the nose, but is rarely done in children.
- CT scan can be obtained if there is concern of a nasolacrimal cyst or dacryocele.

Diagnostic Procedures/Other

- Dye disappearance test:
 - Fluorescein is applied to the conjunctival cul-de-sac, and the patient is observed for 5 minutes.
 - In a negative test (normal), the tear meniscus will become relatively unstained as the tears naturally flow down through the drainage system. Dye can sometimes be found in the nose.
 - In a positive test (abnormal), the height of the stained tear meniscus will either increase or fail to decrease owing to the obstructed lacrimal system.
- In teenagers and adults, in-office irrigation of lacrimal system at the level of the canaliculus can be used diagnostically to evaluate for obstruction.

DIFFERENTIAL DIAGNOSIS

- Causes of increased tear production:
 - Congenital glaucoma
 - Reflex tearing secondary to dry eye
 - 7th nerve palsies
 - Trichiasis
 - Entropion
 - Corneal abrasion
- Causes of decreased drainage:
 - Imperforate puncta or canaliculi
 - Ectropion
 - Lateral canthus dystopia
 - Traumatic injury to the nasolacrimal drainage system

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Initially, in congenital obstruction lacrimal sac, massage and either ophthalmic antibiotic drops or ointment is applied when ocular discharge increases. Polysporin or erythromycin ophthalmic is typically recommended for coverage of the eyelid normal flora. This conservative approach is applied for the 1st year of life.
- If symptoms persist after 12 months of age, probing and irrigation of the nasolacrimal system are performed. An inferior turbinate infraction is performed in cases of distal obstruction to increase the space in the inferior meatus and facilitate outflow.

- If the initial probing and irrigation procedure fails, which it does in about 10% of cases, the procedure is repeated with placement of silastic intubation and/or stretching of the lacrimal duct via balloon dacryoplasty. Silastic intubation can be monocalicular or bicanalicular and is typically maintained for 3–6 months.
- If all else fails, a dacryocystorhinostomy, a permanent surgical connection between the lacrimal sac and the nose, is created to prevent recurrent infections (dacryocystitis).
- Patients with acquired obstructions typically require surgery. Probing and irrigation are performed to determine the location of the obstruction. These patients may also require silastic intubation, balloon dacryoplasty, and/or dacryocystorhinostomy surgery.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Infants with an acute dacryocystitis associated with a lacrimal obstruction should be admitted for IV antibiotic therapy and surgery to drain the collection.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Children with congenital obstruction should be re-evaluated at 9–12 months of age and referred for probing and irrigation if still symptomatic.
- Children with acquired obstruction should be referred to an ophthalmologist for surgical treatment.
- Referral for probing and irrigation is delayed until the patient is ~12 months of age; the probing and irrigation should be performed in a timely fashion to ensure a good outcome.

PROGNOSIS

- Spontaneous resolution in ~90% of children by 12 months of age with congenital obstruction. If no spontaneous resolution, surgical intervention involving a probing and irrigation is recommended.
- Acquired obstruction requires surgical intervention.

COMPLICATIONS

- Acute dacryocystitis (acute infection and inflammation of the lacrimal sac), which rapidly appears as an erythematous nodule and surrounding cellulitis in the inferior medial canthal area and medial lower eyelid
- Chronic low-grade dacryocystitis manifested by subtle mucopurulent discharge from the eye that may be intermittently symptomatic

CODES

ICD9

- 375.55 Obstruction of nasolacrimal duct, neonatal
- 375.56 Stenosis of nasolacrimal duct, acquired
- 743.65 Specified congenital anomalies of lacrimal passages

ICD10

- H04.539 Neonatal obstruction of unspecified nasolacrimal duct
- H04.559 Acquired stenosis of unspecified nasolacrimal duct
- Q10.4 Absence and agenesis of lacrimal apparatus

FAQ

- Q: Is my child in any danger while the nasolacrimal duct remains obstructed?
- A: Not usually. The obstruction presents more of a nuisance. However, occasionally the contents of the sac can become infected and will require oral or parenteral antibiotics.
- Q: Why not wait longer to do the probing and irrigation in congenital nasolacrimal duct obstruction?
- A: The failure rate of the initial procedure increases with age: If performed before 13 months of age, 96% success rate; between 13 and 18 months of age, 77% success rate; and between 18 and 24 months, 54% success rate.

LACTOSE INTOLERANCE

Kathleen M. Loomes
Vera de Matos (5th edition)

BASICS

DESCRIPTION

- Lactose is a disaccharide built from glucose and galactose and is the major carbohydrate in infants' food (breast milk or milk-based formula).
- Lactose is important as a source of energy; it promotes the absorption of calcium, phosphorus, and iron and has a probiotic effect on the gut flora.
- Lactose intolerance is defined as the inability to digest the disaccharide lactose secondary to deficiency of the enzyme lactase, resulting in clinical symptoms.
- Four types of lactase deficiency:
 - Congenital lactase deficiency:
 - Extremely rare
 - Presents during the newborn period, often with the 1st feeding of lactose-containing formula
 - Will cause severe diarrhea and failure to thrive and risk the newborn's life
 - Primary lactase deficiency or adult-type hypolactasia is due to relative or absolute absence of lactase:
 - Develops during childhood at different ages in different racial groups
 - Most common cause of lactose intolerance
 - Secondary lactase deficiency results from small bowel injury (acute gastroenteritis, persistent diarrhea, small bowel bacterial overgrowth, chemotherapy). Can present at any age, but is more common in infancy
 - Developmental lactase deficiency is the relative lactase deficiency observed in premature infants of <34 weeks' gestation.

EPIDEMIOLOGY

Prevalence

- ~70% of the world's population has primary lactase deficiency.
- The prevalence of primary lactase deficiency in Northern Europeans, who have a diet rich in dairy, is 2%.
- In Hispanic people, the prevalence of primary lactase deficiency is 50–80%.

- In Ashkenazi Jewish people as well as in African Americans the prevalence is 60–80%.
- In the Asian population, the prevalence of primary lactase deficiency is almost 100%.
- Nearly 20% of children <5 years from Hispanic, Asian, or African American descent have lactase deficiency and lactose malabsorption.
- Caucasian children usually do not develop symptoms until after 5 years of age.

RISK FACTORS

Genetics

- Posttranslational regulatory mechanisms in primary lactase deficiency or adult-type hypolactasia
- Correlation between the genetic polymorphism of mRNA and persistence of lactase activity with early loss at 1–2 years in Thai children and late loss at 10–20 years in Finnish children

PATHOPHYSIOLOGY

- The symptoms depend on the amount of lactose ingested.
- Malabsorbed lactose creates an osmotic load that draws fluid and electrolytes into the bowel lumen, leading to diarrhea.
- Nonabsorbed lactose is the substrate for intestinal bacteria. In the colon, bacteria metabolize lactose, producing volatile fatty acids and gases leading to flatulence, bowel distension, pain, and low pH.

DIAGNOSIS

HISTORY

- Classic symptoms include bloating, gaseousness, colicky abdominal pain, and diarrhea after digestion of lactose-containing meal.
- Diet history provides important information.
- Detailed history of symptoms: Blood or mucus in the stools, failure to thrive, fat malabsorption, or any extraintestinal symptoms strongly suggest different causes.
- Symptoms vary in severity with dose of lactose ingested.
- Association with milk ingestion may not be evident.

PHYSICAL EXAM

- Height and weight should be measured and plotted against age-appropriate norms; any deviation should not be attributed to lactose intolerance alone.
- Abdomen percussion: Abdomen may be distended and tympanitic.
- Blood in the stool must be further evaluated, because lactose intolerance does not cause bleeding.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool-reducing substances and fecal acidity:
 - A positive result indicates malabsorption of carbohydrates.
 - A pH <6.0 or reducing substances >0.5% are interpreted as a positive result.
- Lactose hydrogen breath test:
 - Noninvasive and highly sensitive
 - The only source of hydrogen is fermented unabsorbed carbohydrates. A rise of breath H₂ concentration of ≥20 ppm over baseline appears to correlate with enzyme deficiency.
 - However, the frequently poor association between symptoms of lactose intolerance and breath H₂ excretion suggests caution in the interpretation of the clinical significance of the breath hydrogen test.
 - False-positive test results occur owing to inadequate fasting before the test, rapid intestinal transit, toothpaste, smoking, and bacterial overgrowth.
 - False-negative results occur owing to diarrhea, hyperventilation, recent antibiotic exposure, and delayed gastric emptying. Up to 10% of the population is colonized with bacteria unable to produce hydrogen and will give a negative result.
- Lactase activity measurement in duodenal (invasive and expensive): Reserved for patients undergoing upper endoscopy to exclude celiac disease

Pathological Findings

- Disaccharidase activity can be measured in biopsy specimens of the small bowel and compared with normal values.
- The small bowel intestinal histology will often be normal in primary lactase deficiency (unless the reason is insult/damage to the small bowel mucosa).

DIFFERENTIAL DIAGNOSIS

Lactose intolerance may be secondary to a generalized small bowel mucosal dysfunction; the presence of other symptoms should prompt an evaluation. The differential diagnosis includes:

- Infection:
 - Viral and bacterial infections can cause secondary lactose intolerance due to villous injury. Most common pathogen is rotavirus.
 - Parasitic infections can mimic lactose intolerance (giardiasis).
- Inflammatory: Small intestinal Crohn disease can have associated lactose intolerance.
- Congenital:
 - Other carbohydrate enzyme deficiencies can mimic lactose intolerance. These include sucrase–isomaltase or glucose–galactose malabsorption.
 - Cystic fibrosis
 - Shwachman-Diamond syndrome (SDS): Primary features include:
 - Bone marrow insufficiency
 - Pancreatic insufficiency
 - Skeletal abnormalities
 - Short stature
- Allergic/Immune:
 - Celiac disease often is associated with lactose intolerance due to small intestinal damage.
 - Protein allergy can cause secondary lactose intolerance.

**TREATMENT****MEDICATION (DRUGS)**

- Oral lactase replacement capsules
- Calcium supplements to meet daily recommended intake levels if dairy-free diets are used

ADDITIONAL TREATMENT**General Measures**

- Removal of lactose from the diet is effective in eliminating symptoms. However, a milk-free diet may result in calcium deficiency.
- Predigestion of lactose can be done by the addition of commercially available enzyme supplementation. Multiple products are available over the counter. Liquid preparations, capsules, and chewable tablets can be obtained.
- Acquired deficiencies, particularly those associated with infection, may resolve over time or with specific treatment. Most patients with lactose intolerance will not recover the ability to digest lactose.
- Supplemental probiotics may improve symptoms of lactose intolerance.

**ONGOING CARE****DIET**

- Lactose-free formula, lactase-containing milk
- Substitutes for cow's milk based on rice or soy
- Yogurt and aged cheeses have a smaller content of lactose.

PROGNOSIS

- Prognosis of lactase deficiency and clinical intolerance is excellent as elimination and enzyme replacements are possible. With lactose avoidance or with enzyme supplementation, the child can control and eliminate symptoms.
- However, lactose intolerance may be secondary to disease processes that should be treated promptly.

**CODES****ICD9**

271.3 Intestinal disaccharidase deficiencies and disaccharide malabsorption

ICD10

- E73.0 Congenital lactase deficiency
- E73.1 Secondary lactase deficiency
- E73.9 Lactose intolerance, unspecified

FAQ

- Q: When is the usual time for presentation of lactose intolerance?
- A: In whites, the age of presentation is after 5 years of age. In blacks, 2–3-year-old children may present with clinical signs and symptoms. The differential diagnosis must distinguish primary from secondary causes.
- Q: Does lactose intolerance prevent the child from ever eating lactose?
- A: No. The patient can take smaller amounts of lactose in the diet or have the enzyme supplemented.
- Q: Does this problem ever get better?
- A: No. It is a lifelong problem, but seems to become less symptomatic for adults, in light of their individual desire to tolerate symptoms. Secondary lactose intolerance may improve with time or treatment of the primary disorder.

LEAD POISONING

Carla Campbell

BASICS

DESCRIPTION

- One of the most common pediatric environmental health problems, involving a systemic intoxication by the heavy metal lead; most commonly this is with inorganic lead.
- The Centers for Disease Control and Prevention (CDC) considers a blood lead level (BLL) of ≥ 10 mcg/dL to represent undue lead exposure and absorption, and to be elevated:
 - The CDC has recently reported on adverse health effects at lower BLLs, with no clear threshold.
 - *Lead poisoning* is an older term that is less specific than an actual BLL.
- CDC classification, by BLL in mcg/dL:
 - Class I (0–9); Class IIa (10–14)
 - Class IIb (15–19); Class III (20–44)
 - Class IV (45–69); Class V (≥ 70)

EPIDEMIOLOGY

- ~83% of American pre-1978 privately owned units contain some lead-based paint.
- A recent national survey estimates that 38 million housing units have lead-based paint and 24 million housing units have hazards from lead-based paint.

Prevalence

- Prevalence of elevated BLLs and geometric mean BLLs have decreased significantly in the past 20 years.
- ~310,000 American children aged 1–5 years (1.6% of a representative national sample) are estimated to have BLLs of ≥ 10 mcg/dL.

RISK FACTORS

- Young children with more oral behaviors are at greatest risk for lead poisoning.
- Children with developmental delays/mental retardation are at greater risk for elevated BLLs.
- Individuals with pica are at higher risk for lead ingestion and poisoning.

GENERAL PREVENTION

- Primary prevention: Removal of potential environmental lead hazards prior to exposure:
 - The CDC recommends that states and cities include primary prevention activities to reach the Healthy People 2020 goals of eliminating elevated BLLs in children.
 - Provide anticipatory guidance to all parents about lead exposure pathways and the prevention of these exposures.
 - Follow CDC guidelines for screening pregnant and lactating women.
- Secondary prevention as screening for elevated BLLs:
 - Minimum screening recommendations: Blood lead test for children at 1 and 2 years and for those 36–72 months old who have not had previous screening.
- Tertiary prevention: Case management and environmental remediation for children with lead poisoning

- Control measures:
 - Abatement of building-based (residential) lead hazards by removal, encapsulation, or enclosure of lead-containing structures
 - Control of environmental lead dust exposure and ingestion by good housekeeping (wet dusting and mopping of household dust) and personal hygiene (cleaning of child's hands, toys, personal items)
 - Removal of any other known lead source from the child's environment

PATHOPHYSIOLOGY

- Lead adversely affects many organ systems including neurologic, hematologic, GI, renal, and reproductive. Many toxic effects result from inhibition of enzymes involved in heme biosynthesis, as the electropositive metal binds to negatively charged sulfhydryl groups on active sites of δ -aminolevulinic acid dehydratase (ALA-D), ferrochelatase, porphobilinogen synthase, co-protoporphyrinogen oxidase, and other enzymes.
- Divalent lead also acts competitively with calcium in various biologic systems.
- Children absorb lead more efficiently from the GI tract and are more likely than adults to ingest lead through hand-to-mouth activities.
- Because the developing, immature CNS is susceptible to toxic effects of lead, the neuropsychologic effects of lead poisoning on fetuses/young children are of particular concern.

DIAGNOSIS

HISTORY

- Etiology/common sources of lead:
 - Ingestion of lead-based paint or contaminated dust or soil through residence in or visitation of older (pre-1980), deteriorated housing
 - A parental occupation or hobby involving lead exposure (e.g., construction or battery plant work, stained glass window or pottery making)
 - Use of remedies, cosmetics, pottery, toys or consumer products containing lead
 - Ingestion of contaminated water, food, or beverages
 - Typical symptoms:
 - Most children asymptomatic
 - Although many of the clinical manifestations of symptomatic lead poisoning are nonspecific, a cluster of complaints including anorexia, intermittent abdominal pain, constipation, sporadic vomiting, change in mental status (such as irritability or lethargy), decreased play activity, and change in developmental status (particularly with regression of developmental milestones) may herald this condition.
 - Lead encephalopathy:
 - Can present with change in consciousness, ataxia, persistent vomiting, seizures, coma
 - Often presents after a prodrome of symptoms mentioned above.
- ### PHYSICAL EXAM
- Not generally helpful at lower lead levels. Symptomatic and/or encephalopathic patients may have acute GI, neurologic, hematologic, and systemic manifestations.
 - Assess for developmental delay.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood lead test, either venous or capillary:
 - Results may be reportable to local health authorities.
 - The test result is a measure only of recent lead exposure and does not indicate total body burden of lead.
 - Capillary testing is associated with more false-positive results. If abnormal, a venous lead should be sent.
- CBC: To assess for anemia:
 - Iron deficiency anemia is often seen concomitantly.
 - Anemia related to lead toxicity is typically normocytic and normochromic; a microcytic, hypochromic anemia may be seen with a mixed etiology.
 - Basophilic stippling is sometimes seen on peripheral blood smear.
- Free erythrocyte protoporphyrin:
 - Marker of lead-induced inhibition of heme synthesis
 - Can be useful clinically to follow the recovery from heme synthesis inhibition during management

Imaging

- Abdominal radiograph: Look for radiopaque foreign material suggestive of ingestion of lead paint chips or other lead-containing foreign body, when ingestion of such is suspected in the history.
- Long-bone radiographs, not recommended for routine use:
 - Look for lead lines or metaphyseal sclerosis, characterized by increased density along transverse lines in the metaphyses of growing long bones, representing increased mineralization owing to interference with the metabolism of the bony matrix. If present, lead lines imply chronic lead exposure.

DIFFERENTIAL DIAGNOSIS

- Consider lead poisoning as the etiology for the following diagnoses:
 - Seizures, altered mental status, and/or coma
 - Anemia

ALERT

Failure to diagnose results from:

- Delay in checking a blood lead test in the presence of clinical signs, symptoms of lead poisoning, or neuropsychologic disorders
- Failure to inquire about lead exposure possibilities

TREATMENT

MEDICATION (DRUGS)

- Chelation therapy:
 - Should complement environmental management in all children with venous levels of ≥ 45 mcg/dL (CDC class IV), using parenteral calcium disodium ethylenediamine tetra-acetate (EDTA; also calcium disodium versenate) or oral agents such as meso 2,3-dimercaptosuccinic acid (DMSA, succimer, Chemet)
 - Chelation of children with levels < 45 mcg/dL is not recommended, as evidence suggests it does not reverse or diminish neuropsychologic effects of lead.

- Outpatient therapy can take place if a lead-safe environment has been identified and compliance is expected.
- Succimer is given at 10 mg/kg (or 350 mg/m²) q8h for 5 days, then q12h for 14 more days. Weekly monitoring for neutropenia, platelet abnormality, and increased liver enzymes is recommended. Succimer is more lead-specific than other chelators and causes less mineral depletion.
- Children with symptomatic lead poisoning or with levels of ≥ 70 mcg/dL (CDC class V) should be admitted immediately to a hospital for parenteral chelation with both intramuscular dimercaprol (British antilewisite, BAL) and IV or IM calcium disodium EDTA. Because there are many issues involved with administration of both chelating agents, consultation of appropriate guidelines and pharmacologic information is recommended.
- Children with encephalopathy constitute a medical emergency and should receive the preceding treatment in an intensive care setting with attentive neurosurgical support. Consultation with a clinician experienced in lead toxicity treatment is advised for these patients.
- Ingested lead-containing foreign bodies should be evacuated with whole-bowel irrigation using a high-molecular-weight glycol solution.

ADDITIONAL TREATMENT

General Measures

- Environmental management:
 - Includes removing children from the lead source(s)
 - Should occur when venous lead levels are recurrently 10 mcg/dL (CDC class IIA) and higher. Could be done for lower BLLs as resources allow.
- Reduction of lead:
 - Wet mopping and dusting with all-purpose household detergents is recommended to reduce lead dust exposure.

ISSUES FOR REFERRAL

- Close communication with the local health department is essential before, during, and after admission.
- Referral may be made to early intervention or development assessment programs, social workers, therapists, neurologists or other specialists, as needed.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Admit all symptomatic children, those with BLLs ≥ 70 , and those with BLLs ≥ 45 for which one cannot ensure a lead-safe environment and/or compliance with oral medication.

Discharge Criteria

Consider discharge when symptoms have resolved, BLL has significantly declined, and a lead-safe discharge environment has been identified.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Prompt environmental follow-up of current lead exposure situations and investigation for additional exposure (e.g., with family moves, visitation of new residences) should occur.
- Follow-up venous lead levels should be performed for those with levels from 10–19 mcg/dL (CDC class IIA, IIB) about every 1–3 months, with less frequent follow-up after levels decline.
- Follow-up venous levels should be performed for those with levels of ≥ 20 mcg/dL at 1–2-month intervals until no additional lead exposure is present and levels have decreased.
- Follow-up venous levels should be performed 1–3 weeks following chelation therapy, with frequent monitoring thereafter.

DIET

- Nutritional support with calcium and iron supplementation should be given if intake is inadequate; deficiencies of these increase lead absorption from the GI tract.
- Iron supplementation should be withheld during chelation therapy.

PROGNOSIS

- In general, there is an increased risk for long-term neuropsychological sequelae, which increases with lead exposure and absorption that is more intense, of longer duration, and begins at an early age when the CNS is still developing.
- Recurrent episodes of symptomatic lead poisoning increase the risk for permanent sequelae.
- More subtle effects may not be detected until school entry.

COMPLICATIONS

- Acute encephalopathy
- Seizures
- Coma
- Death (predominantly owing to cerebral edema)
- Mental retardation
- Cognitive, behavioral, attentional, and neurodevelopmental impairment
- Anemia
- Fanconi syndrome
- Abdominal colic
- Adverse reproductive outcomes

CODES

ICD9

984.9 Toxic effect of unspecified lead compound

ICD10

- T56.OX4A Toxic effect of lead and its compounds, undetermined, initial encounter
- T56.OX4D Toxic effect of lead and its compounds, undetermined, subsequent encounter
- T56.OX4S Toxic effect of lead and its compounds, undetermined, sequela

FAQ

- Q: What is lead abatement?
- A: Lead abatement is removal of a lead hazard from the environment either by replacing it (e.g., installing a new window), enclosing the area with the lead source (e.g., installing paneling), removing the lead-based paint from a surface (burning or dry sanding methods should never be used), or encapsulating the area (placement of a specific coating over the lead-containing surface, which prevents access to the lead hazard).
- Q: Is lead abatement permanent?
- A: Often lead paint that is chipping or peeling is removed from a home. Any areas with intact lead-based paint may become deteriorated with aging, leading to new lead hazards, although ongoing maintenance and repair may prevent this.
- Q: Why didn't my child's brother and sister get lead poisoning at the same age since they lived in the same house?
- A: Children are different; some do much more hand-to-mouth activity than others, which is the main way that children get lead into their bodies. Also, your home may not have had the same lead dangers (hazards) when the siblings were younger.

LEARNING DISABILITIES

Monica Dowling
Jeffrey P. Brosco
Chloe Brittan (5th edition)

BASICS

DEFINITION

Learning problems may be caused by many factors besides specific learning disabilities (e.g., failure to attend school or significant behavioral problems).

- Learning disorders, or learning disabilities (LD), are defined in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) as academic achievement that is substantially below the level expected for age, schooling, and general intellectual ability, that cannot be accounted for by psychosocial factors, economic disadvantage, or major sensory problems.
- Learning disabilities have neurobiologic and genetic roots. Symptoms are lifelong but can improve with early intervention. LD may affect reading, writing, spelling, or math. Any given child may have > 1 learning disability.
- Learning disabilities are not comorbid with intellectual disability, but often coexist with coordination, speech-language, and auditory processing disorders as well as disorders involving executive functions (ADHD).
- Reading disorder (dyslexia) is the most frequently diagnosed type of learning disability, and is typically characterized by impairments in phonologic processing. Phonologic deficits have also been implicated in writing disorder along with motor problems, but further research is needed to identify core deficits. Children with math disorder show procedural and fact fluency deficits.

EPIDEMIOLOGY

- Estimated incidence is 5–10% in school-aged children: 2.7 million public school students in the US have identified LD (2007).
- Learning disabilities are typically not evident until academic demands are placed on affected children.

GENERAL PREVENTION

- High-quality preschool experiences that are developmentally appropriate
- Early literacy initiatives (e.g., Reach Out and Read)
- Early intervention for speech, language, motor difficulties
- Ongoing academic progress monitoring beginning in kindergarten
- Early intervention programs for reading and math skills in children who show early signs of learning problems

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Academic problems:** May stem from a learning disability or other factors, including sensory impairments, intellectual disability, attention disorders, neurologic disorders, poor school attendance, or psychosocial problems
- **ADHD:** May present as a learning problem, especially when the inattentive and distractible symptoms of the diagnosis are greater than the hyperactive symptoms.
- May be difficult to distinguish from a learning disability, and the 2 occur together in approximately half of diagnosed cases of learning disabilities
- Careful psychoeducational assessment may be needed to clarify these diagnoses.
- **Sensory impairments**
 - Hearing or vision impairments may cause learning problems.
 - School screening results should be confirmed in children with learning problems.
- **Neurologic**
 - Absence seizures and other nonconvulsive epileptic disorders are much less common than ADHD but may mimic its symptoms.
 - Neurodegenerative disorders such as Niemann–Pick disease, adrenoleukodystrophy, ceroid lipofuscinosis, and subacute sclerosing panencephalitis may rarely present as school-age learning problems.
 - Intellectual disability (mental retardation): Borderline and mild ID are sometimes not recognized until school entrance.
- **Genetics**
 - Some genetic syndromes may show subtle dysmorphism that is not noted until learning problems arise. Examples include:
 - Sex chromosome aneuploidies
 - Fragile X syndrome in both boys and girls
 - Neurofibromatosis
 - Tuberous sclerosis
 - Velocardiofacial/DiGeorge syndrome
- **Nutritional, toxicologic, infections**
 - Lead intoxication, chronic malnutrition, iron deficiency, hypothyroidism, and HIV infection may have insidious effects on cognitive function.
- **Iatrogenic interventions**
 - Some medications (e.g., antiepileptic drugs) affect cognition.
- **Psychosocial**
 - Issues related to family stress, peer relationships, illness, or adolescence may present as academic difficulty.
 - Conversely, behavior problems at home or at school always should prompt evaluation of school functioning.

- **Psychiatric comorbidity occurs commonly**

- Adjustment disorders, mood disorders, oppositional defiant disorder, conduct disorder, tic disorders, substance abuse, and other behavior problems may precede or follow the presentation of learning problems.
- Less commonly, psychotic disorders, personality disorders, and obsessive-compulsive disorder may underlie learning problems.

APPROACH TO THE PATIENT

- Learning problems in general arise from a complex interplay of genetic and environmental factors.
- Many learning problems respond to appropriate educational interventions, regardless of specific etiology, and failure to respond to intervention is part of the diagnostic process for specific learning disabilities.
- It is the role of the educator to (a) monitor the academic progress of all students; (b) provide early educational intervention and frequent progress monitoring to struggling students; and (c) conduct a psychoeducational assessment of students who do not respond to initial intervention.
- Once a child presents with learning problems, it is the role of the physician to:
 - **Phase 1:** Help the family obtain timely educational interventions
 - **Phase 2:** Educate the family and communicate with the educators regarding the above process
 - **Phase 3:** Identify and treat underlying medical problems:
 - Sensory impairments, lead or other intoxication, absence seizures, medication side effects
 - Consider genetic syndromes that may cause learning problems, especially subtle ones such as Fragile X syndrome in girls
 - **Phase 4:** Identify and help treat underlying psychosocial issues:
 - Psychosocial stresses may exacerbate learning difficulties or be a primary etiologic factor.
 - School attendance is a particularly important factor in learning.
 - **Phase 5:** Identify and treat comorbid conditions
 - ADHD, depression, and anxiety may lead to learning problems or comorbid conditions with specific learning disabilities.

HISTORY

- **Question:** When and how does the child fail in his/her daily academic pursuits?
- **Significance:**
 - Learning disabilities typically impact only school activities and are often limited to one skill area such as reading or math.
 - Children with attention disorders typically show problems in multiple settings (school, home, extracurricular, peers).
 - Children with borderline intellectual disability (mental retardation) usually have a long history of developmental concerns.
- **Question:** Is decline in school performance recent and/or abrupt?
- **Significance:** Consider new pathophysiological processes such as new vision or hearing impairment, side effect from new medication, or neurodegenerative disorders (rare)

- **Question:** Past medical history, medications, review of systems, psychosocial stresses?
- **Significance:**
 - School attendance
 - Early development and behavior
 - Family history of learning problems
 - Sleep patterns

PHYSICAL EXAM

- **Finding:** Subtle dysmorphism?
- **Significance:** May suggest the presence of a genetic syndrome or a pattern of malformation resulting from teratogenic fetal exposures (e.g., alcohol, phenytoin)
- **Finding:** Skin lesions?
- **Significance:** May suggest underlying genetic syndromes such as tuberous sclerosis
- **Finding:** Abnormal neurologic examination?
- **Significance:**
 - Any focal signs demand additional evaluation.
 - Soft signs such as slow rapid alternating finger movements (neuromaturational signs) are often present in children with learning problems, but are generally not helpful in diagnosis or treatment.

DIAGNOSTIC TESTS & INTERPRETATION

- **Physician**
 - Audiology and vision screening
 - Standardized behavior questionnaires (e.g., Teachers and Parent Vanderbilt: for evaluation of ADHD)
 - Consider other screening tools for depression, anxiety, family dysfunction, parental depression, and substance abuse
 - Genetic, neurologic evaluation if indicated by history or physical exam
- **Educator**
 - Teachers typically use a variety of screening measures (e.g., DIBELS) or computer-administered tests to frequently monitor progress. Standardized achievement tests can be administered yearly and are used to measure current functioning and review progress.
- **Psychologist**
 - Testing must be performed individually and should include general intelligence and academic achievement testing as a minimum.
 - Federal law requires schools to provide comprehensive evaluations on written request by the parents to the school. Specific information for each state can be obtained from the National Dissemination Center for Children with Disabilities (800-695-0285; www.nichcy.org).
 - Many centers outside the school system (e.g., hospital-based centers) also conduct evaluations of children with learning problems.
 - For children who do not respond to educational interventions, or if the psychoeducational evaluation is inconclusive, more extensive neuropsychological testing may elucidate specific cognitive strengths and weaknesses that may help in developing an effective educational plan.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- **Physician**
 - Responsible for treatment of underlying medical diagnoses
 - Ensure appropriate treatment of psychosocial problems with pharmacological therapy and behavioral therapy (family therapy, social skills training, cognitive-behavioral therapy) as needed
- **Educator**
 - Educational treatment varies with the age and educational level of the child and should follow an approach of increasing intensity as needed (academic improvement plan to 504 plan to IEP).
 - Tier 1: For patients displaying poor academic achievement, begin with extra support (e.g., homework clinic, tutoring) in the regular educational program (assuming culturally and linguistically appropriate instruction).
 - Tier 2: If academic problems disrupt classroom participation and impede progress as measured by universal screening, refer to school-based child study team and provide intensive assistance as part of general curriculum, such as summer school or specialized materials.
 - Tier 3: If child is >1 year behind or has shown minimal response to Tier 2 interventions, refer for a comprehensive psychoeducational evaluation to identify specialized interventions, typically provided under the umbrella of special education
 - Specialized instruction is at the center of treatment, often within the context of a regular classroom (inclusion) with supplemental instruction through either a consultant special teacher or resource room.
 - Children may also benefit from classroom accommodations such as preferential seating, extra time for test taking, electronic word processors and computer applications, recorded books, calculators, note-takers, and modified instructions (oral or written).
 - Treatment is most effective when it uses a team approach, including parents, teachers, and other therapists.
 - Grade retention, which provides only a repeat of the same educational approaches that have already failed the child, will not be helpful.

ONGOING CARE

Children with learning disabilities require continued monitoring of academic progress. Even when the initial learning problems are resolved, later difficulties may arise in writing, note-taking, composition, or organization, and with more abstract academic subjects.

PROGNOSIS

- In most cases, prognosis is quite good with treatment, although learning disabilities never go away.
- Prognosis varies with intensity, timing, and appropriateness of intervention.

- Early diagnosis and treatment is essential for minimizing impact and to take advantage of typical developmental progression.
- Current brain imaging research shows remedial reading instruction alters brain functioning if provided during critical window of development (before age 8–10 years).

CODES

ICD9

- 315.00 Developmental reading disorder, unspecified
- 315.02 Developmental dyslexia
- 315.2 Other specific developmental learning difficulties

ICD10

- F81.0 Specific reading disorder
- F81.2 Mathematics disorder
- F81.9 Developmental disorder of scholastic skills, unspecified

FAQ

- **Q:** What is the evidence that dietary restriction will help control hyperactivity?
- **A:** Despite the many anecdotal reports of value, random controlled studies have not shown that dietary restriction has value when the patients are followed for long term. There is a new study to take another look at food dyes.

CLINICAL PEARLS

- Discourage a “wait and see” approach to decision-making: Early intervention improves outcomes.
- Begin educational interventions as soon as possible (e.g., evidence-based reading intervention); children who do not respond require more thorough etiological workup.
- Academic or attention difficulties may lead to spiraling psychological problems, from depression or damaged self-esteem to conduct disorder and school dropout.

LEUKOCYTOSIS

Susan R. Rheingold

BASICS

DEFINITION

An increase in WBC count above normal for age

RISK FACTORS

- Allergic disorders
- Hematologic disorders
- Immunodeficiencies
- Inflammatory disorders
- Malignancy
- Rheumatologic diagnoses
- No specific genetic abnormality is associated with leukocytosis.

PATHOPHYSIOLOGY

Most frequent cause is an increase in the total neutrophil count, but leukocytosis may result from other type of conditions where WBC count is elevated, such as lymphocytosis, monocytosis, eosinophilia, and basophilia.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

• Infectious

- Bacterial:
 - *Streptococcus* (especially *S. pneumoniae*)
 - *Staphylococcus aureus*
 - *Haemophilus*
 - *Neisseria*
 - *Brucella*
 - *Bartonella* (cat-scratch disease)
 - *Clostridium difficile*
 - Pertussis
- Viral:
 - Infectious mononucleosis
 - Cytomegalovirus
 - Rubella
 - Mumps
 - Hepatitis
- Fungal:
 - *Aspergillus*
- Parasitic:
 - *Toxocara*
 - *Toxoplasma*
 - *Trichinella*
 - Tapeworms
 - *Strongyloides*
 - Coccidioidomycosis
- Tuberculosis
- Syphilis
- Acute infectious lymphocytosis
 - Benign viral mediated lymphocytosis (often > 25,000/mm³)
- Kawasaki disease

• Congenital/Genetic

- Down syndrome
- Sickle cell disease
- Fanconi anemia
- Thrombocytopenia with absent radii
- Leukocyte adhesion deficiency

• Drugs

- Corticosteroids
- Epinephrine and beta-agonists
- Lithium
- Granulocyte colony-stimulating factor
- Granulocyte–macrophage colony-stimulating factor

• Trauma

- Acute hemorrhage
- Severe burns
- Splenectomy

• Tumor

- Leukemia or lymphoma
- Myeloproliferative disorders

• Metabolic

- Hyperthyroidism
- Acidosis

• Inflammatory

- Juvenile idiopathic arthritis
- Rheumatoid arthritis
- Vasculitis
- Inflammatory bowel disease
- Chronic granulomatous disease
- Pulmonary eosinophilic syndromes: Transient infiltrates with a peripheral eosinophilia

• Allergic

- Asthma
- Seasonal or drug allergies
- Eczema
- Psoriasis

• Hematologic

- Severe hemolysis

• Stress

- Anxiety
- Overexertion/exercise
- Seizures
- Anesthesia

• Artfactual

- Nucleated RBCs

ALERT

Beware of any differential that has a high percentage of monocytes or atypical lymphocytes, whether machine generated or manual. Leukemic blasts can be mistaken for these cell types.

APPROACH TO THE PATIENT

- **Phase 1:** Which WBC line is elevated?
 - Elevated neutrophil count is more likely with bacterial infections; lymphocytosis is usually associated with viral infections.
 - Eosinophilia: Possible allergic disorder
- **Phase 2:** Degree of elevation can be indicative of the diagnosis:
 - Most elevations of WBC count are in the 15,000–20,000/mm³ range.
 - WBC count in the 30,000/mm³ range is more consistent with pertussis, pneumococcal infection, or acute infectious lymphocytosis.
 - Higher counts are worrisome for acute or chronic leukemia or leukemoid reactions.
- **Phase 3:** Other signs/symptoms present?
 - Is there an obvious infectious source?
 - Fever, rash, and mild anemia are nonspecific and associated with infection, rheumatologic process, or malignancy.
 - Pallor or petechiae should make one think of hematologic or oncologic process.
- **Phase 4:** Is the WBC count dangerously elevated?
 - WBC count of 100,000/mm³ can increase viscosity, causing neurologic or respiratory distress.
 - WBC counts this high almost always indicate malignant bone marrow processes (leukemia, myeloproliferative disorder) and should be referred immediately to a hospital with a pediatric oncologist.
 - Children with elevated WBC counts with anemia and/or thrombocytopenia should be referred to a pediatric hematologist or oncologist to evaluate for malignancy.

ALERT

Many laboratories provide only machine-generated differentials. If there are any abnormalities, a manual differential must be obtained. It may be necessary to review the smear with a hematologist or pathologist.

HISTORY

- **Question:** Evidence for infection—fever, rash, or swelling?
- **Significance:**
 - Acute infection is the most common cause for leukocytosis.
 - Thorough history should be taken for apparent or occult infections.
 - Fever can also be a symptom of inflammatory diseases.
- **Question:** Other complaints?
- **Significance:** Chronic cough may point to tuberculosis; a whooping cough may indicate pertussis. Intermittent joint pain, rash, and/or fevers may point to a rheumatologic diagnosis.

- **Question:** Other medical problems?
- **Significance:**
 - Sickle cell disease: Elevated WBC count probably secondary to chronic inflammation or marrow expansion
 - Down syndrome: Transient myeloproliferative disease (especially in the first few months of life) that resolves spontaneously
- **Question:** Medications?
- **Significance:**
 - Corticosteroids will increase the neutrophil precursors.
 - Epinephrine can cause a transitory increase in neutrophil count.
- **Question:** Familial history of inflammatory diseases?
- **Significance:** Rheumatoid arthritis, thyroiditis, Crohn disease
- **Question:** Weight loss, chronic fatigue, night sweats, or pallor?
- **Significance:** Malignancy must be ruled out.

PHYSICAL EXAM

- **Finding:** Foci of infection?
- **Significance:**
 - Look for cellulitis, otitis, pharyngitis, or abscesses on examination
 - A careful lung examination is necessary since pneumonia can cause a WBC count as high as 30,000–40,000/mm³.
 - A murmur or gallop may be a sign of bacterial endocarditis.
 - Urinary tract infections (UTIs) present with dysuria and cloudy urine, vasculitis with bloody urine or stool.
- **Finding:** Lymphadenopathy or hepatosplenomegaly?
- **Significance:** Points toward a possible viral etiology but is also of concern for malignancy
- **Finding:** Tender or swollen joints or nonspecific bone pain?
- **Significance:** May indicate juvenile idiopathic arthritis, septic arthritis, or systemic lupus erythematosus
- **Finding:** Stigmata of Down syndrome?
- **Significance:** Transient Myeloproliferative Disease of infant

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** WBC count including manual differential
- **Significance:**
 - If neutrophilia is present, think of bacterial infections.
 - Pneumonia, UTIs, and soft-tissue infections are the most likely to cause leukocytosis.
 - May see Döhle bodies, toxic granulations, or vacuolization in WBCs in bacteremia
 - Recovering or stressed marrow may have an increase in monocytes or eosinophils.
 - Look for leukemic blasts
- **Test:** Hemoglobin/platelet count
- **Significance:** If either is low, consider a marrow-infiltrative process or a marrow that is hyperstimulated and overproducing WBCs as part of a response to a low hemoglobin or platelet count.
- **Test:** Chemistry panel
- **Significance:**
 - Liver function tests: Possible viral etiology
 - Uric acid and lactate dehydrogenase are elevated in leukemia and lymphoma.

- **Test:** Cultures
- **Significance:** Blood, urine, stool, throat, and others
- **Test:** Screen for infectious mononucleosis
- **Significance:** Mono spot, heterophil antibodies
- **Test:** EBV titers
- **Significance:** Mono spot can be falsely negative in younger children.
- **Test:** Leukocyte alkaline phosphatase
- **Significance:**
 - Elevated in infection but not in leukemia
 - Helps to differentiate chronic myelogenous leukemia from a leukemoid reaction
- **Test:** Antinuclear antibody/rheumatoid factor/anti-neutrophil cytoplasmic antibodies
- **Significance:** Nonspecific screen for rheumatologic etiology
- **Test:** Bone marrow biopsy and aspirate
- **Significance:**
 - Necessary if any other blood cell line is abnormally low or if the WBCs appear dysmorphic
 - Need to rule out malignancy, myelodysplasia, or other marrow processes. Should be performed at a pediatric oncology center.

Imaging

Chest radiograph for pneumonia, tuberculosis

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Antibiotics immediately if a child appears septic, otherwise tailor antibiotics to the underlying infectious etiology
- If an underlying rheumatologic, hematologic, or genetic cause is suspected, refer to the appropriate specialist.
- If leukemia is suspected, start hydration with fluids containing bicarbonate and no potassium, and administer oral allopurinol or urate oxidase.
- If the leukocytosis is > 100,000/mm³ and the patient has symptoms of end-organ failure, emergent leukapheresis should be considered.

ISSUES FOR REFERRAL

- WBC counts > 50,000/mm³
- Associated thrombocytopenia or anemia
- Any indication of malignancy
- Any indication of a rheumatologic etiology
- Inability to find an etiology with a persistent leukocytosis

ONGOING CARE

Following appropriate treatment the WBC should return to normal. If it remains elevated or other symptoms persist the differential should be expanded to include noninfectious etiologies.

CODES

ICD9

- 288.3 Eosinophilia
- 288.8 Other specified disease of white blood cells
- 288.60 Leukocytosis, unspecified

ICD10

- D72.1 Eosinophilia
- D72.828 Other elevated white blood cell count
- D72.829 Elevated white blood cell count, unspecified

FAQ

- Q: What does “left-shifted” mean?
- A: Increased numbers of early granulocyte precursors (metamyelocytes, myelocytes, bands) are seen in the peripheral smear with a bandemia and neutrophilia. They are often seen with bacterial infections or marrow recovery from a suppressing drug/virus.
- Q: Infectious mononucleosis and acute lymphoblastic leukemia have many similar signs and symptoms. How can I differentiate them?
- A: Both can present with fever, malaise, headache, prominent lymphadenopathy, organomegaly, and suppressed hemoglobin and platelet counts. Infectious mononucleosis is associated with a sore throat, and acute lymphocytic leukemia with bone pain. The best test to differentiate between the two is the peripheral smear morphology. A heterophil AB or mono spot, if positive, helps with the diagnosis of infectious mononucleosis.
- Q: Is the degree of elevation of WBC significant?
- A: For most bacterial infections the WBC has not been found to be a sensitive or specific indicator of the seriousness of the infection. Leukocytosis has been found to be a predictor for the development of hemolytic uremic syndrome in patients with *Escherichia coli* O157:H7 infection. Higher presenting WBC count in leukemia has been associated with higher risk and worse outcomes.

LICE (PEDICULOSIS)

Alyssa Siegel

J. Nadine Gracia (5th edition)

BASICS

DESCRIPTION

Infestation of the head, body, or anogenital region

EPIDEMIOLOGY

- Head lice:
 - Common in children 3–12 years of age, especially in daycare settings and school-age children
 - Affects all socioeconomic groups
 - Less common in African American children
 - Not indicative of poor hygiene
 - Not influenced by hair length, or frequency of brushing/shampooing
- Body lice:
 - Found on persons with poor hygiene
 - More common in extreme conditions such as crowding, homelessness
- Pubic lice:
 - Most common in adolescents and young adults

Incidence

Estimated 6–12 million cases per year in US.

GENERAL PREVENTION

- Examine household members and treat those who are infested.
- Prophylactically treat bed mates.
- Environmental cleaning is controversial and may not be necessary. Only items in contact with the infested person within 24–48 hours need be considered:
 - Wash bedding, clothes, and cloth toys in hot water (> 128°F).
 - Treat combs and hairbrushes by washing in hot water and soaking in pediculicide.
 - Seal anything not washable in plastic bags for 14 days.
 - Environmental insecticide is not helpful in the control of head lice.
 - Treatment of pets is not necessary.
- School attendance: “No-nit” school policies do not control head lice transmission and are not recommended. Children who have been treated with appropriate pediculicide should be allowed to return to school.

PATHOPHYSIOLOGY

- Head lice:
 - Female, adult louse survives for 3–4 weeks on scalp, laying up to 10 eggs per day
 - Eggs attach to base of hair, close to the scalp, camouflaged with pigment to match hair color
 - Eggs incubate by body heat, hatch within 7–12 days, leaving white empty shell (nit) on hair
 - Nymph emerges, passing through 3 stages in 9–12 days, reaching the adult stage capable of mating and laying viable eggs
 - Nymphs and adult lice feed on scalp blood, inject saliva, causing sensitization and associated pruritus

- Body lice:
 - 10–20% larger than head lice
 - Prefer to live on clothing, visiting human only to feed
 - Lay eggs along seams of clothing, which hatch when warmed by wear
 - Incubation period 6–10 days
 - Transmitted through contact with infested clothing or bedding
- Pubic lice:
 - Crab-like appearance with predilection for pubic hair
 - May also infest axillary hair, perineal area, eyelashes, eyebrows, and rarely scalp
 - Transmitted almost exclusively by sexual contact
 - Uncommonly spread by fomites (e.g., towels, bedding)
 - May infest eyebrows/lashes (pediculosis palpebrarum) in young children (associated with maternal infestation, but must consider possible sexual abuse)

ETIOLOGY

- 3 species of ectoparasites (6-legged, wingless, 1–4 mm insects that live on humans, feeding on human blood):
 - *Pediculus humanus capitis*: Head louse
 - *P. humanus corporis*: Body louse
 - *Phthirus pubis*: Pubic or crab louse
- Transmission:
 - Direct contact with hair or skin of an infested individual
 - Indirect spread of head lice via personal belongings (i.e., combs, brushes, hats) occurs rarely in head lice, more often in body lice; head lice only survive for 1–2 days away from the scalp, body lice 5–7 days.

COMMONLY ASSOCIATED CONDITIONS

- Head lice: Do not transmit disease. Rarely secondary scalp impetigo, cervical and occipital lymphadenopathy may develop.
- Body lice: Can act as vector for transmission of *Rickettsia prowazekii*, *Bartonella quintana*, and *Borrelia recurrentis* (causing endemic typhus, trench fever, relapsing fever); secondary bacterial skin infections due to pruritus.
- Pubic lice: Up to 50% of patients have another STD, particularly gonorrhea or syphilis.

DIAGNOSIS

HISTORY

- Pruritus is the most common symptom, although some patients are asymptomatic.
- Intense nighttime pruritus is common with body lice.
- Special questions:
 - Ask about possible infested contacts (home, school, or sexual).
 - Ask about special living circumstances such as crowding or institutionalization.

PHYSICAL EXAM

- Direct visualization of live lice provides definitive diagnosis of active infestation:
 - Head lice may be difficult to identify as lice crawl quickly in response to a perceived threat, including light. Body lice sequester in clothing.
 - Wet combing with conditioner, oil, or water has been suggested to slow the movement of lice prior to inspection.
- Nits, empty egg cases attached to base of hair shaft, may indicate historic infestation, but suggest active infestation if within 1 cm of scalp.
 - Often clustered in parietal and occipital regions, in the perianal region (for pubic lice), or in the seams of clothing (for body lice)
 - Difficult to dislodge (unlike dandruff, hair casts, or debris)
- Bites from body lice result in pinpoint, erythematous macules, papules, wheals, or excoriation
- Other findings:
 - Secondary skin lesions (e.g., impetigo, excoriation); dermatitis of the neck, shoulder area
 - Cervical or occipital lymphadenopathy with head lice
 - Secondary infestation in eyebrows and/or eyelashes
 - Post-inflammatory hyperpigmentation with body lice
 - Maculae cerulea (sign of heavy pubic infestation): Bluish/slate macules, 0.5–1-mm diameter, usually on lower abdomen, thighs, buttocks

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

Tests are rarely necessary. Can examine louse or nit using hand lens or under microscope.

DIFFERENTIAL DIAGNOSIS

- Seborrheic dermatitis
- Contact dermatitis
- Eczema
- Impetigo
- Scabies

TREATMENT

MEDICATION (DRUGS)

Head and pubic lice:

- Permethrin (Nix) 1% cream rinse:
 - Neurotoxic to lice, ovicidal, residue on hair kills newly hatching nymphs as they emerge
 - Generally used as first-line therapy
 - High cure rate; resistance reported, but prevalence unknown
 - 10-minute application to damp hair, followed by optional 2nd application 7–10 days later
 - OTC preparation, low toxicity
- Pyrethrins (Rid, A-200):
 - Neurotoxic to lice, low ovicidal activity
 - Efficacy substantially reduced due to resistance, although highly variable among communities; not effective if resistant to permethrin.
 - 10-minute application to dry hair, 2nd application 7–10 days later to kill newly hatched
 - OTC preparation
 - Contraindicated in persons allergic to chrysanthemums or ragweed

- Malathion (Ovide) 0.5%:
 - True ovicidal activity; highly effective, although countries with long-term use now showing resistance
 - Requires 8–12-hour application to dry hair; 2nd application 7–10 days later only if live lice are present
 - Safety concerns: Theoretical risk of respiratory distress if ingested; flammability (due to alcohol base). Patients should be warned not to use external heat sources including hair dryers during treatment.
 - Not for use in children <24 months due to increased absorption through the scalp (safety not established for children <6 years)
- Benzyl alcohol 5%:
 - Kills lice by asphyxiation; no ovicidal activity
 - For use in children >6 months
 - Apply for 10 minutes, repeat in 7–9 days
 - Common adverse reactions include pruritus, erythema, pyoderma, ocular irritation
- Lindane (Kwell) 1% lotion:
 - No longer recommended due to human neurotoxicity, reports of severe seizure and death in children, high resistance/lack of efficacy
- Controversial treatments:
 - Sulfamethoxazole–trimethoprim (Bactrim): Not FDA approved as a pediculicide. Used with topical permethrin, may improve cure rate for treatment failures; 10-day course advised
 - Ivermectin: Not FDA approved as a pediculicide. For cases resistant to topical treatment, can be given as a single oral dose of 200 mcg/kg followed by 2nd dose 7–10 days later. Blocks neural transmission if it crosses blood–brain barrier (younger children at higher risk). Not for use in children <15 kg.
 - Essential oils such as lavender, peppermint, eucalyptus, coconut, anise, ylang-ylang, and tea tree oil may have some activity against lice and eggs, but preparations are unregulated, and some have potential for contact allergy and prepubertal gynecomastia.
 - A mechanical device delivering hot air to the scalp has shown successful desiccation of lice, but is expensive and requires training for use.
- Other considerations:
 - Topical corticosteroids and oral antihistamines for pruritus and inflammation
 - Antibiotics for impetiginized lesions

ALERT

Pediculosis palpebrarum: Pediculicides are oculotoxic and must be avoided.

ADDITIONAL TREATMENT**General Measures**

- Head lice:
 - Wash hair with nonconditioning shampoo and towel dry.
 - Apply pediculicide (See “Medication”)
 - If nit removal desired, comb through with a fine-tooth nit comb.
 - No clinical benefit of vinegar-based products for nit removal has been demonstrated and may interfere with pediculicide use.
 - No data to determine whether suffocation of lice by application of petroleum jelly, olive oil, or mayonnaise is effective.
- Body lice:
 - Pediculicide usually not necessary (insects live in clothing)
 - Improve hygiene.
 - Wash clothing and bedding in hot water at least weekly.
 - Dry cleaning is effective, as is hot ironing (particularly along seams of clothing).
- Pubic lice:
 - Apply pediculicide and retreat 7–10 days later with pediculicide.
 - Treat sexual contact to prevent reinfestation.
 - Removal of nits from pubic hair with fine-tooth comb is helpful.
- *P. palpebrarum*:
 - Petrolatum ointment applied to lashes 2–4 per day for 8–10 days
 - Remove nits by hand from the eyelashes.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Itching or mild burning of scalp is common up to 2 weeks after use of topical agents.
- Risk of transmission is promptly reduced after a single application of pediculicide. Child may return to school or day care immediately after treatment.
- Recurrence of symptoms represents improper use of the treating agent, reinfestation, resistance, failure to recognize and treat other sites of infestation, such as perianal hair, axillary hair, or sexual contacts (in *P. pubis*.)

- B85.3 Phthiriasis
- B85.4 Mixed pediculosis and phthiriasis

FAQ

- Q: Did my child get head lice because my house or my child is not clean enough?
- A: No. Head lice are unrelated to personal hygiene.
- Q: Should I cut my child's long hair to get the lice out?
- A: No. Meticulous application of the pediculicide to the entire scalp and pulling through all hair shafts is adequate treatment. Head lice infestation is not influenced by hair length.
- Q: Can infants become infested with pubic lice (*P. pubis*)?
- A: Yes. Although the primary mode of transmission of the crab louse is via sexual contact, it can be transmitted through close personal contact with an infested individual. Small children become infested on the eyebrows or lashes with crab lice.
- Q: If children are infested with the head lice, how can items such as stuffed animals or other cloth toys be decontaminated?
- A: Machine washable items can be washed in hot water at temperatures > 128°F. An alternative method of decontamination is sealing the items in a plastic bag for 10–14 days.
- Q: Is removal of nits necessary to prevent spread?
- A: No. They can be removed for cosmetic reasons by using a fine-tooth comb.
- Q: What is appropriate treatment of infestation of the eyelashes?
- A: A petroleum ointment should be applied 2–4 times daily for 8–10 days. Nits should be removed mechanically from the lashes.

LOWER GI BLEEDING

Kristin N. Fiorino

Maria R. Mascarenhas

BASICS

DEFINITION

Lower GI bleeding refers to bleeding from the lower GI tract, distal to the ligament of Treitz

ETIOLOGY

Reasons for lower GI bleeding at different ages:

- Neonatal period (birth to 1 month):
 - Anorectal fissure
 - Necrotizing enterocolitis
 - Enteric infections
 - Allergic colitis
 - Upper GI source
 - Duplication cyst
 - Hirschsprung disease enterocolitis
 - Meckel diverticulum
 - Malrotation with volvulus
 - Hemorrhagic disease of the newborn
- Infancy (1 month to 2 years):
 - Anorectal fissure
 - Enteric infections
 - Allergic colitis
 - Intussusception
 - Meckel diverticulum
 - Malrotation with volvulus
 - Lymphonodular hyperplasia
 - Upper GI source
 - Duplication cyst
 - Enterocolitis with Hirschsprung disease
 - Vascular malformation
- Preschool age (2–5 years):
 - Anorectal fissure
 - Enteric infections
 - Polyps
 - Parasites
 - Meckel diverticulum
 - Intussusception
 - Lymphonodular hyperplasia
 - Inflammatory bowel disease
 - Hirschsprung disease enterocolitis
 - Hemolytic uremic syndrome
 - Henoch-Schönlein purpura
 - Vascular malformation
 - Volvulus
 - Rectal prolapse/rectal ulcer
 - Child abuse
 - Perianal streptococcal cellulitis
- School age (5–13 years):
 - Anorectal fissure
 - Enteric infections
 - Inflammatory bowel disease
 - Intussusception
 - Meckel diverticulum
 - Polyps
 - Henoch-Schönlein purpura
 - Hemolytic uremic syndrome
 - Intestinal ischemia
 - Neutropenic colitis (typhlitis)
 - Parasites
 - Child abuse
 - Vascular malformations
 - Perianal streptococcal cellulitis

- Adolescent (> 13 years):
 - Anorectal fissure
 - Enteric infections
 - Inflammatory bowel disease
 - Hemolytic uremic syndrome
 - Intussusception
 - Midgut volvulus
 - Intestinal ischemia
 - Neutropenic colitis (typhlitis)
 - Polyps
 - Vascular malformations
 - Lymphonodular hyperplasia
 - Parasites
 - Hemorrhoids

DIAGNOSIS

- General goals: Determine location of the bleeding and cause, and begin stabilization and treatment.
 - Phase 1: Determine if there is blood or other cause of bright red or black stools.
 - Phase 2: Assess patient to determine etiology; follow history, physical, and laboratory.
 - Phase 3: Stabilize patient, decide if emergency treatment or referral is needed. (See “Emergency Care” under “Treatment.”)
- Hints for screening problem:
 - The more rapid the rate, the larger the volume of lower GI bleeding, and greater the drop in hemoglobin and change in pulse and BP.
 - Any significant blood loss will lead to pallor, tachycardia, orthostasis, poor capillary refill, CNS changes (restlessness, confusion), and hypotension.
 - Hypotension may not be seen even in the face of significant blood loss, because vasoconstriction will occur to maintain BP until decompensation.
 - Initial hemoglobin values may be unreliable, because a delay in hemodilution may falsely result in near-normal values.
 - In newborn, determine if this is swallowed maternal blood by the Apt–Downey test.

HISTORY

- Obtain a detailed history and note if any recently ingested foods resemble blood.
- Color of blood:
 - If bright red, then site of bleeding is probably in left colon, rectosigmoid, or anal canal
 - If darker red, then from right colon
 - If melena or tarry, then bleeding is proximal to ileocecal valve
- Location of blood in relation to the stool:
 - In colitis, the blood will be mixed with stool
 - With a fissure/constipation, it will be in streaks on the outer aspect of the stool
- Consistency of the stool:
 - If diarrhea, more likely to be colitis
 - If hard, then more likely to be a fissure/constipation
- Painful stools suggest anal fissure, local proctitis, or ischemic bowel.

- Painless rectal bleeding is associated with polyps, Meckel diverticulum, nodular lymphoid hyperplasia of colon, intestinal duplication, intestinal submucosal mass (GIST), or vascular anomaly.
- Abdominal pain can be seen with colitis, inflammatory bowel disease, or surgical abdomen.
- Any underlying known GI disease, previous GI surgery: Past history of colitis, Hirschsprung disease, necrotizing enterocolitis
- Any history of jaundice, hepatitis, liver disease, neonatal history: Suggestive of portal vein thrombosis (sepsis, shock, exchange transfusion, omphalitis, IV catheters), portal hypertension, and variceal bleeding
- Any familial history of bleeding diathesis: von Willebrand disease, hemophilia
- Medications: Heparin, warfarin
- Associated symptoms:
 - Mouth ulcers
 - Weight loss
 - Joint pains as in inflammatory bowel disease
 - Petechiae
 - Renal insufficiency
 - History of ingestion of uncooked meat as in hemolytic uremic syndrome
 - Purpuric rash as in Henoch-Schönlein purpura
 - Severe abdominal pain and vomiting as in a surgical abdomen

PHYSICAL EXAM

- Skin:
 - Petechiae or purpura
 - Ecchymosis
 - Hemangiomas
 - Evidence of chronic liver disease (spider angiomas, palmar erythema)
 - Jaundice
- HEENT:
 - Freckles on buccal mucosa: Peutz-Jeghers syndrome
 - Mouth ulcers: Crohn disease
 - Icteric sclera: Portal hypertension
- Abdomen:
 - Hepatosplenomegaly, ascites: Portal hypertension
 - Isolated splenomegaly: Cavernous transformation of the portal vein
- Rectal examination:
 - Evidence of any perianal disease: Inflammatory bowel disease
 - Polyps: Bright red blood in stool
 - Hemorrhoids: Portal hypertension

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC: Iron-deficiency anemia:
 - Leukopenia, anemia, and thrombocytopenia: Consider chronic liver disease and portal hypertension
 - Anemia with normal RBC indices: Truly an acute cause for bleeding
 - RBC indices indicate iron-deficiency anemia: Consider varices or a mucosal lesion, i.e., chronic blood loss
 - Thrombocytopenia: Consider hemolytic uremic syndrome

- Coagulation profile:
 - If PT and PTT are abnormal, consider liver disease or disseminated intravascular coagulation with sepsis.
- Liver function tests: Abnormal in chronic liver disease
- Renal function tests (BUN, creatinine, urine analysis): Abnormal in hemolytic uremic syndrome, Henoch-Schönlein purpura, acute bleed
- ESR or C-reactive protein (CRP): Abnormal in inflammatory disorders or infectious colitis
- Stool tests:
 - Stool culture (Salmonella, Shigella, Campylobacter, Yersinia, Aeromonas, Escherichia coli), Klebsiella
 - Stool for Clostridium difficile toxin A and B
 - 3 stool samples for ova and parasites (Amebae)
 - Stool smears for WBCs (not always positive in colitis) and eosinophils (not always positive in allergic colitis)
 - Stool CMV: Consider in immunocompromised

Imaging

- Abdominal x-ray helpful in surgical abdomen (dilated bowel, air–fluid levels, perforation), constipation (presence of excessive stool), colitis (edematous bowel, thumb-printing), pneumatosis intestinalis, and toxic megacolon
- Ultrasound can show bowel wall thickening and Meckel diverticulum and is diagnostic of intussusception.

Diagnostic Procedures/Other

- Lower and upper endoscopy:
 - Full colonoscopy to the terminal ileum helpful in diagnosing inflammatory bowel disease
 - Upper endoscopy diagnostic in massive upper GI bleeds presenting with hematochezia or melena
 - Push enteroscopy involves the passage of a special endoscope further in the small bowel, identifying rare lesions in the proximal 60–120 cm of the jejunum.
 - Double balloon enteroscopy: assists in further evaluating the entire GI tract
- Barium tests:
 - Air-contrast enema is diagnostic and therapeutic in intussusception and diagnostic in mucosal lesions (polyps).
 - Upper GI series with small-bowel follow-through is helpful in evaluating anatomy and Crohn disease and its complications (fistula, sometimes ulcer may be identified).
 - Enteroclysis or small bowel enema provides good mucosal detail.
- Meckel scan:
 - Diagnostic for Meckel diverticulum that secretes acid (can use H2-receptor antagonist to enhance uptake)
 - There may be false negatives if the Meckel diverticulum has different tissue expression.
- Bleeding scan:
 - Useful when endoscopy is not diagnostic
 - Technetium sulfur colloids versus tagged RBC scan: The former detects rapid bleeding but can miss small bleeds, especially if the patient is not bleeding during the scan. The latter can detect small bleeds, especially if intermittent.
- Angiography:
 - Useful in detecting vascular causes for GI bleeding >0.5 mL/min
 - Can also be therapeutic

- Video capsule endoscopy:
 - Useful in detecting distal small bowel hemorrhage
 - Approved for ages >2 years

DIFFERENTIAL DIAGNOSIS

- The majority of patients with lower GI bleeding have a fissure or infection.
- Mucosal lesions are more likely to be associated with antecedent occult bleeding.
- In most, the bleeding stops spontaneously.
- Pitfalls:
 - Make sure red substance in stool is really blood.
 - Initial hemoglobin, if normal, may be misleading.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Anal fissure: Treat the underlying constipation (mineral oil, lactulose, MiraLax, high-fiber diet, increased water intake). Local therapy consists of sitz baths, local emollient creams, and steroid suppositories.
- Polyp: Colonoscopy and polypectomy
- Intussusception: Ultrasound is diagnostic. Air-contrast enema permits confirmation and hydrostatic reduction.
- Parasites: Antiparasitic drugs

ISSUES FOR REFERRAL

Refer the following patients to a specialist:

- Any patient with significant acute lower GI bleeding after initial stabilization
- Patients with less acute bleeding for whom an easily identifiable cause has not been found or patients with chronic or recurrent lower GI bleeding

SURGERY/OTHER PROCEDURES

In cases of massive or persistent bleeding with no identifiable site, exploratory laparotomy with intraoperative endoscopic evaluation of the entire bowel to identify mucosal lesions may be required.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Emergency care:

- If patient is critical, stabilize with IV fluids and blood products.
- Order laboratory tests: CBC, PT/PTT, disseminated intravascular coagulation screen, liver function tests, blood type, and cross-match
- Insert a nasogastric tube and lavage with saline to distinguish massive bleeding from an upper GI tract source.
- Monitor patient’s vital signs and hemoglobin.
- Make appropriate diagnosis and institute appropriate therapy, i.e., abdominal x-ray, colonoscopy, bleeding scans.

ONGOING CARE

DIET

Introduce hydrolyzed protein formula in infants with cow’s milk protein allergy.

CODES

ICD9

- 565.0 Anal fissure
- 578.9 Hemorrhage of gastrointestinal tract, unspecified
- 777.50 Necrotizing enterocolitis in newborn, unspecified

ICD10

- K60.2 Anal fissure, unspecified
- K92.2 Gastrointestinal hemorrhage, unspecified
- P77.9 Necrotizing enterocolitis in newborn, unspecified

FAQ

- Q: What is the most common cause of lower GI bleeding?
- A: In all age groups, fissures are the leading cause, followed by infections. However, in infancy, the most common cause is a fissure; in toddlers and young children, polyps; and in older children, inflammatory bowel disease.
- Q: What common foods cause stools to be red? Black?
- A: Red: Raspberries, cranberries, Kool-aid, artificial coloring in cereal. Black: Bismuth, spinach, blueberries, licorice.

LUPUS ERYTHEMATOSUS

Elizabeth Candell Chalom

BASICS

DESCRIPTION

Multisystem, autoimmune disease characterized by production of antibodies to various components of cell nucleus, in conjunction with variety of clinical manifestations

EPIDEMIOLOGY

- Age: 20% of lupus begins in childhood, but it is very rare under 5 years old
- Female:Male ratio: Between 3–5:1 (prepubertal) and 9–10:1 (postpubertal)
- SLE occurs about 3 times more often in African Americans than Caucasians. It is also more common in Hispanic, Asian, and Native Americans.

Incidence

- Peak incidence: Between ages 15 and 40 years
- Incidence in children is from 10–20/100,000

Prevalence

- U.S. estimate: 5,000–10,000 children

RISK FACTORS

Genetics

- Increased frequency in 1st-degree family members of patients with SLE
- 10% of patients have ≥ 1 affected relative.
- Concordance rate of 25–50% in monozygotic twins and 5% in dizygotic twins
- Some major histocompatibility antigens are associated with increased incidences of lupus, such as HLA-DR2 and DR3 in whites and DR2 and DR7 in blacks.

ETIOLOGY

Although exact etiology is unknown, lupus is an autoimmune disease, with genetic, environmental, and hormonal factors playing a role.

DIAGNOSIS

Diagnostic criteria: 4 of following 11 criteria, developed by the American College of Rheumatology, must be met to classify a patient as having SLE:

- Malar (butterfly) rash,
- Discoid rash,
- Photosensitivity,
- Oral or nasal ulcers,
- Arthritis,
- Cytopenia: Anemia, leukopenia ($<4,000/\text{mm}^3$), lymphopenia ($<1,500/\text{mm}^3$), or thrombocytopenia ($<100,000/\text{mm}^3$),
- Neurologic disease: Seizures or psychosis
- Nephritis: >0.5 g/d proteinuria or cellular casts
- Serositis: Pleuritis or pericarditis
- Positive immunoserology (revised 1997): Antibodies to double-stranded DNA or Smith nuclear antigen, false-positive serologic test for syphilis, lupus anticoagulant, or antiphospholipid antibodies
- Positive ANA

HISTORY

- History of photosensitivity or malar rash common but not necessary
- Many patients have systemic complaints, such as fevers, fatigue, and malaise.
- Many patients complain of joint pain, Raynaud's phenomenon, or alopecia.
- Chest pain from pericarditis or pleural effusions may be present.
- Signs and symptoms:
 - Immune complex–mediated vasculitis, which can occur in almost any organ system
 - Cutaneous lesions: Very variable. Include:
 - Erythematous malar or “butterfly” rash
 - Maculopapular rashes (which can occur anywhere on body)
 - Periungual erythema
 - Mucosal membrane vasculitis
 - Arthritis: Can affect large and small joints; usually symmetric and nonerosive
 - Hematologic pathology: Includes:
 - Hemolytic anemia
 - Anemia of chronic disease
 - Leukopenia
 - Lymphopenia
 - Thrombocytopenia

– Neurologic symptoms include:

- Headaches
- Psychosis
- Depression
- Seizures
- Organic brain syndromes
- Peripheral neuropathies
- Renal pathology (present in up to 75% children with SLE):
 - Includes mesangial changes and glomerulonephritis (focal, diffuse, proliferative, or membranous)
 - 1st signs of renal disease in lupus patient are often proteinuria and active urinary sediment.
 - Hypertension, nephrotic syndrome, and renal failure can also occur.
- Serositis: Usually seen as pericarditis or pleuritis, but peritonitis can also occur.
- Constitutional symptoms are very common: Fatigue, weight loss, fever

PHYSICAL EXAM

- Rash: May be malar, discoid, or vasculitic. Periungual erythema may also be seen.
- Oral or nasal ulcers (usually on hard or soft palate) that are painless and often go unnoticed by patients
- Arthritis of large and small joints
- Pericardial friction rub if patient has pericarditis
- Edema may be present secondary to renal disease.
- CNS changes such as personality changes, psychosis, or seizures

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- ANA:
 - Found in $>95\%$ patients with SLE, but a positive ANA can occur in many diseases and in up to 20% of normal population
- Anti–double-stranded DNA and anti–Smith nuclear antigen:
 - Very specific to lupus, but not all patients with lupus have these autoantibodies. In many patients, anti-DNA levels vary with activity of disease.
- CBC:
 - Anemia, leukopenia, lymphopenia, and/or thrombocytopenia may be seen.

- Urinalysis:
 - May show proteinuria or active urinary sediment if there is renal dysfunction
- Complement levels:
 - Can fall very low during a lupus flare (C3 and C4)
- PTT:
 - Patients may also have prolonged PTT, as result of antiphospholipid (APL) antibodies, often seen in SLE. Patients with APL antibodies at increased risk for thrombotic events, such as deep venous thromboses, strokes, and fetal losses during pregnancies.

DIFFERENTIAL DIAGNOSIS

- Systemic juvenile-onset rheumatoid arthritis
- Oncologic disease (leukemia, lymphoma)
- Viral or other infectious illness
- Other vasculitic disorders
- Dermatomyositis
- Fibromyalgia
- Drug-induced lupus
- Pitfalls:
 - Avoid overdiagnosis; positive ANA in the absence of clinical signs or symptoms of SLE is not lupus.

TREATMENT

MEDICATION (DRUGS)

- NSAIDs may be used for musculoskeletal and mild systemic complaints, although ibuprofen has been noted to cause aseptic meningitis in a small number of patients with SLE. NSAIDs can also exacerbate renal disease in lupus.
- Hydroxychloroquine often used to help control cutaneous manifestations and to help minimize the chance of lupus flares.
- Steroids often necessary to control systemic and renal manifestations
- Patients with renal disease often need immunosuppressive agents, such as cyclophosphamide (usually given as monthly IV boluses). Mycophenolate mofetil, cyclosporin, or azathioprine may also be used.
- Patients with mainly arthritic symptoms may be treated with weekly methotrexate, PO or SC
- Patients with antiphospholipid antibodies are often treated with a baby aspirin daily. If they have already had a significant clotting event, they need stronger anticoagulation.
- Angiotensin-converting enzyme (ACE) inhibitors are often used to help prevent renal damage from proteinuria.

- Patients with abnormal lipid profiles that do not respond to diet may need statins.
- Rituximab (anti-CD20 antibody) causes B-cell depletion and is used in SLE, especially for thrombocytopenia.
- Other biologic agents also being tested in lupus. A BlyS (B lymphocyte stimulator) inhibitor has been approved in adults but has not yet been tested in children. Antibodies to CD40 and C5 are also being studied.
- Plasmapheresis and IVIG have been used as well.

ADDITIONAL TREATMENT

General Measures

Avoid excessive sun exposure and use sunscreen liberally.

Additional Therapies

For very severe lupus, bone marrow immunoablation or transplantation are options.

ONGOING CARE

PROGNOSIS

- Extremely variable. Renal disease and CNS involvement are poor prognostic signs, whereas systemic complaints and joint findings are not.
- 10-year survival in children presenting with SLE is >90%

COMPLICATIONS

- End-stage renal disease
- Infections secondary to treatments used to control disease
- Atherosclerosis and myocardial infarctions at a young age
- Libman-Sacks endocarditis, which increases risk of subacute bacterial endocarditis.
- Neonatal lupus:
 - Neonatal lupus (NLE) is due to maternal autoantibodies (usually SS-A or SS-B antibodies) that cross the placenta and can cause rashes, congenital heart block, cytopenias, and/or hepatitis in the newborn baby.
 - Most symptoms of NLE resolve by 6 months of age, but the heart block, if it occurs, is permanent.
 - Many mothers of babies with NLE are asymptomatic and unaware that they have these autoantibodies.
 - The rash, erythema annulare, can begin a few days after delivery or within the 1st few weeks of life.
 - Topical steroids can minimize the lesions. Congenital heart block is due to damage of the conducting system of the developing fetal heart.
 - Bradycardia may be noted by 22 weeks' gestation, and CHF with nonimmune hydrops fetalis may ensue.

- 710.0 Systemic lupus erythematosus

ICD10

- L93.0 Discoid lupus erythematosus
- M32.9 Systemic lupus erythematosus, unspecified

FAQ

- Q: If a patient has a positive ANA but no clinical signs of SLE, how often should the ANA be followed?
- A: A positive ANA will usually remain positive indefinitely, but it has no real significance in the absence of clinical or other laboratory disturbances. Up to 20% of the normal population may have a positive ANA, so there is no need to repeat the test.
- Q: Can SLE patients with end-stage renal disease obtain renal transplants?
- A: Yes, and SLE usually does not recur in the new kidney.

LYME DISEASE

Elizabeth Candell Chalom

BASICS

DESCRIPTION

Multisystemic illness caused by the spirochete *Borrelia burgdorferi*, carried by the deer tick

EPIDEMIOLOGY

- Can affect people of all ages, but 1/3–1/2 of all cases occur in children and adolescents
- Male/Female ratio: 1:1–2:1
- Onset most often in summer months
- Endemic areas in northeast, north central, and Pacific Coast states

Prevalence

Has now become most common tick-borne disease in the U.S., with 29,595 confirmed cases reported in 2009. Although Lyme disease can be found anywhere, the majority of the cases in the U.S. are found in southern New England and the mid-Atlantic States. It is also seen frequently in California, Minnesota, and Wisconsin.

RISK FACTORS

Genetics

Chronic Lyme arthritis seems to be associated with increased incidence of HLA-DR4 and less so with HLA-DR2.

PATHOPHYSIOLOGY

B. burgdorferi is injected into skin with saliva of Ixodes tick. Spirochetes 1st migrate within skin, forming the typical rash, erythema migrans. Spirochetes then spread hematogenously to other organs, including heart, joints, and nervous system.

ETIOLOGY

The tick-borne spirochete *B. burgdorferi*

COMMONLY ASSOCIATED CONDITIONS

The same ticks that transmit Lyme disease can also transmit *Ehrlichia* and *Babesia*, so infections with those spirochetes can occur simultaneously.

DIAGNOSIS

HISTORY

- Tick bite:
 - History of tick bite can only be elicited in 1/3 of patients with Lyme disease, and most people with tick bites do not develop Lyme disease. Even in endemic areas, risk of developing Lyme disease after tick bite is <5%.
- Rash:
 - 50–80% will have or will recall the typical rash, which is not painful or pruritic, but does feel warm.
- Other symptoms:
 - Many patients will complain of fatigue, headaches, fevers, chills, myalgias, conjunctivitis, and arthralgias early on.
- Joint pain:
 - Many patients will complain of painful joints early on, and later will develop joint swelling.
- Signs and symptoms:
 - Skin: Erythema migrans (typical rash); starts as red macule or papule and then expands to annular lesion up to 30 cm in diameter with partial central clearing. The lesion is usually painless and lasts 4–7 days.
 - Musculoskeletal:
 - Early on, patient may experience fevers, myalgias, migratory joint pain (often without frank arthritis), and painful tendons and bursae.
 - Weeks to months later, 60% of untreated patients will develop monoarticular or pauciarticular arthritis of large joints, especially knees.
 - Joint fluid can have WBC count anywhere from 500–110,000 cells/mm³, and cells are mostly neutrophils.
 - Neurologic:
 - Several weeks after initial rash, 14% of untreated patients will develop neurologic symptoms including aseptic meningitis, cranial nerve palsies (especially facial nerve palsies), mononeuritis, plexitis, or myelitis.
 - Months to years later, chronic neurologic symptoms may occur, including a subtle encephalopathy: Memory, mood, and sleep disturbances.
 - Significant fatigue can occur early or late in the course of Lyme disease.
 - Cardiac:
 - Several weeks after initial rash, ~5% of untreated patients develop cardiac disease.
 - Most common cardiac lesion is atrioventricular block (primary, secondary, or complete)
 - Pericarditis, myocarditis, or pancarditis can also develop.

PHYSICAL EXAM

- May be completely normal early in course of disease
- Rash of erythema migrans, if seen, is virtually pathognomonic for Lyme disease. If patient does not have the rash, no physical finding exists that gives definitive diagnosis of Lyme.
- Patient may have arthritis, Bell palsy, a cranial nerve palsy, conjunctivitis, or an irregular heartbeat.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- ELISA:
 - Can detect antibodies to *B. burgdorferi* several weeks after tick bite. However, has relatively high false-positive rate and occasionally false-negative results. Remains positive for years after treatment
- Western blot analysis:
 - Much more specific. After 4–8 weeks of infection, ≥5 of the following IgG bands must be present for test to be positive: 18, 21, 28, 30, 34, 39, 41, 45, 58, 66, and 93 kd. During 1st 2–4 weeks of infection, 2 IgM bands may establish diagnosis but false positive IgM blots are common.
- Positive ELISA with negative Western blot:
 - Usually means patient does not have Lyme disease and ELISA was a false-positive but false positive IgM blots are common.
- Polymerase chain reaction (PCR):
 - PCR testing may be done with synovial tissue or fluid, or with CSF. Positive PCR indicates active disease, but negative result does not rule out Lyme.
 - Urine tests for Lyme disease have been shown to be very inaccurate and should not be used.

DIFFERENTIAL DIAGNOSIS

- Viral arthritis/arthralgias
- Septic arthritis
- Juvenile rheumatoid arthritis
- Postinfectious arthritis
- Fibromyalgia syndrome
- SLE
- Pitfalls:
 - Incorrect diagnosis: Many patients with vague systemic complaints (fatigue, headaches, arthralgias) are incorrectly diagnosed with Lyme disease, even though their Lyme tests are negative (or ELISA mildly positive and Western blot negative).
 - These patients are then treated with multiple courses of oral antibiotics; if they do not respond, they are often treated with IV antibiotics, sometimes for prolonged periods.
 - This situation delays diagnosing true problem and subjects patients to unnecessary risks of long-term antibiotic use and occasionally of central venous lines.

TREATMENT

MEDICATION (DRUGS)

- Oral antibiotics:
 - Initial therapy for early Lyme disease
 - Specific therapies:
 - Patients >8 years old: Doxycycline is drug of choice.
 - Younger children or people who do not tolerate tetracyclines: Amoxicillin or cefuroxime preferred, but penicillin V is also acceptable.
 - Penicillin-allergic patients: Erythromycin may be used, but is less effective.
 - Duration of therapy:
 - Patients with only skin rash: 14–21 days of oral antibiotics usually sufficient
 - If other symptoms present: 21–28 days recommended
- IV antibiotics:
 - Become necessary for:
 - Persistent arthritis unresponsive to oral medications
 - Severe carditis
 - Neurologic disease (other than an isolated 7th-nerve palsy)
 - Specific IV therapies
 - Ceftriaxone: Drug of choice
 - Penicillin V: May also be used
 - Duration of therapy: 14–21 days
- Prevention:
 - Some studies suggest that a single dose of doxycycline after tick bite will prevent Lyme disease.
 - Protective clothing, tick repellants, and checking daily for ticks are good preventive measures.

ONGOING CARE

PROGNOSIS

- In general, much better for children than for adults. Only 2% of children have chronic arthritis at 6 months.
- Most of the cardiac manifestations will disappear with or without treatment in a short time (3–4 weeks), but may later recur. Severe cardiac involvement rarely may be fatal.

COMPLICATIONS

- Chronic arthritis occurs in ~2% of children.
- Other complications arise from treatment, such as:
 - Cholecystitis secondary to treatment with ceftriaxone
 - Infections from indwelling catheters used for IV antibiotics
 - Some patients develop what is thought to be a post-Lyme disease syndrome. This is not well defined and is very controversial. It often consists of arthralgias and fatigue, but may include paresthesias and cognitive complaints. Prolonged antibiotics have not been shown to be helpful. Some of these patients present with a fibromyalgia-like syndrome and improve with physical therapy.

CODES

ICD9

088.81 Lyme disease

ICD10

A69.20 Lyme disease, unspecified

FAQ

- Q: What does the deer tick look like?
- A: The deer tick is flat, very small (about the size of a pin head), and has 8 legs. The adult male is black, and the female is red and black. They can grow to 3 times their normal size when they are engorged with blood.
- Q: Do all bites from infected deer ticks cause Lyme disease?
- A: No. Even infected ticks will not cause Lyme disease if they are attached to the skin for a short period of time. If the tick is attached for <24 hours, the chances of transmitting the disease are exceedingly low. The longer the tick is attached, the higher the probability of disease transmission.
- Q: Should all patients be retested for Lyme disease after a full course of treatment?
- A: No. Lyme titers and the Western blot will remain positive for years after adequate treatment for Lyme disease. If the patient's symptoms have resolved, there is no point in rechecking the titer. If the patient is still symptomatic, titers and a Western blot may be checked before starting IV antibiotic therapy to look for a rising titer and to be sure the patient truly has Lyme disease. If symptoms remain after IV therapy, other diagnoses should be considered.
- Q: Should patients with nontraumatic Bell's palsy be tested for Lyme disease?
- A: Bell's palsy is seen in association with Lyme disease infections, so testing for Lyme disease is a good idea.

LYMPHADENOPATHY

Hans B. Kersten

BASICS

DESCRIPTION

- Term used to describe ≥ 1 enlarged lymph nodes > 10 mm in diameter (for inguinal nodes, > 15 mm; for epitrochlear nodes, > 5 mm)
- Any palpable supraclavicular, popliteal, or iliac lymph node considered abnormal
- Normal lymph nodes: Generally < 10 mm
- Lymph nodes often palpable in normal, healthy children. They are present from birth, peak in size between 8 and 12 years of age, and then regress during adolescence.
- Lymph nodes drain contiguous areas:
 - Cervical nodes drain head and neck area.
 - Axillary nodes drain arm, thorax, and breast.
 - Epitrochlear nodes drain forearm and hand.
 - Inguinal nodes drain leg and groin.
 - Supraclavicular nodes drain thorax and abdomen.

EPIDEMIOLOGY

Incidence

Difficult to determine because it depends on the underlying process that causes lymph node enlargement.

Prevalence

Palpable nodes are present in 5–25% of newborns (cervical, axillary, inguinal) and in >50% of older children (all areas except epitrochlear, supraclavicular, and popliteal).

PATHOPHYSIOLOGY

- Lymphatic flow from adjacent nodes or inoculation site brings microorganisms to lymph nodes.
- Lymph node enlargement may occur via any of the following mechanisms:
 - Nodal cells may replicate in response to antigenic stimulation (e.g., Kawasaki disease) or malignant transformation (e.g., lymphoma).
 - Large number of reactive cells from outside node (e.g., neutrophils or metastatic cells) may enter node.
 - Foreign material may be deposited into node by lipid-laden histiocytes (e.g., lipid storage diseases).
 - Vascular engorgement and edema may occur secondary to local cytokine release.
 - Suppuration secondary to tissue necrosis (e.g., *Mycobacterium tuberculosis*)
- Many systemic infections (e.g., HIV) cause hepatic or splenic enlargement in addition to generalized lymphadenopathy.

ETIOLOGY

Usually determined by performing a thorough history and physical exam

COMMONLY ASSOCIATED CONDITIONS

Many systemic infections (e.g., HIV) cause hepatic or splenic enlargement in addition to generalized lymphadenopathy.

DIAGNOSIS

HISTORY

- Preceding symptoms (e.g., upper respiratory symptoms preceding cervical lymphadenopathy)
- Localizing signs or symptoms (e.g., stomatitis may be associated with submandibular lymphadenopathy)
- Duration: Days or weeks
- Constitutional or associated symptoms (e.g., fever, weight loss, or night sweats)
- Exposures: Cat exposure (cat scratch disease), uncooked meat (Toxoplasmosis), tick bite (Lyme disease)
- Medications (e.g., Phenytoin or Isoniazid)
- Travel to or residence in an endemic area should raise suspicion for Tuberculosis, Lyme disease.
- Signs and symptoms:
 - Localized lymphadenopathy: Involves enlarged nodes in any 1 region
 - Generalized lymphadenopathy: Involves ≥ 2 noncontiguous regions secondary to a systemic process, such as EBV infection.
 - Supraclavicular nodes seen with malignancy: Right-sided supraclavicular node is associated with mediastinal malignancy; left-sided node suggests abdominal malignancy.

PHYSICAL EXAM

- Complete physical exam is imperative to look for signs of systemic disease such as skin, oropharyngeal, or ocular findings; or hepatosplenomegaly.
- The child's weight should also be checked to be sure there has been no weight loss.
- If localized lymphadenopathy is suspected, examine the area that the lymph node drains for pathology. For example, an arm papule may be associated with axillary lymphadenopathy in cat scratch disease.
- Cervical, axillary, and inguinal nodes, as well as liver and spleen, must be palpated to help determine if signs of systemic disease or infection are present.
- Characterize nodes. Be sure to note:
 - Location: Be as exact as possible (see above).
 - Size: Specify dimensions.
 - Consistency: Soft, firm, solid, cystic, fluctuant, rubbery. Firm, rubbery nodes may be associated with lymphomas, while soft nodes are generally palpated with reactive lymphadenopathy.
 - Fixation: Normally freely mobile; infection or malignancy may cause adherence to surrounding tissues or nodes.
 - Tenderness: Suggests inflammation

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Consider the following tests if ≥ 1 nodes is persistently enlarged, has increased in size, has changed in consistency or mobility, or if systemic symptoms are present:

- CBC: Consider with generalized lymphadenopathy, or if malignancy is in differential diagnosis.
- Purified protein derivative (PPD) testing: Consider with persistently enlarged node (2–4 weeks) or travel to areas where tuberculosis is endemic.

- ESR or CRP: Increased with infection or inflammation
- Throat culture: If concern for group A β -hemolytic streptococcal (GAS) pharyngitis
- EBV/Cytomegalovirus (CMV) titers: Consider with persistent generalized adenopathy.
- *Bartonella henselae* titers: Consider with persistently enlarged unilateral node and/or history of cat exposure.
- *Toxoplasma gondii* titers: Consider with generalized lymphadenopathy and exposure to undercooked or raw meat.
- HIV testing: Consider with persistent generalized lymphadenopathy and failure to thrive.
- Lactate dehydrogenase (LDH), uric acid, and liver enzymes: Consider if history and physical exam raise concern for malignancy.
- Rapid plasma reagin (RPR): Consider with rash and generalized lymphadenopathy or other signs of syphilis.
- Antinuclear antibody (ANA): If persistent generalized lymphadenopathy and other signs of systemic disease, to rule out systemic lupus erythematosus (SLE)

Imaging

- Chest radiograph: Helpful with supraclavicular nodes, systemic symptoms, or if positive PPD
- US: May help differentiate cystic from solid masses
- CT: May help delineate anatomy or extent of the lesion

Diagnostic Procedures/Other

- Biopsy should be considered if:
 - Nodes are persistently enlarged, especially if accompanied by signs of systemic disease such as hepatosplenomegaly, weight loss, and exanthema.
 - Nodes are fixed to underlying skin.
 - Ulceration is present.
 - Node is supraclavicular, nontender, or increasing in size or firmness.
- Fine-needle aspiration: Cost-effective, but sometimes nondiagnostic; may result in fistulous tract
- Open biopsy: Often diagnostic, but requires general anesthesia

DIFFERENTIAL DIAGNOSIS

Must be carefully differentiated from lymphadenitis, defined as lymph node enlargement with signs of inflammation (including erythema, tenderness, induration, warmth); often treated with antibiotics.

- Localized lymphadenopathy:
 - Generally occurs as reactive adenopathy in response to local infection
 - Differential diagnosis for localized adenopathy varies depending on affected site:
 - Cervical adenopathy: Includes cystic hygroma, branchial cleft cyst, and thyroglossal duct cyst
 - Inguinal adenopathy: Includes inguinal hernia or other mass

- Generalized lymphadenopathy: May be seen in many systemic illnesses:
 - Miscellaneous: Kawasaki disease, Castleman disease, Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy), Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis), Churg-Strauss syndrome, infection-associated hemophagocytic syndrome, Gianotti-Crosti syndrome (papular acrodermatitis), sarcoidosis, lipid storage diseases (Niemann-Pick, Gaucher, Wolman, Faber diseases), hyperthyroidism
 - Viral infections: Adenovirus, rubella, enterovirus, herpes simplex virus, measles virus, varicella virus, EBV, cytomegalovirus, HIV, hepatitis A or B viruses
 - Bacterial infections: *Staphylococcus aureus*, *Bartonella henselae*, GAS, salmonella, yersinia, brucellosis, tularemia, *Mycobacterium tuberculosis*, *Mycoplasma pneumoniae*, rickettsiae
 - Parasitic infections: Chagas disease, Schistosomiasis
 - Autoimmune disorders: SLE, juvenile rheumatoid arthritis, serum sickness
 - Malignancy: Lymphoma (Hodgkin and non-Hodgkin), histiocytosis, neuroblastoma, leukemia
 - Medications: Phenytoin, isoniazid, pyrimethamine, antileprosy drugs, antithyroid drugs, aspirin, barbiturates, penicillin, tetracycline, iodides, sulfonamides, allopurinol, phenylbutazone
 - Lymphoproliferative disorders: Wiskott-Aldrich syndrome, ataxia-telangiectasia syndrome, combined immunodeficiency syndrome, x-linked lymphoproliferative syndrome

TREATMENT

MEDICATION (DRUGS)

Acute lymphadenitis should be treated with antibiotics directed against *Streptococcus* and *Staphylococcus*:

- Cephalexin 50 mg/kg/d in 4 divided doses OR
- Cefadroxil 30 mg/kg/d in 2 divided doses OR
- Dicloxacillin 50–100 mg/kg/d in 4 divided doses. Max 4 g/d.
- Consider using clindamycin 20–30 mg/kg/d in 4 divided doses OR trimethoprim-sulfamethoxazole (TMP-SMX) 8–10 mg/kg/d PO/IV in 2 divided doses in areas with a high prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA)
- Penicillin-allergic patients: Erythromycin 50 mg/kg/d in 4 divided doses

First Line

Empiric treatment with antibiotics: 1st- or 2nd-generation cephalosporin to cover group A *Streptococcus* and *S. aureus* if meticulous history and physical exam are not revealing. Consider empiric treatment with clindamycin or trimethoprim-sulfamethoxazole if there is a high incidence of MRSA in the community.

Second Line

Consider broader antibiotic coverage for *B. henselae* and atypical mycobacterium: Azithromycin 10 mg/kg dose on day 1, followed by 5 mg/kg divided once for 4 more days

ADDITIONAL TREATMENT

General Measures

- Treat underlying disease.
- Close observation, unless history and physical suggest malignancy or lymphadenitis

ISSUES FOR REFERRAL

Refer to surgery or otolaryngology if biopsy or excision required.

SURGERY/OTHER PROCEDURES

Excision for special, prolonged cases

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Localized lymphadenopathy: Observe for several weeks or treat with antibiotics if indicated.
- Serial observation if nodes are persistently enlarged

PROGNOSIS

- Depends on underlying diagnosis
- Excellent for reactive lymphadenopathy

COMPLICATIONS

- Lymphadenitis
- Local infection (e.g., cellulitis)
- Lymph node abscess
- Sepsis via hematogenous spread of inadequately contained infection
- Fistula (e.g., with atypical mycobacteria)
- Fibrosis secondary to purulence or lymphadenitis
- Stridor secondary to enlarged cervical lymph nodes
- Wheezing secondary to enlarged parabranchial mediastinal lymph nodes

CODES

ICD9

- 785.6 Enlargement of lymph nodes

ICD10

- R59.0 Localized enlarged lymph nodes
- R59.1 Generalized enlarged lymph nodes

FAQ

- Q: When should there be concern about malignancy in a child with lymphadenopathy?
- A: Malignancy should be considered in any child who has lymphadenopathy that does not improve in spite of antibiotic therapy, that has a location of concern (e.g., supraclavicular) or physical exam features of concern (hard, large size [>2 cm]) that persistently enlarges, or if the child shows signs of systemic disease.
- Q: How much of a workup does a well child with localized lymphadenopathy need?
- A: As long as the lymph nodes are soft, mobile, and nontender, the lymphadenopathy is likely to be self-limited. If the cause is unclear, then children should be observed for a couple of weeks. Further workup is needed if the nodes persist or enlarge, or if there are signs of systemic disease (e.g., hepatomegaly or weight loss).
- Q: When should a child with lymphadenopathy be referred to a specialist?
- A: Most cases of lymphadenopathy in children are self-limited and can be observed for a few weeks and/or treated with antibiotics, if appropriate. Referral to a surgeon should be considered in any child with persistently enlarged lymphadenopathy (>4 weeks) or immediately if there are signs of malignancy.

LYMPHEDEMA

Robert K. Noll

BASICS

DESCRIPTION

- Lymphedema is a chronic swelling, typically in an extremity or the genitals, which is caused by abnormal accumulation of interstitial fluid. It can be of primary or secondary origin.
- Primary lymphedema has 3 forms, all of which stem from a developmental abnormality of lymphatic flow. Not all primary lymphedemas are clinically evident at birth.
 - Congenital lymphedema
 - Present at birth
 - Female-to-male ratio: 2:1
 - Lower to upper extremity ratio: 3:1
 - 2/3 cases are bilateral
 - May improve with age
 - Lymphedema praecox (65–80% of primary lymphedema)
 - Usually becomes evident at puberty, but may appear between infancy to age 35
 - Female-to-male ratio: 4:1
 - 70% unilateral lower extremity (L>R)
 - Lymphedema tarda: Presents at age 35 or older
- Secondary lymphedema is from an acquired abnormality of lymphatic flow.
 - Common causes in children include:
 - Postsurgical obstruction
 - Burns
 - Insect bites
 - Infection
 - Surgery
 - Neoplasia
 - Trauma

EPIDEMIOLOGY

- Most lymphedemas in childhood are primary (or idiopathic) lymphedema (96%).
- Congenital lymphedema comprises 10–25% of primary lymphedema cases; lymphedema praecox, 65–80%; and lymphedema tarda, 10%.
- Female-to-male ratio in congenital lymphedema is 2:1; in lymphedema praecox the female-to-male ratio is 4:1.
- Affected males—most likely congenital and bilateral; affected females—most likely unilateral lymphedema praecox
- Secondary lymphedema is more common in adults, and rare in children. In the US, commonly from breast cancer; worldwide, due to filariasis.

Incidence

Incidence of 1.15/100,000 in children <20 years

RISK FACTORS

Genetics

- Chromosomal defect in Milroy disease mapped to long arm of 5q35
- Specific genes implicated in lymphedema are VEGFR3, FOXC2, and SOX18
- Genetic disorders are associated with lymphedema: Fabry disease, Milroy disease (congenital familial lymphedema with ocular findings), Meige disease (familial lymphedema praecox), and Down, Turner, Noonan, yellow nail, Klippel–Trenaunay–Weber, pes cavus, and other syndromes.
- Inheritance can be autosomal dominant, recessive, or sex-linked.

PATHOPHYSIOLOGY

- Abnormal accumulation of interstitial fluid due to impaired uptake by lymphatic vessels or excessive production of lymph due to venous obstruction and increased capillary pressure
- Initially edema is pitting, whereas chronic edema is generally non-pitting as a result of fibrosis.

DIAGNOSIS

HISTORY

- Unilateral, painless lower extremity edema in healthy pubertal female strongly suggests lymphedema praecox.
- Painless swelling distal to site of extremity surgery or trauma suggests secondary lymphedema.
- Sites of previous cellulitis, infection, or insect bites can be associated with secondary lymphedema.

PHYSICAL EXAM

- Painless, pitting edema in unilateral limb is strongly suggestive of lymphedema, though nearly half of cases are bilateral.
- Most commonly affected sites: Extremities, usually legs, followed by genitalia
- Chronic inflammation leads to fibrosis and non-pitting or “woody” edema with induration.
- Hair loss and hyperkeratosis of the affected limb develop over time.
- Pain in affected limb uncommon and suggests secondary lymphedema due to thrombophlebitis, cellulitis, or reflex sympathetic dystrophy.
- Global edema suggests other disease states.
- Red streaking of extremity, fever, chills, or nodal enlargement suggests development of cellulitis or lymphangitis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Not usually necessary but may be useful to rule out other causes of edema

- Urinalysis for proteinuria as seen with glomerulonephrosis
- Serum total protein and albumin to rule out hypoproteinemia
- Liver function tests to assess functional status
- Pregnancy test

Imaging

Usually unnecessary to make diagnosis, but may help to plan or evaluate therapy

- Lymphangiography is no longer used since related dyes caused inflammation and worsening of lymphatic obstruction.
- Radionuclide lymphoscintigraphy, when indicated, is the preferred method of imaging to define anatomy and to evaluate lymph flow and obstruction
- CT and MRI may be valuable if a malignancy is suspected.
- Doppler ultrasound may be helpful if deep vein thrombosis is suspected.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Cellulitis
 - Lymphangitis
 - Herpes simplex virus type 2
- Tumors
 - Pelvic mass
 - Multiple enchondromatosis
- Metabolic
 - Cushing disease
 - Hyperthyroidism
 - Lipedema
- Anatomic
 - Venous stasis
 - Deep vein thrombosis
 - Hemihypertrophy
 - Arteriovenous fistula
 - Popliteal arterial aneurysm
 - Popliteal cyst (Baker cyst)
- Miscellaneous
 - Heart failure
 - Glomerulonephrosis
 - Cirrhosis
 - Hypoproteinemia
 - Reflex sympathetic dystrophy
 - Pregnancy

TREATMENT

General Measures

- Therapy should be instituted as soon as possible and before fibrosis develops.
- Goals of therapy are to minimize or decrease edema, and to prevent infection, fibrosis, and skin changes.
- Compression garments (e.g., Jobst stockings or elastic wraps) recommended long term, but compliance can be a challenge
- Extremity elevation, especially at night
- Exercise, swimming, or walking may be beneficial.
- Diligent skin care and appropriately fitting shoes to avoid infection
- Manual massage decompression can be helpful for digital edema and for infants who may not tolerate compression garments.
- Automated intermittent pneumatic compression machines shown to facilitate home regimen compliance
- Published series reports 73% treated with compression stockings, 18% with pneumatic compression, and 13% required surgery
- Psychological effects of cosmesis should not be overlooked.

Diet

In children with chylous reflux syndromes, a diet low in long-chain triglycerides may be of benefit.

SPECIAL THERAPY

Complex or complete decongestive physiotherapy is part of a specialized treatment program offered at a few select centers. It may be more effective than massage or compression garments alone in reducing swelling and maintaining reduction in fluid accumulation.

MEDICATION (DRUGS)

- Diuretics: Not used in children and adolescents; efficacy for adults is debated.
- Prophylactic antibiotic use is indicated for patients with recurrent cellulitis or lymphangitis.

SURGERY

- Microsurgical treatment has been proven to show excellent outcomes in carefully selected patient populations via lymphatic-venous anastomoses or lymphatic-venous-lymphatic anastomoses.
- Traditional surgery has 1 of 2 goals: Removal of excess edematous tissue or attempts to restore lymph drainage
 - Both may decrease the rate of infections but have poor cosmetic results.
 - Recommended only for those with uncontrolled swelling with significant disability

ONGOING CARE

PROGNOSIS

- Edema persists throughout life.
- Natural history: Plateau in severity of edema after an initial few years of progression in 50%, slow constant progression in 50%

COMPLICATIONS

- Cellulitis and lymphangitis are the most common complications and are treated with antibiotics; published series showed 24% of cases developed infection and half of these required hospitalization.
- Poor long-term compliance with compression garments due to uncomfortable nature of therapy
- Lymphangiosarcoma (rare)
- Psychological problems
- Physical limitations
- Chronic inflammation and edema ultimately lead to fibrosis and induration of the involved area.

CODES

ICD9

- 457.1 Other lymphedema
- 757.0 Hereditary edema of legs

ICD10

- I89.0 Lymphedema, not elsewhere classified
- Q82.0 Hereditary lymphedema

FAQ

- Q: Is the swelling going to go away?
- A: No, this is a lifelong disorder in most cases.
- Q: Could this have been prevented?
- A: No, primary lymphedema is typically due to abnormal embryologic development.
- Q: If the lymph channels have been abnormal since birth, why does the swelling present during adolescence?
- A: No one really knows; hormones may play a role in lymphedema.

LYMPHOPROLIFERATIVE DISORDERS

David T. Teachey

BASICS

DESCRIPTION

- Lymphoproliferative disorders are a class of nonmalignant diseases characterized by uncontrolled growth of lymphoid tissues (spleen, bone marrow, liver, lymph nodes)
- Can be congenital or acquired
- Most common in children include:
 - Autoimmune lymphoproliferative syndrome (ALPS)
 - Castleman's Disease (CD)
 - Rosai–Dorfman's Disease (RD)
 - EBV-associated lymphoproliferative disorder (ELD)
 - X-linked lymphoproliferative syndrome (XLP)
- Rarer disorders (not discussed in detail)
 - Angioimmunoblastic lymphadenopathy
 - Caspase eight deficiency syndrome
 - Dianzani autoimmune lymphoproliferative disease
 - Kikuchi–Fujimoto syndrome
 - Lymphomatoid granulomatosis
 - Lymphomatoid papulosis
 - Ocular adnexal lymphoid proliferation
 - Ras-associated leukoproliferative disorder

EPIDEMIOLOGY

Incidence and Prevalence

All uncommon

RISK FACTORS

Often multifactorial with inherited genetic defect and acquired infection

Genetics

- ALPS (80% of patients have identifiable mutation)
 - 60–70% germline mutation in FAS (TNFRSF6)
 - 10% somatic mutation in FAS
 - 2% germline mutation in CASP10
 - <1% germline mutation in FASL
- XLP
 - Majority of cases mutation in SH2D1A
 - XLP-like syndrome caused by XIAP mutations

PATHOPHYSIOLOGY

- ALPS
 - Defective Fas-mediated apoptosis leads to abnormal lymphocyte survival with subsequent lymphoproliferation, autoimmunity, and cancer
- Castleman's Disease (CD)
 - Largely unknown but can be triggered by HHV8 infection, especially in immunocompromised patients
- EBV-associated lymphoproliferative disorder
 - EBV triggered lymphoproliferative disorder found in patients on chronic immune suppression typically after organ or bone marrow transplant (PTLD) or with inherited immune deficiency
- X-linked lymphoproliferative syndrome (XLP)
 - Mutation in SH2D1A leads to abnormal production of SAP protein in NK and T cells, leading to defective SAP-SLAM signaling and inability to appropriately respond to EBV infection.

DIAGNOSIS

HISTORY

- ALPS
 - Typically presents at young age (average 18 months) with massive lymphadenopathy and splenomegaly.
 - Many patients develop secondary autoimmune disease.
 - Most often, autoimmune destruction of blood cells (80% of patients). Can be mild to severe
 - Destruction of platelets: See chapter on Idiopathic thrombocytopenic purpura
 - Destruction of erythrocytes: See chapter on autoimmune hemolytic anemia
 - Destruction of neutrophils: See chapter on neutropenia
 - Can have autoimmune involvement of any organ system, similar to systemic lupus erythematosus
 - In young adult years, 10–20% develop lymphoma
 - Lymphoproliferation can improve or worsen with infection. Often progresses through teenage years and improves in adulthood
 - Autoimmune disease less likely to improve with older age
- Castleman's Disease (CD)
 - 2 variants:
 - Hyaline vascular: presents with enlarged single lymph node or chain of nodes. >90% with no other symptoms. Rarely can have fever, weight loss, fatigue
 - Plasma cell: presents with enlarged single lymph node or chain (unicentric) or diffuse adenopathy (multicentric). Often with constitutional symptoms (fever, sweats, lethargy, rashes, neuropathy, arthritis)
- Rosai–Dorfman's Disease (RDD)
 - Massive painless bilateral cervical lymphadenopathy with or without other involved nodal groups
 - Fever
 - Snoring common
 - Can have extranodal invasion of almost any organ (25% of patients have extranodal disease) and signs and symptoms depend on involved organ
- ELD/PTLD
 - Can be mild, with lymphadenopathy, fever, and/or diarrhea, or severe, with massive lymphadenopathy, high fever, night sweats, rash, and pruritus, and organ compression from involved nodes
- XLP
 - Can present as fulminant infectious mononucleosis or aplastic anemia or lymphoma or hematophagocytic syndrome
 - Often critically ill in the setting of EBV infection

PHYSICAL EXAM

- ALPS
 - Massive lymphadenopathy (90% of patients): Rarely can compress vital organs including trachea. Most common site of adenopathy is anterior cervical. Nodes hard but mobile
 - Splenomegaly (90% of patients)
 - Hepatomegaly (50% of patients)
 - Other physical exam findings as expected with autoimmune destruction of blood cells and/or end organ autoimmune disease.

- CD
 - Hyaline vascular: single enlarged lymph node or chain. Most often, cervical or mediastinal. May have shotty diffuse nonpathologic adenopathy
 - Plasma cell. Single or multiple pathologically enlarged lymph nodes. Abdominal nodes most common. Hepatosplenomegaly common. Peripheral edema, ascites, and pleural effusions may be present
- RDD
 - Massive bilateral anterior cervical lymphadenopathy (90% of patients). Other physical exam findings can vary based on extranodal disease
 - Hepatosplenomegaly (10% of patients)
- ELD/PTLD
 - Similar to other lymphoproliferative disorders (see Epstein–Barr virus chapter)
- XLP
 - Similar to other lymphoproliferative disorders; however, far more acutely ill (see also Epstein–Barr virus chapter and aplastic anemia chapter)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

General

- Complete blood and reticulocyte count for anemia, thrombocytopenia, and neutropenia
- Direct antiglobin test (DAT) to check for autoimmune destruction of red blood cells
- Serum chemistries, uric acid, phosphorus to look for cell turnover (usually normal in lymphoproliferative disorders)
- Liver function tests, PT, PTT, and fibrinogen to measure liver function and for coagulopathy
- EBV PCR and titers, CMV PCR
- If acutely ill, consider ESR or CRP and ferritin
- Quantitative immunoglobulins. Often elevated in lymphoproliferative disorders

Diagnostic Tests for ALPS

- Mandatory criteria:
 - (1) chronic (>6 months) nonmalignant lymphoproliferation (lymphadenopathy and/or splenomegaly)
 - (2) Elevated peripheral blood double negative T cells (DNTs); T cells that are CD3+, TCRalpha/beta+, CD4-, CD8-. DNTs are usually rare in peripheral blood (<1% of total lymphocytes or <2.5% of total T cells). DNTs are elevated and often markedly elevated in ALPS. Slight elevation in DNTs can be found in other autoimmune disorders
- Major (primary) criteria:
 - (1) Genetic mutation in ALPS causative gene (germline or somatic) in FAS, FASL or CASP10
 - (2) *In vitro* evidence of defective Fas mediated apoptosis. This assay requires growing blood cells from patient in culture for weeks and exposing to anti-Fas monoclonal antibody to see if T-cells are resistant to death. Only performed in a few labs

- Minor (secondary) criteria
 - (1) Elevated vitamin B12 (> 1500 ng/L)
 - (2) Elevated IL-10 (>20 pg/mL)
 - (3) Elevated IL-18 (> 500 pg/mL)
 - (4) Elevated sFASL (> 200 pg/mL)
 - (5) Classic histopathologic findings on lymph nodes or spleen biopsy
 - (6) Autoimmune cytopenias AND elevated serum IgG
 - (7) Positive family history
- Diagnosis
 - Definitive: Both mandatory and one major criteria
 - Probable: Both mandatory and one minor criteria (Probable ALPS should be treated the same as definitive ALPS)

Diagnostic Tests for CD

- Castleman syndrome diagnosed by histopathology
- Hypergammaglobulinemia, anemia, high ESR, high IL-6, HHV8 PCR+

Diagnostic Tests for RD

- Rosai–Dorfman’s diagnosed by Histopathology
- Hypergammaglobulinemia, anemia, high ESR, leukocytosis with neutropenia, hematologic autoantibodies

Diagnostic Tests for EPD/PTLD

- Posttransplant lymphoproliferative disorder after bone marrow graft
- Persistent EBV infection (positive EBV PCR or abnormal seroconversion by titers) in setting of immune suppression or immune compromise
- Diagnosis confirmed with imaging and/or histopathology

Diagnostic Tests for XLP

- Persistent EBV infection (positive EBV PCR or abnormal seroconversion on titers)
- Inverted CD4/8 ratio
- High IgM and IgA, Low IgG
- Defective NK activity
- Secondary hemophagocytic syndrome (Elevated ferritin, high triglycerides, low fibrinogen, cytopenias, high fever, splenomegaly, poor NK function, elevated s-IL-2R-alpha, and hemophagocytosis on marrow or node biopsy)
- Diagnosis confirmed by genetic testing for mutations in SH2D1A and XIAP genes, and/or SAP protein quantification

Imaging

- CT scans of head, neck, chest, abdomen and pelvis with IV contrast important for all lymphoproliferative disorders at initial diagnosis to define extent of disease
- IMPORTANT to obtain plain chest X-ray on initial presentation in patient with diffuse lymphadenopathy before CT scan to ensure a large mediastinal mass is not present. If present, it may be unsafe to lie patient flat and/or sedate for CT scan.
- Most lymphoproliferative disorders are very PET-avid

Diagnostic Procedures/Other

- ALPS and PTLD can be diagnosed without histopathology; however, most patients have a lymph node biopsy
- Other lymphoproliferative disorders typically require tissue for diagnosis (Biopsy, not fine needle aspirate)
- Consider bone marrow aspirate and/or biopsy to rule out marrow disease or other disease processes

Pathological Findings

- ALPS: DNTs in lymph node and spleen
- CD: Hyaline vascular (shrunken germinal centers with eosinophilic expansion of mantle zones with and vessel hyalinization); Plasma cell (extensive plasma cell infiltrate in interfollicular regions)
- RD: Emperipoiesis (lymphophagocytosis) hallmark of disease on biopsy. Presence of histiocytes
- XLP/PTLD/EPD: EBER+

DIFFERENTIAL DIAGNOSIS

- Other lymphoproliferative disorders
- Lymphoma
- Infection: EBV, CMV, Toxoplasmosis, HIV, TB
- Evans syndrome
- Rheumatologic disease

TREATMENT

ALPS

First Line

- Corticosteroids or IVIG for acute flares

Second Line

- Sirolimus or mycophenolate mofetil for chronic disease
- Sirolimus (rapamycin): Pros: Improves autoimmune disease and lymphoproliferation and eliminates DNTs. Cons: Drug–Drug interactions; requires therapeutic drug monitoring; 10% of patients develop mouth sores (most common in first month)
- Cellcept (mycophenolate): Pros: No drug–drug interactions, no mouth sores, no therapeutic drug monitoring. Cons: Not as effective. Does not help lymphoproliferation or lower DNTs. GI upset.
- Recommended treatment: Mild to moderate autoimmune disease start with cellcept and transition to sirolimus if poor response or side effects. More severe autoimmune disease or clinically significant lymphoproliferation start with sirolimus

Third Line

- Combination therapy. Stem cell transplant

Relative Contraindications (AVOID, if possible)

- Splenectomy: High incidence of pneumococcal sepsis even with antibiotic prophylaxis and immunization
- Rituximab: Can lead to life-long hypogammaglobulinemia (5–10% of patients)

CD

Localized Disease

- Surgical resection or focal radiation. Steroids may be used to shrink lesions prior to surgery

Multicentric Disease

- Multiagent therapy (vincristine, prednisone, rituximab, cyclophosphamide, doxorubicin)

RD

- May self-resolve (20% of patients)
- If not consider, prednisone, or vinblastine plus prednisone, or mercaptopurine plus methotrexate, or 2CdA.

EPD/PTLD

- Reduce immune suppression or convert immune suppression to sirolimus if possible
- Consider rituximab, adoptive transfer of EBV-specific cytotoxic T cells
- If fails or generalized disease consider multi-agent chemotherapy similar to RD

XLP

- If hemophagocytosis or aplasia: Rituximab, etoposide, steroids, and cyclosporine
- Hematopoietic stem cell transplant is the only cure

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Recommended follow-up imaging varies among institutions. Most physicians will repeat imaging if patient’s history changes OR to determine response to therapy.

PROGNOSIS

- Prognosis is good to fair for most lymphoproliferative disorders
- Prognosis is poor in XLP and advanced CD

MALABSORPTION

Teena Sebastian

Maria R. Mascarenhas

Gabriel Arancibia (5th edition)

BASICS

DESCRIPTION

Malabsorption is characterized as a syndrome, as opposed to a disease entity, and is defined as any state in which there is a disturbance of digestion and/or absorption of nutrients across the intestinal mucosa. Additionally, there seems to be an association of chronic diarrhea with abdominal distention and failure to thrive in malabsorptive states.

EPIDEMIOLOGY

Depends on the underlying disease causing malabsorption

PATHOPHYSIOLOGY

- According to the nutrient affected:
 - Carbohydrate:
 - Monosaccharide: Congenital glucose-galactose deficiency, fructose intolerance
 - Disaccharide: Lactase deficiency (congenital or acquired), sucrase-isomaltase deficiency
 - Polysaccharide: Amylase deficiency (congenital or acquired)
 - Fat:
 - Bile salt deficiency: Cholestasis, resection of terminal ileum
 - Exocrine pancreatic insufficiency: Cystic fibrosis, chronic pancreatitis
 - Inadequate surface area: Celiac disease, flat villous lesions
 - Protein:
 - Protein-losing enteropathy: Intestinal lymphangiectasia, congenital heart failure
 - Exocrine pancreatic insufficiency: Cystic fibrosis, Shwachman syndrome
 - Inadequate surface area: Celiac disease
- According to the place where the alteration occurs:
 - Mucosal abnormality:
 - Anatomical: Post-enteritis syndrome, celiac disease, Inflammatory bowel disease (IBD)
 - Functional: Disaccharidase deficiencies
 - Luminal abnormality:
 - Exocrine pancreatic insufficiency: Cystic fibrosis, Shwachman-Diamond syndrome
 - Bile salt insufficiency: Biliary cholestatic liver disease, ileal resection
 - Anatomical abnormality:
 - Short gut: Surgical resection
 - Motility disturbance: Intestinal pseudo-obstruction

ETIOLOGY

The most common causes of malabsorption in developed countries are:

- Postenteritis syndrome
- Cow's milk protein intolerance
- Giardiasis
- Celiac disease
- Cystic fibrosis
- IBD

DIAGNOSIS

HISTORY

- GI symptoms:
 - Common in patients with malabsorption syndromes and range from mild abdominal gaseous distention to severe abdominal pain and vomiting. Chronic or recurrent diarrhea is by far the most common symptom.
 - Abdominal distention and watery diarrhea, with or without mild abdominal pain associated with skin irritation in the perianal area due to acidic stools, are characteristic of carbohydrate malabsorption syndromes.
 - Fat malabsorption can present with bulky, foul-smelling stools that are oily and thus float in water. Abdominal distension, increased gas, weight loss, and increased appetite are also seen.
 - Periodic nausea, abdominal distention and pain, and diarrhea are common in patients with chronic *Giardia* infections.
 - Vomiting, with moderate-to-severe abdominal pain and bloody stools, is characteristic of protein sensitivity syndromes.
 - Malabsorption syndromes can definitely cause abdominal pain or irritability (particularly seen in celiac disease).
- Stool characteristics:
 - Frequent loose watery stools may indicate carbohydrate intolerance.
 - Bulky, greasy, or loose foul-smelling stools indicate fat malabsorption.
 - In protein malabsorption, stools may be normal or loose.
 - Bloody stools are seen in patients with cow's milk protein allergy, infection, and inflammatory bowel disease.

- Other symptoms:

- Malabsorption of carbohydrates, fats, or proteins can cause failure to thrive.
- Anemia, with weakness and fatigue due to inadequate absorption of vitamin B₁₂, iron, and folic acid
- Edema due to decreased protein absorption and hypoalbuminemia
- Muscle cramping due to decreased vitamin D causing hypocalcemia, and decreased potassium levels
- Failure to maintain growth velocity on standard charts

PHYSICAL EXAM

- In the absence of GI tract symptoms, malabsorption syndromes should be considered during the workup for failure to thrive, malnutrition, poor weight gain, or delayed puberty.
- Malabsorption syndromes should be suspected in infants with weight loss or little weight gain since birth and in infants with low weight and weight-for-height percentiles.
- Malnutrition symptoms may be present, as reduced SC fat, paleness, angular cheilosis, and muscle weakness. Abdominal distension, increased bowel sounds, rash around mouth and/or anus are commonly seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool analysis:
 - The presence of reducing substances and pH <5.5 indicates that carbohydrates have not been properly absorbed.
 - The level of quantitative stool fat and the amount of fat intake in the diet should be measured and monitored for 3 days; a coefficient of fat absorption is calculated thus:
$$\frac{\text{Ingested fat (g)} - \text{fat in stool (g)}}{\text{Ingested fat (g)}} \times 100$$
 - Special stains are used for identification of fat. Normal values for the coefficient of fat absorption: >93% in children and adults, >85% in infants, >67% in premature infants. Moderate fat malabsorption ranges from 60–80%. Fat absorption of <50% indicates severe malabsorption.
 - The presence of large serum proteins in the stool, such as α_1 -antitrypsin, indicates leakage of serum protein. A 24-hour stool collection for α_1 -antitrypsin (along with a serum level) serves as a screening test for protein-losing enteropathy.

- Exam of the stool for ova and parasites or testing for the stool antigen may reveal the presence of *Giardia* species.
- Normally, stool bile acids should not be detected. If bile acid malabsorption is suspected, quantitative conjugated and unconjugated bile acids may be measured in stool, although this test is not commonly available and thus, not used in routine clinical practice.
- Other laboratory studies:
 - CBC may reveal anemia in patients with iron, folate and vitamin B₁₂ malabsorption, and neutropenia is seen in patients with Shwachman-Diamond syndrome.
 - Total serum protein and albumin levels may be lower than reference range in syndromes in which protein is lost or not absorbed, particularly in protein-losing enteropathy and pancreatic insufficiency.
 - With fat malabsorption or ileal resection, fat-soluble vitamin levels in the serum are low.
 - With bile acid malabsorption, levels of LDL cholesterol may be low.
 - Serum calcium may be low due to vitamin D and amino acid malabsorption
 - Serum vitamin A, E, and carotene may be low due to bile salt deficiency and impaired fat absorption.
 - Other studies must be performed when a specific disease is suspected (e.g., mucosal biopsy for celiac disease, sweat test for cystic fibrosis, or appropriate workup for IBD).
 - Urine analysis should be done to rule out proteinuria in patients with low albumin levels.
 - An upper GI radiographic series is helpful for identification of segmental dilatation or stenosis secondary to bacterial overgrowth.
 - Genetic testing may be performed for identification of inherited malabsorption syndromes.
 - If tissue samples are acquired through a biopsy, ultrastructural analysis may be performed using electron microscopy.

DIFFERENTIAL DIAGNOSIS

- Pancreatic disorders:
 - Cystic fibrosis
 - Shwachman syndrome
 - Johanson-Blizzard syndrome
- Chronic cholestasis:
 - Biliary atresia
 - Vitamin E deficiency
 - Alagille syndrome

- Infectious diarrhea:
 - Giardiasis
 - Cryptosporidiosis
- Mucosal defect:
 - Celiac disease
 - Crohn disease
 - Postinfectious diarrhea
- Congenital brush border enzyme deficiencies:
 - Glucose-galactose transporter deficiency
 - Sucrase-isomaltase deficiency
 - Microvillus inclusion disease
- Abnormal intestinal lymphatic drainage:
 - Primary intestinal lymphangiectasia
 - Secondary intestinal lymphangiectasia

TREATMENT

- The treatment depends on the underlying disease causing malabsorption. Appropriate nutritional support is of paramount importance.
- Specific treatment depends on etiology, for example, gluten-free diet for celiac disease, metronidazole for *Giardia* infection, or removal of the offending agent in a case of food intolerance.

ONGOING CARE

COMPLICATIONS

- Complications vary according to the underlying disease, but malnutrition and its consequences may worsen progressively if the cause is not determined and appropriate treatment prescribed.
- Some of the most frequent complications of malabsorption and malnutrition are: Growth failure, vitamins and micronutrient deficiency (zinc, magnesium, calcium), bone disease, hypoproteinemia and edema, essential fatty acid deficiency, perianal dermatitis, immune dysfunction and anemia.

- K90.9 Intestinal malabsorption, unspecified

FAQ

- Q: When should a patient with malabsorption be referred?
- A: Children with growth failure in whom malabsorption is suspected should be referred to a pediatric gastroenterologist because of the associated high morbidity.
- Q: What is the prognosis of malabsorption?
- A: Some malabsorption syndromes are transient, while others simply require a change in diet. Most disorders that cause secondary malabsorption are progressive and result in significant morbidity due to systemic complications.

MALARIA

Rakesh D. Mistry

BASICS

DESCRIPTION

- Malaria is a febrile illness due to the *Plasmodium* species of protozoan parasites. *P. falciparum* and *P. vivax* most commonly infect humans, although *P. malariae* and *P. ovale* may also produce infection. The *Anopheles* mosquito serves as the vector for *Plasmodium* transmission.
- Malaria was described by the earliest medical writers in China, Assyria, and India, and by the 5th century B.C. Hippocrates was able to describe the characteristic fever patterns and clinical manifestations of the disease.

EPIDEMIOLOGY

- High-risk areas of endemic malaria include parts of Central and South America, Africa, and tropical regions of Asia.
- Malaria is a major cause of infant death in the tropical regions of the world.
- Malaria is the most common cause of fever in travelers returning from foreign countries.
- Risk of malaria infection is highest among travelers to Sub-Saharan Africa and Oceania.

Incidence

- Worldwide, an estimated 300–500 million cases of malaria occur annually.
- ~1,500 cases of malaria are imported into the U.S. each year.

RISK FACTORS

Genetics

- Sickle cell disease and trait confer protection against malaria by 2 postulated mechanisms:
 - Release of a toxic form of heme that possess antimalarial properties
 - The hemoglobin S erythrocyte tends to lose potassium required for adenosine triphosphatase (ATPase) activation, thereby depriving the parasites of nutrients.
- Thalassemia and G6PD deficiency may also provide innate resistance to malaria.

GENERAL PREVENTION

- In the hospital setting, universal precautions should be followed.
- Personal protective measures against *Anopheles* mosquito bites are extremely important:
 - Remain in well-screened areas.
 - Protective clothing is advised, including pants and long-sleeved shirts.
 - Insect repellents, such as DEET, are recommended. However, in children <2 years, concentrations of <10% are recommended; concentrations <35% may be used in older child.
- Chemoprophylaxis is strongly advised for travelers in endemic areas:
 - Chloroquine is the drug of choice in resistant areas (500 mg once a week or 5 mg/kg once a week)
 - Mefloquine is recommended in chloroquine-resistant areas (250 mg once a week; if weight is <15 kg, 5 mg/kg; if weight is 15–19 kg, 1/4 tablet; if weight is 20–30 kg, 1/2 tablet; if weight is 31–45 kg, 3/4 tablet).

- Contraindications include patients taking β blockers or other drugs that alter cardiac conduction, patients with seizure disorders or psychosis, and patients requiring fine-motor skill performance.
- Atovaquone-proguanil (Malarone) is equally effective, with fewer side effects than mefloquine.
- Doxycycline or chloroquine plus proguanil are also alternatives to mefloquine.
- Chloroquine and mefloquine should begin 1 week before travel, continued during the period of exposure, and 4 weeks after leaving the endemic region. Atovaquone-proguanil is started 2 days prior to travel, and continued 1 week after return.
- Travelers should use pyrimethamine-sulfadoxine (Fansidar) if a febrile illness occurs while on chloroquine and access to medical care is not readily available.

ETIOLOGY

- Infection may be acquired throughout the life of the female *Anopheles* mosquito but can also occur through contaminated blood transfusions or needles, or through congenital acquisition.
- The most common infecting species are *P. falciparum* and *P. vivax*.
 - *P. vivax* and *P. ovale* are associated with relapsing disease because of the persistent hepatic stage of the infection.

COMMONLY ASSOCIATED CONDITIONS

- Severe malaria is usually caused by *P. falciparum*.
- Defined as parasitemia >5% with CNS and other end-organ dysfunctions (shock, acidosis, renal failure, and/or hypoglycemia).
- Cerebral malaria is the most serious consequence of malaria infection. Prognosis depends on the management of other complications (e.g., acidosis, renal failure).
- Hemolytic anemia, the most common disease finding, can be severe, especially in *P. falciparum*; the predominant mechanism is due to IV hemolysis from fragile erythrocytes rather than solely rupture from infected cells.
- Tropical splenomegaly syndrome seen in chronic infections caused by *P. malariae* produces splenomegaly, hepatomegaly, portal hypertension, and pancytopenia. In *P. vivax* malaria, acute splenomegaly can induce rupture.
- Blackwater fever is due to acute renal failure caused by accumulation of hemoglobin in the renal tubules resulting in hemoglobinuria with dark urine. This often occurs after repeated attacks of *P. falciparum*.
- Pulmonary edema, distributive shock, dysentery, and nephrotic syndrome have been described.

DIAGNOSIS

HISTORY

- Travel to malaria endemic region
- Pattern of fevers
- Poor compliance with malaria prophylaxis
- Signs and symptoms:
 - Upon return from a malaria endemic zone, presenting findings often include high fevers, headache, chills, sweating, and rigors.
 - Periodicity of fever is dependent on the *Plasmodium* species and is less commonly seen in young children and travelers.
 - Cough, irritability, anorexia, vomiting, abdominal pain, back pain, and arthralgias may be present.
 - Dark urine
 - Cerebral malaria will manifest with signs of increased intracranial pressure, encephalopathy, and seizures.

ALERT

- Failure to obtain a thorough travel history to determine exposure risk to developing malaria can delay the diagnosis and appropriate therapy.
- Delay in the diagnosis of malaria has been shown to increase the morbidity and mortality up to 20-fold compared with diagnosis and treatment within 24 hours of presentation.

PHYSICAL EXAM

- Ill-appearance during fever, with relatively well appearance in between
- Jaundice or pallor
- Hepatosplenomegaly may be present and is more likely observed in chronic infections due to *P. falciparum*.
- There is no rash present in malaria; presence of rash should elicit consideration of alternative diagnoses.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hemoglobin:
 - Hemolytic anemia is present initially as mild then more severe, depending on the *Plasmodium* species.
- WBC:
 - Leukocyte counts are usually normal or low; there is no eosinophilia.
 - Thrombocytopenia due to liver and splenic sequestration occurs in the more severe cases.
- Peripheral smear:
 - Thick and thin peripheral blood smears are required for definitive diagnosis (thick smears enable better sensitivity if the parasitemia is low; thin smears provide for species identification).
 - If initial smears are negative, repeated specimens should be obtained q8–12h during a 72-hour period to confirm a truly negative result.
 - The percent of red cells involved is an important risk factor for severe disease.
 - A parasitemia >5% of red cells, signs of CNS (mental status changes), or other organ involvement are indications for more intensive therapy.

- Rapid diagnostic tests:
 - Newly developed techniques exhibit excellent sensitivity for *Plasmodium* spp., require a small amount of blood for testing, and provide results in <20 minutes
 - Detection of parasitemia levels as low as 0.002%
 - Rapid testing is particularly useful in highly endemic areas; negative results may allow for expectant management and avoid unnecessary empiric therapy.
- Serologic tests:
 - Using indirect immunofluorescent assays may be helpful, but they have a low sensitivity in the early phases of acute infections.

DIFFERENTIAL DIAGNOSIS

- Because of its potential for severe disease, malaria must be ruled out in any febrile traveler returning from an endemic zone.
- Other causes of fever in travelers should be considered, based on the region of travel:
 - Typhoid fever
 - Dengue fever
 - Yellow fever
 - Hepatitis
 - Hemolytic-uremic syndrome
 - Leptospirosis
- Common etiologies of fever, such as sinusitis, pneumonia, and influenza should also be considered.

ALERT

Consider malaria when a patient with unexplained fever has a history of travel.

TREATMENT

MEDICATION (DRUGS)

- Chloroquine phosphate is recommended at a dose of 10 mg/kg PO (maximum, 600 mg), then 5 mg/kg PO in 6 hours (maximum, 300 mg), then 5 mg/kg PO at 24 and 48 hours (maximum, 300 mg) For all *Plasmodium* species except chloroquine-resistant *P. falciparum* and chloroquine-resistant *P. vivax*
- If parenteral therapy is necessary, treatment with quinidine gluconate, 10 mg/kg IV initial dose (maximum, 600 mg) over 2 hours followed by 0.02-mg/kg/min infusion until PO therapy can be started.
- For chloroquine-resistant *P. falciparum* or chloroquine-resistant *P. vivax*; quinine sulfate, 25 mg/kg/d PO in 3 doses for 3–7 days plus doxycycline, 2 mg/kg/d PO b.i.d. for 7 days (maximum, 1 g/d) is recommended.
 - Instead of doxycycline, clindamycin 20–40 mg/kg/d PO in 3 doses for 5 days.
- A safe alternative for children is mefloquine, 15 mg/kg PO followed by 10 mg/kg PO 8–12 hours later.
- Other alternatives include pyrimethamine–sulfadoxine (Fansidar), quinine sulfate plus doxycycline, or atovaquone plus proguanil.

- Primaquine phosphate is used for the prevention of *P. vivax* and *P. ovale* relapses, but should not be used in patients with G6PD deficiency or in pregnancy.
- Artemisinin-based compounds such as artesunate are effective but are not currently licensed in the U.S. or United Kingdom.
- Artemisinin-based combinations are often used in 2nd and 3rd trimester of pregnancy in developing countries.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Travelers diagnosed with malaria infection should be managed as inpatients.

ONGOING CARE

PATIENT EDUCATION

- Consultation with a travel clinic is advisable when traveling into a malaria endemic zone.
- Chemoprophylaxis is not 100% effective; therefore, prevention measures against mosquito bites are equally important.

PROGNOSIS

- The prognosis depends on the *Plasmodium* species, relapsing nature of the disease, chloroquine resistance, and age of the patient.
- Infants with *P. falciparum* infection account for most of the mortality due to malaria, with case-fatality rates between 0.6–3.8%.
- If treated promptly, even *P. falciparum* malaria will respond well to current treatment options.

COMPLICATIONS

- *P. falciparum* tends to cause more severe disease, and morbidity is significantly increased due to multiorgan system involvement.
- Chronic relapses occur from *P. vivax* and *P. ovale* infections, and can occur during periods ranging from every few weeks to a few months.
- Pregnant women remain at higher risk for complication from malaria infection and should strongly be encouraged to refrain from travel to malaria endemic areas.
- Additionally, for semi-immune or nonimmune mothers, transplacental antibodies may be lacking, and the risk of congenital infection may be higher in this subgroup; fortunately, in pregnant patient, increased perinatal mortality has not been reported with malaria in stable, endemic regions.

CODES

ICD9

- 084.1 Vivax malaria [benign tertian]
- 084.6 Malaria, unspecified
- 084.9 Other pernicious complications of malaria

ICD10

- B50.0 Plasmodium falciparum malaria with cerebral complications
- B51.9 Plasmodium vivax malaria without complication
- B54 Unspecified malaria

FAQ

- Q: What is the optimal drug regimen for the young infant or child or the lactating or pregnant female?
- A: The only drug not contraindicated in any of these patients is chloroquine. In chloroquine-resistant areas, mefloquine has been shown to be safe in the 2nd and 3rd trimesters. Limited data suggest safety in the 1st trimester also. Mefloquine is excreted in breast milk; however, limited data suggest safety for young infants. Atovaquone-proguanil is not recommended in pregnant or breastfeeding women, or in children <11 kg.
- Q: Is there a vaccine available to prevent malaria?
- A: No adequate vaccination is currently available; however, recent advances in the technology for introducing malarial DNA coding into bacteria may lead to an effective vaccine in the future.
- Q: How can I determine if the area my patient is traveling to has chloroquine-resistant malaria?
- A: The CDC has an automated traveler’s hotline accessible from a touch-tone phone 24 hours a day, 7 days a week: (404) 332-4559. Questions can also be faxed to (404) 332-4565. The Internet address for information is www.cdc.gov.

MAMMALIAN BITES

Margaret Wolff
Jill C. Posner

BASICS

DESCRIPTION

Injury to the human skin and/or subcutaneous tissues caused by bite, causing local, and in some cases systemic, effects

EPIDEMIOLOGY

- Animal bites:
 - Dogs are responsible for 90–95%, cats, 3–8%; rodents or rabbits, 1%; and raccoons and other animals, 1%.
 - 90% of the offending animals are well known to the victim.
 - Children are the most common victims:
 - Boys are twice as likely as girls to be bitten by dogs; girls are more likely to be bitten by cats.
- Human bites:
 - Incidence is unknown, due to lack of reporting.
 - Most common in children ages 2–5 years.
 - In older children, bites may occur accidentally during sports activities or intentionally during altercations or abusive situations.

Incidence

An estimated 4.5 million dog bites, 400,000 cat bites, and 250,000 human bites occur annually in the U.S.

GENERAL PREVENTION

Ensure that children receive routine immunizations against tetanus and hepatitis and that family pets are immunized against rabies. Encourage children to avoid contact with wild animals and dead animals.

PATHOPHYSIOLOGY

- Animal bites:
 - Dog: Crush and tear injuries, may involve bone
 - Cat: Puncture-type wounds, penetrate deeper and carry a higher risk of infection
 - Human: Generally only violate skin, although penetration into joint and tendon sheath spaces may occur (especially bites overlying the metacarpal-phalangeal areas).
- Infection:
 - Rate of infection:
 - Dog bites: 3–18%
 - Cat bites: 28–80%
 - Human bites: 15–20%
 - More recent studies have suggested an incidence of infection after dog and cat bites to be closer to 2–3%.

- Infections are most commonly polymicrobial with both aerobic and anaerobic organisms.
- Infected dog and cat bites:
 - *Pasteurella* species are the most frequent isolates.
 - Dog: *P. canis*
 - Cat: *P. multocida* and *P. septica*
 - Common anaerobes include *Fusobacterium*, bacterioids, *Porphyromonas*, and *Prevotella*.
- Infected human bites:
 - *Streptococcus anginosus*
 - *Staphylococcus aureus*
 - *Eikenella corrodens*
 - *Fusobacterium* species
 - *Prevotella* species

ETIOLOGY

- Animal bites:
 - Dogs
 - Cats
 - Rodents
 - Wild animals
- Human bites

DIAGNOSIS

HISTORY

Animal bites:

- Type of animal
- Apparent health of the animal
- Provocation for the attack
- Location of the bite or bites
- Availability of animal for undergoing observation (i.e., is it a known animal as opposed to a stray or wild animal?)
- Rabies immunization status of the animal
- Tetanus immunization status of the child
- Hepatitis B immunization status of child
- PMH of patient: Is patient immunocompromised or asplenic?

PHYSICAL EXAM

- Carefully assess neurovascular integrity.
- Location of bite:
 - If bite is located over a joint, assess for violation of joint capsule.
- Examine entire patient to ensure that all wounds are identified and treated.
- Older wounds:
 - Assess for signs of infection such as erythema, induration, purulence, regional adenopathy, and elevated temperature.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood culture if fever or systemic toxicity
- Aerobic and anaerobic cultures from infected wounds

Imaging

In penetrating injuries overlying bones or joints, consider radiography to evaluate for presence of fracture, foreign body (e.g., tooth), and air within joint.

Diagnostic Procedures/Other

No tests routinely done

TREATMENT

MEDICATION (DRUGS)

- Antibiotics: Data are often contradictory. In general:
 - All cat bites should be treated with prophylactic antibiotics, due to high risk of infection with *P. multocida*.
 - Amoxicillin–clavulanic acid is drug of choice (50 mg/kg/d divided b.i.d. or t.i.d. for 5 days).
 - All human bites should be treated with antibiotic prophylaxis. Amoxicillin–clavulanic acid is drug of choice (50 mg/kg/d divided b.i.d. or t.i.d. for 5 days).
 - An alternative antibiotic regimen for penicillin-allergic patients is trimethoprim-sulfamethoxazole plus clindamycin.
 - Bites to the hand, face, deep puncture wounds, and wounds in immunocompromised patients may be treated empirically.
 - Skin and soft-tissue infections requiring hospitalization: Ampicillin/sulbactam 150 mg/kg/d in 4 divided doses. For penicillin-allergic patients, 3rd-generation cephalosporin. Antibiotics with poor activity against *Pasteurella* include penicillinase-resistant penicillins, clindamycin, and aminoglycosides.
- Tetanus prophylaxis if indicated

- Rabies prophylaxis if indicated:
 - Unknown dog or cat; dogs or cats with unknown immunization status that cannot be observed for 10 days
 - Bites from wild animals, including raccoons, bats, skunks, foxes, coyotes
 - Because bat bites may go undetected, especially by a sleeping child, rabies prophylaxis is now recommended after exposure to bats in a confined setting.
 - Rabies is unlikely if the child was bitten by an immunized dog, cat, or other pet (e.g., hamsters, guinea pigs, gerbils).
 - Rabies is unlikely if the child was bitten by a small rodent (squirrels, mice, or rats) or rabbit.
 - The regimen for patients who have not been vaccinated previously should include both human rabies vaccine (a series of 4 doses administered IM on days 0, 3, 7, and 14) and rabies immune globulin (20 IU/kg) administered as much as possible into the wound, the remainder given IM at a site distant from the site used for vaccine administration.
- HIV postexposure prophylaxis (PEP):
 - There are case reports describing transmission of HIV by human bites; however, the risk of transmission due to biting is unknown. It is estimated to be extremely small. Bites with saliva containing no visible blood have no associated risk for transmission and, therefore, are not considered exposures.
 - HIV PEP requires a multidrug regimen administered over 28 days that can be associated with significant toxicity.
 - Decisions to initiate PEP might best be made in consultation with local experts or by contacting the National Clinicians Post-Exposure Prophylaxis Hotline at 888-448-4911.
 - Hepatitis B has been transmitted from nonbloody saliva. Check the vaccination status of the bitten (or biter if necessary) to consider PEP. Unvaccinated children should begin the hepatitis B vaccine series.
 - The transmission rate of hepatitis C via human bites is unknown and no regimen for PEP currently exists.

ALERT

A bite with a break in the skin is considered low risk, and a bite with intact skin is felt to pose no risk.

ADDITIONAL TREATMENT

General Measures

- Wound care:
 - Copious irrigation with normal saline or tap water to remove visible debris
 - Do not use antimicrobial solutions to irrigate.
 - Cleanse but do not irrigate puncture wounds.
- Human bites over metacarpals (clenched-fist injuries) require orthopedic evaluation for possible surgical exploration and irrigation.
- Débride devitalized tissue.
- The increased risk of infection associated with suturing a potentially contaminated wound must be weighed against the cosmetic effect due to nonclosure:
 - Primary closure of larger wounds or significant facial wounds may be indicated unless wound is old or has evidence of infection.
- Hand wounds may be an exception, due to high propensity for infection.

ISSUES FOR REFERRAL

Local regulations dictate the reporting of animal bites to health departments.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Signs and symptoms of infection
- All patients with significant bites should receive follow-up 48 hours after bite.

PROGNOSIS

Most injury from animal bites is trivial, but infections, and rarely deaths, do occur.

COMPLICATIONS

Human bites over metacarpals (clenched fist) can penetrate tendon sheaths, become infected, and result in a tenosynovitis.

MASTOIDITIS

Sadiqa Edmonds

Frances M. Nadel

Oluwakemi Badaki (5th edition)

BASICS

DESCRIPTION

Infection of the mastoid air cells, characterized clinically by protrusion of the pinna and erythema/tenderness over the mastoid process; can range from an asymptomatic illness to a severe life-threatening disease.

EPIDEMIOLOGY

- Most patients are between 6–24 months old.
- Males more than females, ratio of 2:1
- It is unusual to see mastoiditis in the very young, because of incomplete pneumatization of the mastoid air cells.

Incidence

- At the start of the 20th century, 20–50% of cases of otitis media developed into coalescent mastoiditis. The routine use of antibiotics for otitis media and aggressive management of treatment failures has decreased incidence to 0.2–0.4%.
- Although some single-site reports have suggested that mastoiditis is on the rise, larger population-based studies demonstrate a stable incidence.

RISK FACTORS

- Age <2 years of age
- Acute otitis media

GENERAL PREVENTION

- Appropriate early treatment of otitis media and timely follow-up to identify treatment failures
- Avoid factors that predispose to otitis media, including caretaker smoking and bottle-feeding.
- Early recognition of mastoiditis decreases the risk of intracranial complications.
- Streptococcal vaccination may help decrease the occurrence of otitis media.

PATHOPHYSIOLOGY

- The mastoid process is the posterior portion of the temporal bone and consists of interconnecting air cells that drain superiorly into the middle ear. Because these mastoid air cells connect with the middle ear, all cases of acute otitis media are associated with some mastoid inflammation.
- Acute mastoiditis develops when the accumulation of purulent exudate in the middle ear does not drain through the eustachian tube or through a perforated tympanic membrane but spreads to the mastoid.
- Acute mastoiditis can progress to a coalescent phase after the bony air cells are destroyed and may then progress to subperiosteal abscess or to chronic mastoiditis.

ETIOLOGY

- Acute mastoiditis is generally caused by an extension of the inflammation and infection of acute otitis media into the mastoid air cells. However, up to 50% of patients present without evidence of preceding otitis media.
- The bacteria isolated from middle ear drainage or from the mastoid are usually *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Haemophilus influenzae*, or *Staphylococcus aureus*. However, many patients' cultures are sterile:
 - *S. pneumoniae* is the most frequently isolated cause of mastoiditis in pediatric patients. *S. pneumoniae* resistance to penicillin may be as high as 30%, with the 19A serotype being the most common. With the advent of the new 13 valent pneumococcal vaccine (which contains the 19A serotype), the epidemiology may change in the coming years.
- Chronic mastoiditis is usually caused by *S. aureus*, anaerobic bacteria, enteric bacteria, and *Pseudomonas aeruginosa*:
 - Chronic mastoiditis is often a multiple-organism infection.
- Unusual agents of chronic mastoiditis include *Mycobacterium tuberculosis*, atypical mycobacteria, *Nocardia asteroides*, and *Histoplasma capsulatum*.
- Cholesteatomas may contribute to the development of mastoiditis by impeding mastoid drainage or erosion of underlying bone.

DIAGNOSIS

HISTORY

- Usually includes a recent or a chronic history of treatment for otitis media
- Sign and symptoms:
 - May include fever, otalgia, otorrhea, and postauricular swelling:
 - Children who are already on antibiotics may present with more subtle findings.
 - Intracranial extension should be suspected if there is lethargy, a stiff neck, headache, focal neurologic symptoms, seizures, visual changes, or persistent fevers despite appropriate antibiotic treatment.
 - Labyrinthitis initially presents with tinnitus and nausea, which can progress to vomiting, vertigo, nystagmus, and loss of balance.

PHYSICAL EXAM

- The ear may protrude away from the scalp:
 - In infants, the ear protrudes out and is displaced down.
- The tympanic membrane often is hyperemic, with decreased mobility:
 - The tympanic membranes of children on antibiotics may have a normal appearance.

- The mastoid process is tender, with soft-tissue swelling:
 - The overlying skin may be warm and erythematous, with posterior auricular fluctuance.
- In chronic mastoiditis, the fever and posterior auricular swelling are often not present, and the patient presents with ear pain, persistent drainage, or hearing loss.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential:
 - May show a leukocytosis with a neutrophil predominance
- ESR/CRP:
 - May be elevated in acute mastoiditis but is usually normal in the chronic stage; more often seen elevated in complicated mastoiditis
- Purified protein derivative (PPD):
 - Should be done if tuberculosis is suspected
- Middle-ear aspirate obtained by myringotomy:
 - Gram stain and cultures for aerobic and anaerobic bacteria
 - There is some correlation between middle-ear bacterial cultures and mastoid cultures.

Imaging

- X-rays:
 - Reveal haziness of the mastoid air cells and can show bony destruction in more advanced disease
 - Are unreliable and can be falsely normal, as well as falsely abnormal
- Temporal bone and cranial CT:
 - Helpful in the confirmation of the diagnosis, identification of coalescence or a subperiosteal abscess, and evaluation for concomitant intracranial complications
 - Intracranial complications are best seen with MRI.

Diagnostic Procedures/Other

Lumbar puncture must be performed in any child with symptoms of meningitis.

DIFFERENTIAL DIAGNOSIS

- Parotitis
- Posterior auricular lymphadenopathy or cellulitis
- Otitis externa or an ear canal furuncle
- Neoplastic disease:
 - Leukemia
 - Lymphoma
 - Rhabdomyosarcoma
 - Histiocytosis X
- Branchial cleft anomaly
- Tuberculosis

TREATMENT

MEDICATION (DRUGS)

- Parenteral antibiotics are chosen on the basis of the most likely organisms and regional bacterial resistance patterns.
- In acute mastoiditis, broad-spectrum antibiotics such as ampicillin-sulbactam, ceftriaxone, or clindamycin can be used. If pseudomonas is suspected, antibiotic coverage should be expanded to cover this organism.
- Broad-spectrum coverage, such as oxacillin and gentamicin is recommended for chronic mastoiditis.
- If *M. tuberculosis* is suspected, then antituberculosis therapy should be started.

ADDITIONAL TREATMENT

General Measures

Middle-ear drainage is essential; therefore, a myringotomy with or without tube placement should be performed early.

SURGERY/OTHER PROCEDURES

- Indications for surgical intervention include:
 - Subperiosteal abscess
 - Coalescence
 - Facial nerve palsy
 - Meningitis
 - Intracranial abscess
 - Venous thrombosis
 - Persistent symptoms despite adequate antibiotic treatment
- In the preantibiotic era, mastoidectomy was the treatment of choice for mastoiditis. Currently, this therapy is generally reserved for cases complicated by the indications above.

IN-PATIENT CONSIDERATIONS

Admission Criteria

Admit for IV antibiotics, and for ear, nose, and throat (ENT) evaluation to ensure response to antibiotics and to rule out complications.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- If patients respond quickly to parenteral therapy, they can complete a 3-week course with oral antibiotics and weekly follow-up visits.
- Audiograms should be performed later to screen for hearing loss.

PROGNOSIS

- Mastoiditis has a good prognosis if treated early. However, intracranial extension of mastoiditis can lead to permanent neurologic deficits and death.
- Chronic mastoiditis can lead to irreversible hearing loss.

COMPLICATIONS

- The mastoid's proximity to many important structures can result in serious complications from extension of infection or as a response to the inflammatory process.
- Complication rates may be as high as 16%.
- Intracranial complications include meningitis and extradural, subdural, or brain parenchymal abscesses.
- Venous sinus thrombophlebitis results from extension of disease to the sigmoid or lateral sinus:
 - Sepsis, increased intracranial pressure, or septic emboli may result.
- Facial nerve palsy is usually unilateral and can be permanent.
- Labyrinthitis, petrositis, or osteomyelitis may result from extension of the infection into adjacent bones.
- Subperiosteal abscess
- Hearing loss can occur from destruction of the ossicles or from labyrinthine damage.
- Bezold abscess is a deep neck abscess along the medial sternocleidomastoid muscle that develops when the infection erodes through the tip of the mastoid bone and dissects down tissue planes.
- Gradenigo syndrome:
 - Triad of 6th nerve palsy, retro-orbital pain and otorrhea

FAQ

- Q: Do all children with mastoiditis need a CT scan of the head if mastoiditis is suspected?
- A: No. In general, if the child with mastoiditis has mild swelling, no fluctuance of the mastoid, and responds to therapy, no CT scan is needed. A patient who appears toxic or fails to respond to appropriate antibiotic therapy, or one who may be a surgical candidate, should undergo additional imaging studies.
- Q: Should all children with mastoiditis be admitted to the hospital?
- A: Yes. In general, admission with IV antibiotics and ENT evaluation is warranted to ensure response to antibiotics and rule out complications.

MEASLES (RUBEOLA, FIRST DISEASE)

Jeffrey S. Gerber

BASICS

DESCRIPTION

- An exanthematous disease that has a relatively predictable course, making clinical diagnosis possible.
- Misdiagnosis is common. Because it is rare and may occur in outbreaks, cases are often initially misdiagnosed as Kawasaki disease or Stevens-Johnson syndrome.
- Patients are contagious from 1–2 days before onset of symptoms (3–5 days before rash) until 5 days after the appearance of the rash. The incubation period is generally 8–12 days from exposure to onset of symptoms and ~14 days until the appearance of rash.
- Types of measles include the following:
 - Typical measles
 - Modified measles: Occurs in children with partial antibody protection (after post-exposure administration of immunoglobulin or in infants <9 months old with transplacental antibodies).
 - Clinically similar to typical measles but is generally mild
 - The patient may be afebrile and the rash may last only 1–2 days.
 - Atypical measles: Caused by a hypersensitivity reaction to measles infection in those who received killed virus vaccine between 1963 and 1967 and are subsequently exposed to wild-type virus.

EPIDEMIOLOGY

- Measles is one of the most highly contagious of all infectious diseases.
- Hospital or clinic waiting rooms (especially pediatric emergency department waiting rooms) have been identified as a major risk, accounting for up to 45% of the known exposures. With adequate immunization (2 doses = 99% effective), measles could be eliminated as a disease.
- Although no longer endemic in the U.S., networks of intentionally unvaccinated children have led to several recent U.S. outbreaks originating from measles virus imported from abroad.
- Since 20 million cases of measles occur globally per year (>150,000 deaths), it is critical to maintain high levels of vaccination coverage.

Incidence

- Before the 1963 licensure of vaccine, an estimated 3–4 million people acquired measles in the U.S. each year; by 1983, there were only 0.7 cases per 100,000 population.
- Delays in immunization facilitated large outbreaks in the U.S. from 1989–1991, peaking in 1990 when 27,672 cases were reported, 89 of which were fatal.
- From 2001–2008, 557 cases of measles and 38 outbreaks were reported in the U.S.; 42% were known to be imported from 44 countries.

GENERAL PREVENTION

- Vaccine recommendations:
 - Routine vaccination against measles, mumps, and rubella (MMR) for children begins at 12–15 months of age, with a second MMR vaccination at age 4–6 years.
 - With the recent resurgence of measles, aggressive employee immunization programs should be pursued for all health care workers.
 - Health care workers born after 1956 who have no documentation of vaccination or evidence of measles immunity should be vaccinated at the time of employment and revaccinated ≥ 28 days later.
- Infection control measures:
 - Any inpatient suspected of having measles should be in a negative-pressure respiratory isolation room; health care workers must wear masks, gloves, and gowns (airborne and contact precautions).
 - Isolation is required for 4 days after the 1st appearance of the rash; immune-compromised patients require isolation for the course of the illness.
 - All suspected cases of measles should be reported immediately to the local health department.

PATHOPHYSIOLOGY

Transmission of measles occurs through direct contact with infectious droplets; less commonly by airborne spread.

ETIOLOGY

Measles is an RNA virus (paramyxovirus, genus *Morbillivirus*) with only 1 serotype.

DIAGNOSIS

- The disease involves fever, cough, conjunctivitis, and coryza with an erythematous rash, which has a characteristic progression:
 - The rash appears on the face (often the nape of the neck, initially) and abdomen 14 days after exposure. The rash is erythematous and maculopapular and spreads from the head to the feet, often becoming confluent at more proximal sites.
- Pharyngitis, cervical lymphadenopathy, and splenomegaly may accompany the rash.

- Atypical measles:
 - This group of young adults (2nd and 3rd decades of life) may become quite ill, with sudden onset of fever from 103–105°F and headache. The rash, unlike typical measles, appears initially on the distal extremities, progressing cephalad.
 - Most patients with atypical measles have pneumonia, often with pleural effusions.
 - Diagnosis depends on clinical recognition and by serologic and molecular (RNA) testing.

HISTORY

- Case definition from the CDC includes:
 - Generalized rash lasting ≥ 3 days; and
 - A temperature of $\geq 38.3^\circ\text{C}$ (101°F); and
 - Cough, coryza, or conjunctivitis; and
 - Positive testing or epidemiologic linkage to known case
- The mean incubation period is 10 days (range: 8–21 days).
- The prodrome of measles lasts 2–4 days and begins with symptoms of upper respiratory infection, fever up to 104°F, malaise, conjunctivitis, photophobia, and increasing cough.
- During the prodrome, Koplik spots (white spots on the buccal mucosa) appear on most people.
- Following this prodrome, the rash appears on the face (often initially at the hairline) and abdomen (14 days after exposure). The rash is erythematous and maculopapular and spreads from the head to the feet.
- After 3–4 days, the rash begins to clear, leaving a brownish discoloration and fine scaling.
- Fever usually resolves by the 4th day of rash.

DIAGNOSTIC TESTS & INTERPRETATION

- The course of typical measles follows a predictable pattern; therefore, laboratory studies to confirm infection are rarely indicated.
- At the beginning of a suspected case, confirmation of the index cases is important.

Lab

- Serum measles-specific IgM titer (simplest):
 - Sensitivity may be diminished if assay performed <72 hours from onset of rash; repeat if negative. IgM detectable for at least 1 month from onset of rash.
 - A comparison of IgG titers obtained during the acute and convalescent stages can be done. Blood samples must be taken at least 7–10 days apart.
- Culture or RNA (RT-PCR) testing of nasopharyngeal, throat, blood, or urine.

DIFFERENTIAL DIAGNOSIS

With a careful history and physical exam, it is usually possible to diagnose measles. The differential diagnosis includes:

- Steven-Johnson syndrome
- Kawasaki disease
- Other viral exanthem
- Meningococemia
- Rocky Mountain spotted fever (RMSF)
- Toxic shock syndrome

TREATMENT

ADDITIONAL TREATMENT

General Measures

- No specific therapy; supportive care.
- Ribavirin active in vitro, but not approved by FDA for treatment of measles.
- Antipyretics, oral fluids, and room humidification to help reduce cough are usually sufficient.
- Vitamin A treatment of children with measles in developing countries has been associated with decreases in both morbidity and mortality.
 - The World Health Organization recommends vitamin A for all children with measles worldwide.
 - Vitamin A is given once daily for 2 days:
 - 200,000 IU for children ≥12 months of age.
 - 100,000 IU for infants 6–11 months of age.
 - 50,000 IU for infants <6 months of age.
 - The higher dose may be associated with vomiting and headache for a few hours.
 - For children with ophthalmologic evidence of vitamin A deficiency, a 3rd dose at 4 weeks is indicated.
 - Vitamin A is available in 50,000 IU/mL solution and may be given orally.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

In uncomplicated measles infection, clinical improvement and fading of rash typically occur on the 3rd or 4th day.

PROGNOSIS

- Mortality in the modern outbreak of 1989–1990 occurred in 3 of every 1,000 cases in the U.S.
- Case fatality rates are increased in immunocompromised children.

COMPLICATIONS

- Complication rate in 1989–1990 outbreaks that occurred throughout the country was 23% and included diarrhea (9%), otitis media (7%), pneumonia (6%), and encephalitis (0.1%):
 - Encephalitis, which can lead to permanent neurologic sequelae, occurs in 1 of every 1,000 cases reported in the U.S.
 - Croup, myocarditis, pericarditis, and disseminated intravascular coagulation (black measles) can also occur.
- In 1990, ~18–20% of patients required hospitalization, many for either dehydration or pneumonia.
- In patients with poor nutrition, most common in developing countries, mortality is higher.
- Subacute sclerosing panencephalitis (SSPE) occurs in 1 per 100,000 children with naturally occurring measles:
 - After an incubation period of several years (mean 10.8), a progressive, usually fatal, encephalopathy develops among unvaccinated children.
 - Patients with SSPE are not infectious.

FAQ

- Q: If a health care worker has had a natural measles infection or measles immunization, should one be concerned about infection following exposure?
- A: Those persons born before 1957 who had wildtype measles virus infection are usually immune from reinfection. However, in a report in 1993, 4 health care workers who were previously vaccinated with positive preillness measles antibody levels developed modified measles following exposure to infected patients. Therefore, all health care workers should observe respiratory precautions in caring for patients with measles.
- Q: During an outbreak of measles, should children <12 months of age be vaccinated?
- A: In an outbreak of measles, public health officials may recommend vaccination of infants ages 6–11 months with a single-antigen measles vaccine; children initially vaccinated before their 1st birthday should be revaccinated at 12–15 months of age. A 2nd dose should be administered during the early school years.

MECKEL DIVERTICULUM

Edisio Semeao

BASICS

DESCRIPTION

- Meckel diverticulum is the most common congenital abnormality of the GI tract.
- A congenital anomaly that is part of the group known as the omphalomesenteric duct remnants
- In pediatric patients, the most common clinical presentation is with painless rectal bleeding.
- Other symptoms that may also be described include recurrent abdominal pain, abdominal distention, nausea, and/or vomiting.

EPIDEMIOLOGY

- Meckel diverticulum was 1st described by Johann Meckel in 1809.
- A remnant of the embryonic yolk sac found in ~2% of all infants
- Although the presence of Meckel diverticulum is 2% in the population, the rarity of this anomaly in clinical practice is that only 4–6.5% of patients are symptomatic.
- The development of symptoms seems to be age related, with the peak incidence being early childhood (2 years).
- 80% of all patients requiring surgery were <10 years of age, and nearly 50% were <2 years of age.

Incidence

- Meckel diverticulum tends to be more common in males, with a male/female ratio of 3:2, and also with males having more symptomatic diverticula.
- These have also been associated with several other congenital anomalies that include:
 - Anorectal atresia (11%)
 - Esophageal atresia (12%)
 - Minor omphalocele (25%)
 - Cardiac malformations
 - Exophthalmos
 - Cleft palate
 - Annular pancreas
 - Some central nervous system malformations

PATHOPHYSIOLOGY

- Meckel diverticulum is a true diverticulum containing all 3 layers of the bowel wall, and its vascular supply comes from a remnant of the vitelline artery.
- Most of these diverticula are lined with ileal mucosa, but ectopic tissue is often present.
- ~50% of diverticula contain ectopic tissue.
 - Gastric tissue accounts for 60–85%.
 - Pancreatic tissue accounts for 5–16%.
 - Other less common tissue types include colonic and duodenal.
- Of the symptomatic cases of Meckel diverticulum, 40–80% have some type of ectopic tissue, with the most common being gastric or pancreatic type.

ETIOLOGY

- This abnormality results from the incomplete obliteration of the fetal omphalomesenteric (vitelline) duct between the 7th and 8th weeks of gestation.
- The vitelline duct communicates with the yolk sac and involutes as the placenta replaces the yolk sac as the source of fetal nutrition. Failure of this process results in various anomalies; Meckel diverticulum accounts for 90% of the vitelline duct anomalies.
- This diverticulum originates from the antimesenteric border of the bowel in the region of the terminal ileum and proximal to the ileocecal valve. It can be between 3 and 6 cm in length.
- Other intestinal diverticula are more common in the jejunum and on the mesenteric border of the bowel.

COMMONLY ASSOCIATED CONDITIONS

Malignancies have also been reported in association with Meckel diverticulum. These are present within the diverticulum and can cause obstructive symptoms or can be found incidentally. Sarcomas are most common, followed by carcinoids and adenocarcinomas.

DIAGNOSIS

HISTORY

- Bleeding:
 - In children, the most common presentation is with painless rectal bleeding, which may range from occult blood to frank bright red blood and hemodynamic instability.
 - Bleeding is thought to occur owing to the highly acidic secretions of the gastric tissue on the adjacent tissues, which may cause ulcerations that lead to bleeding. Similarly, the alkaline secretions of the pancreatic tissue may also cause ulcerations and lead to bleeding.
 - The bleeding, even in the most severe cases, tends to be self-limiting, because of constriction of the splanchnic vessels secondary to hypovolemia.
 - Bleeding is most commonly seen in children <5 years of age. In diverticula that bleed, 90% have ectopic gastric mucosa.
- Obstruction:
 - Partial or complete small bowel obstruction
 - The clinical symptoms in this setting include recurrent abdominal pain, abdominal distention, nausea, and vomiting.
 - This is the most common type of presentation in adults and can also occur in up to 40% of pediatric patients. It results from intussusception, in which the Meckel diverticulum serves as a lead point.
 - Intraabdominal bands, volvulus, or internal herniation may also lead to an obstructive presentation.

- Inflammation/fever:

- Another common presentation for symptomatic Meckel diverticulum is inflammation/diverticulitis, which can occur in 12–40% of cases.
- Patients often present with signs and symptoms consistent with appendicitis, and the diagnosis is made at the time of surgical exploration.
- In a subset of this group (~1/3), the diverticulum may perforate from infarction or ulceration and lead to a more acute and toxic presentation.
- The rule of 2s: 2% of the population, 2 inches in length, 2 feet from the ileal cecal valve, 2 types of tissue, 2% are symptomatic, 2 times more boys affected than girls.

PHYSICAL EXAM

- Physical exam findings are variable and are dependent upon the type of presenting complications.
- In children with rectal bleeding, the exam is usually benign except for a positive rectal exam and usually low BP and tachycardia.
- Patients with obstructive symptoms may have abdominal distention and tenderness and hyperactive bowel sounds.
- Patients with an inflammatory (diverticulitis) type of presentation will have findings similar to those in appendicitis, with the possibility of peritoneal signs in cases of perforation.
- Signs and symptoms:
 - Rectal bleeding
 - Obstruction: Abdominal pain/vomiting
 - Inflammation: Fever

DIAGNOSTIC TESTS & INTERPRETATION

- The diagnosis of symptomatic Meckel diverticulum is difficult to make and requires a high index of suspicion.
- This diagnosis should be considered in any patient with recurrent unexplained abdominal pain, nausea and vomiting, or rectal bleeding.

Lab

- The diagnosis cannot be made with laboratory evaluation or plain radiography.
- Laboratory analysis may be helpful to determine the degree of bleeding with a hemoglobin count and a coagulation profile to rule out an underlying bleeding disorder.
- Plain radiographs may show evidence of obstruction, but are not diagnostic of Meckel diverticulum.

Imaging

- Contrast studies such as upper gastrointestinal series with small bowel follow-through or enteroclysis studies are limited in value because the layers of barium in the bowel can obscure the diverticulum.
- CT scan and ultrasound are often nonspecific in diagnosis but can be helpful in looking for other causes of presenting symptoms.

- Endoscopy and colonoscopy are not sensitive for the diagnosis but can be helpful in identifying other causes that may explain symptoms.
- Angiography may not be helpful because the vascular supply is usually normal.
- Red cell–tagged scans are not specific for Meckel diverticulum, but may be useful in localizing the site of bleeding.

Diagnostic Procedures/Other

- The most useful method of diagnosis of Meckel diverticulum is with a Meckel scan (technetium-99m pertechnetate scan):
 - This technique, however, depends on the presence of ectopic gastric mucosa within the diverticulum to have uptake of the isotope by the gastric mucosa. Because not all diverticula contain gastric mucosa, this scan may not be of value in all situations.
 - However, because complications such as bleeding are usually (90%) associated with ectopic gastric tissue, this test may be diagnostic in many symptomatic cases.
 - In children, the scan has a sensitivity and specificity of 85% and 95%, respectively, but in adults these values fall to 62.5% and 9%, respectively.
 - Technetium-99m pertechnetate is taken up by the ectopic gastric tissue (mucous neck secreting cells). Certain substances enhance the detection of the ectopic gastric tissue, including cimetidine, glucagon, and pentagastrin.
- False results can occur in 20% of the scans.
 - False-positive results with bleeding: Intussusception, hemangioma, arteriovenous malformation (AVM), inflammatory lesion, Crohn disease, peptic ulcer, carcinoid and uterine fibroids
 - False-positive results without bleeding: Ureteral obstruction, sacral meningocele
 - False-negative results: Barium, bladder overdistention, no gastric mucosa present
- Surgery: In situations in which the Meckel scan is nondiagnostic or in patients with nonbleeding symptoms (but when there is a high index of suspicion for Meckel diverticulum), laparoscopy has been shown to be effective and have less morbidity than an exploratory laparotomy.

DIFFERENTIAL DIAGNOSIS

Based on the 2 main clinical symptoms:

- Bleeding:
 - Rectal fissure
 - Polyps
 - Allergic proctitis
 - Infectious colitis
 - Lymphonodular hyperplasia
 - AVM
 - Hirschsprung enterocolitis
 - Peptic ulcer disease
 - Inflammatory bowel disease
 - Hemolytic uremic syndrome
 - Henoch-Schönlein purpura

- Obstruction:
 - Appendicitis
 - Intussusception
 - Malrotation/volvulus
 - Intestinal duplication
 - Colonic diverticulitis
 - Adhesions/strictures

TREATMENT

ADDITIONAL TREATMENT

General Measures

The treatment for Meckel diverticula that are symptomatic and identified is surgical removal.

SURGERY/OTHER PROCEDURES

- Surgical resection can be done with simple diverticulectomy, but in cases in which the adjunct ileum is damaged or there is further evidence of ectopic tissue, a limited resection may be required.
- The bigger dilemma is what should be the approach when a Meckel diverticulum is found incidentally and the patient is asymptomatic:
 - Previous research had indicated that the morbidity for diverticulectomy is ~9% and that, because the risk of developing symptoms in a lifetime was 4%, these diverticula should be left in place. More recent work has shown a much lower morbidity (2%) associated with the removal of the diverticulum; thus, some researchers have advocated removal of the diverticulum that is found incidentally.
 - The development of new techniques such as laparoscopy and stapling devices has aided in decreasing the morbidity and mortality in this procedure.
- There have been several series that have compared features of symptomatic versus asymptomatic diverticula to see if there are characteristics that would help in deciding the approach to asymptomatic diverticulum. If these features are noted, the risk of developing symptoms later in life if the diverticulum is not removed is significantly increased. These include:
 - Age, younger patients (<8–10 years of age)
 - Longer diverticulum (≥ 2 cm)
 - Narrower base (≤ 2 cm in diameter)

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Bleeding: Address issues of anemia and volume status based on vital signs and blood tests.
- Obstruction: Evaluate the need for acute management (surgical) and decompression.

CODES

ICD9

751.0 Meckel's diverticulum

ICD10

Q43.0 Meckel's diverticulum (displaced) (hypertrophic)

FAQ

- Q: What are the reasons for resection of a Meckel diverticulum?
- A: Narrowing at base of diverticulum or presence of ectopic tissue resulting in bleeding
- Q: What is the most common ectopic tissue present in Meckel diverticulum?
- A: Gastric
- Q: What is the most common presentation of a Meckel diverticulum?
- A: Intermittent, painless rectal bleeding

MEDIASTINAL MASS

Charles Bailey

BASICS

DEFINITION

Space-occupying lesion of the mediastinum:

- Anterior mediastinum includes the thymus and other structures anterior to the pericardium.
- Middle mediastinum contains the heart, great vessels, ascending aorta, and aortic arch, as well as lymph nodes.
- Posterior mediastinum contains the tracheobronchial tree, esophagus, descending aorta, and neural structures.

PATHOPHYSIOLOGY

Morbidity is due to compression of adjacent normal structures, particularly large airways, heart, and great vessels.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Congenital/anatomic:
 - Thoracic meningocele (posterior)
 - Large normal thymus in neonate (anterior)
 - Bronchogenic, pericardial, or foregut cyst (middle)
 - Aortic aneurysm and other vascular anomalies (middle)
- Infectious (may cause mediastinal adenopathy and/or pulmonary nodules) (middle/posterior):
 - Tuberculosis
 - Histoplasmosis
 - Aspergillosis
 - Coccidioidomycosis
 - Blastomycosis
- Foreign body in the trachea or esophagus
- Sarcoidosis
- Tumor:
 - Benign:
 - Thymoma (anterior)
 - Teratoma/Dermoid cyst (anterior)
 - Lymphangioma/Cystic hygroma (middle/posterior)
 - Hemangioma (posterior/middle)
 - Ganglioneuroma (posterior)
 - Neurofibroma (posterior)
 - Malignant:
 - Hodgkin's lymphoma (anterior/middle)
 - Non-Hodgkin's lymphoma or leukemia (anterior/middle)
 - Neuroblastoma (posterior)
 - Ganglioneuroblastoma (posterior)
 - Ewing sarcoma or osteogenic sarcoma (anterior/posterior)
 - Malignant germ cell tumor (anterior)
 - Pheochromocytoma (posterior)
 - Rhabdomyosarcoma or pleuropulmonary blastoma (any)
 - Neurofibrosarcoma (posterior)

APPROACH TO THE PATIENT

Goal is to establish diagnosis promptly and begin treatment as indicated, because condition may progress rapidly and become life threatening. If you suspect a malignancy, the child should be immediately referred to an oncologist.

HISTORY

- **Question:** Systemic symptoms (fever, weight loss, night sweats, fatigue)?
- **Significance:** May be associated with infection or malignancy.
- **Question:** Cough, wheeze, dyspnea on exertion, orthopnea?
- **Significance:** May indicate early airway compromise.
- **Question:** Face/neck swelling?
- **Significance:** Suggests superior vena cava syndrome.

PHYSICAL EXAM

- Pulse oximetry
- Check for signs and symptoms noted below
- **Finding:** Edema/suffusion of face and neck, jugular venous distension, conjunctival injection, headache, altered mental status?
- **Significance:** Superior vena cava syndrome.
- **Finding:** Cough (nonproductive), orthopnea or dyspnea, stridor or wheezing?
- **Significance:** Airway compression.
- **Finding:** Quiet heart sounds, hypotension, narrowed pulse pressure, or pulsus paradoxus?
- **Significance:** Cardiac tamponade/diastolic dysfunction.
- **Finding:** Lymphadenopathy or hepatosplenomegaly?
- **Significance:** Suggests malignancy or infection. Low cervical, posterior, or supraclavicular adenopathy particularly concerning for malignancy.
- **Finding:** Ecchymoses, petechiae, and mucosal bleeding?
- **Significance:** Suggest thrombocytopenia, which can be seen in leukemia.
- **Finding:** Horner syndrome.
- **Significance:** Posterior mediastinal mass, most commonly a neuroblastoma in a young child?

DIAGNOSTIC TESTS & INTERPRETATION

Consider pulmonary function tests if respiratory reserve is in question.

- **Test:** CBC with differential.
- **Significance:** Anemia, thrombocytopenia, neutropenia, or circulating blasts frequently noted in leukemia or lymphoma; leukocytosis in infection.
- **Test:** Lactate dehydrogenase, uric acid, electrolytes, phosphate, creatinine.
- **Significance:** Tumor lysis screen.
- **Test:** Purified protein derivative (PPD) skin test.
- **Significance:** Tuberculosis.

- **Test:** Other assays for specific pathogens based on history of exposure.
- **Significance:** For a patient with a large mass or potential cardiopulmonary compromise, goal is rapid diagnosis using least invasive/painful procedure, to minimize need for sedation/anesthesia.
- **Test:** Bone marrow aspiration/biopsy.
- **Significance:** Simplest procedure if CBC is suspicious.
- **Test:** Lymph node biopsy.
- **Significance:** If adenopathy at easily accessible site.
- **Test:** Biopsy of mass.
- **Significance:** Consider radiologically guided needle biopsy.
- **Test:** Pleurocentesis, pericardiocentesis, or excision of isolated mass.
- **Significance:** May have both diagnostic and therapeutic roles.
- **Test:** Lumbar puncture.
- **Significance:** May be combined with other procedures if meningitis or hematologic malignancy is suspected.

ALERT

Recumbent positioning, sedation, or positive pressure ventilation may lead to catastrophic respiratory or cardiovascular collapse in patients with partial compromise. Procedures may need to be done with local anesthesia or minimal sedation in these patients.

Imaging

- Chest radiograph (lateral film required) to establish size and location of mass
- CT of the chest (if patient can tolerate semirecumbent positioning) to define size, location, and consistency of mass, and to assess large blood vessels and airways
- Echocardiogram to assess diastolic filling and vascular patency

TREATMENT

- First Line
 - Steroids may be given after diagnosis is obtained to treat hematologic malignancies or decrease edema/inflammation.
 - Additional therapy depends on diagnosis (e.g., chemotherapy, antibiotics).

SPECIAL THERAPY

- Radiotherapy
 - May be indicated for emergent management of malignancies

ADDITIONAL TREATMENT

General Measures

- Close monitoring of cardiorespiratory status
- With cardiorespiratory compromise, attempt to avoid positive-pressure ventilation, if feasible
- Definitive therapy will be based on the diagnosis.

ALERT

- Do not treat a patient with wheezing who has no history of asthma with steroids without obtaining a chest radiograph to confirm that there is no mediastinal mass.
- If symptoms are progressing rapidly or there is evidence of superior vena cava syndrome, tracheal compression, or spinal cord compression, emergent steroids or radiation may be required, following rapid diagnostic procedures if possible.

SURGERY/OTHER PROCEDURES

- May be required for diagnostic biopsy
- Excision may relieve acute compression, and may be primary therapy for isolated benign mass.

 **ONGOING CARE**

DISPOSITION

Admission Criteria

- All patients with significant mass, until cardiopulmonary risk defined
- All patients with evidence of significant airway or vascular compression

Discharge Criteria

- Resolution/resection of mass, or clear evidence of cardiopulmonary stability through all activities of daily living (ADLs), including sleep.

COMPLICATIONS

- Superior vena cava syndrome
- Tracheal compression
- Spinal cord compression

- Pleural and pericardial effusions
- Secondary infection
- Horner syndrome: Ptosis, miosis, and anhidrosis resulting from compression of the cervical sympathetic nerve trunk
- Esophageal narrowing or erosion: May result in feeding difficulty or bleeding

 **CODES**

ICD9
786.6 Swelling, mass, or lump in chest

- ICD10**
- D38.3 Neoplasm of uncertain behavior of mediastinum
 - R22.2 Localized swelling, mass and lump, trunk

FAQ

- Q: What should be done if the child is asymptomatic and a mediastinal mass is an incidental finding on chest x-ray?
- A: Careful history and physical with specific attention to pulmonary, cardiac, and hematologic systems.
 - Vital signs to include temperature and pulse oximetry
 - CBC, differential, ESR, tumor lysis labs
 - PPD, anergy panel if high risk for tuberculosis or initial evaluation negative
 - CT of chest
 - Referral to oncologist, surgeon, or infectious disease specialist pending above results
- Q: When should an oncologist be consulted?
- A: With any of the following:
 - Rapidly enlarging mass
 - Signs and symptoms of tracheal compression, superior vena cava syndrome, or spinal cord compression
 - Hepatomegaly, lymphadenopathy, bruises, or petechiae on physical examination
 - Anemia, thrombocytopenia, or leukocytosis suggesting bone marrow involvement
 - Malignant histology demonstrated with biopsy
 - When help is needed in establishing diagnosis

MEGALOBLASTIC ANEMIA

Kim Smith-Whitley

BASICS

DESCRIPTION

Anemia characterized by megaloblastic RBCs (large cells with abundant cytoplasm) in the bone marrow and hypersegmented neutrophils on peripheral blood smears.

EPIDEMIOLOGY

Exact incidence and prevalence figures in American children are unknown, but overall the disease is rare.

PATHOPHYSIOLOGY

- Abnormal DNA synthesis in hematopoietic precursors
- Anemia is due to ineffective hematopoiesis and hemolysis.

ETIOLOGY

Overall causes are numerous, but the following are the most common general etiologic categories:

- Vitamin B₁₂ (cobalamin) deficiency
- Folate (folic acid) deficiency
- Refractory dyserythropoietic anemias—rare in children
- In adults, pernicious anemia is a common cause.

DIAGNOSIS

HISTORY

Insidious onset of anemia and associated symptoms such as pallor, fatigue, poor appetite, irritability. GI history may include:

- Malabsorption/diarrhea
- Special diets: Particularly strict vegan diets
- Prior gastrointestinal surgery
- Medications such as anticonvulsants and chemotherapeutic agents that interfere with folate metabolism
- Neurologic symptoms are commonly associated with vitamin B₁₂ deficiency; symptoms may include:
 - Difficulty walking
 - Numbness/tingling in hands and/or feet

PHYSICAL EXAM

- Pallor and other associated signs of anemia:
 - Smooth and sometimes tender tongue
- Neurologic findings:
 - Abnormal position and vibratory sensation
 - Ataxia
 - Muscular weakness
 - Peripheral neuropathy
 - Positive *Babinski* sign

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC:
 - Decreased hemoglobin
 - Increased mean corpuscular volume
 - Increased red cell distribution width
 - Normal to decreased WBC count and platelets
- Peripheral blood smear:
 - Macro-ovalocytes
 - Hypersegmented neutrophils
 - Increased anisocytosis (variation in RBC size)
 - Increased poikilocytosis (variation in RBC shape)
- Reticulocyte count: Low
- Serum B₁₂: Low
- Folate: Low in serum and RBCs
- Serum methylmalonic acid (MMA) and homocysteine levels: May help to distinguish vitamin B₁₂ deficiency and folate deficiency

Imaging

Barium studies may be needed to evaluate gastric, small bowel, and large bowel anomalies.

Diagnostic Procedures/Other

- Bone marrow aspirate and biopsy examination:
 - Large RBC, WBC, and platelet precursors with nuclear-to-cytoplasmic dissociation prominent in red cell line
 - Increased iron stores
 - Multiple binucleate and trinucleate RBC precursors
 - Multiple mitotic figures
- Schilling test assesses B₁₂ absorption:
 - Part 1 evaluates vitamin B₁₂ absorption by measuring urine radioactivity after oral radioactive vitamin B₁₂.
 - This test may be performed after the patient has been treated, but the test involves administration of vitamin B₁₂; therefore, all other tests, particularly bone marrow examination, should be performed beforehand or shortly thereafter.
 - If the urinary excretion is lower than expected, abnormal absorption is present, from either malabsorption or intrinsic factor disorders.
 - Part 2 should be performed if part 1 is abnormal; this involves oral intrinsic factor.
 - If part 2 is normal and part 1 is abnormal, pernicious anemia is highly likely.
 - If part 2 remains abnormal, a malabsorption syndrome is the most likely diagnosis.

DIFFERENTIAL DIAGNOSIS

- Macrocytic anemias must be differentiated from megaloblastic anemias. In macrocytic anemias, the mean corpuscular volume is increased but without megaloblastic bone marrow changes. Macrocytic red cells may be seen in aplastic anemia, liver disease, pregnancy and hypothyroidism.
- Diets deficient in vitamin B₁₂ or folate
- Pernicious anemia: B₁₂ deficiency due to loss of intrinsic factor normally produced in the stomach and necessary for B₁₂ absorption in the terminal ileum. Caused by autoimmune disease affecting gastric parietal cells.

TREATMENT

MEDICATION (DRUGS)

ALERT

Treating undiagnosed vitamin B₁₂ deficiency with high doses of folate may worsen neurologic complications, although a hematologic response may occur.

First Line

- Folic acid deficiency:
 - Folic acid at 1–5 mg PO daily for ≥2–3 months
 - Parenteral preparation also available if needed
- Vitamin B₁₂ deficiency:
 - Acutely, daily doses of 25–100 mg IM
 - Long term, 200–1,000 mg monthly IM
 - Most patients with vitamin B₁₂ deficiency require lifelong treatment because the underlying cause is abnormal absorption.

ADDITIONAL TREATMENT

General Measures

General considerations: The following 3 categories should be addressed for all patients:

- Replacement of deficient substance, vitamin B₁₂, or folate at adequate doses for an adequate duration
- Treatment/management of underlying disorder, such as malabsorption syndromes, chronic hemolytic anemias
- Monitoring response to therapy

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The reticulocyte count should increase within the 1st 2 weeks of therapy, whereas the hemoglobin will take longer, in some cases months, to increase.
- If the hemoglobin fails to rise in 2 months, then other causes of anemia including iron deficiency and anemia of chronic disease should be considered.

PROGNOSIS

- Depends on cause of megaloblastic anemia; usually good if dietary deficiency
- Poor prognoses may be associated with inborn errors of metabolism that sometimes present with megaloblastic anemia.

COMPLICATIONS

- Mild congestive heart failure may develop as a result of anemia, but this is uncommon because of the insidious onset of megaloblastic anemia in general.
- Neurologic complications from vitamin B₁₂ deficiency
- Folate deficiency may complicate vitamin B₁₂ deficiency.

ALERT

- Microcytic anemias such as iron deficiency, thalassemia, and anemia of chronic disease may obscure the diagnosis of a megaloblastic anemia by falsely lowering the mean corpuscular volume; however, hypersegmented neutrophils should be present to aid in the correct diagnosis.
- Serum B₁₂ and folate rise rapidly after beginning supplements; therefore, diagnostic levels must be drawn prior to administration of supplements or normal diets.

CODES

ICD9

281.3 Other specified megaloblastic anemias not elsewhere classified

ICD10

D53.1 Other megaloblastic anemias, not elsewhere classified

FAQ

- Q: What are common dietary sources of vitamin B₁₂?
- A: Meat, eggs, and milk; liver contains the greatest amount of vitamin B₁₂.
- Q: What are common dietary sources of folate?
- A: Vegetables (primarily green, leafy vegetables), citrus fruits and berries, liver
- Q: Can food preparation destroy vitamin B₁₂ and folate?
- A: Food preparation cannot destroy vitamin B₁₂, but excessive heating can destroy folate.

MENINGITIS

Ross Newman
Jason Newland
Louis M. Bell (5th edition)

BASICS

DESCRIPTION

Inflammation of the membranes of the brain or spinal cord, usually caused by bacteria or viruses, and rarely fungi or parasites

EPIDEMIOLOGY

- Bacterial meningitis:
 - Most common agents in children of all ages include: *Streptococcus pneumoniae* and *Neisseria meningitidis*.
 - Underlying host factors, age, exposure, and geographic location alter incidence.
 - *S. pneumoniae* isolates are becoming more resistant to penicillin. Up to 50% of isolates causing invasive disease are resistant to penicillin.
- Viral meningitis:
 - Most commonly from enteroviruses that tend to occur in outbreaks in summer and early fall.
- Fungal meningitis:
 - *Cryptococcus neoformans* is a budding encapsulated yeast-like organism found in soil and avian excreta. Although associated with meningitis in immunocompromised adults (especially those with AIDS), this is rare in children with AIDS. 30% of patients with cryptococcal meningitis have no underlying immunodeficiency.
 - Meningitis caused by *Candida* species occurs in ill premature infants and other immunocompromised individuals.
- Tuberculous meningitis:
 - The incidence of disease due to *Mycobacterium tuberculosis* (TB) is on the rise throughout the world.
 - TB meningitis occurs in 0.5% of untreated primary TB infections.
 - Most common in children aged 6 months to 4 years
 - In ~50% of cases miliary TB is accompanied by meningitis.
 - Increasing number of patients suffer from multidrug-resistant TB.

GENERAL PREVENTION

- *Haemophilus influenzae* type b (HIB) vaccine has significantly reduced the incidence of meningitis and other invasive HIB infections by up to 99%.
- A 13-valent *S. pneumoniae* protein conjugate vaccine (PCV 13) has replaced the 7-valent vaccine (PCV 7) for use in all infants given at 2, 4, 6, and 12–15 months of age.
- A tetravalent meningococcal vaccine (MCV4) is recommended for all patients ≥11 years of age and select at-risk populations <11 years. A booster dose is recommended for all patient who receive the first dose of the vaccine between 11 and 15 years of age.

ETIOLOGY

- Bacterial:
 - Cause differs depending on age:
 - <1 month old: Group B streptococcus, *Escherichia coli*, other enteric bacteria, *Listeria monocytogenes*, *S. pneumoniae*
 - 1–3 months old: Group B streptococcus, *E. coli*, *S. pneumoniae*, HIB (almost disappearing secondary to immunization)
 - 3 months to 5 years old: *S. pneumoniae*, *N. meningitidis*, HIB
 - >5 years old: *S. pneumoniae*, *N. meningitidis*

- Viral:
 - Herpes simplex virus (HSV) in the neonatal population
 - Enteroviruses: ~70 different strains that include polioviruses, Coxsackie A, Coxsackie B, and echoviruses. Recently discovered enteroviruses are not placed in these 4 groups, but are numbered (e.g., enterovirus 68).
 - Other, less common: Arboviruses (e.g., West Nile virus), mumps
- Fungal:
 - Fungi most commonly isolated include *Candida* species, *Coccidioides immitis*, *C. neoformans*, *Aspergillus* species
- Aseptic meningitis:
 - Agents not easily cultured in the viral or microbiology laboratory can cause meningitis and include *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis)
- Tuberculous meningitis
- Unusual pathogens more likely in immunocompromised patients

DIAGNOSIS

- Age specific
- Pain
- Fever
- Nausea and/or vomiting

HISTORY

- Bacterial meningitis:
 - Children >12 months old will often complain of classic meningeal inflammation signs including neck pain, headache, or back pain as well as photophobia, anorexia, and myalgias.
 - Nausea and vomiting are common.
 - In children <12 months old, symptoms are often nonspecific, including fever, hypothermia, irritability, and poor feeding as well as signs of increased intracranial pressure, including seizures and apnea.
 - Attention should be noted to the patient's immunization status, birth history, travel history, trauma, health status, geographic location, and exposure to high-risk contacts.
 - Common chief complaints by the infants' caregivers include the following:
 - Irritable or "sleeping all the time"
 - "Won't take to bottle"
 - "Not acting right"
 - "Cries when moved or picked up"
 - "Won't stop crying"
 - "Soft spot bulging out"
- Recurrent meningitis:
 - Recurrent meningitis with *S. pneumoniae* or *Enterococcus* may indicate a history of trauma causing a skull fracture or cribriform plate fracture with contamination of the CSF by nasopharyngeal secretions.
- Viral meningitis:
 - Headache and fever may precede signs of meningitis, such as stiff neck, vomiting, and photophobia.
 - Duration 2–6 days
- Fungal meningitis:
 - Cryptococcal meningitis is often indolent, with complaints of worsening headaches and vomiting for days to weeks.

- Exposure to pigeon droppings or other bird droppings can be a valuable clue to etiology if present.
- Tuberculous meningitis:
 - Symptoms are often nonspecific initially, with personality changes, fever, nausea, and vomiting progressing to anorexia, irritability, and lethargy (stage I disease).
 - Stage II disease is characterized by focal neurologic signs (most often involving the cranial nerves III, VI, and VII).
 - Stage III disease is characterized by coma and papilledema.

PHYSICAL EXAM

- Stiff neck in older children. Infants have poor neck muscle tone and this finding may be absent.
- Brudzinski and Kernig signs may be present.
 - Brudzinski sign: With the patient supine, flexion of the neck elicits involuntary flexion of the hips or knees.
 - Kernig sign: With the patient supine, the legs are flexed 90 degrees at the hip, extensions of the lower legs are unable to be accomplished beyond 135 degrees.
 - Negative Brudzinski or Kernig sign does not rule out meningitis.
- Children <12 months old may not have nuchal rigidity, Kernig, and/or Brudzinski signs.
- Classically, there may be "paradoxical" crying—crying that increases when child is picked up.
- Signs of increased intracranial pressure, including papilledema, asymmetric pupils, bulging fontanelle, diplopia.
- Skin exam for exanthems consistent with enterovirus infection, erythema migrans from borreliosis (Lyme disease), petechiae or purpura with invasive meningococcal disease, or vesicles in an infant <6 weeks old with HSV.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC, platelet count, prothrombin time (PT), partial thromboplastin time (PTT), electrolytes, BUN, creatinine, glucose, liver function tests, arterial blood gas
- CSF analysis
- Blood culture

Diagnostic Procedures/Surgery

- Lumbar puncture with analysis of the CSF:
 - Contraindicated with cardiopulmonary compromise, uncorrected coagulopathy, and signs of increased intracranial pressure or focal neurologic findings until head imaging can be obtained
- If no etiology is discovered after the first lumbar puncture and the child is not responding to therapy, repeated lumbar puncture at 36–48 hours.
- Opening pressure: Normal is <200 mm H₂O in lateral recumbent position.
- Depending on the presentation, age, history, and physical exam findings, some or all of the following tests should be requested for CSF analysis:
 - Cell count with differential and gram stain
 - Bacterial meningitis is characterized by CSF pleocytosis (>1.0 × 10³/μL) with predominance of neutrophils. Culture is the gold standard for diagnosis.

- Viral meningitis typically has a lower CSF cell count ($0.05\text{--}0.5 \times 10^3/\mu\text{L}$) compared to bacterial meningitis with a predominance of lymphocytes.
- Glucose: Compare with serum glucose; normal is >40 mg/dL or 1/2–2/3 of the serum glucose.
- Protein: Normal 5–40 mg/dL except in newborns, who may have protein levels of 150–200 mg/dL
 - >1.0 g/dL in bacterial meningitis and normal to slightly elevated in viral meningitis
- Cultures for bacteria, fungi, virus, and mycobacteria
 - 80% of blood cultures are positive in children with bacterial meningitis.
- Polymerase chain reaction (PCR) analysis for enterovirus, TB, HSV, Epstein–Barr virus
 - *Borrelia burgdorferi* PCR for CSF samples has a diagnostic yield as low as 17%. Antibody studies for neuroborreliosis are recommended.

DIFFERENTIAL DIAGNOSIS

- Encephalitis
- Toxic encephalopathy
- Epidural abscess
- Cerebral abscess

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Assure adequate ventilation and cardiac function
 - Airway, breathing, circulation (ABCs)
- Initiate hemodynamic monitoring and support by achieving venous access and treat shock syndrome, if present
- Prompt initiation of appropriate antimicrobials
 - If a lumbar puncture cannot be obtained or is contraindicated a blood culture should be obtained and antimicrobials initiated.
- Monitor serum sodium concentrations because syndrome of inappropriate ADH secretion (SIADH) is a frequent complication during the first 3 days of treatment.
- Glucose should be given IV if <50 mg/dL at a dose of 0.25–1 g/kg.
- If pH is <7.2 , acidosis should be corrected with 1–2 mEq/kg of sodium bicarbonate.
- Coagulopathy should be treated with platelet concentrates (0.2 U/kg) if platelets are $<50,000/\text{mm}^3$ and with fresh frozen plasma (10 mL/kg) if PT/PTT is prolonged.
- Steroids should be used in the initial therapy of TB meningitis along with anti-tuberculosis medication.
- Steroids indicated for HIB meningitis are controversial but can be considered in *S. pneumoniae* meningitis. Consult ID expert for use.
 - If giving steroids, use dexamethasone 0.6 mg/kg/d divided into 4 doses and given for 4 days. The first dose should be given before or with the first dose of antibiotic.

MEDICATION (DRUGS)

- Antimicrobial agents:
 - <1 month of age: Ampicillin IV 200–300 mg/kg/d divided q6–12h based on postnatal age and weight. If <7 days of age 200 mg/kg/d divided q8h; if >7 days of age, ampicillin 300 mg/kg/d divided q6h and cefotaxime IV 200 mg/kg/d divided q6h
 - >1 month of age: Vancomycin IV 60 mg/kg/d divided q6h; cefotaxime IV 300 mg/kg/d divided q6h or ceftriaxone 100 mg/kg/d divided q12h (should not be used in infants <2 months of age)

- Vancomycin IV 60 mg/kg/d divided q6h should be considered in a patient of any age suspected of *S. pneumoniae*.
- Alternative therapy for penicillin or cephalosporin allergic patients can include carbapenem or a quinolone in addition to vancomycin. Infectious disease specialist input should be considered in these patients.
- Fungal meningitis:
 - Amphotericin B with or without 5-flucytosine, depending on the type of fungi isolated
- Tuberculous meningitis:
 - Treatment is generally with 4 drugs for 2 months followed by 2 drugs for 10 months.
 - Initially, treat with isoniazid, rifampin, pyrazinamide, and streptomycin.
- Viral meningitis:
 - Enterovirus: No specific therapy other than supportive
 - HSV: Acyclovir 60 mg/kg/d divided q8h

ALERT

- Remember that in tuberculous meningitis, up to 50% of children will not react to the 5-tuberculin unit Mantoux tests. Therapy should be started if suspicious; do not rely on the skin testing.
- Be aware that the isolation of resistant strains of *S. pneumoniae* is increasing; therefore, antibiotics such as vancomycin and cefotaxime or ceftriaxone should be used until antibiotic sensitivity data are available.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Neonatal HSV meningitis should be evaluated with a repeat CSF HSV DNA PCR at day 21 and therapy extended if the PCR remains positive.
- Prophylaxis in HIB:
 - Rifampin (20 mg/kg/dose, maximum 600 mg/d for 4 days) should be given to all household contacts if 1 member is <4 years of age and is unvaccinated.
- Prophylaxis in *N. meningitidis*:
 - Rifampin (10 mg/kg/dose, maximum 600 mg b.i.d. for 2 days) for all household contacts, daycare contacts, and other persons with close contact 7 days prior to onset of illness.
- Note: If cefotaxime or ceftriaxone was used for treatment, the patient with *N. meningitidis* or HIB meningitis does not need to receive prophylaxis.

PATIENT MONITORING

- Most children with bacterial meningitis become afebrile by 7–10 days after starting therapy, with gradual improvement in activity with less irritability.
- Evaluation for neurologic sequelae, such as hearing and vision testing, is essential.

PROGNOSIS

- Bacterial meningitis:
 - Fatality approaches 100% if untreated.
 - $\sim 500\text{--}1,000$ deaths each year, or 5–10% of cases
 - Hearing deficits and neurologic damage may occur in up to 30% of children.
- Viral meningitis:
 - Prognosis for enteroviral meningitis is quite good.
- Aseptic meningitis:
 - Lyme disease: Prognosis with diagnosis and treatment is quite good (see “Lyme Disease”).
- Tuberculous meningitis:

- The long-term prognosis in children with tuberculous meningitis depends on the stage of disease in which treatment is begun.
- Complete recovery occurs in 94% of those whose treatment was started in stage I, but only 51% and 18% for those whose treatment began in stage II or stage III, respectively.

COMPLICATIONS

- Bacterial meningitis:
 - Acute complications: SIADH, seizures occur in up to 1/3 of patients, focal neurologic signs occur in 10–15%.
 - Long-term complications: Mental retardation, hearing defects
- Viral meningitis:
 - Acute complications: SIADH in 10%
 - Long-term complications: Complications from viral meningitis are rare. However, neonates (<1 month of age) may develop severe EV disease and older agammaglobulinemic children may develop chronic EV meningoencephalitis.
- Tuberculous meningitis:
 - Acute complications: Most common are cranial nerve findings, especially 6th cranial nerve palsy affecting the eyes; hydrocephalus
 - Long-term complications: Many, including blindness, deafness, and mental retardation

CODES

ICD9

- 047.9 Unspecified viral meningitis
- 320.9 Meningitis due to unspecified bacterium
- 322.9 Meningitis

ICD10

- A87.9 Viral meningitis, unspecified
- G00.9 Bacterial meningitis, unspecified
- G03.9 Meningitis, unspecified

FAQ

- Q: Is a lumbar puncture required before starting antibiotics in the patient with suspected meningitis with unstable vital signs requiring resuscitation?
- A: No. In the unstable patient, it is contraindicated to perform a lumbar puncture. Appropriate IV antibiotics should be started. When resuscitated, a lumbar puncture should be performed.

MENINGOCOCCEMIA

Andrew P. Steenhoff

BASICS

DESCRIPTION

- A systemic infection with the bacterium *Neisseria meningitidis*, a Gram-negative diplococcus that is relatively fastidious. Despite treatment with appropriate antibiotics, this disease may have a fulminant course with a high likelihood of mortality.
- 13 serogroups have been described on the basis of capsular polysaccharide antigens; serotypes B, C, and Y account for most of the cases in the US. Serogroup Y accounted for 30% of cases between 1996 and 1998.

GENERAL PREVENTION

- Isolation of the hospitalized patient.
 - Hospitalized patients require respiratory isolation until 24 hours after initiation of appropriate antibiotic therapy.
- Exposed contacts, including household, day care, and nursery school, should receive rifampin, 10 mg/kg (maximum 600 mg) q12h for 4 doses. Contacts younger than 1 month of age should receive 5 mg/kg PO q12h for 4 doses.
 - Ceftriaxone is effective prophylaxis for contacts ≤ 15 years of age; a single dose of 125 mg IM is recommended. For contacts > 15 years old, 250 mg IM is recommended. Its safety profile is preferred for pregnant women.
- Medical personnel should receive prophylaxis only if they had close contact with respiratory secretions.
- Vaccines for types A, C, Y, and W-135 are available and produce an immune response in 10–14 days.
- A tetravalent conjugate meningococcal vaccine, MCV4, is licensed for use in people in the age range of 2–55 years. It is recommended in all unimmunized 11- to 12-year-old adolescents with a booster dose at age 16 years.
- By February 2008, 26 cases of Guillain-Barré syndrome (GBS) had been reported in children within 6 weeks after receiving MCV4 vaccination. The currently available data cannot determine with certainty whether MCV4 increases the risk for GBS and the Centers for Disease Control (CDC) continues to recommend routine adolescent immunization with the exception of persons with a history of GBS who are not in a high-risk group for invasive meningococcal disease. An updated fact sheet on GBS and MCV4 is available at <http://www.cdc.gov/vaccinesafety/Concerns/gbsfactsheet.html>

EPIDEMIOLOGY

- The rates of meningococcal disease in the US have remained stable at 0.9–1.5 cases per 100,000 population per year.
- Children < 5 years of age are most often affected, with peak incidence between 3 and 5 months of age.
- During epidemics, more school-aged children may be affected.
- The disease occurs most commonly in winter and spring months.
- Increased disease activity may follow an influenza A outbreak.

RISK FACTORS

- Patients with asplenia, deficiencies of properdin C3, or a terminal complement component (C5-9), and HIV are at increased risk for invasive and recurrent disease.
- Organism virulence factors, such as differences in the bacterial cell wall lipopolysaccharide, play a role in disease severity. Less virulent organisms are more likely in chronic meningococemia which has a favorable prognosis.

Genetics

Inherited deficiency of terminal complement may be found in 5–10% of patients during epidemics. The frequency increases to 30% in patients with recurrent disease.

PATHOPHYSIOLOGY

- Fulminant disease is signified by diffuse microvascular damage and disseminated intravascular coagulation (DIC; see "Septic Shock").
- Death results from effects of endotoxic shock, including circulatory collapse and myocardial dysfunction.

ETIOLOGY

- Colonization and infection of the upper respiratory tract occurs after inhalation of, or direct contact with, the organism, usually in oral secretions.
- Disseminated disease occurs when the organism penetrates the nasal mucosa and enters the bloodstream, where it replicates.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Fever
- Malaise
- Rash
- Petechiae
- Tachycardia
- Delayed capillary fill
- Abnormal mental status
- Bacteremia without sepsis presents with fever, malaise, myalgias, and headache. Patients may clear the infection spontaneously, or it may invade meninges, joints, lungs, and so forth.
- Meningococemia without meningitis occurs after initial bacteremia with systemic sepsis. A rash erupts, which may be nonspecific maculopapular, morbilliform, or urticarial. Progression to petechiae or purpura signifies evolution of disease.
- Fulminant disease is signified by hypotension, oliguria, DIC, myocardial dysfunction, and vascular collapse. Death occurs in $\sim 20\%$ of these patients.

HISTORY

Time of onset of fever, malaise, and rash

PHYSICAL EXAM

- Physical examination of a child with fever should include careful evaluation of the skin for petechiae and signs of early shock (tachycardia, delayed capillary refill, abnormal mental status, etc.).
- Recognition of abnormal vital signs and lethargy is necessary.
- Nuchal rigidity, lethargy, and irritability should be carefully evaluated.

DIAGNOSTIC TESTS & INTERPRETATION

The organism can be cultured from blood, CSF, and skin lesions.

Lab

- Gram stain of CSF or scraped petechial lesion (pressed against a glass slide):
 - Revealing Gram-negative diplococci will give a presumptive diagnosis.
- Rapid test for antigen detection: Supports diagnosis if found in CSF but not sensitive for serogroup B

Diagnostic Procedures/Other

Lumbar puncture: Antigen detection although culture remains the gold standard

DIFFERENTIAL DIAGNOSIS

- Meningitis due to *N. meningitidis* is indistinguishable from that of other causes, except for 1/3 of children who have a petechial rash.
- Sepsis from other microbial causes may appear identically, including the petechiae or purpuric rash.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Patients with acute onset of petechial rash and fever should receive a prompt initial dose of antibiotics (preferably after blood culture)
- Close monitoring of vital signs and clinical status should follow, preferably in an ICU setting.

MEDICATION (DRUGS)

- Cefotaxime or ceftriaxone can be initiated as presumptive therapy. After sensitivity is confirmed, penicillin is preferred.
- After isolate is proven sensitive to penicillin, treatment of choice is aqueous penicillin G IV at a dose of 300,000 IU/kg/d q4–6h (maximum 12 million U/d) for 5–7 days.
- In penicillin-allergic patients, 3rd-generation cephalosporins or chloramphenicols are acceptable alternatives.

ISSUES FOR REFERRAL

Public health officials should be notified of *N. meningitidis* cases.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Patients with bacterial meningitis should have hearing test as a follow-up.

PROGNOSIS

- Fatality rate of meningococemia is 20%, even when recognized and treated.
- Fatality rate of meningococcal meningitis is 5%. The most severe cases often have a rapid progression from onset of symptoms to death over a matter of hours. At the time of hospital admission, the following signs predict poor survival:
 - Lack of meningitis
 - Shock
 - Coma
 - Purpura
 - Neutropenia
 - Thrombocytopenia
 - DIC
 - Myocarditis

COMPLICATIONS

- Complications may result directly from the infection or be classified as allergic immune complex mediated.
- Meningococemia may be complicated by myocarditis, arthritis, hemorrhage, and pneumonia, digit or limb amputation and skin scarring.
- Meningococcal meningitis is most commonly complicated by deafness in 5–10% of survivors.
- Other complications of meningitis include seizures, subdural effusions, and cranial nerve palsies.
- Allergic complications include arthritis, vasculitis, pericarditis, and episcleritis.

ICD10

- A39.2 Acute meningococemia
- A39.3 Chronic meningococemia
- A39.4 Meningococemia, unspecified

FAQ

- Q: How long should antibiotic therapy be given to a patient with septic shock?
- A: 7 days.
- Q: Is MCV4 meningococcal vaccine indicated for all adolescents?
- A: Yes, MCV4 is now recommended in all previously unimmunized adolescents at the doctor visit from 11 to 12 year or at high school entry, whichever comes first. A booster dose is recommended at age 16 years.
- Q: How does one approach MCV4 immunization of adolescents who previously received MPSV4?
- A: If 3–5 years have elapsed since their MPSV4 vaccination, then MCV4 immunization is indicated.
- Q: When should one test for complement deficiency?
- A: In patients with recurrent disease.
- Q: Which hospital personnel should receive prophylaxis?
- A: Only those with direct exposure to index patient’s secretions.

MENTAL RETARDATION

Rita Panoscha

BASICS

DESCRIPTION

- Mental retardation or intellectual disability essentially means slow rate of learning or slow cognitive processing abilities. By definition, there are significant cognitive and adaptive delays 1st evident in childhood. Significant cognitive delays are defined as 2 standard deviations below the population mean on a standard cognitive or IQ test.
 - Usually indicates an IQ score of <70–75
- Adaptive skills are the functional skills of everyday life, including communication, social skills, daily living/self-care skills, and the ability to safely move about the home and community.
- Mental retardation is typically subdivided into mild, moderate, severe, and profound categories, depending on the severity of the delays. A more recent definition by the American Association on Mental Retardation (AAMR) puts more emphasis on the level of functioning and the amount of support required by an individual.

ALERT

- Children with behavioral problems may also be masking cognitive delays.
- Hearing impairment may present as a delay in development.
- Children with mild mental retardation may not be diagnosed as having a problem until they are having difficulties keeping up in elementary school.

EPIDEMIOLOGY

Found in both sexes and all racial and socioeconomic groups

Prevalence

- Prevalence of mental retardation is generally listed as 2–3% of the population.
- Of the different subcategories of mental retardation, the mild form is the most prevalent, at 85% of those with mental retardation:
 - Profound mental retardation is least prevalent, at ~1% of this group.

GENERAL PREVENTION

- There is no specific prevention, but prevention of some underlying causes may be possible.
- Immunization programs, early detection of metabolic disorders, and education programs for head injury/asphyxia prevention may be useful in some cases.
- Avoidance of alcohol and some drugs during pregnancy may also decrease some brain insults.

ETIOLOGY

- The cause of the mental retardation is usually an insult to the brain or abnormal development of the CNS but is not evident in many cases. The following represent potential causes.
- Genetic/Familial/Metabolic:
 - Fragile X syndrome
 - Trisomy 21 (Down syndrome) and other chromosomal abnormalities
 - Tuberous sclerosis
 - Neurofibromatosis
 - Phenylketonuria (PKU)
 - Other inborn errors of metabolism

- Nervous system anomalies:
 - Hydrocephalus
 - Lissencephaly
 - Seizures
- Endocrinologic:
 - Congenital hypothyroidism
- Infectious:
 - Prenatal cytomegalovirus, rubella, toxoplasmosis, HIV
 - Postnatal bacterial meningitis, neonatal herpes simplex
- Environmental toxins:
 - Heavy-metal poisoning such as lead
 - In utero drug or alcohol exposure, including fetal alcohol syndrome
- Traumatic:
 - Closed-head trauma
 - Asphyxia

COMMONLY ASSOCIATED CONDITIONS

- Associated findings are more common in the more severe forms of mental retardation.
- Mental retardation has many associated findings, including seizures, autism, cerebral palsy, communication disorders, failure to thrive, sensory impairments, and psychiatric disorders.
- Behavioral disorders can be seen, including attention deficit hyperactivity disorder, self-injurious and self-stimulating behaviors.
- Families often face additional stressors when caring for a child with mental retardation.

DIAGNOSIS

HISTORY

Complete information regarding the following:

- Pregnancy history:
 - Maternal age and parity
 - Maternal complications (including infections and exposures)
 - Medications/Drugs used
 - Tobacco or alcohol used, along with quantities
 - Fetal activity
- Birth history:
 - Gestational age
 - Birth weight
 - Route of delivery
 - Maternal or fetal complications/distress
 - Apgar scores
- General health:
 - Significant illnesses, hospitalizations, or surgeries
 - Accidents or injuries
 - Hearing and vision status
 - Medications used
 - Known exposures to toxins
 - Any new or unusual symptoms
- Developmental history:
 - Current developmental achievement in each stream of development
 - Age when developmental milestones were achieved
 - Any loss of skills
 - Where parents think their child is functioning developmentally

- Educational history:
 - Type of schooling and services received, if any
 - Any previous educational/developmental testing
- Behavioral history:
 - Any perseverative or stereotypical behaviors
 - Interaction skills
 - Attention and activity levels
- Family history:
 - Family members with developmental delays, neurologic disorders, syndromes, inherited disorders, or consanguinity
- Signs and symptoms are dependent on etiology:
 - Developmental delays
 - Slow learning behavior

PHYSICAL EXAM

A complete physical exam including growth parameters is needed looking for etiology. Key features to include are the following:

- Observation of interactions and behavior:
 - Atypical behaviors and general impressions
- Head circumference:
 - Macro- or microcephaly
- Skin exam:
 - Neurocutaneous lesions
- Major or minor dysmorphic features:
 - Indication of a syndrome or anatomic malformation
- Neurologic exam:
 - Assess for cranial nerve deficits, neuromuscular status, reflexes, balance and coordination, and any soft signs.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- There is no specific laboratory test battery for mental retardation. Testing must be tailored to the individual situation based on history and physical exam. A high index of suspicion should be maintained for any associated findings and delays in the other streams of development. Listed below are some of the more common studies.
- Genetic testing:
 - For any dysmorphic features, or a family history of delays or genetic disorder
 - A karyotype and fragile X DNA should be considered, particularly for significant cognitive delays, although the comparative genomic hybridization (CGH) microarray is increasingly recommended as a first line genetic test.
- Metabolic tests:
 - Quantitative plasma amino acid, quantitative urine organic acid, lactate, pyruvate, or ammonia levels should be considered if there is any loss of skills or indication of a metabolic disorder.
 - Additional metabolic tests may be indicated depending on symptoms.
- Thyroid function tests:
 - Most infants will have had screening for hypothyroidism shortly after birth. This should be rechecked if symptoms indicate.

Imaging

Head MRI: Consider for head abnormalities, significant neurologic findings, loss of skills, or for workup of a specific disorder, such as trauma or leukodystrophy.

Diagnostic Procedures/Other

- When developmental delays are present and mental retardation is suspected, more formal developmental screening or testing should be done.
- Possible tests for the pediatrician are the Denver-II Developmental Screening Test or the Cognitive Adaptive Test/Clinical Linguistic & Auditory Milestone (CAT/CLAMS).
- Diagnosis needs to be made based on standardized tests, usually done by a clinical psychologist. Such standardized testing might involve the Stanford Binet Intelligence Scale, the Wechsler Scales, and the Vineland Adaptive Behavior Scales.
- Audiological testing:
 - For any child with speech and language and/or cognitive delays
- EEG:
 - An EEG should be considered if there is any concern about seizures.

DIFFERENTIAL DIAGNOSIS

The differential can include several other developmental diagnoses, including the following:

- Borderline cognitive abilities
- Developmental language disorder
- Autism
- Learning disability
- Cerebral palsy
- Significant visual or hearing impairment
- Degenerative disorders

TREATMENT

ADDITIONAL TREATMENT

General Measures

- There is no specific cure for mental retardation. The ultimate goal of all therapies is to help the child reach his or her full potential.
- Therapy should consist of appropriate treatment for any underlying or associated medical condition.
- Early intervention and special education programs are available for an individualized education program based on the child's needs and abilities.
- Behavior management programs or selected use of medications is available for patients with severe behavioral problems.

ISSUES FOR REFERRAL

- A referral is made to a clinical psychologist for the formal diagnosis.
- Subspecialists:
 - Referral to other medical specialists may also be indicated.
 - These specialists may include developmental pediatrics, neurology, genetics, or ophthalmology.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Children with mental retardation will need regular pediatric preventative care in addition to management of any underlying medical conditions.
- Ongoing monitoring of the educational programs, to ensure that it is still meeting the child's needs, is important.
- The family will also need ongoing counseling and support in dealing with a child having special needs.

PROGNOSIS

- The prognosis for longevity varies with the associated findings and overall health, but individuals with mental retardation can live to adulthood and old age.
- An individual's level of functioning is variable depending on the level of retardation, special individual skills, and family or community supports. In general, the following applies:
 - Mild mental retardation (IQ 55–70): Formerly called educable. May be in school with extra help and may achieve roughly a 4th–6th grade level in reading and math. May be employed in an unskilled to semiskilled job. May live in a group home or independently. Some marry.
 - Moderate mental retardation (IQ 40–54): May learn to recognize basic words and learn basic skills. May work in a sheltered workshop or with supported employment in an unskilled job. May live with family or in a group home doing much of their own care.
 - Severe mental retardation (IQ 25–39): May live with family, or in a group home or institution. Some may be in a sheltered workshop. May be able to do some daily self-care or chores with supervision.
 - Profound mental retardation (IQ <25): Live with family, in group home, or in institution. Usually require full-time care

CODES

ICD9

- 315.9 Unspecified delay in development
- 317 Mild intellectual disabilities
- 319 Unspecified intellectual disabilities

ICD10

- F70 Mild mental retardation
- F79 Unspecified mental retardation
- F81.9 Developmental disorder of scholastic skills, unspecified

FAQ

- Q: Will my child be “normal” by adulthood?
- A: Generally, mental retardation is considered a life-long condition. Some individuals, usually with the milder form of mental retardation, can function well in the community, especially when given added supports.
- Q: Can my child learn?
- A: Except for the most severe forms of mental retardation, children do learn. This learning may not be as rapid or as extensive as that of a typically developing child.
- Q: But my child looks fine and has had appropriate motor development. How can he be mentally retarded?
- A: Mental retardation is a slowed rate of cognitive development. Many children with mental retardation do not have obvious dysmorphic features. Other streams of development, such as gross motor skills, may be reached on time or nearly so, yet the cognitive developmental streams can be significantly delayed.

MESENTERIC ADENITIS

Michelle Rook
Vera de Matos (5th edition)

BASICS

DESCRIPTION

Mesenteric adenitis is defined as inflammation of the mesenteric lymph nodes. The inflamed nodes are usually clustered in the right lower quadrant (RLQ) small bowel mesentery or ventral to the psoas muscle.

EPIDEMIOLOGY

- Age related, most common in patients <15 years of age
- Affects males and females equally
- History of recent sore throat or upper respiratory tract infection found in 20–30% of subjects
- Most common cause of acute abdominal pain in young adults and children
- Self-limiting condition
- Most common cause of inflammatory adenopathy, more common than tuberculosis
- Acute RLQ pain; can mimic acute appendicitis
- Mesenteric adenitis in childhood is related to a decreased risk of ulcerative colitis in adulthood.

PATHOPHYSIOLOGY

- Lymph nodes involved are those draining the ileocecal area. Lymph nodes absorb toxic products or bacterial products secondary to stasis.
- Nodes are enlarged up to 10 mm, discrete, soft, and pink, and with time become firm. Calcification and suppuration are rare.
- Cultures of the nodes are negative.
- Reactive hyperplasia: Adenitis results from a reaction to some material absorbed from the small intestine, reaching the intestine from the blood or lymphatic system.
- Hypersensitivity reaction to a foreign protein

ETIOLOGY

- Viral: Adenovirus, echovirus 1 and 14, coxsackie viruses, Epstein-Barr virus (EBV), cytomegalovirus (CMV), (HIV)
- Bacterial: Tuberculosis, *Streptococcus* species, *Staphylococcus* species, *Escherichia coli*, *Yersinia enterocolitica*, *Bartonella henselae* (cat-scratch disease)

DIAGNOSIS

Can be difficult to differentiate from acute appendicitis clinically, and many patients may have a laparotomy before the right diagnosis is made

HISTORY

- Abdominal pain:
 - Ache to severe colic is the 1st symptom, due to stretch on the mesentery.
 - May initially be in the upper abdomen/RLQ or generalized
 - If generalized, eventually becomes localized to RLQ
 - An important point is that the patient cannot localize the exact point of the most intense pain, unlike appendicitis.
- Spasms: Between spasms, the patient feels well and can walk without any difficulty.
- Signs and symptoms:
 - Abdominal pain (RLQ)
 - Anorexia and fatigue are common.
 - Nausea and vomiting usually precede abdominal pain.
 - Fever
 - Diarrhea

PHYSICAL EXAM

- Patient flushed: Early in the attack, fever may be 38°C (100.4°F) to 38.5°C (101.3°F).
- May have associated upper respiratory tract infection symptoms, such as rhinorrhea or hyperemic pharynx
- Peripheral lymphadenopathy
- Abdominal examination shows tenderness of the RLQ: May be a little higher, more medial, and less severe than acute appendicitis
- Point of maximal tenderness may vary from one examination to the next.
- Voluntary guarding with or without rebound tenderness, and without rigidity
- Rectal tenderness

DIAGNOSTIC TESTS & INTERPRETATION

- Mesenteric adenitis is a diagnosis of exclusion. It can only be diagnosed accurately at laparoscopy or laparotomy. Ultrasound or CT scan may demonstrate enlarged mesenteric lymph nodes.
- See "Differential Diagnosis."

Lab

Complete blood count and C-reactive protein can be increased but are not specific.

Imaging

- Abdominal ultrasound: Differentiates among acute appendicitis, pelvic inflammatory disease, ovarian pathology, and mesenteric adenitis
- Contrast-enhanced CT scan of the abdomen and pelvis shows enlarged mesenteric lymph nodes, with possible ileal or ileocecal wall thickening, normal appendix
- MRI

Diagnostic Procedures/Other

- Laparoscopic surgery
- Laparotomy

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Acute appendicitis: 20% of patients treated for possible acute appendicitis had mesenteric adenitis.
 - Infectious mononucleosis: Associated lymphadenopathy more generalized
 - Associated splenomegaly: Can screen for positive EBV titers
 - Tuberculosis: Associated intestinal involvement, positive purified protein derivative (PPD) test, elevated erythrocyte sedimentation rate (ESR)
 - Pelvic inflammatory disease: A consideration in sexually active adolescents; pelvic examination useful
 - Urinary tract infections/pyelonephritis: Urinalysis and urine culture are helpful.
 - Abscess: Related to missed acute appendicitis or inflammatory bowel disease (IBD)
 - *Y. enterocolitica* infection: Bloody diarrhea, arthropathy present; stool culture is diagnostic.
 - Typhlitis: Transmural inflammation of the cecum seen in patients with neutropenia
- Tumors:
 - Lymphoma: Adenopathy can be more generalized
 - CT scan of the abdomen and/or laparotomy to confirm the diagnosis
- Trauma:
 - Hematomas of the abdominal wall and intestines
 - History of trauma

- Metabolic:
 - Acute intermittent porphyria
 - Cyclic episodes of acute abdominal pain and vomiting
 - Appropriate metabolic workup diagnostic
- Congenital:
 - Duplication cysts: May present with abdominal pain due to rupture, bleeding, intussusception, or volvulus
 - Meckel diverticulum: May present with diverticulitis or act as a lead point for intussusception
- Miscellaneous:
 - Crohn disease: Associated mesenteric adenitis and intestinal involvement
 - Intussusception: Acute abdominal pain with “currant jelly” stools; barium/air enema is diagnostic and therapeutic.
 - Ovarian cysts: May need abdominal/pelvic ultrasound to differentiate between the two
 - Chronic mesenteric ischemia

TREATMENT

Most patients recover completely without any specific treatment.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Watch for:

- Increasing abdominal pain
- Vomiting
- Fevers
- Toxic appearance
- Severe tenderness that is persistent
- Guarding
- Rigidity
- Decreasing bowel sounds

PROGNOSIS

- Most patients recover completely without any specific treatment.
- Death is very unusual and may occur only when secondary specific bacterial infection occurs with suppuration and rupture of the nodes with resulting abscess and peritonitis.
- When to expect improvement: Acute symptoms may take days to resolve and generally last a few days after the associated viral symptoms have resolved.

COMPLICATIONS

- Suppuration
- Intussusception (enlarged lymph nodes can be a lead point for intussusception)
- Rupture of lymph nodes
- Peritonitis
- Abscess formation

CODES

ICD9

- 014.80 Other tuberculosis of intestines, peritoneum, and mesenteric glands, unspecified
- 289.2 Nonspecific mesenteric lymphadenitis

ICD10

- I88.0 Nonspecific mesenteric lymphadenitis
- A18.39 Retroperitoneal tuberculosis

FAQ

- Q: Can one differentiate clinically between acute appendicitis and nonspecific mesenteric adenitis?
- A: Patients with nonspecific mesenteric adenitis cannot localize the exact point of the most intense pain, unlike those with appendicitis. Between spasms, patients with nonspecific mesenteric adenitis feel well and can walk without any difficulty. Abdominal examination shows tenderness of the RLQ that is a little higher, more medial, and less severe than that in acute appendicitis. Point of maximal tenderness may vary between examinations in patients with nonspecific mesenteric adenitis. There is no rigidity on abdominal examination in patients with nonspecific mesenteric adenitis. However, it is clinically difficult to differentiate the two entities.
- Q: Which investigations can be diagnostic for RLQ pain?
- A: An ultrasound or CT scan of the RLQ can differentiate between acute appendicitis, ovarian pathology, and lymphadenopathy. An upper gastrointestinal series with small bowel follow-through or a magnetic resonance enterography study can be diagnostic for IBD.

METABOLIC DISEASES IN HYPOGLYCEMIC NEWBORNS

Kristin E. D'Aco

Samantha A. Schrier

Ralph J. DeBerardinis (5th edition)

Sulagna C. Saitta (5th edition)

BASICS

DESCRIPTION

Inborn errors of metabolism are inherited defects in biochemical pathways affecting metabolism of fats, amino acids, or carbohydrates. Some inborn errors of metabolism predispose newborns to hypoglycemia. Because these conditions are life-threatening if not treated promptly, maintaining a high degree of clinical suspicion in sick neonates is essential. In the newborn period, the immediate goals should be to:

- Establish a tentative diagnosis.
- Initiate presumptive management.
- Send confirmatory studies.
- Involve a team trained in treating patients with inborn errors of metabolism.

RISK FACTORS

Genetics

Almost all inborn errors of metabolism causing hypoglycemia are autosomal recessive. One form of hyperinsulinism is autosomal dominant.

PATHOPHYSIOLOGY

- Through glycolysis and oxidative phosphorylation, glucose is a major source of cellular energy (ATP). Failure to produce ATP is probably the main source of hypoglycemia-associated tissue dysfunction.
- The brain preferentially uses glucose metabolism to produce energy and is particularly sensitive to hypoglycemia.
- A long list of metabolic disturbances in a variety of pathways can result in hypoglycemia.
- Neonates are at particular risk for hypoglycemia because they use glucose more rapidly than adults and have immature ability to obtain energy from other sources (glycogen, muscle protein, adipose tissue).

ETIOLOGY

Inherited defects in biochemical pathways affecting metabolism of fats, amino acids, or carbohydrates

DIAGNOSIS

HISTORY

- Family history: Because inborn errors of metabolism are genetic disorders, patients may have a family history of poorly explained pediatric death. Diagnoses to ask about include:
 - Sepsis (was an organism identified?)
 - Sudden infant death syndrome
 - Cardiomyopathy
 - Uncontrollable seizures
 - Coma
 - Liver failure
- Unexplained developmental delay or hypoglycemia in older siblings
- Complications with the pregnancy:
 - Maternal diabetes
 - Certain disorders of fatty acid oxidation are associated with fatty liver of pregnancy or the HELLP (hypertension, elevated liver enzymes, low platelets) syndrome.
- Results of newborn screen: Children are tested for a variety of inborn errors of metabolism through newborn screening programs. Some of these disorders predispose to hypoglycemia and have specific therapies.
- Current diet and feeding schedule: Timing of hypoglycemia helps form differential diagnosis:
 - Hypoglycemia occurring shortly after feeding (0–4 hours) is suggestive of hyperinsulinism or inability to process carbohydrates.
 - Hypoglycemia between 2 and 10 hours after feeding is concerning for glycogen storage diseases or counter-regulatory hormone deficiencies.
 - Hypoglycemia after a prolonged fast (>6 hours) is suggestive of ketotic hypoglycemia, defects in gluconeogenesis, or fatty acid oxidation defects.

PHYSICAL EXAM

- ABCs and vital signs: Tachycardia and hypotension are commonly seen in hypoglycemia.
- Facies: Decreased interpupillary diameter or other midline anomalies occur in association with abnormalities of the pituitary.
- Skin: Diaphoresis is an effect of the catecholamine surge that accompanies hypoglycemia.

- Respiratory: Tachypnea may be the result of either respiratory compensation of metabolic acidosis or hyperammonemia.
- GI: Hepatomegaly occurs in many inborn errors of metabolism causing hypoglycemia and is a key feature in differentiating possible diagnoses. It can be a result of abnormal accumulation of lipid (e.g., in fatty acid oxidation defects) or glycogen (e.g., glycogen storage disease).
- Neurologic: Every neonate with a suspected inborn error of metabolism needs a complete neurologic exam to evaluate level of consciousness, tone, unusual movements, reflexes:
 - Tremulousness is a common early sign of hypoglycemia.
 - Stupor and coma occur if hypoglycemia is not reversed.
- Growth parameters: Infants of diabetic mothers may be large for gestational age. Beckwith-Wiedemann syndrome presents with an infant that is large for gestational age, hyperinsulinism, and physical stigmata (hemihypertrophy, macroglossia, abdominal wall defects).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

The goal of the lab evaluation is to make a presumptive diagnosis as soon as possible. In many cases, definitive diagnosis requires specialized and time-consuming tests. Critical management points:

- Presumptive treatment should not await a definitive diagnosis, but should be based on clinical suspicion and initial labs. Delays in treatment can be fatal.
- Involvement of a biochemical genetics team is invaluable in directing the workup of suspected inborn errors of metabolism.
- In a neonate with a hypoglycemic dextrose stick, obtain the following critical labs as soon as possible:
 - Basic metabolic profile including glucose
 - Urinalysis for ketones: Inappropriately low or absent in hyperinsulinism and fatty acid oxidation defects
 - Arterial blood gas with lactate: Lactic acidosis occurs in gluconeogenic defects and in glycogen storage disease type I.
 - Insulin: Inappropriately high in hyperinsulinemic states
 - Cortisol, growth hormone levels: Inappropriately low in deficiency states
 - Plasma acylcarnitine profile: Diagnostic for fatty acid oxidation defects, some organic acidemias
 - Urine organic acids: Helps quantify accumulation of ketones and intermediates of amino acid and lipid metabolism
 - Review of the state newborn screen

DIFFERENTIAL DIAGNOSIS

Hypoglycemia is caused by increased glucose use or decreased glucose availability. Examples of disorders causing each:

- Increased glucose use:
 - Sepsis increases metabolic demand and is a leading cause of neonatal hypoglycemia.
 - Hyperinsulinemia
 - Decreased insulin counter-regulatory hormones (glucagon, cortisol, growth hormone)
- Decreased glucose availability/production:
 - Infants of diabetic mothers
 - From ingested carbohydrate: Galactosemia, hereditary fructose intolerance
 - Glycogen storage diseases
 - Decreased gluconeogenesis: Phosphoenolpyruvate carboxykinase deficiency, fructose-1,6-diphosphatase deficiency, pyruvate carboxylase deficiency
 - From decreased efficiency of pathways providing alternate energy sources: Organic acidemias, fatty acid oxidation defects
- Various toxins or medications interfere with pathways needed to maintain glucose homeostasis, including salicylates, valproate, β blockers, ethanol, and exogenous insulin.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- A well-appearing neonate with a low dextrose stick should be fed immediately. If feeds are contraindicated or not tolerated, obtain IV access.
- In children with associated physical or laboratory findings consistent with an inborn error of metabolism or other serious illness (e.g., vital sign instability, lethargy, acidosis), IV access should be obtained.
- A dextrose bolus (e.g., 5 cc/kg D10) and infusion rapidly corrects hypoglycemia in most cases. Infants requiring high glucose infusion rates are suspicious for hyperinsulinism.

Additional Therapies

Specific therapies vary according to the diagnosis and are best carried out with the help of a specialist familiar with each disease. Examples include:

- Hyperinsulinism:
 - May require continuous glucose administration (IV or via continuous gastric feeds)
 - Medical therapies including diazoxide and octreotide
 - Pancreatectomy
- Deficiencies in counter-regulatory hormones: Hormone supplementation
- Galactosemia, hereditary fructose intolerance: Eliminate offending agent from diet.
- Fatty acid oxidation disorders, glycogen storage disease type I, defects in gluconeogenesis: Frequent feeds, fasting avoidance, increase caloric intake during stress. Some children may benefit from cornstarch supplementation before bedtime to prevent nocturnal hypoglycemia.

ONGOING CARE

COMPLICATIONS

- Hypoglycemic episodes must be recognized and treated promptly or permanent CNS injury (“hypoglycemic stroke”) may occur.
- For many inborn errors of metabolism, episodes of hypoglycemia may recur. These are avoided by specific dietary measures during times of stress.

CODES

ICD9

- 775.6 Neonatal hypoglycemia
- 277.9 Unspecified disorder of metabolism

ICD10

- E88.9 Metabolic disorder, unspecified
- P70.4 Other neonatal hypoglycemia

FAQ

- Q: Why is hypoglycemia dangerous?
- A: Glucose is a crucial source of rapidly available energy for many tissues, especially the brain. Prolonged hypoglycemia causes CNS damage.
- Q: Why are the critical labs so important?
- A: In some metabolic disorders, the biochemical disturbance is apparent only during hypoglycemic episodes. Collecting this panel of informative labs during an episode greatly increases the chance of making a diagnosis.
- Q: If an infant dies before a diagnosis is made, what can be done to provide information for family members regarding future pregnancies?
- A: A postmortem exam and biochemical tests performed on various tissues obtained immediately after death can establish the diagnosis. A skin biopsy (obtained pre-mortem or post-mortem) yields fibroblasts for a variety of biochemical assays, including enzyme defects in fatty acid oxidation disorders and organic acidemias. Workup of primary lactic acidosis syndromes requires electron transport chain analysis of muscle, which must be harvested immediately (within 30 minutes) after death.

METABOLIC DISEASES IN ACIDOTIC NEWBORNS

Kristin E. D'Aco

Samantha A. Schrier

Ralph J. DeBerardinis (5th edition)

Sulagna C. Saitta (5th edition)

BASICS

DESCRIPTION

- Inborn errors of metabolism are inherited defects in biochemical pathways affecting fats, amino acids, or carbohydrates. Many affect the conversion of fuel to energy. Some present with catastrophic neonatal metabolic acidosis.
- Because these conditions are life-threatening if not treated promptly, a high degree of suspicion is essential. In the newborn period, the immediate goals should be to:
 - Establish a tentative diagnosis.
 - Initiate presumptive management.
 - Send confirmatory studies.
 - Involve a team trained in treating patients with inborn errors of metabolism.

RISK FACTORS

Genetics

Generally autosomal recessive. Exceptions include pyruvate dehydrogenase deficiency (a form of lactic acidosis, usually X-linked) and diseases of the mitochondrial genome (maternally inherited).

PATHOPHYSIOLOGY

- Inborn errors of metabolism presenting with metabolic acidosis usually produce an elevated anion gap owing to accumulation of an acidic intermediate. *Identification of this acid is the 1st step in establishing the diagnosis.*
- Tissue dysfunction results from toxicity of the accumulated byproduct and/or failure to produce sufficient energy to meet cellular needs.
- CNS toxicity results in increased intracranial pressure, emesis, lethargy, coma, seizures, abnormalities in muscle tone.
- Hepatic toxicity causes jaundice, failure to thrive, hypoglycemia, hyperammonemia, coagulopathy.
- Other organ systems may be involved, depending on the disease. These include the heart, the proximal renal tubule, the pancreas, and the bone marrow (see below).

ETIOLOGY

Inherited defects in biochemical pathways affecting fats, amino acids, or carbohydrates.

DIAGNOSIS

HISTORY

- Complications with the pregnancy: Some inborn errors of metabolism, particularly certain disorders of fatty acid oxidation, are associated with fatty liver of pregnancy or the HELLP (hypertension, elevated liver enzymes, low platelets) syndrome.
- Current diet and feeding schedule (does baby wake spontaneously to feed?): Acidotic episodes may be triggered by specific food exposures or by prolonged fasting, including relatively short delays. In addition, diets low in protein content may delay the onset of symptoms in disorders of amino acid metabolism.
- Unusual odors to the urine or secretions: Some organic acids are associated with specific odors.

- Family history: Because inborn errors of metabolism are genetic disorders, there may be a family history of poorly explained pediatric death. Diagnoses to inquire about include:
 - Sepsis (was an organism identified?)
 - Sudden infant death syndrome
 - Cardiomyopathy
 - Uncontrollable seizures
 - Coma
 - Liver failure
 - Unexplained developmental delay or hypoglycemia in older siblings

PHYSICAL EXAM

- ABCs and vital signs: Cushing's triad (apnea, bradycardia, hypertension) should prompt immediate evaluation for elevated intracranial pressure. Are there signs of dehydration?
- Skin: Jaundice owing to liver toxicity occurs in many neonates with inborn errors of metabolism. Rashes are associated with biotinidase deficiency.
- Head, eyes, ears, nose, throat: Bulging fontanelle suggests elevated intracranial pressure. Minor dysmorphic features (e.g., frontal bossing, short/upturned nose, long philtrum, low-set ears) are sometimes seen in pyruvate dehydrogenase deficiency and severe disorders of fatty acid oxidation.
- Respiratory: Tachypnea may result from either respiratory compensation of metabolic acidosis or from hyperammonemia.
- Cardiovascular: Arrhythmias or signs of heart failure may signal a cardiomyopathy.
- GI: Hepatomegaly occurs in many inborn errors of metabolism that also cause acidosis. It can be the result of abnormal accumulation of lipid or glycogen. Abdominal pain and emesis can be caused by ketosis.
- Neurologic: Inborn errors of metabolism presenting with acidosis are often associated with neuronal toxicity. Every neonate with a suspected inborn error of metabolism must have a complete neurologic exam.
- Assessment for odors:
 - Burnt sugar: Maple syrup urine disease
 - Fruity: Ketosis
 - Sweaty feet: Isovaleric acidemia
- Growth parameters: Normal at birth for most inborn errors of metabolism

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The goal of the lab evaluation is to make a presumptive diagnosis as soon as possible. In most cases, definitive diagnosis requires specialized and time-consuming tests. Critical management points:
 - Presumptive treatment should not await definitive testing, but should be based on clinical suspicion and initial testing. Delays in treatment can be fatal.
 - Involvement of a biochemical genetics team is invaluable in directing the workup of suspected inborn errors of metabolism.
- A rational approach for acidotic neonates is to determine the inborn error of metabolism category using the tests below, then to send metabolic follow-up studies as indicated:
 - Initial tests:
 - Urinalysis for ketones. Can be bagged urine, but obtain by catheterization if necessary.
 - Dextrose stick
 - Basic metabolic profile
 - Arterial blood gas
 - Blood lactate*
 - Ammonia*
 - Liver function tests
 - Review of the state newborn screen
 - *must be collected without tourniquet, from free flowing blood, and delivered to laboratory on ice
- Patterns and follow-up testing: These studies establish a presumptive diagnosis in most inborn errors of metabolism presenting with acidosis:
 - If elevated ketones, consider:
 - Branched-chain and other organic acidemias (methylmalonic acidemia, propionic acidemia, isovaleric acidemia, others): Ketoacidosis, hyperammonemia, with or without hypoglycemia. Obtain plasma amino acids, urine organic acids, plasma acylcarnitine profile with total/free carnitine.
 - Primary lactic acidosis syndromes (below)
 - If elevated blood lactate, consider:
 - Primary lactic acidosis syndromes: May be associated with ketosis (oxidative phosphorylation deficiency) and/or hypoglycemia (gluconeogenesis defects). Obtain lactate/pyruvate ratio, urine organic acids, creatine phosphokinase and biotinidase quantitation. Consider brain MRI and MR spectroscopy if CNS symptoms present.
 - Fatty acid oxidation defects: Hypoketotic hypoglycemia with or without hyperammonemia and lactic acidosis: Obtain hepatic phosphokinase, plasma acylcarnitine profile with total/free carnitine, urine organic acids. Perform ECG/echo for signs of cardiac failure.
 - If anion is not identified on initial tests, consider branched-chain and other organic acidemias.
- Other tests: Consider organic acid, amino acid, and lactate/pyruvate analysis of the CSF in neonates with neurologic dysfunction.
- Definitive diagnosis may require enzyme testing or mutation analysis.

DIFFERENTIAL DIAGNOSIS

In neonates, many different inborn errors of metabolism present with similar symptoms, which can easily be confused with other serious diseases.

- Differential diagnosis in sick, acidotic neonate:
 - Sepsis
 - Congenital heart disease
 - Toxin/Drug exposure
 - Perinatal depression
 - Inborn error of metabolism
- Categories of inborn error of metabolism presenting with neonatal acidosis:
 - Lactic acidosis:
 - Pyruvate dehydrogenase deficiency
 - Pyruvate carboxylase deficiency
 - Phosphoenolpyruvate carboxykinase deficiency
 - Defects in tricarboxylic acid cycle enzymes
 - Mitochondrial diseases or other conditions affecting oxidative phosphorylation
 - Severe disorders of gluconeogenesis (e.g., glucose-6-phosphatase deficiency)
 - Multiple carboxylase deficiency, biotinidase deficiency
 - Disorders of fatty acid oxidation
 - Ketoacidosis:
 - Disorders of ketone utilization (e.g., β -ketothiolase deficiency)
 - Ketosis can also occur in lactic acidosis syndromes (above) and organic acideurias (below)
 - Other organic acids:
 - Maple syrup urine disease
 - Branched chain organic acideurias (methylmalonic acidemia, propionic acidemia, isovaleric acidemia)
 - Many others. Note that in some cases, other abnormalities (e.g., lethargy, hyperammonemia) may occur prior to severe acidosis.

TREATMENT

ADDITIONAL TREATMENT

General Measures

Metabolic derangement usually worsens during times of stress (e.g., perinatal period, infection, fasting) and accompanying catabolism. Provide sufficient calories to reverse the catabolic state. Considerations include:

- IV access
- Many decompensated patients will have altered mental status and dehydration. Consider intubation if obtunded.
- Bicarbonate boluses and infusions may be necessary, especially if pH <7.22 or bicarb <14. Monitor sodium carefully in patients receiving NaHCO₃.
- In most cases, a high glucose infusion rate (e.g., with D10-based fluid) speeds stabilization. One important exception is pyruvate dehydrogenase deficiency, a primary lactic acidosis syndrome, in which rapid glucose infusion can worsen the lactic acidosis. These children should receive D5.
- Specific dietary measures require a presumptive diagnosis.

- Total parenteral nutrition is a useful option when a presumptive diagnosis has been made. Note that special amino acid mixtures are available for particular disorders (e.g., maple syrup urine disease).
- Insulin can be used to reverse states of severe catabolism.
- Nasogastric feeding using appropriate formulas is useful.
- In patients with large acid load and/or concomitant hyperammonemia, hemodialysis may be indicated.

Additional Therapies

Specific therapies are best carried out with the help of a biochemical geneticist or other specialist with experience treating inborn errors of metabolism, and a clinical nutritionist.

- Organic acideurias:
 - Protein restriction, protein elimination during times of stress, and avoidance of fasting
 - High glucose infusion rates during decompensation
- Primary lactic acidosis syndromes: Therapy is supportive and involves avoidance of stresses such as fasting.
- In pyruvate dehydrogenase deficiency, a ketogenic diet may improve chronic acidosis.
- Fatty acid oxidation disorders:
 - Low-fat, high-carbohydrate diets with frequent feeds

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Should be determined with the input of a metabolic specialist, but may include:

- Serial ABG or basic metabolic profile to trend pH and bicarbonate levels
- Serial blood lactates
- Cardiorespiratory monitoring
- Frequent assessment of patient’s mental status and peripheral perfusion

COMPLICATIONS

- Failure to treat patients promptly can be fatal or result in severe CNS insult and developmental disability. The basal ganglia are particularly susceptible to a variety of metabolic disturbances, and damage to these structures can cause “metabolic stroke.”
- For many inborn errors of metabolism, recurrent episodes of acidosis, triggered by stress, intercurrent illness, or dietary noncompliance, are a major source of morbidity.
- Long-term effects may include progressive tissue dysfunction (e.g., liver or renal failure, cardiomyopathy) or failure to thrive.

FAQ

- Q: If an infant dies before a diagnosis is made, what can be done to provide information for family members regarding future pregnancies?
- A: Postmortem exam and biochemical tests on tissues obtained immediately after death can establish the diagnosis. Skin biopsy (obtained pre-mortem or post-mortem) yields fibroblasts for a variety of biochemical assays. Workup of primary lactic acidosis syndromes requires electron transport chain analysis of muscle, which must be harvested within 30 minutes after death.
- Q: What determines developmental outcome in children with inborn errors of metabolism?
- A: Disease severity depends in part on the specific mutations in each patient. However, prompt initiation of appropriate therapy in the newborn period, as well as compliance with chronic management and avoidance of decompensation periods, all contribute to developmental outcome.

METABOLIC DISEASES IN HYPERAMMONEMIC NEWBORNS

Kristin E. D'Aco

Samantha A. Schrier

Ralph J. DeBerardinis (5th edition)

Sulagna C. Saitta (5th edition)

BASICS

DESCRIPTION

- Inborn errors of metabolism are inherited defects in biochemical pathways affecting metabolism of fats, amino acids, or carbohydrates.
- Some inborn errors of metabolism present with elevated ammonia in newborns (> 100 micromolar). Because these conditions are life-threatening if not treated promptly, maintaining a high degree of clinical suspicion in sick neonates is essential. In the newborn period, the immediate goals include:
 - Establish a tentative diagnosis.
 - Initiate presumptive management.
 - Send confirmatory studies.
 - Involve a team trained in treating patients with inborn errors of metabolism.

RISK FACTORS

Genetics

Generally autosomal recessive. Ornithine transcarbamylase deficiency (the most common urea cycle defect) is X-linked. Incidence of urea cycle defects is ~1 in 45,000 births.

PATHOPHYSIOLOGY

The urea cycle converts ammonia (NH₃) to water-soluble urea in the liver and is the major mechanism for ammonia disposal. Inborn errors of metabolism causing hyperammonemia interfere with urea cycle function, either directly or indirectly, including the following mechanisms:

- Genetic defects in a urea cycle enzyme *per se*
- Decreased production, increased use, or defective transport of a urea cycle intermediate. Examples:
 - Hyperornithinemia, hyperammonemia, homocitrullinemia (HHH) syndrome
 - Lysinuric protein intolerance
 - Fatty acid oxidation defects
 - Hyperammonemia/Hyperinsulinemia syndrome
 - Organic acidemias
 - Pyruvate carboxylase deficiency
- Hepatotoxicity (galactosemia, hereditary fructose intolerance)

DIAGNOSIS

HISTORY

- Evidence of systemic disease: A variety of systemic newborn illnesses, including sepsis, can be complicated by a secondary hyperammonemia.
- Family history of poorly explained pediatric death or developmental disability raises suspicion for a genetic disorder, such as an inborn error of metabolism. Diagnoses to ask about:
 - Sepsis (was an organism identified?)
 - Sudden infant death syndrome
 - Cardiomyopathy
 - Uncontrollable seizures
 - Coma
 - Liver failure
- Current diet and feeding schedule: In urea cycle defects, hyperammonemia is exacerbated by protein intake.
- Failure to wake and feed spontaneously is a sign of CNS dysfunction in neonates.
- Perinatal hypoxia can cause temporary liver dysfunction and reduced urea cycle capacity. Relative immaturity of the urea cycle can cause hyperammonemia in premature infants.

PHYSICAL EXAM

- ABCs and vital signs: Cushing's triad (apnea, bradycardia, hypertension) should prompt immediate evaluation for elevated intracranial pressure, a complication of hyperammonemia.
- Skin: Jaundice is not typical in urea cycle defects, but occurs in other inborn errors of metabolism associated with hepatotoxicity.
- Head, eyes, ears, nose, and throat: Bulging fontanelle suggests elevated intracranial pressure.
- Respiratory: Effects of hyperammonemia on the brainstem respiratory center may cause tachypnea, leading to respiratory alkalosis.
- GI: Hepatomegaly occurs in some of these disorders (fatty acid oxidation, galactosemia).
- Neurologic: Hyperammonemia causes a variety of neurologic abnormalities, including abnormal tone, obtundation, and coma.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

The goal of lab testing is to make a presumptive diagnosis as soon as possible. In many cases, definitive diagnosis requires specialized tests. Critical management points:

- Presumptive treatment should not await a definitive diagnosis, but should be based on clinical suspicion and initial labs. Delays in treatment can be fatal.
- Involvement of a biochemical genetics team is invaluable in directing the workup of suspected inborn errors of metabolism.
- Initial labs to evaluate neonatal hyperammonemia:
 - Dextrose stick
 - Electrolytes, BUN, creatinine
 - CBC, blood culture
 - Blood gas with lactate
 - Liver function tests and PT/PTT
 - Urinalysis for ketones, reducing substances
 - Frequent ammonia levels (q3–12 hours depending on level of elevation). These should be obtained as free-flowing samples without tourniquets and placed on ice.
 - Review state newborn screen
- Suspected disorders and follow-up testing:
 - Urea cycle defects: Plasma amino acids and urine orotic acid
 - Organic acidemias: Urine organic acids, plasma amino acids, and acylcarnitine profile
 - Fatty acid oxidation defects: Creatine phosphokinase, urine organic acids, plasma acylcarnitine profile
 - Galactosemia: Urine galactitol, red blood cell galactose-1-phosphate uridylyltransferase (GALT) activity, and total galactose from blood
 - Definitive diagnosis may require enzyme testing or mutation analysis.

DIFFERENTIAL DIAGNOSIS

- Neonatal hyperammonemia not caused by inborn errors of metabolism:
 - Sepsis or other severe illness
 - Liver failure (any cause)
 - Transient neonatal hyperammonemia
 - Perinatal depression/hypoxia
 - Iatrogenic (valproic acid, asparaginase)

- Inborn errors of metabolism:
 - Urea cycle defects (N-acetylglutamate synthetase deficiency, carbamoyl phosphate synthase deficiency, ornithine transcarbamylase deficiency, argininosuccinate synthetase deficiency (citrullinemia), argininosuccinate lyase deficiency)
 - Organic acidemias (isovaleric acidemia, propionic acidemia, methylmalonic acidemia, multiple carboxylase deficiencies, others)
 - Fatty acid oxidation defects (medium-chain acyl-CoA dehydrogenase deficiency, multiple acyl-CoA dehydrogenase deficiency, others)
 - Hyperornithinemia, hyperammonemia, homocitrullinemia (HHH) syndrome
 - Pyruvate carboxylase deficiency
 - Hyperammonemia/Hyperinsulinemia syndrome
 - Galactosemia
 - Hereditary fructose intolerance

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Discontinue protein intake, which exacerbates ammonia production. Protein/Amino acid-free formula or parenteral nutrition should be used.
- Obtain IV access.
- Many patients will require intensive care transfer. Hyperammonemia interferes with normal CNS and respiratory function, so hyperammonemic neonates often require intubation.
- Nitrogen scavenging agents (e.g., sodium benzoate, sodium phenylacetate, sodium phenylbutyrate) are used in some settings. They improve hyperammonemia by combining with amino acids to yield products that can be excreted into the urine.
- Arginine or citrulline therapy may be used to supplement the residual function of the urea cycle. Use should be only under the supervision of a metabolic specialist.
- In severe hyperammonemia, dialysis may be indicated.
- In many disorders, catabolism and associated breakdown of endogenous protein exacerbates the nitrogen load. This can be treated with calories from high-rate dextrose infusion with insulin, if indicated, to enhance anabolism.
- Administration of N-carbamyl-L-glutamic acid (Carbaglu) has been shown to reduce ammonia levels in NAG synthetase deficiency, CPS1 deficiency, and the organic acidemias. Use should only be under the supervision of a metabolic specialist.

Additional Therapies

Specific therapies are best carried out with the help of a specialist experienced in treating inborn errors of metabolism, and a clinical nutritionist. Examples include:

- Urea cycle defects:
 - Protein-restricted diet, with protein elimination during illness/stress
 - Chronic therapy with nitrogen scavenging agents
 - Amino acid supplements when indicated (e.g., citrulline in ornithine transcarbamylase deficiency; arginine in citrullinemia, argininosuccinate lyase deficiency)
 - Long-term therapy may involve an orthotopic liver transplant.
- Fatty acid oxidation disorders:
 - Low-fat, high-carbohydrate diets with frequent feeds
- Organic acidemias:
- Protein restriction, protein elimination during times of stress, and avoidance of fasting

ONGOING CARE

COMPLICATIONS

- Recurrent episodes of hyperammonemia
- Elevated intracranial pressure
- Developmental disability
- Coma
- Death

CODES

ICD9

- 270.6 Disorders of urea cycle metabolism
- 277.9 Unspecified disorder of metabolism

ICD10

- E72.4 Disorders of ornithine metabolism
- E88.9 Metabolic disorder, unspecified

FAQ

- Q: Can females have ornithine transcarbamylase deficiency?
- A: Because ornithine transcarbamylase is an X-linked gene, females are generally asymptomatic carriers. However, “skewed” X inactivation, in which the normal ornithine transcarbamylase gene is inactive in a large majority of hepatocytes, has caused symptomatic disease in a number of females. Affected carrier females may exhibit protein intolerance, migraines, and personality changes. They are treated similarly to affected males.
- Q: Can any of these disorders present outside of the newborn period?
- A: Disease severity depends in large part on a patient’s enzyme activity. In some patients, there is enough activity so that hyperammonemia does not occur until later in life during a period of illness, stress, or high protein intake.
- Q: What determines developmental outcome in children with inborn errors of metabolism?
- A: In most inborn errors of metabolism, severe mutations cause very low enzyme activity and a greater disease severity. However, prompt initiation of appropriate therapy in the newborn period, as well as compliance with chronic management, contributes to developmental outcome.

METABOLIC SYNDROME

George A. Datto, III
Sandra Gibson Hassink

BASICS

DESCRIPTION

- A cluster of metabolic disorders that is the antecedent to cardiovascular disease and type 2 diabetes in adults
- The presence of 3 or more of the following metabolic abnormalities is required to meet the diagnosis:
 - Obesity:
 - BMI > 97% (BMI Z score > 2)
 - Low HDL cholesterol:
 - < 5% for age and gender
 - Elevated triglycerides:
 - > 95% for age and gender
 - Hypertension:
 - Systolic and/or diastolic BP > 95% for age and gender
 - Impaired fasting blood sugar/impaired glucose tolerance:
 - Fasting blood sugar > 100 mg/dL
 - 2-hour glucose tolerance test > 140 mg/dL

EPIDEMIOLOGY

Prevalence

- Uncommon in children of normal weight
- 30% of obese children meet criteria for the metabolic syndrome.
- Rates increase with higher BMI.
- Highest rates in Mexican Americans > whites > African Americans
- More prevalent in males than females

RISK FACTORS

- Obesity
- Family history of cardiovascular disease
- Family history of type 2 diabetes mellitus

Genetics

Strong family history of early coronary heart disease and type 2 diabetes supports genetic component.

PATHOPHYSIOLOGY

- Visceral fat:
 - Deposition of fat centrally, which can be influenced by diet and genetics
- Adipocytes:
 - Adipocytes produce proinflammatory mediators (adiponectin, resistin, and tumor necrosis factor- α).
- Insulin resistance:
 - Inflammatory mediators affect cell's ability to respond to insulin.

ETIOLOGY

- Obesity
- Physical inactivity
- Insulin resistance
- Aging
- Genetics

COMMONLY ASSOCIATED CONDITIONS

- Polycystic ovarian syndrome
- Nonalcoholic steatohepatitis (NASH)
- Sleep apnea

DIAGNOSIS

HISTORY

- Obesity trigger:
 - Age at which weight gain started
 - Family or patient stress
 - Life events
- Parents'/patient's beliefs:
 - Level of concern and motivation
 - Self-assessed reasons for weight gain
 - Previous attempts at weight control
- Family history:
 - Early coronary heart disease and diabetes mellitus
- Lifestyles:
 - Eating behavior
 - Sugared beverage consumption
 - Snacks: Frequency and content
 - Eating structure
 - Physical activity
 - Hours of screen time
 - Sports and activity participation
 - Time outdoors
- Parenting skills
 - Assessing the environment
 - Ability to set boundaries
 - Role modeling
 - Anger management
 - Hunger management
- Signs and symptoms:
 - Obese patients with the metabolic syndrome usually lack any symptoms, but may complain of:
 - Easy and rapid weight gain
 - Excessive hunger
 - Tiredness
 - Headaches
 - Darkening of neck and axillae (findings suggestive of acanthosis nigricans)
 - Nocturia

PHYSICAL EXAM

A complete physical should be done on all patients. Special attention should be paid to the following:

- Weight, height, and BMI
- Waist circumference
- Blood pressure
- Acanthosis nigricans
- Abdominal striae
- Hepatomegaly
- Tanner stage
- Affect

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Metabolic screening (fasting specimens) should be done on all obese patients:

- Lipid profile: Cholesterol, HDL, and triglycerides
- Glucose
- Hemoglobin A1c
- Liver function tests: ALT and AST
- Thyroid function tests: Free T₄ and TSH
- A 2-hour glucose tolerance test should be considered in patients with a fasting blood sugar > 100 mg/dL or a hemoglobin A1c > 6% to document either impaired glucose tolerance or type 2 diabetes.
- Abnormal lab tests should be repeated after a trial of weight management.
- Normal lab studies should be repeated yearly with significant weight gain.

Imaging

All patients with hypertension (BP > 95th percentile \times 3) should have an ECG to evaluate for left ventricular hypertrophy.

DIFFERENTIAL DIAGNOSIS

- Hereditary dyslipidemia
- Essential hypertension
- Hypertriglyceridemia
- Diabetes mellitus
- Secondary hypertension

TREATMENT

MEDICATION (DRUGS)

Medications may be appropriate in certain clinical situations to treat the components of the metabolic syndrome when lifestyle interventions fail to show clinical improvement.

- Dyslipidemia
 - Statin therapy to treat hypercholesterolemia should be considered in adolescent patients with the following problems:
 - LDL > 190 mg/dL
 - LDL > 160 mg/dL with strong family history of early coronary artery disease (1st-degree relatives with coronary artery disease at age < 55)
 - Patients with type 2 diabetes with dyslipidemia
 - Atorvastatin: 10 mg PO daily to max of 40
 - Treatment goal: LDL < 130 mg/dL
 - Side effects: Elevation of liver function tests
- Hypertension (see "Hypertension" chapter)
 - Antihypertensive drug therapy should be considered in the following patients:
 - Stage 2 hypertension (99% + 5 mm Hg)
 - Hypertensive patients with insufficient clinical response to lifestyle modification
 - Patients with evidence of left ventricular hypertrophy on echocardiogram
 - Patients with type 2 diabetes

- ACE inhibitors or angiotensin-receptor blockers may have renal protective effects in diabetic patients.
- Impaired fasting blood sugar/impaired glucose tolerance; type 2 diabetes mellitus (see “Diabetes” chapter)
 - Drug therapy should be considered in all patients with a fasting blood sugar > 126 mg/dL or a hemoglobin A1c > 7.0%.

ADDITIONAL TREATMENT

General Measures

In the adults, lifestyle intervention has been more effective than metformin in decreasing the incidence of diabetes mellitus in patients who have the metabolic syndrome. Modest decreases in BMI by incorporating lifestyle interventions will decrease risk factors of the metabolic syndrome. Effective pediatric obesity management incorporates the following principles:

- Effective communication with patient and family:
 - Nonblaming approach
 - Be positive that change can occur.
- Assessing family’s understanding of problem and readiness to make lifestyle change(s)
 - Incorporate motivational interviewing to help families with their stage of change.
- Identifying energy balance abnormalities
- Providing options for change
- Supporting families in planning and making lifestyle change
 - Goal setting
 - Parenting skills
 - Controlling the environment
 - Ongoing evaluation of treatment efficacy

Additional Therapies

- Activity: Increased physical activity has been shown to reduce insulin resistance and lower inflammatory markers associated with the metabolic syndrome.
- When possible, add structured physical activity into daily routine.
- Incorporate both resistance and aerobic activities.
- Non-weight-bearing activities such as swimming and stationary bike riding may be easier for the morbidly obese deconditioned patient.
- Limit sedentary activity to no more than 2 hours per day.
- Home monitoring:
 - Food and activity record logs may increase awareness and importance of healthy lifestyles.
- At home or in school, blood pressure monitoring may rule out white coat hypertension.
- Preprandial and 2-hour postprandial blood sugars are helpful in monitoring impairments in glucose metabolism:
 - Preprandial blood sugar < 100 mg/dL
 - Postprandial blood sugar < 140 mg/dL

ISSUES FOR REFERRAL

Refer for components of the metabolic syndrome that do not improve with reductions in BMI or treatment of complications (i.e., dyslipidemia, hypertension, diabetes).

SURGERY/OTHER PROCEDURES

Gastric bypass surgery should be considered for morbidly obese adolescent patients (BMI > 40) who have severe comorbid conditions, including the following:

- Diabetes mellitus
- Sleep apnea
- Disabling orthopedic complications
- NASH with fibrosis

 **ONGOING CARE**

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients should be followed frequently, every 1–2 months, when they are implementing lifestyle changes.
- Therapy should be intensified (lifestyle and/or pharmacologic) if components of the metabolic syndrome are not clinically improving or worsening.

DIET

- Limiting intake of simple sugars has been shown to improve insulin resistance.
- Eliminate sugared beverages from the diet
- Increase amount of fruits, vegetables, whole grains, and protein in diet.
- Portion control junk food.
- Portion control carbohydrates.
- Family eats healthy together.
- Parents monitor child’s food intake.

PROGNOSIS

Improvement in the components of the metabolic syndrome depends on the ability to implement lifestyle changes and achieve modest weight loss.

COMPLICATIONS

- Short term:
 - Increased risk of progression to type 2 diabetes mellitus with weight gain
- Long term:
 - Metabolic syndrome in adults increases risk of coronary heart disease:
 - 2–4-fold depending on population studied
 - 3.5-fold increase in cardiovascular mortality

FAQ

- Q: Why is it important to diagnose the metabolic syndrome in children?
- A: Making the diagnosis can help clinicians to educate patients and families that the metabolic syndrome is the antecedent to type 2 diabetes mellitus and increases risk of premature cardiovascular disease.
- Q: What is the 1st-line therapy for the metabolic syndrome?
- A: Weight loss, as modest as 5% reductions in body mass index, can improve the components of the metabolic syndrome.
- Q: How early can the metabolic syndrome be diagnosed?
- A: Prepubertal children can be diagnosed with the metabolic syndrome.

METHEMOGLOBINEMIA

Kevin C. Osterhoudt

BASICS

DESCRIPTION

- Methemoglobin is dysfunctional hemoglobin in which the deoxygenated heme moiety has been oxidized from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state.
- Methemoglobinemia is an undue accumulation of methemoglobin within the blood.

EPIDEMIOLOGY

- Toxic methemoglobinemia, resulting from exposure to oxidant chemicals or drugs, is the most common cause of methemoglobinemia among children older than 6 months.
- Enteritis-associated methemoglobinemia is the most common cause among children younger than 6 months:
 - As many as 2/3 of infants with severe diarrhea have methemoglobinemia.

PATHOPHYSIOLOGY

- Hemoglobin in the allosteric configuration of methemoglobin cannot carry oxygen.
- Methemoglobin increases the oxygen affinity of normal heme moieties in the blood and results in impaired oxygen delivery to tissues.
- NADH-dependent cytochrome b5 methemoglobin reductase is the major source of physiologic reduction of methemoglobin.
- A normally dormant NADPH-dependent methemoglobin reductase is the site of action for antidotal methylene blue therapy.

ETIOLOGY

- Toxic methemoglobinemia:
 - Dietary or environmental chemicals: Chlorates, chromates, copper sulfate fungicides, naphthalene, nitrates, and nitrites
 - Industrial chemicals: Aniline and other nitrogenated organic compounds
 - Drugs: Amyl nitrite, benzocaine, dapsone, lidocaine, metoclopramide, nitric oxide, nitroprusside, phenazopyridine, prilocaine, many others
 - Methemoglobinemia is a common iatrogenic complication of drug therapy.
- Enteritis-associated methemoglobinemia is multifactorial in origin:
 - Intestinal nitrate and nitric oxide promotes methemoglobin formation.
 - Innate enzymatic methemoglobin reduction systems may be underdeveloped during infancy.
 - Acidemia further inhibits enzymatic methemoglobin reduction systems.
 - Methemoglobinemia is also reported with nitrite-producing bacterial infections of the intestines or urinary tract.

- Congenital methemoglobinemia (rare):
 - Hemoglobin M: Heterozygotes for autosomal dominant hemoglobin M will exhibit lifelong cyanosis.
 - NADH-dependent methemoglobin reductase deficiency: Homozygotes for this autosomal recessive enzyme will have lifelong cyanosis; heterozygotes may have increased susceptibility to oxidative hemoglobin injury.

COMMONLY ASSOCIATED CONDITIONS

- Heinz body hemolytic anemia
- Oxidant stress on the globin protein may cause hemolysis.
- Sulfhemoglobinemia
- Oxidant stress on the hemoglobin porphyrin ring may cause sulfhemoglobinemia.

DIAGNOSIS

HISTORY

- Age of onset:
 - New onset of cyanosis in children older than 6 months is unlikely to be due to congenital or enteritis-associated methemoglobinemia.
- Source of water:
 - Well water may be contaminated with nitrates.
- Drug or chemical exposure:
 - May suggest a source of toxic methemoglobinemia
- Diarrhea:
 - May suggest enteritis-associated methemoglobinemia

PHYSICAL EXAM

- Cyanosis:
 - Cyanosis becomes apparent in the presence of 1.5 g/dL of methemoglobin (in contrast to 4–5 g/dL of deoxyhemoglobin).
- Heart murmur:
 - May suggest right-to-left intracardiac shunting, rather than methemoglobinemia
- Abnormal lung auscultation:
 - May suggest cyanosis due to pulmonary disorder
- Signs and Symptoms:
 - Malaise
 - Fatigue
 - Dyspnea
 - Tachycardia
 - Cyanosis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Oxygen saturation:
 - Oxygen saturation measured by pulse oximetry is artificially low, but oxygen saturation calculated from arterial blood gas is normal (a “saturation gap”).
- Co-oximetry:
 - Multiple-wavelength co-oximetry is the standard for quantifying methemoglobin in the blood.
- Hemoglobin quantitation:
 - The percent methemoglobin concentration must be considered in relation to the total hemoglobin.
 - Anemia may suggest concurrent hemolysis.
- Serum bicarbonate:
 - Metabolic acidosis is relatively mild in cases of <40% toxic methemoglobinemia.
 - Metabolic acidosis is typically profound in cases of enteritis-associated methemoglobinemia.
- Glucose-6-phosphate dehydrogenase (G6PD) assay:
 - G6PD deficiency does not predispose to methemoglobinemia and should not be routinely ordered.
- Hemoglobin electrophoresis:
 - Hemoglobin M is rare and does not respond to therapy.
 - This test should not be routinely ordered.

Diagnostic Procedures/Other

- Pulse oximetry may be inaccurate in the setting of methemoglobinemia or methylene blue therapy.
- Blood may have a “chocolate brown” appearance despite exposure to air.

DIFFERENTIAL DIAGNOSIS

- Environmental hypoxia
- Cardiovascular disease
- Pulmonary disease
- Sulfhemoglobinemia
- Factitious skin discoloration

TREATMENT

MEDICATION (DRUGS)

- Consider administration of 1% methylene blue.
 - Dose: 1–2 mg/kg IV over 5 minutes, repeated as necessary (caution above 4–7 mg/kg total)
 - Indications: Signs of tissue hypoxia, CNS depression, >30% methemoglobinemia
 - Contraindications (relative): Known, severe G6PD deficiency
- Methylene blue therapy may be ineffective if:
 - Patient is G6PD deficient.
 - Ongoing drug or chemical absorption or biotransformation leads to continuing methemoglobin formation.
 - Sulfhemoglobin is present.
 - Hemoglobin M is present.
 - High doses of methylene blue add to, rather than ameliorate, the oxidant stress.

ADDITIONAL TREATMENT

General Measures

- Acquired methemoglobinemia:
 - Administer 100% oxygen.
 - Decontaminate or remove from toxic source of oxidative stress.
 - Alleviate enteritis with IV fluids or elemental formulas.
 - Treat identified bacterial infections.
 - Exchange transfusion is a consideration of last resort.
- Congenital methemoglobinemia:
 - No beneficial therapy exists for hemoglobin M.
 - Oral methylene blue or ascorbic acid may provide alternative reduction pathways for patients with NADH-dependent reductase deficiencies.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Toxic methemoglobinemia:
 - Consider consultation with a medical toxicologist.
 - May require environmental investigation
- Enteritis-associated methemoglobinemia:
 - Careful formula rechallenge warranted if possibility exists for milk protein allergy or other dietary intolerance
- Congenital methemoglobinemia:
 - Consider consultation with a hematologist.

PROGNOSIS

- Toxic methemoglobinemia:
 - Full recovery with recognition, removal of oxidant stress, and appropriate therapy
- Enteritis-associated methemoglobinemia:
 - Methemoglobinemia may be prolonged and relapsing until enteritis healed
- Congenital methemoglobinemia:
 - Lifelong cyanosis expected

COMPLICATIONS

- >10% methemoglobinemia:
 - Cyanosis
- >30% methemoglobinemia:
 - Malaise, fatigue, dyspnea, tachycardia
- >50% methemoglobinemia:
 - Somnolence, tissue ischemia
- 60% methemoglobinemia:
 - Potential lethality

CODES

ICD9

289.7 Methemoglobinemia

ICD10

- D74.0 Congenital methemoglobinemia
- D74.8 Other methemoglobinemias
- D74.9 Methemoglobinemia, unspecified

FAQ

- Q: Can methemoglobinemia be diagnosed by the color of the blood?
- A: The “chocolate brown” blood of methemoglobinemia is most easily noted when compared to “control” blood on a white filter paper background. In contrast to deoxygenated blood from patients with cardiopulmonary disease, methemoglobin-darkened blood does not redden on exposure to room air.
- Q: Is methemoglobin responsible for the profound metabolic acidosis often found in diarrheal infants?
- A: Benzocaine-induced methemoglobinemia rarely causes acidosis in infants. In contrast, infants with enteritis-associated methemoglobinemia often have a profound acidemia with a relatively narrow anion gap. Acidosis should be considered a contributing or coexisting factor, rather than a result, of methemoglobinemia among infants with diarrhea.

MICROCYTIC ANEMIA

Alexis Teplick

Janel L. Kwiatkowski (5th edition)

BASICS

DEFINITION

Low hemoglobin level and reduced red cell size:

- Mean corpuscular volume (red cell size) varies with age. Adult normal values cannot be applied to young children. Newborns have larger red cells with an average mean corpuscular volume of 108 fL and a lower limit of normal of 98 fL. The mean corpuscular volume then gradually declines. Lower limit of normal:
 - At 2 weeks: 86 fL
 - 2 months: 77 fL
 - 6 months to 2 years: 70 fL
 - 2–5 years: 75 fL
 - 6–12 years: 77 fL
 - 13–18 years: 78 fL
- A quick estimate of the lower limit of normal for mean corpuscular volume for children > 1 year old can be made with the following formula:
 - Lower limit of normal mean corpuscular volume = 70 + age (years)

EPIDEMIOLOGY

- Iron deficiency anemia occurs with a prevalence of 1–5% in the US:
 - Young children and adolescent females are at greatest risk.
- β -Thalassemia mutations are common in Mediterranean countries, Southeast Asia, China, Africa, and India.
- Hemoglobin E mutations are common in certain Southeast Asian countries, particularly Cambodia, Laos, and Thailand.
- α -Thalassemia mutations occur in the Chinese subcontinent, Malaysia, Indochina, and Africa.

PATHOPHYSIOLOGY

- Disorders of globin chain synthesis include the thalassemias and hemoglobin E disease.
- β -E mutation leads to decreased production of functional β -globin messenger RNA (mRNA):
 - In the heterozygous form, there is usually mild microcytosis with minimal or no anemia and no clinical symptoms.
 - Homozygous E disease is also asymptomatic, but there is marked microcytosis and a mild anemia (hemoglobin is usually ≥ 10 g/dL).
- Combination of hemoglobin E and β -thalassemia often results in more severe anemia, similar to β -thalassemia intermedia or major.

ETIOLOGY

- Limited number of causes of microcytic anemia
- Hemoglobin molecule is made up of heme and globin components. Disorders of the production of either of these components may result in a microcytic anemia:
 - Heme production requires iron and is affected by iron deficiency or inadequate iron utilization as is seen in the anemia of chronic inflammation.
 - Inadequate production of porphyrin component can also impair heme synthesis; such disorders are known as sideroblastic anemias. Sideroblastic anemias can be inherited or acquired.
 - Disorders of globin production, the thalassemias, also cause microcytosis.

DIAGNOSIS

HISTORY

- Child's age:
 - Microcytic anemia in children age 9 months to 3 years and in adolescence is most commonly iron deficiency:
 - Term infants are born with adequate iron stores for 6 months and therefore should not have nutritional iron deficiency causing anemia.
 - β -Thalassemia major often presents in 1st year of life as fetal hemoglobin production declines.
- Child's diet:
 - Evaluate dietary iron intake as appropriate for age:
 - Iron in breast milk is more bioavailable (50% vs. 10%) than iron in formula.
 - Infants who are exclusively breastfed after 6 months are at an increased risk for iron deficiency if they do not receive supplements.
 - Infant formulas and cereals should be iron fortified. In preschool children and adolescents, assess intake of high iron-containing foods including red meats, fish, poultry, beans, and peanut butter.
 - Introduction of whole cow's milk at age < 1 year provides little dietary iron and can cause occult intestinal bleeding leading to iron loss.
 - High intake of milk also causes a decreased appetite for other foods with a higher iron content.
 - Cow's milk intake > 24 ounces daily is a risk factor for iron deficiency.
 - History of pica suggests iron deficiency and/or lead intoxication.

- Other factors:
 - History of blood loss:
 - Decreases iron stores
 - Ask about loss from stool, urine, chronic nosebleeds, and menorrhagia.
 - Premature birth or blood loss at birth:
 - Premature infants have lower total body iron stores and an increased growth rate that leads to increased iron requirements.
 - Significant blood loss at birth can deplete iron stores.
 - Child's ethnic background and familial history of anemia:
 - α -Thalassemia is most common among children of African or Asian descent.
 - β -Thalassemia is most common in children of Mediterranean, Asian, or African descent.
 - Hemoglobin E occurs most commonly in children of Southeast Asian descent.
 - Symptoms suggestive of a chronic disease such as joint pain/swelling or abdominal pain

PHYSICAL EXAM

- Child's general appearance: Most children with mild to moderate microcytic anemia are well appearing with a normal physical exam.
- Irritability or pallor:
 - Anemia is likely more severe.
 - Irritability is a common finding with iron deficiency.
- Cardiovascular examination:
 - Check for instability including tachycardia, hypotension, and presence of a gallop.
 - Flow murmurs are common with chronic anemia.
- Abnormal sclerae:
 - Blue sclera is associated with iron deficiency (very rare).
 - Icterus is seen with severe thalassemia syndromes and hemolytic anemias.
- Mouth lesions: Glossitis and stomatitis are signs of iron deficiency.
- Splenic enlargement: May be seen with thalassemia syndromes depending on the severity. The spleen is a site of extramedullary hematopoiesis and clears abnormal red cells.

DIAGNOSTIC TESTS & INTERPRETATION

- In the patient:
 - CBC: Low hemoglobin level and low mean corpuscular volume for age
 - Red cell distribution width:
 - Measures variation in red cell size
 - Elevated in iron deficiency
 - Normal in thalassemia trait, infection, and lead poisoning

- Reticulocyte count: Decreased in iron deficiency anemia and increased in moderate and severe thalassemia syndromes
 - Peripheral blood smear:
 - Microcytosis and hypochromia
 - Marked poikilocytosis and anisocytosis with iron deficiency and thalassemia syndromes
 - Basophilic stippling with lead poisoning
 - Target cells are found with heterozygous or homozygous hemoglobin E.
 - Ferritin:
 - Serum ferritin reflects tissue iron stores. It is reduced in iron deficiency.
 - Ferritin is an acute-phase reactant and is increased with infection, inflammation, and liver disease.
 - Normal or increased in thalassemia
 - Serum iron:
 - Reduced in iron deficiency
 - Normal in thalassemia (unless chronically transfused, which leads to increased iron levels)
 - Normal or reduced in infection or inflammatory states
 - Can rise within hours of single oral dose
 - Transferrin saturation:
 - Measures iron available for hemoglobin synthesis
 - Low in iron deficiency and chronic infection
 - Normal in thalassemia
 - Lead level: Increased in lead intoxication
 - Hemoglobin electrophoresis with quantitation:
 - Increased hemoglobin A2 in β -thalassemia trait and normal in α -thalassemia trait and other microcytic anemias
 - Iron deficiency anemia may cause a reduction in hemoglobin A2 production.
 - If microcytosis persists after iron is replenished, hemoglobin electrophoresis should be repeated.
 - Soluble transferrin receptor:
 - Indicator of increased tissue iron demand
 - Increased in iron deficiency anemia and also in thalassemia syndromes, but not with the anemia of chronic inflammation
 - Bone marrow aspirate:
 - Rarely needed to establish diagnosis
 - Iron stores can be assessed by hemosiderin staining.
 - In sideroblastic anemias, > 10% of the nucleated red cell precursors are ringed sideroblasts.
 - Family studies:
 - CBC
 - Peripheral blood smear
 - Hemoglobin electrophoresis
- Diagnostic Procedures/Other**
- Most commonly identified in children through routine screening
 - Often the result of a chronic condition that does not require immediate intervention
 - Review of the child's history, red cell indices, and peripheral blood smear should guide further laboratory evaluation.
 - General guidelines for evaluation:
 - Initially identify severe anemia that requires inpatient observation and possible blood transfusion.

- Consider chronic lead intoxication early. If history is suspicious (e.g., peeling paint, pica), draw lead level.
- Iron deficiency is the most common cause of microcytic anemia. Screen by history. If history is suspicious, consider therapeutic iron trial prior to additional workup.
- If suspicious of a thalassemia syndrome, send hemoglobin electrophoresis with hemoglobin A2 quantification. CBCs and hemoglobin electrophoresis from parents may also be helpful.

DIFFERENTIAL DIAGNOSIS

- Metabolic: Iron deficiency (most common)
- Environmental: Chronic lead poisoning
- Congenital:
 - Thalassemia syndromes
 - Hemoglobin E trait (single gene affected) or disease (2 genes affected)
 - Selected congenital hemolytic anemias with unstable hemoglobin
- Inflammatory:
 - Recent inflammation or infection
 - Anemia of chronic inflammation (also known as anemia of chronic disease) may cause a microcytic anemia or normocytic anemia. Common causes of anemia of chronic inflammation include:
 - Chronic infection
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Inflammatory bowel disease (may also be a component of iron deficiency due to gastrointestinal blood loss)
 - Malignancy
- Miscellaneous: Sideroblastic anemia (rare in children)

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Consider therapeutic trial of iron supplementation if history is suspicious.
- May require initial inpatient observation in cases of severe anemia
- Red cell transfusion only if evidence of cardiovascular compromise (rarely indicated)
- Removal of environmental exposure and possible chelation for lead poisoning to prevent CNS toxicity
- No treatment needed for α - or β -thalassemia trait or hemoglobin E heterozygous or homozygous conditions:
 - Iron therapy is not indicated.
 - If concomitant iron deficiency is suspected, iron studies should be sent and treatment commenced if iron deficiency is documented.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- In iron deficiency, reticulocyte count begins to increase in 3–4 days, and hemoglobin concentration should rise by ≥ 1 g/dL in 2–3 weeks following iron supplementation.
- Children with thalassemia trait have a persistent mild, microcytic anemia that is not clinically significant, but they require genetic counseling as they become older.
- Children with other thalassemia syndromes (β -thalassemia major, hemoglobin H disease) should be referred to a hematologist.

ALERT

Lead poisoning and iron deficiency can occur concurrently because iron deficiency causes increased lead absorption. If history is concerning for increased lead exposure in cases of documented iron deficiency, send lead levels.

D50.8 Other iron deficiency anemias

MILIA

Albert C. Yan

BASICS

DESCRIPTION

White papules that occur commonly and spontaneously on the face and frequently elsewhere; after healing of blisters when present on mucous membranes; referred to as *Epstein pearls*

EPIDEMIOLOGY

- Common in all age groups
- Up to 40% of newborns have milia on the skin.
- In older patients, most often related to trauma, sites of irradiation, or re-epithelializing blisters

PATHOPHYSIOLOGY

- Retention of keratin and sebaceous material within the pilosebaceous duct, eccrine sweat duct, or sebaceous collar surrounding vellus hair
- Lamellated keratin deposits are found in the superficial papillary dermis.

ETIOLOGY

Spontaneous, or related to trauma or healing blisters in older patients

DIAGNOSIS

HISTORY

- Asymptomatic
- Recent trauma
- History of blistering diseases
- Special question:
 - If present periocularly, ask about history of atopy/allergic conjunctivitis.

PHYSICAL EXAM

- 1–2 mm bright white papules with smooth surface
- Most often found on cheeks, nose, chin, forehead, but occasionally on dorsal surface of hands and over knees, especially if related to trauma
- Occasionally, lesions may be seen on upper trunk, extremities, penis, or mucous membranes. Epstein pearls represent milia on the palate (often seen at the junction of the soft and hard palates).
- Distinguish from pustules by palpation.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

Milia are firm and, when incised, reveal solid keratin rather than liquid contents.

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Molluscum contagiosum
 - Impetigo (pustules)
 - Herpes simplex (clouded vesicles)
 - Environmental (poisons)
- Tumors:
 - Sebaceous gland hyperplasia.
- Miscellaneous:
 - Neonatal acne
 - Keratosis pilaris

TREATMENT

ADDITIONAL TREATMENT

General Measures

- No need for treatment in infants because milia are benign, asymptomatic, and often resolve on their own.
- Alternatively, cyst contents may be expressed by squeezing or with a comedone extractor, or after incision of the overlying epidermis with a needle or no. 11 scalpel blade.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Without treatment, most lesions resolve in 1–2 weeks in infants.

PROGNOSIS

- Spontaneous regression of milia occurs in infants.
- In older individuals, the lesions are usually chronic unless treated.
- Lesions uncommonly recur.

COMPLICATIONS

- Primarily of cosmetic concern
- Rare potential for foreign body reaction to occur
- If persistent milia in an unusual or widespread distribution when seen with other defects: Hereditary trichodysplasia (Marie Unna hypotrichosis), oral-facial-digital syndrome type I, absence of fingerprints (dermatoglyphs) associated with fragile skin (Baird or Basan or Rombo syndrome), or Loews-Dietz syndrome (periocular milia, arachnodactyly, craniofacial and cardiovascular anomalies). Often seen in healed areas of dystrophic forms of epidermolysis bullosa

FAQ

- Q: Will the lesions get bigger before they go away?
- A: No. There is no tendency to enlarge with time.

MILK PROTEIN INTOLERANCE

Rosalyn Diaz

BASICS

DESCRIPTION

- A condition in which symptoms affecting the GI tract, skin, and respiratory tract result from ingestion of cow's milk protein
- Currently no distinction is being made between cow's milk protein allergy and intolerance since both seem to have similar pathogenesis and clinical presentation.

EPIDEMIOLOGY

Prevalence has been estimated at 2–7.5% of otherwise normal infants. The condition usually presents in the 1st 3 months of life. It may rarely present for the 1st time in older children (0.4%) and recur in adults.

PATHOPHYSIOLOGY

- Unprocessed cow's milk protein is 80% casein and 20% whey. The whey fraction contains >20 types of antigenic proteins, including α -lactoglobulin (the most allergenic of all), α -lactalbumin, bovine serum albumin, α_2 -microglobulin, transferrin, and lactoferrin. Casein is thought to be weakly allergenic.
- Exclusively breastfed infants may also develop milk protein intolerance through exposure to allergens that appear in breast milk. Nevertheless, breastfeeding is protective in decreasing food allergies.
- Although α -lactoglobulin is suspected to be an antigen, no single protein fraction has been proven. Most children appear to be allergic to multiple cow's milk proteins; rarely are patients allergic to only 1 fraction.
- There is 25–30% cross-reactivity between milk proteins and soy proteins.

ETIOLOGY

Predisposing factors include:

- Age (diagnosis usually <2 years)
- Immune deficiency (immaturity of the mucosal immune system, immaturity or damage of mucosal barrier function, low IgA levels)
- History or presence of atopy
- Early milk protein–based formula feeding
- Allergenic formula
- GI infection
- Positive family history

DIAGNOSIS

HISTORY

- Diagnosis is implied if clinical symptoms resolve upon removal of cow's milk protein–containing products.
- In some cases, no resolution is seen on soy-based formula, and hydrolyzed formula and even crystalline amino acid–based formulas are needed.
- Signs and symptoms:
 - GI manifestations such as blood and mucus in the stool in a normal-appearing infant are the most common presentation.
 - GI: Diarrhea, bloody stools, vomiting, feeding problems, constipation, GERD
 - Dermatologic: Atopic dermatitis, urticaria, angioedema, eczema
 - Respiratory: Allergic rhinitis, coughing, wheezing
 - General: Anaphylaxis, failure to thrive (FTT), hypoproteinemia

PHYSICAL EXAM

- Usually healthy-appearing child with normal physical exam
- Most patients will present in the 1st few months of life with:
 - Occult blood loss (without anemia in most cases)
 - Hematochezia
 - Emesis/reflux symptoms
- Some patients may present with:
 - Profuse watery diarrhea with signs of dehydration
 - Malabsorption (edema due to hypoalbuminemia, FTT, hemorrhage, rickets)
 - Abdominal distention

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Clinical diagnosis
- No single laboratory test appears to have significant sensitivity for detecting this syndrome.
- Radioallergosorbent testing (RAST) and skin testing may be used with positive predictive value of only 50%.
- Occasionally, peripheral blood and stool eosinophilia may be documented.
- Infectious causes of enteropathy may mimic the disorder; therefore, infection should be ruled out with stool cultures and duodenal fluid cultures, if available.

- Rectosigmoid biopsies are not routinely performed.
- Histologic changes in bowel mucosa tend to be nonspecific.
- Grossly, the mucosa appears friable and inflamed, rarely with erosions or gross ulcerations.
- Pathologic findings may include:
 - Partial villous atrophy with reduction in villous height on upper endoscopy
 - Moderate increase in intraepithelial lymphocytes
 - Prominent eosinophilic infiltrate

ALERT

In the rare situation of severe food allergy with shocklike picture and acidosis, fluid resuscitation and refeeding should be done in the hospital.

DIFFERENTIAL DIAGNOSIS

- GERD and colic are most often misdiagnosed in these infants.
- Diseases characterized by watery diarrhea, abdominal pain, and blood and mucus in the stool should be considered.
- Infectious causes (dysentery, *Clostridium*) should be excluded.
- Inflammatory bowel disease (IBD), celiac disease, autoimmune enteropathy, toddler diarrhea, anal fissures, and Meckel diverticulum (among others) should be considered, depending on the presentation.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Removal of cow's milk protein–containing products from the diet is the cornerstone of treatment.
- ~10–30% of children with cow's milk protein intolerance will also be intolerant to soy protein. For this reason, soy-based formulas are rarely recommended.
- Casein hydrolysate formulas (Pregestimil, Nutramigen, Alimentum) are the formulas of choice for infants with cow's milk protein intolerance. Whey hydrolysate formula is not usually recommended for these patients.
- Resolution of grossly bloody stools usually occurs within 24–72 hours, but stool occult blood testing may continue to be positive for 2–6 weeks.

- Neocate, Nutramigen AA, and EleCare formulas are amino acid–, simple carbohydrate–, and fat-based formulas that have been more effective in recalcitrant cases of intolerance.
- If no clinical response is seen after 2–3 weeks of diet restriction, then other diagnoses should be considered.
- Epinephrine may be needed in cases of severe milk protein allergy and anaphylaxis.
- Corticosteroids are sometimes used to treat skin and respiratory manifestations.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- It is important to restrict the diet completely for milk and soy protein during the 1st year of life.
- With the introduction of solids, it is important to read labels carefully for the presence of any milk or soy proteins.
- In most cases, tolerance to cow's milk protein develops at age 1–2 years, and a normal diet can be safely reintroduced.
- Occasionally, symptoms of intolerance may persist past the 3rd year of life; ~10% will have symptoms that persist at 6 years of age.
- Cow's milk protein challenge with RAST, skin testing, and possible GI biopsies can help to monitor the degree of allergic response in these older children.
- In cases of severe anaphylactic reactions or acute urticaria, the cow's milk challenge should be performed in a hospital under medical supervision.
- GI intolerance seems to persist in a certain proportion of subjects, with intestinal symptoms and increased prevalence of lactose intolerance.

ICD10

- T78.1XXA Other adverse food reactions, not elsewhere classified, initial encounter
- Z91.011 Allergy to milk products

FAQ

- Q: Can a fully breastfed infant develop milk protein intolerance?
- A: Fully breastfed infants rarely develop milk protein intolerance because there are fewer cow's milk protein antigens in breast milk, but it may still occur. To continue to nurse, the mother needs to follow a strict elimination diet for milk and soy protein, and sometimes even fish, eggs, and other common allergens.
- Q: When does this problem usually resolve?
- A: In most infants who develop minimal symptoms, the problem will resolve by the 1st year of life, but the range can be several years. Some reports of residual GI disease exist.
- Q: When should a patient be referred to an allergist?
- A: Infants with severe symptoms, persistence of symptoms despite a strict elimination diet, and/or those > 12 months of age should be referred to an allergist.

MUMPS/PAROTITIS

Nicholas Tsarouhas

BASICS

DESCRIPTION

CDC clinical case definition: Illness with acute onset of unilateral or bilateral, tender, self-limited swelling of the parotid or other salivary gland, lasting ≥ 2 days, without other apparent cause

EPIDEMIOLOGY

Incidence

- In the prevaccine era, 90% of all children contracted mumps virus infection by 14 years of age.
- Incidence of this once very common disease has declined dramatically since the advent of universal childhood immunization.
- Outbreaks, however, continue to occur.
- Since 2001, 200–300 cases per year reported in the US
- In early 2006, a large epidemic broke out in Iowa and neighboring states:
 - 11 states reported $> 2,500$ cases.
 - Largest epidemic since 1988
 - Median age of patient was 21 years (mostly college students).
 - Led CDC and American College Health Association to recommend 2 doses of MMR be a requirement for college entry.
- In 2006, 81–100% of children entering US schools had received 2 doses of mumps vaccine.
- Seroprevalence of antibody to mumps virus in the US population (1999–2004) estimated at 90%

GENERAL PREVENTION

- 2 combination mumps vaccine are used:
 - MMR: Measles, mumps, rubella
 - MMRV: Measles, mumps, rubella, varicella
- A single 0.5-mL SC injection of live mumps vaccine (MMR or MMRV) is recommended at 12–15 months.
- A 2nd vaccination is recommended between 4 and 6 years of age.
- Primary vaccine failure and waning vaccine-induced immunity have been reported.
- Some have suggested the need for a 3rd vaccination to mitigate waning immunity.
- The 1st dose of MMR vaccine sometimes causes fever and rash:
 - This occurs 7–10 days after immunization.
 - Measles component is usually the culprit.
- Both MMRV and MMR vaccines, but not varicella vaccine alone, are associated with increased outpatient fever visits and seizures 7–10 days after vaccination in 12–23-month-olds, with MMRV vaccine increasing fever and seizure twice as much as the MMR + varicella vaccine.
- Vaccine should not be administered to children who are immunocompromised by disease or pharmacotherapy, or to pregnant women.
- Children with HIV infection who are not severely immunocompromised should be immunized with the MMR vaccine.
- 1 attack of mumps (clinical or subclinical) usually confers lifelong immunity.
- Links of the MMR vaccine to autism by Dr. Andrew Wakefield in a 1998 *Lancet* publication have now been completely exposed as fraudulent and false.

PATHOPHYSIOLOGY

- The virus is spread by contact with respiratory secretions.
- The mumps virus enters via the respiratory tract, and a viremia ultimately ensues.
- The viremia spreads to many organs, including the salivary glands, gonads, pancreas, and meninges.
- Period of communicability: 7 days before to 9 days after onset of parotid swelling
- Most communicable period: 1–2 days before to 5 days after onset of parotid swelling
- Incubation period: 12–25 days after exposure
- Humans are the only known host for mumps.

ETIOLOGY

- Parotitis is usually caused by mumps, a Rubulavirus in the paramyxovirus family.
- Other viral causes of parotitis include cytomegaloviruses, influenza, parainfluenza, and enteroviruses.
- Bacterial cases are usually secondary to *Staphylococcus aureus* (suppurative parotitis).
- Streptococci, gram-negative bacilli, and anaerobic infections are also possible.
- Rare childhood cases may be secondary to an obstructing calculus, foreign body (sesame seed), or various drugs (antihistamines, phenothiazines, iodine-containing drugs/contrast media).

COMMONLY ASSOCIATED CONDITIONS

- Salivary adenitis:
 - Most common manifestation of mumps
 - 1/3 of cases occur subclinically
- Epididymo-orchitis:
 - Up to 35% of adolescent mumps cases are complicated by orchitis.
 - Orchitis develops within 4–10 days of the onset of the parotid swelling.
 - Sterility is uncommon.
- Pancreatitis:
 - Mild inflammation is common.
 - Serious involvement is rare.

DIAGNOSIS

HISTORY

- Prodromal symptoms uncommon, but may include the following:
 - Fever
 - Anorexia
 - Myalgia
 - Headache
- Onset usually pain and swelling in front of and below ear
- Swelling:
 - Usually starts on one side of the face, then progresses to the other
- Mild fever:
 - Usually accompanies parotid swelling
- Dysphagia and dysphonia are common.
- Testicular pain and swelling, along with constitutional symptoms, usually begin ~ 1 week after the parotid swelling of mumps.
- Epigastric pain and constitutional symptoms with pancreatic involvement

- Fever, headache, and stiff neck with meningitis
- Behavioral changes, seizures, and other neurologic abnormalities are rare.
- Other symptoms are analogous to the particular organ involved.
- Parotid enlargement can be an initial sign in HIV-infected children.

PHYSICAL EXAM

- Nonerythematous, tender parotid swelling (erythema seen with suppurative parotitis)
- Swelling ultimately obscures the mandibular ramus.
- The ear is displaced upward and outward.
- Importantly, up to 30% of symptomatic cases of mumps are not associated with parotitis.
- Submaxillary and sublingual glands also may be swollen.
- Inflammation may be noted intraorally at the orifice of Stensen duct.
- Presternal edema is occasionally noted.
- Mumps are infrequently associated with truncal rash.
- Tender, edematous testicle in mumps orchitis (usually unilateral)
- Ask the patient if the pain (at the parotid) intensifies with the tasting of sour liquids:
 - Have the patient suck on a lemon drop or lemon juice, and note any discharge from Stensen duct.

DIAGNOSTIC TESTS & INTERPRETATION

ALERT

Skin tests should not be used for test of immunity; serologic studies are more reliable.

Lab

- Uncomplicated parotitis:
 - Mild leukopenia with lymphocytosis
- Suppurative parotitis and mumps orchitis:
 - Leukocytosis
- Pancreatic involvement:
 - Hyperamylasemia and elevated serum lipase
- Salivary adenitis without pancreatic involvement:
 - Isolated hyperamylasemia
- Gram stain and culture of pus expressed from Stensen duct is diagnostic in suppurative parotitis.
- CDC lab criteria for mumps diagnosis:
 - Isolation of mumps virus from clinical specimens: Blood, urine, buccal swab (Stensen duct exudates), throat washing, saliva, or CSF
 - Detection of mumps virus nucleic acid by reverse transcriptase PCR
 - Positive serologic test for mumps IgM
 - Significant rise between acute and convalescent titers in mumps IgG levels by any standard assay (complement fixation, neutralization, hemagglutination inhibition, or enzyme immunoassays)

Imaging

Sialography is useful to evaluate for stones or strictures but is contraindicated in acute infection.

Diagnostic Procedures/Other

Lumbar puncture if meningitis is suspected: CSF pleocytosis (predominately mononuclear)

DIFFERENTIAL DIAGNOSIS

- Mumps parotitis can be distinguished from the other viral causes by clinical presentation along with specialized laboratory studies.
- Cases of tuberculous and nontuberculous (atypical) mycobacterial parotitis are rare but have been reported.
- Salivary calculus can be diagnosed by sialogram.
- Recurrent childhood parotitis, aka juvenile recurrent parotitis:
 - Rare, recurrent swelling of parotids
 - Seen in children 3–6 years old
 - Not associated with suppuration or external inflammatory changes
 - Largely a diagnosis of exclusion
- Cervical or preauricular adenitis:
 - May simulate parotitis
 - Close anatomic localization should be diagnostic
- Infectious mononucleosis and cat-scratch disease are other considerations.
- Drug-induced parotid enlargement occasionally occurs.
- Malignancies of the parotid are extremely rare.
- Pneumoparotitis is seen in those with a history of playing a wind instrument, glass blowing, scuba diving, and even general anesthesia.

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Supportive therapy is all that is required in mumps parotitis.
- Antibiotics directed against *S. aureus* should be used in cases of suppurative parotitis.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Most children have resolution of glandular swelling by ~1 week.
- Disappearance of testicular pain and swelling can be expected 4–6 days after onset.
- Testicular atrophy is common, although infertility is rare.
- Markedly elevated pancreatic enzymes should be monitored until they improve.
- Children should not return to school until at least 9 days after the onset of parotid swelling.

PROGNOSIS

Complete recovery in 1–2 weeks is the rule.

COMPLICATIONS

- Meningitis:
 - >50% have a CSF pleocytosis.
 - This “aseptic meningitis” is usually benign.
- Encephalitis: Rarely causes permanent sequelae
- Cerebellitis
- Facial nerve palsy
- Oophoritis, nephritis, thyroiditis, myocarditis, mastitis, arthritis, transient ocular involvement, deafness, and sterility (all rare)

FAQ

- Q: Should immunization be deferred in children with intercurrent illness?
- A: No. Children with minor illnesses, even with fever, should be vaccinated.
- Q: Should vaccination be withheld in children living with immunocompromised hosts?
- A: No. Vaccinated children do not transmit mumps vaccine virus.

MUNCHAUSEN SYNDROME BY PROXY

Cheryl L. Hausman

BASICS

DESCRIPTION

- Illness in a child that is fabricated by someone else (usually the parent)
- May also be known as “pediatric condition falsification” (PCF)
- Results in repeated interactions with the medical care system, often leading to multiple medical procedures
- Perpetrator denies the cause of the child’s illnesses.
- Symptoms decrease when the child is separated from the perpetrator.

EPIDEMIOLOGY

- Typical victims are <4 years of age, equally divided between males and females. However, there have been case reports of older children.
- Victims average 21.8 months from onset of symptoms to diagnosis.
- Varies with presentation
- Of infants monitored in apnea programs, 0.27% are believed to be secondary to Munchausen syndrome by proxy.
- 5% of allergy patients in some clinic settings are estimated to be secondary to Munchausen syndrome by proxy.
- Mortality is ~6–9%.

ETIOLOGY

- The parent, commonly the mother, fabricates the illnesses.
- Little is known about the etiology in the parent:
 - Parent may have Munchausen syndrome.
 - Parent may be seeking secondary gain from the attention of medical staff or financial gain by having the child be disabled.

DIAGNOSIS

HISTORY

- Unexplained or unusual illness, symptoms, and signs that are incongruous or present only when the perpetrator is present
- Usual medical treatment is ineffective in treating the presenting symptom.
- Perpetrator may not be concerned about the patient, may be constantly present while the patient is in the hospital, or may form unusually close relationships with the hospital staff.
- Special questions:
 - History of frequent moves, or of other siblings who have either died or had unusual medical illnesses, may suggest Munchausen syndrome by proxy.
 - In the context of divorce, repeated allegations of sexual abuse may represent Munchausen syndrome by proxy.

PHYSICAL EXAM

- Examination of the patient with apnea presentation may indicate evidence of intentional suffocation.
- Patients who present with unusual bleeding may have lacerations on other parts of the body.
- Perpetrator also may have lacerations.
- Note the presence of indwelling IV, CSF, or bladder catheters.
- Patient may have evidence of old fractures.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

Workup is dictated by presentation:

- Pneumogram to rule out apnea
- If bleeding is the major presentation, identify the blood as the patient’s (as opposed to that of the perpetrator or an animal).
- A toxicology screen may be helpful for unusual presentations of poisoning.
- Separating the perpetrator from the patient, with resultant decrease in symptoms, may suggest the diagnosis.
- Suspect Munchausen syndrome by proxy when there is blood or urine culture with many organisms.
- If GI bleeding is the presenting symptom, use endoscopy or a Meckel scan to rule out anatomic causes of bleeding.
- Video monitoring of a patient’s room may demonstrate the perpetrator harming the child.
- Ensure that the perpetrator cannot tamper with testing.

DIFFERENTIAL DIAGNOSIS

Diagnosis depends on presentation. Munchausen syndrome by proxy should be considered in unusual presentations of:

- GI bleeding
- Apnea/apparent life-threatening event
- Asthma
- Seizures
- Genitourinary bleeding
- Unexplained abnormalities in electrolytes
- Chronic diarrhea or vomiting
- Infections with multiple organisms found in blood or urine culture

ALERT

- Diagnosis is often delayed: Mean length of time to diagnosis is 21.8 months.
- Physicians and nursing personnel may be reluctant to suspect the parent because of their own involvement with the family.

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- If Munchausen syndrome by proxy is documented, the patient must be separated from the perpetrator. Psychotherapy for the perpetrator is warranted.
- As long as the perpetrator is in need of intensive psychotherapy, the patient should be protected.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- If the perpetrator agrees to seek help, improvement usually occurs, but long-term follow-up is necessary.
- Watch for recurrence of original presentation, unusual new symptoms.

PROGNOSIS

- If undiagnosed, mortality has been estimated at 6–9%.
- Some children go on to develop Munchausen syndrome themselves.
- Long-term consequences to the child are unknown.

**CODES****ICD9**

301.51 Chronic factitious illness with physical symptoms—Munchausen syndrome

ICD10

F68.13 Factitious disorder with combined psychological and physical signs and symptoms

FAQ

- Q: Is it legal to use video surveillance or to separate the parent from the patient?
- A: If suspicions of Munchausen syndrome by proxy are high and other laboratory tests are negative, it is important to make the diagnosis. Hospital administration and/or risk management should be consulted on how to proceed.
- Q: Should this be reported to child abuse authorities?
- A: If documented, this should be reported to protect the child.

MUSCULAR DYSTROPHIES

Hugh J. McMillan

Molly E. Rideout (5th edition)

BASICS

DESCRIPTION

- Muscular dystrophies (MDs) are a heterogeneous group of disorders characterized by progressive skeletal muscle weakness. Cardiac muscle can be involved in some forms.
- Muscular dystrophies with childhood onset can be divided into 5 groups:
 - Dystrophinopathies (i.e., Duchenne MD [DMD], Becker MD [BMD])
 - Limb girdle MDs (LGMDs)
 - Congenital MD (CMD)
 - Facioscapulohumeral MD (FSH-MD)
 - Emery-Dreifuss MD (EDMD)
- Types of MDs can be differentiated by their clinical features (i.e., pattern of muscle weakness, joint contractures), age of onset, genetic test results, and/or muscle biopsy.

EPIDEMIOLOGY

Incidence

- Dystrophinopathies:
 - DMD: 1 per 3,500 boys (most common)
 - BMD: 1 per 30,000 boys
- LGMD (childhood onset): 5–10 per million
- CMD (all types): 1–10 per 100,000
- FSH-MD: 1 per 20,000
- EDMD: 1 per 300,000

RISK FACTORS

Genetics

Genetic testing is clinically available for most MDs:

- Dystrophinopathies (DMD/BMD): X linked:
 - DMD exon duplication/deletion in 70% cases
 - DMD point mutation in almost 30% cases
- LGMD: Most childhood-onset LGMDs are autosomal recessive.
 - Sarcoglycanopathies (LGMD2C–F) make up roughly 70% of childhood-onset LGMDs.
 - LGMD2I (FKRP): 5% childhood-onset LGMDs
- CMD: Most autosomal recessive (12 genes)
 - Nonsyndromic (LAMA2, COL6A1–COL6A3)
 - Syndromic (e.g., POMT1, POMG1T1, FKRP)
- FSH-MD: Autosomal dominant (D4Z4 deletion)
- EDMD: X linked (EMD or FHL1 mutations) or autosomal dominant (LMNA mutation)

PATHOPHYSIOLOGY

- Deficient or defective muscle fiber proteins causing fiber dysfunction and/or increased membrane fragility
- Muscle biopsy: Increased variability in muscle fiber size (i.e., degenerating, regenerating, and necrotic fibers); split muscle fibers and increased internal nuclei; fibrosis. Immunohistochemistry may note decreased/absent sarcolemma proteins (e.g., DMD, LGMDs, CMDs).

DIAGNOSIS

HISTORY

- Neonatal hypotonia, feeding difficulty (CMD)
- Gross motor delay/regression
- Global developmental delay (syndromic CMD) or learning disorders (DMD)
- Exercise intolerance/cramping
- Myalgia (BMD, DMD)
- Seizures: Merosin-negative and syndromic CMD
- **DMD**: Onset typically <5 years old with gross motor delays, increasing falls, toe walking, and proximal muscle weakness (e.g., difficulty climbing stairs, rising from floor). Calf pseudohypertrophy is common. Serum creatine kinase (CK) levels are markedly elevated (often >50× normal). Serum transaminases may be elevated (muscle origin). Higher incidence of learning difficulties, ADHD, autism, OCD. Loss of ambulation occurs around 13–16 years old. Incidence of cardiomyopathy increases with age, although respiratory muscle weakness (e.g., ineffective cough, hypoventilation, and eventual respiratory failure) is the cause of death in about 75% of DMD boys.
- **BMD**: Milder version of DMD phenotype. Onset typically >8 years old. Boys remain ambulatory into their 20s. Higher incidence of myalgia, cramps, and myoglobinuria in BMD (vs. DMD). Rarely, cardiomyopathy may be sole or presenting feature.
- **LGMD**: Proximal muscle weakness (neck flexors, hip flexors, shoulder girdle). Disease onset and progression highly variable. Sarcoglycanopathies (LGMD2C–F) can mimic DMD (including calf pseudohypertrophy). Patients are cognitively normal.
- **CMD**: Hypotonia, gross motor delay, weakness, and feeding difficulty typically noted from birth. Two main groups of CMDs: (1) **nonsyndromic** CMD due to defective structural proteins (e.g., merosin-negative CMD, Ullrich/Bethlem MD) and (2) **syndromic** CMD due to defective glycosylation (e.g., Fukayama MD, muscle-eye-brain disease, Walker-Warburg syndrome):
 - Most children with nonsyndromic CMD are cognitively normal. Seizures may occur in merosin-negative CMD (20–30%). Ullrich MD shows characteristic proximal contractures and distal joint hyperlaxity (fingers, toes). Bethlem MD shows proximal muscle weakness and distal contractures.
 - Syndromic CMDs show variable severity, often associated with intellectual disability, eye manifestations, and brain anomalies (e.g., neuronal migration disorders, seizures, hydrocephalus).

- **FSH-MD**: Onset typically <20 years old with facial weakness, scapular winging, and humeral (biceps, triceps) weakness. Relative sparing of deltoid strength is seen. Rare infantile-onset cases have been reported. Retinal vasculopathy (Coates disease) can occur. Cardiac arrhythmia is occasionally noted (<10%), while cardiomyopathy is exceedingly rare.
- **EDMD**: Onset typically in 1st decade. Patients initially present with joint contractures (neck, elbow, and ankles) disproportionate to degree of weakness. Muscle weakness and wasting develop in biceps, triceps, spinatus muscles, and (later) tibialis anterior and peroneal muscles. Cardiac arrhythmias are common by 2nd decade. Pseudohypertrophy is not seen.

PHYSICAL EXAM

- Facial weakness (FSH-MD)
- Pattern of muscle weakness and atrophy
- Scapular winging (FSH-MD)
- Pattern of joint contractures (EDMD) or joint hypermobility (Ullrich MD)
- Pattern of muscle pseudohypertrophy (e.g., calf muscles in DMD, BMD, LGMD)
- Reflexes normal to mildly decreased (except for joints with contractures). Reflexes are not lost until late in disease course.
- Normal sensory exam
- Scoliosis: Rapid progression if nonambulatory
- Gower maneuver (when arising from sitting to standing position patient must put his hand on his knees and “climb up himself”)
- Gait abnormalities (e.g., toe walking, exaggerated lumbar lordosis, Trendelenburg gait)
- Cardiomyopathy (tachycardia, hypotension)
- Respiratory weakness (weak cough)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Serum CK: Markedly elevated in DMD, BMD, some LGMD and CMDs (e.g., Fukayama MD). CK may be normal late in disease owing to severe muscle atrophy. CK is typically normal in FSH-MD and some CMDs (e.g., Ullrich MD). Normal to mild CK elevation is seen in EDMD.

Diagnostic Procedures/Other

- Nerve conduction study: Merosin-negative CMD may show mild conduction velocity slowing.
- EMG: Nonspecific myopathic changes
- MRI muscle: Signal change noted reflecting muscle atrophy and fatty infiltration (may guide site of muscle biopsy but is not valuable for diagnostic purposes)

- MRI brain: Merosin-negative CMD show diffuse white matter signal abnormalities (typically visible by 6 months old)
- Muscle biopsy can be used to confirm dystrophy (see “Differential Diagnosis”), while immunohistochemistry can help in diagnosis of nondystrophic MDs (e.g., LGMD) if DMD genetic testing is normal.

DIFFERENTIAL DIAGNOSIS

- Inflammatory myopathy (e.g., dermatomyositis)
- Metabolic myopathy
- Congenital myopathy
- Anterior horn cell disease (e.g., SMA)
- Polyneuropathy (e.g., CIDP)
- Myotonic dystrophy (different pathology)

TREATMENT

MEDICATION (DRUGS)

- For DMD: Corticosteroids (prednisone [0.75 mg/kg/day] or deflazacort) 0.9 mg/kg/day: Improve muscle strength, prolong independent ambulation (mean = 2.5 years), delay onset of cardiomyopathy and scoliosis, and improve pulmonary function testing. Patients must be monitored for adverse effects of steroid therapy (weight gain, bone demineralization, behavior issues).
- All other MDs: No treatment

ADDITIONAL TREATMENT

General Measures

- Supportive care (e.g., routine immunizations)
- Psychological and/or school support
- Night splinting (DMD, LGMD) to prevent progression of joint contractures
- Physiotherapy: Passive stretching
- Orthopedic evaluation: Scoliosis surveillance and/or management of joint contractures
- Genetic counseling
- Ophthalmology (retinal) evaluation (FSH-MD); cataract surveillance (DMD patients on steroids)

Additional Therapies

Several potential therapies for DMD are being studied (e.g., antisense oligonucleotide therapy, DMD nonsense mutation read-through therapy, myostatin inhibitor therapy, stem cell therapy). These therapies remain experimental and are not commercially available in North America or Europe.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Respiratory surveillance:
 - Baseline respirology evaluation (DMD, CMD) with periodic PFT surveillance, incentive spirometry, and/or cough assist devices
 - Monitor for decline in PFT scores (especially FVC) and/or clinical evidence of nocturnal hypoventilation (e.g., morning headache/nausea, daytime somnolence, orthopnea). If noted, obtain sleep study to evaluate for potential need for nocturnal bilevel positive airway pressure (BiPAP).
 - Monitor kyphoscoliosis.
- Cardiology surveillance:
 - Cardiomyopathy is well documented for many MDs, necessitating periodic echocardiogram and ECG surveillance studies for DMD, BMD, LGMD1B, LGMD2C–F (20–30% risk), LGMD2I (30–60% risk), merosin-negative CMD, and EDMD.
 - American Academy of Pediatrics (AAP) guidelines recommend DMD patients receive complete cardiac evaluation every 2 years (until age 10 years) and annually thereafter.
 - Cardiac arrhythmia surveillance is required for EDMD, LGMD1B, and FSH-MD (<10% risk); also consider for any MD patient showing echocardiogram evidence of a cardiomyopathy.
 - Cardiac transplantation should be considered for BMD patients with severe cardiomyopathy, particularly if they have relatively minor skeletal muscle involvement.

PROGNOSIS

- DMD: Life expectancy into late 20s, death typically from respiratory failure
- BMD: Life expectancy into mid-40s, death typically due to cardiomyopathy
- LGMD: Variable. Sarcoglycanopathies may show a DMD-like progression. Autosomal dominant LGMD later onset with slow progression

- 359.1 Hereditary progressive muscular dystrophy

ICD10

- G71.0 Muscular dystrophy
- G71.2 Congenital myopathies

FAQ

- Q: What test should be ordered 1st in a boy with suspected DMD?
- A: After confirmation that CK is elevated, 1st-line testing is DMD duplication/deletion analysis (detects 70% cases). If negative, DMD gene should be sequenced. Muscle biopsy is typically reserved for patients with negative genetic testing (i.e., LGMD) or if there is clinical suspicion for inflammatory myopathy (e.g., dermatomyositis). Nerve conduction studies can help differentiate neurogenic disorders (i.e., SMA, polyneuropathy) but show nonspecific myopathic changes in MDs.
- Q: What is the recurrence risk in DMD?
- A: About 2/3 of mothers of males with DMD are carriers. If a female DMD carrier has a son, that boy has a 50% chance of having DMD. If she has a daughter, that girl has a 50% chance of becoming a DMD carrier. Males with DMD or BMD will transmit the mutated gene to all daughters (who become carriers). The sons of DMD males will not be affected (X linked).
- Q: Can female DMD carriers be symptomatic?
- A: Yes. Owing to the random nature of X-chromosome inactivation, roughly 10% of female DMD heterozygotes may develop cardiomyopathy and/or proximal muscle weakness. The American Academy of Pediatrics recommends female carriers receive a cardiac evaluation in early adulthood and every 5 years after 25–30 years old.

MYASTHENIA GRAVIS

Diana X. Bharucha-Goebel

Brenda E. Porter (5th edition)

Grant T. Liu (5th edition)

BASICS

DESCRIPTION

A neuromuscular (NM) disease presenting with varying weakness that worsens with exercise and improves with rest.

- Rare—Incidence 4–6 per million per year
- Prevalence of 40–80 per million
- Children account for 10–15% of cases of myasthenia gravis annually.
- 3 types of myasthenia gravis seen in childhood:
 - Neonatal transient: 10–20% of infants born to mothers with autoimmune myasthenia
 - Congenital myasthenia: Rare; <10% of all childhood myasthenia. Weakness usually starts in the 1st year of life and is caused by an inherited disorder in NM transmission. Can be classified by the site of mutation (e.g., presynaptic/postsynaptic) or by molecular genetics.
 - Juvenile myasthenia: Autoimmune disorder similar to adult-onset, autoimmune myasthenia gravis. Caused by aberrant production of antibodies against the acetylcholine receptor (AChR). Relatively rare: 1 new diagnosis per million per year. The average age of onset is 10–13 years, with a female predominance of 2:1 or 4:1.

RISK FACTORS

Genetics

- Congenital type: Generally autosomal-recessive (check consanguinity)
- Occasional family history

PATHOPHYSIOLOGY

- Caused by a disruption in signal transmission from the motor neuron to the muscle. Sensory or cognitive symptoms are absent.
 - The motor nerve terminal lies in close proximity to the end plate, a region of the muscle cell membrane with a high concentration of AChR.
 - Normally, when stimulated, the motor nerve terminal releases acetylcholine that binds receptors, causing contraction of the muscle. The cleft contains acetylcholinesterase (AChE), an enzyme that breaks down acetylcholine and helps terminate the muscle contractions.
- Autoimmune form (Juvenile)
 - Autoantibody blocks AChR activity → increased rate of receptor breakdown → fewer receptors are present → leads to decreased muscle contraction.
 - Thymic pathology is believed to be central to the pathogenesis of autoimmune myasthenia; hyperplasia is present in most children who undergo thymectomy.

- Neonatal (transient) myasthenia: Infants are born with weakness and hypotonia.
 - Due to maternal–fetal transmission of antibodies against the AChR
 - The severity of maternal symptoms does NOT predict the likelihood that the infant will be affected. Occasional arthrogryposis (joint contractures) reflects decreased fetal movement in utero.
 - High levels of maternal antibodies against the fetal form of AChR pose an increased risk of disease.
 - A previous pregnancy with an affected infant places future pregnancies at much higher risk. In rare cases, the mother is asymptomatic, despite presence of a (placentally transmitted) antibody.
- Congenital myasthenic syndromes—group of genetic disorders of NM junction; classified by site of NM transmission defect and more recently by molecular genetics
 - Includes presynaptic defects, synaptic defect (due to end-plate AChE deficiency); postsynaptic defects (primary AChR deficiency; primary AChR kinetic abnormality; OR perijunctional skeletal muscle sodium channel mutation)

COMMONLY ASSOCIATED CONDITIONS

- In juvenile myasthenia, other autoimmune disorders may occur:
 - Hyperthyroidism is present in 3–9% of patients.
 - Small increase in the incidence of rheumatoid arthritis and diabetes
- Some reports suggest an increased incidence of seizures in autoimmune myasthenia.
- Screening for thymoma at initial diagnosis is appropriate (by chest CT scan):
 - Children appear to have a lower incidence of thymic tumor than adults with autoimmune myasthenia.

DIAGNOSIS

Most patients present with ptosis and diplopia alone or in combination with swallowing difficulties, dysphonia, and generalized weakness.

HISTORY

- Neonatal transient: Mother with known autoimmune myasthenia or a history of weakness, ptosis, or dysphagia
- Congenital myasthenia:
 - Usually presents in the 1st year of life (rarely later) with hypotonia, poor feeding, ptosis, and delayed motor milestones
 - Possible family history of similar weakness
 - No response to thymectomy or immunosuppressant medications

- Juvenile myasthenia:
 - Gradual onset of weakness over weeks, months, or even years
 - Symptoms are worse after prolonged activity or late in the day.
 - Intermittent ptosis, diplopia, dysphagia, and dysphonia are common.
 - Ocular myasthenia gravis: A subset of 10–15% of patients with myasthenia who have isolated ptosis and ophthalmoplegia (weakness in extraocular muscles) in absence of systemic or bulbar symptoms

PHYSICAL EXAM

- Neonatal transient: From birth, the infant is hypotonic, with a weak suck, a weak cry, and ptosis.
- Congenital and juvenile myasthenia:
 - Weakness of neck flexion
 - Reflexes often preserved
 - Ptosis, ophthalmoplegia, and variable-feeding problems are often the earliest findings.
 - Generalized weakness may be asymmetric in the limbs. The weakness is more pronounced with endurance tasks.
 - Shallow, rapid respirations suggest impending ventilatory failure. Vital capacity of <50% of predicted (in older children) suggests impending respiratory failure.
 - Check for scoliosis (anti-MuSK variant)

DIAGNOSTIC TESTS & INTERPRETATION

- Juvenile myasthenia:
 - Nerve conduction and electromyography studies: Repetitive stimulation of a nerve shows a diagnostic decremental response due to decreased AChR.
 - Single-fiber electromyography measures the variability in firing rates of 2 muscle fibers innervated by different branches of the same motor neuron. A large variability suggests a higher threshold for activation.
 - Edrophonium chloride (Tensilon) is a fast-acting AChE-blocking agent (no longer widely available in the US).
 - Patients with myasthenia often show an immediate, transient improvement in muscle strength after IV infusion of this drug.
 - A measurable weakness should be present prior to testing, and a placebo dose of saline should be given initially.
 - Although the risk of a hyperreactive cholinergic response with muscle weakness and bradycardia is low, atropine should always be available, and the patient's vital signs should be closely monitored during the test (contraindicated in patients with heart disease).
 - Measurable cranial nerve dysfunction, such as ptosis, is often responsive to edrophonium.
 - Children receive 20% of 0.2 mg/kg dose of Tensilon over 1 minute; if there is no response after 45 seconds, the rest of the dose is then given, up to a maximum of 10 mg. Have atropine and epinephrine readily available.

Lab

- AChR antibody levels (most specific): Elevated in ~80% of patients with generalized myasthenia and about 50% of patients with isolated ocular myasthenia
- Second most common—serum antibody to muscle-specific receptor tyrosine kinase (MuSK-Ab)

DIFFERENTIAL DIAGNOSIS

- Generalized botulism:
 - In endemic areas, may cause generalized weakness in infants; caused by *Clostridium* toxin that blocks the release of acetylcholine from nerve terminal.
- Guillain-Barré syndrome or acute inflammatory demyelinating polyneuropathy:
 - A frequent cause of rapidly progressive generalized weakness
 - Unlike myasthenia, there are often sensory symptoms, and areflexia occurs even with minimal weakness.
- Acute spinal cord compression:
 - Can present as generalized (but not variable) weakness of the extremities
 - Look for sparing of facial and extraocular muscles; a sensory level, bowel, or bladder dysfunction; and hyperactive reflexes
- Organophosphate ingestion: Pyridostigmine bromide (Mestinon)
 - Can cause profound weakness
 - Symptoms of parasympathetic hyperactivity, such as hypersalivation, miosis, diarrhea, and bradycardia, will usually be present.
- Penicillamine used for the treatment of autoimmune disorders can induce autoantibodies that bind the AChR, causing myasthenia gravis.

TREATMENT

INITIAL STABILIZATION

Treat respiratory failure, a rare but serious complication of juvenile myasthenia gravis:

- Shallow breathing, a vital capacity of <50% predicted, or a rapidly worsening vital capacity suggests impending respiratory failure.

General Measures

- Neonatal myasthenia:
 - Severity of disability should be used to guide the aggressiveness of therapy.
 - Respiratory or swallowing impairment: Pyridostigmine syrup, 60 mg/5 mL, 7 mg/kg, 30 minutes before feeds; 1 mg IM = 30 mg PO dose
- Juvenile myasthenia:
 - Most patients benefit from pyridostigmine bromide (Mestinon) given 3–4× per day. A long-acting formulation prior to bedtime may alleviate obstructive hypoventilation during sleep.
 - Pyridostigmine → blocks AChE activity → results in increased acetylcholine
 - A normal starting dosage is approximately 7 mg/kg/d. The dosage is slowly titrated upward, following symptoms, at several-day intervals. Common side effects are hypersalivation, blurry vision, and diarrhea.

- Glycopyrrolate (1 mg PO) may decrease diarrhea.
- Prednisone
 - Consider in patients with disabling symptoms and inadequate response to pyridostigmine
 - Watch for transient worsening within weeks in up to 50% of patients
 - Start daily dose at 2 mg/kg, watch for improvement in 3–6 weeks, taper toward 1.5 mg/kg/d on alternate-day schedule for 4 months. Taper slowly thereafter by 5 mg/wk.
 - Monitor for side effects, including growth stunting
 - Calcium and every-other-day dosing may limit the bone deterioration from chronic steroids.
- Azathioprine
 - Induces remission in 30% of patients and significant improvement in another 25–60%
 - Useful adjunctive to steroids and thymectomy; however, it takes 3–12 months for benefits to occur
- Juvenile myasthenics with profound weakness and respiratory failure (myasthenic crisis) should undergo immediate therapy to decrease the number of circulating antibodies:
 - Plasmapheresis or IV immunoglobulin can help within days by decreasing AChR antibodies.
 - Steroids diminish antibody production over weeks to months.
 - Newer immunosuppressants reported effective in small series (mycophenolate mofetil and anti-CD20)

SURGERY

Thymectomy:

- 20–60% remission; another 15–30% show marked improvement
- Thymectomy earlier in the course of illness appears to produce a higher rate of remission.

ONGOING CARE

- The following medications can exacerbate myasthenia gravis:
 - Corticosteroids may worsen symptoms.
 - Aminoglycosides
 - Ciprofloxacin
 - β-Adrenergic blocking agents, including eye drops
 - Lithium
 - Procainamide
 - Quinidine
 - Phenytoin
- Prolonged recovery after exposure to nondepolarizing NM blocking agents
- Always start new medications cautiously

PROGNOSIS

- Neonatal transient:
 - A self-limited disorder that resolves spontaneously over weeks or months of life as maternal antibodies disappear
 - The infant may require ventilatory and nutritional support during the first few months of life.
 - Infants with arthrogryposis multiplex congenita (born to mothers with antibodies against the fetal form of AChR) may gain mobility over time and with passive range-of-motion therapy.

- Congenital myasthenia:
 - Prognosis varies, depending on the specific defect
 - Autosomal-recessive disorders tend to be more severe than the dominant disorders. Weakness shows variable response to cholinesterase inhibitors.
 - Immunosuppressants are not helpful. In general, these are indolent disorders.
 - Ptosis and fatigability resemble the juvenile type, but are more stable over time.
- Juvenile myasthenia:
 - Most patients do extremely well with treatment; patient selection for early surgery requires experience and may improve outcome.
 - Longitudinal studies suggest that the rate of spontaneous remission is ~2% per year.
 - Patients with generalized weakness are slightly less likely to experience remission.
 - The mortality rate from myasthenia is near that of the general population in patients <50 years.

PATIENT MONITORING

- Watch for transient worsening of symptoms
- Monitor for side effects of corticosteroids, including growth stunting
- Medication effects: GI upset due to AChE inhibitors

COMPLICATIONS

Respiratory failure, nocturnal hypoventilation, visual disturbance, thymic cancer, other autoimmune disorders

MYOCARDITIS

Bradley S. Marino

John L. Jefferies

BASICS

DESCRIPTION

Myocarditis is defined as inflammation of the myocardium on histologic examination.

EPIDEMIOLOGY

Cardiovascular complications may be significant including myocardial dysfunction, arrhythmias, conduction abnormalities, and cardiac arrest.

Incidence

- True incidence of acute myocarditis is difficult to estimate because of the wide range in clinical severity, various etiologies, and under-diagnosis.
- Estimates of incidence from autopsy range from ~0.1% to 12%.
- More than 50% of pediatric cases seen are in infants <1 year of age.

Prevalence

Viral myocarditis has a seasonal distribution, which varies according to the viral species.

RISK FACTORS

- Exposure to infectious agents, drugs, toxins, and systemic diseases
- Drug exposure
- Autoimmune disease
- Systemic disease

PATHOPHYSIOLOGY

- Pathophysiology of myocarditis may vary based on cause (See Etiology)
- Viral myocarditis is best characterized and involves a complex interaction among the virus, host immune response, and environmental factors. 3 stages include: 1) Viral injury and innate immune response; 2) Acquired host immune response; and 3) Recovery or chronic cardiomyopathy.
- Inflammatory response from innate and acquired immune response may result in significant damage to the myocardium and conduction system
- Development of autoantibodies may also play a key role in acute and chronic myocardial damage.
- Virus may cause direct damage to the myocardium independent of inflammation secondary to cleavage of structural proteins.
- Pathogenesis of nonviral myocarditis is poorly understood.
- Regardless of the cause, symptom severity increases with worsening ventricular function and/or with worsening arrhythmias.
- Fulminant myocarditis may be characterized by both severe systolic and diastolic dysfunction.
- Progressive left ventricular systolic dysfunction may lead to hypotension, acidosis, and end-organ dysfunction.
- Left ventricular diastolic dysfunction may result in elevated left ventricular end diastolic pressures, leading to pulmonary venous and arterial hypertension, with concomitant pulmonary edema and right-sided heart failure.

ETIOLOGY

- Causes include infection, toxins, drugs, autoimmune disease, and systemic disease
- Infectious causes include: Viral, bacterial, rickettsial, fungal, helminthic, spirochetal, and protozoal infections
- Viral infection is the most common in developed countries. Both RNA and DNA viruses have been implicated. Previously, the enteroviruses, specifically Coxsackie B, were commonly seen. However, there has been a recent shift in the spectrum. Currently, parvovirus B19 is most commonly seen. There are growing reports of certain herpes viruses, specifically HHV6, becoming more prevalent.
- Nonviral infectious causes are far less common but must be considered especially in endemic areas, such as Central and South America where Chagas disease is prevalent.
- Nonviral myocarditis may be secondary to exposure to toxins, drug hypersensitivity, autoimmune disease such as SLE, or systemic disease such as Churg–Strauss or sarcoidosis.
- Giant cell myocarditis (GCM) is a very rare form of myocarditis in children that is associated with autoimmune disease and drug hypersensitivity. These patients respond poorly to typical care and frequently require cardiac transplantation.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Prodromal:
 - Antecedent flu-like illness
 - Gastroenteritis
 - Rheumatologic symptoms
 - Fever
- Left-sided heart failure:
 - Exercise intolerance
 - Easy fatigability
 - Dyspnea
 - Orthopnea
 - Anorexia, loss of appetite/poor feeding, early satiety
 - Emesis (especially in children)
- Right-sided heart failure:
 - Abdominal pain/cramping
 - Swelling of abdomen/lower extremities
 - Loose stools

HISTORY

- Duration of symptoms
- Travel history
- Family history

PHYSICAL EXAM

Any of the following may be present:

- Pulmonary:
 - Rales
 - Tachypnea
 - Retractions

- Cardiovascular:
 - Jugular venous distention
 - Normal to hyperdynamic precordium with or without right ventricular heave
 - Lateral displacement of the point of maximal impulse (PMI)
 - Tachycardia: Arrhythmia (atrial and/or ventricular ectopy may be present)
 - Heart sounds: Accentuation of second heart sound (secondary to pulmonary artery hypertension), murmur (mitral and/or tricuspid insufficiency), gallop, and/or rub.
- Abdomen: Hepatomegaly, splenomegaly, ascites
- Extremities:
 - Weak pulses
 - Poor capillary refill
 - Cool extremities

DIAGNOSTIC TESTS & INTERPRETATION

- Despite limited sensitivity and specificity, endomyocardial biopsy (EMB), using the Dallas criteria for histopathologic classification, remains the gold standard for confirming the diagnosis of acute myocarditis.
 - These criteria are limited in that they provide information with regard to inflammation but do not assess for the presence of viral pathogens.
 - Current approaches indicate benefit in analyzing the tissue for viral DNA by polymerase chain reaction.
 - EMB has inherent problems, including sample selection bias, as tissue is only obtained from the right ventricular endocardium, and possible morbidity and mortality associated with an invasive procedure.
- Other studies supportive of the diagnosis may include: EKG:
 - Highly variable findings may include sinus tachycardia, low voltage QRS, ST segment depression/elevation, flattening or inversion of the T wave, conduction system disease including complete heart block, prolongation of the QT interval, and arrhythmias (premature atrial contractions/supraventricular tachycardia, or premature ventricular contractions/ventricular tachycardia).

Lab

- ESR and C-reactive protein level may be elevated.
- Creatinine kinase MB fraction and troponin T and I levels may be elevated.
- Cultures (bacterial, viral, fungal) of blood, urine, stool, and nasopharyngeal swabs may be considered.
- Viral PCR analysis of tissue including myocardium, blood, or sputum may be considered.
- Acute and convalescent serologic studies may be considered for selected antibody studies.

Imaging

- Chest radiograph:
 - Cardiomegaly and varying degrees of pulmonary edema
 - Possible pleural effusions
- Echocardiography:
 - Depressed systolic function (may biventricular with normal to mildly dilated chamber sizes)
 - Depressed diastolic function
 - Focal wall motion abnormalities
 - Valvular insufficiency
 - Pericardial effusion
- Cardiac MRI
- Assessment of chamber size and systolic function
- Fibrosis by delayed enhancement
- Abnormal delayed enhancement and edema as seen by T₂ weighting

DIFFERENTIAL DIAGNOSIS

- Severe left-sided obstructive heart lesions:
 - Mitral stenosis
 - Valvular aortic stenosis
 - Coarctation of the aorta
- Congenital coronary artery anomalies:
 - Anomalous left coronary artery from the pulmonary artery and other coronary variants
- Incessant arrhythmias:
 - Incessant supraventricular tachycardia
 - Ventricular tachycardia
- Metabolic disorders including mitochondrial disease
- Drug use
 - Cocaine or other stimulants
- Acquired disease
 - Kawasaki disease
 - Coronary artery disease
- Genetic syndromes:
 - Neuromuscular disease
 - Genetically mediated cardiomyopathies

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Initial management should be based on the clinical presentation. These include the following: Bed rest and limited activity (during acute phase).
- Standard medical regimens for acute care should be based on appropriate heart failure therapies and may include (a more complete list of recommendations for the management of acute and chronic heart failure may be found elsewhere; Jessup M et al.):
 - Inotropic support should be considered for patients with evidence of low cardiac output. Medication infusions may include milrinone, dopamine, dobutamine. If epinephrine is required, mechanical support should be considered.
 - Diuretics: Afterload reduction may be considered if volume overload exists with preserved cardiac output (e.g., nitroglycerin and nitroprusside)
 - Anti-arrhythmics may be used in cases of hemodynamically significant arrhythmias.

- Standard medical regimens for chronic care should be based upon appropriate heart failure therapies and may include:
 - Angiotensin converting inhibitors (ACEi)
 - β -blockers
 - Angiotensin receptor blockers
 - Diuretics (e.g., spironolactone for ventricular remodeling)
 - Immunosuppression/immunomodulation may be considered in the form of intravenous immunoglobulin
 - Steroids may also be considered in patients with evidence of myocardial necrosis or refractory arrhythmias
 - Anticoagulation with unfractionated or low molecular weight heparin acutely and aspirin and/or coumadin chronically for patients with severe myocardial depression and ventricular dilation
 - Implantable devices may be considered for patients with conduction system disease or those at risk for sudden cardiac death
 - Permanent pacemaker
 - Implantable cardioverter–defibrillator
 - Mechanical ventilation in patients with respiratory failure secondary to myocardial failure
 - Mechanical support (in patients with rapidly progressing, severe heart failure; used as a bridge to transplantation): Left ventricular or biventricular assist devices, extracorporeal membrane oxygenation (ECMO)
 - Rescue therapy: Cardiac transplantation

MEDICATION (DRUGS)

- Immunosuppression: High-dose gamma globulin (2 g/kg IV immunoglobulin [Ig] over 24 hours) during the acute phase has been associated with improved recovery of left ventricular function and with a tendency for better survival during the first year after presentation.
- Steroids, azathioprine, calcineurin inhibitors, cyclosporine, cyclophosphamide, and other immunosuppressive medications have all been proposed as effective agents, although insufficient evidence of therapeutic benefit is currently available to recommend routine use.
- Antiviral therapy does not currently have an accepted role in myocarditis management. Use of interferon therapy is being widely studied but there continues to be a lack of demonstrable benefit.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

- Clinical changes in systolic and diastolic function
- Observation for life-threatening arrhythmias
- Effects of the illness on other systems:
 - Nutritional status
 - Growth
 - Development
 - Comorbid illnesses

PROGNOSIS

- Statistics are hampered by the lack of complete ascertainment of all cases of acute myocarditis, with many patients likely exhibiting only mild symptoms, which spontaneously resolve.

- Prognosis is often dictated by clinical presentation. However, if treated appropriately early in the course, outcome can be quite favorable. Prognosis is poor in patients with fulminant lymphocytic myocarditis with significant hemodynamic compromise with a mortality of >40% in adults and ~75% in children without aggressive management strategies. Mortality is higher in children presenting in the neonatal period. Giant cell myocarditis represents a unique subgroup with a particularly poor prognosis unless transplanted.

COMPLICATIONS

- Acidosis
- End-organ hypoperfusion
- Pulmonary venous and arterial hypertension
- Pulmonary edema
- Unfavorable ventricular remodeling
- Conduction system disease including heart block
- Arrhythmias

NARCOLEPSY

Kiran P. Maski

Sanjeev V. Kothare

BASICS

DESCRIPTION

- Lifelong neurologic disorder that, often, initially manifests in childhood or adolescence and can cause significant functional impairment and disability
- Excessive daytime somnolence and inappropriate transition from wakefulness into REM sleep
- Principal features include uncontrollable and overwhelming daytime sleep attacks, cataplexy, hypnagogic hallucinations, and sleep paralysis.

GENERAL PREVENTION

- Narcolepsy is not preventable.
- Narcolepsy is an under-recognized disease, especially in children.
- Physicians should screen for sleep dysfunction and excessive sleepiness in anticipatory guidance.

EPIDEMIOLOGY

- Prevalence in the USA is reported to range from 3 to 16 per 10,000; prevalence may be higher in the Japanese population
- An estimated 200,000 Americans have narcolepsy, but fewer than 50,000 of these individuals have been diagnosed with the disorder
- Most often diagnosed in the third and fourth decade, but 34% of patient have symptoms before age 15
- Cataplexy is present in 50–70% of adult patients but is correctly identified in only 15% of children with a diagnosis of narcolepsy

RISK FACTORS

- First-degree relatives of patients with narcolepsy have a 1–2% risk (which is 10- to 40-fold more than the general population) of developing narcolepsy.
- Both genetic and environmental factors may be involved in the development of narcolepsy
- There is an association between narcolepsy and histocompatibility leukocyte antigens (HLA) sub-types DQ (specifically DQB1 0602 and DQA1 0102) and DR2 antigens.

PATHOPHYSIOLOGY

- Hypocretin/orexin is a neuropeptide produced by neurons in the perifornical area of the posterior and lateral hypothalamus that is supplied to several areas of the brain that promote wakefulness, and it possibly also inhibits REM sleep
- Idiopathic narcolepsy is caused by selective loss of the hypocretin/orexin-producing neurons in the hypothalamic region
- The association between narcolepsy and specific HLA antigens may indicate immunologic pathogenesis; however, this is yet to be established.

COMMONLY ASSOCIATED CONDITIONS

- Secondary narcolepsy may be seen with CNS trauma, strokes, brain tumors, and demyelinating diseases, particularly involving the lateral and posterior hypothalamus, midbrain, and the pons.
- Genetic syndromes such as Prader–Willi syndrome, Myotonic dystrophy, and Niemann–Pick type C syndrome may be associated with secondary narcolepsy

DIAGNOSIS

HISTORY

- Excess daytime sleepiness with irresistible urge to fall asleep and unintentional naps may be early signs of disease.
- In adults, naps tend to be restorative, but are more likely to be described as “unrefreshing” in children.
- Cataplexy, the abrupt loss of muscle tone provoked by strong emotions such as surprise, sadness, laughter, or anger, is the second most common symptom in narcolepsy. Loss of muscle tone can range from sagging of face, eyelids or jaw, blurred vision, knee buckling, to complete collapse, but with preservation of consciousness.
- Hypnagogic (on sleep onset)/hypnopompic (on awakening) hallucinations involve vivid auditory or visual hallucinations during transitions between sleep and wakefulness. Such hallucinations are also experienced infrequently by normal individuals.
- Sleep paralysis is the inability to move or speak for a few seconds or minutes at sleep onset or offset. Normal individuals can also occasionally experience sleep paralysis.

PHYSICAL EXAM

- Normal in most idiopathic cases; children with narcolepsy are often overweight/obese.
- Vertical gaze palsy, confusion, poor memory, developmental regression, impaired thermoregulation, and signs of endocrine dysfunction may be present in cases of secondary narcolepsy

DIAGNOSTIC TESTS & INTERPRETATION**Lab**

- Levels of CSF hypocretin <100 pg/ml are strongly indicative of narcolepsy with cataplexy in children (range in healthy controls are reported as 280.3 ± 33 pg/mL).
- HLA antigen typing with HLA DQB1 0602 and DQA1 0102 and DR2 are strongly associated with idiopathic narcolepsy with cataplexy, but also present in 12–38% of the normal population.

Imaging

MRI brain is indicated with sudden onset of sleepiness, recent head injury, or an abnormal neurological exam

Diagnostic Procedures/Other

- Overnight polysomnography (PSG) and multiple sleep latency test (MSLT) are essential components of diagnosis
- MSLT is a series of four or five 20-minute naps, 2 hours apart after an overnight PSG to determine mean sleep latency (MSL) and sleep onset REM (SOREM) within 15 minutes of falling asleep. MSL <8 minutes and ≥2 SOREMs during the MSLT are diagnostic of narcolepsy

DIFFERENTIAL DIAGNOSIS

- Chronic sleep deprivation with erratic sleep–wake schedule
- Idiopathic CNS hypersomnia (without cataplexy or REM intrusion in wakefulness or sleep)
- Primary sleep disorders such as obstructive sleep apnea, restless leg syndrome, periodic limb movement disorder
- Klein–Levin syndrome (cyclical episodes of hypersomnolence, overeating, and hypersexuality lasting days to weeks with normal intervals in between)
- Psychiatric disorder/depression
- Medication side effects, drug/alcohol abuse
- Atonic drip attacks associated with childhood epilepsy syndromes such as Lennox Gastaut syndrome

**TREATMENT****MEDICATION (DRUGS)**

- Daytime sleepiness
 - Modafinil Provigil, 100–400 mg/day
 - Methylphenidate, 10–30 mg (max. 60 mg/d). Consider other long-acting formulations such as Concerta, Ritalin SR, Metadate CD, Focalin XR, etc.
 - Dextroamphetamine (Dexedrine) 20–25 mg/d
 - Methamphetamine (Desoxyn) 10–40 mg/d
 - Amphetamine/dextroamphetamine mixture (Adderall XR) 10–30 mg/d
- Cataplexy
 - Clomipramine (Anafranil) 3 mg/kg/d in divided doses
 - Imipramine 1.5–5 mg/kg/d
 - Protriptyline (Vivactil) 2.5–10 mg/d in divided doses
 - Selective serotonin reuptake inhibitors. Fluoxetine (Prozac) 5–30 mg/d or sertraline (Zoloft) 25–100 mg/d
 - Sodium oxybate (Xyrem): A new drug that recently became available to treat hypersomnia and cataplexy in refractory cases of narcolepsy. Dose is given at 10 pm and 2 am.

**ONGOING CARE****PROGNOSIS**

With proper sleep hygiene, including regular sleep hours and scheduled daytime short naps, and medications to reduce sleepiness and cataplexy, the prognosis is good, with normal life expectancy, and normal intellectual functioning.

FAQ

- Q: What is the chance that a sibling of the patient may develop narcolepsy
- A: There is a 1% possibility that siblings and offspring could be affected.
- Q: Will a patient with narcolepsy be able to drive a car?
- A: Narcolepsy patient can legally drive, provided they are on the appropriate medications to keep them from falling asleep at the wheel.

NECK MASSES

Nicholas Tsarouhas

BASICS

DESCRIPTION

Any mass in the tissues of the neck; cervical adenopathy is usually defined as a neck node > 1 cm.

ETIOLOGY

Varies depending on underlying condition

DIAGNOSIS

To diagnose and appropriately manage neck masses, one must combine the history with a careful examination of the mass. The major task of the differential diagnosis is to distinguish infections from congenital and malignant causes.

HISTORY

- Fever: Infection, Kawasaki disease, malignancy, “PFAPA” syndrome (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis)
- Noticed with intercurrent infection: Reactive hyperplasia, mononucleosis, adenitis, abscess, congenital cyst
- Subacute or chronic cervical lymphadenitis: Cat-scratch disease, toxoplasmosis, Epstein–Barr virus (EBV), and mycobacterial infection
- Increasing size: Infection, congenital lesion newly infected, malignancy
- Sore throat: Mononucleosis, peritonsillar or retropharyngeal abscess
- Swallowing problems: Retropharyngeal or peritonsillar abscess, thyroglossal duct cyst
- Contact with cats: Cat-scratch disease, toxoplasmosis
- History of scratch or papule on face: Cat-scratch disease
- Recurrently infected neck mass: Infected congenital cyst (thyroglossal duct, branchial cleft)
- Mass noticed at or shortly after birth: Cystic hygroma, hemangioma, sternocleidomastoid tumor of infancy
- Weight loss, cough, or other chronic constitutional symptoms: Malignancy, tuberculosis
- Hypothyroid or hyperthyroid symptoms: Thyroglossal duct cyst, thyroidal diseases

PHYSICAL EXAM

- Tender, erythematous, indurated mass may indicate cervical adenitis, infected congenital lesion, or cat-scratch disease.
- Nontender, enlarged lymph nodes(s) suggest reactive hyperplasia or malignancy.
- Fluctuant mass may indicate adenitis with abscess or cystic hygroma.
- Drainage suggests adenitis with abscess, atypical mycobacterial disease, infected thyroglossal duct, or branchial cleft cyst.
- Regional adenopathy suggests reactive hyperplasia or cat-scratch disease.
- Exudative pharyngitis may be a sign of mononucleosis.
- Asymmetric soft palate with uvular deviation suggests peritonsillar abscess.
- Pulmonary findings may indicate tuberculosis or malignancy.
- Midline mass suggests thyroglossal duct or dermoid cyst, or thyroidal disease.

- If mass moves with tongue protrusion, thyroglossal duct cyst may be present.
- Sinus opening may indicate thyroglossal duct, branchial cleft, or dermoid cyst.
- Multiloculated mass which transilluminates suggests cystic hygroma.
- Matted-down mass may indicate malignancy.
- Mass posterior to sternocleidomastoid muscle may be malignancy or infection.
- Inferior deep cervical nodes (scalene and supraclavicular) suggest malignancy.
- Generalized adenopathy suggests malignancy.
- Hepatosplenomegaly may indicate malignancy or infectious mononucleosis.
- Skin discoloration suggests trauma, abscess, or atypical mycobacterial disease.
- A skin papule is a clue to cat-scratch disease.
- Conjunctivitis, oral involvement, extremity changes, rash, and adenopathy, in the context of fever, are the key diagnostic criteria in Kawasaki disease.
- Torticolis in a neonate suggests sternocleidomastoid (pseudo) tumor of infancy.

DIAGNOSTIC TESTS & INTERPRETATION

- CBC:
 - Leukocytosis in infections
 - Atypical lymphocytosis in mononucleosis
 - Thrombocytosis after 1st week in Kawasaki disease
 - Most patients with neck malignancies initially have a normal CBC.
- EBV titers, mononucleosis spot test: “Mono spot” test less reliable in children <4 years old; therefore, titers more useful
- Indirect fluorescent antibody titers for *Bartonella*: Reliable test to confirm clinical suspicion of cat-scratch disease
- Purified protein derivative: Negative or only weakly positive in atypical mycobacterial infections
- Chest radiograph: Cavitory lesions and infiltrates in tuberculosis; adenopathy in malignancies and tuberculosis
- Lateral neck radiograph: Prevertebral soft-tissue space at C2–C3 abnormally wide (> 1/2 adjacent vertebral body diameter) in cases of retropharyngeal abscess
- Ultrasound:
 - Often the first imaging modality for neck masses
 - Provides immediate, noninvasive information on location, size, and composition of mass (cystic vs. solid)
 - Doppler adds information about vascularity.
- CT or MRI scan: Useful in evaluating deep neck infections and complex or extensive neck masses
- Thyroid scintigraphy: Useful in evaluating thyroid lesions, especially when malignancy is a concern
- Gram stain and culture of specimen after needle aspiration or incision and drainage: Diagnostic as well as therapeutic procedure when infection suspected
- Histologic evaluation of specimen after fine-needle aspiration or biopsy: Diagnostic to distinguish malignant causes from congenital and infectious ones

DIFFERENTIAL DIAGNOSIS

• Infectious

- Reactive hyperplasia: Self-limited, usually viral enlargement of bilateral minimally tender nodes
- Bacterial lymphadenitis:
 - Usually staphylococcal or streptococcal infection of unilateral, tender, swollen, warm, erythematous node
 - In neonates, a cellulitis–adenitis syndrome is usually caused by group B *Streptococcus*.
- Cat-scratch disease:
 - A usually self-limited, though sometimes protracted, illness (2–4 months)
 - Caused by the Gram-negative bacillus *Bartonella henselae*
 - Starts as a papule at a cat-scratch site and then progresses to tender, regional adenopathy, 5–50 days later (median, 12 days)
 - Cervical nodes are second most commonly involved; axillary adenopathy is most common.
 - Nodes stay enlarged several weeks to several months.
- Tuberculosis: Acute or insidious onset of fever and firm, nontender adenopathy in children exposed to adult infected with the acid-fast bacillus *Mycobacterium tuberculosis*
- Atypical mycobacterial disease:
 - Infection usually caused by *Mycobacterium avium* complex or *Mycobacterium scrofulaceum* (ubiquitous agents found in the soil)
 - Rapidly enlarging mass of firm, nontender nodes in young children with no known exposure to tuberculosis
 - Nodes often occur with overlying skin discoloration and thinning; some spontaneously drain.
- Infectious mononucleosis: EBV infection most commonly seen in older children who present with fever, exudative pharyngitis, adenopathy, and hepatosplenomegaly
- Toxoplasmosis:
 - Parasitic disease caused by *Toxoplasma gondii* which presents with cervical adenopathy, rash, fever, malaise, and hepatosplenomegaly
 - Acquired from contact with cat feces or inadequately cooked meat
- Retropharyngeal abscess:
 - Suppurative adenitis of the retropharyngeal nodes that presents in children <5 years of age
 - These children often have fever, neck stiffness, dysphagia, respiratory distress, drooling, and stridor.
- Peritonsillar abscess: Suppurative sequela of a severe tonsillopharyngitis, usually caused by group A β -hemolytic *Streptococcus* (GABHS), which commonly presents in older children and adolescents with trismus, “hot potato” voice, and uvular deviation from a bulging palatal abscess.
- Ludwig angina:
 - Rapidly expanding, diffuse inflammation of the submandibular and sublingual spaces
 - May compromise the airway
 - Often occurs with dental infections

• Congenital

- Thyroglossal duct cyst: Most common congenital neck mass; a remnant of the embryonic thyroglossal sinus, which presents as a nontender (unless infected) mobile, anterior midline mass near the hyoid bone
- Branchial cleft cyst: Remnant of the 2nd branchial cleft, which presents as a nontender (unless infected) cyst at the anterior border of the sternocleidomastoid
- Cystic hygroma (lymphangioma): Complex, multiloculated mass of lymphatic tissue, which presents in the 1st year of life as a large, soft, compressible neck structure
- Dermoid cyst: Small, firm, nontender mass, usually high in the midline
- Hemangioma: Bluish purple, blanching mass appearing in 1st year of life
- Sternocleidomastoid (pseudo) tumor of infancy (congenital muscular torticollis): Benign perinatal fibromatosis, often associated with difficult deliveries or abnormal uterine positioning, that results in a hard, immobile, fusiform mass in the sternocleidomastoid
- Cervical wattle: Benign pedunculated congenital anomaly on lateral neck with a core of elastic cartilage
- Cervical bronchogenic cyst: Cervical neck mass in the anteromedial neck (superior to the sternal notch), resulting from abnormal development of the tracheobronchial tree
- Ectopic cervical thymus: Rare neck mass resulting from abnormal development of pharyngeal pouches and branchial clefts

• Malignant

- Hodgkin lymphoma: Slowly enlarging, unilateral, firm, nontender neck malignancy, which usually presents in previously well adolescents
- Non-Hodgkin lymphoma: Presents in young adolescents as a painless, rapidly growing, firm collection of lymph nodes
- Leukemia: Most common tumor associated with cervical lymphadenitis in first 6 years of life
- Neuroblastoma: Most commonly presents in toddlers as a large, nontender, abdominal mass, often associated with a myriad of signs and symptoms as a result of its propensity for metastasis
- Rhabdomyosarcoma: Head and neck malignancy that usually presents as a rapidly enlarging mass

• Thyroid

- Chronic lymphocytic thyroiditis (Hashimoto thyroiditis): Autoimmune childhood goiter that may be euthyroid, hypothyroid, or hyperthyroid
- Thyrotoxicosis (Graves disease): Clinically hyperfunctioning thyroid caused by circulating thyroid cell-stimulating antibodies
- Thyroiditis: Painful bacterial infection of the thyroid caused by *Staphylococcus* or *Streptococcus*

• Miscellaneous

- Kawasaki disease:
 - Idiopathic vasculitis distinguished by prolonged fever, conjunctivitis, oral involvement, extremity changes, rash, and adenopathy
 - Cervical node: Least common clinical feature
 - Unilateral cervical node should be > 1.5 cm.
- PFAPA syndrome:
 - Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis
 - Idiopathic, periodic, febrile syndrome most commonly described in young children
- Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease): Benign form of histiocytosis that presents as massive, painless enlargement of cervical nodes
- Hematoma: Secondary to trauma
- Hypersensitivity reaction: Secondary to bites, stings, or other allergens
- Drugs: Notably phenytoin and isoniazid, may be associated with lymphadenopathy
- Immunization: Lymphadenopathy has been reported following immunization with diphtheria–pertussis–tetanus and poliomyelitis.

TREATMENT

GENERAL MEASURES

- Infectious: Antibiotics; drainage for abscesses
- Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) infections continue to rise, especially in purulent abscesses.
- The mainstay of therapy for abscesses is I&D; if antibiotics are used adjunctively, clindamycin or trimethoprim–sulfamethoxazole should be used to cover *S. aureus*.
- Congenital: Antibiotics if infected; ENT referral for surgical excision
- Malignancy: Oncology referral for chemotherapy/radiation/excision
- Thyroidal: Endocrine referral for pharmacotherapy
- Miscellaneous:
 - Kawasaki disease: IV immunoglobulin (IVIG) and aspirin therapy to prevent coronary artery aneurysms; cardiology referral for echocardiography
 - PFAPA syndrome: Steroids (a single dose) are efficacious in aborting fever attacks.
 - Sternocleidomastoid tumor of infancy: Massage, range of motion, and stretching exercises

ONGOING CARE

Close follow-up is essential for all neck masses; consider referral for biopsy in the following cases:

- Nodes not responding to antibiotics
- Toxic illness/systemic symptoms
- Clinical signs of malignancy (weight loss, peripheral adenopathy, hepatosplenomegaly)
- Firm, nontender nodes fixed to deep tissues

- Nodes located posterior to the sternocleidomastoid or in the lower cervical/supraclavicular regions
- Bilateral nodes > 2 cm
- Increasing size after 2 weeks
- No decrease in size after 4–6 weeks
- Not back to normal size after 8–12 weeks

CODES

ICD9

784.2 Swelling, mass, or lump in head and neck

ICD10

R22.1 Localized swelling, mass and lump, neck

NECROTIZING ENTEROCOLITIS

Edisio Semeao

BASICS

DESCRIPTION

- Necrotizing enterocolitis (NEC) is an acquired condition of diffuse necrotic injury to the mucosal and submucosal layers of the bowel. It is the most common and serious GI disorder that occurs during the neonatal period. The entire GI tract, from the stomach to the anus, is susceptible, but the distal small bowel and proximal colon are involved most frequently. The lesions may be diffuse and contiguous or patchy and more focal in nature. Systemic signs and symptoms accompany GI injury.
- NEC affects mostly premature infants, but up to 10% of cases occur in term infants.

EPIDEMIOLOGY

- NEC usually has an onset within the 1st 2–3 weeks of life (3–20 days) and after enteral feedings have been initiated. The more premature the infant, the longer the child is at risk for developing NEC, and cases have been reported 3 months after birth.
- Mean gestational age is 31 weeks.

Incidence

- The incidence of NEC varies. It is stated most often as 1–7% of all neonatal intensive care unit (NICU) admissions, or 1–3 per 1,000 live births.
- Preterm infants account for 70–90% of total NEC cases; the more preterm the infant the higher the risk. By 36 weeks of gestation, there is a sharp decrease in incidence.
- Highest in infants with birth weights between 500 and 750 g (15%)
- Prevalence in infants weighing between 500 and 1,500 g is 7%.

RISK FACTORS

- The risk of NEC in full-term infants is ~10% of all cases. Risk factors include:
 - Cyanotic heart disease
 - Polycythemia
 - Exchange transfusions
 - Other coexisting conditions including hypothyroidism, Down syndrome, small bowel atresia, or gastrostochisis
- Perinatal asphyxia
- Small size for gestational age
- Umbilical catheters
- Maternal preeclampsia
- Antenatal cocaine abuse
- Use of IV antibiotics

GENERAL PREVENTION

- Modifying the feeding regimen, especially with using maternal breast milk exclusively, has been advocated.
- Also using a low-osmolar protein hydrolysate, high medium-chain triglyceride (MCT) fat formula has been reported to reduce the risk of developing NEC.
- The rate of feeding advancement and the timing of initiation of feedings has been explored and does not seem to consistently contribute to the development of NEC.
- Interventions to prevent bacterial proliferation (formula supplemented with IgA–IgG preparation, use of probiotics) and enhancing the intestinal maturity of the neonate have been used with some success.

- The use of probiotics has been shown to be effective in decreasing incidence for very-low-birth-weight (VLBW) infants. However, 1 recent multicenter trial has shown no change in overall mortality. Some studies have also raised concern of an increased risk of sepsis when using probiotics.
- There are some suggestions that the use of various growth factors, anticytokine agents, and glucocorticoids may have some benefit.

PATHOPHYSIOLOGY

- Varying degrees of inflammation early in the course cause superficial mucosal ulcerations and submucosal edema and hemorrhage, leading to transmural coagulation necrosis and perforation.
- NEC can be transmural in nature in the most severe cases.
- The most common sites for NEC include the terminal ileum, ileocecal region, and ascending colon.
- 50% of infants have both colonic and small intestine disease, whereas the other 50% is divided fairly equally between isolated ileal and colonic involvement.

ETIOLOGY

- The etiology of NEC is unknown but thought to be a multifactorial process.
- Various factors causing direct and indirect mucosal disruption, which in turn may lead to an increased permeability in the gut of agents that lead to injury, include the following:
 - Hypoxia/ischemia leading to mucosal injury
 - GI immaturity, immature host defense
 - Enteral feedings
 - Patent ductus arteriosus (PDA), indomethacin therapy
 - Bacteria within the GI lumen
- Enteral alimentation:
 - Because 95% of infants who develop NEC have been enterally fed, the act of initiation of feedings has been implicated as a possible cause of NEC.
 - The composition of the formula (osmolarity), the rate of volume increase, and the immaturity of the mucosa have all been implicated as factors that may increase the risk of NEC.
- Because of the frequent report of epidemic, cluster-type episodes, a variety of microorganisms has been implicated in the development of NEC:
 - In most cases, no identifiable organism is recovered, but at times, certain microbes, such as *Escherichia coli*, *Klebsiella*, *Salmonella*, and *Staphylococcus epidermidis*, have been recovered.
 - Blood cultures may be positive in 20–30% of cases.
- Immaturity of the GI mucosal defense system against invading organisms has been noted in NEC.
- PDA, indomethacin therapy:
 - Both the left-to-right shunt and mesenteric steal associated with PDA and the acute decreased blood flow associated with indomethacin therapy increase the preterm infant's risk for NEC.

DIAGNOSIS

ALERT

The major pitfall occurs when there is a delay in making the correct diagnosis and instituting appropriate therapy. This delay leads to a rapid progression of symptoms and usually a worse outcome.

PHYSICAL EXAM

- The triad of abdominal distention, heme-positive stools, and bilious emesis is frequently seen shortly after initiating enteral feedings.
- Perforation in the setting of other clinical symptoms is also indicative of NEC.
- The clinical spectrum varies dramatically from nonspecific symptoms of feeding intolerance and sepsis to severe abdominal distention and shock. An organized staging system that ranks the disease into 3 categories based on severity of the clinical signs and symptoms has been developed. The staging criteria can be used to formulate individual treatment plans according to the specific stage of NEC:
 - Stage I (suspected NEC):
 - Temperature instability
 - Apnea
 - Bradycardia
 - Lethargy
 - Cyanosis
 - Glucose instability
 - Increased gastric residuals
 - Emesis (may be bilious)
 - Abdominal distention
 - Heme-positive stools
 - Stage II (definitive NEC): Stage I plus:
 - Mild metabolic acidosis
 - Mild thrombocytopenia
 - Poor perfusion
 - Severe abdominal distention
 - Absent bowel sounds
 - Abdominal tenderness
 - Grossly bloody stools
 - Possible abdominal wall cellulitis, fullness/mass
 - Ascites
 - Stage III (advanced NEC): Stage I and II plus:
 - Shock/deterioration of vital signs
 - Metabolic acidosis
 - Thrombocytopenia
 - Disseminated intravascular coagulation (DIC)
 - Significant abdominal tenderness/peritonitis
 - Respiratory compromise
 - Neutropenia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

No single laboratory feature is diagnostic of NEC. Some laboratory findings that are important if present include:

- Thrombocytopenia
- Acidosis, metabolic
- Anemia
- Neutropenia
- DIC

Imaging

Abdominal radiographs will vary based on the stage of NEC:

- Stage I: Normal or possible mild dilatation of bowel loops
- Stage II:
 - Dilated loops
 - Loops may be fixed.
 - Pneumatosis intestinalis (presence of submucosal or subserosal air in the intestinal wall)
 - Possible portal venous gas
- Stage III: Likely pneumoperitoneum, free air

DIFFERENTIAL DIAGNOSIS

- Systemic:
 - Sepsis with ileus
 - Pneumothorax causing a pneumoperitoneum
 - Hemorrhagic disease of the newborn
 - Swallowed maternal blood
 - Postasphyxial bowel necrosis
- GI tract:
 - Volvulus
 - Malrotation
 - Pseudomembranous colitis
 - Hirschsprung colitis
 - Intussusception
 - Spontaneous bowel perforation
 - Stress ulcer
 - Meconium ileus
 - Milk protein allergy
 - Umbilical arterial thromboembolism

TREATMENT

Early recognition of the disease and rapid medical management of infants with NEC are critical to minimize the progression of this aggressive disease.

ADDITIONAL TREATMENT

General Measures

- Length of therapy and reinstitution of feedings tend to be based on the severity of the episode and on clinical, laboratory, and radiologic abnormalities.
- If the infant responds immediately to therapy and there are no laboratory or radiographic abnormalities, feedings may be started as early as 72 hours after the episode.
- If mild abnormalities arise and the patient remains only mildly ill, a 10-day course of therapy is considered.
- In cases in which laboratory and radiologic abnormalities include pneumatosis intestinalis, acidosis, and/or thrombocytopenia, a 14-day course is indicated.
- Overall, the best therapy for NEC is prevention.

SURGERY/OTHER PROCEDURES

- NEC is medically managed in 50–75% of infants.
- Surgical intervention is required in 25–50% of all cases.
- Indications include:
 - Pneumoperitoneum
 - Cellulitis of the anterior abdominal wall, abdominal mass
 - Suspicion of intestinal infarction with a fixed loop of dilated bowel over 24 hours on radiography
 - Metabolic acidosis unresponsive to medical therapy
 - Progressive respiratory failure

- The goal of any surgical procedure for the treatment of NEC is to remove all necrotic bowel and to preserve as much bowel length as possible. Different surgical approaches have been adopted with varying degrees of success and complications:
 - The most widely accepted procedure is laparotomy with resection of gangrenous intestine and exteriorization of all viable ends as stomas.
 - Primary anastomosis prevents the necessity of a 2nd procedure to reconnect the gut and establish intestinal continuity.
 - Patch, drain, and wait technique: The infant undergoes a laparotomy, and the major perforations are patched without resection.
 - Clip and drop-back technique can be used if there is extensive intestinal necrosis. Areas of obvious necrosis with perforation are resected, and the ends of the bowel are clipped or stapled closed.
 - Peritoneal drains at the bedside: Developed as a palliative procedure to decrease surgical morbidity and mortality in infants weighing <1,000 g. The purpose of peritoneal drains is to decompress the peritoneal cavity of gas, necrotic debris, and stool. Recent studies have shown that this approach has a higher overall mortality rate than initial laparotomy.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- For patients who develop NEC, therapy is based on the severity and progression of the symptoms.
- Initial management of all patients with suspected or proven NEC:
 - NPO status
 - IV fluids
 - Nasogastric (NG) tube placement for decompression
 - IV antibiotics: Broad spectrum
 - Total parenteral nutrition (TPN) to ensure adequate nutrition and growth
 - Severely ill patients may require hemodynamic support, acid-base regulation, and respiratory support.
- Evaluate every 6 hours to once a day, depending on the severity of the episode:
 - Blood and stool cultures
 - CBC, electrolytes, DIC screen
 - Fluid status
 - Abdominal radiograph

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Despite early recognition and intervention, NEC is associated with a significantly high morbidity and mortality.

DIET

- NPO
- TPN

PROGNOSIS

- Overall mortality for infants with NEC is between 20% and 40% but can be as high as 60% in patients with stage III NEC:
 - Related to the presence of bacteremia, low birth weight, and low gestational age
 - Results from perforation, sepsis, shock, and DIC
- Prognosis for infants surviving the acute stage of NEC is very good: 80–95% of infants who are discharged from their 1st hospitalization have a good long-term survival.

- Morbidity may be related to anemia, IV access difficulties, and the risk for infection: The other most common long-term sequelae seen in 15–35% of infants with NEC are intestinal strictures and short gut syndrome if the patient undergoes a lengthy surgical resection of bowel.
- Recent studies are showing some long term neuro developmental concerns. Infants recovering from NEC have a 25% risk of microcephaly and serious neuro developmental delays.

COMPLICATIONS

- A variety of complications may occur in infants with this disease process. In the acute setting, these include GI perforation, DIC, sepsis and shock, fluid and electrolyte imbalance, and respiratory failure.
- Complications related to long-term effects on the GI tract occur in 10–30%. These include the following:
 - Intestinal strictures
 - Acquired short bowel syndrome
 - Enterocolic fistulas
 - Malabsorption
 - Cholestasis
 - Anastomotic leaks
- Most common complication (10–35%) is intestinal stricture: Occurs mainly in the left colon

ICD10

P77.9 Necrotizing enterocolitis in newborn, unspecified

FAQ

- Q: What is the most common complication of NEC?
- A: Not recognizing the problem and the development of intestinal strictures
- Q: Is this preventable?
- A: The development of NEC is not clearly preventable, but clinicians should be careful to start feedings in extremely premature infants and use preferably breast milk or low-osmolar protein hydrolysate, medium-chain triacylglycerol (MCT) formulas.
- Q: Is NEC exclusively a process that occurs in the premature infant?
- A: ~10% of cases occur in full-term infants.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Kim Smith-Whitley

BASICS

DESCRIPTION

Neonatal alloimmune thrombocytopenia is analogous to hemolytic disease of the newborn.

EPIDEMIOLOGY

Incidence

- Occurs in 1 in every 1,000–5,000 live births, including 1st-born offspring
- Severe thrombocytopenia (platelet counts $< 50,000/\mu\text{L}$) caused by human platelet antigen (HPA)-1a antibodies occurs in 1 in 1,100 births.

GENERAL PREVENTION

Although the disease cannot be prevented, mothers of infants with neonatal alloimmune thrombocytopenia can be monitored and possibly treated during subsequent pregnancies. Recent studies support the use of intravenous γ -globulin with or without steroids for fetal alloimmune thrombocytopenia.

PATHOPHYSIOLOGY

Antibody-coated platelets in the fetus or newborn are destroyed at an increased rate.

ETIOLOGY

Caused by maternal antibodies directed against fetal platelet antigens, inherited from the father. IgG antibodies cross the placenta and enter the fetal circulation:

- The most common antigens responsible are HPA-1a (formerly PLA1), in $> 75\%$ of cases, HPA-5b (formerly Bra), and HPA-3 (formerly Bak); however, many other antigens can be responsible and vary in frequency according to ethnic group.
- Mothers who are HPA-1a negative and human leukocyte antigen (HLA)-DR3, -B8, or -DR52a positive form platelet antibodies at increased rates and are more likely to have severely affected neonates.
- Less commonly, maternal antibodies directed against fetal histocompatibility antigens may cause thrombocytopenia or neutropenia.

DIAGNOSIS

HISTORY

- Family history of bleeding disorders, particularly a history of thrombocytopenia or idiopathic thrombocytopenic purpura in the mother
- Medications used during pregnancy or in the newborn
- Infectious diseases in mother and/or newborn
- Affirmative answers to the following questions increase the likelihood of neonatal alloimmune thrombocytopenia in the thrombocytopenic newborn:
 - Is the mother's platelet count presently normal?
 - Has the mother had prior newborns with thrombocytopenia, neonatal alloimmune thrombocytopenia, or in utero intracranial hemorrhage?
 - Has the mother ever been told that she was HPA-1a or PLA1 negative?

PHYSICAL EXAM

- Most neonates with neonatal alloimmune thrombocytopenia are well appearing unless they have already experienced an intracranial hemorrhage.
- Skin and mucous membrane bleeding, petechiae, and ecchymoses are common findings.
- Less commonly, if significant hemorrhaging occurs, the following signs may be noted:
 - Irritability
 - Pallor
 - Lethargy
 - Focal neurologic deficits
 - Seizure
- If congenital anomalies, hepatosplenomegaly, or masses are present, causes of thrombocytopenia, other than immune mediated, should be investigated.

ALERT

Neonatal alloimmune thrombocytopenia is a difficult diagnosis to confirm and often requires expensive tests, the results of which are often not available to guide the acute management of the newborn; however, a complete workup is necessary for management of future pregnancies in the affected neonate's mother.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Low platelet count: $< 150,000/\mu\text{L}$, often $< 50,000/\mu\text{L}$ at birth
- Hemoglobin and hematocrit should be normal. Infants with low values may have experienced perinatal blood loss or could have active bleeding.
- WBC count should be normal in uncomplicated neonatal alloimmune thrombocytopenia.
- PT/PTT should be considered to evaluate for disseminated intravascular coagulation, particularly if the infant is ill-appearing or has a complicated prenatal and/or perinatal history.
- Maternal platelet count: Usually normal in neonatal alloimmune thrombocytopenia, but a normal maternal platelet count does not rule out autoimmune thrombocytopenia.
- Maternal serum for antiplatelet antibody analysis: To confirm the diagnosis of neonatal alloimmune thrombocytopenia, the antibody detected should be specific for a known platelet antigen.
- Maternal and paternal platelet antigen typing: Crucial for counseling regarding future pregnancies
- Newborn platelet antigen typing: Use only when absolutely necessary to make the diagnosis, as large amounts of blood may be required for this test. Molecular diagnostic methods require less sample.
- Consider urine and stool for detection of occult blood.

Imaging

Head ultrasound to rule out intracranial hemorrhages

DIFFERENTIAL DIAGNOSIS

- Infection: Primarily related to disseminated intravascular coagulation:
 - Bacterial: Sepsis
 - Viral: Congenital rubella or cytomegalovirus
 - Spirochetal: Syphilis
 - Protozoal: Toxoplasmosis
- Tumor/malignancy: Marrow disease (congenital leukemia, neuroblastoma)
- Metabolic: Methylmalonic or isovaleric acidemia
- Congenital:
 - Thrombocytopenia with absent radii syndrome
 - Wiskott-Aldrich syndrome
 - May-Hegglin anomaly
 - Hemangiomas with Kasabach-Merritt syndrome
- Immunologic:
 - Autoimmune neonatal thrombocytopenia: Primarily seen in infants of mothers with a history of idiopathic thrombocytopenia purpura
 - Infants of mothers with systemic lupus erythematosus
- Miscellaneous:
 - Catheter-associated thrombosis with increased platelet consumption
 - Renal vein and other large-vessel thromboses
 - Disseminated intravascular coagulation
 - Necrotizing enterocolitis

TREATMENT

General Measures

- Therapy primarily involves close monitoring for severe bleeding, including intracranial hemorrhage:
 - Daily platelet counts at minimum during the 1st several days of life
 - If significant bleeding occurs, the neonate should receive a platelet transfusion with the 1st available product, in order of preference:
 - Washed, irradiated maternal platelets
 - Irradiated platelets selected by cross-match with maternal serum
 - Irradiated PLA1-negative platelets
 - Irradiated random donor platelets: Often very limited success in increasing platelet count, as 98% of the US population is PLA1 positive
- Platelet transfusions, when needed, are usually required only once:
 - The treatment of severely thrombocytopenic neonates without evidence of significant bleeding is controversial because of the small but real risk of intracranial hemorrhages.
 - Often transfusions are performed at platelet counts of 20,000–30,000.
 - Other therapies have been reported with limited success, such as steroids, IV γ -globulin, and exchange transfusions.
 - Isolation of hospitalized patients is not required.
 - Head ultrasound to detect recent intracranial hemorrhage.
 - General avoidance of arterial and lumbar punctures.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The thrombocytopenia of neonatal alloimmune thrombocytopenia usually resolves within 3–4 weeks, but can be present for up to 12 weeks.
- Family counseling regarding management of future pregnancies after a thorough diagnostic evaluation is strongly recommended.

Patient Monitoring

If the thrombocytopenia persists after 3 months, other causes of thrombocytopenia should be investigated.

PROGNOSIS

- Overall prognosis is fair, as most patients will experience little morbidity or mortality associated with bleeding; however, the risk of bleeding is higher than in infants of mothers with idiopathic thrombocytopenic purpura, and reported mortality is 10% in some series.
- Most future pregnancies are equally or more severely affected, but this is controversial.

COMPLICATIONS

Abnormal bleeding: Primarily skin and mucous membrane bleeding, including but not limited to:

- Petechiae and ecchymoses: These lesions are progressive and not confined to areas of birth trauma, such as the head and shoulders.
- Prolonged bleeding from the umbilical stump, from phlebotomy sites, and/or at circumcision
- Cephalohematoma
- Hematuria
- GI bleeding
- Intracranial hemorrhages: Reported in 2–20% of cases; 50% of these occur in utero.

CODES

ICD9

776.1 Transient neonatal thrombocytopenia

ICD10

P61.0 Transient neonatal thrombocytopenia

FAQ

- Q: What is the HPA-1a- or PLA1-negative mother's risk of having other affected newborns?
- A: This depends on the genotype of the father:
 - If the father is homozygous for HPA-1a or PLA1, all offspring will be heterozygous PLA1 positive and at great risk for developing neonatal alloimmune thrombocytopenia.
 - If the father is heterozygous for HPA-1a or PLA1, 50% of offspring will be at risk for developing neonatal alloimmune thrombocytopenia.
- Q: What is the management of future pregnancies in mothers known to be HPA-1a or PLA1 negative?
- A: This depends on the risk of having an affected child and the clinical course of past affected children. Some perinatal monitoring and therapeutic techniques have shown limited success but not without risks. However, if the risk of having an affected child is high and the clinical course of prior affected newborns was associated with significant morbidity and/or mortality, consider the following perinatal management:
 - Percutaneous umbilical blood sampling for a platelet count
 - Maternal IV γ -globulin therapy
 - Maternal steroid therapy
 - Weekly intrauterine platelet transfusions
 - Early elective cesarean section to avoid birth trauma
- Q: Will the affected neonate be at increased risk for other bleeding problems later in life?
- A: If the neonate has confirmed neonatal alloimmune thrombocytopenia, there is no increased risk for bleeding problems later in life relative to the general population.

NEONATAL APNEA

Carl Tapia

BASICS

DESCRIPTION

- Apnea of infancy is the unexplained cessation of breathing for ≥ 20 seconds—or a shorter pause associated with cyanosis, pallor, bradycardia, hypoxia, or hypotonia—with an onset after 37 weeks' gestational age.
- Apnea of prematurity is an abrupt respiratory pause for ≥ 20 seconds, accompanied by desaturation and bradycardia, in an infant < 37 weeks' gestational age.
- Apnea has been traditionally classified into 3 categories:
 - Central: No evidence of upper airway obstruction
 - Obstructive: Obstructed upper airway, typically with respiratory effort, but no airflow
 - Mixed: Obstructed respiratory efforts, usually heralded by central pauses
- Periodic breathing is a normal neonatal breathing pattern, defined by ≥ 3 pauses, each ≥ 3 seconds, with < 20 seconds of regular respiration between pauses.
- Apparent life-threatening event (ALTE) is a sudden event that is frightening to the observer, and characterized by apnea, color change, change in tone, and/or gagging.

EPIDEMIOLOGY

- Apnea and bradycardia occur in $\sim 2\%$ of all healthy term infants.
- Apnea of prematurity is inversely correlated to gestational age. It occurs in $< 10\%$ of neonates 34–35 weeks' gestational age and in almost all neonates < 28 weeks' gestational age at birth.
- ALTE occurs in 2.4 per 1,000 live births.

RISK FACTORS

- Prematurity
- Respiratory syncytial virus (RSV) infection
- Sepsis
- Following pertussis vaccine administration
- Gastroesophageal reflux
- Fluctuating incubator temperatures
- Large patent ductus arteriosus
- CNS insult, such as hemorrhage, hypoxia, or seizures
- Head flexion during holding or sleeping
- Maternal medications, such as magnesium sulfate, prostaglandins, or narcotics
- Anemia

PATHOPHYSIOLOGY

- Immature chemoreceptors in the brainstem may be responsible for the decrease in respiratory drive, especially in response to hypoxia.
- Hypercapnia leading to decreased muscle tone and uncoordination of respiratory muscles may result in mixed apnea.
- Activation of laryngeal afferent nerves, as with gastroesophageal reflux, may result in glottal closure.
- Vagally mediated responses to hypoventilation have been suggested as the cause of bradycardia.

DIAGNOSIS

HISTORY

- Review the prenatal history for prematurity, birth weight, maternal tobacco or other substance use, and the immediate postpartum course. In breastfeeding infants, ask about maternal medications that might cause drowsiness, such as pain or anxiety medications.
- Relevant factors in the past medical history include prior ALTE, feeding and respiratory patterns, and history of seizure, breath-holding spells, reflux, foreign-body aspiration, cardiac disease, metabolic or endocrine disease, or food allergy.
- Evaluate for recent illness, fever, poor feeding, irritability, weight trends, recent vaccine administration, and sick contacts.
- Probe for evidence or suspicion of child maltreatment.
- Pertinent family history includes sudden infant death syndrome (SIDS), home tobacco use, previous infant deaths, congenital problems, and cardiac disease.
- The event should be reviewed in detail for location, timing and duration, associated respiratory effort, color change, infant position and tone, relation to feeding, and resuscitative measures used.

PHYSICAL EXAM

- Monitor vital signs for fever, respiratory effort, arrhythmia, and oxygen saturation.
- Evaluate for dysmorphic features, abnormal growth parameters, and distress.
- Cardiac exam for evidence of arrhythmia or heart failure
- Respiratory evaluation for cyanosis, breathing pattern and effort, wheezing, rales, and absent air sounds
- Complete neurological exam, with emphasis on abnormalities in tone or development
- Examine for signs of child abuse, including bruises, loop marks, belt marks, and other suspicious lesions.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential to look for infection or anemia
- Electrolytes, glucose, calcium, magnesium to evaluate for acidosis, dehydration, or metabolic disease
- Lactate level to evaluate for hypoxia, toxic ingestions which cause acidosis, or inborn errors of metabolism
- Liver function tests when hepatic dysfunction or severe hypoxia is a consideration
- Ammonia when an inborn error of metabolism or a liver disorder is suspected
- Arterial blood gas when acidosis is considered
- Blood culture if sepsis is suspected
- Urinalysis to evaluate for infection
- Urine drug screen when ingestion or overdose is a concern

Imaging

- Chest x-ray to evaluate for infection or cardiac disease
- Head CT or head ultrasound (if < 6 months old) to look for evidence of acute bleed if trauma or elevated intracranial pressure is suspected
- Head MRI, if indicated, to evaluate for congenital malformations
- Skeletal survey if child abuse is suspected

Diagnostic Procedures/Other

- EKG to evaluate arrhythmias or conduction problems
- Lumbar puncture if sepsis/meningitis is in the differential diagnosis
- Nasal aspirate for RSV if respiratory infections are considered
- Pertussis PCR, culture, and serology if suspected contact with pertussis, or a prolonged or paroxysmal cough
- Modified barium swallow if aspiration is suspected or if concerning event is associated with feeding
- Pneumography may be used when the diagnosis of apnea is uncertain. A 5-channel pneumogram records chest wall excursion, heart rate, EKG, pulse oximetry, and nasal airflow. A pH probe for gastroesophageal reflux or end-tidal CO_2 monitor may provide further information.

DIFFERENTIAL DIAGNOSIS

Although apnea of prematurity is very common, careful attention should be made for underlying illness or medical conditions. Apnea of infancy is uncommon and should warrant a thorough evaluation.

- Infections:
 - Respiratory illness, particularly due to RSV, pertussis, or pneumonia
 - Sepsis, urinary tract infection, necrotizing enterocolitis, or CNS infection
- Environmental:
 - Suffocation
 - Head injury
 - Child abuse
 - Hypothermia or hyperthermia
- Tumors:
 - CNS tumors, metastasis, or chest mass
- Neurologic:
 - Seizure
 - CNS bleeding
 - Brainstem malformation
 - Hydrocephalus
- Pulmonary/Airways:
 - Obstruction: Obstructive sleep apnea, nasal obstruction, airway obstruction, foreign-body aspiration
 - Breath-holding spells
 - Vocal cord abnormality
 - Laryngotracheomalacia
- Metabolic:
 - Inborn errors
 - Neuromuscular disease
 - Hypoglycemia or electrolyte disturbance

- Cardiovascular:
 - Congenital heart disease
 - Arrhythmia: Long QT syndrome, Wolff-Parkinson-White syndrome
 - Cardiomyopathy
 - Myocarditis
- GI:
 - Gastroesophageal reflux
 - Dysphagia or swallowing disorder
 - Intussusception
- Toxin/Drugs:
 - Overdose: Sedatives, seizure medications, pain medications

ALERT

Exclusion of specific causes should be performed before specific treatment for apnea is undertaken.

**TREATMENT****MEDICATION (DRUGS)**

- Theophylline and caffeine citrate have been the mainstays of treatment, but should be undertaken in consultation with a pulmonary or neonatal specialist. Caffeine has the advantage of a higher therapeutic index, lower toxicity, and once-daily dosing.
- Caffeine citrate is commonly administered as a 20 mg/kg bolus (IV or PO), followed by a once-daily dose of 5 mg/kg. The therapeutic range of caffeine is 5–25 mg/L. The alternative salt, caffeine benzoate, is not commonly used, as there is a theoretical risk of bilirubin displacement from albumin.
- Common side effects of theophylline and caffeine include tachycardia, arrhythmia, feeding intolerance, seizures, and diuresis.

ADDITIONAL TREATMENT**General Measures**

- Appropriate resuscitation and supportive care directed at underlying disease and presenting signs/symptoms
- Continuous positive airway pressure may decrease airway obstruction and improve oxygenation. Positive-pressure ventilation may be needed for severe or persistent apnea.
- Gastroesophageal reflux and apnea frequently coexist; however, there is little evidence that treatment of reflux has a beneficial effect on apnea of prematurity.
- Aggressively treating anemia does not seem to reduce the incidence of apnea of prematurity.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- A car seat challenge test should be considered for preterm infants with respiratory problems and all infants born at <37 weeks. Parents should be advised to use car seats only for travel and with careful supervision during the 1st few months of life.
- Home cardiorespiratory monitoring may be considered for premature infants at high risk for recurrent apnea, particularly infants with frequent bradycardia and short, but not apneic, respiratory pauses. Monitoring of these infants should be discontinued at 43 weeks' corrected gestational age or when episodes cease.
- Infants who are technology-dependent, have unstable airways, symptomatic chronic lung disease, and medical conditions affecting the regulation of breathing may also be candidates for home monitoring.

PROGNOSIS

- Most apnea of prematurity resolves by 36–40 weeks' corrected gestational age, although infants born at <28 weeks gestation often continue with apnea until 40 weeks' corrected gestational age. After 43–44 weeks' corrected gestational age, the rate of apnea for preterm infants is the same as for term infants.
- Large studies have not found apnea of prematurity to be a precursor or predictor of SIDS.
- The mortality rate for ALTE is between 0–4%. There may be an increased risk of SIDS in infants with apnea of infancy and ALTE.
- There is mixed evidence regarding the occurrence of neurodevelopment delay or behavioral disorders in infants with ALTE. One study found that ≥ 5 apneic events in infants who were home monitored were associated with lower developmental achievement at 1 year.

**CODES****ICD9**

- 770.82 Other apnea of newborn
- 786.03 Apnea
- 798.0 Sudden infant death syndrome

ICD10

- P28.2 Cyanotic attacks of newborn
- P28.3 Primary sleep apnea of newborn
- P28.4 Other apnea of newborn

FAQ

- Q: What recommendations should be given at discharge for neonates with apnea?
- A: Appropriate instruction in the supine sleeping position, a safe sleeping environment (adequate mattress size and removal of pillows and toys that represent a suffocation hazard), and tobacco cessation should be provided. Training in CPR/basic life support and monitor training should be provided.
- Q: What should be included in home monitoring training?
- A: When home monitoring is prescribed, families should be provided with realistic expectations (i.e., lack of efficacy regarding the prevention of SIDS), anticipated cessation of the monitor, and guidelines for intervention when the monitor alarms.
- Q: Should caffeine be given to prevent apnea?
- A: Caffeine is an effective treatment for apnea of prematurity, and recent evidence suggests its use may be beneficial in decreasing outcomes such as developmental delay and cerebral palsy. However, prophylactic caffeine in infants without apnea has not been well-studied, and the side effects likely outweigh any potential benefits.

NEONATAL CHOLESTASIS

Binita M. Kamath

BASICS

DESCRIPTION

- Neonatal cholestasis presents at or shortly after birth with the accumulation of bilirubin, bile acids, and cholesterol in blood and extrahepatic tissues. Neonatal cholestasis most often manifests with conjugated hyperbilirubinemia and jaundice. Any infant who is jaundiced beyond 2 weeks of life warrants further evaluation for neonatal cholestasis.
- Biochemical definition: Serum conjugated bilirubin > 2 mg/dL or > 15% of the total bilirubin concentration

EPIDEMIOLOGY

Estimated frequency of causes of neonatal cholestasis:

- Biliary atresia: 25–30%
- Idiopathic neonatal hepatitis: 15%
- α_1 -Antitrypsin deficiency: 7–10%
- Intrahepatic cholestasis syndromes (e.g., Alagille syndrome): 20%
- Infection: 3–8%
- Metabolic/Endocrine: 2–7%

Incidence

Overall incidence of neonatal liver disease is 1 in 2,500 live births

RISK FACTORS

Genetics

Genetics of biliary atresia, neonatal hepatitis, and most causes of neonatal cholestasis are unknown.

- α_1 -Antitrypsin deficiency:
 - Autosomal recessive
 - 10–15% of individuals with at risk genotypes (e.g., PIZZ) develop liver disease
- Alagille syndrome:
 - Autosomal dominant, variable expressivity
 - Caused by mutations in Jagged1 and Notch2
- Progressive familial intrahepatic cholestasis:
 - Autosomal recessive
 - Caused by mutations in FIC1, BSEP, and MDR3

PATHOPHYSIOLOGY

Cholestasis is defined physiologically as a reduction in bile flow. In infancy, bile flow is primarily dependent on the secretion of bile acids by hepatocytes. The hepatobiliary excretory system is functionally and structurally immature at birth, leaving the neonate vulnerable to cholestasis. In neonates, bile acid synthesis and secretion are impaired; in addition, there is inefficient enterohepatic bile acid cycling due to reduced expression of bile acid transport proteins.

ETIOLOGY

- Idiopathic neonatal hepatitis
- Cholestasis associated with infection:
 - Sepsis (especially urinary tract infection)
 - Congenital viral infections (cytomegalovirus, adenovirus, herpesvirus, coxsackievirus, echovirus, rubella, hepatitis B, HIV, parvovirus B19)
 - Toxoplasmosis
 - Listeriosis
 - Syphilis
 - Tuberculosis
- Biliary obstruction:
 - Biliary atresia
 - Choledochal cyst
 - Inspissated bile
- Other biliary disorders:
 - Neonatal sclerosing cholangitis
 - Alagille syndrome
 - Caroli disease
 - Congenital hepatic fibrosis
- Metabolic and genetic disorders:
 - α_1 -Antitrypsin deficiency
 - Cystic fibrosis
 - Tyrosinemia
 - Galactosemia
 - Neonatal hemochromatosis
 - Niemann-Pick disease
 - Gaucher disease
 - Bile acid synthetic defects
 - Progressive familial intrahepatic cholestasis
- Endocrine disorders:
 - Hypothyroidism
 - Panhypopituitarism
- Toxic:
 - Drugs
 - Total parenteral nutrition
- Vascular disorders:
 - Budd-Chiari syndrome
 - Perinatal asphyxia (shock)

COMMONLY ASSOCIATED CONDITIONS

- Biliary atresia (syndromic form):
 - Heterotaxy
 - Polysplenia
 - Malrotation
 - Congenital heart disease
- Alagille syndrome:
 - Cardiac lesions, typically peripheral pulmonary stenosis
 - Butterfly vertebrae
 - Posterior embryotoxon in the eye
 - Characteristic facies

DIAGNOSIS

HISTORY

- Pregnancy and birth history
- Family history
- Presence of extrahepatic anomalies
- Stool color
- Signs and symptoms:
 - Jaundice
 - Hepatomegaly
 - Splenomegaly
 - Rickets
 - For specific diagnoses:
 - Acholic stools in biliary obstruction (usually biliary atresia)
 - Characteristic facies, heart murmur in Alagille syndrome
 - Low birth weight, microcephaly, purpura, chorioretinitis in congenital infections
 - Irritability, poor feeding, lethargy in metabolic disorders

PHYSICAL EXAM

- Dysmorphic facial features
- Cardiac exam
- Hepatomegaly
- Splenomegaly

DIAGNOSTIC TESTS & INTERPRETATION

- Ophthalmologic evaluation (for chorioretinitis, posterior embryotoxon)
- Sweat chloride/cystic fibrosis mutation analysis

Lab

- Fractionated serum bilirubin (total and conjugated)
- Serum transaminases (alanine transferase, aspartate transferase)
- Alkaline phosphatase, gamma glutamyl transpeptidase
- Serum albumin
- Prothrombin time, partial thromboplastin time, INR
- Serum cholesterol and triglycerides
- CBC
- Bacterial blood culture
- Urine culture
- Serologies for infectious serologies (hepatitis B surface antigen [HepBsAg], TORCH [toxoplasmosis rubella cytomegalovirus herpes], Venereal Disease Research Laboratory [VDRL], HIV, other)

- Serum α_1 -antitrypsin level and PI type
- Metabolic screen (plasma and urine amino acids, urine organic acids, lactate/pyruvate)
- Red cell galactose-1-phosphate uridyl transferase (galactosemia)
- Urine succinylacetone (tyrosinemia)
- Thyroid function tests
- Serum iron and ferritin
- Serum and urine bile acids
- Genetic testing for Alagille syndrome
- Genetic testing for progressive familial intrahepatic cholestasis

Imaging

- Abdominal US
- Hepatobiliary scintigraphy
- X-rays of spine (for butterfly vertebrae)
- X-rays of skull and long bones (for congenital infections)

Diagnostic Procedures/Other

- Liver biopsy
- Percutaneous transhepatic cholangiogram
- Intraoperative cholangiogram
- Consider bone marrow exam (for storage disorders)

DIFFERENTIAL DIAGNOSIS

See "Etiology." Conjugated hyperbilirubinemia must be distinguished from physiologic or breast milk jaundice. Any infant who is jaundiced for > 14 days should have a total and conjugated hyperbilirubinemia measured to identify neonatal cholestasis.

ALERT

Certain causes of neonatal cholestasis require expedited management (potentially life-threatening if not treated quickly):

- Sepsis
- Biliary atresia
- Galactosemia
- Tyrosinemia
- Hypothyroidism

TREATMENT

MEDICATION (DRUGS)

- Ursodeoxycholic acid (choleretic)
- Vitamin E (antioxidant)
- Antihistamines, rifampin, cholestyramine (pruritus)
- Antibiotics or antivirals (congenital infections)

ISSUES FOR REFERRAL

All neonates with conjugated hyperbilirubinemia should be referred to a pediatric gastroenterologist. In cases of suspected biliary atresia, sepsis, or metabolic disease, referral should be prompt.

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Fat-soluble vitamin supplementation
- Water-soluble vitamin supplementation
- Milk thistle has been used in cholestasis, but its use is not validated.

SURGERY/OTHER PROCEDURES

- Kasai procedure (hepatportoenterostomy) for biliary atresia
- Surgical drainage (cholechoenterostomy) for choledochal cyst
- Biliary diversion for Alagille syndrome and PFIC

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Identify and treat coagulopathy with parenteral vitamin K.
- Identify and treat sepsis.

IV Fluids

Limit sodium intake in children with liver disease. Use D10 1/2 normal saline.

ONGOING CARE

DIET

- Aggressive nutritional support is vital. A hydrolysate formula with a high content of medium-chain triglycerides is better absorbed in cholestasis.
- Special diets:
 - Galactose-free (galactosemia)
 - Low tyrosine/phenylalanine (tyrosinemia)

PROGNOSIS

Dependent on etiology. Biliary atresia is the most common indication for pediatric liver transplantation.

COMPLICATIONS

- Growth failure
- End-stage liver disease (ascites, coagulopathy) and portal hypertension
- Fractures

- P78.89 Other specified perinatal digestive system disorders

NEPHROTIC SYNDROME

Rebecca Ruebner
Lawrence Copelovitch

BASICS

DESCRIPTION

Nephrotic syndrome (NS) applies to any glomerular disorder associated with nephrotic-range proteinuria, hypoalbuminemia, edema, and hypercholesterolemia. Nephrotic-range proteinuria is found when there is 3–4+ protein on the urine dipstick, which usually correlates with proteinuria of >40 mg/m²/hr or 50 mg/kg/d, or a spot protein-to-creatinine ratio >2 mg protein/mg creatinine.

EPIDEMIOLOGY

- Minimal change nephrotic syndrome (MCNS) is the most frequent cause of nephrotic syndrome in younger children:
 - Occurs mainly between 2–8 years, with a peak at 3 years.
 - Boys are more commonly affected than girls (3:2).
 - Atopy and minimal change nephrotic syndrome have an association.
- Focal segmental glomerulosclerosis (FSGS) is the 2nd most frequent cause of nephrotic syndrome in childhood:
 - Children with FSGS are more likely than children with MCNS to have steroid-resistant nephrotic syndrome (SRNS).
- Less common than MCNS and FSGS are congenital NS (<3 months) and infantile NS (<1 year).

Incidence

- 2–7 per 100,000 in children <16 years
- Black and Hispanic children have a higher incidence of FSGS than do white and Asian children.

Prevalence

16 per 100,000 in children <16 years

RISK FACTORS

- Risk factors for hypovolemia in NS:
 - Severe relapse, GI illness, diuretic use, or sepsis
- Risk factors for immunologic abnormalities that predispose to infection in patients with NS:
 - Defective opsonization, decreased serum levels of complement factors D and B, abnormal humoral immunity, decreased delayed hypersensitivity and proliferative responses, and increased suppressor-cell activity and suppressor lymphokine levels.
- Risk factors for thrombosis in patients with NS:
 - Hypovolemia, immobilization, thrombocytosis, increased platelet aggregability, urinary losses of protein C, protein S, and antithrombin III
- Risk factors for acute renal failure in patients with NS:
 - Hypovolemia, bilateral renal vein thrombosis, diuretics, or ACE inhibitors

Genetics

A positive family history is present in 3.5% of patients.

PATHOPHYSIOLOGY

- Disruption of podocyte architecture composing the glomerular filtration barrier leads to proteinuria, hypoalbuminemia, and subsequently edema.
- Hypercholesterolemia occurs due to increased liver production of cholesterol in response to hypoalbuminemia, as well as to loss of lipoprotein lipase in urine.
- Pathology MCNS:
 - The glomerular tuft and size are normal.
 - Mesangial expansion is absent or minimal.
 - Immunofluorescence is usually negative, although scanty staining for C3, IgM, and IgA may occasionally be found; these patients are usually steroid-dependent.
 - Electron microscopy reveals effacement of the visceral (podocyte) epithelial foot processes, which is reversible.

ETIOLOGY

- Most pediatric cases are primary; 5–10% are secondary to other diseases.
- The most common primary cause of NS in childhood is MCNS. It is characterized by minimal histologic changes on light microscopy and is usually a steroid-sensitive nephrotic syndrome (SSNS).
- Other causes of primary nephrotic syndrome include FSGS, membranous, and membranoproliferative glomerulonephritis (GN).
- Secondary causes of NS include infections, vasculitis, diabetes, drugs (e.g., NSAIDs), and hereditary disorders.
- Examples of congenital NS include Finnish type, diffuse mesangial sclerosis (DMS), and syphilitic nephrosis.
- NS can also be caused by inherited mutations in proteins involved in the podocyte cytoskeleton, which often results in steroid-resistant NS and FSGS.

DIAGNOSIS

HISTORY

- Inquire about known atopy or food intolerance.
- Inquire about drug exposure (especially NSAID agents).
- Inquire about any infections or hernias.
- Signs and symptoms:
 - Fatigue and general malaise
 - Reduced appetite
 - Weight gain and facial swelling
 - Puffy eyes
 - Abdominal swelling or pain
 - Foamy urine
 - Atopy
 - Pitting-dependent edema
 - Fluid accumulation in body spaces (ascites, pleural effusions, scrotal swelling)
 - White nails, lusterless hair, soft ear cartilage
 - Mild hypertension (10–20% of patients)

PHYSICAL EXAM

Look for edema in the most dependent area of the child:

- Legs
- Lumbar spine
- Scalp
- Soft ear cartilage
- Scrotum/labia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- The urine dipstick usually shows 2,000 mg/dL (4+) of protein:
 - In small children with NS, the urine dipstick may show $<4+$.
- Timed or spot urine protein collection:
 - 24-hour urine shows >50 mg/kg/d.
 - Spot urine protein/creatinine ratio is >2 .
- Microscopic hematuria in 10–20% of cases, but the presence of RBC casts more suggestive of glomerulonephritis
- Serum creatinine usually normal
- Serum albumin usually <2.5 g/dL
- Total cholesterol elevated, usually >200 mg/dL but can be as high as 500 mg/dL
- Home testing:
 - The 1st morning urine is tested for protein with urine dipsticks.

Imaging

In complicated cases, renal US to evaluate kidney size, parenchymal architecture, and renal venous thrombosis.

DIFFERENTIAL DIAGNOSIS

- Edema:
 - CHF
 - Liver failure
 - Protein-losing enteropathy
 - Protein energy malnutrition (Kwashiorkor)
- Minimal change nephrotic syndrome:
 - Focal glomerulosclerosis (FSGS)
 - Membranous GN
 - Membranoproliferative GN
 - Diffuse mesangioproliferative GN

TREATMENT

MEDICATION (DRUGS)

First Line

- Corticosteroids used as first-line therapy. There are a number of similar regimens:
 - On presentation: Daily corticosteroids for 4 weeks, followed by alternate-day therapy for 4 weeks, then taper over 3–6 months.
 - On relapse: Daily corticosteroids until in remission, followed by alternate-day therapy for 8–12 weeks

Second Line

- Alkylating agents (cyclophosphamide, chlorambucil)
- Mycophenolate mofetil (MMF)
- Calcineurin inhibitors (cyclosporine A, tacrolimus)
- Diuretics
- Albumin
- Rituximab

ALERT

- Live vaccines are contraindicated while daily corticosteroids or alkylating agents are being given.
- Children in relapse, on corticosteroids, or on alkylating agents and who are nonimmune and exposed to varicella should receive VZIG.
- Albumin and/or Lasix must be used cautiously to prevent fluid overload or intravascular dehydration.

ADDITIONAL TREATMENT

General Measures

- Influenza vaccination yearly
- Pneumococcal vaccination according to the “high-risk” schedule (23 valent pneumococcal vaccine)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- When to expect improvement:
 - Remission occurs 2–4 weeks after starting corticosteroids in MCNS.
- Signs to watch for:
 - Fever, abdominal pain, oliguria
- Pitfalls:
 - Recognize situations in which hypovolemia may occur.
- Monitor complications of glucocorticoid therapy:
 - Growth failure
 - Cataracts
 - Hypertension
 - Osteopenia
 - Steroid-induced gastritis

DIET

Restrict salt intake while in relapse or on daily corticosteroids.

PATIENT EDUCATION

Educate the family about urine testing, complications, diet, and therapy.

PROGNOSIS

- The prognosis for MCNS is excellent, with a mortality rate of <1%:
 - 90% of MCNS are steroid-sensitive.
 - 20–30% of MCNS never have relapse.
 - 40% of MCNS become steroid-dependent or frequent relapsers.
 - Remaining 30–40% MCNS have infrequent relapses.
- Patients with FSGS, genetic forms of NS, or other secondary causes are more likely to be steroid-resistant and may progress to develop chronic kidney disease.

COMPLICATIONS

- Most complications are secondary to steroid therapy and include growth retardation, glaucoma, posterior lens cataracts, obesity, mood changes, hirsutism, osteoporosis, and infection.
- Primary peritonitis and cellulitis may occur de novo or with steroid therapy.
- Diarrhea and vomiting may result in rapid, severe hypovolemia.
- Vascular thromboses are found with NS in relapse, especially if hypovolemia is present.
 - Sites of thrombosis include lower extremities, IVC, renal veins, cerebral sinuses, and pulmonary emboli.
- Viral infections (measles, varicella) may be life-threatening in immunocompromised patients.
- Acute reversible renal failure is an uncommon complication of NS of childhood.

CODES

ICD9

- 582.1 Chronic glomerulonephritis with lesion of membranous glomerulonephritis
- 581.3 Nephrotic syndrome with lesion of minimal change glomerulonephritis
- 581.9 Nephrotic syndrome with unspecified pathological lesion in kidney

ICD10

- N04.0 Nephrotic syndrome with minor glomerular abnormality
- N04.9 Nephrotic syndrome with unspecified morphologic changes
- N05.1 Unspecified nephritic syndrome with focal and segmental glomerular lesions

FAQ

- Q: Will the MCNS recur?
- A: The clinical course tends to be one of multiple remissions and relapses. Relapses usually stop about the time of puberty.
- Q: Can the NS return in adult life?
- A: Yes. This does occur.
- Q: Is macroscopic hematuria ever found with MCNS?
- A: Gross hematuria suggests a renovascular event or a diagnosis other than MCNS. Microscopic hematuria occurs in ~10–20% of cases.
- Q: What other agents are used to treat NS?
- A: Cyclosporin A, tacrolimus, mycophenolate mofetil (MMF), cyclophosphamide, and ACE inhibitors/angiotensin receptor blockers are used in children with steroid-dependent or -resistant NS.

NEURAL TUBE DEFECTS

Sabrina E. Smith

Dennis J. Dlugos

BASICS

DESCRIPTION

Neural tube defects (NTD) include clinical and subclinical defects resulting from failure of neural tube closure between the 3rd and 4th weeks of gestation. NTDs include anencephaly, encephalocele, myelomeningocele, meningocele, and occult spinal dysraphism. The latter 3 are different types of spina bifida.

GENERAL PREVENTION

- Folic acid supplementation in early pregnancy can reduce the incidence of NTDs by 50% in the general population and by 70% in women with a history of NTD in a previous pregnancy.
- Because many pregnancies are not discovered until after the 4th week of gestation, when neural tube closure occurs, the Centers for Disease Control and Prevention (CDC) recommend that all women of childbearing age receive a minimum of 0.4 mg of folic acid daily.
- The American Academy of Pediatrics recommends that women with a history of NTD in a previous pregnancy receive 4 mg of folic acid daily, starting 1 month before and through the first 3 months of pregnancy.
- Women on anticonvulsants and other medications linked to NTDs may benefit from receiving 4 mg (high-risk dose = 4,000 mcg) of folic acid daily.

EPIDEMIOLOGY

Prevalence

- 1 in 1,000 live births in the US (not including occult defects, for which no accurate epidemiologic data are available)
- Anencephaly: 3.7 in 10,000
- Encephalocele: 1.4 in 10,000
- Spina bifida: 5.5 in 10,000
- Myelomeningocele: 2–4 in 10,000

RISK FACTORS

Genetics

- Most cases are due to a combination of genetic, environmental, and dietary factors. Numerous candidate genes have been studied with mixed results. A chromosomal or gene abnormality can be identified in ~10% of children with NTDs, and this number increases if there are multiple congenital anomalies.
- Some recent studies suggest that the 677C > T mutation in the methylenetetrahydrofolate reductase gene in mother or child is associated with increased risk of NTDs, though other studies have not confirmed this association.
- 5% of patients are born to a couple with a family history of NTD.
- After 1 child with NTD, the recurrence rate is 2–4% for subsequent pregnancies.

PATHOPHYSIOLOGY

- Neural tube closure begins midway along the neural axis, spreads like a zipper in both rostral and caudal directions, and is completed in a few days.
- Failure of neural tube closure most often occurs in the lumbosacral region.

ETIOLOGY

- Genetic
- Maternal folic acid deficiency
- Gestational diabetes
- Maternal obesity
- Maternal hyperthermia during days 20–28 of gestation
- Use of valproic acid, carbamazepine, or alcohol during pregnancy

COMMONLY ASSOCIATED CONDITIONS

The defect itself may be only the tip of the iceberg, because the malformation may involve the entire central nervous system:

- Disorganized brain stem nuclei or brain stem herniation (Chiari II malformation) occurs.

DIAGNOSIS

HISTORY

- Thorough health history: NTDs are associated with maternal folic acid deficiency, gestational diabetes, maternal obesity, maternal hyperthermia during days 20–28 of gestation, and use of valproic acid, carbamazepine, or alcohol during pregnancy.
- Activity and development:
 - Occult frontal encephaloceles may come to attention because of a history of developmental delay, seizures, or focal neurologic signs.
 - Occult spinal dysraphism presents with lower extremity weakness or sensory loss, gait abnormalities, bowel and bladder dysfunction, foot deformities, and (rarely) recurrent meningitis.

PHYSICAL EXAM

- Plot head circumference as a marker of developing hydrocephalus.
- Look for evidence of dysmorphic features: May indicate a syndrome.
- Check for integrity of the skin covering the defect, because this affects the timing of surgical intervention. A bony defect or sinus may be palpable in occult cases.
- Neurologic exam of the lower extremities in a myelomeningocele outlines the functional level of the lesion and can indicate ambulatory potential: Intact hip flexion (L1–L2) and knee extension (L3–L4) are favorable signs for future ambulation.
- Flaccid paralysis is present below the level of the lesion, and limb growth may be asymmetric:
 - Sensory level may not correspond to motor level.
 - Cranial neuropathies, such as strabismus, laryngeal paresis, and stridor, may be present at birth or may develop in the first months of life.
- Local signs of occult spinal dysraphism include a dimple, sinus, lipoma, skin pigment change, or tuft of hair in the lumbosacral area.
- Examination may show foot deformities, tight heel cords, unequal leg or foot length, decreased sphincter tone, lower extremity weakness, or sensory changes.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Maternal serum alpha fetoprotein (MSAFP) testing, done at 16–18 weeks' gestation, can identify 88% of cases of anencephaly and 79% of cases of myelomeningocele.

Imaging

- Ultrasonography:
 - Reveals >99% of cases of anencephaly and 90% of cases of myelomeningocele
- Encephalocele is more likely to be detected by ultrasound than by MSAFP testing.
- Serial cranial ultrasounds or CT scans can evaluate hydrocephalus, which can occur without rapid head growth in patients with NTDs.
- MRI for other brain anomalies, including areas of cortical dysplasia, found in 92% of patients in one neuropathologic study
- Suspected occult spinal dysraphism (often asymptomatic):
 - Incidentally noted on spine radiographs
 - Ultrasound (in the newborn period)
 - CT scan provides more detail of bony anatomy and MRI more detail of spinal cord anatomy.

Diagnostic Procedures/Surgery

- EEG for suspected seizures
- Urodynamic evaluation should be performed in all children with myelomeningocele to anticipate/prevent renal damage owing to reflux.

DIFFERENTIAL DIAGNOSIS

Diagnosis reflects the embryogenesis and anatomy of each defect:

- Anencephaly results from failure of anterior neural tube closure:
 - The diagnosis is obvious at birth.
 - The cerebral hemispheres, basal ganglia, and variable amounts of the upper brain stem are absent.
 - 75% are stillborn; the remainder die in the neonatal period.
- Encephalocele reflects partial failure of anterior neural tube closure:
 - Abnormal brain tissue protrudes through a skull defect usually covered by skin.
 - 70–80% are occipital, 20% are frontal.
 - 10–20% of occipital defects are meningoceles and contain no brain tissue.
 - Frontal encephaloceles, unless accompanied by craniofacial abnormalities, may not be identified unless a neuroimaging study is performed for an associated symptom (such as developmental delay or seizures).
- Myelomeningocele is a failure of posterior neural tube closure:
 - Abnormal neural tissue protrudes through a vertebral column defect.
 - 80% are thoracolumbar, lumbar, or lumbosacral.
 - By definition, this is an open defect, and the diagnosis is obvious at birth.

- Occult spinal dysraphism: Intact skin over the defect:
 - Wide spectrum of defects includes dermal sinus tracts, cysts, lipomas, other tumors, diastematomyelia (bifid spinal cord), and tethered spinal cord.
- Non-neural congenital defects suggest syndromic basis (e.g., telecanthus [Waardenburg syndrome]; heart defect [chromosome 22q11 deletion]).

TREATMENT

ADDITIONAL TREATMENT

Initial Stabilization

- Acute hydrocephalus from shunt failure or tethered spinal cord from occult spinal dysraphism may arise later in life.

General Measures

- Route of delivery:
 - For most patients with NTDs who do not undergo fetal surgery and have vertex presentation, no clear benefit of cesarean delivery
 - One study demonstrated improved neurologic outcome in patients delivered via cesarean.
 - Infants who undergo fetal surgery must be born via cesarean delivery.
- Infants with high bladder pressure may be treated with anticholinergics and clean intermittent catheterization.

SURGERY/OTHER PROCEDURES

- Fetal closure of a myelomeningocele has been associated with reduced risk of hydrocephalus and improved mental development and motor outcomes in one prospective randomized trial.
- Fetal surgery should be considered in selected patients prior to 26 weeks' gestational age. In patients for whom fetal surgery is not an option, urgent stabilization in the newborn period should be provided, followed by prompt neurosurgical closure:
- Neurosurgical closure of a myelomeningocele is indicated within the first few days of life to prevent infection. Closure of the defect in the first hours of life is not necessary; keep defect clean and moist:
 - An encephalocele with adequate skin covering can be repaired less urgently.
- Ventriculoperitoneal shunts should be placed in infants with hydrocephalus; early shunting may improve cognitive outcome.

ONGOING CARE

- Multidisciplinary approach may include primary pediatrician, neurosurgeon, urologist, orthopedist, neurologist, physiatrist, and others.
- Anticipation of skin breakdown, decubitus ulcers, and leg injuries is important.
- Loss of motor or bladder function, pain, spasticity, or scoliosis may indicate tethered cord.

ISSUES FOR REFERRAL

Occult spinal dysraphism is most often benign/asymptomatic, but if there are possible neurologic signs or symptoms patient should be referred to neurosurgery for evaluation.

PROGNOSIS

- Anencephaly is uniformly fatal.
- Encephalocele: Prognosis is largely dependent on the size of the defect, the amount of brain tissue contained within the sac, and any associated brain malformations.
- Myelomeningocele:
 - Prognosis for ambulation depends on the location of the lesion: The lower the lesion, the more likely the patient will ambulate:
 - Most with sacral lesions can ambulate; 95% of adolescents and 40% of younger children with low lumbar lesions will ambulate; 30% of adolescents with high lumbar or thoracic lesions will ambulate.
 - ~80% of children with myelomeningocele will have a neurogenic bladder (urodynamic testing). The goal of therapy is urinary continence and control of high bladder pressure.
- Bowel programs involve high-fiber, low-fat foods; enemas; stool softeners; and biofeedback.
- ~60% of children with encephalocele and 80–85% with myelomeningocele are of normal intelligence.
- Risk of epilepsy corresponds to degree of mental retardation; high with frontal encephaloceles.

COMPLICATIONS

- Encephalocele:
 - Hydrocephalus (50%)
 - Intellectual deficits (40%)
 - Motor and cognitive deficits
 - Seizures likely owing to dysplastic cortex surrounding the encephalocele
- Myelomeningocele:
 - Hydrocephalus (80% with postnatal treatment vs. 40% with fetal surgery)
 - Chiari II malformation (80%), potential feeding difficulties, stridor, and apnea due to lower cranial nerve dysfunction
 - Neurogenic bladder (80%): Risk of renal damage
 - Orthopedic deformities; seizures (25%)
 - Below-average intelligence (15–20%)
 - Tethered spinal cord later in childhood
- Occult dysraphism:
 - Progressive lower extremity motor or sensory deficit
 - Sphincter dysfunction
 - Foot deformities
 - Scoliosis

Patient Monitoring

- The neurologic status of a patient with a repaired NTD should remain stable. Have a high index of suspicion for worsening hydrocephalus, syringomyelia, and tethered spinal cord.
- Tethered cord may accompany occult dysraphism and is a surgically treatable cause of cauda equina syndrome in young children.
- Vocal cord paralysis may appear episodically, resembling croup, in children with myelomeningocele.

OTHER

Patient Information:
Spina Bifida Association of America Web site:
<http://www.sbaa.org>

CODES

ICD9

- 740.0 Anencephalus
- 742.0 Encephalocele
- 742.8 Other specified congenital anomalies of nervous system

ICD10

- Q00.0 Anencephaly
- Q01.9 Encephalocele, unspecified
- Q07.9 Congenital malformation of nervous system, unspecified

FAQ

- Q: Will my child have learning problems?
- A: At least 80% of those with myelomeningocele have normal intelligence. Cognitive outcome appears improved with early shunting of hydrocephalus.
- Q: Could my baby have other problems besides neurologic problems?
- A: Infants with NTDs need to be checked periodically for signs of bladder problems. Some develop problems with control of eye movements (strabismus), but this is often correctable.
- Q: Should I stop taking anticonvulsants during pregnancy to reduce my risk of NTDs?
- A: Not unless your doctor recommends doing so. In general, continuing the lowest dose of the medicine that best controls your seizures is recommended during pregnancy. There are risks to the fetus from poorly controlled seizures during pregnancy. The overall risks and benefits of medications must be weighed. Any woman of childbearing age who is taking anticonvulsants should receive folic acid supplementation.

NEUROBLASTOMA

Edward F. Attiyeh

BASICS

DESCRIPTION

- Neuroblastoma is the most common extracranial solid tumor of childhood and the most common malignancy of infancy.
- It is derived from neural crest cells and can arise anywhere along the sympathetic chain of the peripheral nervous system, most commonly in the adrenal medulla.
- Neuroblastoma has the highest rate of spontaneous regression of any human malignancy; however, in most cases, it is one of the most aggressive cancers of childhood.
- Neuroblastoma should be distinguished from ganglioneuroma and ganglioneuroblastoma, which show features of differentiation or maturation.
- The International Neuroblastoma Staging System (INSS) is the current staging system:
 - Describes localized tumors (stages 1 and 2), more extensive primary tumors (stage 3), and metastatic tumors (stage 4)
 - Stage 4S (“Special”) describes a distinct group of infants <365 days old who have a small primary mass with dissemination limited to the liver, skin, and/or <10% of the bone marrow.
- Risk grouping relies on patient age, tumor stage, MYCN amplification status, Shimada histopathology status, and tumor ploidy. In general:
 - Low-risk groups have localized disease and do not have MYCN amplification.
 - High-risk groups have disseminated disease (often involving the bones, bone marrow, liver, and/or skin) as well as unfavorable biologic characteristics (e.g., MYCN amplification).

EPIDEMIOLOGY

- Most children are <5 years of age at diagnosis.
- ~50% of children have disseminated disease at diagnosis.
- Male:female ratio 1.1:1
- More common in whites
- Most primary tumors are in the abdomen.

Incidence

About 800 new cases per year in the US (10 per million children per year)

Prevalence

Neuroblastoma accounts for ~7–10% of all childhood cancers.

RISK FACTORS

Genetics

- Neuroblastoma can rarely (~1%) show a genetic predisposition (autosomal dominant with variable penetrance).
- Most are due to inherited mutations of the *ALK* tyrosine kinase.
- Also associated with congenital central hypoventilation syndrome and *PHOX2B* mutations

PATHOPHYSIOLOGY

- One of the “small round blue cell” tumors of childhood
- Tumor growth causes mass effect:
 - Nerve/cord compression
 - Renal artery stenosis
- Bone metastases cause pain. Characteristic involvement of the bony orbit
- Bone marrow metastases may cause cytopenias.
- Amplification of the *MYCN* protooncogene is present in ~20% of tumors.
- There has not been a tumor suppressor gene identified: Many candidate tumor suppressor genes may lie in genomic regions frequently lost in neuroblastomas (e.g., 1p, 3p, and 11q).

ETIOLOGY

No known etiology or causative environmental exposures

COMMONLY ASSOCIATED CONDITIONS

- Neuroblastoma has been found to occur along with:
 - Neurofibromatosis type I
 - Hirschsprung disease
 - Central congenital hypoventilation syndrome
- This suggests that a dysregulated development of the peripheral nervous system may play a role in neuroblastoma initiation.

DIAGNOSIS

HISTORY

- General appearance, activity level, appetite:
 - Patients with localized, low-risk disease may be very well-appearing (i.e., tumor is an incidental finding on imaging study).
 - Patients with disseminated, high-risk disease typically appear ill.
- Based on tumor location:
 - Thoracic:
 - Chest pain
 - Cough
 - Respiratory distress
 - Abdominal:
 - Pain
 - Swelling
 - Bone marrow:
 - Fatigue (anemia)

PHYSICAL EXAM

- Presenting signs and symptoms depend on the primary site of the tumor and the degree of dissemination.
- Abdomen:
 - Abdominal mass is usually firm, fixed, and irregular and often crosses the midline.
 - Abdominal distention with or without tenderness
 - Signs of bowel obstruction: Anorexia, vomiting, low stool output
 - Hypertension (renal artery compression)
 - Genital and lower extremity edema from obstruction of venous and lymphatic drainage

- Cervical/thoracic mass (posterior mediastinal):
 - Respiratory distress or stridor with thoracic masses
 - Horner syndrome with cervical or high thoracic masses: Ptosis, myosis, and anhidrosis
 - Superior vena cava syndrome with large mediastinal tumors
- Paraspinal mass:
 - Vertebral body involvement and nerve root compression
 - Bladder and bowel dysfunction, paraplegia, and back pain secondary to spinal cord compression
- Metastatic disease:
 - Liver: Hepatomegaly
 - Bone:
 - With or without bony pain
 - Periorbital ecchymoses
 - Proptosis
 - Bone marrow:
 - Cytopenias
 - Pain from marrow expansion
 - Lymph nodes: Adenopathy
 - General:
 - Fever
 - Irritability
 - Failure to thrive

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC: Decreased hemoglobin, platelets, and/or WBC counts may indicate bone marrow involvement.
- Electrolytes, liver function tests, and renal function tests in anticipation of starting chemotherapy
- Urine catecholamine metabolites are typically elevated: Homovanillic acid (HVA) and vanillylmandelic acid (VMA).

Imaging

- Generally an ultrasound or CT scan of the suspected primary tumor site (MRI may be necessary for paraspinal tumors): Calcification suggests neuroblastoma.
- Metaiodobenzylguanidine (MIBG) scan:
 - MIBG is taken up by 90% of neuroblastomas.
 - Radioisotope-labeled MIBG can detect both bone and soft tissue involvement.
- Bone scan to evaluate for bony metastasis: Only necessary if the tumor is not MIBG avid

Diagnostic Procedures/Other

- Tumor biopsy
- Bilateral bone marrow aspirates and biopsies

DIFFERENTIAL DIAGNOSIS

- Abdominal masses:
 - Wilms tumor
 - Lymphoma
 - Germ cell tumor
 - Hepatoblastoma
 - Pancreaticoblastoma

- Thoracic masses:
 - Lymphoma (usually non-Hodgkin)
 - Leukemia with bulky disease
 - Germ cell tumors
- “Small round blue cell tumors”:
 - Non-Hodgkin lymphoma
 - Ewing sarcoma
 - Peripheral primitive neuroectodermal tumors (PNETs)
 - Rhabdomyosarcoma

TREATMENT

MEDICATION (DRUGS)

- Multiagent chemotherapy typically includes a combination of vincristine, doxorubicin, cyclophosphamide, cisplatin, carboplatin, etoposide (VP-16), and/or topotecan.
- High-dose myeloablative chemotherapy is followed by autologous stem cell transplant.
- 13-cis-Retinoic acid induces differentiation of neuroblastoma cells and improves patient survival following stem cell transplant.
- Immunotherapy with antibodies directed against GD2, which is present on most neuroblastoma cells

ADDITIONAL TREATMENT

General Measures

Treatment protocols are based on risk classification:

- Patients with low-risk disease, such as stage 1 or 4S with favorable biologic features, may undergo spontaneous regression or only require surgery.
- Patients with intermediate-risk disease receive 2–8 cycles of outpatient chemotherapy.
- Patients with high-risk disease, such as stage 4 or MYCN amplified, receive a combination of surgery, high-dose chemotherapy requiring stem cell rescue, radiation therapy, and biologic response modification therapy.

Additional Therapies

Radiotherapy

- Radiation therapy is used for control of local disease or for palliation.
- Total-body irradiation may be part of high-dose therapy prior to stem cell transplant.

SURGERY/OTHER PROCEDURES

- Total surgical resection at the time of diagnosis may be attempted but not if it would involve significant morbidity.
- Neoadjuvant chemotherapy results in smaller tumors that make a future resection attempt more straightforward.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Referral to a pediatric oncologist is essential before any diagnostic procedures or therapeutic interventions.

Patient Monitoring

- On therapy:
 - Frequent laboratory evaluations to monitor for effects of chemotherapy:
 - Marrow suppression
 - Organ toxicity
 - Disease re-evaluation prior to surgery or stem cell transplant:
 - Imaging
 - Bone marrow evaluation
- Off therapy:
 - Close follow-up for disease recurrence for 2–3 years after completion of therapy:
 - Imaging of site of primary tumor
 - Urine catecholamine metabolites
 - Late effects of chemotherapy and radiation therapy require close monitoring.

PROGNOSIS

- Adverse prognostic factors:
 - Age > 18 months
 - Advanced stage (especially stage 4 metastatic disease)
 - MYCN amplification (very powerful marker of poor outcome)
 - Unfavorable histology
 - Diploid tumor genome (primarily infants)
 - Loss of heterozygosity at chromosome arms 1p or 11q
- These factors stratify children at diagnosis as low, intermediate, or high risk of relapse. These risk groups predict survival:
 - Low- and intermediate-risk patients have excellent outcomes (> 80–90% survival).
 - High-risk patients have poorer outcomes (30–50% survival) despite aggressive therapy.

COMPLICATIONS

Paraneoplastic syndromes:

- Vasoactive intestinal peptide (VIP) syndrome:
 - Neuroblastoma may secrete VIP, which causes watery diarrhea, abdominal distention, and electrolyte imbalances.
 - Usually resolves with removal of tumor
- Opsoclonus-myoelonus-ataxia (2–4%):
 - Chaotic eye movements (dancing eyes) and myoclonic jerks (dancing feet) with or without cerebellar ataxia
 - Up to 80% of patients have long-term neurologic deficits.
 - Likely due to autoimmune effect of antineural antibodies
 - Specific therapies: High-dose steroids and intravenous immunoglobulin (IVIG).
- Symptoms of catecholamine excess are rare.

CODES

ICD9

- 194.0 Malignant neoplasm of adrenal gland
- 195.1 Malignant neoplasm of thorax

ICD10

- C74.90 Malignant neoplasm of unspecified part of unspecified adrenal gland
- C74.91 Malignant neoplasm of unspecified part of right adrenal gland
- C74.92 Malignant neoplasm of unspecified part of left adrenal gland

FAQ

- Q: Are siblings of children with neuroblastoma at increased risk for neuroblastoma compared with the general population?
- A: No, except in rare families with a known history of neuroblastoma (< 1%).
- Q: Can neuroblastoma spontaneously regress?
- A: Yes, but this is usually seen only in children < 1 year of age with lower-stage disease or in infants with stage 4S disease.
- Q: What are the biggest risks during therapy?
- A: As with all intensive chemotherapy regimens, the risk of infection is high. This is especially true during the autologous stem cell transplant phase.
- Q: What therapy is available to patients who either fail to go into remission or relapse following aggressive therapy?
- A: There is no curative therapy after disease recurrence in high-risk neuroblastoma. However, the disease can be controlled with phase 1 or 2 therapies for many years, which allows patients to maintain a good quality of life.

NEUROFIBROMATOSIS

Leah Burke

Sunil Thummala

BASICS

DESCRIPTION

- Neurofibromatosis (NF) types 1 and 2 are multisystem neurocutaneous autosomal dominant genetic conditions. NF1 (Von Recklinghausen disease) is diagnosed based on the presence of any 2 of the following from National Institutes of Health (NIH) diagnostic criteria:
 - 2 or more cutaneous neurofibromas or 1 plexiform neurofibroma
 - 2 or more Lisch nodules
 - Inguinal or axillary freckling
 - 6 or more (smooth-edged) café au lait spots, at least 1.5 cm in diameter in postpubertal individuals or 0.5 cm in diameter in prepubertal individuals
 - Optic nerve glioma
 - Osseous lesions, including sphenoid wing dysplasia, pseudoarthrosis
 - A 1st-degree relative (parent, sibling, or offspring) with NF
- Approximately half of sporadic NF1 patients fail to meet NIH criteria by 1 year of age
- Tumors may be cosmetically disfiguring and physically limiting; 5–13% of plexiform neurofibromas undergo sarcomatous transformation.
- NF2 is 10 times less common than NF1 and is characterized by bilateral vestibular schwannomas, intracranial and spinal meningiomas, and cutaneous schwannomas.

EPIDEMIOLOGY

Incidence

- NF1: 1 in 2,700 live births
- NF2: 1 in 33,000 live births

Prevalence

- NF1: 1 in 4,560
- NF2: 1 in 56,161

RISK FACTORS

Genetics

- 50% of the cases are inherited; others occur as sporadic (new) mutations.
- One of the most commonly inherited autosomal dominant disorders, with no known gender or ethnic predisposition
- Penetrance is complete; however, expression is variable.
- *NF1* gene, which codes for neurofibromin, is located on chromosome 17q11.2.
- Expression varies widely within and among families, from mildly affected to severely impaired.
- Course impossible to predict; relative's disease cannot predict disease course in a patient.

COMMONLY ASSOCIATED CONDITIONS

- Hypertension
- Headache, brain tumor, cerebrovascular dysplasia
- Sarcoma, CML, Wilms tumor, pheochromocytoma
- Short stature, scoliosis, osteoporosis, thin long bones

DIAGNOSIS

HISTORY

- "Positive family history": Affecting a 1st-degree relative, mother, or father of the proband: 100% penetrance
- Vision: Optic pathway tumors (OPTs) generally occur between the ages of 2 and 6 years.
- Development: Speech delay, motor incoordination, learning problems and attention deficit hyperactivity disorder (ADHD), >50%
- Seizures: Twice as common in NF1 than in general population
- Joint/extremity pain: Neuropathic pain or abrasion due to neurofibroma
- Back pain: Could signal potentially serious cord or root compression
- Headache: Hydrocephalus; migraine also common in NF
- Neurofibromas may encroach on the airway
- Aberrant sexual development, abnormalities due to hypothalamic disease, psychiatric/behavioral symptoms, and depression are common.
- NF2 patients: Hearing loss, visual impairment, skin lesions

PHYSICAL EXAM

- Macrocephaly
- Café au lait spots are noted at birth or within the 1st year of life:
 - Macules are generally flush and circular, although they may have jagged edges or areas of hypertrichosis.
 - Café au lait spots result from a collection of heavily pigmented melanocytes of neural crest origin in the epidermis.
 - The macules will appear for the 1st 5 years of life and then slow or stop, although they will grow with the child.
- Axillary and inguinal freckling is generally seen by puberty. The freckling is a cluster often seen in the skinfolds.
- Lisch nodules are best assessed by slit-lamp examination:
 - Small bumps on the iris that do not interfere with vision
 - They are uncommon during infancy, but by age 20, 99% of patients with NF1 have Lisch nodules.
- OPTs are present in 20% of patients with NF1, although only ~20% of those will require intervention:
 - Funduscopy and acuity check for evidence of OPT
 - Treatment should be limited to those patients who have uncorrectable visual acuity, a change in visual fields, and/or endocrine abnormalities, or to those lesions that extend to the hypothalamus.

- Bony dysplasias occur in ~3% of patients with NF1:
 - Dysplasias especially affecting the tibia or the sphenoid wing
 - A pseudoarthrosis: Due to thinning of the long bone and its inability to heal after it breaks
- Hypertension
- Review of palpable tumors for extension or "stony" feel that could signal cancerous change
- Abdominal exam for masses
- Neck and spine palpation/mobility
- Reflexes for evidence of nerve root tumor
- Growth parameters (including head circumference) for evidence of hydrocephalus, hypothalamic disturbance
- Scoliosis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Urine catecholamines for pheochromocytoma

Imaging

- MRI brain:
 - Bright areas in cerebral white matter on T2-weighted MRI images are common in NF1, and their clinical significance is uncertain.
 - Indications for neuroimaging depend on findings such as progressive macrocephaly, sensory deficits (especially visual), new-onset seizure, chronic headaches, and hearing deficit (NF2).
- Renal studies may be indicated for persistent hypertension or difficulty with urine flow.

Diagnostic Procedures/Other

In most cases, the diagnosis of NF1 remains a clinical diagnosis. Radiologic tests to identify complications (see below)

- DNA testing has become more available and therefore may be useful in atypical cases or in making reproductive choices:
 - DNA-based testing of the NF1 gene is undertaken in a stepwise approach using a cascade of complementary tests that are able to detect a mutation in the NF1 gene in 95% of patients who meet the NIH criteria.

Pathological Findings

Biopsy of tumors that are enlarging, as this may be evidence of sarcomatous change

DIFFERENTIAL DIAGNOSIS

- Café au lait spots are most often benign findings unrelated to NF.
- NF2 may resemble NF1:
 - NF2 is also known as central bilateral acoustic NF, a rare disorder characterized by multiple tumors on the cranial and spinal nerves and by other lesions of the brain and spinal cord.
 - NF2 is genetically and clinically distinct from NF1. The NF2 gene, which codes for merlin protein, is located on chromosome 22.
 - The diagnosis of NF2 is made if the individual has the following: Bilateral acoustic neuromas or a 1st-degree relative with NF2 and either a unilateral acoustic neuroma or 2 of the following: Meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity.

- Soto syndrome features macrosomia, hypertelorism, ventriculomegaly, and cognitive difficulties.
- McCune-Albright syndrome has large café au lait spots with irregular margins and polyostotic fibrous dysplasia.
- Tuberous sclerosis (TS) may share autosomal dominant transmission and café au lait lesions in common with NF:
 - Features distinctive for TS include adenomatous sebaceous, cardiac and renal tumors, and prominent epilepsy.
 - Genetic testing for TS is now available.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Treatment of NF is multidisciplinary.
- There is no treatment for tumor growth except surgical intervention, if symptomatic.
- Interventions are palliative and supportive.

ISSUES FOR REFERRAL

Orthopedic, oncology, ophthalmology, endocrine, surgery, and plastic surgery consultants may be helpful, depending on individual issues.

SURGERY/OTHER PROCEDURES

Surgical intervention is performed on those tumors that are compressive, painful, or cosmetically disfiguring:

- Subcutaneous nodules are flesh colored, raised, pealike nodules that may be present during childhood.
- These commonly appear and grow during puberty or pregnancy and do not grow into plexiform tumors.
- Resection of vestibular schwannomas, if symptomatic

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Longitudinal care is essential for early detection and management of complications.
- Optimism: Natural history studies indicate that people with NF1 can live long, full lives.
- Pitfalls:
 - Macrocephaly is a common feature of NF, but growth curve for the head is necessary to determine whether it signifies a concern.
 - Regrowth of plexiform neurofibromas: Even after apparent total resection, regrowth is common and should be discussed before surgery.
 - The possibility of nerve injury after surgery on plexiform neurofibromas should also be discussed with the family/individual before surgery.

Patient Monitoring

- Vigilance/anticipatory care regarding common psychological and developmental issues, such as speech delay, incoordination, ADHD, and learning disabilities
- Early educational assessment and interventions may improve developmental outcome.

- Continuous yearly ophthalmologic examinations:
 - Goldman visual field perimetry is suggested in those with any question of an optic nerve tumor.
 - Some practitioners use yearly visual field testing (by an ophthalmologist) in addition to or as prescreen to MRI scanning.
- BP checks are increasingly important in adolescents and adults with NF.
- Monitoring for the development of tumors, hypertension, and psychological and developmental disabilities

PATIENT EDUCATION

- Family counseling regarding genetic implications, possible genetic testing using linkage, or, in some cases, mutation testing of the gene neurofibromin
- The children's tumor foundation: <http://www.nfnetwork.org/>
- NIH information page: <http://www.ninds.nih.gov/disorders/neurofibromatosis/neurofibromatosis.htm>

PROGNOSIS

- Deaths have been associated with cancer, heart disease, and strokes, similar to the general population.
- Tumors cannot be predicted on the basis of their occurrence in another member of the family with NF.

COMPLICATIONS

- Skeletal: Pseudoarthrosis, scoliosis, osteoporosis
- Oncologic: Overall risk of malignancy in NF1 is 2.7 times that of general population:
 - Neurofibromas are benign tumors of Schwann cells, nerve fibers, and fibroblasts that arise along the nerves.
 - Plexiform neurofibromas occur in ~15% of patients with NF1; these are extensive tumors that grow along the nerve root and may invade adjacent structures, threatening vital structures (especially in the neck and throat), or cause gross disfigurement. ~10% of these tumors undergo sarcomatous degeneration.
 - CNS tumors include optic nerve/pathway gliomas or gliomas elsewhere in the brain.
- Neurologic: Learning disability, language disorders, incoordination, autism, seizures, retardation, and attention deficit occur with higher-than-background frequency in NF.
- Renal: Hypertension
- Circulatory: Moyamoya disease, stroke
- Endocrine: Pheochromocytoma
- Hematologic: Leukemia

FAQ

- Q: Can NF develop into cancer?
- A: Most tumors caused by NF are benign and remain benign (even large tumors). In rare cases, they may become malignant.
- Q: My child has NF1. What specialists must he see?
- A: Your child should have yearly checkups with a physician familiar with the issues of NF (could be a family physician, pediatrician, child neurologist, or geneticist) who will know when to refer to other specialists. Otherwise, periodic visits to an ophthalmologist with experience in NF are the only routine recommendation.

NEUTROPENIA

Cynthia F. Norris

BASICS

DESCRIPTION

A decrease in the number of circulating neutrophils (both segmented and band forms), strictly defined as an absolute total neutrophil count (ANC) of $< 1,500/\text{mm}^3$

- To calculate ANC, multiply the total WBC count by the percentage of segmented neutrophils and band forms.
- For example: WBC count 5,200 with 15% segs/polys, 4% bands, 76% lymphocytes, 5% monocytes: $\text{ANC} = 5,200 \times (0.15 + 0.04) = 988$.

EPIDEMIOLOGY

- Normal values for total WBC counts and ANC vary with age and race.
- Black children have lower total WBC counts and lower ANCs than do white children.
- Infants have a higher total WBC count and a higher percentage of lymphocytes in their differential counts.

RISK FACTORS

Genetics

- Some neutropenia syndromes can be inherited: Kostmann syndrome = SCN: severe congenital neutropenia: Autosomal recessive.
- Cyclic neutropenia: Autosomal dominant

ETIOLOGY

- Decreased production of neutrophils:
 - Marrow failure syndromes
 - Marrow suppression by drugs, chemotherapy, or radiation
 - Nutritional deficiencies
- Increased destruction of neutrophils:
 - Immune-mediated destruction
 - Increased utilization (usually with overwhelming infection)
 - Sequestration in the spleen
- Factitious causes of a low WBC count:
 - Long time period between when blood sample is drawn and when it is tested
 - Excessive leukocyte clumping (in presence of certain paraproteins)
 - Leukocyte fragility secondary to leukemia or medication use

DIAGNOSIS

HISTORY

- Current or recurrent fever, skin abscesses, infection, or oral ulceration helps establish pattern and duration of neutropenia.
- Medication use: Many can cause neutropenia.
- Results of prior CBC with differential: Prior normal WBC count and ANC essentially rule out Kostmann syndrome.
- Diet: Evidence of nutritional deficiency
- Family history of neutropenia, recurrent infection, or early death suggests an inherited condition.

PHYSICAL EXAM

- Fever (temperature should not be taken rectally), tachycardia, and hypotension may indicate systemic infection.
- Oral ulceration, gingival irritation, pharyngitis, thrush
- Cellulitis, perirectal, or labial abscesses
- Hepatomegaly or splenomegaly
- Bruises, petechiae, pallor (other cell lines may be involved)
- Phenotypic abnormalities (thumb anomalies, dwarfism, joint findings)
- Systemic infection: Fever, rash, upper respiratory symptoms, jaundice

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential
- Antineutrophil antibodies: Present in autoimmune and isoimmune neutropenia on the neutrophils (direct) and in the serum (indirect)
- Cultures
- Genetic testing for Kostmann syndrome (HAX1) and cyclic neutropenia (ELA2)
- ELA2 mutations may also account for some cases of Kostmann syndrome.

Diagnostic Procedures/Other

Bone marrow aspirate and biopsy may be normal or may reveal a decrease in the number of myeloid precursors or a maturational arrest of the myeloid line (usually in the later stages), depending on the cause of neutropenia.

DIFFERENTIAL DIAGNOSIS

- Neutropenia associated with infection:
 - Bacterial: Group B streptococcal disease, tuberculosis, brucellosis, tularemia, typhoid, paratyphoid
 - Viral: Hepatitis A and B, parvovirus B19, respiratory syncytial virus (RSV), influenza A and B, rubeola, rubella, varicella, cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV
 - Other: Malaria, visceral leishmaniasis, scrub typhus, sandfly fever

- Drug induced:
 - Antibiotics: Sulfonamides (trimethoprim/sulfamethoxazole is a common offender), penicillin, chloramphenicol (may be irreversible)
 - Chemotherapy agents: Alkylating agents, antimetabolites, anthracyclines
 - Antipyretics: Aspirin, acetaminophen (uncommon)
 - Sedatives: Barbiturates, benzodiazepines
 - Phenothiazines: Chlorpromazine, promethazine
 - Antirheumatic agents: Gold, penicillamine, phenylbutazone
- Tumors:
 - Leukemia
 - Solid tumors that invade bone marrow
- Metabolic:
 - Nutritional: Malnutrition, copper deficiency, megaloblastic anemia secondary to folate or vitamin B₁₂ deficiency
 - Inborn errors of metabolism: Hyperglycemia, isovaleric acidemia, propionic acidemia, methylmalonic acidemia
- Congenital:
 - Kostmann syndrome: Severe congenital neutropenia
 - Cyclic neutropenia: Regular oscillations in the number of circulating neutrophils (periodicity every 7–36 days; duration of neutropenia, 3–10 days)
- Chronic benign neutropenia of childhood: This is a diagnosis of exclusion.
- Shwachman-Diamond syndrome: Neutropenia and exocrine pancreatic insufficiency
- Cartilage/hair hypoplasia: Neutropenia, dwarfism, abnormal cellular immunity
- Reticular dysgenesis
- Immunologic:
 - Neutropenia associated with primary immunodeficiencies: Abnormalities in T and B lymphocytes
 - Autoimmune neutropenia: Idiopathic (common in childhood; onset usually < 2 years of age; diagnosis established by demonstrating antineutrophil antibodies; typically a benign course with resolution within several years; steroids may help in severe cases)
 - Felty syndrome (neutropenia, splenomegaly, and rheumatoid arthritis)
 - Secondary to drugs, infection, or rheumatologic process
 - Isoimmune neonatal neutropenia

- Miscellaneous:
 - Hypersplenism
 - Part of evolving aplastic anemia: Idiopathic, Fanconi anemia, familial aplastic anemia, dyskeratosis congenita
 - Bone marrow infiltration: Tumor, osteopetrosis, Gaucher disease
 - Radiation injury

TREATMENT

MEDICATION (DRUGS)

- Hematopoietic growth factors:
 - Granulocyte colony-stimulating factor (G-CSF): Drug of choice for Kostmann syndrome
 - Granulocyte-macrophage colony-stimulating factor (GM-CSF)
- Corticosteroids and/or plasmapheresis: Most helpful in immune-mediated neutropenia
- IVIG may also be used in autoimmune neutropenia.

ADDITIONAL TREATMENT

General Measures

- Isolation of hospitalized patient: Prudent until the cause of the neutropenia is identified
- Correction of underlying cause of neutropenia (discontinue drug, treat infection, correct nutritional deficiency)
- Treatment of fever and suspected infection when neutropenic: Initially, broad-spectrum antibiotics are indicated; after the diagnosis has been established, this may not always be necessary (i.e., individuals with chronic benign neutropenia).
- Prophylactic antibiotics are not usually beneficial and may predispose to systemic fungal infection.
- Stool softeners may be helpful in the profoundly neutropenic patient at risk for constipation to prevent development of a perirectal abscess.
- No therapy may be required if neutropenia is not severe and there are no serious or recurrent infections (often the case in autoimmune neutropenia and chronic benign neutropenia).

Additional Therapies

Granulocyte transfusions: Rarely indicated for severe or refractory infections

ISSUES FOR REFERRAL

- Chronic or profound neutropenia
- History of recurrent skin infections
- When bone marrow examination is indicated
- When hematopoietic growth factors, plasmapheresis, or granulocyte transfusion is being considered

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Management of febrile episodes:

- Prompt evaluation by a physician
- Obtain CBC with differential.
- Obtain blood culture.
- Hospitalize.
- Treat with IV antibiotics.
- Monitor daily CBC with differential.

Patient Monitoring

CBCs and physical exams at regular intervals while the patient is neutropenic

PROGNOSIS

- Death from overwhelming infection does occur.
- Outcome varies according to diagnosis
 - Neutropenia resulting from infection or drug-related marrow suppression is usually short lived.
 - Congenital neutropenia syndromes may result in chronic lifelong neutropenia.
 - Immune-mediated neutropenia frequently improves with age.

COMPLICATIONS

- Systemic bacterial infection
- Localized infections such as cellulitis, labial abscesses, perirectal abscesses, oral mucosal ulceration, thrush

FAQ

- Q: Do all episodes of fever and neutropenia require antibiotics?
- A: In severe neutropenia syndromes (i.e., Kostmann syndrome) or when the cause of the neutropenia is unclear, it is prudent to evaluate the child promptly, draw a blood culture, and administer IV broad-spectrum antibiotics. Certain neutropenia syndromes are not associated with an increased risk of infection (i.e., chronic benign neutropenia of childhood); children with these syndromes should be evaluated when they have fever, but probably do not require IV antibiotics if they look well.
- Q: Should a child with neutropenia be allowed to go to school?
- A: Yes
- Q: Does he or she need to wear a mask?
- A: No

NON-HODGKIN LYMPHOMA

Anne F. Reilly

BASICS

DESCRIPTION

- Non-Hodgkin lymphoma (NHL) is a malignant proliferation of cells of lymphocytic or histiocytic lineage that spread in a pattern similar to the migration of normal lymphoid cells.
- No uniform staging system exists for childhood NHL. The commonly used Murphy's staging system is as follows:
 - Stage I: Single tumor (extranodal) or single nodal area, excluding mediastinum or abdomen
 - Stage II: Single tumor with regional nodal involvement, 2 or more tumors or nodal areas on the same side of the diaphragm, or a primary GI tract tumor (resected) with or without regional node involvement
 - Stage III: Tumors or lymph node areas on both sides of the diaphragm, any primary intrathoracic or extensive intra-abdominal disease (unresectable), or any paraspinal or epidural tumors
 - Stage IV: Bone marrow or CNS disease regardless of other sites; marrow involvement defined as 0.5–25% of malignant cells

EPIDEMIOLOGY

- 3rd most common childhood malignancy (~12% cancers in individuals <20 years of age in developed countries)
- Male/female ratio: 3:1

Incidence

- 1–1.5 per 100,000
- Higher frequency of endemic Burkitt-type in equatorial African countries (10–15 per 100,000 children younger than age 5–10)
- Incidence increases steadily with age; in children, usually seen in 2nd decade of life (unusual in those <3 years of age)

RISK FACTORS

Environmental factors:

- Drugs: Immunosuppressive therapy and diphenylhydantoin
- Radiation: Atomic bomb survivors and ionizing radiation
- Viruses: Epstein-Barr virus (EBV), HIV; EBV present in >95% of cases of endemic Burkitt versus <20% cases of sporadic

Genetics

Genetic predisposition: Increased risk in patients with immunologic defects (e.g., Bruton agammaglobulinemia, ataxia–telangiectasia, Wiskott–Aldrich, severe combined immunodeficiency)

PATHOPHYSIOLOGY

- In contrast to adult lymphomas, childhood NHL is almost never nodular alone and rarely occurs in peripheral nodal areas.
- Pediatric NHL can be divided into 3 major categories according to the National Cancer Institute (NCI) formulation:
 - Small noncleaved cell lymphomas (B cell):
 - 40% of childhood NHL
 - Subdivided into Burkitt and non-Burkitt based on the degree of pleomorphism

- A variety of B-cell markers are usually present (e.g., CALLA, CD20).
- Expresses surface immunoglobulins (Ig), most bearing IgM of either κ or λ light-chain subtype
- Terminal deoxyribonucleotidyl transferase (TdT) is negative.
- Characteristic chromosomal translocation, usually t(8;14), rarely t(8;22) or t(2;8); all translocations involve the c-myc protooncogene.
- Lymphoblastic lymphomas (LL):
 - Make up 30% of childhood NHL
 - In children, 90% T-cell and 10% B-cell origin
 - Predominantly of thymocyte (T-cell) origin: Morphologically identical to acute leukemia T lymphoblasts. Bone marrow involvement of >25% blasts is considered leukemia.
 - T-cell lymphomas are positive for TdT and have a T-cell immunophenotype (e.g., CD7).
 - Most lack chromosomal translocations and seldom involve T-cell receptor genes on chromosomes 7 and 14q.
- Large cell lymphomas:
 - 30% of childhood NHL
 - 2/3 are a large noncleaved or cleaved type of B-cell origin; these can be diffuse large B-cell lymphoma (DLBCL) or mediastinal large cell lymphoma (LCLM).
 - 1/3 are anaplastic large cell lymphoma (ALCL) and are positive for CD30 (Ki-1).
 - ALK (anaplastic lymphoma kinase) positivity seen in systemic ALCL disease; ALK-negative ALCLs are more often localized/cutaneous. ALK-negative disease is rare in children.

DIAGNOSIS

A diagnosis needs to be made expeditiously, as pediatric lymphomas generally have a rapid growth rate.

HISTORY

- B-cell lymphomas:
 - Systemic manifestation (e.g., fever, weight loss, anorexia, fatigue) if disseminated; less likely if tumor localized
 - Lump in neck unresponsive to antibiotics
 - Abdominal mass with pain, swelling, change in bowel habits, nausea, or vomiting
- T-cell lymphomas:
 - Mediastinal tumor symptoms include cough, hoarseness, dyspnea, orthopnea and chest pain, anxiety, confusion, lethargy, headache, distorted vision, syncope, and a sense of fullness in the ears.
 - Marrow involvement: Bleeding and/or bruising, bone pain, pallor, fatigue

PHYSICAL EXAM

- Small noncleaved cell lymphomas:
 - Intra-abdominal mass (up to 90%):
 - Involving ileocecal region, appendix, ascending colon, or a combination
 - Lymphadenopathy may be present in inguinal or iliac region.
 - Hepatosplenomegaly may be present.
 - Acute abdomen with intussusception, peritonitis, ascites, and acute GI bleeding
 - Lymphoma is the most frequent cause of intussusception in children >6 years.

- In endemic Burkitt lymphoma, jaw tumors are the most frequent; orbital involvement in infants; abdominal masses in 50%
- Other sites: Testis, unilateral tonsil hypertrophy, peripheral lymph nodes, parotid gland, skin, bone, CNS, and marrow
- Lymphoblastic lymphoma:
 - Mediastinal mass (50–70%), possibly pleural effusion present with decreased breath sounds, rales, and cough with or without superior vena cava (SVC) syndrome or superior mediastinum syndrome (SMS):
 - Signs include swelling, plethora, and cyanosis of the face, neck, and upper extremities; diaphoresis; stridor; and wheezing.
 - Lymphadenopathy (50–80%); primarily above diaphragm
 - Abdominal involvement uncommon: Likely to involve only liver and spleen
 - Cranial nerve involvement: Rarely
- Large cell lymphomas:
 - Sites: Mediastinum, bone, inguinal nodes, skin
 - Bone marrow and CNS involvement: Rare at diagnosis

DIAGNOSTIC TESTS & INTERPRETATION

- Establish diagnosis with least invasive method.
- Bone marrow aspirate and biopsy may establish the diagnosis without further testing.
- Fluid from ascites in patients with abdominal disease or pleural fluid should be obtained for cytology, immunophenotyping, and cytogenetics.
- Take a biopsy of an enlarged lymph node.

Lab

- CBC
- Liver and renal function studies
- Serum lactate dehydrogenase (LDH) and uric acid levels
- Ascitic, CSF, or pleural fluid:
 - Cytology
 - Immunophenotyping
 - Cytogenetics

Imaging

- Abdominal ultrasound
- Chest radiographs: Posteroanterior and lateral
- CT scan of chest, abdomen, and pelvis
- PET/CT scan
- MRI (especially for bone involvement)

Diagnostic Procedures/Other

- Adequate surgical biopsy
- Bone marrow aspiration and biopsy
- Lumbar puncture with CSF cytology

DIFFERENTIAL DIAGNOSIS

- Abdominal mass:
 - Newborn: Hydronephrosis, renal cysts, Wilms tumor, or neuroblastoma
 - Older children: Constipation, full bladder, hamartoma, hemangioma, cysts, leukemic or lymphomatous involvement of the liver and/or spleen, Wilms tumor, or neuroblastoma

- Mediastinal mass:
 - Anterior: Masses of thymic origin, teratomas, angiomas, lipomas, or thyroid tumors
 - Middle: Metastatic or infectious lesions involving the lymph nodes, pericardial or bronchogenic cysts, esophageal lesions, or hernias
 - Posterior: Neurogenic tumors (e.g., neuroblastoma, ganglioneuroma, neurofibroma), enterogenous cysts, thoracic meningocele, or hernias

TREATMENT

MEDICATION (DRUGS)

- Chemotherapy:
 - Histology and stage determine choice of a particular protocol.
 - Because of a high conversion rate of lymphomas to leukemias, prophylactic CNS treatment is given (except in patients with totally excised intra-abdominal tumor).
 - Duration: 1–8 months; lymphoblastic lymphomas longer, up to 24 months
 - Drugs: Cyclophosphamide, vincristine, methotrexate (IV and intrathecal [IT]), prednisone, daunorubicin, asparaginase, cytarabine, thioguanine, carmustine, hydroxyurea, hydrocortisone, doxorubicin, mercaptopurine, etoposide
 - Common side effects: Hair loss, myelosuppression with transfusions required, nausea/vomiting
- Immunotherapy: Rituximab:
 - A chimeric monoclonal antibody directed against the CD20 antigen, which is almost universally expressed on tumor cells in pediatric B-cell NHL
 - A new active agent for lymphoma
 - Has been used successfully in patients with relapsed/refractory B-cell NHL
 - Few overlapping side effects with the combination of rituximab and conventional chemotherapeutic agents

ADDITIONAL TREATMENT

General Measures

A multidisciplinary approach is imperative to ensure the best therapy.

- Prechemotherapy management:
 - Allopurinol, hydration, and alkalinization of urine to promote uric acid excretion; may use rasburicase for uric acid >8 mg/dL
 - Vigorous hydration with maintenance of brisk urine flow to prevent tumor lysis syndrome
 - Monitor uric acid, BUN, calcium, creatinine, potassium, and phosphate levels closely.
- Management of relapse:
 - Relapse indicates extremely poor prognosis.
 - No uniform approach to rescue therapy; different chemotherapy combinations may induce a new response.
 - For patients with chemosensitive relapse, salvage therapy followed by high-dose therapy with stem cell support is recommended, because this may result in prolonged survival.

Additional Therapies

Radiotherapy

- Adds no therapeutic benefit in children with limited disease. May be indicated in mediastinal DLBCL
- Used occasionally as emergent treatment for SVC obstruction or CNS or testicular involvement
- Cranial radiotherapy given for CNS-positive children with lymphoblastic lymphoma
- Increases short- and long-term toxicity

SURGERY/OTHER PROCEDURES

- Performed if total resection can be achieved
- Additional indications: Intussusception, intestinal perforation, suspected appendicitis, or serious GI bleeding
- Avoid extensive surgery in patients with NHL

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patient monitoring weekly to monthly with CBC and physical examination
- Radiologic imaging at intervals during and off therapy
- Monitor for toxicity-related complications:
 - Cardiac
 - Gonadal function
 - Second malignancies

Patient Monitoring

Late effects from therapy:

- Cardiomyopathy from anthracyclines
- Impaired reproductive function or infertility from alkylating agents or radiation
- Second malignant neoplasms from etoposide and alkylators
- Psychological consequences of severe illness

PROGNOSIS

- Important prognostic factors for outcome include tumor burden at presentation.
- Favorable:
 - Stages II and I with primary site head and neck (nonparameningeal), peripheral nodes, or abdomen ($\geq 90\%$ 2-year survival)
 - Burkitt: Most >90% 2-year survival
- Less favorable:
 - Stage III or IV ALCL, LL
 - Parameningeal stage II
 - Stage IV with CNS involvement (worst)
 - Incomplete initial remission within 2 months (50–80% 2-year survival)

COMPLICATIONS

- Tumor lysis syndrome:
 - Combination of hyperuricemia, hyperkalemia, and hyperphosphatemia with hypocalcemia, resulting in uric acid nephropathy that leads to renal failure
 - Correct before starting chemotherapy.
- GI obstruction, perforation, bleeding, intussusception
- Inferior vena cava obstruction and venous thromboembolism
- Neurologic (e.g., paraplegia, increased intracranial pressure)

- SVC syndrome and SMS: Associated with lymphoblastic lymphomas that invade the thymus and nodes surrounding the vena cava and airways
- Massive pleural effusion
- Cardiac tamponade or arrhythmia

CODES

ICD9

- 200.10 Lymphosarcoma, unspecified site, extranodal and solid organ sites
- 202.70 Peripheral T cell lymphoma, unspecified site, extranodal and solid organ sites
- 202.80 Other malignant lymphomas, unspecified site, extranodal and solid organ sites

ICD10

- C83.50 Lymphoblastic (diffuse) lymphoma, unspecified site
- C83.70 Burkitt lymphoma, unspecified site
- C85.90 Non-Hodgkin lymphoma, unspecified, unspecified site

FAQ

- Q: Did I do something to cause this?
- A: No. Most cases are sporadic and not associated with diet, underlying immune dysfunction, or viral illness.
- Q: When will my child be “cured”?
- A: For patients with small or large cell lymphomas, relapse most commonly occurs in the 1st year after therapy finishes. Therefore, a child may be considered cured if he or she remains in remission after the 1st year off therapy. A patient with lymphoblastic lymphoma is considered cured if he or she remains in remission after ~3 years from onset of therapy.
- Q: Is this contagious?
- A: No. Siblings may have slightly higher inherent risk than the general population, but they are not at risk from the affected child.

NOSEBLEEDS (EPISTAXIS)

Sheila M. Nolan

BASICS

DESCRIPTION

- Epistaxis: Bleeding from the nose
- Bleeding may be evident anteriorly through the nares or posteriorly through the nasopharynx.

EPIDEMIOLOGY

- Nosebleeds occur in all ages throughout the year.
- Children aged 2–10 years are most commonly affected.
- Nosebleeds are more common in the winter.

GENERAL PREVENTION

- Vaporizers, humidifiers, or saline sprays prevent desiccation of the nasal mucosa.
- Petroleum jelly applied to the anterior nasal septum aids healing of inflamed nasal mucosa.
- Antigen avoidance and medical therapy should be used to reduce allergic symptoms.
- Fingernails should be cut short, and nose-picking behavior should be discouraged.
- Protective athletic equipment should be worn.

PATHOPHYSIOLOGY

- The nasal mucosa has a rich blood supply originating from both the internal and external carotid arteries.
- Blood vessels of the nasal septum and lateral nasal walls have little anatomic support or protection. The thin mucosal surface is prone to drying.
- Blood vessels of the nose form many plexiform networks. Especially important is Kiesselbach plexus in the anterior nasal septum, the most common site of nosebleeds in children.
- The nose is subject, by position, to traumatic injury.

ETIOLOGY

- Inflammation of, or trauma to, the nasal passages accounts for most nosebleeds:
 - Viral upper respiratory infections, allergic rhinitis, bacterial rhinitis
 - Nose picking, external trauma, foreign bodies, postsurgical bleeding, chemical or caustic agents/inhalants

- Local structural abnormalities may predispose to epistaxis:
 - Rhinitis sicca, or environmental drying of the nasal mucosa, commonly promotes epistaxis.
 - Nasal polyps, telangiectasias, meningoceles, angiofibromas, vascular malformations, septal deviations or spurs
- Less commonly, nosebleeds may herald, or accompany, systemic illnesses:
 - Hematologic diseases such as leukemias, thrombocytopenias, hemophilias (and von Willebrand disease), and hemoglobinopathies
 - Clotting disorders owing to infection, hepatic failure, or poisoning/envenomation
 - Hypertension (usually not the cause, but can make hemostasis difficult)
- Pseudoepistaxes from pulmonary hemoptysis, bleeding esophageal varices, or pharyngeal/laryngeal tumors that bleed can be mistaken for epistaxis.

COMMONLY ASSOCIATED CONDITIONS

Hemoptysis, hematemesis, or melena may be the presenting concerns in individuals with bleeding from the nasopharynx.

DIAGNOSIS

HISTORY

- Frequency of occurrence
- Persistence of bleeding
- Nose-picking behavior/traumatic injury
- Nasal congestion, discharge, obstruction
- Allergies
- Medications or drugs of abuse (especially cocaine)
- Previous or concurrent bruising or bleeding
- Menstrual history
- Family history of systemic disease or hemorrhagic disorder

PHYSICAL EXAM

- Vital signs with blood pressure determination
- Inspection of nose, nasopharynx, and oropharynx
- General exam with attention to lymph nodes, liver and spleen size, rashes, icterus, pallor
- Procedure:
 - Exam of the nose may be facilitated by application of a topical vasoconstricting agent and/or anesthetic agent.
 - Anxiety may interfere with exam and treatment of children. Sedation and analgesia may be beneficial in some circumstances.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Laboratory evaluation is not indicated in healthy children with readily controlled epistaxis from an anterior site.
- Recurrent or refractory nosebleeds or suspicious findings from the history and physical exam may warrant a directed laboratory evaluation (such as platelet count, PT and PTT, CBC, and/or bleeding time) and/or consultation.

DIFFERENTIAL DIAGNOSIS

Epistaxis is a common event in normal children. A careful history and physical exam should identify those children with unusual predisposing causes for nosebleeds.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Elevate the head of the bed.
- Direct pressure, applied by gently squeezing the nostrils, is usually sufficient to stop most nosebleeds.
- Ice or cold packs to the neck or nasal dorsum appear not to have a significant benefit, but may be combined with application of pressure.
- A cotton pledget beneath the upper lip may aid hemostasis by compressing the labial artery.

- Vasoconstricting agents (0.25% phenylephrine, 0.05% oxymetazoline, 1:1,000 epinephrine, or 1–5% cocaine) will help reduce bleeding, as well as improve visualization.
- Application of topical thrombin or fibrin glue may be used when direct visualization of the bleeding site is achieved.
- Once identified, an offending vessel may be cauterized with a silver nitrate stick or a swab dipped in trichloroacetic acid:
 - For recurrent nosebleeds silver nitrate cauterization with antiseptic cream may have a slight advantage over the use of antiseptic cream alone.
 - Cautery should only be applied to one side of nasal septum to avoid the risk of septal perforation, as the septal cartilage receives its blood supply from the overlying mucous membrane.
- Anterior nasal packing with oxycellulose or petroleum jelly gauze may be required to control refractory epistaxis when the site of bleeding cannot be precisely identified.
- Parental reassurance is an important, but often neglected, aspect of therapy.

ISSUES FOR REFERRAL

Otorhinolaryngologic consultation may be needed for severe nosebleeds or when posterior nasal packing, fracture reduction, surgery, or embolization is required. Nasal endoscopy is now routinely used.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Nosebleeds are easily controlled and self-limited in most instances.
- Postsurgical nosebleeds can be particularly problematic.
- Referral to an otorhinolaryngologist is indicated for patients with specific local abnormalities, such as polyps, tumors, or vascular malformations, or severe nosebleeds, recurrent nosebleeds, and/or posteriorly located nosebleeds.
- Identification of systemic illness may require referral to the appropriate specialist.

PATIENT MONITORING

- Blood clots in the nasopharynx should be removed because they may obscure engorged, bleeding vessels.
- Failure to detect a posterior location within the nasal cavity as the source of bleeding may interfere with measures to control bleeding.
- After nasal packing, it is essential to examine the oropharynx to confirm adequate hemostasis.
- Absorbable-type packings should be used, if required, in patients with bleeding disorders. Standard packings are prone to rebleeding on removal.
- Impregnation of nasal packings with antibiotic ointment reduces the risk of toxic shock syndrome.

PATIENT EDUCATION

Families should be given instructions in basic first aid for nosebleeds, because minor insults, such as sneezing or excessive manipulation, may cause nosebleeds to recur.

PROGNOSIS

- Uncomplicated epistaxis is most often self-limited or resolves with simple first-aid techniques.
- Refractory or recurrent epistaxis may require more specialized techniques, surgical intervention, and/or otorhinolaryngologic intervention.

COMPLICATIONS

- Usually uncomplicated
- Rare complications: Significant blood loss, airway obstruction, aspiration, and vomiting

ICD10

R04.0 Epistaxis

FAQ

- Q: How should the patient with nosebleeds be positioned?
- A: When possible, patients with nosebleeds should be kept erect. The upright position decreases vascular congestion. Recumbent patients may appear to have less bleeding, but this is owing to redirection of blood flow through the posterior pharynx.
- Q: How does rhinitis sicca contribute to epistaxis, and why does it occur?
- A: The nose warms, humidifies, and filters inspired air. Many modern heating systems and air-conditioning units reduce household humidity to unnaturally low levels. Rhinitis sicca is the direct result of inhaling dry air and results in friable nasal mucosa. Turbulent airflow from a septal deformity also promotes drying.

OBESITY

George A. Datto
Sandra Gibson Hassink

BASICS

DESCRIPTION

A chronic disease defined as having an excess of body fat. Body mass index (BMI), which is defined as weight in kilograms divided by height in meters squared, is accepted as a proxy measurement of adiposity in children.

- Children <2 years of age:
 - Weight for length >95% for age: Obese
- Children ≥2 years of age:
 - BMI <5%: Underweight
 - BMI 5–84%: Normal weight
 - BMI 85–94%: Overweight
 - BMI 95–99%: Obese
 - BMI >99%: Morbid obesity

EPIDEMIOLOGY

Prevalence

2007 data:

- 2–5 years of age: 10.4%
- 6–11 years of age: 19.6%
- 12–19 years of age: 19.1%
- Highest rates in Native American and Hispanic children
- 61% of overweight children have at least 1 additional risk factor for heart disease.

RISK FACTORS

- Intrauterine environment:
 - Gestational diabetes
 - Intrauterine growth retardation
- Obese parents:
 - 1 obese parent: 40% chance of having an obese child. 2 obese parents: 70% chance of having an obese child
- Low socioeconomic status/minority ethnic groups
- Limited intake of fruits and vegetables
- Postnatal environment:
 - Television viewing >2 hr/d
 - Consumption of sugared beverages
 - Inadequate sleep

GENERAL PREVENTION

- Prevention of gestational diabetes: Children of diabetic pregnancies have a greater risk of obesity and diabetes.
- Prevention of intrauterine growth retardation: Infants with intrauterine growth retardation are at increased risk of later obesity and cardiovascular disease; this risk is enhanced in infants and children who have had rapid weight gain or “catch-up growth.”
- Encourage breastfeeding: There is a response effect on reduction of risk of obesity in children who have been breastfed.
- Early preventive counseling in patients with obese parents
- Early preventive counseling in children crossing BMI percentiles
- Promotion of nutrition guidelines, free play, and limited screen time in the general population

PATHOPHYSIOLOGY

Complex gene–environment–behavior interaction:

- Hypothalamus: Appetite regulation. Energy balance is regulated at the hypothalamic level. Neuropeptide regulation of hunger and satiety with input from cortical stimuli and gut hormone secretion. Energy stores and energy expenditure are regulated with input from leptin on energy stores and regulation of energy expenditure via the sympathetic nervous system.
- Adipose cells: Cytokines. Adipose tissue produces leptin (energy regulation) and adiponectin (cardiovascular risk).
- Tumor necrosis factor- α (inflammation)
- Psychobehavioral

ETIOLOGY

Energy imbalance:

- Excessive caloric intake: High caloric foods readily available in large portions and often preferred by children
- Inadequate caloric expenditure: Television, video games, and computers part of child’s daily activities

COMMONLY ASSOCIATED CONDITIONS

- Type 2 diabetes mellitus
- Hypertension
- Dyslipidemia
- Metabolic syndrome
- Sleep apnea
- Asthma
- Polycystic ovarian syndrome
- Nonalcoholic steatohepatitis
- Slipped capital femoral epiphysis (SCFE)
- Blount disease (tibial bowing)
- Binge-eating disorder
- Mood disorder: Anxiety and depression
- Low self-esteem

DIAGNOSIS

HISTORY

- Obesity trigger:
 - Age at which weight gain started
 - Family or patient stress
 - Life events
- Parents’/patient’s beliefs:
 - Level of concern and motivation
 - Self-assessed reasons for weight gain
 - Previous attempts at weight control
- Family history:
 - Weight of parents
 - Obesity comorbidities in family
- Lifestyles:
 - Eating behaviors:
 - Age-appropriate meal structure
 - Sugared beverage (including juice, soda, sports drink) consumption
 - Snacks: frequency and content
 - Physical activity:
 - Hours of screen time from TVs, handheld devices, game stations, computers
 - Sports participation
 - Time outdoors

- Parenting skills:
 - Hunger management
 - Role modeling
 - Ability to set boundaries
- Obesity review of symptoms:
 - CNS: Pseudotumor
 - Respiratory: Sleep apnea, asthma
 - GI: Reflux
 - Orthopedics: SCFE/Blount disease
 - Psychology: Depression, attention deficit hyperactivity disorder (ADHD), anxiety, school difficulties
 - Skin: Acanthosis nigricans
- Prior interventions:
 - Ask about prior use of diet pills, laxatives.
 - Ask family about previous or current complementary and alternative medicine (CAM) weight loss products they have tried.

PHYSICAL EXAM

- Anthropometrics:
 - Weight, height
 - BMI
 - Blood pressure
- General:
 - Short stature
 - Dysmorphic features
 - Developmental delay
- Head, eyes, ears, nose, and throat (HEENT):
 - Papilledema
 - Tonsillar hypertrophy
- Cardiopulmonary:
 - Breath sounds
 - Heart murmur
- Abdomen: Hepatomegaly
- Genitourinary: Tanner stage
- Musculoskeletal:
 - Joint range of motion
 - Limp
 - Flat feet
- Skin:
 - Acanthosis nigricans
 - Hirsutism
 - Striae
- Psychological:
 - Mood: Assess for evidence of depression.
 - Affect

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Metabolic screening (fasting specimens) should be done on all obese patients:

- Lipid profile: Cholesterol, HDL, and triglycerides
- Glucose or hemoglobin A1c
- Liver function tests to assess for liver disease
- Thyroid tests, cortisol, insulin, androgens (as indicated)

Diagnostic Procedures/Other

- Body composition: Excessive fat confirmation
 - Skinfold measurement
 - Bioelectric impedance analysis: Clinical estimate of basal metabolic rate and lean body mass
 - Indirect calorimetry: Clinical use in determining dietary requirements; calculates basal metabolic rate
- Comorbidity confirmation:
 - Sleep study: Assess for sleep apnea.
 - Hip radiographs: Rule out SCFE.
 - Knee and lower extremity radiographs: Rule out Blount disease.
 - Echocardiogram (echo): If hypertension present
 - Liver ultrasound: Nonalcoholic steatohepatitis (NASH)
 - Chromosomes: If dysmorphic features are present on examination
- DNA methylation study: Prader-Willi syndrome

DIFFERENTIAL DIAGNOSIS

Diseases in which obesity may be a component:

- Hypothalamic obesity
- Cushing syndrome
- Hypothyroidism
- Growth hormone deficiency
- Down syndrome

**TREATMENT****MEDICATION (DRUGS)**

- Appetite suppressant:
 - Sibutramine (Meridia): Currently not marketed in US because of concerns about a 16% increase risk of cardiovascular disease as compared to patients taking placebo
- Lipase inhibitor:
 - Orlistat (Xenical):
 - Side effects: Abdominal pain, oily stools, flatulence
 - Minimal weight loss as compared to placebo
 - Not recommended for routine use

ADDITIONAL TREATMENT**General Measures**

Early obesity recognition and treatment to prevent further excessive weight gain and obesity complications. Weight loss (initial goal of 5–10% reduction in BMI) and comorbidity treatment when clinically appropriate:

- Effective communication with patient and family:
 - Nonblaming
 - Using growth charts as visual aids
 - Being positive that change can occur
- Identify energy balance abnormalities.
- Supply developmentally appropriate nutrition and activity information.
- Support parents in planning and in making lifestyle changes:
 - Set goals.
 - Enhance parenting skills related to developing structure, setting boundaries, maintaining consistency, communication, and knowledge of child development.

Additional Therapies

Improve/change activity habits:

- Limit total screen time (television, video games, and computer) to a maximum of 2 hr/d.
- When possible, add structured physical activity into daily routine.
- Encourage non-weight-bearing activities, such as swimming or stationary bike riding, which may be easier for the severely deconditioned patient.
- Help family find opportunities for increased activity in both the child's school and community.

SURGERY/OTHER PROCEDURES

Gastric bypass or gastric banding (Lap-Band is not currently approved by the FDA in children) surgery may be appropriate for some adolescent patients with BMI >40 and severe comorbid conditions, including the following:

- Diabetes mellitus
- Sleep apnea
- Disabling orthopedic complications

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Initially monthly to assess weight and behavioral change:
 - Intensify follow-up with weight gain
 - Spread out visits when efficacy of treatment has been established.
- Comorbidities that do not improve with reductions in BMI, or complications beyond a provider's expertise: Refer to appropriate specialist/pediatric obesity center.

DIET

Improve/change dietary habits:

- Encourage age-appropriate eating:
 - Review frequency of eating.
 - Review portion sizes.
- Discuss access to food.
- Discuss family meals.
- Limit sugared beverage consumption.
- Limit amount of junk food in house.
- Increase fruit and vegetable intake.
- Have parents model healthy eating habits.
- Encourage parents to work with child care, school, and extended family on supporting dietary changes.

PROGNOSIS

- Better prognosis in younger and less obese patients
- Better prognosis in patients and families who maintain ability to self-monitor health habits and maintain physical activity
- Long-term prognosis is guarded in morbidly obese patients.

COMPLICATIONS

- Medical emergencies:
 - Pseudotumor cerebri
 - SCFE
 - Nonketotic hyperosmolar hyperglycemia
 - Diabetic ketoacidosis
 - Pulmonary emboli

- Acute but generally nonemergent:
 - Hypertension
 - Sleep apnea
 - Gallstones
 - Type 2 diabetes
 - Polycystic ovarian syndrome
 - Gastroesophageal reflux
 - Asthma
 - Blount disease
- Chronic:
 - Dyslipidemia
 - Psychosocial issues
 - Increased risk of cardiovascular disease
 - Increased mortality of all causes in adulthood

**CODES****ICD9**

- 278.00 Obesity, unspecified
- 278.01 Morbid obesity

ICD10

- E66.01 Morbid (severe) obesity due to excess calories
- E66.3 Overweight
- E66.9 Obesity, unspecified

FAQ

- Q: How do I start addressing a child's weight?
- A: Review the height, weight, and BMI charts as part of the visit routine. Discuss family history in light of obesity and comorbidities, and link to the child's risk. Make obesity risk assessment part of the visit.
- Q: What do I do if family is not interested in addressing the child's weight?
- A: Introduce your concern about the child's health, ask the family to think about their priorities for the child and family, and help make links to good nutrition and activity habits (motivational interviewing).
- Q: How early can I start managing a child's weight?
- A: Attention to good nutrition and activity starts even before birth, at the prenatal visit. Parents need to see this as part of every interaction with their child's pediatrician.

OBSESSIVE COMPULSIVE DISORDER

C. Pace Duckett

BASICS

DESCRIPTION

- Obsessive compulsive disorder (OCD), is a psychiatric illness manifested by repetitive obsessions and compulsions.
- Obsessions are defined as unwanted thoughts, images, or impulses that the patient recognizes as unwanted and intrusive.
- Compulsions are repetitive actions that are frequently in response to an obsession and are often preceded by an internal urge:
 - Compulsions are frequently performed according to a set of rules and often to prevent something from happening in the future.
- DSM-IV criteria:
 - Either obsessions or compulsions:
 - Obsessions: Recurrent or persistent ideas, thoughts, impulses, or images that are recognized as a product of one's own mind.
 - Compulsions: Repetitive behaviors or mental acts that a person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly. These behaviors are aimed at reducing distress or preventing a feared event or situation.
 - It is not necessary that children recognize these thoughts or behaviors to be excessive or unreasonable.
 - The obsessions or compulsions cause marked distress, are time consuming (> 1 hour daily), and cause impairment in daily functioning.

EPIDEMIOLOGY

Incidence

From 0.5–3%:

- The variability in these rates is understood in the context of the high prevalence of subclinical obsessions and compulsions in the population.

RISK FACTORS

- Acute streptococcal infection
- Familial heritability pattern
- Moderate genetic component based on twin studies

COMMONLY ASSOCIATED CONDITIONS

- Depression
- Anxiety disorders
- Tourette syndrome
- Trichotillomania

DIAGNOSIS

HISTORY

- The diagnostic evaluation should entail gathering data through separate interviews with the child/adolescent and the parents.
- Current symptoms should be elicited within attention to severity, duration, and level of functional impairment.
- Core symptoms should be elicited concerning the content of obsessions and the nature of compulsions. These are most frequently checking behaviors, repetition rituals, or a focus on symmetry and organization.
- Sensitivity in assessing violent or sexually intrusive thoughts is necessary, as children may be uncomfortable disclosing these.
- Compulsions may manifest in physical action or in mental repetition.
- Assess the amount of functional impairment by estimating the time spent occupied by obsession and compulsions and how it interferes with their daily lives.
- Explore their level of insight into the irrationality of the symptoms. Diagnostically, children do not have to recognize the symptoms to be excessive. However, poor insight in an adult may represent a delusional disorder.
- Assess any parental accommodation of the ritualized behaviors, such as excessive cleaning.
- Determine if the onset was acute, severe, and temporally associated with symptoms of a streptococcal infection.

PHYSICAL EXAM

No pertinent findings

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No pathognomonic laboratory findings
- If onset is acute, severe, and associated with symptoms of a streptococcal infection, it may be reasonable to obtain an ASO titer.

Diagnostic Procedures/Other

Diagnostic scales:

- Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS)

DIFFERENTIAL DIAGNOSIS

- Anorexia nervosa
- Body dysmorphic disorder
- Delusional disorder
- Obsessive-compulsive personality disorder
- Pervasive developmental disorders
- Trichotillomania
- Tourette syndrome
- Schizophrenia
- Sydenham's chorea
- Pediatric autoimmune neuropsychiatric disorders associated with Strep infections (PANDA)

TREATMENT

General Measures

There are 2 types of treatment for OCD, psychosocial treatment and pharmacotherapy.

- Cognitive behavioral therapy (CBT) is most effective and well-studied psychosocial treatment:
 - SSRIs are the 1st-line agents for medication management.
 - Start intervention with CBT alone and add medication if treatment response limited.
- Emphasis is placed on graduated exposure with response prevention.
- Parental education is an important aspect of treatment adherence.

MEDICATION (DRUGS)

- SSRIs (1st-line) initiate 1/2 the starting dose for children with anxiety disorders:
 - Side effects include GI upset, headaches, dizziness, and agitation.
 - A black box warning by the FDA indicates that all antidepressants may increase suicidal thinking and behavior in children and adolescents.
 - Close monitoring is recommended following initiation.
 - Fluoxetine (Prozac) (10–60 mg)
 - Sertraline (Zoloft) (25–200 mg)
 - Fluvoxamine (Luvox) (25–200 mg)
- TCAs (2nd line):
 - Side effects include dizziness, xerostomia, blurred vision, postural hypotension, tachycardia, sedation, and constipation.
 - Clomipramine (Anafranil) (25–250 mg)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Monitoring of response to psychosocial treatment should be performed routinely every 2–3 months.
- If medication is initiated, close monitoring on a weekly basis is recommended for the 1st 4 weeks, followed by monthly monitoring.
- CBT is performed on a weekly or twice weekly regimen.
- Monitoring of any emerging comorbidities is suggested.

PROGNOSIS

- OCD is a chronic condition. Treatments have been demonstrated to show significant response, but remission of symptoms is rare.
- Childhood onset is a poor prognostic indicator.

CODES

ICD9

- 300.3 Obsessive-compulsive disorders
- 312.39 Other disorders of impulse control
- 315.9 Unspecified delay in development

ICD10

- F42 Obsessive-compulsive disorder
- F63.3 Trichotillomania
- F84.9 Pervasive developmental disorder, unspecified

CLINICAL PEARLS

Pitfalls include:

- Failing to utilize appropriate psychosocial treatments
- Not identifying the extent of the functional impairment

FAQ

- Q: Is OCD inherited?
- A: While no specific genes for OCD have been identified, there appears to be familial relationship to its inheritance.
- Q: What causes OCD?
- A: There is no proven cause of OCD. Research suggests that OCD involves problems in communication between the front part of the brain (the orbital cortex) and deeper structures (the basal ganglia).
- Q: Is there a cure?
- A: OCD is a chronic condition, but effective treatments are available.

OBSTETRIC BRACHIAL PLEXUS (ERB) PALSY

Richard S. Finkel

BASICS

DESCRIPTION

- The brachial plexus is a network of nerves in the neck and shoulder usually derived from the 5th cervical through the 1st thoracic nerve roots, consisting of anatomic structures termed trunks, divisions, and cords, terminating in specific nerves to individual muscles of the shoulder girdle, arm, and hand.
- Lesions of the brachial plexus can result in motor impairment—weakness, atrophy, and secondary joint contracture; sensory impairment—dermatomal or peripheral nerve distribution; functional and cosmetic impairment; limb length discrepancy; and chronic pain.
- Clinical and anatomic relationships:
 - 5th and 6th cervical (C5, C6) nerve roots fuse to form the upper trunk of the plexus:
 - C5 root impairment causes weakness of arm elevation to the front and side (flexion and abduction, due to deltoid and supraspinatus impairment).
 - C6 root compromise causes weakness of external rotation of the arm at the shoulder (infraspinatus), elbow flexion (mainly biceps), and partial supination (supinator) weakness.
 - If the lesion is at the C5, C6 root level or very proximal upper trunk, then winging of the scapula (serratus anterior) occurs. The biceps and brachioradialis deep tendon reflexes (DTRs) are depressed or absent.
 - 7th cervical (C7) nerve root alone forms the middle trunk of the plexus and is largely responsible for weakness in extension of the elbow (triceps), wrist (extensor carpi ulnaris), and fingers (extensor digitorum) and of wrist flexion (flexor carpi radialis).
 - 8th cervical (C8) and 1st thoracic (T1) nerve roots fuse to form the lower trunk of the plexus and innervate the intrinsic hand muscles responsible for grip and thumb opposition/abduction. The triceps DTR reflects the C7, C8 roots, but is difficult to obtain in newborns. The pectoralis DTR has the same distribution and is easier to elicit.

EPIDEMIOLOGY

- Erb palsy is the most commonly encountered partial lesion of the plexus seen in children, accounting for ~73–90% of all newborn cases, and occurs in ~1–4 per 1,000 live births. It involves the C5–6 and sometimes the C7 nerve roots and/or upper-middle trunks of the plexus:
 - Risk factors: Mainly large for gestational age (gestational diabetes), shoulder dystocia during vaginal delivery, and having a prior infant with Erb palsy
 - Antepartum compressive causes are well described in a minority of cases.
- Klumpke palsy in ~2% of neonatal cases, and is due to C8–T1 nerve root avulsion:
 - Risk factors: Breech delivery and face presentation

DIAGNOSIS

HISTORY, FOR BRACHIAL PLEXUS LESIONS IN OLDER CHILDREN

- Pregnancy and birth history, birth weight
- Trauma
- Recent viral infection
- Recent tetanus injection
- Family history, prior similar episodes that have resolved

PHYSICAL EXAM

- Testing of limb tone, strength, muscle bulk, joint range of motion, sensation, muscle stretch reflexes (DTRs) and elicited infant reflexes (Moro, asymmetric tonic neck response), diaphragm excursion, pupil size, pulses, and perfusion of the affected limb. Compare to the other side and the legs as well. Acute lesions often have severe pain, accentuated by movement of the arm.
- Sensory loss is difficult to assess because of overlap of dermatomes.
- Upper plexus lesion, such as Erb palsy (C5–6):
 - Arm hangs limply at the shoulder, adducted and internally rotated, the elbow extended and the forearm pronated, wrist and fingers flexed (“waiter’s tip posture”).
 - Hand grip is preserved.
 - Sensory impairment is often present over the lateral deltoid.
 - The biceps and brachioradialis muscle stretch reflexes (DTRs) are unelicitable; the triceps is present but often difficult to elicit in normal newborns.
 - The Moro reflex is asymmetric.
- Lower plexus lesion, such as Klumpke palsy (C8, T1):
 - Elbow flexion, supination of the forearm, wrist and finger extension, and an odd cupped-hand position
 - Triceps jerk is often absent.
 - Sensation may be impaired in the C8–T1 dermatomes.
 - An ipsilateral Horner sign (ptosis and miosis) indicates T1 involvement.
- Complete plexus lesion:
 - The entire upper limb and shoulder girdle is flaccid, anesthetic, and areflexic.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Chest and arm radiograph: Identifies subluxation of the spine or shoulder, fracture of the humerus or clavicle, and diaphragmatic palsy
- MRI has now largely replaced CT: Myelogram imaging of the cervical spinal cord, nerve roots, and plexus. There are occasional false-positive and false-negative findings for root avulsion, and many plexus lesions are not apparent on MRI.

Diagnostic Procedures/Other

Electrophysiologic testing: Electromyography (EMG) and nerve conduction velocity studies (NCV) can confirm the localization of the lesion, determine whether there has been axonal damage, and estimate timing of the lesion and the extent of reinnervation. Somatosensory and motor evoked potentials are not commonly done outside of the OR but can demonstrate conduction through a lesion in the plexus or nerve root. Usually the physical exam can give much the same information, reducing the need for EMG to selected settings.

DIFFERENTIAL DIAGNOSIS

- Lesions of the brain and spinal cord can produce focal weakness in mainly 1 limb. Usually the ipsilateral leg will have at least mild findings to indicate a hemiparesis.
- The pattern of weakness and hyperreflexia distinguish a central brain or spinal cord lesion from a peripheral nerve, root, or plexus lesion. A “congenital hemiparesis” presenting in early infancy, usually due to an antenatal stroke, often presents with arm and leg involvement and can mimic a brachial plexus lesion.
- Congenital malformations (Sprengel deformity) and contractures may mimic a brachial plexus palsy.
- Acute orthopedic problems such as a fracture or subluxation of the radial head
- Fascioscapulothoracic dystrophy has scapular winging and proximal arm weakness as main features, and when asymmetric can be similar to a brachial plexus lesion.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Mild weakness will recover in most cases without special treatment.
- For severe injury, with flaccid shoulder girdle and arm:
 - Immobilization: Babies with a fracture or who have significant pain with shoulder movement should have the limb partly immobilized for 2–3 weeks, to allow for rest during the acute phase of pain.
 - Cuff of the jersey can be pinned to the midline of the garment at the umbilicus level.
 - Caregivers should be instructed in proper lifting and positioning techniques to avoid pressure at the axilla.
 - Passive range-of-motion stretching: After 3 weeks, immobilization should be discontinued and gentle passive range of motion (PROM) should be initiated under the supervision of a therapist.
 - Fracture or shoulder subluxation needs to be excluded on radiography before starting PROM.
 - Regular visits to a pediatric occupational or physical therapist are necessary.
 - Electrical muscle stimulation: The data to support this therapy are limited, and there is no consensus at present regarding selection of patients for this treatment. It is not used routinely.

SURGERY/OTHER PROCEDURES

- Surgical issues: The critical window of time to consider surgical intervention is at 3–6 months if the deltoid/biceps remain flaccid and between 6 and 12 months when at least some early and steady recovery of strength is seen within the 1st 3 months but with later plateau. Primary repair of the nerve never results in full functional recovery.
- Surgical outcome is best if performed by 6–12 months and probably not useful if done after 24 months. Secondary surgery, usually after age 2 years, is often needed to address release of contractures, tendon transfers, and glenohumeral dysplasia.
- When an EMG at 1 month demonstrates no reinnervation in a flaccid deltoid or biceps, the prognosis for functional recovery is poor.
- There are no data to support the conjecture that repair at 4 months is more effective than later in the 1st year in the severely affected group.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- The newborn with brachial plexus palsy should be re-evaluated at 2 weeks and if not nearly back to normal, then referred for weekly occupational or physical therapy and seen again at 2 to 3 months.
- When there is persisting weakness but steady improvement between 2 and 12 weeks, focus on therapy to prevent contractures.
- If elbow flexion against gravity has not evolved by 3 months of age, then referral to a surgical center with expertise in the management of Erb palsy should be considered.

PROGNOSIS

- ~75–85% of all patients regain very good to full strength and function, with 1/2 doing so rapidly (the mild group) and 1/2 more slowly (the moderate group).

Clinical Spectrum of Erb Palsy and Natural History

- For typical Erb palsy, return of elbow flexion (biceps) is the single most important prognostic factor in predicting functional recovery. Return of external rotation of the shoulder and forearm supination best predicts full recovery of function. Full recovery has been reported in 69–95% of patients. An estimated 1/4 of Erb palsy patients have some degree of permanent functional impairment.
- Pure C5, C6 Erb palsy patients do the best as a group.
- Prognosis is more guarded when C7 is involved.
- Involvement of the whole plexus or C8, T1 (Klumpke palsy) distribution fares least well.

- Mild: ~1/2 of patients have a mild injury due to stretching of the myelin sheath of the nerve fibers:
 - Initially there can be weakness limited to elevation of the arm and elbow flexion, or there can be full flaccidity of the arm and hand. Recovery of at least antigravity power in all muscle groups is seen by 2 weeks, and full strength returns by 3 weeks of age.
- Moderate: Another 1/4 of babies are very weak to fully flaccid at birth. This group appears initially like the mild one, but has slower recovery:
 - Those infants likely to recover fully develop at least antigravity strength in shoulder abduction and elbow flexion/extension by 3 months of age and recover full functional strength at a mean age of 6.5 months (range of 1.5–16 months). External rotation of the shoulder and forearm supination are the last motor functions to return. Mild weakness, contractures, and motor deficits may persist.
- Severe: If the arm remains flaccid at 3 months, the prognosis for spontaneous recovery of functional strength in the arm is guarded and with a high likelihood of developing shoulder and elbow joint contractures. When some improvement is seen at 3 months but is still less than antigravity, it is not possible to predict if a specific patient will be in the moderate or severe group. By 5–6 months, the group destined to recover functional strength will usually have developed antigravity strength in elbow flexion. If severe wrist and finger extensor weakness is still present at 6 months, there is little chance that a good functional recovery will occur.

COMPLICATIONS

- Ipsilateral diaphragm weakness is seen in about 5%, due to phrenic nerve (C4, C5) compromise.
- Bilateral arm weakness, typically asymmetric in degree, is noted in ~10%.
- Torticollis is frequent, and facial palsy is seen in ~10%. These do not carry an added unfavorable prognosis.
- Associated subluxation of the cervical spine and related spinal cord injury is identified in up to 5% and requires urgent neurosurgical attention.

**CODES****ICD9**

- 767.6 Injury to brachial plexus due to birth trauma
- 767.7 Other cranial and peripheral nerve injuries due to birth trauma

ICD10

- P14.0 Erb's paralysis due to birth injury
- P14.3 Other brachial plexus birth injuries

FAQ

- Q: What if my baby does not get better?
- A: About 1 in 4 babies have poor or limited recovery within the 1st few months, in which case it is advised to consult with a surgeon expert in this area and address whether an operation to fix the nerve injury will enhance the recovery. In the older child with some functional use of the arm, there may be a role for latter soft tissue surgery, to release contractures, transfer tendons, or stabilize the shoulder joint. Occupational therapy is important for infants and children with residual deficits in function.
- Q: When should an EMG be performed?
- A: If a baby with Erb palsy has no sign of recovery of biceps function at 1 month of age, then an EMG is helpful in establishing the prognosis. Lack of reinnervation features suggests a poor chance spontaneously gaining functional recovery, and surgical referral should be considered.

OMPHALITIS

Samir S. Shah

BASICS

DESCRIPTION

Omphalitis, an infection of the umbilical stump, begins in the neonatal period as a superficial cellulitis, but may progress to necrotizing fasciitis, myonecrosis, or systemic disease.

EPIDEMIOLOGY

- Episodes of omphalitis are usually sporadic, but rare epidemics occur.
- Mean age of onset is 5–9 days in term infants and 3–5 days in preterm infants.

Incidence

- Incidence varies from 0.2–0.7% in industrialized countries.
- Incidence is higher in hospitalized preterm infants compared with term infants.

RISK FACTORS

- Low birth weight
- Prior umbilical catheterization
- Septic delivery
- Prolonged rupture of membranes

GENERAL PREVENTION

- Antimicrobial agents applied to the umbilicus decrease bacterial colonization and prevent omphalitis.
- Effective methods of umbilical cord care include:
 - Triple dye daily until cord separation
 - Triple dye once and then alcohol daily until cord separation
 - Triple dye once and no further treatment
 - Povidone-iodine daily until cord separation
 - Silver sulfadiazine daily until cord separation
 - Bacitracin daily until cord separation
 - Chlorhexidine (4%) daily for 7 days
- There are no significant differences in the incidence of omphalitis with these regimens. However, the duration of umbilical cord attachment is significantly longer with triple dye daily compared with the other regimens (17 days vs. 6–12 days).
- Dry cord care: Spot cleaning of soiled skin in periumbilical area without application of any antibacterial agents is acceptable, but requires extreme vigilance for signs of infection. Infants treated with dry cord care as opposed to any of the above regimens are more likely to experience foul-smelling umbilical exudates (7% vs. <1%), bacterial colonization of umbilical stump, and omphalitis.

PATHOPHYSIOLOGY

- Potential bacterial pathogens normally colonize the umbilical stump after birth.
- These bacteria invade the umbilical stump, leading to omphalitis.
- Established aerobic bacterial infection, necrotic tissue, and poor blood supply facilitate the growth of anaerobic organisms.
- Infection may also extend beyond the subcutaneous tissues to involve fascial planes (fasciitis), abdominal wall musculature (myonecrosis), and the umbilical and portal veins (phlebitis).

ETIOLOGY

- Most (85%) cases of omphalitis are polymicrobial.
- The most common organisms include gram-positive cocci (*Staphylococcus aureus*, group A streptococci) and gram-negative enteric bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*).
- Gram-positive organisms predominated in the past; however, the introduction of antistaphylococcal cord care (triple dye) has led to an increase in colonization and infection with gram-negative organisms.
- Anaerobic bacteria, including *Bacteroides fragilis* and *Clostridium perfringens*, are isolated in 1/3 of infections.
- Anaerobic organisms are more likely in cases complicated by necrotizing fasciitis or myonecrosis than in cases of superficial abdominal wall cellulitis.
- *Clostridium tetani* and *Clostridium sordellii* have been reported when deliveries have occurred outside a medical facility and when the cultural practice of placing cow dung on the umbilical stump after delivery was observed.

COMMONLY ASSOCIATED CONDITIONS

- Omphalitis may be the initial manifestation of an underlying disorder of neutrophil migration such as leukocyte adhesion deficiency, a rare immunologic disorder with an autosomal-recessive pattern of inheritance. These infants present with leukocytosis, delayed separation of the umbilical cord, and recurrent infections.
- Omphalitis may also be a manifestation of neutropenia in the neonate:
 - In neonatal alloimmune neutropenia, maternal IgG antibodies cross the placenta and result in an immune-mediated destruction of fetal neutrophils bearing antigens that differ from the mother's. The resultant neutropenia can last for several weeks to as long as 6 months. Antineutrophil antibodies are found in the serum of the mother and the infant. Affected infants may also present with other cutaneous bacterial infections, pneumonia, sepsis, and meningitis.
 - Causes of neutropenia associated with immune dysfunction include autoimmune neutropenias, X-linked agammaglobulinemia, hyper-IgM immunodeficiency syndromes, and HIV.
 - Other causes of neutropenia include metabolic disorders such as hyperglycemia, isovaleric acidemia, propionic acidemia, methylmalonic acidemia, tyrosinemia, and glycogen storage disease type IB.
- Omphalitis complicated by sepsis can also be associated with neutropenia. Therefore, the underlying disease process producing neutropenia may not be immediately appreciated in affected newborns.
- Rarely, an anatomic abnormality such as a patent urachus or patent omphalomesenteric duct may be present.

DIAGNOSIS

HISTORY

- Identify risk factors such as prolonged membrane rupture, septic or home delivery, and dry cord care.
- A history of change in mental status such as irritability, lethargy, somnolence, or decreased level of activity may indicate systemic dissemination of the infection.
- A history of urine or stool discharge from the umbilicus suggests an underlying anatomic abnormality.
- Family history may reveal individuals with metabolic disorders or recurrent infections.

PHYSICAL EXAM

- Varies with the extent of disease
- Localized infection:
 - Abdominal tenderness
 - Periumbilical edema and erythema
 - Purulent or malodorous discharge from the umbilical stump
- Indications of more extensive local disease, such as necrotizing fasciitis or myonecrosis:
 - Periumbilical ecchymoses or gangrene
 - Abdominal wall crepitus
 - Progression of cellulitis despite antimicrobial therapy
- Signs of systemic disease are nonspecific and include thermo dysregulation and evidence of multiorgan dysfunction:
 - Fever or temperature instability
 - Tachycardia, hypotension, delayed capillary refill
 - Apnea, tachypnea, flaring of the alae nasi, grunting, intercostal/subcostal retractions, hypoxemia
 - Abdominal distention, diminished bowel sounds
 - Cyanosis, petechiae, jaundice
 - Lethargy, hypotonia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Umbilical stump Gram stain and culture for aerobic and anaerobic organisms:
 - Identify potential organisms and antimicrobial susceptibility patterns. Although suggestive, cultures of umbilical discharge may reflect only colonization of the stump and are not proof of an etiologic role in the underlying process. Therefore, if myonecrosis is suspected, specimens of muscle should be sent for culture.
- Blood culture:
 - Risks systemic dissemination of infection in the neonate.

- CBC:
 - Neutropenia or neutrophilia may be present.
 - An immature-to-total neutrophils ratio >0.2 is suggestive of systemic infection.
 - Thrombocytopenia may be present.
- D-dimers or prothrombin time, partial thromboplastin time, fibrinogen, and fibrinogen split products:
 - Indicated for sepsis or disseminated intravascular coagulation

Imaging

Radiographs (case dependent):

- Abdominal radiographs:
 - Portal venous or intramural air requires immediate surgical consultation.
- Abdominal CT:
 - Confirms involvement of fascia and muscle and delineates the extent of infection
- Voiding cystourethrogram:
 - Reveals patent urachus

Diagnostic Procedures/Other

Lumbar puncture is indicated in any neonate with a focal bacterial infection

DIFFERENTIAL DIAGNOSIS

- The characteristic clinical picture of omphalitis allows diagnosis on clinical grounds.
- Determine the presence of associated complications, such as necrotizing fasciitis, myonecrosis, or systemic infection.
- Consider an underlying immunologic or metabolic disorder.

TREATMENT

MEDICATION (DRUGS)

Empiric coverage:

- Antistaphylococcal agent (e.g., oxacillin, vancomycin) plus an aminoglycoside (e.g., gentamicin, amikacin, tobramycin) or cefepime
- Add anaerobic coverage (e.g., metronidazole) in cases complicated by necrotizing fasciitis or myonecrosis. Clindamycin also provides anaerobic coverage and may be substituted for the antistaphylococcal penicillin.
- As with antimicrobial therapy for other infections, consider local antibiotic susceptibility patterns.
- Duration of therapy is typically 10–14 days; 7 days may be adequate for uncomplicated cases

ADDITIONAL TREATMENT

General Measures

Antibiotics and supportive care

Additional Therapies

The use of hyperbaric oxygen to treat anaerobic necrotizing fasciitis and myonecrosis is controversial:

- No prospective data are available.
- The delivery of high concentrations of oxygen to marginally perfused tissues may have a detrimental effect on the growth of anaerobic organisms and improve phagocyte function.
- Surgical therapy remains the highest priority.

SURGERY/OTHER PROCEDURES

- Early and complete surgical débridement of affected tissue and muscle is important.
- Delay in diagnosis or surgical intervention allows local progression of infection and worsening systemic toxicity.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Emergency care: Immediate evaluation, antimicrobial therapy, and supportive care are essential to survival.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Infants developing associated portal vein thrombosis require follow-up for complications owing to portal hypertension.

PROGNOSIS

- The outcome of infants with uncomplicated omphalitis is generally good.
- The mortality rate among all infants with omphalitis, including those who develop complications, is 7–15%.
- The mortality rate is significantly higher (38–87%) with necrotizing fasciitis or myonecrosis.
- Risk factors for poor prognosis include male gender, prematurity, low birth weight, and septic delivery, including delivery outside a medical facility.

COMPLICATIONS

- Necrotizing fasciitis, a bacterial infection of the subcutaneous fat, and superficial and deep fascia, complicates 8–16% of cases of omphalitis. It is characterized by rapidly spreading infection, often with systemic toxicity.
- Myonecrosis refers to infectious involvement of the muscle. The rapid development of edema may constrict the muscle within its fascia and cause a superimposed ischemic myonecrosis. Extensive areas of necrotic tissue facilitate the growth of anaerobic organisms.
- Portal vein thrombosis and septic embolization follow infection of the umbilical vessels.
- Sepsis complicates omphalitis in 13% of cases.

CODES

ICD9

- 041.00 Streptococcus infection in conditions classified elsewhere and of unspecified site, streptococcus, unspecified
- 041.10 Staphylococcus infection in conditions classified elsewhere and of unspecified site, staphylococcus, unspecified
- 771.4 Omphalitis of the newborn

ICD10

- B95.0 Streptococcus, group A, as the cause of diseases classified elsewhere
- P38.1 Omphalitis with mild hemorrhage
- P38.9 Omphalitis without hemorrhage

FAQ

- Q: Do all infants who develop omphalitis require evaluation for immunologic disorders?
- A: No, particularly if predisposing factors such as an umbilical catheter are present. Infants requiring further evaluation include those with persistent neutropenia, recurrent infections, delayed separation of the umbilical cord, or a family history of immunologic disorders.
- Q: Is surgical consultation required for all infants with omphalitis?
- A: No. Surgical consultation is not required for uncomplicated omphalitis. However, a high degree of suspicion should exist for associated complications. The presence of necrotizing fasciitis or myonecrosis requires immediate surgical consultation.

OSTEOGENESIS IMPERFECTA

Vikas Trivedi

John P. Dormans

BASICS

DESCRIPTION

Osteogenesis imperfecta (OI) is a group of genetically and clinically heterogeneous connective tissue disorders affecting bone and soft tissue, causing abnormal fragility of bone, resulting in recurring fractures and deformity.

EPIDEMIOLOGY

Incidence

1 in 30,000 births

Prevalence

~20,000–50,000 cases in U.S.

RISK FACTORS

Genetics

- Majority of OI cases are caused by dominant mutations in type I collagen: *COL1A1* and *COL1A2*, and by recessive mutations in recently identified *CRTAP* (cartilage-associated protein gene) and *LEPRE1*.
- Sillence classification:
 - Type I (mild, nondeforming): Autosomal dominant *COL1A1*, blue sclera, onset preschool:
 - A: Teeth involved
 - B: Teeth not involved
 - Type II (perinatal, lethal): Autosomal recessive, *CRTAP* and *LEPRE1*, lethal, blue sclera
 - Type III (severely deforming): Autosomal recessive, *CRTAP* and *LEPRE1*, severe, normal sclera
 - Type IV (moderately deforming): Autosomal dominant, *COL1A2*, normal sclera, mild form:
 - A: Teeth involved
 - B: Teeth not involved
- New descriptive phenotypic classification (type I–VIII) has been proposed that incorporates traditional Sillence classification with new genetic mutations as described above.

PATHOPHYSIOLOGY

- In general, both enchondral and intramembranous bone formation are disturbed:
 - Osteoid seams are wide and crowded by osteoblasts (woven bone).
 - Osteoclasts are normal.
 - Collagen fibrils are disorganized (by electron microscope).
- Physis broad and irregular:
 - Osteopenia
 - Long bones are slender and smaller.
 - Fractures (recent or healed)
 - Deformities:
 - Spine: Scoliosis, compression fractures, kyphosis, upper cervical spine instability
 - Skull: Multiple centers of ossification, wormian bones, basilar invagination/platybasia

ETIOLOGY

- Abnormality of collagen production and organization
- Failure of maturation of procollagen to type I collagen and failure of normal collagen cross-linking

DIAGNOSIS

HISTORY

- Variable
- Family history

PHYSICAL EXAM

- Severe congenital forms:
 - Multiple fractures
 - Limbs deformed and short
 - Skull soft
- Mild and moderate forms:
 - General: Short stature, hernias
 - Extremities: Bowing, coxa vara deformity, cubitus varus, hypermobility of joints: Subluxations and dislocations
 - Pelvis: Trefoil pelvis, protrusio acetabuli

- Spine (cause: osteoporosis, compression fractures, and ligamentous laxity): Kyphoscoliosis (30–40%), platybasia
- Skin: Thin skin, subcutaneous hemorrhages, wide surgical scars
- Eyes: Blue sclera caused by thin collagen layer, Saturn ring (white sclera immediately) hyperopia, embryotoxon or arcus juvenilis occasionally, retinal detachment occasionally
- Teeth: Dentinogenesis imperfecta, enamel normal, both deciduous and permanent teeth affected, teeth easily broken, discoloration
- Deafness: Either conduction or nerve type

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum calcium and phosphorus levels:
 - Normal
- Alkaline phosphatase:
 - May be elevated
- No widely available specific diagnostic laboratory test
- Dermal biopsy involving collagen testing
- Current evidence favors DNA analysis over dermal biopsy

Imaging

- Osteopenia
- Fractures:
 - New, healing, or healed
 - Malunions
- Deformity
- Metaphyseal ends of long bones:
 - Honeycomb appearance of ends of long bones, popcorn calcifications, Erlenmeyer flask appearance, acetabular protrusion
- Spine:
 - Atlantoaxial subluxation, spondylolisthesis, scoliosis, compression fractures

DIFFERENTIAL DIAGNOSIS

- Severe:
 - Congenital hypophosphatasia
 - Achondroplasia
 - Camptomelic dwarfism
- Mild:
 - Cystinosis
 - Pyknodysostosis
 - Child abuse
 - Leukemia
 - Idiopathic juvenile osteoporosis
 - Steroid treatment
 - Rickets in very-low-weight infants
 - Menkes kinky hair syndrome (newborn male [X-linked recessive] with failure to thrive)
 - Metaphyseal corner fractures
 - Abnormal hair
- Hyperplastic callus formation may be confused with osteogenic sarcoma.

**TREATMENT****MEDICATION (DRUGS)**

- Bisphosphonates are being used currently in clinical trials for children with severe involvement (gene therapy possibly in future).
- Sex hormones, fluoride, magnesium oxide, and calcitonin

ADDITIONAL TREATMENT**General Measures**

- Fracture treatment:
 - Fractures heal at a normal rate; splinting, orthoses, casting, operations (intramedullary rod)
- Scoliosis:
 - Seen in ~50%
 - Orthoses usually ineffective
 - Spinal fusion for curves >50 degrees after the onset of puberty
- Correction of deformities (e.g., realignment osteotomies with intramedullary fixation most common for long-bone deformity)

IN-PATIENT CONSIDERATIONS**Initial Stabilization**

Emergency care:

- For unstable fractures, such as femur fractures, spine instability
- Depends on location of fracture and details of individual situation
- Multidisciplinary approach:

Team member	Care problem
Pediatric Endocrinologist	Maintenance of bone mass
Pediatric orthopaedic surgeon	Fracture repair, rodding, scoliosis correction
Dentist	Dentinogenesis imperfecta: capping, orthodontics
Physiotherapist	Post operative Rehabilitation of all joints and spine, muscle strength and gait training
Psychologist/Social worker	School adjustment from kindergarten to college, work guidance

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Techniques for safe handling, protective positioning, and safe movement are taught to parents.
- Children and youth learn which activities to avoid and how to practice energy conservation.
- Following a healthy lifestyle including not smoking, and maintaining a healthy weight is beneficial.

PATIENT EDUCATION

Education and fracture and injury prevention are important.

PROGNOSIS

- In general, the earlier the fractures occur, the more severe the disease.
- For moderate and mild types, there is a gradual tendency to improvement, with the incidence of fractures decreasing after puberty.
- Depends on severity of OI
- Moderate and mild types:
 - Gradual tendency to improvement, with incidence of fractures decreasing after puberty

COMPLICATIONS

- Pathological fractures
- Scoliosis
- Cardiorespiratory problems (aortic dilatation, mitral valve prolapse, and aortic regurgitation)
- Otosclerosis and hearing loss
- Dwarfism
- Skull fractures
- Intracranial bleeding and brain damage

ICD10

Q78.0 Osteogenesis imperfecta

OSTEOSARCOMA

Naomi J. Balamuth

Susan R. Rheingold (5th edition)

BASICS

DESCRIPTION

A tumor of the bone composed of spindle cells that produce malignant osteoid

EPIDEMIOLOGY

- Osteosarcoma is the most common malignant bone tumor of childhood and adolescence, representing 60% of all bone tumors in the pediatric age group.
- Overall, it accounts for <1% of all malignant neoplasms.
- ~90% of tumors occur at the metaphyseal ends of long tubular bones, but any portion of the skeleton may be involved.
- The most frequent site is the distal femur, followed by the proximal tibia and the proximal humerus.

Incidence

- Peak incidence is in adolescence and early adulthood, with a median age of 18 at diagnosis.
- Thought to begin during the adolescent growth spurt

RISK FACTORS

- Radiation exposure
- Paget disease of the bone
- Rothman–Thompson syndrome
- Enchondromatosis
- Hereditary multiple exostoses
- Fibrous dysplasia
- Hereditary retinoblastoma

Pathophysiology

- Osteosarcoma most often involves the medullary region of bone.
- Rarely, osteosarcoma occurs in soft tissue separate from underlying bone.
- Classic or conventional osteosarcoma, the largest group of osteosarcomas, is composed of connective tissue stroma containing highly malignant spindle-shaped cells as well as areas of osteoid production and calcification.
- 4 microscopic subtypes are osteoblastic, chondroblastic, fibroblastic, and telangiectatic. These variants are rare in the pediatric population and lack prognostic significance at present.
- 2 rare clinical subtypes, periosteal and parosteal osteosarcomas, rarely metastasize and carry a better prognosis.

ETIOLOGY

- The etiology of most cases is unknown.
- There is an association of osteosarcoma with exposure to ionizing radiation:
 - Secondary osteosarcoma is seen in up to 5% of patients who received radiation therapy for an initial malignancy.
- Children with hereditary retinoblastoma are at increased risk of developing osteosarcoma with and without prior exposure to radiation.

DIAGNOSIS

SIGNS AND SYMPTOMS

- A tender, soft-tissue mass and increased warmth may be present in the involved area.
- Localized erythema is uncommon.
- Unless there exists an underlying fracture, range of motion of the limb is normal and there is no difficulty weight bearing.
- Regional lymphadenopathy is rare.

HISTORY

- Pain at the site of the tumor is the most common presentation.
- Swelling over the involved area is also reported.
- The duration of symptoms varies.
- A history of recent trauma is common but unrelated. Trauma often brings the affected area to the patient's or parents' attention, but does not actually cause osteosarcoma.
- Weight loss is rare, but may occur in advanced disease.
- If fever is present, it may indicate an infectious cause (osteomyelitis) rather than osteosarcoma.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Laboratory tests are not generally helpful in osteosarcoma.
- Serum lactate dehydrogenase (LDH) and alkaline phosphatase may be elevated: The prognostic significance is controversial.
- An elevated WBC count, C-reactive protein, or sedimentation rate may suggest osteomyelitis.

Imaging

- A plain radiograph of the involved area always reveals some abnormality. Radiographic examination should include the primary tumor site as well as areas of potential metastases:
 - Most commonly, one sees a lytic or blastic region of the bone with ill-defined borders.
 - Other findings may include periosteal elevation adjacent to the primary lesion, a sunburst appearance of the primary lesion caused by neoplastic spicules adjacent to the bony cortex, or a pathologic fracture.
- A chest CT and bone scan should be done to assess for pulmonary and bone metastases.
- An MRI should be done to better evaluate the extent of the tumor:
 - Include the joint above and below the involved bony area.
 - MRI can delineate the intraosseous and extraosseous extent of the tumor as well as evaluate the neurovascular structures involved.

Diagnostic Procedures/Surgery

The diagnosis of osteosarcoma can be confirmed only by a biopsy, which should be done by an experienced pediatric orthopedic surgeon in conjunction with a pediatric oncologist and pediatric pathologist

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Osteomyelitis
 - Septic arthritis
- Trauma: Stress fracture
- Benign tumors:
 - Unicameral bone cyst
 - Osteoblastoma
 - Eosinophilic granuloma
 - Giant-cell tumor
 - Aneurysmal bone cyst
 - Osteochondroma
 - Fibrous dysplasia
- Malignant tumors:
 - Ewing sarcoma
 - Chondrosarcoma
 - Fibrosarcoma
 - Leukemia
 - Metastatic lesions of other primary tumors

TREATMENT

RADIOTHERAPY

Osteosarcoma is not a radiation sensitive tumor. Radiation may be used in cases that are not surgically accessible.

Physical Therapy

- All patients need to work with specialists to learn how to adapt to their surgically induced disability.
- The duration of physical therapy and rehabilitation is dependent on the disability and the individual patient's needs.

MEDICATION (DRUGS)

- The goals of adjuvant chemotherapy are treatment of micrometastases and shrinkage of the primary tumor mass, particularly when limb-salvage procedures are surgical options. Response to adjuvant chemotherapy (degree of necrosis at the time of complete resection) is an important prognostic factor.
- Groups such as the Children's Oncology Group (COG) have developed chemotherapy protocols for osteosarcoma. Most children and adolescents with osteosarcoma are treated on these chemotherapy protocols. Many protocols are open to young adults up to the age of 30.

- The mainstays of treatment are cisplatin, high-dose methotrexate and doxorubicin, with many protocols adding ifosfamide and etoposide:
 - The duration of chemotherapy varies from 8–12 months according to the extent of the tumor at diagnosis, tumor response to therapy, and the individual protocol.

SURGERY/OTHER PROCEDURES

- In the past, when osteosarcoma was managed by surgery alone, most patients subsequently developed pulmonary metastases and died of progressive disease.
- Surgical options depend on the primary site of the tumor and the extent of tumor involvement.
- Complete surgical resection with wide margins is necessary for cure. Surgical options for osteosarcomas of the extremities include:
 - Amputation
 - Limb salvage with allograft or prosthetic reconstruction
 - Rotationplasty
- Macroscopic pulmonary metastases should be resected at the time of surgery if still visible by radiographic examination:
 - Localized pulmonary recurrences that develop after treatment also should be resected, as this can result in long-term cure or a prolonged symptom-free period.

ONGOING CARE

ISSUES FOR REFERRAL

When a malignant bone tumor is suspected, the patient should be referred immediately to a pediatric cancer center:

- Children's cancer centers can provide the multidisciplinary team needed to diagnose, biopsy, treat, and rehabilitate children with bone tumors.

PROGNOSIS

- Most patients with osteosarcoma involving an extremity without pulmonary metastases can be cured.
- 5-year survival for nonmetastatic disease ranges from 60–70%. The following have been associated with a poorer prognosis:
 - Pulmonary metastases
 - Disseminated bone metastases
 - Poor response of the tumor to preoperative chemotherapy with tumor necrosis <95%
 - Inability to achieve a total surgical excision of the tumor

COMPLICATIONS

- 10–20% of patients have pulmonary metastases at the time of diagnosis; a smaller proportion has metastases to other bones
- Wound infections may develop in surgical sites in the initial postoperative period. Significant pain, fever, swelling, discharge, and foul odor from the surgical site should be evaluated, preferably by the surgeon.
- Poor healing of the surgical site may be a problem, particularly in patients receiving chemotherapy or in those with poor nutrition. Patients may require IV antibiotics, supplemental feeding, and/or surgical revision of the wound.

Patient Monitoring

- If prostheses are required, skin breakdown and fitting difficulties with prosthetic devices, such as adjustments for changes in height and weight, should be diagnosed and corrected. Scoliosis and back pain may develop in patients using improperly adjusted crutches and/or prosthetic devices after lower extremity or pelvic procedures. This requires expertise in prosthetic devices for children.
- Phantom pain is a normal phenomenon after amputation. Patients and their families should be reassured if this occurs. Sometimes medication can reduce the pain.
- All children need to be followed by an oncologist regularly after treatment is completed to monitor for recurrence as well as long-term side effects of the chemotherapy, such as cardiac toxicity, infertility, or secondary malignancy.

FAQ

- Q: How does one differentiate osteosarcoma from Ewing sarcoma, the second most common bone tumor of childhood?
- A: Ultimately, only a biopsy can differentiate the two. In general, Ewing sarcoma is seen in younger children and tends to affect the axial bones, such as the pelvis. When found in the long bones, it is usually in the diaphyseal regions. Symptomatology does not differ, but Ewing sarcoma can be metastatic to the bone marrow, as well as the bone and lung.
- Q: How does one differentiate osteosarcoma from a benign bone lesion?
- A: Ultimately, only a biopsy can differentiate the two. Benign lesions tend to be very well circumscribed with smooth edges on radiograph. They are generally not associated with soft tissue masses, swelling, or fever. Fractures are just as likely through benign bone lesions as malignant ones. Only in very rare situations should bony lesions be presumed to be benign and observed without biopsy.
- Q: Is there an increased risk of osteosarcoma in the contralateral limb?
- A: No.
- Q: Does limb salvage incur a greater risk of recurrence than does amputation?
- A: Recent studies have shown that there is no increase in recurrence if wide margins are achieved at the time of surgery.

OSTEOMYELITIS

Virginia M. Pierce

Mitchell R. M. Schwartz (5th edition)

BASICS

DESCRIPTION

- Infection of the bone
- Any bone can be involved, but most commonly occurs in the metaphysis of a long bone (especially the femur or tibia)

EPIDEMIOLOGY

- One of the most common invasive bacterial infections in children, accounting for 1% of all pediatric hospitalizations
- ~50% of cases occur in children ≤ 5 years of age
- A history of minor trauma to the affected site is common, but of unclear significance.

RISK FACTORS

- Sickle hemoglobinopathy
- Primary or acquired immunodeficiency
- Bone trauma (open fractures, puncture wounds, bites, surgical manipulation)
- Implanted orthopedic devices
- Pressure ulcers

PATHOPHYSIOLOGY

- Usually, osteomyelitis is of hematogenous origin in children (inoculation of bone during an episode of bacteremia). The infecting organism enters the bone via a nutrient artery and then is deposited in the metaphysis due to its rich vascular supply. The organism replicates in metaphyseal capillary loops, causes local inflammation, spreads through vascular tunnels, and adheres to the bone matrix. Increased pressure in the metaphysis allows pus to perforate through the cortex and lift the periosteum.
- Local spread from a contiguous focus of infection and direct inoculation (e.g., penetrating injury) are less common mechanisms of infection.

ETIOLOGY

- *Staphylococcus aureus* is responsible for 70–90% of osteomyelitis in all age groups, with MRSA an increasingly common problem.
- *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Kingella kingae* are the next most common pathogens in infants and children.

- Group B *Streptococcus* and gram-negative enterics are important causative organisms in neonates.
- *Salmonella* spp. can be the cause in children with sickle cell disease.
- *Pseudomonas aeruginosa* can be found after puncture wounds to the foot.
- There has been a significant decline in the incidence of *Haemophilus influenzae* type b (Hib) osteomyelitis since immunization with the Hib conjugate vaccine became widespread.
- Other, more unusual pathogens may be seen in patients with specific risk factors (e.g., coagulase-negative staphylococci in the presence of prosthetic material, anaerobes after animal or human bites).
- In a significant percentage of cases, a definitive causative microorganism is not identified.

DIAGNOSIS

HISTORY

- Persistent, increasing pain and tenderness over the affected bone
- Restricted use of the involved limb, refusal to bear weight, or limp
- Fever, malaise, anorexia
- Swelling, warmth, and erythema of the soft tissues over the affected bone may be noted.
- Exaggerated immobility/pain with micromotion of an adjacent joint suggests pyogenic arthritis (alternatively, or in addition to osteomyelitis).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- The white blood cell count may be normal or elevated.
- The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are usually elevated.
- Blood cultures are positive in ~50% of patients.

Imaging

- Plain radiographs may show deep soft-tissue swelling early in the course of infection and may help to suggest or exclude alternative diagnoses. Evidence of bone destruction and periosteal elevation are not typically seen until 10–14 days after the onset of symptoms.
- Bone scans are sensitive and are especially useful if the site of infection is poorly localized or if there is concern for multifocal osteomyelitis. However, they may be positive in other illnesses that cause osteoblastic activity.
- MRI is sensitive and offers superior anatomic resolution, making it a more useful modality for surgical planning and for identification of intraosseous, subperiosteal, and soft tissue abscesses.

Diagnostic Procedures/Other

- Biopsy or aspiration of the infected bone (or an associated abscess) for Gram stain and culture is useful for determining the etiologic organism. Inoculating a portion of an aspirated sample into a blood culture bottle enhances yield for *Kingella kingae*.
- If a plan is in place to rapidly obtain a bone culture in a clinically stable patient, it is reasonable to defer initiation of antibiotic therapy until after the culture specimen is secured.
- Biopsy may also help differentiate osteomyelitis from noninfectious bone pathology.

DIFFERENTIAL DIAGNOSIS

- Trauma
- Cellulitis
- Abscess
- Pyomyositis or fasciitis
- Septic arthritis
- Aseptic bone necrosis or bone infarction (sickle cell disease)
- Tumor (e.g., Ewing sarcoma, osteoid osteoma, eosinophilic granuloma)
- Acute leukemia, neuroblastoma with bone invasion
- Chronic recurrent multifocal osteomyelitis (CRMO)
- Inflammatory arthritis or juvenile idiopathic arthritis
- Transient synovitis

TREATMENT

MEDICATION (DRUGS)

- Empiric antibiotics should cover the most likely pathogens considering patient age, history of presentation, physical findings, and underlying medical conditions.
- Empiric therapy should always include an agent directed against *S. aureus*. In the past, oxacillin or nafcillin was the standard agent, but the increasing prevalence of MRSA has altered this approach. In areas where the rate of methicillin resistance among community *S. aureus* isolates exceeds 10%, an antibiotic effective against community-acquired MRSA should be selected (i.e., clindamycin or vancomycin).
- Clindamycin and vancomycin are also usually effective against *S. pneumoniae* and *S. pyogenes*, but are not effective in vitro against *K. kingae*.
- *Salmonella* spp. coverage is needed in patients with sickle cell disease.
- Gram-negative coverage should also be added to the empiric regimen for neonates.
- If the patient recently had a foot puncture wound, coverage for *P. aeruginosa* should be considered.
- If an organism is isolated and susceptibilities determined, antibiotic therapy should be modified based on the susceptibility profile.
- When clindamycin is considered for treatment of an identified MRSA isolate, the D-test (to exclude inducible macrolide, lincosamide, and streptogramin B resistance) should be performed by the clinical microbiology laboratory.

ADDITIONAL TREATMENT

General Measures

- Antibiotic therapy for 4–6 weeks is generally provided.
- Total treatment duration is individualized based on the extent of infection, the promptness and completeness of surgical débridement (when indicated), the rate of clinical response, the presence or absence of distant foci of infection, and the patient's underlying risk factors and comorbid conditions.
- If an intraosseous, subperiosteal, or soft tissue abscess is present, surgical débridement may be necessary in addition to antibiotic therapy.
- After an initial period of parenteral antibiotic administration, many patients can be transitioned to an oral regimen to complete therapy (assuming the availability of an oral antibiotic with an appropriate spectrum of activity and adequate bone penetration, as well as patient ability to adhere to and absorb an oral regimen). This sequential IV–oral approach reduces the risk of complications (e.g., catheter associated bloodstream infection, catheter malfunction, and thrombosis) associated with the prolonged presence of a central venous catheter.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Most children who receive appropriate treatment have no long-term sequelae.
- Inflammatory markers (ESR and CRP) are typically measured serially until they normalize during the course of antibiotic therapy.
- Patients should be followed to ensure medication compliance, adequacy of treatment, side effects of therapy, and continued growth of the involved extremity.

COMPLICATIONS

- Septic arthritis
- Recurrence or progression to chronic osteomyelitis in ~5% of patients
- Disturbances of bone growth, limb length discrepancy
- Arthritis
- Pathologic fractures

OTITIS EXTERNA

Lee R. Atkinson-McEvoy

BASICS

DESCRIPTION

- Inflammation or infection of the external auditory canal and/or the auricle
- May be categorized as follows:
 - Acute: Also known as “swimmer’s ear,” usually an acute bacterial infection of the external auditory canal
 - Chronic: Persistent, low-grade infection and inflammation of the external ear
 - Atopic: Encompasses otitis externa due to atopic dermatitis, seborrheic dermatitis, psoriasis, and other inflammatory conditions
 - Fungal: Occurs more commonly in patients with diabetes mellitus or an immunodeficiency
 - Malignant or necrotizing: Severe otitis externa with invasive disease into the surrounding soft tissue, cartilage and bone; seen more commonly in patients with diabetes mellitus or immunodeficiency; may progress to invasive disease of the surrounding structures

EPIDEMIOLOGY

- Occurs more commonly in summer months
- 90% of cases are unilateral.
- Uncommon before 2 years of age

Incidence

1:100–250 annually in the general population

Prevalence

10% of the population is diagnosed with acute otitis externa at some point in their lives.

RISK FACTORS

- Increased environmental temperature
- High humidity
- Local trauma
- Exposure to water with high bacterial counts.

GENERAL PREVENTION

- Earplugs that prevent water from entering the ear canal should be used when swimming or participating in other water sports.
- Acetic acid drops (which can be made at home with 1 part vinegar to 2 parts rubbing alcohol) followed by wicking away moisture with cotton; can be used to restore the acidic pH of the ear canal and decrease moisture to prevent otitis externa after swimming.
- Discourage removal of cerumen with vigorous ear cleaning, especially by using cotton swabs in the ear. Remove impacted cerumen with cerumenolytics.
- Avoid known allergens.

PATHOPHYSIOLOGY

- Cerumen provides an acidic layer that prevents infection of the external auditory canal. Warm, humid air (i.e., in summer) can disrupt the integrity of cerumen.
- Trauma to the squamous epithelium of the external auditory canal or an increase in the pH of the external auditory canal increases the risk of inflammation and infection.

- Cleaning or removal of cerumen or introduction of water into the canal (i.e., from swimming, playing water sports) can lead to maceration of the canal and the onset of infection.
- Other factors such as sweating, allergy, stress, and alkaline eardrops have been implicated in disturbing the normal acidic pH of the external auditory canal, leading to infection.

ETIOLOGY

- Bacteria: Most commonly *Pseudomonas aeruginosa* 20–60% (particularly in malignant otitis externa) and *Staphylococcus aureus* 10% to 70%, *Staphylococcus epidermidis*. Other organisms make up ~2–3% of cases and usually are other staphylococcal species *Microbacterium* spp., *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Escherichia coli*, *Haemophilus influenzae*, *Klebsiella*, and other gram-negative bacteria.
- Fungal: More common in chronic otitis externa or acute otitis externa after treatment with topical antibiotics; *Candida albicans*, *Aspergillus niger*, *Aspergillus versicolor*
- Viral: Herpes simplex virus (acute infection and herpes zoster) and varicella

DIAGNOSIS

HISTORY

- Known risk factors:
 - Host: Excess wax leading to moisture retention, chronic skin conditions, immunocompromise
 - Environment: Excess moisture (i.e., swimming, high humidity), trauma, heat
- Hearing loss (associated with involvement of the tympanic membrane), pain that is worse with chewing or activities that result in motion of the ear, pruritus (associated with inflammation of the external auditory canal), and/or ear discharge
- Fever may suggest a more severe infection.
- Earrings or other ear jewelry:
 - Associated with atopic dermatitis as the etiology of the otitis externa
- Use of topical treatments for the ear or canal (including tattooing, permanent or nonpermanent), which is also associated with atopic dermatitis as the cause of the otitis externa
- Pain in jaw, particularly in temporomandibular joint area (referred pain).

PHYSICAL EXAM

- Rapid onset
- Pain with pressure applied to tragus and with traction on the pinna
- Canal appears macerated with erythema, purulent discharge, and/or edema.
- Look for the presence of foreign bodies, including pieces of cotton from cleaning with cotton swabs.
- Tympanic membrane should appear intact with normal landmarks. If not, there may be a concurrent otitis media.

- In cases of fungal infection, “mold” or black or white fungal hyphae with spores may be seen.
- In viral infections, vesicles may be present.
- In eczematous otitis externa, the skin is dry and flaky with crust. Excoriation may be visible as well.
- A somewhat fruity smell suggests infection due to *Pseudomonas*.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- In simple, uncomplicated otitis externa, testing is generally not indicated.
- If there is concern for concurrent acute otitis media, pneumatic otoscopy or tympanometry can be performed. These are normal in acute otitis externa, and show limited or absent mobility with pneumatic otoscopy or a flat tracing with tympanometry in acute otitis media.
- In more severe infections, recalcitrant infections, or immunocompromised patients, bacterial culture with Gram stain and fungal cultures should be obtained. *P. aeruginosa* is a frequent pathogen in malignant otitis externa
- Herpes has been described as an etiologic agent; therefore, direct fluorescence antibody (DFA) testing for herpes may be helpful. Viral cultures should be considered when there is a vesicular component to the otitis externa.

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Acute otitis media
 - Mastoiditis
 - Furunculosis
- Tumors:
 - Squamous cell carcinoma
 - Basal cell carcinoma
 - Acoustic neuroma
 - Other metastatic tumors
- Miscellaneous:
 - Foreign body
 - Cerumen impaction
 - Cholesteatoma
 - Atopic dermatitis

TREATMENT

MEDICATION (DRUGS)

- Topical antibiotics are the treatment of choice. They have been shown to be efficacious and to deliver a higher concentration of medication than can be achieved with systemic therapy.
- Otological drops should be placed with the patient lying down with the affected ear up. Drops should fill the canal. Gentle tugging on the pinna allows expulsion of ear and introduction of the drops. The patient should remain in this position for 5 minutes.
- In cases of severe canal edema, clinicians may place a wick, made of compressed cellulose that expands, or ribbon gauze to assist in medication delivery.
- Acetic acid drops are available, with similar efficacy to other antibiotic drops. These are least expensive.

- Polymyxin B, neomycin, and hydrocortisone combination otic solution or suspension can be used to treat a simple infection.
- In some cases, the neomycin component may cause allergy, leading to exacerbation of the otitis externa. If there is a suspected perforation of the tympanic membrane, neomycin is an ototoxic medication and should not be used.
- Fluoroquinolones, such as ofloxacin and ciprofloxacin (available only as a combination with hydrocortisone), have also shown high cure rates.
- Antibiotic–steroid combination drugs have not been shown to have greater clinical or bacteriologic cure than antibiotics alone. However, newer studies suggest that they result in rapid treatment response and symptom resolution.
- Topical ophthalmic antimicrobial/steroid drops, such as Cortisporin ophthalmic solution, may be tolerated better if there is severe maceration of the canal, since they are less acidic.

ADDITIONAL TREATMENT

General Measures

- Hydrogen peroxide or 3% hypertonic saline may be used to clean the ear:
 - Use a cotton swab to dry the canal after cleansing.
- Pain management is an important factor. Pain can usually be managed with mild analgesics, such as acetaminophen or NSAIDs. Benzocaine otic solution with or without antipyrine has not been evaluated for efficacy in clinical trials in acute otitis externa. This type of solution can mask progression of the disease and lead to a contact dermatitis.
- If there is significant edema of the canal, using ophthalmic drops (which tend to be less viscous than otic drops) in combination with a wick to facilitate introduction of medication into the ear canal may be useful. However, if there is concern about a concomitant acute otitis media with perforation, caution must be used with the introduction of any topical treatment to the external auditory canal.
- Specific therapies, depending on the presentation:
 - Remove foreign body if present.
 - For acute localized otitis externa with abscess, incision and drainage of the abscess in combination with antistaphylococcal penicillins or 1st-generation cephalosporins
 - For fungal otitis externa, antifungal drops such as clotrimazole 1% solution are used.
 - For atopic otitis externa, management of the underlying dermatologic condition is appropriate, along with the topical application of corticosteroid to the affected parts of the ear. Skin testing for specific allergies should be considered if atopic otitis externa is severe or recalcitrant.
 - For cellulitis, lymphadenitis, or otitis media, oral antimicrobials are used.
 - When pseudomonal infection is suspected, an antipseudomonal agent, such as a 3rd-generation cephalosporin (e.g., ceftriaxone sodium) or a fluoroquinolone (ofloxacin) should be used.

Additional Therapies

- No data are available regarding efficacy of these therapies.
- Isopropyl alcohol alone, isopropyl alcohol with equal part 5% acetic acid (white vinegar), and 5% acetic acid with an equal part water are common home remedies.
- Tea tree oil is effective in vitro against many bacteria associated with acute otitis externa, but *Pseudomonas* is commonly resistant to this and no controlled efficacy trials have been described.
- Ear candles should not be used to treat acute otitis externa; they have not been shown to be efficacious but they have been shown to cause ear obstruction from the wax, tympanic membrane perforation, and hearing loss.

ISSUES FOR REFERRAL

- Ear, nose, and throat specialist (ENT) referral when indicated:
 - Malignant otitis media (often caused by *P. aeruginosa* and found in immunocompromised individuals) and/or mastoiditis
 - Cases of chronic otitis externa with failure of long-term medical therapy: Refer for débridement and further evaluation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Re-evaluate if there is no symptomatic improvement 24–48 hours after starting treatment.
- Fever or progression of symptoms in spite of treatment warrants more aggressive or broader therapy.
- Immunocompromised patients, including those with diabetes mellitus, should be followed closely depending on severity, to ensure improvement.

PROGNOSIS

Very good, with rapid response to treatment

COMPLICATIONS

- Cellulitis of adjacent tissues (facial or auricular), including facial nerve paralysis, mastoiditis, and osteomyelitis of the skull base.
- Lymphadenitis of upper neck or parotid lymph nodes
- Acute otitis media and rarely mastoiditis
- Facial nerve neuritis
- Canal stenosis (usually in chronic otitis externa that results in hypertrophy of the canal walls)
- Hearing loss, if there is significant edema of the canal walls

FAQ

- Q: How should I clean my child’s ear?
- A: Only the external tragus, pinna, and visible parts of the ear should be cleaned with a cotton ball or washcloth. No foreign object should be placed in the canal. Ear cerumen is a normal protective substance to maintain protection of the fragile tympanic membrane. If impaction is suspected, use a cerumen-loosening agent such as carbamide peroxide. Although there is still common use of ear candles (small narrow candles that are placed at the opening of the external auditory canal and then lit with the goal of the heat causing the cerumen to loosen and exit the ear), this method has not been shown to remove significant impacted cerumen and can leave candle wax in the ear canal.
- Q: When can my child return to swimming after an episode of otitis externa?
- A: After completion of the prescribed therapy, your child may resume water sports. He or she should use waterproof earplugs and acetic acid drops to prevent another infection.
- Q: When should otitis externa be referred to an otolaryngologist?
- A: In refractory cases, chronic otitis externa, or persistent hearing loss after treatment, and when there are severe complications (e.g., malignant otitis externa, mastoiditis).

OTITIS MEDIA

William R. Graessle

BASICS

DESCRIPTION

Otitis media refers to inflammation of the middle ear. A distinction is usually made between otitis media with effusion (OME) and acute otitis media (AOM). AOM implies that infection is present.

EPIDEMIOLOGY

- More common in fall and winter, and less common in spring and summer
- Inverse relationship with breastfeeding duration

Incidence

Increased incidence in those <2 years of age, with the peak incidence between 6–12 months of age

RISK FACTORS

- Exposure to environmental tobacco smoke is an independent risk factor.
- Risk is increased with exposure to large numbers of children (e.g., child care). Additive factors include number of hours spent in child care, younger age at child care entry, and type of child care setting (center vs. family child care).

GENERAL PREVENTION

- Breastfeeding decreases the risk of acute otitis media.
- Preventing exposure to environmental tobacco smoke can decrease the risk of otitis media.
- Decreasing exposure to multiple respiratory pathogens by delaying entrance to group child care or choosing settings with fewer numbers of children may be helpful.
- Vaccines: In addition to preventing invasive disease, conjugated pneumococcal vaccine significantly reduces the risk of AOM.

PATHOPHYSIOLOGY

- Dysfunction of the eustachian tube is the most important factor:
 - The eustachian tube in younger children is shorter, more compliant, and more horizontal than in older children and adults.
 - Children with craniofacial anomalies have an increased risk of eustachian tube dysfunction and subsequent otitis media.
- Viral upper respiratory tract infection often precedes or coincides with AOM. Viral infections may lead to development of AOM by several mechanisms:
 - Inducing inflammation in the nasopharynx and eustachian tube
 - Enhancing nasopharyngeal bacterial colonization
- Impairing host immune system and increasing susceptibility to secondary bacterial infection

ETIOLOGY

- *Streptococcus pneumoniae*: Up to 40%
- Nontypeable *Haemophilus influenzae*: 25–30%
- *Moraxella catarrhalis*: 10–20%
- Other organisms include group A streptococcus, *Staphylococcus aureus*, and gram-negative organisms, such as *Pseudomonas* species. Respiratory viruses are often noted as part of AOM, but are the sole pathogen in <10% of cases.

DIAGNOSIS

HISTORY

- History of current episode with presence of ear pain, fever, and associated symptoms
- Past medical history, including underlying disorders (e.g., cleft palate, Down syndrome), immune deficiency, and previous history of otitis media
- Recent treatment with antibiotics
- Exposure to large numbers of children (school, child care, large family)
- Ear pain
- Fever
- Irritability

PHYSICAL EXAM

- Look for other causes of fever and irritability in children: Upper respiratory tract infections, pharyngitis, lymphadenitis, meningitis, urinary tract infection (UTI), and bone and joint infections.
- Physical exam of the ear is best done with pneumatic otoscopy:
 - The patient should be adequately restrained if uncooperative.
 - Cerumen in the canal should be removed if view of the tympanic membrane is inadequate.
 - The tympanic membrane is visualized at rest, and with gentle positive and negative pressure via pneumatic otoscopy.
- The presence of a middle ear effusion is determined by the characteristics of the tympanic membrane:
 - Contour: Normal, retracted, full, or bulging; associated bulla(e)
 - Color: Gray, pink, yellow, white, or red; hemorrhagic
 - Translucency: Translucent or opaque
 - Mobility: Normal, decreased, or absent
- The presence of a middle ear effusion is suggested by abnormal color, opacification, decreased mobility, air–fluid levels, or visible air bubbles within fluid.
- A diagnosis of AOM is suggested if a middle ear effusion is present along with ear pain, fever, erythema, fullness, or bulging of tympanic membrane.
- The concomitant presence of conjunctivitis (otitis media–conjunctivitis syndrome) suggests the presence of *H. influenzae* or a virus as a causative organism.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Tympanometry:
 - Easily performed by office personnel
 - Provides information on middle ear pressure and tympanic membrane compliance
 - Sensitive in detecting middle ear effusion, but poor positive predictive value
- Tympanocentesis:
 - For episodes of AOM that are resistant to antibiotic therapy, tympanocentesis and culture and sensitivity of the middle ear fluid may help guide antibiotic therapy.
- Tympanocentesis or myringotomy may also be required as part of the treatment of suppurative complications.

DIFFERENTIAL DIAGNOSIS

- OME: Tympanic membrane may appear dull with a diffuse light reflex, fluid bubbles may be visible, and mobility may be decreased.
- Otitis externa
- Auricular lesions like a furuncle or laceration
- Other causes of fever, including viral upper respiratory tract infections, pharyngitis, pneumonia, meningitis, UTIs, and bone and joint infections
- Pharyngitis and dental pain may be mistaken for otalgia.

TREATMENT

MEDICATION (DRUGS)

Note: Because as many as 80% of patients who have physical findings consistent with the diagnosis of AOM may recover without treatment, some experts recommend treating pain and fever 48–72 hours before starting antibiotics, especially in older patients. For patients <2 years of age, antibiotic treatment results in faster resolution than placebo and is recommended as initial therapy.

First Line

- Amoxicillin (80–90 mg/kg/d b.i.d.) is the drug of choice for most episodes of AOM. The higher doses are recommended to cover resistant *S. pneumoniae*.
- Recommended duration of therapy is 10 days, but a 5–7-day course, as well as lower dosing of amoxicillin (25–50 mg/kg/d divided b.i.d. or t.i.d.) may be considered for uncomplicated and isolated cases of AOM in children >2 years.
- Azithromycin may be used in patients who are allergic to penicillin (type I hypersensitivity). For patients who do not have type I reactions, a cephalosporin may be used. Clindamycin 30–40 mg/d divided into 3 doses is an alternative for the penicillin-allergic patient.

Second Line

- Failure of antibiotic therapy may be related to bacterial resistance or a viral etiology. The choice of a 2nd-line antibiotic depends on suspected mechanism of resistance. *H. influenzae* and *M. catarrhalis* produce β -lactamase. *S. pneumoniae* alters penicillin-binding proteins. Failure caused by a resistant pathogen is more likely due to *S. pneumoniae* than *H. influenzae* or *M. catarrhalis*.
- Amoxicillin–clavulanate (80–90 mg/kg/d of the amoxicillin component b.i.d.) is recommended for most treatment failures.
- Cefdinir, cefuroxime axetil, and IM ceftriaxone are also effective against resistant strains of bacteria.
- Amoxicillin–clavulanate or a second-generation cephalosporin may be used if *H. influenzae* (i.e., otitis media–conjunctivitis syndrome) or *M. catarrhalis* is suspected.
- The macrolides and trimethoprim–sulfa do not provide reliable coverage for resistant *S. pneumoniae*.

- Clindamycin 30–40 mg/d t.i.d. is effective against resistant pneumococci and is an alternative for penicillin-allergic patients.
- IM ceftriaxone:
 - Not recommended for routine treatment of AOM.
 - May be considered when PO therapy is impossible or when appropriate 1st- and 2nd-line therapies for *S. pneumoniae* have failed.
 - When used for treatment of resistant organisms, ceftriaxone 50 mg/kg IM should be given every 1–3 days for 3 doses.

ADDITIONAL TREATMENT

General Measures

- Antibiotics (see “Medication”)
- Adjunctive therapy:
 - Fever relief may be provided with acetaminophen or other antipyretic.
 - Pain may be treated with acetaminophen, ibuprofen, or topical anesthetic drops.

ISSUES FOR REFERRAL

- Consider otolaryngology referral:
 - Persistent otitis media not responding to antibiotic therapy; tympanocentesis with culture of middle ear fluid may be helpful.
 - Recurrent acute otitis media with >4 episodes during a respiratory season, especially if earlier in the season
 - Persistent and/or recurrent otitis with abnormal hearing and/or speech

 **ONGOING CARE**

FOLLOW-UP RECOMMENDATIONS

- Expect symptomatic improvement within 48–72 hours of treatment. May need to switch antibiotic therapy and/or re-evaluate for complications.
- Tympanic membrane may appear abnormal for some time after treatment. In infants or young children, initial follow-up exam should be scheduled 3–4 weeks after completion of antibiotic therapy. If effusion is present, follow monthly. For persistent effusions of >3 months’ duration, a hearing evaluation is recommended.

PROGNOSIS

- Symptoms of acute infection (fever and otalgia) are relieved within 48–72 hours in most patients.
- Treatment failures are more likely with increased severity of disease and younger age.
- Development of another infection within 30 days usually represents a recurrence caused by a different organism, rather than a relapse.
- Recurrences are frequent and more common in younger children and if initial episode is severe.
- 30–70% of treated children will have an effusion at 2 weeks.
- Middle ear effusion may persist for weeks to months.

COMPLICATIONS

- Suppurative complications of AOM are much less common with current antibiotic therapy. The recent increase in resistant organisms could lead to a resurgence of suppurative complications.
- Hearing loss:
 - Acute conductive hearing loss is common and usually resolves as the effusion resolves.
 - Fluid of longstanding duration may lead to permanent conductive hearing loss.
 - Sensory-neural hearing loss may result from spread of infection into the labyrinth.
- Tympanic membrane perforation
- Chronic suppurative otitis media
- Tympanosclerosis
- Cholesteatoma
- Acute mastoiditis
- Petrositis
- Labyrinthitis
- Facial nerve paralysis
- Bacterial meningitis
- Epidural abscess
- Subdural empyema
- Brain abscess
- Lateral sinus thrombosis

CODES

ICD9

- 381.00 Acute nonsuppurative otitis media, unspecified
- 381.4 Nonsuppurative otitis media, not specified as acute or chronic
- 382.9 Unspecified otitis media

ICD10

- H66.90 Otitis media, unspecified, unspecified ear
- H66.91 Otitis media, unspecified, right ear
- H66.92 Otitis media, unspecified, left ear

FAQ

- Q: When should children with acute otitis media be treated?
- A: The presence of a middle ear effusion may occur commonly with an upper respiratory tract infection. The presence of AOM, as described above, usually warrants treatment with antibiotics, especially in children <2 years, those who are prone to infection, and those with AOM during the winter season. Because a number of cases of acute otitis media resolve spontaneously in older children, treatment with antibiotics may be deferred for 48–72 hours while treating pain.
- Q: What is the antibiotic of choice for initial therapy of acute otitis media?
- A: Amoxicillin, 80–90 mg/kg/d, is recommended as initial therapy for most children. *S. pneumoniae* is currently the most important pathogen causing acute otitis media, being more common and more virulent than other bacteria isolated from middle ear fluid. Increased resistance of *S. pneumoniae* to lower doses of amoxicillin necessitate use of higher doses. Initial therapy with amoxicillin–clavulanate at 80–90 mg/kg of amoxicillin may be considered as initial therapy for patients recently treated with amoxicillin (i.e., within the past month) and for patients with more severe disease, including those with fever >39°C and/or those with severe otalgia.
- Q: What can be done to prevent the development of AOM in an individual child?
- A: A number of factors appear to put children at risk for AOM, including genetic, immune, and environmental factors and exposure to viral upper respiratory tract infections. Breastfeeding during the 1st year of life decreases the risk of AOM and is recommended. Eliminating exposure to environmental tobacco smoke may also be helpful. Development of upper respiratory tract infections at an early age is probably the most important factor in the development of otitis media. Limiting the exposure to large numbers of children by delayed entry to child care or by choosing a setting with smaller numbers of children should decrease a child’s risk of otitis media. Pneumococcal vaccine has reduced the incidence of AOM. Administering influenza vaccine may also be helpful.

PALLOR

David T. Teachey

BASICS

DEFINITION

- Pallor is defined as paleness of the skin and may be a reflection of anemia or poor peripheral perfusion.
- The normal range for hemoglobin is age dependent.
- Anemia can be defined functionally as the inability of hemoglobin to meet cellular oxygen demand.
- Parents often fail to notice pallor of gradual onset.
 - Grandparents or others who see child less often may be the first to suspect pallor.

RISK FACTORS

- Age between 6 months and 3 years, or adolescent females:
 - Peak age ranges for iron deficiency
- Gender:
 - Some red cell–enzyme X-linked defects, such as glucose-6-phosphate dehydrogenase (G6PD) and phosphoglycerate kinase deficiencies are sex linked.
- Race:
 - Black: Hemoglobins S and C, - and -thalassemia trait, G6PD deficiency
 - Southeast Asian: Hemoglobin E and -thalassemia
 - Mediterranean descent: -thalassemia and G6PD deficiency

Genetics

Familial history:

- Some of the congenital hemolytic anemias are autosomal dominant.

DIAGNOSIS

- Determine first that the child appears pale, not simply fair skinned. Second, decide if there is a medical emergency associated with circulatory failure. If not, the goal is to investigate the etiology and intervene appropriately.
- Phase 1: Assess for signs of shock.
 - If present, initiate emergency procedures as required to stabilize the patient, such as airway, breathing, and circulation.
- Phase 2: If patient is stable, perform history, physical examination, and CBC with reticulocyte count to establish time of onset of pallor, associated symptoms, and level of anemia.
- Phase 3: Follow specific diagnostic workup based on findings in phase 2.

SIGNS AND SYMPTOMS

- Pallor
- Other signs and symptoms dependent on etiology

HISTORY

- Acute versus chronic onset:
 - Helps with differential diagnosis.
- Associated symptoms: Weight loss, fever, night sweats, cough, and/or bone pain:
 - Suggest an underlying systemic illness, such as leukemia, infection, or rheumatologic disorder
- Jaundice, scleral icterus, dark urine:
 - Suggest hemolysis
- Age <6 months:
 - May represent a congenital anemia or isoimmunization
- Premature infant:
 - Increased risk of both iron and vitamin E deficiency.
 - Exaggerated hyperbilirubinemia can be the presenting symptom of isoimmune hemolytic or other congenital hemolytic anemia.
- Pica:
 - Often associated with plumbism and iron deficiency
- Medications:
 - Can cause bone marrow suppression and/or hemolysis
- Milk intake:
 - Cow's milk <12 months of age and high milk intake are associated with iron deficiency.
- Recent trauma and/or surgery:
 - Blood loss can result in iron deficiency.
- Recent infection:
 - Can be associated with hemolysis or bone marrow suppression
 - Most common form of mild anemia in childhood
- Family history:
 - Familial history of splenectomy and/or early cholecystectomy can be a clue for a previously undiagnosed hemolytic anemia.

PHYSICAL EXAM

- Rapid respiratory rate, decreased BP, weak pulses, slow capillary refill
 - Indications of uncompensated anemia and/or shock
- Frontal bossing and prominence of the malar and maxillary bones:
 - Extramedullary erythropoiesis
- Enlarged spleen:
 - Hemolytic anemias, malignancy, infection
- Glossitis:
 - Vitamin B₁₂ deficiency
- Scleral icterus or jaundice:
 - May indicate hemolysis
- Systolic flow murmur:
 - Anemia

- Bruits:
 - May indicate vascular malformations
- Petechiae and bruising:
 - May indicate an associated thrombocytopenia, coagulopathy, or vasculitis
- Dysmorphic features:
 - Diamond-Blackfan and Fanconi anemia are associated with other congenital defects, including thumb abnormalities, short stature, and congenital heart disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with red cell indices:
 - Establishes the diagnosis of anemia, distinguishes by size: Normocytic, macrocytic, microcytic
- Reticulocyte count:
 - Distinguishes between decreased production and increased destruction of red cells
- Coombs test and antibody screen:
 - Identifies immune-mediated red cell destruction
 - Can have false positives and negatives
- Peripheral blood smear:
 - Specific morphologic findings can be diagnostic.
- Iron studies: Iron-binding capacity, serum iron, ferritin, transferrin
 - Iron-deficiency anemia or anemia of chronic disease
- Hemoglobin electrophoresis with quantification:
 - Hemoglobinopathy
- Lead studies: Serum lead, free erythrocyte protoporphyrin:
 - Plumbism
- Stool guaiac:
 - Occult blood loss
- Osmotic fragility:
 - Red cell membrane defects (spherocytosis)
 - Any spherocytic anemia may be positive
- Quantitative red cell–enzyme assays:
 - Inherited RBC enzyme deficiencies
- Serum folate, RBC folate, and serum vitamin B₁₂ levels:
 - Deficiency

Diagnostic Procedures/Surgery

Bone marrow aspiration and biopsy:

- Malignancy or bone marrow failure syndrome

DIFFERENTIAL DIAGNOSIS

- Congenital:
 - Hemoglobinopathies: Sickle cell syndromes, thalassemia syndromes, other unstable hemoglobins
 - Erythrocyte membrane defects: Hereditary spherocytosis, elliptocytosis, stomatocytosis, pyropoikilocytosis, infantile pyknocytosis
 - Erythrocyte enzyme defects: G6PD deficiency, pyruvate kinase deficiency
 - Diamond–Blackfan anemia: Congenital pure red cell aplasia (rare)
 - Fanconi anemia: Constellation of varied cytopenias, multiple congenital anomalies, abnormal bone marrow chromosomal fragility

- Infectious:
 - Septic shock
 - Can get mild anemia after mild infections in childhood (anemia of inflammation)
 - Infection-related bone marrow suppression: Parvovirus B19 infection
 - Infection-related hemolytic anemias: Epstein-Barr virus, influenza, Coxsackievirus, varicella, cytomegalovirus, *Escherichia coli*, *Pneumococcus species*, *Streptococcus species*, *Salmonella typhi*, *Mycoplasma species*
- Nutritional/toxic/drugs:
 - Iron-deficiency anemia: Common cause of anemia in children, especially those <3 years of age and in female adolescents
 - Plumbism: Anemia usually due to coexisting iron deficiency. Very high lead levels associated with altered heme synthesis
 - Vitamin B₁₂ and/or folate deficiency: Results in a megaloblastic anemia
 - Medication-induced bone marrow suppression: Chemotherapy; antibiotics, especially trimethoprim-sulfamethoxazole
 - Drug-related hemolytic anemia: Antibiotics, antiepileptics, azathioprine, isoniazid, nonsteroidal anti-inflammatory drugs
- Trauma:
 - Acute blood loss
- Tumor:
 - Leukemia with bone marrow infiltration
 - Metastatic tumors with bone marrow infiltration
- Genetic/metabolic:
 - Metabolic derangements: Severe electrolyte disturbance, pH disturbance, inborn errors
 - Schwachmann–Diamond syndrome: Marrow hypoplasia with associated pancreatic insufficiency and associated failure to thrive
- Other:
 - Transient erythroblastopenia of childhood: Acquired pure RBC aplasia
 - Aplastic anemia: Bone marrow failure syndrome with at least 2 of the 3 blood cell lines eventually affected
 - Systemic diseases: Anemia of chronic disease, chronic renal disease, uremia
 - Hypothyroidism
 - Sideroblastic anemia: Defective iron utilization within the developing erythrocytes
 - Autoimmune and isoimmune hemolytic anemias
 - Microangiopathic hemolytic anemias: Thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), disseminated intravascular coagulation (DIC)
 - Mechanical destruction: Vascular malformation, abnormal or prosthetic cardiac valves

TREATMENT

ADDITIONAL TREATMENT

Initial Stabilization

- Severe anemia of unclear etiology with hemodynamic instability:
 - Transfuse with packed RBCs cautiously.
 - In an autoimmune hemolytic process, the child is at risk for a transfusion reaction and there may be delay in obtaining crossmatched blood
 - Obtain blood for diagnostic studies before transfusion if possible.
- Circulatory failure without anemia:
 - Requires intensive monitoring and access to critical care in an emergency department or intensive care unit
 - Fluid resuscitation and/or inotropic pressor support as needed
- Acute blood loss:
 - Treat circulatory failure as described.
 - Transfuse with packed RBCs, platelets, and fresh frozen plasma as needed.
- Malignancies:
 - Emergency care should be directed toward treatment of circulatory failure and possible associated infection, and then to rapid diagnosis and treatment of the malignancy.
 - Consultation with an oncologist should be sought as soon as possible.

General Measures

- Treat underlying cause.
- Consider packed RBC transfusion if in extremis or severe anemia and low likelihood of recovery in near future.
- Consider emergent plasmapheresis if microangiopathic hemolytic anemia.
- Consider immunosuppressive medications (corticosteroids, intravenous immunoglobulin (IVIgG) if autoimmune hemolytic anemia.
- Iron-deficiency anemia:
 - Elemental iron

MEDICATION (DRUGS)

Elemental iron:

- 4–6 mg/kg divided b.i.d.–t.i.d.
- Absorbed best with acidic drinks, including orange juice; dairy products decrease absorption.
- Reticulocyte should improve 72 hours after starting iron therapy; the hemoglobin may take a week to rise.
- Iron should be continued for at least 3 months to replenish iron stores.

ONGOING CARE

ISSUES FOR REFERRAL

- Severe or unexplained anemia
- Anemias other than dietary iron deficiency or thalassemia trait
- Recurrent iron deficiency
 - May suggest ongoing bleeding or iron malabsorption.
- All bone marrow failure or infiltrative processes

PANCREATIC PSEUDOCYST

Raman Sreedharan

Devendra I. Mehta

BASICS

DESCRIPTION

- Localized intrapancreatic or peripancreatic fluid collection that is rich in pancreatic enzymes but devoid of significant solid debris, enclosed by a wall of nonepithelialized granulation tissue
- Arises as a complication of acute or chronic pancreatitis

PATHOPHYSIOLOGY

- Pancreatic pseudocysts develop shortly after an attack of acute pancreatitis or insidiously in chronic pancreatitis.
- Disruption in the pancreatic ductular system results in the extravasation of pancreatic enzymes evoking an inflammatory response.
- The inflammatory reaction leads to a fluid collection that is rich in pancreatic enzymes and is termed *acute pancreatic fluid collection (PFC)*.
- If the duration of the fluid collection is >4 weeks, becomes localized (intrapaneatic or extrapancreatic), and develops a fibrin capsule, it is called as a *pseudopancreatic cyst*.
- The pseudocyst does not have a true epithelial lining.
- If there is communication between the pseudocyst and the pancreatic duct, the enzyme level in the fluid remain elevated, and if there is no communication, the enzyme level falls with time.

DIAGNOSIS

HISTORY

Acute or chronic pancreatitis: Suspect pancreatic pseudocyst in patients recovering from acute pancreatitis or in the patient with chronic pancreatitis who has recurrent/persistent abdominal pain, a palpable abdominal mass, or persistently elevated pancreatic enzymes in blood.

PHYSICAL EXAM

- Abdominal pain
- Abdominal mass
- Abdominal tenderness
- Nausea and vomiting
- Weight loss
- Jaundice
- Abdominal distention:
 - Mass/Ascites
- In many situations, no clinical signs are seen.
- Clinical signs may be secondary to complications:
 - Jaundice in hepatobiliary obstruction
 - Lower limb edema in compression of inferior vena cava
 - Ascites in peritonitis
 - Pleural effusion

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Pancreatic enzyme levels:

- Persistently elevated enzymes in blood could be a clue, but is not an absolute indicator.
- The fluid drained from a pancreatic pseudocyst has high levels of amylase.

Imaging

- CT scan:
 - Reveals pseudopancreatic cyst and gauges size and relationship to adjacent organs
- Ultrasonography:
 - Visualizes pancreatic pseudocysts
 - Follow-up of cyst size
- Endoscopic ultrasonography:
 - Common modality in adult patients and increasingly used in pediatrics
- Endoscopic retrograde cholangiopancreatography (ERCP):
 - Used in some cases to delineate the pancreatic ductular system before drainage to distinguish ductal stenosis, stones, and other obstructions

DIFFERENTIAL DIAGNOSIS

- Congenital/Genetic:
 - Congenital cysts
 - Polycystic disease
 - Von Hippel-Lindau disease
 - Cystic fibrosis
- Infections:
 - Pancreatic abscess
 - Echinococcal (hydatid) cyst
 - Taenia solium cyst
- Tumor:
 - Serous cystadenoma
 - Mucinous cystadenoma
 - Cystic islet cell tumors
 - Teratoma
 - Pancreatoblastoma
 - Cystadenocarcinoma
 - Franz tumor
 - Angiomatous cystic neoplasms
 - Lymphangiomas
 - Hemangioendothelioma
- Miscellaneous:
 - Splenic cyst
 - Adrenal cyst
 - Enterogenous cyst
 - Duplication cysts
 - Endometriosis

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Medical management:
 - Most cases resolve with supportive care. If eating precipitates pain, short-term nasojejunal feedings or parenteral nutrition is warranted.
 - Follow-up with ultrasound or CT scan to make sure there are no complications.
 - >60% have complete resolution by the end of 1 year.
 - Usually no medications are used for managing pseudocysts. Somatostatin analogue (octreotide) has been reported to be used to decrease fluid collection along with drainage.
 - Antibiotics are used in situations of infected pseudocyst.
- Drainage:
 - Indications: Infection, rupture with cardiopulmonary compromise, biliary and gastric outlet obstruction, persistent symptoms, rapid enlargement, failure of large pseudocysts (>6 cm) to shrink after 6 weeks
 - Modalities:
 - Percutaneous drainage (aspiration or catheter drainage) is done in cases in which the pseudocyst has a less mature wall.
 - Percutaneous aspiration has a high recurrence rate of 63% and failure rate of 54%.
 - Continuous drainage has a recurrence rate of 8% and a failure rate of 19%.
 - Endoscopic procedures are becoming the 1st-line drainage modality, as they are less invasive than surgery.
 - Endoscopic procedures include transmural cystoenterostomies and transpapillary route procedures like stent placement for pseudocysts that communicate with the main pancreatic duct.
 - Endoscopic procedures in experienced hands report success rates of 82–89%, complication rates of 10–20%, and recurrence rates of 6–18%.

SURGERY/OTHER PROCEDURES

- Reserved for failed endoscopic procedures, complicated pseudocysts, and multiple pseudocysts
- Includes internal drainage (cystogastrostomy, cystoduodenostomy, and Roux-en-Y cystojejunostomy), resection, and external drainage
- Success rate is 85–90%.
- Recurrence rate is 0–17%.
- Mortality rate is between 3% and 5%.

ONGOING CARE

PROGNOSIS

Majority of pseudocysts resolve without intervention.

COMPLICATIONS

- Perforation/Rupture:
 - Cardiopulmonary compromise secondary to pleural effusion and ascites
 - Peritonitis and ascites, which can be fatal
- Hemorrhage:
 - Erosions of vessels lining the cyst cause intracystic bleeding and rapid increase in the cyst size.
 - Bleeding may occur directly into stomach, duodenum (clinically manifesting as GI bleeding), or peritoneal cavity.
- Obstruction:
 - Biliary obstruction: Jaundice
 - Portal obstruction: Portal hypertension
 - Gastric outlet obstruction
 - Inferior vena cava obstruction: Peripheral edema
 - Urinary obstruction
 - Colonic obstruction
- Infection is rare in children compared to adults:
 - High mortality rate for children and adults
 - Management usually requires surgical drainage.

CODES

ICD9

577.2 Cyst and pseudocyst of pancreas

ICD10

K86.3 Pseudocyst of pancreas

FAQ

- Q: How often does acute pancreatitis lead to pseudocyst formation?
- A: ~10% of cases of acute pancreatitis develop pseudocyst.
- Q: Can a pancreatic pseudocyst go unnoticed?
- A: Yes, as the natural history of the disease process is healing by itself.
- Q: What mode of therapy has the least recurrence rate?
- A: Surgical excision.

PANCREATITIS

Raman Sreedharan

Devendra I. Mehta

BASICS

DESCRIPTION

- Inflammation of the pancreas characterized by variable local and systemic inflammatory responses.
- Classified into acute and chronic:
 - Acute:
 - Characterized by abdominal pain, nausea, and vomiting with elevation of pancreatic enzymes
 - Usually self-limiting
 - Recurrent episodes of pancreatitis may occur, but the pancreatic function and morphology are restored between episodes.
 - Severe acute pancreatitis is rare in children and has a high mortality.
 - Chronic:
 - Characterized by recurrent or persistent abdominal pain with morphologic changes in the pancreas, leading to pancreatic exocrine and endocrine insufficiency in some patients

ETIOLOGY

- Idiopathic (20–25%)
- Trauma:
 - Bicycle handle injuries
 - Motor vehicle collisions
 - Child abuse
 - Postoperative:
 - Endoscopic retrograde cholangiopancreatography (ERCP)
 - Scoliosis surgery
- Infections:
 - Bacterial:
 - Typhoid
 - Mycoplasma
 - Viral: Measles, mumps, Epstein-Barr virus, Coxsackie B, rubella, influenza, echovirus, hepatitis A and B
 - Parasites (*Ascaris lumbricoides*, *Echinococcus granulosus*, *Cryptosporidium parvum*, *Plasmodium falciparum*)
- Biliary tract disease:
 - Gallstones
 - Sclerosing cholangitis
 - Congenital anomalies:
 - Pancreatic divisum
 - Annular pancreas
 - Anomalous choledochopancreatic–duodenal junction
 - Biliary tract malformations
 - Duplication cyst of the duodenum/gastropancreatic/common bile duct
 - Metabolic:
 - Hyperlipidemia
 - Hypercalcemia
 - Uremia
 - Inborn errors of metabolism
 - Systemic disease:
 - Shock/Hypoxemia
 - Hemolytic uremic syndrome
 - Crohn disease
 - Celiac disease

- Malnutrition: Anorexia nervosa, bulimia, and refeeding syndrome
- Diabetes mellitus
- Mitochondriopathy
- Hemochromatosis
- Vasculitis: Systemic lupus erythematosus (SLE), Henoch-Schönlein purpura, Kawasaki disease
- Drugs: L-asparaginase, azathioprine/6-MP, mesalamine, sulfonamides, thiazides, furosemide, tetracyclines, valproic acid, corticosteroids, estrogens, procainamide, ethacrynic acid, and others
- Toxins:
 - Alcohol, organophosphates, scorpion poison, snake poison
- Autoimmune pancreatitis: A relatively new entity mostly described in adults, but pediatric cases have been reported.

DIAGNOSIS

HISTORY

- Trauma:
 - Even trivial abdominal trauma should be a red flag.
 - Evaluate for evidence of child abuse.
 - Autoimmune pancreatitis can occur as a primary disorder or can be associated with other autoimmune diseases including Sjögren syndrome, primary sclerosing cholangitis, primary biliary sclerosis, sarcoidosis, rheumatoid arthritis, retroperitoneal fibrosis, and kidney diseases with autoimmune etiology.
- Family history:
 - Hereditary pancreatitis
 - Hypertriglyceridemia (I, IV, or V)
 - CFTR mutations/FH of CF
- Upper abdominal pain:
 - Usually epigastric with radiation to the back
 - May have some relief of pain on stooping forward
 - Aggravated by food intake
- Fever:
 - Low-grade fever
 - High-grade fever is usually due to infection.
- Nausea and vomiting common:
 - Vomiting may be bilious.

PHYSICAL EXAM

- General exam:
 - Growth parameters (weight and height), vital signs, capillary refill, pulse oximetry, pallor, jaundice, edema, and clubbing
 - Pallor could be due to chronic systemic disease or hemorrhage.
 - Clubbing could be an indicator of cystic fibrosis.

- GI:
 - Mouth: Presence of aphthous lesions; possibility of Crohn disease
 - Inspection: Abdominal distention or flank fullness (ascites or pseudopancreatic cyst); bluish discoloration of the flanks (Grey Turner sign) and periumbilical region (Cullen sign) in hemorrhagic pancreatitis.
 - Palpation: Guarding, tenderness, and rebound tenderness, especially in the epigastric region or upper abdomen; palpable mass could be a pancreatic pseudocyst; palpate for liver, gall bladder, spleen, and other masses.
 - Percussion: Dullness and fluid thrill in ascites
 - Auscultation: Bowel sounds decreased in ascites or absent in paralytic ileus
 - Rectal exam: Perianal region for skin tags, fistulas, abscesses, or healed scars, which could be indicative of inflammatory bowel disease; peri-rectal exam for mass, melena, or occult blood
- Respiratory system:
 - Pleural effusion and acute respiratory distress syndrome (ARDS)
 - Diffuse respiratory findings could be indicative of cystic fibrosis.
- CNS:
 - Stupor or coma

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC:
 - Hemoglobin may be decreased in hemorrhagic pancreatitis or intestinal hemorrhage.
- Basic metabolic panel:
 - Electrolyte imbalance due to fluid shift and renal complications
 - Calcium is decreased.
 - Glucose may be transiently elevated.
- Liver function tests:
 - Elevated transaminase levels suggest biliary cause.
 - Elevated bilirubin level
- Amylase level:
 - 3-fold elevation in the level increases the specificity for the diagnosis of pancreatitis.
 - Starts rising 2–12 hours after the insult and remains elevated for 3–5 days
 - Persistent elevation could be due to complication such as pseudocyst.
 - Degree of elevation does not have any correlation to the severity or the course of the illness.
 - Necrotizing and hemorrhagic pancreatitis may develop with normal amylase levels.
 - Other causes of elevated amylase levels include bowel obstruction, acute appendicitis, biliary obstruction, salivary duct obstruction, diabetic ketoacidosis, cystic fibrosis, pneumonia, salpingitis, ruptured ectopic pregnancy, ovarian cyst, cerebral trauma, burns, renal failure, and macroamylasemia.

- Lipase level:
 - Lipase levels are more specific than amylase for the diagnosis of pancreatitis.
 - Starts rising 4–8 hours after the insult and remains elevated for 8–14 days
 - 3-fold increase in the level is very sensitive and specific for pancreatitis.
 - Levels do not correlate with severity or with clinical outcome.
 - Other causes of elevated lipase levels include intestinal perforation, intestinal obstruction, appendicitis, mesenteric infarction, cholecystitis, diabetic ketoacidosis, renal failure, and macrolipemia.
- Serologic testing for autoimmune pancreatitis:
 - IgG4 levels are usually elevated but not specific.
 - Anti-PBP (plasminogen binding protein)

Imaging

- Abdominal x-rays:
 - Sentinel loop: Distended small intestinal loop near the pancreas
 - Colon cutoff sign: Absence of gas shadow in the colon distal to the transverse colon
 - Multiple fluid levels in paralytic ileus
 - Calcification or stones in pancreas or gallbladder
 - Diffuse haziness: Ascites
- Upper GI series
 - “Reverse 3 sign”/Frostberg sign: The curves of the “3” indicate swelling of the pancreas and the middle apex of the “3” suggests the origin of the duct.
 - Anterior displacement of the stomach is seen in pseudopancreatic cyst or retroperitoneal swelling.
- Barium enema: Rarely indicated
- Chest x-ray:
 - Pleural effusion or ARDS
 - Diaphragmatic involvement
- US abdomen:
 - Pancreatic size, echogenicity, calcification, stones, abscess, and pseudocysts
 - Endoscopic US is more useful than the transabdominal US study but is difficult in children.
- CT scan:
 - In acute cases, as in trauma, to look at extent of injury to pancreas and other intra-abdominal structures
 - Can show complications such as abscess, hemorrhage, pseudocyst, etc.
 - Reveals pathology in the pancreaticobiliary system in most instances.
- Magnetic resonance cholangiopancreatography (MRCP):
 - More popular than CT for identifying pancreaticobiliary disorders.
 - Useful for delineation of the ductal structure of the pancreas and also to identify pathology in the hepatobiliary system
 - Serotonin stimulated MRCP (sMRCP) is becoming more popular in adults as it delineates the pancreatic ducts better.

- Endoscopic retrograde cholangiopancreatography (ERCP):
 - Indicated in persistent/chronic pancreatitis for delineation of pancreatic ducts and for therapeutic interventions.
 - Limitations include postprocedure complications and accessibility to gastroenterologist experienced with ERCP in children.

TREATMENT

MEDICATION (DRUGS)

- Antibiotics:
 - Prophylaxis in severe cases when necrotizing pancreatitis is suspected
 - Few antimicrobials, such as imipenem–cilastatin, achieve adequate penetration.
- Pain management:
 - Narcotics
 - Meperidine is preferable to morphine because it has less effect on the sphincter of Oddi.
- H₂ blockade/PPI for acid suppression:
 - Prevents pancreatic stimulation in severe cases
- Autoimmune pancreatitis is treated with corticosteroids.

ADDITIONAL TREATMENT

General Measures

- NPO for pancreatic rest.
- In moderate to severe cases of pancreatitis and in cases with vomiting, nasogastric decompression by placement of nasogastric (NG) tube:
 - Pain management
- Acid suppression with H₂ blockers or PPI

SURGERY/OTHER PROCEDURES

- Peritoneal lavage rarely for salvage in necrotizing/hemorrhagic pancreatitis
- Management of pancreatic abscess and in some cases of pseudocysts

ONGOING CARE

DIET

- NPO initially
- Mild cases may be started on a low-fat diet after a few days.
- Nasojejunal feeds worth considering when oral feeding is not possible even after the 1st few days:
 - Alternative is total parenteral nutrition (TPN).

PROGNOSIS

Acute pancreatitis is usually a self-limiting disorder in children.

COMPLICATIONS

- Pancreatic edema
- Peripancreatic fat necrosis
- Pancreatic phlegmon
- Pancreatic abscess
- Pancreatic pseudocyst
- Hemorrhagic pancreatitis

- Necrotizing pancreatitis
- Pancreatic calculi
- Pancreatic fistula
- Pancreatic ductal strictures
- Pancreatic ductal dilatation
- Systemic complications
- Shock and multiorgan failure
- GI and hepatobiliary:
 - Paralytic ileus
 - Ascites, peritonitis
 - Stress ulcer
 - Intestinal hemorrhage
 - Portal vein thrombosis/splenic vein thrombosis/obstruction
 - Bile duct obstruction
- Pulmonary:
 - Atelectasis, pleural effusion, pneumonitis, ARDS
- Cardiovascular:
 - Hypotension/Circulatory collapse
 - Pericarditis/Pericardial effusion
 - EKG changes
- Sudden death

ICD10

- K85.9 Acute pancreatitis, unspecified
- K86.1 Other chronic pancreatitis

FAQ

- Q: What is hereditary pancreatitis?
- A: Hereditary pancreatitis presents as recurrent inflammation of the pancreas and runs in families over ≥2 generations. It is inherited as an autosomal dominant trait with variable penetrance.
- Q: Do normal findings on US or CT scan of the pancreas exclude a diagnosis of acute pancreatitis?
- A: No. Normal US and CT findings are common in mild cases.

PANHYPOPITUITARISM

Craig A. Alter

Jeffrey D. Roizen

Vaneeta Bamba (5th edition)

BASICS

DESCRIPTION

Deficiency of >1 pituitary hormone

EPIDEMIOLOGY

- Congenital forms affect both sexes equally and are diagnosed at a young age.
- The epidemiology of acquired or secondary forms depends on the underlying cause.

RISK FACTORS

Genetics

Most cases are not thought to be genetic; however, there are rare cases of autosomal recessive, autosomal dominant, and X-linked forms.

PATHOPHYSIOLOGY

- Pathology is based on specific deficiency.
- Growth hormone (GH): Hypoglycemia in newborns and poor growth in patients older than 6–12 months
- Adrenocorticotropic hormone: Hypercortisolism
- Thyroid-stimulating hormone (TSH): Hypothyroidism
- Luteinizing hormone (LH)/Follicle-stimulating hormone (FSH): Hypogonadism
- Antidiuretic hormone: Diabetes insipidus
- Prolactin: Hyperprolactinemia

ETIOLOGY

- Idiopathic (some may be due to hypophysitis)
- Congenital:
 - Absence of the pituitary (empty sella syndrome)
 - Genetic disorders due to mutations in genes or transcription factors (POU1F1, HESX1, LHX3, LHX4, OTX2, SIX6, SOX2, SOX3, PTX2, PROP1, etc.)
 - Pituitary malformations (ectopic posterior pituitary, hypoplastic infundibular stalk, hypoplastic pituitary)
 - Familial panhypopituitarism
 - Rathke's cleft cyst
- Acquired:
 - Birth trauma or perinatal insult
 - Surgical resection of the gland or damage to the stalk
 - Traumatic brain injury
 - Hypophysitis
 - Child abuse or psychosocial deprivation
 - Iron deposition secondary to chronic transfusion therapy (e.g., β -thalassemia)
- Infection:
 - Viral encephalitis
 - Bacterial or fungal infection
 - Tuberculosis
- Vascular:
 - Pituitary infarction
 - Pituitary aneurysm
- Cranial irradiation
- Chemotherapy
- Tumors:
 - Craniopharyngioma
 - Germinoma
 - Glioma
 - Pinealoma
 - Primitive neuroectodermal tumor (medulloblastoma)
- Histiocytosis
- Sarcoidosis

COMMONLY ASSOCIATED CONDITIONS

- Midline defects such as cleft lip/palate, hypotelorism, single central maxillary incisor
- Septo-optic dysplasia (de Morsier syndrome)
- Holoprosencephaly

DIAGNOSIS

HISTORY

- Birth weight: Hypopituitary infants are usually normal or small for gestational age, in contrast to hyperinsulinemic infants, who are typically large for gestational age.
- Birth history:
 - Documented or symptoms of hypoglycemia, which include poor feeding, lethargy, irritability, or seizures
 - Hypoglycemia may be secondary to hyperinsulinism (HI), but HI babies are typically large for gestational age.
 - Hypopituitary babies are not large.
 - Midline defects are associated with hypopituitarism and not HI.
- Complications during pregnancy or delivery:
 - Birth trauma may be associated with pituitary injury.
 - Breech delivery or vacuum extraction has been associated.
- History of surgeries and previous diseases: Congenital hypopituitarism is often associated with midline facial defects, such as a single central incisor, bifid uvula, or cleft palate, which require repair.
- Growth pattern: Plot previous heights and look for growth pattern. GH deficiency usually manifests as poor linear growth by the end of the 1st year of life.
- Delayed puberty:
 - Children with delayed puberty show further growth failure in adolescence.
 - Sense of smell should be assessed to rule out Kallmann syndrome (isolated central hypogonadism and anosmia).
- Increased thirst and urination: Children with hypothalamic disorders may present with symptoms of diabetes insipidus.
- Special questions:
 - Complaints of headache and/or a visual defect: Headache can be a symptom of a brain tumor. Focal neurologic symptoms are highly suggestive of CNS pathology.

PHYSICAL EXAM

- Height and weight:
 - Patients with panhypopituitarism have normal size in the newborn period, whereas patients with hyperinsulinism are typically large for gestational age.
- Prolonged conjugated hyperbilirubinemia:
 - May be 1st sign of hypothyroidism with or without hypopituitarism. Some state newborn screens will not detect central hypothyroidism.
 - Hypopituitarism can lead to neonatal cholestasis.

- Micropenis in male newborns: Neonatal penis should be ≥ 2.5 cm in length; micropenis suggests gonadotropin and/or GH deficiency
- Physical exam tricks:
 - Penile and testicular size: Measure stretched phallic length (from pubic ramus to glans) with patient lying supine and phallus at 90 degrees to the body; use Prader beads to assess testicular volume.
 - Midline defects: Palpate for submucosal cleft palate, look for central incisor.
 - Visual field testing: Visual field defects suggest a brain tumor.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Liver function tests: LFTs in newborns with congenital hypopituitarism are often elevated and accompanied by conjugated hyperbilirubinemia, as opposed to simple congenital hypothyroidism, in which unconjugated hyperbilirubinemia exists.
- Thyroid function tests including free thyroxine (FT₄): TSH may be normal, but free T₄ will be low.
- TSH stimulation test: Delayed, normal, or exaggerated TSH response is consistent with a hypothalamic lesion.
- Serum insulinlike growth factor-I (IGF-I) and insulinlike growth factor binding protein-3 (IGFBP-3): May be low, but normal growth factors do not exclude GH deficiency in children with brain tumors. IGF-1 may be low due to poor nutrition.
- Free T₄ by equilibrium dialysis: Must measure, not calculate, the free T₄ concentration in serum
- GH stimulation tests: Should be performed by a pediatric endocrinologist
- Cortrosyn stimulation test: More helpful in the diagnosis of primary adrenal insufficiency than secondary (adrenocorticotropic hormone) or tertiary (corticotropin-releasing hormone) deficiency
- Metyrapone or corticotropin-releasing hormone stimulation test:
 - Tests for adrenocorticotropic hormone or corticotropin-releasing hormone deficiency
 - Metyrapone not currently available in the U.S.
 - Must be performed by a pediatric endocrinologist
- Estradiol, testosterone, ultrasensitive LH, and FSH: Delayed puberty if no breast development by 13 years in girls, and no testicular enlargement by 14 years in boys
- Water deprivation test:
 - Definitive test for antidiuretic hormone deficiency (diabetes insipidus)
 - Should be performed by a pediatric endocrinologist
- Comments on testing: Measurement of water intake and urine output over 24 hours at home can help diagnosis of diabetes insipidus. Baseline serum tests (prolactin, 8AM cortisol, free-T₄, IGF-1, IGF-BP3, serum and urine osmolality, testosterone for males in the first 6 months of life and again after the age of 11 years) can all be done in a nonfasting state:
 - Stimulation tests must be performed by a pediatric endocrinologist.

Imaging

- Bone age: Typically significantly delayed in GH deficiency or hypothyroidism
- MRI with contrast of brain with fine cuts through the hypothalamus and pituitary:
 - Look for tumors, but also size of pituitary, infundibulum and presence of normal “bright spot” in posterior pituitary.
 - Absence of the “bright spot” is highly associated with central diabetes insipidus of any etiology.
 - Ectopic pituitary consistent with GH deficiency and other anterior pituitary deficiencies

ALERT

- If adrenocorticotrophic hormone deficient, stress dosing of glucocorticoids is necessary.
- A patient with diabetes insipidus who does not have an intact thirst mechanism and access to free water is at high risk for acute hyponatremia.

DIFFERENTIAL DIAGNOSIS

- Hyperinsulinism (HI) in newborns
- Isolated hormone deficiency, such as GH deficiency in newborns
- Constitutional growth delay

TREATMENT

MEDICATION (DRUGS)

- Recombinant human GH (rhGH) by SC injection daily: 0.15–0.3 mg/kg/wk
- Desmopressin acetate (DDAVP): Available in oral and intranasal formulations. Dose is variable.
- Estrogen/Testosterone: Started at puberty at low doses and slowly increased over 1–2 years to mimic endogenous secretion of sex steroids.
- Estrogen given as daily oral or topical forms to girls, whereas testosterone given as injection to boys every month
- Levo-thyroxine (Levo-T) PO: 25–200 levo-T₄ mcg daily, based on weight, age, and free T₄ levels
- TSH levels will not be useful in monitoring therapy, even after treatment is initiated.
- Hydrocortisone:
 - Replacement doses if needed: 8–15 mg/m²/d PO, divided q8h (or t.i.d.)
 - In stress circumstances such as fever, severe illness, vomiting, or surgery, dose is increased to 50–100 mg/m²/d PO
 - If dosed IV, provide a loading dose of 50–100 mg/m² IM or IV followed by 50–100 mg/m² divided q4h; oral stress doses should be divided q8h.
 - To calculate hydrocortisone dose, estimate body surface area (BSA) using a nomogram or the following formula: $BSA (m^2) = \text{square root of } (\text{height [cm]} \times \text{weight [kg]}/3,600)$
- Duration: Long-term therapy: Monitored by a pediatric endocrinologist
 - rhGH: In children and adolescents: Until growth velocity drops to 2.5 cm/yr; once puberty is complete

- GH-deficient adults may benefit from lifelong rhGH because of the impact of GH on body composition, lipid profile, and cardiac function.
- Patient should again undergo GH provocative testing off rhGH therapy to determine if adult treatment is necessary.
- DDAVP: For life as needed to control symptoms of polyuria/polydipsia
- Acute hyponatremia may be managed with DDAVP, IV vasopressin, or fluids alone.
- Sex steroids: Around age 12; may be continued for lifetime
- Levo-thyroxine for life
- Hydrocortisone: Replacement dose based on individual’s need
- Stress dose coverage for life
- Possible conflicts with other treatments: There is a theoretical risk that GH might stimulate tumor growth because of its mitogenic effect. Current data argue against GH as a tumor stimulant.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Initially, every 3 months by a pediatric endocrinologist
- When pituitary hormones are replaced, expect:
 - GH: Immediate resolution of hypoglycemia; and improved growth velocity within 3–6 months
 - T₄ levels should normalize within 4–6 weeks.
 - Side effects of GH therapy: Headache, vision problems, seizures, changes in activity level, limp, knee or hip pain

PROGNOSIS

- For congenital forms, the prognosis is excellent with endocrine replacement.
- Diabetes insipidus in infants can be challenging to manage.
- For secondary forms, the overall prognosis depends on the primary disease.

COMPLICATIONS

- Hypoglycemia in the newborn period
- Short stature
- Adrenal crisis
- Dehydration/Hyponatremia

ALERT

- rhGH therapy is associated with idiopathic intracranial hypertension (pseudotumor cerebri), which usually improves whether or not medication is stopped.
- rhGH deficiency/therapy is associated with slipped capital femoral epiphysis (SCFE). Carefully evaluate any limp or knee or hip pain in patients on rhGH therapy. SCFE mandates orthopedic consultation.
- The diagnosis of panhypopituitarism must be considered in patients with hypoglycemic seizures.
- GH is a mitogenic factor, so there is a theoretical potential for increasing the incidence of leukemia. Clinical studies have not confirmed this hypothesis.
- The family and the patient must understand the importance of taking stress doses of steroid appropriately (e.g., with surgery, vomiting, or febrile illnesses).
- 20% of normal children will fail a single GH provocative test.

- A TSH level is generally not helpful when evaluating pituitary/hypothalamic causes of hypothyroidism. The unbound free T₄ level (by equilibrium dialysis) is the most useful test both to establish the diagnosis and to monitor L-thyroxine replacement therapy.

FAQ

- Q: When do I give stress doses of steroid, and for how long?
- A: Whenever the patient has fever, vomiting, serious illness, or surgery. Continue until 24 hours after stress resolves (e.g., the day after fever breaks or vomiting stops).
- Q: What are the chances of cretinism if hypopituitarism is congenital?
- A: Minimal, if medication is taken properly.

PARVOVIRUS B19 (ERYTHEMA INFECTIONOSUM, FIFTH DISEASE)

Julia F. Shaklee

J. Nadine Gracia (5th edition)

BASICS

DESCRIPTION

Parvovirus B19 (B19) is a common viral infection of school-aged children that is most commonly associated with an erythematous macular rash in an otherwise well-appearing patient. B19 is a single-stranded DNA virus, one of the smallest of the human viruses, 1st isolated from asymptomatic blood donors in 1975.

EPIDEMIOLOGY

- B19 infections are ubiquitous worldwide, occurring most often in school-aged children. Humans are the only hosts.
- Incubation period is 4–14 days.
- Modes of transmission:
 - Contact with respiratory secretions
 - Percutaneous exposure to blood or blood products (1,011 virions/mm of serum in patients with hereditary hemolytic anemias)
 - Vertical transmission from mother to fetus

Incidence

Attack rates: 15–60% of susceptibles (i.e., seronegative) will become infected upon exposure.

Prevalence

- Seroprevalence of B19 IgG antibodies:
 - > 5 years old: 2–9%
 - 5–18 years old: 15–35%
 - Adults: 30–60%
 - Elderly: 90%

GENERAL PREVENTION

- B19 transmission can be decreased through routine infection-control practices, including hand hygiene and appropriate disposal of contaminated facial tissues.
- For hospitalized children with suspected aplastic crisis, immunocompromised patients with chronic infection and anemia, and patients with papulopurpuric gloves-and-socks syndrome secondary to B19, droplet precautions in addition to standard contact precautions are recommended.
- No additional measures are needed for normal hosts with rash.
- Due to the potential risks to the fetus from B19 infections, pregnant health care workers should pay attention to strict infection control procedures and avoid contact with immunocompromised hosts with B19 infection or those with aplastic crisis. Routine exclusion of pregnant women from the workplace where B19 infections is suspected is not recommended.

PATHOPHYSIOLOGY

- Parvovirus B19 inhibits erythropoiesis by lytically infecting RBC precursors in the bone marrow. It is associated with a number of clinical manifestations, ranging from benign to severe.
- There is no practical in vitro system for isolation or culture of the virus.

COMMONLY ASSOCIATED CONDITIONS

- Fifth disease, or erythema infectiosum, caused by B19 occurs in up to 35% of school-aged children.
- Transient aplastic crisis secondary to B19 may cause severe anemia in patients with hereditary hemolytic anemias or any condition that shortens the RBC lifespan, such as sickle cell disease or spherocytosis.
- Polyarthropathy syndrome, symmetric joint pain and swelling, especially of the hands, knees, and feet, is seen in adults more often than in children; among women with B19 infection, 80–100% develop polyarthritis.
- Hydrops fetalis may develop after maternal B19 infection with intrauterine involvement (typically within the first 20 weeks of pregnancy).
- Chronic anemia/pure red cell aplasia due to persistent B19 infection has been reported in immunocompromised patients.
- Papulopurpuric gloves-and-socks syndrome (PPGSS) consists of painful and pruritic papules, petechiae, and purpura localized to the hands and feet and is often associated with fever.
- Sporadic reports of extremity numbness and tingling, hemophagocytic syndrome, and Henoch-Schönlein purpura have been associated with B19 infection.

DIAGNOSIS

Diagnosis depends upon recognition of typical symptoms and the results of laboratory testing.

HISTORY

- Asymptomatic infection may occur in ~20% of children and adults.
- Erythema infectiosum (Fifth disease):
 - Most common form of parvovirus infection recognized
 - Characterized by an erythematous facial rash with a distinctive “slapped cheek” appearance, often accompanied by circumoral pallor.

- A symmetric, maculopapular, often lace-like rash occurs on the trunk, spreading outward to the rest of the body and extremities. The rash is often pruritic and may intensify with exposure to sunlight, heat, or exercise. It occasionally involves the palms and soles. Rarely, the rash can be papular, vesicular, or purpuric. It may last for ~7 days, but can persist >20 days.
- A brief, mild prodrome of systemic symptoms, including headache, sore throat, myalgias, and low-grade fevers, often precedes the appearance of rash by 7–10 days.
- The child is usually well-appearing and remains active and playful.
- Arthralgias and arthritis occur infrequently in children, but are seen in up to 80% of adults, especially women. Arthritis in children most commonly involves the knees.
- Aplastic crisis:
 - Prodromal symptoms in B19-infected children with sickle cell disease or other hereditary hemolytic anemias are nonspecific and consist of fever, malaise, and headache. Rash is usually absent.
 - Symptoms are usually self-limited, lasting 7–10 days.
 - Severe anemia, CHF, stroke, and acute splenic sequestration have also been associated.
- Chronic anemia/pure red cell aplasia:
 - In immunocompromised patients, B19 infection may persist for months, leading to chronic anemia with B19 viremia.
 - Low-grade fever and neutropenia may accompany anemia.

PHYSICAL EXAM

Fifth disease:

- An erythematous facial rash with a “slapped cheek” appearance, often associated with circumoral pallor
- Truncal, maculopapular, lacy-appearing rash spreading to the arms, buttocks, and thighs
 - Often pruritic and may become more intense with exercise or heat exposure
- Occasionally can be found on the palms and soles, and rarely can be papular, vesicular, or purpuric

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Antibodies:
 - Detection of parvovirus B19-specific IgM or IgG antibodies as determined by EIA or radioimmunoassay
 - The presence of B19-specific IgM antibodies is diagnostic in patients with symptoms of erythema infectiosum or aplastic crisis. IgM- and IgG-specific antibodies are detected in 90% of such patients by 3–7 days of illness.
 - B19-specific IgG antibodies persists for years, while specific IgM antibodies begin to decrease 30–60 days after onset of illness.
- Polymerase chain reaction (PCR) techniques:
 - Immunocompromised patients with chronic marrow suppression may be unable to produce B19-specific IgG or IgM antibodies. In such cases, B19 viral DNA can be detected using nucleic acid hybridization or PCR techniques. These techniques may also be used to detect virus in the fetus.
- Hematocrit and reticulocyte count in patients with aplastic crisis:
 - Laboratory studies reveal reticulocytopenia, usually with counts of <1%. During the illness, the patient’s hematocrit may fall as low as 15%.

DIFFERENTIAL DIAGNOSIS

B19 infection should be considered in all patients with arthritis or viral exanthems with a consistent history and exam.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- There is no specific antiviral therapy for B19 infection.
- Most patients require supportive care only. However, transfusions may be required for treatment of severe anemia in patients with aplastic crisis.
- IV immunoglobulin (IVIG) therapy has been given with some success to a few patients with chronic marrow suppression secondary to B19 infection.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Expected course of illness:

- The rash of erythema infectiosum in a child or adult may last up to 20 days. It may, at times, fade and/or intensify, depending on sunlight exposure, exercise, or body surface temperature changes (e.g., bathing).
- During aplastic crisis secondary to B19, the reticulocyte count usually remains low (often <1%) for ~8 days before spontaneous recovery.

PROGNOSIS

- The prognosis is quite good for all manifestations of B19 infections.
- Most patients recover spontaneously and require only supportive care.

COMPLICATIONS

- Parvovirus B19 during pregnancy:
 - 30–50% of pregnant women are susceptible to B19 infection.
 - Fetal loss, intrauterine growth retardation, or hydrops fetalis may result from maternal infection with B19 during pregnancy.
 - B19 has not been proven to cause congenital anomalies.
 - The greatest risk for B19 infection affecting the fetus exists in the first 20 weeks of gestation.
 - The risk of fetal death after exposure, if antibody status is unknown, is from 0.05–1%.
 - Fetal death occurs in 2–6% of cases.
 - There is no indication for elective abortion in cases of maternal infection.
 - The mainstay of treatment for an infected fetus is delivery, but intrauterine transfusions may be life-saving.
- Arthritis/Arthropathy:
 - Although most cases of polyarthritis resolve within 2 weeks, persistent symptoms for months to even years (rarely) have been reported.

B08.3 Erythema infectiosum [fifth disease]

FAQ

- Q: When may children with B19 infection return to school?
- A: Children are contagious only during the prodromal phase of illness, which is often unrecognized. Once the rash appears, they are no longer infectious and may return to school or day care.
- Q: What can be done to reduce risk of fetal infection?
- A: Because B19 infections during pregnancy may result in fetal death, and B19 infections often occur in community outbreaks, fetal risks following maternal exposure to persons with recognized B19 infection are a frequent concern. Risk to the fetus appears to be greatest if the infection occurs prior to the 20th week of gestation. Among pregnant women of unknown antibody status, the risk of fetal death after exposure to B19 is estimated to be <1.5%. Routine exclusion of pregnant women from the workplace when B19 infection is suspected is not recommended. However, pregnant teachers who are at risk for infection may consider a leave of absence during community outbreaks of B19.

PATENT DUCTUS ARTERIOSUS

Alexander Lowenthal
Ron E. Tanel (5th edition)

BASICS

DESCRIPTION

- Patent ductus arteriosus (PDA) is the persistence into postnatal life of the normal fetal vascular conduit between the central pulmonary and systemic arterial systems. Normally, the ductus arteriosus (DA) functionally closes within the 1st 1–3 days of life. Structural closure is usually completed by the 3rd week of life. If the DA remains patent beyond 3 months of life, it is considered abnormal and is unlikely to close spontaneously (spontaneous closure rate 0.6% per year).
- In the infant with a normal left aortic arch, the DA connects the main pulmonary artery (MPA) at the origin of the left pulmonary artery to the descending aorta, distal to the origin of the left subclavian artery.
- Many variations can occur, although they are less common. The main, proximal right, or proximal left pulmonary artery may be connected to virtually any location on the aortic arch or proximal portions of the brachiocephalic vessels.
- 5 distinct clinical conditions are associated with PDA:
 - Isolated cardiovascular lesion in premature infants
 - Isolated cardiovascular lesion in otherwise healthy term infants and children
 - Incidental finding associated with more significant structural cardiovascular defects
 - Compensatory structure in cases of neonatal pulmonary hypertension (without congenital heart disease (CHD))
 - Critical compensatory structure in some cyanotic or left-sided obstructed lesions

EPIDEMIOLOGY

- As an isolated defect, PDA is the 6th most common congenital cardiovascular lesion.
- Female : Male : 2:1

Incidence

- 1 per 2,000 (5% of all types of CHD)
- Increases with the degree of prematurity (50–80% in preterm infants <26 weeks' gestation)
- 60–70% of preterm infants of <28 weeks' gestation receive medical or surgical therapy for a PDA
- Varies significantly depending on management style (e.g., amount of maintenance fluid prescribed, surfactant administration), coexisting diseases (e.g., respiratory distress syndrome, hypoxemia, fluid overload, necrotizing enterocolitis, sepsis, hypocalcemia), and environmental factors (altitude).

PATHOPHYSIOLOGY

- Fetal blood flows from the MPA to the DA to the aorta, thus bypassing the pulmonary vascular bed and supplying systemic blood flow. With the 1st postnatal breaths, the pulmonary vascular resistance falls abruptly, the DA constricts, and pulmonary blood flow is directed into the lungs. With a PDA, excessive blood flow will continue from the aorta into the pulmonary artery, causing increased pulmonary blood flow and volume overloading of the left side of the heart.
- In premature infants and term infants with pulmonary hypertension, delayed closure represents an impaired developmental process, whereas in the healthy full-term infant, PDA probably reflects an anatomic abnormality of the ductal tissue.

ETIOLOGY

- Prematurity
- Rubella infection in the 1st trimester
- Genetic or familial factors
- High altitude
- Idiopathic

DIAGNOSIS

HISTORY

- Premature infants:
 - Variable: Ranging from asymptomatic to complete cardiovascular collapse
 - Increased ventilatory support, pulmonary hemorrhage, respiratory or metabolic acidosis from low cardiac output and excessive pulmonary blood flow
 - Tachypnea, feeding intolerance, apnea, bradycardia, necrotizing enterocolitis, and decreased urine output
- Infants and older children:
 - Small PDA: Usually asymptomatic, with incidental heart murmur found on routine exam
 - Moderate PDA: Possible CHF, poor feeding, and poor weight gain
 - Large PDA: Symptoms as above and recurrent respiratory infections

PHYSICAL EXAM

- Premature infants:
 - Tachypnea, rales, tachycardia (\pm S3 gallop)
 - Hyperdynamic precordium and bounding pulses with wide pulse pressure (due to diastolic “runoff” from the aorta to the pulmonary artery)
 - The typical PDA murmur in a premature infant is a pansystolic murmur audible at the left upper or midsternal border.

- With a large PDA and equalization of pressure between the MPA and the aorta, no murmur may be heard.
- Hepatomegaly may exist with heart failure (late sign).
- Infants and older children: Findings vary with size of shunt.
 - Small PDA:
 - Pansystolic murmur may be heard at the 2nd left intercostal space. Murmur becomes continuous (i.e., extends into diastole) as the pulmonary vascular resistance decreases over the 1st months of life.
 - Moderate or large PDA:
 - The murmur is louder, has a harsh quality, and acquires a machine-like quality often being heard posteriorly. In that case, a systolic thrill may be felt at the left upper sternal border.
 - Tachycardia, bounding pulses with a wide pulse pressure, and a mid-diastolic low-frequency rumbling murmur may be audible at the apex with a large PDA.
 - With severe left ventricular failure the classic PDA signs may disappear, but there will be findings consistent with CHF (tachycardia, S3 gallop at the apex, hepatomegaly, tachypnea, rales).
 - In extreme cases, pulmonary hypertension may occur, with the murmur shortening, the diastolic component disappearing, and S2 becoming accentuated. At advanced stages of irreversible pulmonary vascular disease, cyanosis begins to appear, often more pronounced in the lower limbs, with reversal of shunting.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- EKG:
 - Usually normal with a small PDA
 - Left atrial enlargement and left ventricular hypertrophy with moderate and large PDA
 - Biventricular hypertrophy in later stages
- Chest x-ray:
 - Usually normal with a small PDA, although prominence of main and peripheral pulmonary arteries may be seen
 - In moderate and large PDAs, these findings become more pronounced, along with an enlarged heart. Increased pulmonary vascular markings are proportionate to the left-to-right shunt. Pulmonary edema can be seen if CHF develops. In premature infants with respiratory distress syndrome, there is evidence of deteriorating lung disease with unclear cardiac borders.

- Echocardiogram:
 - Delineates the PDA and assesses the size of the left atrium and the left ventricle
 - Doppler techniques assess the ductal flow pattern and may be useful for estimating the pulmonary artery pressure.
- Cardiac catheterization:
 - Most often not essential for diagnosis
 - Indicated for suspected concomitant pulmonary hypertension
 - Can be performed for treatment via transcatheter closure techniques

DIFFERENTIAL DIAGNOSIS

- Aortopulmonary window
- Systemic or pulmonary arteriovenous communications
- Ruptured sinus of Valsalva
- Coronary artery fistula
- Truncus arteriosus
- Innocent venous hum in older children
- Pulmonary atresia with collaterals
- Ventricular septal defect with aortic regurgitation
- Ventricular septal defect in infancy

 **TREATMENT**

ADDITIONAL TREATMENT

General Measures

- Premature infant:
 - Supportive treatment (careful use of oxygen, respiratory assistance, correction of metabolic acidosis)
 - Management of CHF with fluid restriction and diuretics
 - If PDA persists or patient is symptomatic, closure of PDA is indicated.
 - Medical closure: Indomethacin most often used; ibuprofen is as effective.
 - Contraindications to medical management include: Renal failure (creatinine > 1.8 mg/dL), thrombocytopenia (platelets < 100,000), associated conditions (necrotizing enterocolitis, intraventricular hemorrhage)
 - Surgical closure indicated if medical treatment fails or use of indomethacin is contraindicated.
- Infants and older children:
 - Medical management of CHF with digoxin and diuretics
 - PDA is no longer a stated indication for subacute bacterial endocarditis (SBE) prophylaxis, but clinical practice may vary.

- Spontaneous closure rate is low, and closure with indomethacin is not usually effective in this group of patients.
- Closure is indicated whenever a symptomatic or hemodynamically significant PDA exists.
- For asymptomatic audible PDA, closure can be performed electively and is primarily performed to reduce the risk of endocarditis. Recommendations for closure of an asymptomatic, incidentally found (“silent” ductus) are not standard.
- Most infants and children can have a PDA safely and effectively closed during cardiac catheterization, obviating the need for a surgical procedure.

SURGERY/OTHER PROCEDURES

Surgical closure of PDA can be achieved by 1 of 3 means:

- Open surgical ligation and division: Mostly in premature infants
- Video-assisted thoracoscopic ligation: Dependent on the institution
- Transcatheter occlusion with coils or other devices

 **ONGOING CARE**

PROGNOSIS

- Outcome in treated premature infants is generally good but depends mostly on the degree of prematurity and the presence of associated conditions.
- Outcome in term infants and older children is excellent if no complications have occurred.
- PDA among adults may be associated with significant mortality with or without surgery.
- After closure of PDA, no endocarditis prophylaxis is needed if complete obliteration of flow is achieved. Most cardiologists continue prophylaxis for 6 months after the procedure that closed the PDA.

COMPLICATIONS

- Pulmonary edema and CHF
- Pulmonary hemorrhage
- Pulmonary vascular obstructive disease
- Increased chronic lung disease
- Failure to thrive
- Recurrent respiratory infections
- Lobar emphysema or collapse
- Infective endarteritis
- Thromboembolism of cerebral arteries

- Aneurysm of the ductus
- Intracranial hemorrhage
- Necrotizing enterocolitis
- Renal dysfunction

PELVIC INFLAMMATORY DISEASE (PID)

Jonathan R. Pletcher

BASICS

DESCRIPTION

- PID is an ascending, polymicrobial infection of the female upper genital tract. It includes an array of inflammatory disorders, including endometritis, parametritis, salpingitis, oophoritis, tubo-ovarian abscess (TOA), peritonitis, and perihepatitis.
- Pelvic inflammatory disease (PID) is a clinical diagnosis.
- The CDC has established the minimal clinical criteria; if present and no other cause can be identified, empiric therapy for PID should be initiated in sexually active young women who have either:
 - Uterine tenderness, *OR*
 - Adnexal tenderness, *OR*
 - Cervical motion tenderness
- Additional criteria can be used to enhance the specificity of the diagnosis of PID in women with more severe clinical signs:
 - Oral temperature $>38^{\circ}\text{C}$ (101°F)
 - Abnormal cervical or vaginal mucopurulent discharge
 - Presence of WBCs on a wet mount of vaginal secretions
 - Elevated ESR or CRP
 - Laboratory-documented evidence of infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*
- Definitive criteria:
 - Histopathologic evidence of endometritis on endometrial biopsy
 - Transvaginal sonography or MRI showing thickened fluid-filled tubes with or without free pelvic fluid or TOA
 - Laparoscopic abnormalities consistent with PID

EPIDEMIOLOGY

- Clinical diagnosis of PID is imprecise.
- Positive predictive value of clinical diagnosis ranges from 65–90% compared to laparoscopy.
- No single history item, physical exam finding, or laboratory test is either completely sensitive or specific for the diagnosis.

RISK FACTORS

- Adolescent women possess biologic factors that increase risk of PID:
 - Increased cervical ectopy
 - Decreased cervical immunity
- Risk also increases with:
 - Failure to use condoms
 - Prolonged menses or dysfunctional uterine bleeding (DUB)
 - Increasing number of lifetime partners
 - Having new partners in the last 3 months
 - History of STIs
- Lack of access to confidential health care

GENERAL PREVENTION

- Primary prevention involves early education and aggressive screening for STIs with onset of sexual activity or in high-risk populations.
- Abstinence should be advocated.
- For those individuals unable to commit to abstinence, consistent condom use should be advocated and facilitated.
- At a minimum, annual screening for STIs and treatment of sexual partners should be encouraged and facilitated. More frequent screening is indicated with new partners.

PATHOPHYSIOLOGY

- PID begins as an infection or inflammation of the cervix.
- Direct spread of bacteria to ascending structures, via migration, sperm transport, or refluxed menstrual blood
- Direct migration may be facilitated by menstrual flow, as there is loss of protective cervical mucus.
- Microbes invade epithelial cells, mucosa, and serosa, causing inflammation with subsequent scarring.

ETIOLOGY

- Although a polymicrobial infection, cervical infection, or vaginal bacterial overgrowth with the following organisms can lead to acute PID:
 - *N. gonorrhoeae* cervicitis
 - *C. trachomatis* cervicitis: Tends to be associated with less fever, pain, and systemic symptoms than PID due to gonococcus.
 - Organisms associated with bacterial vaginosis: Gram-negative rods, bacteroides, *Mobiluncus*, and *Peptostreptococcus* species.
 - CMV, *M. hominis*, *U. urealyticum*, and *M. genitalium* have all been associated with PID.

DIAGNOSIS

HISTORY

- Assessment begins with sensitive, confidential interview.
- Review of systems:
 - Presentation may be silent, with relatively few or mild symptoms.
- Complete medical, gynecologic, menstrual, sexual, GI, and urinary histories:
 - Associated symptoms may include dysmenorrhea, dyspareunia, vomiting, diarrhea, or constipation.
 - Supportive historic data include recent menstruation, use of IUD or douche, inconsistent condom use, and multiple or new sexual partners.
- Signs and symptoms: Classic presentation of PID includes:
 - Lower abdominal pain
 - Dyspareunia
 - Abnormal vaginal discharge
 - Dysuria
 - Irregular vaginal bleeding
 - Fever
 - Right upper quadrant abdominal pain

PHYSICAL EXAM

- Perform a thorough abdominal exam, noting tenderness, rebound or guarding, and signs of perihepatic involvement.
- Pelvic exam: Document the following:
 - Presence of external or vaginal lesions
 - Origin, quality, and quantity of discharge (e.g., “copious, mucopurulent cervical discharge,” or “scant, thin vaginal discharge”)
 - Signs of cervical inflammation (e.g., erythema, friability)
 - Cervical motion tenderness
 - Adnexal tenderness and/or fullness
 - Blot away discharge to better assess the source of new fluid accumulation

DIAGNOSTIC TESTS & INTERPRETATION

- Caution: Most bacteriologic studies are technique-dependent and require trained clinicians.
- All home pregnancy tests should be repeated.

Lab

- Urine β -human chorionic gonadotropin (β -hCG):
 - It is essential to know if the patient is pregnant, regardless of sexual history.
- CBC with differential
- ESR or CRP
- Wet prep of discharge for trichomonads, hyphae, clue cells, presence of WBCs (>10 WBC/high-power field is suggestive of infection)
- Gram stain of cervical discharge:
 - Testing for *N. gonorrhoeae* and *C. trachomatis*
 - Culture is technique-dependent, yielding 80% sensitivity with ideal collection technique.
- Antigen detection tests (e.g., direct fluorescent antibody [DFA], enzyme-linked immunosorbent assay [ELISA]) have lower sensitivities.
- Nucleic acid amplification tests (NAAT) require a single specimen for both organisms, offer a 24-hour turnaround time, and have $>90\%$ sensitivity.
- Syphilis serology in high-risk populations (e.g., rapid plasma reagin [RPR] testing) and HIV testing for all adolescents are recommended with appropriate counseling and follow-up.

Imaging

Pelvic US:

- Rule out TOA or other pelvic pathology.
- Pelvic US requires a full urinary bladder, unlike transvaginal US.

Diagnostic Procedures/Other

Laparoscopy: Not routinely used, but considered the gold standard for diagnosis

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Cervicitis
 - Vulvovaginal candidiasis
 - Trichomoniasis
 - Bacterial vaginosis
 - Tubo-ovarian abscess (TOA)
 - Pyelonephritis or cystitis
 - Appendicitis

- Appendiceal abscess
- Tuberculosis
- Viral or bacterial enteritis
- Acute cholecystitis
- Mesenteric lymphadenitis
- Pelvic thrombophlebitis
- Gynecologic:
 - Dysmenorrhea
 - Pregnancy: Intrauterine or ectopic
 - Ovarian cyst or torsion
 - Chronic pelvic pain
 - Endometriosis
 - Teratoma or other mass
- Miscellaneous:
 - Foreign body or pelvic trauma
 - Functional pain

TREATMENT

MEDICATION (DRUGS)

- Inpatient management:
 - CDC regimen A:
 - Cefotetan 2 g IV q12h OR cefoxitin 2 g IV q6h
 - Plus, doxycycline 100 mg PO b.i.d. for 14 days
 - Regimen A should be continued for at least 24 hours after clinical improvement, and is followed by the completion of a 14-day course of doxycycline 100 mg PO b.i.d.
 - CDC regimen B:
 - Clindamycin 900 mg IV q8h
 - Plus, gentamicin loading dose 2 mg/kg IV or IM, followed by maintenance dose 1.5 mg/kg q8h
 - Regimen B should be continued for at least 24 hours after clinical improvement, and is followed by completion of a 14-day course of either doxycycline or clindamycin 450 mg PO b.i.d.
 - Alternative parenteral regimens include the following:
 - Ampicillin–sulbactam 3 g IV q6h
 - Plus, doxycycline 100 mg PO q12h
 - Regimen A versus regimen B: Choice based on availability and the drug allergy history of the patient. Data to support the use of alternative regimens are limited.
- Outpatient management:
 - Ceftriaxone 250 mg IM once OR cefoxitin 2 g IM with probenecid 1 g PO once or other parenteral 3rd-generation cephalosporins
 - Plus doxycycline 100 mg PO b.i.d. for 14 days
 - With or without metronidazole 500 mg PO b.i.d. for 14 days
- Because of the emergence of quinolone resistant *N. gonorrhoeae*, ofloxacin and levofloxacin are no longer recommended and should only be considered when the parenteral cephalosporins are not available.

ADDITIONAL TREATMENT

General Measures

- The goal of treatment is to eliminate infection and to reduce or prevent the likelihood of long-term adverse outcomes.
- A patient may be treated as an outpatient or inpatient based on a clinician’s judgment as to the severity of the disease and the patient’s ability to follow through with medical care.
- Hospitalization is recommended in the following cases:
 - Surgical emergency (e.g., appendicitis) cannot be ruled out.
 - Patient is pregnant.
 - Suspected TOA
 - Patient has failed or cannot comply with outpatient treatment (e.g., recurrent vomiting).
 - Patient is clinically ill or is at high risk for sequelae.
- When choosing outpatient treatment:
 - Repeat bimanual exam within 72 hours of initiating therapy.
 - Patient must be willing to take the medications and follow-up.
 - Patient should be given a full course of doxycycline (or other oral medications) and tolerate the 1st dose under supervision.
 - All patients with PID should receive intensive education about STI prevention and partner treatment.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- For inpatients, substantial clinical improvement should occur within 3 days if the patient has been properly diagnosed and treated.
- Outpatients should have significant improvement after 72 hours of treatment.
- Test-of-cure exam and laboratory testing should be considered for all patients 6–8 weeks after diagnosis.

PROGNOSIS

- Excellent, if adequate treatment is obtained early and acute complications are absent
- One episode of PID increases the risk of future ectopic pregnancy 10-fold.
- Long-term sequelae are present in 25% of affected women, with a higher likelihood in adolescents owing to later presentation, delay in diagnosis, and inadequate treatment.

COMPLICATIONS

- Chronic pelvic pain or dyspareunia (≤18%)
- Ectopic pregnancy
- Infertility:
 - 1 episode is associated with a 13–21% risk of infertility, 2 episodes with a 35% risk, and ≥3 episodes with a 55–75% risk.
- TOA
- Fitz-Hugh–Curtis syndrome (perihepatitis resulting from tracking of pus along the paracolic gutters)

CODES

ICD9

- 614.4 Chronic or unspecified parametritis and pelvic cellulitis
- 614.9 Unspecified inflammatory disease of female pelvic organs and tissues
- 617.9 Endometriosis, site unspecified

ICD10

- N73.2 Unspecified parametritis and pelvic cellulitis
- N73.9 Female pelvic inflammatory disease, unspecified
- N80.9 Endometriosis, unspecified

FAQ

- Q: A patient states that she is not sexually active. Should I continue to consider PID?
- A: Yes. Because of the risk and severity of sequelae, PID should always be considered. Furthermore PID can occur in non–sexually active women. In fact, infections with *C. trachomatis* or *N. gonorrhoeae* are identified in <50% of PID cases.
- Q: A patient does not meet the criteria for PID; however, it is still the most likely diagnosis. Should I start therapy while other studies are pending?
- A: Yes. Appropriate therapy for PID may be initiated while further evaluation is in progress. Delay in therapy results in increased risk of adverse sequelae from PID.
- Q: An adolescent patient with PID has inquired about fertility. What should I tell her?
- A: Many clinicians would argue that an episode of PID could serve as a wake-up call to teenagers, inspiring them to abstain or comply with barrier contraception. However, a young woman who is told that she may have impaired fertility might try testing it through unprotected sex.
- Q: Does the absence of cervical motion tenderness exclude the diagnosis of PID?
- A: No. Cervical motion tenderness is only 1 of the 3 clinical signs that may be present in PID.

PENILE AND FORESKIN PROBLEMS

Caroline Mitchell

J. Christopher Austin (5th edition)

BASICS

DESCRIPTION

- Complaints relating to problems with retracting the foreskin, discharge from the foreskin, and circumcision. The most common diagnoses are listed below.
- Phimosis:
 - Physiologic attachment of the prepuce to the glans, which it protects and gradually separates from to allow retraction of the foreskin.
 - Ring of fibrotic scar tissue that prevents the foreskin from being retracted.
- Penile adhesions:
 - Attachments of the foreskin back to the glans after circumcision
- Meatal stenosis:
 - Narrowing of the urethral meatus
 - Significant narrowing will produce an upwardly deflected stream, which is tiny and strong. In severe cases, straining and prolonged voiding
- Epidermal inclusion cysts:
 - Small, enlarging white lesions growing subcutaneously along the scar from circumcision
- Balanitis:
 - Infection of the glans
 - May involve the prepuce (balanoposthitis)
 - Probably overdiagnosed owing to physiologic drainage of smegma or urea dermatitis from failure to retract foreskin during voiding in potty-trained boys
 - When infections do present, there can be significant cellulitis of the penis, edema, and fever.
 - Most common causative organisms are gram positive. Yeast is another causative organism.

RISK FACTORS

Genetics

Epidermal inclusion cysts may occur from congenital rests of skin cells buried during development, but these are rare and occur along the median raphe of the penis.

GENERAL PREVENTION

Some may be prevented with proper hygiene and education of the caretakers.

ETIOLOGY

- Phimosis:
 - Probably results from recurrent bouts of irritation of the foreskin from improper hygiene habits such as voiding through the foreskin.
- Penile adhesions:
 - Physiologic adhesions: The prepuce has adhered down to the glans after circumcision.
 - Surgical adhesions (skin bridges): Adherence between the scar of the circumcision and the glans due to healing of the crushed tissue where the foreskin was removed and the raw surface of the glans.
- Meatal stenosis:
 - Narrowing of the urethral meatus secondary to recurrent irritation of the meatus, likely from rubbing against moist diapers. Occurs almost exclusively in circumcised boys
- Epidermal inclusion cysts:
 - Caused by small islands of epithelium buried beneath the skin surface that progressively accumulate desquamated skin cells.

DIAGNOSIS

HISTORY

- Problems associated with newborn circumcision
- Inquire as to when the changes occurred.
- Character of urinary stream
- Presence of fever
- Penile discharge in cases of balanitis
- Retraction of foreskin in uncircumcised males during voiding
- Ballooning of the foreskin with voiding
- In older boys, inquire about sexual activity.

PHYSICAL EXAM

- Circumcised males:
 - Size and position of meatus
 - Redundancy of inner preputial skin
 - Presence of adhesions to the glans and whether or not they involve the scar line between the shaft skin and the inner preputial skin
 - Lesions or erythema of glans or shaft
 - Watch patient void if meatal stenosis is suspected.
- Uncircumcised males:
 - Ability to retract foreskin with gentle retraction
 - Presence of phimotic ring
 - Lesions or erythema of prepuce

ALERT

Do not try to forcefully retract the foreskin. It can take 3–5 years before the foreskin can be retracted.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In cases of balanitis with drainage, cultures may be taken.
- If urethral discharge is present, culture for gonorrhea and chlamydia in an adolescent male.

TREATMENT

MEDICATION (DRUGS)

Balanitis: If the child is afebrile, oral antibiotics such as a 1st-generation cephalosporin would be the 1st line of treatment. If the child develops fever or there is progression of cellulitis, then treatment with IV antibiotics (cefazolin or ampicillin–sulbactam).

ADDITIONAL TREATMENT

General Measures

- Phimosis:
 - Physiologic: No need for intervention
 - Good hygiene practices should be encouraged, such as pulling the foreskin back to expose the meatus when voiding and not voiding through the foreskin.

- Pamphlets or Web sites that explain the care of the penis for uncircumcised males are helpful to give to the parents.
- If there is a fibrotic ring of scar tissue preventing the retraction of the foreskin, a trial of betamethasone cream 0.05% applied to the foreskin b.i.d. for 4 weeks with daily gentle retraction may soften the scar tissue enough to resolve the phimosis. In cases where conservative measures fail, a circumcision is indicated.
- Penile adhesions:
 - Physiologic: Practices in the past have included separation using anesthetic (EMLA) cream. If there is redundancy of the foreskin or a prominent suprapubic fat pad that can tend to hide the penis in infants, adhesions often recur or require constant application of barrier creams or ointments to the penis and manual retraction of the redundant foreskin by the parents to prevent recurrence:
 - In many cases, no treatment is necessary, as the adhesions will break down over a period of years.
 - If there are extensive adhesions with significant redundancy of foreskin, consideration should be given to revision of the circumcision if the adhesions are to be treated.
 - Surgical (skin bridges):
 - These are due to scar tissue formation between the raw cut edge where the foreskin was removed and the raw surface of the glans.
 - As this represents true scarring and not 2 epithelial surfaces stuck together, the surfaces cannot be simply pulled apart like physiologic adhesions. They will not resolve with time, and if left in place, with growth, penile skin will be transferred to the glans, resulting in discoloration, especially in patients with darker skin tones.
 - These adhesions need sharp division either in the office with EMLA cream anesthesia or under general anesthesia if they are extensive.
- Meatal stenosis:
 - When the narrowing at the meatus is producing an upwardly deflected, narrow stream (which can make aiming into the toilet difficult) or is causing straining and prolonged voiding, treatment is indicated.
 - A meatotomy can be done in the office using EMLA anesthesia or as an outpatient surgical procedure.

- Epidermal inclusion cysts:
 - These subcutaneous islands of skin cells will progressively enlarge over time.
 - Complete excision is generally curative.
- Balanitis:
 - When the inflammation and irritation seem to be from chronic dampness and exposure to urine, treat with barrier creams or ointments.
 - Keeping the area clean and dry will help prevent future episodes.
 - If there are small whitish plaques (not smegma), associated with redness, yeast may be present and an antifungal cream such as 1% clotrimazole can be used to help speed the healing.
 - Antibiotics as necessary (see "Medication")
 - In cases where there is purulent drainage and cellulitis of the penis, which can often be rapidly spreading over 24 hours, treatment with antibiotics is recommended.
 - Genital infections of this nature should be taken quite seriously, and if treatment as an outpatient is attempted, close follow-up (return visit in 24–48 hours) is prudent.

ONGOING CARE

PATIENT EDUCATION

- It is important that all parents of uncircumcised boys teach them proper hygiene habits during potty training.
- Do not forcibly retract the foreskin. Gently clean with warm water during baths and dry after. Retract the skin when voiding in potty-trained boys.

CODES

ICD9

- 605 Redundant prepuce and phimosis
- 607.1 Balanoposthitis
- 753.6 Atresia and stenosis of urethra and bladder neck

ICD10

- N47.1 Phimosis
- N47.5 Adhesions of prepuce and glans penis
- Q64.33 Congenital stricture of urinary meatus

FAQ

- Q: The foreskin is stuck down to my son's penis. Does that mean he needs another circumcision?
- A: Not necessarily. If there is minor redundancy and a small physiologic adhesion, then no treatment is needed.
- Q: My uncircumcised son had some thick white drainage from his foreskin. Is that from an infection?
- A: Probably not. The thick white material is probably shed skin cells, which have been slowly separating the foreskin from the glans.

PERICARDITIS

Meryl S. Cohen

BASICS

DESCRIPTION

Inflammation of the pericardium, usually resulting in the accumulation of fluid in the pericardial space between the visceral (serosa tissue intimately related to the myocardium) and parietal (fibrous layer composed of elastic fibers and collagen) pericardium. Pericarditis may be serous, fibrinous, purulent, hemorrhagic, or chylous.

EPIDEMIOLOGY

- Infectious pericarditis is more frequently seen in children <13 years, with predominance in children <2 years.
- Postpericardiotomy syndrome occurs in ~5–10% of children following uncomplicated cardiac surgery, particularly when the atrium has been entered.

PATHOPHYSIOLOGY

- Fine deposits of fibrin develop next to the great vessels, leading to altered function of the membranes of the pericardium, including changes in oncotic and hydrostatic pressure with subsequent accumulation of fluid in the pericardial space.
- Effusion is defined as excessive pericardial contents secondary to inflammation, hemorrhage, exudates, air, or pus.
- In postpericardiotomy syndrome, there appears to be a nonspecific hypersensitivity reaction to the direct surgical entrance into the pericardial space.

ETIOLOGY

- Infectious:
 - Viral: Coxsackievirus, echovirus, mumps, varicella, Epstein-Barr, adenovirus, influenza, human immunodeficiency virus
 - Bacterial: Streptococcus, pneumococcus, staphylococcus, meningococcus, mycoplasma, tularemia, *Haemophilus influenzae* type B, *Pseudomonas aeruginosa*, *Listeria monocytogenes*, *Pasteurella multocida*, *Escherichia coli*
 - Tuberculosis, atypical mycobacterium
 - Fungal: Candidiasis, histoplasmosis, actinomycosis
 - Parasitic: Toxoplasmosis, echinococcus, *Entamoeba histolytica*, rickettsia
- Rheumatologic/Inflammatory:
 - Acute rheumatic fever
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Systemic sclerosis
 - Sarcoidosis
 - Dermatomyositis
 - Kawasaki disease
 - Familial Mediterranean fever
 - Inflammatory bowel disease

- Metabolic/Endocrine:
 - Hypothyroidism
 - Uremia (chemical irritation)
 - Gout
 - Scurvy
- Neoplastic disease:
 - Lymphoma
 - Lymphosarcoma
 - Leukemia
 - Sarcoma
 - Metastatic disease to the pericardium
 - Radiation therapy induced
- Postoperative:
 - Postpericardiotomy syndrome (after cardiac surgery)
 - Chylopericardium
- Other:
 - Trauma
 - Drug-induced (hydralazine, isoniazid, procainamide)
 - Aortic dissection
 - Postmyocardial infarction
 - Idiopathic

DIAGNOSIS

SIGNS AND SYMPTOMS

- Most common:
 - Precordial chest pain
 - Fever
 - Cough
 - Shoulder pain aggravated by changes in position
- Rapid accumulation of fluid:
 - Respiratory distress/dyspnea
 - Signs of hypotension
 - Change in mental status/loss of consciousness
- Pain: Often relieved if the child sits leaning forward
- Slow, chronic accumulation may be associated with no symptoms at all until tamponade develops.
- Other symptoms are dependent on the etiology of the pericarditis.

HISTORY

- Dependent on etiology
- Recent upper respiratory infection or gastroenteritis (viral pericarditis)
- Sepsis or other source of bacterial infection
- Symptoms of rheumatic disease
- Known thoracic neoplasm

PHYSICAL EXAM

- Pericardial friction rub is the pathognomonic finding (typically heard if only a small amount of fluid is in the pericardial space).
- Quiet precordium, tachycardia, hypotension and muffled heart sounds may be heard when there is a large amount of fluid and/or tamponade.
- Evidence of right-sided heart failure:
 - Peripheral edema, jugular venous distention, and hepatomegaly

- Pulmonary edema: Rare because the heart is underfilled, and left atrial pressure, although elevated, does not exceed right atrial pressure
- Pulsus paradoxus: An exaggerated decrease in systolic BP with inspiration
- Kussmaul sign: Paradoxical rise in jugular venous pressure during inspiration, often considered diagnostic of tamponade

DIAGNOSTIC TESTS & INTERPRETATION

EKG:

- Nonspecific, but generally demonstrates low-voltage QRS complexes secondary to dampening of the signal transmitted through the pericardial fluid
- One can also see diffuse ST segment elevation with or without T-wave inversion.
- These findings may be secondary to inflammation of the myocardium.
- Electrical alternans can be seen with large effusions.

Imaging

- Chest x-ray:
 - Often shows enlargement of the cardiac silhouette (“water bottle sign”), usually in association with normal pulmonary vascular markings. However, heart size may appear normal in acute pericarditis.
 - Calcification may be seen in constrictive pericarditis.
- CT
 - CT can also demonstrate calcification of the pericardium with excellent sensitivity
- Echocardiogram:
 - Most sensitive and specific test for pericardial thickening and fluid in the pericardial space
 - In the presence of a large effusion, the heart may appear to swing within the pericardial cavity.
 - In tamponade, diastolic collapse of the right atrium may be seen. Collapse of the left atrium and right ventricle occur in severe cases.
 - Tamponade can be diagnosed using Doppler inflow patterns of the tricuspid and mitral valves. In tamponade, mitral inflow E-wave velocity decreases by >30% during inspiration while the tricuspid inflow E-wave velocity increases by >50% during inspiration.

Diagnostic Procedures/Surgery

- Pericardiocentesis is performed when the etiology of the effusion is in question or tamponade has developed.
 - Fluid obtained should be sent to the lab for cell count, cytology, and culture (including bacteria, viruses, *Mycobacterium tuberculosis*, and fungi).
 - Complications include myocardial puncture, coronary artery/vein laceration, hemothorax, and pneumothorax.
 - Echocardiogram or fluoroscopic guidance is useful for this procedure, but is not required if there is impending cardiovascular collapse.
- Pericardial window:
 - In cases of chronic pericardial effusion, removal of part or all of the pericardium may be performed (pericardial window).

DIFFERENTIAL DIAGNOSIS

- History, physical examination, and laboratory findings of acute pericarditis can be quite similar to those found in acute myocarditis. In addition, myocarditis can be associated with pericardial disease and vice versa. Echocardiogram is an excellent tool to help differentiate between these two entities.
- Acute myocarditis
- Restrictive cardiomyopathy
- Other causes of chest pain
- Myocardial infarction

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

- Treatment should be directed toward the etiology of the disease. However, no matter the cause, pericardiocentesis is required if there is an effusion that causes hemodynamic compromise. It may be life-saving in patients with bacterial pericarditis.
- Viral pericarditis usually resolves spontaneously in 3–4 weeks with bed rest and analgesics (NSAIDs).
- Bacterial pericarditis is potentially life threatening and requires immediate decompression of the pericardial space (often with open drainage and pericardial window creation), IV antibiotic therapy for at least 4 weeks, and supportive therapy (i.e., volume expansion, inotropes).
 - *Staphylococcus aureus* is the most common organism responsible for bacterial pericarditis.
- Rheumatologic causes of pericardial inflammation usually respond to corticosteroids and/or salicylates and rarely require pericardiocentesis.
- Uremic pericarditis usually responds to dialysis, but pericardiectomy (surgical removal of the pericardium) may be necessary in chronic situations.
- Neoplastic pericarditis is addressed by treating the primary disease and performing pericardiocentesis if indicated for diagnostic and/or hemodynamic reasons.
- Hemorrhagic pericarditis with effusion accumulation secondary to trauma should be drained because of the risk of subsequent development of constrictive pericarditis.
- Constrictive pericarditis is treated with complete stripping of the pericardium (pericardiectomy). Often, immediate clinical improvement is not seen because there has been myocardial damage. However, eventual full recovery is the norm.
- Postpericardiectomy syndrome occurs 1–4 weeks after cardiac surgery. Treat with anti-inflammatory drugs, bed rest, and occasionally steroids.
 - Pericardiocentesis is indicated if tamponade develops.

**ONGOING CARE**

- Most forms of pericarditis resolve on their own, or with anti-inflammatory medication, over the course of several weeks.
 - Follow-up is necessary to ensure that effusions have resolved and to assess for recurrence (up to 15% relapse).
 - Patients with bacterial pericarditis require long-term antibiotic therapy and close follow-up to assess for the development of constrictive pericarditis.
- Signs to watch for include the following:
 - Postpericardiectomy syndrome: All cardiac surgical patients need an evaluation 2–4 weeks after surgery to assess for postpericardiectomy syndrome, with treatment and follow-up as necessary.
 - Signs of low cardiac output and right-sided heart failure indicate impending cardiac tamponade.
 - Constrictive pericarditis may present with a rapidly decreasing cardiac silhouette, calcifications on chest roentgenogram, and signs or symptoms of right-sided heart failure.

PROGNOSIS

- Most children recover fully from pericarditis, even if it is bacterial in etiology.
 - However, there is significant morbidity and mortality associated, especially in young infants, when the diagnosis is delayed and/or when *S. aureus* is the etiologic agent.
- Pericarditis can also recur in as many as 15% of patients.
- Prognosis varies with the cause of pericarditis, but generally is related directly to the primary disease.

COMPLICATIONS

- Cardiac tamponade:
 - Intrapericardial pressure increases at a rapid rate secondary to decreased compliance of the pericardial membranes, resulting in restriction of ventricular filling and eventual decrease in stroke volume and cardiac output.
 - The compliance of the pericardium is influenced by the disease process itself (i.e., the pericardium is thickened and stiff in bacterial and tuberculous pericarditis).
 - During cardiac tamponade, ventricular end-diastolic, atrial, and venous pressures are all equal.
 - In acute pericarditis, tamponade may occur with small amounts of fluid because of a rapid increase in the intrapericardial pressure. In contrast, large amounts of fluid may be tolerated if the accumulation is a chronic, slow process.
- Constrictive pericarditis:
 - Thick, fibrotic, and often calcified pericardium is seen, usually a late result of purulent or tuberculous pericarditis; it can occur months to years after the initial infection. It can also be seen in oncology patients with direct invasion of tumor into the pericardium or after significant radiation to the chest.

- Poor compliance of the pericardium leads to diminished diastolic filling of the ventricle. Patients may complain of exercise intolerance and fatigue. Additionally, they may have signs of right heart failure.
- This entity may be difficult to distinguish from restrictive cardiomyopathy.

**CODES****ICD9**

- 420.90 Acute pericarditis, unspecified
- 420.91 Acute idiopathic pericarditis
- 423.9 Unspecified disease of pericardium

ICD10

- I30.1 Infective pericarditis
- I30.9 Acute pericarditis, unspecified
- I31.9 Disease of pericardium, unspecified

FAQ

- Q: How does cardiac tamponade present?
- A: Patients with impending tamponade appear quite ill, with tachycardia, chest pain, and signs of right heart failure including jugular venous distention, hepatomegaly, ascites, and peripheral edema. They may also have signs of poor systemic perfusion secondary to low cardiac output. Chest x-ray may or may not show an enlarged cardiac silhouette, depending on how acutely the process occurs. It takes much less fluid to cause tamponade in an acute process than in a chronic process. Echocardiography is the standard diagnostic tool, and pericardiocentesis is the treatment.
- Q: What is pulsus paradoxus and how does one measure it?
- A: Pulsus paradoxus is an exaggerated response of the systolic BP to the normal respiratory cycle. Normally with inspiration, the systolic BP drops ~5 mm Hg secondary to the increased capacitance of the pulmonary veins from the increased systemic venous return. In tamponade, this response becomes more profound (>10 mm Hg), most likely secondary to diminished filling of the left heart. Pulsus paradoxus can also be seen in patients with severe respiratory distress associated with asthma and emphysema.
- To assess for pulsus paradoxus, measure the systolic BP first in expiration; then allow it to fall to the place where it is heard equally well in inspiration and expiration. A difference of >10 mm Hg is considered abnormal.

PERIODIC BREATHING

Richard M. Kravitz

BASICS

DESCRIPTION

- A respiratory pattern consisting of regular oscillations in breathing amplitude.
- Typically, a respiratory pattern in which ≥ 3 apneas lasting ≥ 3 seconds occur, separated by < 20 seconds of respiration.

ALERT

Don't confuse periodic breathing with obstructive and/or central apnea.

EPIDEMIOLOGY

- Usually absent in the 1st 48 hours of life
- More frequent during rapid eye movement (REM or active) sleep vs. non-REM (quiet) sleep
- Less common in prone vs. supine position
- In full-term infants:
 - Amount of periodic breathing usually $< 4\%$ of sleep time
 - Amount gradually decreases through the 1st year of life
 - By 1 year of age, the mean amount of periodic breathing is $< 1\%$ of total sleep time.
- In premature infants:
 - Amount of periodic breathing is higher than in full-term infants.
 - Amount correlates inversely with gestational age.

PATHOPHYSIOLOGY

- No common pathologic finding
- Abnormalities, when they exist, are related to the underlying disorder causing the periodic breathing.

ETIOLOGY

- Periodic breathing can be seen in healthy infants, children, and adults.
- Abnormalities in any component of the breathing control system may result in an increased amount of periodic breathing.
- Possible etiologies:
 - A delay in detecting changes in blood gas values by the chemoreceptors
 - Increased chemoreceptor gain

COMMONLY ASSOCIATED CONDITIONS

- Periodic breathing in infants is associated with the following:
 - Apnea of prematurity or infancy
 - Familial history of sudden infant death syndrome (SIDS)
 - Anemia of prematurity
 - Hypoxemia
 - Hypochloremic alkalosis
- Periodic breathing with adults is associated with:
 - Cardiac abnormalities (especially congestive heart failure [CHF])
 - Neurologic dysfunction (meningitis, encephalitis, brainstem dysfunction)
 - Exposure to high altitudes

DIAGNOSIS

HISTORY

- In most cases, parents notice periodicity in the child's respiratory pattern.
- An apparent life-threatening episode (ALTE) might precipitate an evaluation in which periodic breathing is documented.
- In otherwise healthy premature or term infants, there are no other symptoms.

PHYSICAL EXAM

In otherwise healthy premature or term infants, the physical exam is normal.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

Chest x-ray: Usually normal findings

Diagnostic Procedures/Other

- Polysomnography:
 - Assesses the extent of periodic breathing episodes
 - Determines if there is accompanying hypoxemia, hypercarbia, or bradycardia with the events
 - Distinguishes between periodic breathing and obstructive and/or central apnea
 - Useful for following response to treatment (i.e., normalization of polysomnography)
- pH probe done in combination with the polysomnogram (if gastroesophageal reflux is suspected): Record for a minimum of 6 hours
- 2-channel pneumogram:
 - Gives less information than polysomnography
 - Can document periodic breathing, but it may miss episodes of obstructive apnea
 - Monitors heart rate and respiratory effort (if oxygen saturation monitoring is desired, an additional channel is required)

DIFFERENTIAL DIAGNOSIS

- Other forms of apnea:
 - Central apnea
 - Mixed apnea
 - Obstructive apnea (or hypopnea)
- Other forms of periodic breathing:
 - Cheyne-Stokes respirations
 - Biot breathing
 - Kussmaul respirations
- Normal irregular respiration seen in infants

TREATMENT

MEDICATION (DRUGS)

- Stimulants
 - Caffeine:
 - Loading dose: 10 mg/kg
 - Maintenance dose: 2.5 mg/kg/d
 - Therapeutic level: 5–20 mg/L
 - Theophylline:
 - Loading dose: 4–5 mg/kg
 - Maintenance dose: 3–5 mg/kg/d divided t.i.d.
 - Therapeutic level: 6–10 mg/L

ADDITIONAL TREATMENT

General Measures

- Therapy should be directed at treating the underlying primary disease:
 - If periodic breathing is associated with apnea, hypoxemia, and/or other sleep disturbances, appropriate treatment should be instituted.
 - In cases secondary to CHF, appropriate cardiac interventions need to be instituted.
 - In cases associated with high altitude, treatment options include:
 - Acclimation (if tolerated)
 - Descent to lower altitude, then gradual ascent
 - Medication (acetazolamide most commonly used)
- Duration of therapy:
 - Depends on the underlying cause of the periodic breathing
 - Treatment does not change the natural course of periodic breathing in otherwise healthy infants.
 - Therapy should continue until the periodic breathing resolves or is no longer clinically significant.

Additional Therapies

- Supplemental oxygen: Useful if periodic breathing is secondary to hypoxemia
- Nasal continuous positive airway pressure (CPAP): Very effective in eliminating periodic breathing
- Home monitoring should be considered (although not absolutely indicated) in the following cases:
 - Significant amount of periodic breathing
 - Accompanying apnea
 - Associated hypoxia and/or bradycardia
 - History of a significant ALTE
 - Parental anxiety

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Time to improvement depends on the underlying cause of the periodic breathing.
- Improvement is anticipated as the infant ages.
- When treatment is started, a decrease in the amount of periodic breathing should be seen almost immediately.

PROGNOSIS

- Excellent in otherwise healthy premature or term infants
- Governed by primary process in patients with an underlying cardiac or neurologic disorder

COMPLICATIONS

Relationship between periodic breathing and SIDS is controversial.

CODES

ICD9

- 770.81 Primary apnea of newborn
- 786.04 Cheyne-Stokes respiration
- 786.9 Other symptoms involving respiratory system and chest

ICD10

- R06.3 Periodic breathing
- R09.02 Hypoxemia
- P28.4 Other apnea of newborn

FAQ

- Q: What is the risk of the patient dying of SIDS?
- A: The relationship between periodic breathing and SIDS is not clear, although most studies have not found a higher frequency of SIDS among patients with periodic breathing.

PERIORBITAL CELLULITIS

Scott M. Goldstein
Femida Kherani (5th edition)

BASICS

DESCRIPTION

- Periorbital cellulitis is an acute infection of the superficial skin and subcutaneous tissues of the eyelids. It is also known as preseptal cellulitis because the inflammation is localized in the tissues anterior to the orbital septum. Thus, the eyeball and orbital structures are not involved.

EPIDEMIOLOGY

- Usually occurs in young children, commonly <5 years of age, but can occur at any age

RISK FACTORS

- Predisposing factors that may lead to infection include skin trauma, insect bites, and upper respiratory infections with paranasal sinusitis.

ETIOLOGY

- A variety of bacteria
 - Most common pathogens are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Staphylococcus epidermidis*.

COMMONLY ASSOCIATED CONDITIONS

- Periorbital cellulitis may be a secondary extension of another process such as sinusitis.

DIAGNOSIS

SIGNS AND SYMPTOMS

- The lids will be edematous, erythematous, warm to the touch, and typically tender on palpation.
 - The findings can start in one eyelid, but both the upper and lower eyelids are usually swollen.
 - May be signs of previous trauma, cutaneous injury, etc

HISTORY

- Onset, time course of symptom progression, and any predisposing factors
- Trauma or underlying respiratory infection
 - These types of questions have a low yield.
- The presence of pain supports cellulitis, whereas complaints of itching are more suggestive of an allergy.
- Quantify systemic symptoms such as fever and lethargy
 - These indicate a more severe, disseminated infection.

PHYSICAL EXAM

- Occasionally the eyelids are so swollen that it is difficult to examine the globe. To do so, place anesthetic eyedrops on the eye and fashion a paperclip into a lid retractor to lift the eyelid.
- The globe should be carefully examined. In preseptal cellulitis, the ocular exam is normal. The eye is usually white, although patients can have some conjunctival edema. Any change in vision or pupillary function, or limitations in eye motility suggest orbital involvement. Pediatric orbital cellulitis is an ophthalmologic emergency and requires prompt therapy.
- Many patients with preseptal cellulitis appear to have proptosis but actually do not. The presence of proptosis suggests deep orbital involvement.
- Evaluate for signs of fever, respiratory infection, and sepsis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Lab tests are usually not helpful or indicated.
- CBC is warranted only if bacteremia is suspected.
- Skin cultures and blood cultures have a low yield.
 - Blood cultures are obtained only when the child is febrile or appears septic.
 - Wound cultures can be obtained if there is an abscess.

Imaging

- CT scanning is a helpful modality to appreciate sinus and orbital disease. It is important to obtain imaging studies if orbital cellulitis is suspected, and especially in cases that do not respond to medical treatment.
 - CT scans will lag behind clinical findings once treatment is started. In fact, a repeat scan 24 to 48 hours after starting antibiotics will usually look worse than the preantibiotic scan. Thus, serial CT scanning should be done only if the child is not improving with treatment.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Early orbital cellulitis, dacryocystitis, stye, severe viral conjunctivitis
- Allergic
 - Periocular allergic reaction: insect bite, angioneurotic edema, contact dermatitis
- Other
 - Periocular trauma
 - Rhabdomyosarcoma
 - Idiopathic orbital inflammatory syndrome (IOIS)

TREATMENT

ADDITIONAL TREATMENT

General Measures

- New antibiotics are constantly being introduced to replace older medications. Antibiotics that cover *gram-positive organisms and sinus pathogens*, such as second-generation cephalosporins or β -lactamase-resistant penicillins, should be started as soon as possible.
 - MRSA has become a leading cause of skin infections and must be considered when starting treatment
- Children <1 year of age should be hospitalized for IV therapy and very close observation.
- Children between the ages of 1 and 5 years should be watched closely.
 - Mild cases may be managed on an outpatient visit.
- Children >5 years of age can usually be treated with an oral regimen as long as they do not appear toxic or have orbital involvement.

MEDICATION (DRUGS)

- In nontoxic children, oral antibiotics (Clindamycin, Augmentin, cefaclor, Pediazole, Bactrim, etc.) are started on an outpatient basis; the child should be seen again within 24–48 hours.
- Children who do not improve or who deteriorate, and children who present with fever or septic symptoms, should be admitted for IV antibiotic (Clindamycin, Unasyn, ceftriaxone, etc.). These children should be watched closely.

SURGERY/OTHER PROCEDURES

- Surgical intervention is usually required when an abscess or a foreign body is present.

ONGOING CARE

- Patients usually take 24–48 hours to respond to therapy.
- Patients should be seen daily until a definite improvement is noted.

PROGNOSIS

- Excellent, with minimal incidence of long-term sequelae unless a complication is encountered

COMPLICATIONS

- Orbital extension (2.5–17%)
- Skin abscess (8%)
- Eyelid necrosis (1–2%)
- Sepsis
- Intracranial extension (2–3%)

Patient Monitoring

- Watch patients closely for signs of orbital extension, bacteremia, or other forms of disseminated infection.
- Neonates and infants can become septic very quickly, so they need to be closely monitored.

PERIRECTAL ABSCESS

Calies Menard-Katcher

Judith Kelsen

Vera de Matos (5th edition)

BASICS

DESCRIPTION

- Abscess in the perirectal area, most often arising from an anal gland.
- May be associated with fistula-in-ano.
- Classification of the abscess is based on the location in relation to the levator and sphincteric muscles of the pelvic floor.
- Classification by decreasing frequency: perianal, ischioanal, intersphincteric, and supralelevator.

EPIDEMIOLOGY

- May occur at any age.
 - More common between the ages of 20–45 years.
 - In children, more common in infants.
- More common in boys.

PATHOPHYSIOLOGY AND ETIOLOGY

- Most often originate from occluded anal glands with subsequent bacterial overgrowth and abscess formation.
- Infection from within the anal glands penetrates through the internal sphincter and ends in the intersphincteric space.
- The most common *enteric* organism cultured is *Escherichia coli*.
- Chronic infection and inflammation may result in fistula-in-ano.
- May be a result of or associated with:
 - Nonspecific anal gland infection
 - Crohn disease
 - Immune deficiency (e.g., neutropenia, diabetes mellitus, AIDS)
 - Perforation by a foreign body
 - External trauma
 - Tuberculosis
 - Chronic granulomatous disease (CGD)
 - Tumor (e.g., carcinoma, rhabdomyosarcoma)

DIAGNOSIS

SIGNS AND SYMPTOMS

- Constant anal or perianal pain that often precedes local findings
- Localized swelling, erythema and fluctuance
- Painful defecation or ambulation
- Constitutional symptoms (e.g., fever or malaise)

PRESENTATION BY CLASSIFICATION

Perianal Abscess

- Result of distal vertical spread of the infection to the anal margin
- Presents as tender, fluctuant mass
- Most common type of perianal abscess

Ischiorectal Abscess

- Secondary to horizontal spread of infection across the external anal sphincter into the ischiorectal fossa
- Infection may track across the internal anal sphincter into the anal canal.
- Presents as diffuse, tender, indurated, fluctuant area
- Patients may have pain and fever prior to visible swelling.

Intersphincteric Abscess

- Limited to the intersphincteric space between the internal and external sphincters, therefore often does not cause perianal skin changes
- Associated with painful defecation
- Accounts for only 2–5 percent of all anorectal abscesses

Supralelevator Abscess

- May arise from two different sources:
 - Proximal vertical spread from the gland through the intersphincteric space to the supralelevator space
 - Pelvic inflammation or infection (e.g., Crohn disease)

- Presents with pelvic or anorectal pain, fever, and, at times, urinary retention
- Rectal exam usually reveals an indurated swelling above the anorectal ring.
- Imaging may be necessary to establish the diagnosis.

Horseshoe Abscess

- Secondary to abscessed anal gland located in the posterior midline of the anal canal
- Due to presence of anococcygeal ligament, the infection is forced laterally into the ischiorectal fossae and is therefore known as “horseshoe.”
- May be unilateral or bilateral
- Presents with pain

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
- Culture

Imaging

- CT scan
- MRI
- Rectal ultrasound

DIFFERENTIAL DIAGNOSIS

- Pilonidal infection
- Bartholin abscess
- Presacral epidermal inclusion cyst
- Hidradenitis suppurativa
- Rectal duplication cyst

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Abscess should be drained.
- Lack of fluctuation should not delay treatment.
- Antibiotics are reserved for situations in which infection does not appropriately respond to drainage or in the case of associated conditions such as adjacent cellulitis, immunocompromised patient, patient with abnormal cardiac valves, enteric organism on culture or in Crohn disease.
- Abscess should be cultured at time of drainage to direct therapy in the case antibiotics are needed.
- Sitz baths may be helpful with drainage.

SURGICAL TREATMENT

- Drainage may be performed either with conservative incision and drainage or with judicious probing for fistulae.
- It is a matter of debate as to whether a fistulotomy or fistulectomy should be performed at the time of drainage for an accompanying fistula.

ONGOING CARE

- If abscess recurs, exploration for fistula-in-ano is recommended in an attempt to prevent recurrence.
- In the setting of recurrent abscess or fistula, consider other associated conditions (e.g., neutropenia, HIV, diabetes mellitus, Crohn disease, rectal duplication cyst).

PROGNOSIS

- Prognosis is good if there is early detection and drainage of abscesses.
- Patients typically recover well after surgical drainage without the need for antibiotics.

COMPLICATIONS

- Sepsis
- Fistula formation

SPECIAL CONSIDERATIONS

- Crohn disease should be considered in patients with perirectal abscess with or without fistula-in-ano.
- Signs and symptoms that increase suspicion for Crohn disease include: Weight loss or poor growth, chronic diarrhea or abdominal pain.
- Topical tacrolimus may be used in the treatment of perirectal abscess in the setting of Crohn disease.

CODES

ICD9

- 565.1 Anal fistula
- 566 Abscess of anal and rectal regions

ICD10

- K60.3 Anal fistula
- K61.0 Anal abscess
- K61.1 Rectal abscess

FAQ

- Q: What are complications of this problem?
- A: Fistula formation is seen in $\leq 25\%$ of patients with a predilection for males.
- Q: What are the most common organisms of the abscess?
- A: Staphylococcus species
- Q: What other disease may perirectal abscess be associated with?
- A: Crohn disease. If there has been exposure, tuberculosis should also be excluded.
- Q: What treatments can be done other than surgery?
- A: Sitz baths and warm compresses may be able to help with more superficial abscess.

PERITONITIS

Kathleen M. Loomes
Vera de Matos (5th edition)

BASICS

DESCRIPTION

- Inflammation of the peritoneum in reaction to infection or chemical irritation by organic fluids (GI contents, bile, blood, or urine). Infectious peritonitis can be:
 - Primary or spontaneous bacterial peritonitis (SBP). Pathogens can reach the peritoneum by translocation from the intestinal lumen, from the bloodstream, from the lymphatics, from the vagina, from foreign bodies inserted in the peritoneal cavity, or from the pharyngeal or skin flora.
 - Secondary peritonitis occurs after bowel perforation, abscess formation, ischemic necrosis, or penetrating abdominal injury.
- Infectious organisms include aerobic gram-negative organisms (*Escherichia coli* [~50%] and *Klebsiella* species [~13%]) and aerobic gram-positive organisms (*Streptococcus* [~19%] and *Enterococcus* [5%] species).
- Anaerobes rarely cause SBP, and polymicrobial infections occur in relatively few patients (~8%).
- Urine cultures have been found to be positive for the same organism in ~44% of patients.
- Pneumonia and soft tissue infections have also been suggested as sources.

RISK FACTORS

- Liver cirrhosis (10–30% of adults hospitalized with cirrhosis have SBP), nephrotic syndrome (staphylococcal species, streptococci, enteric organisms, and fungi)
- Splenectomy (encapsulated organisms: Group A streptococci, *E. coli*, *Streptococcus pneumoniae*, *Bacteroides* sp.)
- Decreased serum complement levels
- Decreased ascitic protein and complement levels
- Presence of gastrointestinal hemorrhage

PATHOPHYSIOLOGY

- When bacteria or chemicals reach the peritoneal cavity, a local peritoneal and systemic response is initiated:
 - Hyperemia and exudation of fibrinogen, albumin, opsonins, and complement
 - Mesothelial cells secrete cytokines (interleukins [IL-6, IL-8], tumor necrosis factor- α [TNF- α]). IL-6 stimulates T- and B-cell differentiation, and IL-8 is a selective chemoattractant for polymorphonuclear (PMN) leucocytes.

- In SBP, pathogenic bacteria are cultured from peritoneal fluid without any apparent intra-abdominal surgical treatable source of infection. Recognized as a complication in patients with ascites as a result of cirrhosis of any etiology:
 - Generalized bacteremia and translocation of organisms from the gut (*E. coli*, *Klebsiella* sp.) into the portal veins or lymphatics or, less likely, directly into the ascitic fluid may account for the source of the infection.
 - Clearance of bacteria from the bloodstream may be impaired in patients with cirrhosis and ascites because of diminished phagocytic activity of the hepatic reticuloendothelial system secondary to cellular functional defects or shunting of blood away from the liver.
 - Complement, necessary for the opsonization of bacteria and ultimately clearance by phagocytes, is decreased in the ascitic fluid of patients with ascites.
- In secondary bacterial peritonitis, the underlying bacterial infection tends to be a complex polymicrobial infection with an average of 3 or 4 different isolates; the most common isolates are combinations of *E. coli* and *Bacteroides fragilis*, and the most common gram-positive organisms are nonenterococcal streptococci and enterococci.

ETIOLOGY

- Primary peritonitis: Liver cirrhosis (differential diagnosis in “Cirrhosis” chapter) or other conditions associated with ascites, such as:
 - Budd-Chiari syndrome
 - CHF
 - Nephrotic syndrome
 - Systemic lupus erythematosus
 - Rheumatoid arthritis
- The etiology of secondary peritonitis varies with age.
 - Neonate:
 - Necrotizing enterocolitis
 - Idiopathic gastrointestinal perforation
 - Perforation due to Hirschsprung disease
 - Spontaneous biliary perforation
 - Omphalitis
 - Perforation of a urachal cyst
 - Children and adolescents:
 - Secondary to appendicitis
 - Perforation of Meckel diverticulum
 - Gastric ulcer perforation
 - Pancreatitis
 - Traumatic perforation of the intestine
 - Intussusception
 - Neutropenic colitis (typhlitis)
 - Crohn disease with fistula and abscess formation
 - Toxic megacolon
 - Tuberculosis
 - Salpingitis

DIAGNOSIS

HISTORY

- Dependent on stage, age, and etiology
- Fever, chills, vomiting
- Generalized abdominal pain with rebound tenderness
- Decreased bowel sounds
- In SBP, ~10% of cases are entirely asymptomatic.
- Other less common findings include:
 - Hypothermia
 - Hypotension
 - Diarrhea
 - Increased ascites despite diuretics
 - Worsening encephalopathy
 - Unexplained decrease in renal function

PHYSICAL EXAM

- Swollen rigid and painful abdomen
- Decreased bowel sounds
- Evidence of chronic liver disease
- Evidence of ascites

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Leucocytosis, increased C-reactive protein (CRP), leucopenia, and thrombocytopenia are also possible.
- Diagnosis may be confirmed with paracentesis. To improve culture yield, culture bottles should be inoculated immediately at the bedside in large-volume blood culture bottles.
- Elevated PMN count in ascitic fluid is important in the early diagnosis of SBP and is considered the most important laboratory indicator of SBP:
 - Diagnostic criteria for SBP include PMN leukocyte counts of $>250/\text{mm}^3$ in ascitic fluid. Culture is usually positive for a single organism.
 - Diagnostic criteria for secondary bacterial peritonitis include ascitic fluid culture positive for polymicrobial infection, total protein >1 g/dL, glucose <50 mg/dL, and lactate dehydrogenase (LDH) level >225 mU/mL.
 - Ultrasound, abdominal radiography, and CT scan may reveal fluid, thickening of bowel wall, abscesses, or pneumoperitoneum.

TREATMENT

MEDICATION (DRUGS)

- Empiric antibiotic coverage should be directed primarily toward enteric gram-negative aerobes and gram-positive cocci:
 - After the organism is identified, the antibiotic coverage may be optimized.
 - No particular antibiotic regimen has been shown to be superior in controlled clinical trials. Both single agents and combination regimens have been used.
- In SBP, cefotaxime has been shown to have higher resolution of infection and lower hospital mortality than the traditional ampicillin and an aminoglycoside as empiric coverage.

ADDITIONAL TREATMENT

General Measures

- Support the patient's cardiovascular and respiratory systems.
- Control the underlying infection with antibiotics or surgery (in secondary bacterial peritonitis).
- Decompression with nasogastric tube
- Patients at significant risk for SBP will benefit from selective intestinal decontamination as an effective preventive measure:
 - Antibiotics that have been studied for this use in adults include norfloxacin, ciprofloxacin, trimethoprim-sulfamethoxazole, and rifaximin.

SURGERY/OTHER PROCEDURES

In secondary bacterial peritonitis, surgery is the primary management tool with control of the source of the intra-abdominal infection:

- Control of the underlying source of the abdominal infection by repairing the affected bowel through laparotomy/laparoscopy should be considered.
- The degree of contamination may be decreased through intraoperative peritoneal lavage and débridement of loculations and abscesses.
- Adding antibiotics to lavage fluid has lost favor after the discovery that this procedure appears to impair neutrophil chemotaxis, inhibit neutrophil bactericidal activity, and increase the formation of adhesions.
- Catheters may be placed to drain a well-defined abscess cavity, form a controlled fistula, or provide access for continuous postoperative peritoneal lavage.

ONGOING CARE

PROGNOSIS

- SBP is associated with a high mortality. In reports from the 1970s, the mortality exceeded 90%. Currently with intensive treatment the in-hospital mortality in adults is still between 10% and 30%.
 - The combination of underlying disease and the infection causes acute decompensation in a marginally compensated host.
- Retrospective studies have indicated that SBP is a recurrent problem, with 60% of patients who survive the 1st episode going on to develop 1 or more recurrences.
- Severe secondary peritonitis is associated with a mortality rate of 30–55% in adults.

COMPLICATIONS

- Hypovolemia results from extravasation of fluid from the inflamed peritoneal membrane. Intravascular volume must be supported with crystalloids and blood products.
- Respiration may be impaired via mechanical mechanisms through diaphragmatic spasm and reflex abdominal rigidity and through increased permeability of the pulmonary vasculature in response to systemic inflammation.
- Long-term complications include adhesions.

CODES

ICD9

- 567.9 Unspecified peritonitis
- 567.21 Peritonitis (acute) generalized
- 567.23 Spontaneous bacterial peritonitis

ICD10

- K65.0 Generalized (acute) peritonitis
- K65.2 Spontaneous bacterial peritonitis
- K65.9 Peritonitis, unspecified

FAQ

- Q: Is peritonitis common in children with ascites?
- A: Despite the frequency of ascites from many different causes, peritonitis occurs rarely. In the setting of children with chronic liver disease and ascites, SBP may occur.
- Q: What are the most useful laboratory aids for this diagnosis?
- A: Paracentesis and analysis of the fluid for pH, glucose content, and number of inflammatory cells provides the most useful information regarding the diagnosis of peritonitis.

PERITONSILLAR ABSCESS

Nicholas Tsarouhas

BASICS

DESCRIPTION

Infectious complication of tonsillitis or pharyngitis resulting in an accumulation of purulence in the tonsillar fossa. Also referred to as “quinsy”

EPIDEMIOLOGY

- Most common deep space infection of head and neck
- Seen most commonly in adolescents, but occasionally in younger children

RISK FACTORS

- Tonsillitis
- Pharyngitis

GENERAL PREVENTION

Abscess formation can often be prevented if appropriate antimicrobial therapy is initiated while the infection is still at the cellulitis stage.

PATHOPHYSIOLOGY

- Infectious tonsillopharyngitis progresses from cellulitis to abscess.
- The infection starts in the intratonsillar fossa, which is situated between the upper pole and the body of the tonsil, and eventually extends around the tonsil.
- The abscess is a suppuration outside the tonsillar capsule, in proximity to the upper pole of the tonsil, involving the soft palate.
- Purulence usually collects within 1 tonsillar fossa, but it may be bilateral.
- Tonsillar and peritonsillar edema may lead to compromise of the upper airway.

ETIOLOGY

- Most of these true abscesses are polymicrobial
- Group A β -hemolytic streptococci (GABHS)
- α -Hemolytic streptococci
- *Staphylococcus aureus*: Prevalence of methicillin-resistant *S. aureus* continues to increase.
- Anaerobic bacteria play an important role:
 - *Prevotella*
 - *Porphyromonas*
 - *Fusobacterium*
 - *Peptostreptococcus*
- Possible synergy between anaerobes and GABHS
- Gram negatives like *Haemophilus influenzae*, and, more rarely, *Pseudomonas* species, may be isolated.

COMMONLY ASSOCIATED CONDITIONS

- Tonsillitis or pharyngitis usually precedes its development.
- Peritonsillar cellulitis is often associated with infectious mononucleosis.

DIAGNOSIS

HISTORY

- Fever and sore throat:
 - Most common initial complaints
- Trouble swallowing, pain with opening the mouth (trismus), muffled (“hot potato”) voice:
 - Classic presenting symptoms
- Unilateral neck or ear pain:
 - Other common presenting symptoms

PHYSICAL EXAM

- Unilateral peritonsillar fullness, or bulging of the posterior, superior, soft palate:
 - Diagnostic finding
- Uvular deviation:
 - Classic finding, though it may be absent in the more rare bilateral peritonsillar abscess
- Palpable fluctuance of palatal swelling:
 - Calls for urgent aspiration
- Erythematous, edematous pharynx, with enlarged and exudative tonsils:
 - Coexisting tonsillopharyngitis is common.
- Cervical adenopathy:
 - Common
- Drooling:
 - Often present
- Torticollis:
 - Sometimes seen

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- WBC count:
 - Usually elevated with prominent left shift
- Rapid streptococcal throat antigen studies:
 - Helpful to diagnose GABHS infection
- Gram stain and culture of aspirate specimen:
 - Confirms causative microorganism

Imaging

- Radiographic studies are rarely necessary.
- CT scan or intraoral ultrasound:
 - Differentiation of peritonsillar cellulitis from peritonsillar abscess
 - CT scan most useful if patient cannot open mouth secondary to trismus
 - CT scan also important if deep neck extension is suspected

DIFFERENTIAL DIAGNOSIS

- Peritonsillar cellulitis:
 - Most common diagnostic consideration
 - Can be distinguished by its lack of peritonsillar space fullness, uvular deviation, dysphonia, and trismus
- Retropharyngeal abscess:
 - Minimal peritonsillar findings, along with a widened prevertebral space on lateral neck radiograph, are diagnostic of this airway-compromising disease, which usually occurs in preschool children.
- Epiglottitis:
 - This life-threatening airway emergency presents abruptly with fever, stridor, increased work of breathing, and drooling.
 - Usually occurs in toxic-appearing children 3–7 years old
 - Becoming a rare entity since the advent of the *Haemophilus influenzae* type B vaccine
- Other infectious causes of severe tonsillopharyngitis:
 - Epstein-Barr virus (infectious mononucleosis), coxsackievirus (herpangina), *Corynebacterium diphtheriae*, and *Neisseria gonorrhoeae*

TREATMENT

MEDICATION (DRUGS)

First Line

- Clindamycin or ampicillin/sulbactam are the most commonly used 1st-line antibiotics owing to their efficacy versus GABHS, *Staphylococcus*, and anaerobes.
- As methicillin-resistant *S. aureus* isolates continue to increase, clindamycin becoming more popular as drug of choice
- Some initiate therapy with high-dose IV penicillin—in the presence of a positive strep antigen or culture study.

Second Line

- Nafcillin, oxacillin, and cefazolin are acceptable antibiotic alternatives.
- Steroids:
 - Some experts recommend steroids to decrease swelling, pain, and trismus.
 - Methylprednisolone, dexamethasone, and prednisone are all acceptable.

ADDITIONAL TREATMENT

General Measures

Treating a true abscess without incision and drainage is inadequate and can have airway-threatening implications:

- Abscesses should be urgently/emergently drained via either needle aspiration or surgical incision and drainage.
- Antibiotic therapy
- Steroid therapy debatable
- Surgical drainage
- Appropriate analgesia and adequate hydration should be ensured.

ISSUES FOR REFERRAL

Peritonsillar abscess: Otorhinolaryngology consultation for acute and chronic management

SURGERY/OTHER PROCEDURES

Surgical drainage with tonsillectomy: Consider in children not responding to parenteral antibiotics within 24–48 hours.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients may be discharged on oral antibiotics to complete a 10–14-day course when afebrile and peritonsillar swelling has subsided.
- Tonsillectomy should be considered after severe or recurrent peritonsillar abscesses.

PROGNOSIS

- Complete recovery with appropriate therapy.
- Recurrence of the abscess may occur.

COMPLICATIONS

- Upper airway obstruction is the most feared complication.
- Abscesses left untreated can rupture spontaneously into the pharynx, leading to aspiration and pneumonia.
- Other serious complications include parapharyngeal abscess, jugular vein thrombophlebitis, sepsis, cavernous sinus thrombosis, brain abscess, meningitis, and dissection into the internal carotid artery.
- Dehydration from decreased oral intake is the most common complication, however.
- Even after appropriate drainage, a small number of peritonsillar abscesses may reform.

J36 Peritonsillar abscess

FAQ

- Q: Are radiographs necessary to make the diagnosis of peritonsillar abscess?
- A: No. The physical examination is diagnostic; a lateral neck radiograph is useful only if retropharyngeal abscess or epiglottitis is a diagnostic concern.
- Q: Is surgical consultation necessary in cases of peritonsillar abscess?
- A: Yes. Otorhinolaryngology consultation is indicated for both acute as well as chronic management.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN (PPHN)

Wendy J. Kowalski

BASICS

DESCRIPTION

Clinical syndrome of severe respiratory failure and hypoxia in a neonate characterized by high systemic pulmonary arterial pressures, tricuspid regurgitation, and intracardiac shunting from right to left through persistent fetal pathways, including a patent foramen ovale and ductus arteriosus

EPIDEMIOLOGY

- Incidence of ~6.8 per 1,000 term live newborns
- Mostly occurs in full-term newborns owing to the presence of the muscular layer of arterioles, the risk of uteroplacental insufficiency, and the potential for the passage of meconium in utero, but it can complicate the course of an older premature baby with chronic lung disease
- Meconium aspiration is the number one cause of PPHN.
- PPHN complicates the course of about 10% of newborns with respiratory failure.

RISK FACTORS

Genetics

- Sporadic in occurrence
- Alveolar capillary dysplasia has been documented in 1 set of siblings; however, it too is primarily sporadic.
- Surfactant B deficiency has also been implicated but it is a rare, lethal, autosomal recessive disorder.

PATHOPHYSIOLOGY

- At a neonate's 1st breath after delivery, the pulmonary vascular resistance normally decreases to redirect ~50% of the cardiac output to the pulmonary circulation. This fails to occur in PPHN, hence the previous name of this condition, "persistent fetal circulation."
- Increased pulmonary vascular resistance increases right ventricular afterload, causing a backflow of blood to the right heart (and subsequent tricuspid regurgitation) and increased right heart pressures, which can lead to right ventricular failure.
- Increased pulmonary arterial pressures also cause intracardiac shunting across any patent foramen ovale, ductus arteriosus, or atrioseptal or ventriculoseptal defect that may be present. Blood shunts from right to left because of the supranormal systemic pulmonary arterial pressures. This causes more deoxygenated blood to go to the left heart and then to the body, which manifests as lower oxygen saturation in the lower extremities (postductally), cyanosis, and hypoxia.
- Deoxygenated blood in the left heart can lead to ischemic damage to the heart and right or left ventricular failure.
- If there is no shunting of blood, or the blood cannot get from the right to left heart because of a lack of persistent fetal pathways, a neonate may develop poor systemic perfusion, severe acidosis, shock, right ventricular failure, and even death.
- Any hypoxia, acidosis, or stress that occurs after birth further increases pulmonary vascular resistance.
- Usually, the pulmonary vasculature begins to relax within 3–5 days of life, and the process reverses. Sometimes, the pulmonary vascular resistance remains elevated as a result of an underlying disease process or anatomic abnormality.

ETIOLOGY

- Idiopathic: The pulmonary vasculature is remodeled due to chronic in utero stress or hypoxia, maternal use of NSAIDs near term, or maternal use of SSRIs in the 2nd trimester.
- Abnormally constricted pulmonary vasculature secondary to underlying disease: Infection, pneumonia, or meconium aspiration
- Secondary to an anatomic abnormality that has caused hypoplastic vasculature: Congenital diaphragmatic hernia, oligohydramnios and pulmonary hypoplasia, or alveolar capillary dysplasia

COMMONLY ASSOCIATED CONDITIONS

Related to the underlying disease or as a complication of treatment:

- Pneumothorax or air leak syndrome
- Chronic lung damage
- Long-term developmental delays
- Cerebral palsy
- Seizure disorder
- Sensorineural hearing loss

DIAGNOSIS

HISTORY

- Pregnancy history:
 - Congenital diaphragmatic hernia, congenital pulmonary airway malformation (CPAM), and congenital heart disease can all be diagnosed with a prenatal ultrasound.
 - History of oligohydramnios, which may be associated with pulmonary hypoplasia in the neonate
- Problems during labor and delivery:
 - Events that can cause fetal distress and/or hypoxia: Maternal chorioamnionitis, group B streptococcal infection, difficult delivery, or meconium aspiration
- Initial clinical course:
 - Infants with PPHN usually present with mild respiratory distress that worsens in the 1st minutes to hours of life, progressing to respiratory failure, labile oxygenation, hypoxia, and poor perfusion.
- Infants with cardiac disease, CPAM, or congenital diaphragmatic hernia are usually cyanotic and in significant distress from birth.

PHYSICAL EXAM

- The following physical exam findings suggest a diagnosis of PPHN:
 - Significant respiratory distress with nasal flaring, grunting, and retractions
 - Clear breath sounds (if idiopathic disease)
 - Pale, gray color with poor perfusion
 - Tricuspid regurgitation murmur heard at the left lower sternal border
- The following physical exam findings suggest diagnoses other than idiopathic PPHN:
 - Any murmur other than tricuspid regurgitation would suggest congenital heart disease.
 - Barrel chest shape suggests a pneumothorax or meconium aspiration.
 - Scaphoid abdomen suggests congenital diaphragmatic hernia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential: Leukocytosis, leukopenia, bandemia, or neutropenia suggests bacterial infection.
- Blood culture: Should be performed in all cases of PPHN to rule out infection
- Frequent arterial blood gases:
 - Help to determine degree of hypoxia, hypercapnia, acidosis, and illness
 - Help manage ventilator support
 - Determine need for ECMO by calculating the oxygenation index (OI)
- OI:
 - $OI = (\text{mean airway pressure} \times \text{FiO}_2 / \text{PaO}_2) \times 100$
 - Used to express severity of respiratory distress and to determine if neonate is a candidate for ECMO
 - Should be calculated with every blood gas. 3 OIs > 40 suggest the need for ECMO.
- Hyperoxia test: While exposed to FiO₂ of 100% oxygen, a PaO₂ > 250 mm Hg almost completely rules out cyanotic heart disease.

Imaging

- Chest radiograph:
 - In idiopathic disease, usually shows clear lungs
 - Will help to rule out pneumothorax, hyperinflation, meconium aspiration, and atelectasis
 - Assessing cardiac silhouette and pulmonary vascular markings may help rule out some congenital heart disease.
- Echocardiogram, important:
 - To diagnose PPHN and to rule out congenital heart disease
 - To follow cardiac output and function

DIFFERENTIAL DIAGNOSIS

- Congenital:
 - Cyanotic congenital heart disease
 - Total anomalous pulmonary venous return
 - Congenital diaphragmatic hernia
 - CPAM
 - Alveolar capillary dysplasia
- Infectious:
 - Pneumonia
 - Sepsis
- Pulmonary:
 - Surfactant deficiency (respiratory distress syndrome)
 - Meconium aspiration syndrome
 - Blood or amniotic fluid aspiration
 - Pneumothorax or air leak syndrome
 - Idiopathic pulmonary hypertension

TREATMENT

ADDITIONAL TREATMENT

General Measures

- All infants should be transferred to a Level III neonatal intensive care unit where high-frequency ventilation and inhaled nitrous oxide are available. If the neonate meets or nearly meets criteria for starting ECMO (OI >40 on 3 different blood gases), then ECMO should be available at the receiving institution.
- Support respiratory status:
 - Conventional ventilation or high-frequency ventilation to improve oxygenation and ventilation while minimizing lung damage
 - No set guidelines for ventilator management
 - Most institutions feel that high-frequency ventilation minimizes lung damage when high mean airway pressures (> 15 cm H₂O) are needed.
 - Frequent monitoring to keep PaO₂ between 80 and 100 mm Hg, PCO₂ >35–45 mmHg, and OI below ECMO criteria (oxygen index >40 times 3)
 - Avoid hyperventilation, which has been associated with poor neurodevelopmental outcome.
- Lower the pulmonary vascular resistance and thus promote pulmonary blood flow:
 - Give 100% oxygen.
 - Keep blood gas pH alkalotic (pH >7.40) while keeping PaCO₂ >35–45 mm Hg by ventilator manipulation or bicarbonate infusion.
 - Keep systemic BP high (mean BP >45–50) with volume, transfusions, or medications.
 - Treat acidosis with fluid, blood, or bicarbonate infusion.
- Improve oxygen saturation and thus oxygen delivery to the tissues:
 - Initially 100% oxygen should be used to keep the PaO₂ >80–100 mmHg and the oxygen saturation around 99–100%. The oxygen can be weaned very slowly (2% per hour if saturation remains >98%).
 - Inhaled nitric oxide (iNO), a pulmonary vasodilator, should be used if the infant is on 100% (FiO₂) oxygen and the PaO₂ goal is not achieved. It is better to start iNO sooner rather than later:
 - Has been shown to decrease the need for ECMO in term neonates with hypoxic respiratory failure secondary to PPHN, except for those babies with congenital diaphragmatic hernia
 - Should be used only as a bridge to ECMO in babies with congenital diaphragmatic hernia
 - Wean slowly! If oxygen and iNO are weaned too quickly, the infant can become critically ill because PPHN is a very labile condition.
- Reduce oxygen demand:
 - Sedatives and paralytics may be given to prevent fluctuations in oxygenation during care. Minimize the use of paralytics because they have been shown to increase mortality.
 - Minimize stimulation.

- Treat any underlying lung disease with the following, if applicable:
 - Antibiotics
 - Surfactant
 - Chest tube placement
 - Surgery

ALERT

- Can be difficult to differentiate cyanotic congenital heart disease from PPHN. Infants who fail to improve should be re-evaluated for an underlying disease process.
- PPHN is a very labile condition. Neonates can change from being stable to being very sick and emergently needing ECMO.
- ECMO, though life saving and with a good survival rate, is not without problems. Side effects include:
 - Repeated exposure to blood products
 - Risk of intra-abdominal or intracardiac bleed
 - Potential for long-term neurologic sequelae
 - Long-term risk of having only 1 patent carotid artery

ONGOING CARE

PROGNOSIS

- PPHN usually resolves either spontaneously or as the underlying parenchymal lung disease improves.
- Survival rate is good even for neonates who receive ECMO. Survival rate and incidence of long-term sequelae depend on underlying disease and severity of illness.
- Survival rate for all causes of PPHN in patients not requiring ECMO is >90%. ~10–20% have sensorineural hearing loss or an abnormal neurologic exam at follow-up.
- For those requiring ECMO, survival rate is 80% for idiopathic disease, 90% for meconium aspiration syndrome, 80% for disease secondary to sepsis, and only 50–60% for patients with congenital diaphragmatic hernia. Roughly 20% of these survivors have sensorineural hearing loss or abnormal neurologic examinations at follow-up.
- Even with advances in technology and the availability of ECMO, the prognosis is poor for those babies with severe underlying lung pathology, such as congenital diaphragmatic hernia.

COMPLICATIONS

- Myocardial dysfunction
- Congestive heart failure (CHF)
- Hypoxic ischemic insult

FAQ

- Q: Does iNO improve outcome in newborns with severe PPHN?
- A: Yes. iNO, used at a dose of 20 ppm, has been shown to decrease the need for ECMO and the incidence of death in term infants with PPHN without congenital diaphragmatic hernia. Follow-up studies have shown no difference in long-term disabilities between those babies treated and not treated with iNO. Long-term outcome is mainly determined by the underlying disease and the severity of illness.
- Q: Are there any other potential therapies for treating PPHN?
- A: Yes. Inhaled tolazoline, sildenafil (Viagra), other smooth muscle relaxants (dipyridamole, zaprinast, and E4021), iloprost, bosentan, and phosphodiesterase inhibitors have been studied and have been shown to be effective in enhancing the vasodilatory effects of iNO. Sildenafil is being used in select cases, particularly in older neonates, in centers without iNO or ECMO, or as an adjuvant to iNO, and it has shown the most promise for routine clinical use.

PERTHES DISEASE

Ali Al-Omari

Wudbhav Sankar

John P. Dormans (5th edition)

BASICS

DESCRIPTION

Self-limited osteonecrosis of the proximal femoral epiphysis of unknown etiology that can produce permanent deformity of the femoral head

EPIDEMIOLOGY

- Seen most commonly between ages 4–12 years
- Boys affected more than girls (5:1)
- 10–15% bilateral
- Most have delayed bone age

PATHOPHYSIOLOGY

- Disruption of blood supply to the femoral head
- Stages:
 - Synovitis
 - Necrosis: Sclerosis and density of the femoral head
 - Fragmentation: Fragmentation of necrotic bone with early revascularization
 - Reossification: Revascularization, resorption, and repair via creeping substitution
 - Healing: Remodeling

ETIOLOGY

- Unknown
- Factors that may contribute:
 - Trauma
 - Susceptible child (delayed bone age, low birth weight)
 - Hereditary factors
 - Coagulopathy
 - Hyperactivity
 - Smoke exposure

DIAGNOSIS

HISTORY

- Age at onset of symptoms/signs:
 - Older age at onset implies worse prognosis.
- Limping:
 - The most frequent complaint; especially after strenuous activities
 - Weeks to months duration
- Hip, thigh, or knee pain:
 - Hip pathology may cause referred pain at thigh or knee.
- There may be waxing and waning of symptoms for several months.
- There may be a history of trauma.
- Distribution of pain may follow the sensory distribution of the obturator nerve:
 - Medial thigh and knee (i.e., referred pain from hip pathology)

PHYSICAL EXAM

- Limping
- Trendelenburg gait:
 - Leaning over affected leg during stance phase of gait cycle
- Positive Trendelenburg test: As patient stands with weight on the affected hip, the pelvis on the opposite normal side drops owing to weakness of the hip abductor muscles.
- Limitation of range of motion:
 - Especially internal rotation and abduction
- Irritability and tenderness of hip joint area:
 - Usually early; related to synovitis from early repair
- Atrophy of thigh muscles:
 - Late finding
- Slight shortening of affected limb owing to collapse (real) or contracture (apparent)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Generally, labs are not helpful, but may be necessary to rule out other conditions, such as infection and juvenile rheumatoid arthritis (JRA).

Imaging

- The 1st plain radiographic sign of Perthes is smaller size of the femoral head epiphysis and a widened articular cartilage space compared with the other side; the 2nd sign is the subchondral fracture:
 - Incipient (or initial) stage (1st)
 - Aseptic or avascular stage (2nd)
 - Fragmentation stage (3rd)
 - Residual or remodeling stage (4th)
- Bone scan maybe helpful in the early stage of the disease when the diagnosis is questionable.

DIFFERENTIAL DIAGNOSIS

- Toxic synovitis
- Chondrolysis (idiopathic and secondary)
- Infection (Brodie abscess: Subacute osteomyelitis of proximal femoral epiphysis)
- Tuberculosis of the hip
- Juvenile rheumatoid arthritis
- Tumors (chondroblastoma of proximal femoral epiphysis)
- Bone dysplasias:
 - Multiple epiphyseal dysplasia
 - Trichorhinophalangeal syndrome
 - Spondyloepiphyseal dysplasia
- Hypothyroidism, juvenile cretinism
- Sickle cell disease, hemophilia
- Gaucher disease
- Hemophilia
- Traumatic aseptic necrosis

TREATMENT

MEDICATION (DRUGS)

NSAIDs for pain and inflammation

ADDITIONAL TREATMENT

General Measures

- Surgical treatment needed generally for those with more severe involvement (1/2 of head involved or late onset)
- 2 basic treatment principles:
 - Maintenance and/or restoration of range of motion
 - Containment of the femoral head epiphysis in the acetabulum
- General treatment modalities:
 - Bed rest early during collapse
 - Weight relief early during collapse (usually crutches)
 - Physical therapy to maintain range of motion
 - Traction (less popular now)
 - Bracing
 - Surgery to reposition acetabular or proximal femur

ISSUES FOR REFERRAL

Patients with Perthes disease preferably should be seen and followed by a pediatric orthopedic surgeon.

SURGERY/OTHER PROCEDURES

Younger patients with Perthes do not generally need surgery. Older patients with more significant collapse can benefit from surgical intervention. Early recognition and referral are key.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Therapy generally continues until patient enters the reossification phase.
- The magnitude and duration of symptoms depend on the age of the patient at onset of the disease and the degree of involvement of the disease process. Most patients show improvement in symptoms by 6 months after the onset of disease.

Patient Monitoring

Signs to watch for:

- Stiffness: Loss of range of motion
- Limping
- Pain
- Subluxation of the hip joint

PROGNOSIS

- Overall, good prognosis for most patients
- Based on the following factors:
 - Age of the patient at onset of the disease (earlier onset gives better prognosis); if onset > 8 years of age, poorer prognosis than if onset at younger age
 - Extent of femoral head involvement; if more than 1/2 of epiphysis involved, poorer prognosis
 - Subluxation of femoral head, poorer prognosis
 - Spherical congruency between the femoral head and acetabulum has good prognosis, and vice versa.
 - Growth disturbance of the physis, poorer prognosis

COMPLICATIONS

- Mild limb length discrepancy
- Restriction of hip range of motion
- Pain, limping
- Osteoarthritis (late)

CODES

ICD9

732.1 Juvenile osteochondrosis of hip and pelvis

ICD10

- M91.10 Juvenile osteochondrosis of head of femur [Legg-Calve-Perthes], unspecified leg
- M91.11 Juvenile osteochondrosis of head of femur [Legg-Calve-Perthes], right leg
- M91.12 Juvenile osteochondrosis of head of femur [Legg-Calve-Perthes], left leg

FAQ

- Q: How long do you observe a patient with hip pain before ordering a radiograph?
- A: It depends on the presence or absence of abnormalities on the physical exam. If any of the signs mentioned are seen in conjunction with significant hip pain, a radiograph is indicated. A radiograph should be done early to establish the diagnosis and rule out other abnormalities.
- Q: Why do patients with hip pathology have knee pain?
- A: This is because the nerves that innervate the hip joint also have cutaneous sensory distributions. Both the obturator and femoral nerves innervate the hip joint, and both have cutaneous sensory distribution in the region of the thigh and knee joint.

PERTUSSIS

Laura K. Brennan
Louis M. Bell (5th edition)

BASICS

DESCRIPTION

Pertussis is a classic “whooping cough” syndrome of prolonged paroxysmal coughing spells with a characteristic inspiratory whoop, caused by *Bordetella pertussis* infection.

EPIDEMIOLOGY

- Pertussis is one of the most highly communicable diseases with attack rates close to 80–90% in susceptible individuals.
- Humans are the only hosts of *B. pertussis*.
- Route of spread is primarily via large aerosolized respiratory droplets generated by coughing or sneezing.
- Pertussis occurs with seasonal peaks and 3–5-year cycles of increased incidence of disease.

Incidence

- Despite improved childhood vaccination rates in the US, pertussis infection rates have steadily risen since the early 1980s.
 - This may be in part because immunity to pertussis wanes ~5–10 years after completion of childhood vaccination, leading to a large susceptible adult population, who then are the major source of pertussis infection in children.
 - There also has been an increase in the detection and reporting of cases.
- Pertussis has been a disease of young children, with the highest incidence in infants <6 months of age, but rates in adolescents have been steadily increasing and now approach rates in infants.
- Disease in adolescents and adults often goes unrecognized:
 - In a recent Canadian study, the prevalence of pertussis in 422 adolescents and adults with prolonged cough illness was 20%.

GENERAL PREVENTION

- Infection control:
 - Isolation of hospitalized patient: Respiratory (droplet precautions) isolation for 5 days after starting appropriate antimicrobial therapy or until at least 3 weeks after the onset of the paroxysmal stage, if antibiotics were not given, is recommended.
 - Care of exposed people: Exposed individuals (all household contacts, other close contacts, other children in child care) should receive chemoprophylaxis to limit secondary transmission, regardless of immunization status. Immunization should be given to all unimmunized and underimmunized children <7 years of age, and to adolescents and adults who have not yet received the Tdap booster vaccination.

- Immunizations:
 - All pertussis vaccines available in the US are acellular vaccines in combination with diphtheria and tetanus toxoids, as this is the preferred vaccination product over previous whole-cell pertussis products.
 - Universal immunization of all children <7 years of age with DTaP vaccine is recommended as per CDC and AAP guidelines.
 - It is now also recommended that under-vaccinated children ages 7–10, all adolescents ages 11–18, adults ages 19–64, as well as certain adults ages 65 and older should receive a single dose of Tdap vaccine as this is paramount to control the rate of infection in infants and young children.

PATHOPHYSIOLOGY

- Replicates only in association with ciliated epithelium, causing congestion and inflammation of the bronchi; peribronchial lymphoid hyperplasia followed by a necrotizing process occurs and results in a bronchopneumonia; atelectasis can also occur owing to bronchiolar obstruction from accumulated secretions.
- The long incubation period (7–21 days) reflects the time necessary for *B. pertussis* to increase in numbers needed for progressive spread of infection in the respiratory tract and to produce enough toxin for eliciting damage and dysfunction of the respiratory epithelium.

ETIOLOGY

Infection with *B. pertussis*, a small, nonmotile, fastidious, gram-negative rod.

DIAGNOSIS

HISTORY

- The most likely source of pertussis in young infants is from the adolescent or adult with mild symptoms of pertussis. Therefore, a thorough history, including presence of cough in adult family members, must be taken and a high index of suspicion for pertussis must be maintained when evaluating infants and children for cough.
- 3 clinical stages:
 - Catarrhal stage (1–2 weeks) with symptoms of an upper respiratory infection
 - Paroxysmal stage (≥ 2 –4 weeks) characterized by paroxysmal cough with increased severity and frequency producing the characteristic whoop during the sudden forceful inspiratory phase; posttussive vomiting is also observed during this stage.
 - The convalescent stage begins and lasts 1–2 weeks, but cough can persist for several months. In the adolescent or adult, long-standing cough of 2–3 weeks is the hallmark symptom. Most patients report a paroxysmal or staccato quality to the cough.
- Apnea is a common manifestation in infants <6 months. The characteristic whoop is typically absent.

PHYSICAL EXAM

- Rhinorrhea, lacrimation, conjunctival hyperemia, and fever can be seen in the early stage of disease.
- Cyanosis can be observed during the paroxysmal stage.
- Lung auscultatory examination is usually normal unless significant atelectasis or pneumonia has occurred.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC:
 - Leukocytosis with predominant lymphocytosis (77%) is commonly observed at the end of the catarrhal stage and throughout the paroxysmal stage of illness, although this phenomenon is more common in infants and children than adolescents.
- Culture of *B. pertussis*:
 - Achieved using calcium alginate or Dacron swabs of the nasopharynx and plated onto selective media such as Regan–Lowe or Bordet–Gengou and incubated for 10 days
 - Most frequently successful during the catarrhal or early paroxysmal stages and is rarely found beyond the third week of illness.
 - Specificity 100%; overall sensitivity is 60–70% but can be lower in previously vaccinated individuals, if antibiotics have already been given, or if beyond the third week of illness.
- Polymerase chain reaction (PCR):
 - Available in most centers and have been shown to have a higher sensitivity than culture in the detection of *B. pertussis* from nasopharyngeal specimens, although specificity can vary
 - PCR techniques vary by institution; there is no FDA-licensed PCR test available, and there are no standardized protocols or reagents.
- Direct immunofluorescent assays (DFA) of nasopharyngeal specimens:
 - Can provide a rapid and specific diagnosis, but is generally less sensitive than culture and is limited by the experience of the laboratory personnel for interpretation
- Serology:
 - Has excellent sensitivity and specificity when the acute serum is collected early in the course of illness (≤ 2 weeks after cough onset) and compared with the convalescent serum specimen (collected ≥ 4 weeks after cough onset)

Imaging

Chest radiograph: May reveal perihilar infiltrates or a shaggy right-sided heart border, although these findings are neither sensitive nor specific.

DIFFERENTIAL DIAGNOSIS

- *Bordetella parapertussis* and adenoviruses
- Bronchiolitis
- Bacterial pneumonia
- Cystic fibrosis
- Tuberculosis
- Foreign-body aspiration
- Reactive airway disease

**TREATMENT****MEDICATION (DRUGS)****First Line**

Azithromycin (10 mg/kg as a single dose on day 1, then 5 mg/kg/d as a single dose on days 2–5) is recommended for ages ≥ 6 months.

- For infants < 6 months of age, dosage is 10 mg/kg/d as a single dose for 5 days.
- For adolescents and adults, dosage is 500 mg as a single dose on day 1, followed by 250 mg as a single dose on days 2–5.

Second Line

- Erythromycin (50 mg/kg/d) in 4 doses for 14 days is recommended:
 - Alternative dose: 40 mg/kg erythromycin estolate b.i.d. for 14 days has shown equal efficacy.
 - *Note:* An association between oral erythromycin use and hypertrophic pyloric stenosis has been reported in infants < 4 weeks, such that azithromycin is the drug of choice for treatment or prophylaxis of pertussis in that age group.
- Clarithromycin (15 mg/kg/d divided b.i.d. for 7 days) has similar effectiveness to erythromycin, and can be used in children ≥ 1 month of age.
- Trimethoprim/Sulfamethoxazole is another alternative to erythromycin in children ≥ 2 months of age, although its efficacy is unproven.

ADDITIONAL TREATMENT**General Measures**

- Patients with more severe disease manifestations (apnea, cyanosis, feeding difficulties) or other complications require hospitalization for supportive care:
 - Infants < 6 months may develop apnea from fatigue secondary to excessive coughing. They need close observation, preferably in the hospital.
- If antibiotic treatment is initiated during the catarrhal stage, it can prevent disease from progressing. Antibiotics have not been shown to shorten the course of illness if begun during the paroxysmal stage, although they will eliminate the organism from the nasopharynx within 3–4 days, thus shortening the potential for contagion.

IN-PATIENT CONSIDERATIONS**Admission Criteria**

- Young infant (< 6 months of age) with concern for apnea or fatigue with coughing
- Patients with severe disease manifestations or complications

Discharge Criteria

- No evidence of cardiorespiratory instability
- Able to self-recover from coughing spells

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

The paroxysmal stage can last up to 4 weeks, and the convalescent stage up to several months.

PROGNOSIS

Directly related to patient age:

- Highest mortality is observed in infants < 6 months of age, with a 0.5–1% risk of death.
- In the older child, prognosis is good.

COMPLICATIONS

- The complications of pertussis are more likely to occur in infants < 6 months of age and therefore tend to have a more serious, protracted course:
 - Pneumonia, which occurs in 22% of these infants, is responsible for $> 90\%$ of deaths in young children with pertussis and is usually from secondary bacterial disease rather than *B. pertussis*.
 - Superinfections owing to viruses (adenovirus, respiratory syncytial virus, cytomegalovirus), bacteria (*Streptococcus pneumoniae*, *Staphylococcus aureus*), and gram-negative iatrogenic infections can complicate pneumonias.
 - Other pulmonary complications include atelectasis, pneumothorax, pneumomediastinum, and subcutaneous emphysema.
 - Seizures (2%) and encephalopathy (0.5%) have also been observed in infants with pertussis.
- Complications of pertussis in adolescents and adults include cough syncope, incontinence, rib fractures, and pneumonia.

**CODES****ICD9**

- 033.0 Whooping cough due to *Bordetella pertussis*
- 033.9 Whooping cough, unspecified organism
- 484.3 Pneumonia in whooping cough

ICD10

- A37.00 Whooping cough due to *Bordetella pertussis* without pneumonia
- A37.01 Whooping cough due to *Bordetella pertussis* with pneumonia
- A37.90 Whooping cough, unspecified species without pneumonia

FAQ

- Q: Why is the transmission of pertussis difficult to control in the young infant?
- A: Unfortunately, many physicians do not consider pertussis in adolescents or adults because the symptoms can be nonspecific and often are not severe. They also assume that childhood immunization will protect adults against pertussis. Therefore, delays in antimicrobial treatment are common in adults owing to the lack of index of suspicion of pertussis by their providers. Finally, there was not a universal recommendation for adolescents and adults to receive pertussis boosters until 2005, even though the immunity protection by pertussis vaccination is limited. It is largely adolescents and adults with pertussis who then spread the disease to young infants and children.
- Q: When should adults get the Tdap vaccine?
- A: All adults ages 19–64 should receive a single dose of Tdap vaccine regardless of the interval since the last diphtheria or tetanus containing vaccine. Additionally, adults ages 65 years and older, especially those who have or anticipate having close contact with an infant aged < 12 months, may receive a single dose of Tdap.

PHARYNGITIS

Mark L. Bagarazzi

BASICS

DESCRIPTION

Pharyngitis (i.e., sore throat) is inflammation of the mucous membranes and underlying structures of the pharynx and tonsils, usually secondary to viral or bacterial infection.

GENERAL PREVENTION

- Long-term penicillin prophylaxis for patients with a history of rheumatic fever. Droplet precautions for hospitalized children with streptococcal pharyngitis until 24 hours after initiation of therapy
- Isolation of hospitalized patient with respiratory viruses and pharyngitis
- Control measures:
 - Children with group A streptococcal (GAS) pharyngitis can return to school or day care 24 hours after starting antimicrobial therapy.
 - Cultures of asymptomatic contacts of patients with streptococcal pharyngitis are not indicated except in outbreak situations in school or day care (where treatment of patients with positive rapid streptococcal antigen detection test [RADT] or culture is indicated) or in contacts with a history of nonsuppurative complications.

EPIDEMIOLOGY

- Streptococcal pharyngitis:
 - Most common in children 5–15 years of age, causing 15–20% of pharyngitis cases in this age group
 - Peak incidence in winter, early spring
- Viral disease is more common in younger children during winter months.

ETIOLOGY

- Viral:
 - Adenovirus types 1 through 7, 7a, 9, 14, 15, and 16
 - Epstein–Barr virus (EBV)
 - Influenza A, B: Usually associated with more severe systemic complaints
 - Parainfluenza 1, 2, and 3.
 - Enteroviruses: Coxsackievirus A and B and echoviruses
 - Measles and rubella and coronavirus, cytomegalovirus
 - Herpes simplex virus (HSV)
 - Rhinovirus and respiratory syncytial virus (RSV): not usually associated with pharyngeal inflammation
 - Human immunodeficiency virus (HIV)
- Bacterial:
 - *Streptococcus pyogenes* (group A β -hemolytic streptococcus)
 - Group C or G streptococci
 - *Fusobacterium necrophorum* (Lemierre syndrome)
 - *Corynebacterium diphtheriae* (diphtheria)
 - *Corynebacterium hemolyticum*
 - *Neisseria gonorrhoeae* and *Neisseria meningitidis*
 - *Mycoplasma pneumoniae*
 - *Mycoplasma hominis*
 - *Chlamydia pneumoniae*, *Chlamydia psittaci*
 - *Yersinia enterocolitica*
 - *Treponema pallidum* (syphilis)
 - Oral anaerobes (Vincent angina)
- Fungi: *Candida* species (oral thrush)

DIAGNOSIS

ALERT

- Caution: Diagnostic pitfalls:
 - Swabbing the throat from anywhere other than the tonsils and posterior pharyngeal wall
 - Use of clinical grounds alone, even experienced clinicians may overestimate the diagnosis of GAS pharyngitis by up to 80%.
 - About 20% of children with GAS pharyngitis who have mild symptoms may go unrecognized if cultures are not performed.
 - Failure to request identification of other organisms in the appropriate clinical setting. (e.g., *N. gonorrhoeae* or *A. hemolyticum*, *F. necrophorum*)
 - Reliance on monospot test in young children (<5 years) because of a high incidence of false-negatives (Consider EBV serology instead.)
 - Positive throat culture or RADT in patients with viral pharyngitis may represent streptococcal carrier state. Diagnostic tests for GAS should be used in patients suspected of having streptococcal disease on clinical and epidemiologic grounds, not on all patients who complain of a sore throat. In a meta-analysis, 9–14% of well children were found to be GAS carriers.

SIGNS AND SYMPTOMS

- Sore throat
- Fever
- Headache
- Nausea, vomiting, abdominal pain
- Rhinorrhea
- Cough
- Hoarseness
- Conjunctivitis
- Ulcerative pharyngeal lesions

HISTORY

- Sudden onset of fever, sore throat, with headache, nausea, and vomiting is frequent in streptococcal pharyngitis, which is usually exudative but cough or rhinorrhea is present in about 10% of cases
- Pharyngitis associated with rhinorrhea, cough, hoarseness, conjunctivitis, diarrhea, non-scarlatiniform exanthems, and ulcerative pharyngeal lesions: More likely to have a viral cause but GAS pharyngitis cannot be ruled out on this basis.
- Significant systemic complaints such as fever and malaise: Characteristic of EBV or HIV (acute retroviral syndrome)
- Appearance of papular eruption after administration of ampicillin or amoxicillin: Consider EBV.

PHYSICAL EXAM

- Tonsillar enlargement and moderate to severe pharyngeal erythema, which may be associated with petechiae, exudate, or ulceration.
- Follicular, exudative pharyngotonsillitis that may occur in association with conjunctivitis: Common with adenovirus infections (e.g., pharyngoconjunctival fever)

- Ulcerative lesions or characteristic enanthem consisting of 2–14 ulcers and vesicles (1–2 mm) in the posterior pharynx: Common with enteroviral infections (e.g., Coxsackievirus A, B, echovirus)
- Ulcerative lesions on anterior oropharynx (gingivostomatitis): Characteristic of HSV infection, which can also cause an exudative pharyngitis in adolescents that may be difficult to differentiate from streptococcal or EBV pharyngitis
- Scarletiform rash: Strongly suggests diagnosis of GAS, but also reported with *A. hemolyticum*.
- Varying degrees of cervical adenopathy: Tender anterior lymphadenopathy more likely associated with streptococcal disease
- Splenomegaly and/or generalized adenopathy: Suggests EBV
- Presence of >6 palatal petechiae: Strongly associated with streptococcal pharyngitis

DIAGNOSTIC TESTS & INTERPRETATION

Because of the importance of its complications, streptococcal disease should be confirmed or excluded by laboratory testing, except in presentations suggestive of viral or other etiology of pharyngitis (e.g., a toddler with conjunctivitis and rhinorrhea, presence of gingivostomatitis, findings consistent with infectious mononucleosis, and so forth).

Lab

- RADT:
 - As effective as initial tests with >95% specificity and 50–80% sensitivity.
 - Cultures should be performed when rapid test is negative.
 - *Hint*: Culture throat using two swabs initially, keeping one for culture if the rapid test is negative.
 - Positive rapid tests do not require culture confirmation.
 - The best technique is to swab both tonsillar pillars and the retropharynx.
- Throat culture: Gold standard with best sensitivity (>90%) for group A β -hemolytic streptococci
- Monospot (heterophile antibody) test or EBV serology:
 - For infectious mononucleosis: Rate of heterophile antibody response appears to increase from infancy up to 4 years, after which the rate of response approaches values similar to that reported in young adult patients.
- Complete blood count (CBC) with differential:
 - May be helpful in diagnosing EBV if atypical lymphocytes are present

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Herpangina (enterovirus)
 - Hand-foot-and-mouth disease (enterovirus–coxsackievirus)
 - Peritonsillar abscess or cellulitis
 - Retropharyngeal abscess or cellulitis
 - Lemierre syndrome
 - Laryngitis
 - Epiglottitis
 - Kawasaki disease
 - Tularemia
- Ingestions:
 - Caustic or irritant ingestions
 - Inhaled irritant

- Tumors:
 - Leukemia
 - Lymphoma
 - Rhabdomyosarcoma
- Trauma:
 - Vocal abuse from shouting
- Inflammatory:
 - Allergy
- Miscellaneous:
 - PFAPA syndrome (periodic fever, aphthous ulcers, pharyngitis, and cervical adenitis)
 - Psychogenic pain (globus hystericus)
 - Vitamin deficiency (A, B complex, C)
 - Dehydration

TREATMENT

MEDICATION (DRUGS)

First Line

- Oral penicillin V is the drug of choice for GAS pharyngitis except in penicillin-allergic individuals. Resistant strains have not been documented in vitro.
 - Children: 400,000 units (250 mg) b.i.d. or t.i.d. for 10 days
 - Adolescents/adults: 800,000 units (500 mg) b.i.d. for 10 days or 400,000 units (250 mg) t.i.d. or q.i.d. for 10 days
- Intramuscular (IM) benzathine penicillin G: Ensures compliance, useful in outbreaks
 - Children (<60 lb [27.2 kg]): 600,000 units IM (single dose)
 - Children (>60 lb [27.2 kg]) and adults: 1,200,000 units IM (single dose)
 - Procaine penicillin combinations are less painful.
 - Treatment failures with penicillin have risen steadily leading some experts to recommend other agents as first-line (e.g., cephalosporins). Failures occur even with benzathine penicillin (up to 37%) therefore compliance is not the cause. Potential causes include presence of β -lactamase-producing normal oropharyngeal flora that may be protecting GAS by inactivating penicillin.

Second Line

- Amoxicillin, clindamycin, and first-generation oral cephalosporins ($\leq 10\%$ of penicillin-allergic persons are also allergic to cephalosporins) are reasonable alternatives to penicillin in GAS pharyngitis:
 - Amoxicillin suspension is reported to be more palatable than penicillin VK.
 - Amoxicillin may be given in once daily 50 mg/kg (max 1 g) dose
- Clarithromycin and azithromycin have also been shown to eradicate streptococci; however, because of the broad spectra of these antibiotics and the increasing incidence of antibiotic-resistant bacteria, penicillin is still recommended by most experts except in cases of penicillin hypersensitivity, when patient nonadherence to a 10-day penicillin regimen is suspected, or for patients who fail therapy with a β -lactam:
 - Azithromycin, total dose of 60 mg/kg, given either as 12 mg/kg once daily for 5 days or 20 mg/kg once daily for 3 days
 - Clarithromycin, 15 mg/kg/d, given q12h for 10 days or 500 mg extended-release tablets given once a day for 5 days (studied in adolescents ≥ 12)
 - Oral erythromycin is indicated in penicillin-allergic individuals: Erythromycin ethyl succinate, 40–50 mg/kg/d in 2–4 divided doses. Resistance is rare in the US ($<5\%$ of isolates).

- Cefdinir, 14 mg/kg/day divided b.i.d. for 5 or 10 days or per day for 10 days (good palatability) and cefpodoxime proxetil, 10 mg/kg divided b.i.d. are approved for use in a more convenient 5-day dosing schedule.
- Clindamycin, 20 mg/kg per day divided in 3 doses (max 1.8 g/day) for 10 days
- Tetracyclines and sulfonamides should not be used owing to resistance of group A streptococci.

SURGERY/OTHER PROCEDURES

- Tonsillectomy for recurrent pharyngitis is still controversial, with only modest reductions in the number of subsequent episodes weighed against the morbidity of the procedure.

ONGOING CARE

COMPLICATIONS

- Streptococcal pharyngitis:
 - Suppurative complications include peritonsillar abscess, cervical lymphadenitis, and mastoiditis.
 - Most significant nonsuppurative complication is acute rheumatic fever.
 - Post-streptococcal glomerulonephritis
- Lemierre syndrome:
 - Postanginal sepsis or necrobacillosis originates as pharyngitis or tonsillitis, then progresses to sepsis and suppurative thrombophlebitis of the internal jugular vein. Septic thromboemboli seed various organs, especially the liver, lungs, and joints.
 - Treatment requires anaerobic coverage, macrolides should be avoided.
- Pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) is a recently recognized nonsuppurative complication that now appears to be more common than rheumatic fever or glomerulonephritis.
 - Identified at National Institute of Mental Health (NIMH) while studying Sydenham chorea in setting of rheumatic fever.
 - NIMH Diagnostic Criteria for PANDAS
 - Presence of obsessive compulsive disorder (OCD) and/or tic disorder
 - Pediatric onset, usually between 3 and 12 years of age
 - Abrupt symptom onset and/or episodic course of symptom severity
 - Temporal association between symptom exacerbation and GAS infection
 - Presence of neurologic abnormalities during periods of symptom exacerbation
 - Treatment within 9 days of symptom onset appears to be necessary to halt progression of autoimmune antibody response.

CODES

ICD9

- 034.0 Streptococcal sore throat
- 074.0 Herpangina
- 462 Acute pharyngitis

ICD10

- J02.0 Streptococcal pharyngitis
- J02.8 Acute pharyngitis due to other specified organisms
- J02.9 Acute pharyngitis, unspecified

FAQ

- Q: How many days after onset of GAS pharyngitis will therapy be effective in preventing acute rheumatic fever?
 - A: Therapy started as late as 9 days after illness onset has been shown to be effective in preventing acute rheumatic fever.
- Q: Is there any benefit to starting therapy while waiting for culture results?
 - A: Immediate therapy probably shortens the symptomatic period, but waiting for a positive test result avoids overuse of antibiotics.
- Q: Does an asymptomatic patient with a positive test for GAS from the pharynx (e.g., chronic carriers) require therapy?
 - A: Usually not. Between 8% and 20% of children in school or day care will have asymptomatic carriage of GAS and generally do not require therapy. Exceptions are those with a history of acute rheumatic fever, outbreak situations, or to achieve eradication in families with recurrent episodes of GAS pharyngitis.
- Q: Is there any evidence of GAS resistance to penicillin and other β -lactam antibiotics?
 - A: No, GAS has never been found to be resistant to penicillin where penicillin is bacteriostatic rather than bactericidal. However, 2–8% of GAS strains will be resistant to macrolides.
- Q: Is tonsillectomy indicated for recurrent GAS pharyngitis?
 - A: Rare patients in whom multiple symptomatic episodes of laboratory-confirmed GAS pharyngitis occur despite appropriate therapy may be considered for tonsillectomy.
- Q: Is continuous antimicrobial prophylaxis for recurrent GAS pharyngitis recommended?
 - A: No, there is insufficient evidence to show that it is effective, except for preventing recurrences of acute rheumatic fever.
- Q: What is the association of pharyngitis and recurrent fever?
 - A: There is an increasingly recognized syndrome of periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis, also known as PFAPA. The fever is usually high, recurs at fixed intervals of 2–8 weeks, and resolves spontaneously within 4 days. It does not appear to be familial, begins before the age of 5 years, the patient is well between episodes, and there are no known sequelae or etiology. Tonsillectomy was found to be effective treatment in a small randomized trial.

PHOTOSENSITIVITY

Leslie Castelo-Soccio
Albert Yan (5th edition)

BASICS

DESCRIPTION

Adverse or abnormal reaction of the skin to sunlight

EPIDEMIOLOGY

- Variable for each disorder
- Photosensitivities with onset in childhood include albinism, hydroa aestivale, hydroa vacciniforme, the porphyrias (e.g., erythropoietic, erythropoietic protoporphyria, hepatoerythropoietic), and genetic disorders (e.g., xeroderma pigmentosa, Hartnup disease, poikiloderma congenitale, Bloom syndrome, and Cockayne syndrome).
- Photosensitivities that occur frequently in adults but can occur in childhood are vitiligo, chemically induced photosensitivities, polymorphous light eruption, and connective tissue disease.

RISK FACTORS

- Family history
- Disease
- Exposure to toxins

Genetics

- Genetic disorders include the porphyrias and others as previously listed:
 - The various porphyrias have variable inheritance patterns, whereas most of the other genetic disorders are inherited in an autosomal-recessive pattern.
 - There is a positive familial history in many cases of polymorphous light eruption.

PATHOPHYSIOLOGY

Findings are diverse for the different disorders and rarely diagnostic.

ETIOLOGY

- Combination of sunlight with some abnormality in the skin such as loss of pigment, a chemical agent, a metabolic product, another skin disorder, a genetic disease, or an unknown factor produces a cutaneous abnormality.
- Specific wavelengths of the radiant energy emitted by the sun and reaching the earth are usually responsible for each photosensitivity disorder, most commonly ultraviolet B (UVB, 290–320 nm), ultraviolet A (UVA, 320–400 nm), and visible light (400–800 nm).

DIAGNOSIS

HISTORY

- Age of onset of rash
- Occurrence:
 - Season: Spring and summer
 - Relation to sun exposure: Time frame, effect of sun through glass
- Oral medications:
 - May be related to oral contraceptives, tetracyclines (doxycycline in particular), sulfa drugs, iodines/bromides, or phenytoin
- New topical agents (e.g., perfumes, lemons, limes, sunscreens, etc.):
 - Photosensitivity may occur on neck or places where agents were placed on skin.
- Rash:
 - Accentuation of the rash on the nose, cheeks, and forehead with sparing of the eyelids and the submental portion of the chin
 - There is often a sharp cutoff in the nuchal area at the collar line.

PHYSICAL EXAM

- Distribution:
 - Distribution of lesions is the main sign of photosensitivity reactions.
 - Lesions are prominent on sun-exposed skin such as the face, pinnae of the ears, the V of the neck, the nuchal area, and the dorsa of the hands.
 - Often, sparing of the philtrum, the area below the chin, the eyelids, and other covered areas is seen.
 - In phytophotodermatitis, linear or bizarre shapes can occur, including, as an example, hand prints if a caregiver has been squeezing limes and then picks up a child and the child is then exposed to sunlight.
- Lesion characteristics:
 - Vary with the particular disease and can include papules, vesicles, and plaques (polymorphous light eruption), sunburn (chemical reaction to a systemic agent), linear areas of hyperpigmentation (chemical reaction to a topical agent), skin cancers (xeroderma pigmentosum), vesicles (porphyria)
 - In some cases, scarring can also be seen related to severe burns (porphyria).

DIAGNOSTIC TESTS & INTERPRETATION

- Phototesting:
 - Using an artificial source of light, can confirm the presence of certain photosensitivities. Procedures are of 2 types:
 - The 1st is exposure of skin to increasing doses of UVA and UVB to determine the erythema response (present at lower exposures than usual) and possibly reproduce lesions in certain diseases.
 - The 2nd is photopatch testing in which photoallergic chemicals are applied under patches in duplicate, and 1 set is subsequently exposed to UVA. Patients who have photoallergic contact dermatitis develop a reaction under only the exposed patch of the agent causing the problem.

Lab

Initial lab tests

- Genetic tests (optional): Find labs that perform genetic tests at www.genetests.org and enter disease name:
 - Cell culture: Evaluates DNA repair for xeroderma pigmentosum or shows chromosomal breaks in Bloom disease
 - Measurement of specific amino acid and indole excretion patterns in Hartnup disease
 - Measurements of antinuclear antibodies are helpful in connective tissue diseases.
- Biochemical tests:
 - Helpful for the diagnosis of the porphyrias, with elevated levels of various porphyrins specific to each type in the urine, blood, or stool
- Screening for connective tissue diseases should be done where appropriate.

DIFFERENTIAL DIAGNOSIS

- Photosensitivity resulting from pigment loss:
 - Albinism
 - Vitiligo
- Idiopathic photosensitivity:
 - Polymorphous light eruption
 - Solar urticaria
- Chemically induced reactions:
 - Topical agents: Perfumes, plant-associated phytophotodermatitis (e.g., lemons, limes, celery, parsnips, carrots, dill, parsley, figs, meadow grass, giant hogweed, mangos, wheat, clover, cocklebur, buttercups, shepherds purse, and pigweed), blankophores (e.g., optical brighteners in detergents), sunscreens, topical retinoids (e.g., tretinoin, adapalene, tazarotene)

- Systemic agents: Tetracyclines, sulfonamides, nalidixic acid, griseofulvin, phenothiazines, oral hypoglycemic agents, amiodarone, quinine, isoniazid, and thiazide diuretics
- Metabolic disorders:
 - Porphyrrias: Disorders of hemoglobin synthesis producing various porphyrins that are photosensitizers
- Genetic disorders: See “Genetics”
- Cutaneous diseases aggravated by sunlight:
 - Connective tissue diseases

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Protection against sun exposure:
 - Avoiding the sun, particularly between 10 a.m. and 3 p.m., and wearing protective clothing is important.
 - Sunscreens are helpful for those sensitive to UVB.
 - Sunscreens should be waterproof and reapplied q2h.
 - The higher the sun protection factor (SPF; ratio of minimal erythema dose of sunscreensed skin to minimal erythema dose of unprotected skin), the better.
 - Sunscreens are less effective for blocking UVA and therefore less effective in helping patients with sensitivities to longer wavelengths.
 - Sunscreens that contain both UVA- and UVB-blocking capabilities offer better protection than most. These include sunscreens containing avobenzone, titanium dioxide, and zinc oxide. Avobenzone has a relatively short lifespan but is now available in a chemically stabilized form known by the trade names: Helioplex and Active Photobarrier Complex. Mexoryl is another long-acting broad-spectrum sunscreen that has especially good UVA protection.
 - Opaque formulations such as zinc oxide and titanium dioxide block UV and visible light, but may be less cosmetically appealing; however, new formulations made from microfine particles of titanium dioxide or zinc oxide make it more appealing.
 - Patients with severe photosensitivities may have to avoid any significant light exposure.
 - Most patients require chronic protection against sun exposure. However, the problem is generally more acute in spring and summer months.

- Removal of the offending agent is necessary in chemically induced photosensitivities:
 - Any severe and acute eruptions may require a short course of oral prednisone.
- Antimalarial agents have been used for polymorphous light eruption, lupus erythematosus, solar urticaria, and porphyria cutanea tarda and require the experience of a specialist.

ISSUES FOR REFERRAL

If possible, it is important to accurately document the specific wavelength of light and the degree of photosensitivity to accurately advise the patient. This requires phototesting by a specialist.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Skin exams for skin cancers routinely with frequency dependent on type of photosensitivity; for example, more monitoring for genetic causes like xeroderma pigmentosa

PATIENT EDUCATION

Education regarding significance of using sunscreen

PROGNOSIS

With the exception of chemically induced photosensitivities, most of the conditions are chronic.

- E70.30 Albinism, unspecified

FAQ

- Q: What is the best sunscreen to use?
- A: It depends on your particular problem. If you are sensitive to UVB, use a sunscreen with the highest SPF. If you are sensitive to UVA, sunscreens containing avobenzone, titanium dioxide, or zinc oxide are best.
- Q: I have heard that sunscreens with an SPF > 15 are not necessary. Is this true?
- A: This is definitely not true for patients with photosensitivities, who have abnormal responses to light and require excessive protection. Even for the healthy person, it is often not true. An SPF of 15 suggests that someone may receive 15 times more sun exposure with the sunscreen applied than without and not become sunburned. Some physicians have suggested that this is more than anyone should need. However, this number is calculated by testing in a controlled laboratory. Normal outdoor conditions, such as wind, reflection from water and sand, perspiration, and water exposure can significantly decrease the effectiveness of the sunscreen.
- Q: What is “sun allergy”?
- A: This is a lay term for polymorphous light eruption, one of the most common photosensitivities, presenting with papules, vesicles, and plaques 1–2 days after sun exposure. It usually recurs every spring, and most patients learn to avoid sun exposure. However, ironically, it can improve with slow, gradual sun exposure.
- Q: Can I become allergic to sunscreens?
- A: Certain active agents in sunscreens can produce an allergic response in rare individuals. If the rash recurs with each use, switch to another sunscreen with different ingredients. If the problem continues, consult a specialist for evaluation.

PINWORMS

Terry Kind
Hope Rhodes

BASICS

DESCRIPTION

- Infection by a small, white nematode (roundworm), typically *Enterobius vermicularis*
- Pinworms may also be caused by *Enterobius gregorii* in Europe, Africa, and Asia.

EPIDEMIOLOGY

- Considered the most common helminthic infection of humans (the only known natural host) and the most common worm infection in US
- Occurs in school-aged children (5–10 years) and preschool children predominantly
- Does occur in adults, usually in those caring for infected children. Some individuals may be predisposed to having either heavy or light worm burdens.
- Independent of socioeconomic status

Incidence

- US infection rates: 5–15%
- Occurs worldwide, but is more prevalent in temperate climates

GENERAL PREVENTION

- Decontaminate the environment by washing underclothes, bedclothes, bed sheets, and towels.
- Maintain good hand hygiene, including handwashing and proper toileting.
- Keep fingernails short and avoid nail biting.
- Treat family members and close contacts.

PATHOPHYSIOLOGY

- *E. vermicularis* eggs are ingested and hatch in the human's stomach and duodenum. Then the larvae migrate to the ileum and cecum. Adult worms copulate in the cecum.
- The pregnant female pinworm migrates from the cecum to the anus ~5 weeks later and deposits eggs on the perianal skin (at which point the female pinworm usually dies). Thousands of eggs are laid, which may result in hundreds of worms.

- Pruritus is caused by the perianal deposition of eggs and a mucosal mastocytosis response. Other GI symptoms, such as anorexia or abdominal pain, may occur because of the mucosal inflammatory response.
- Granulomas may form if dead worms and eggs invoke an inflammatory response in ectopic locations such as the peritoneal cavity, vulva, cervix, uterus, and fallopian tubes.

ETIOLOGY

- Ingestion of organism via fecal–oral transmission
- Can be spread directly, hand to mouth, or via fomites, such as toys, bedding, clothing, toilet seats, and baths

DIAGNOSIS

HISTORY

- Prior pinworms or sibling with pinworms:
 - Eggs can survive for several days in the environment, and the incubation period can be 1–2 months.
 - Spread can occur between family members.
- Daytime itching:
 - Pinworm infections usually cause perianal itching during the night or just before waking in the morning.
 - Daytime perianal or perivulvar itching or irritation is likely due to other causes.
- Fevers, diarrhea, or vomiting:
 - Pinworms are highly unlikely to cause systemic symptoms (except in rare cases where they migrate aberrantly).
- Visible worms at night:
 - Pinworms may be seen 2–3 hours after the child has gone to sleep. Female worms are 8–13 mm, and males are 2–5 mm.
 - They may be visible as small, white worms in the perianal area at night.

PHYSICAL EXAM

- Exam may be normal, and the child may be well appearing.
- May have self-inflicted, perianal excoriation
- Pinworms may be visible perianally.
- Infection is characterized by perianal pruritus that occurs at night or just before waking.
- Difficulty sleeping, decreased appetite, and/or abdominal pain may occur.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool or urine samples for ova or parasites:
 - Generally not helpful or recommended
 - Very few ova present in stool (even more rare in urine)
- Blood count for eosinophilia:
 - Generally not helpful or recommended
 - Eosinophilia is not observed because usually there is no tissue invasion.

Diagnostic Procedures/Other

- Transparent tape, Scotch tape test:
 - In the morning, prior to the child awakening and before defecation or washing, the adhesive side of transparent tape is applied to the perianal area.
 - After removal, the tape is applied to a glass slide and examined under light microscopy for pinworm ova. Several samples may be necessary to see the pinworms.

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Other parasites (e.g., *Strongyloides stercoralis*)
 - Nonparasitic vulvovaginitis (due to bacterial, fungal, or viral causes)

- Dermatologic:
 - Contact or irritative diaper dermatitis
 - Hidradenitis suppurativa
 - Irritative vulvovaginitis secondary to soaps, bubble baths, or lotions
 - Anal fissures (usually cause pain rather than itching)
- Miscellaneous:
 - Behavioral: Self-touching (normal)
 - Sleep disorders not owing to nocturnal pruritus
 - Hemorrhoids

TREATMENT

MEDICATION (DRUGS)

Single-drug and -dose therapy with one of the following agents:

- Mebendazole, 100 mg (available as a chewable tablet) PO once, may repeat in 2 weeks if symptoms still present
- Pyrantel pamoate, 11 mg/kg (maximum 1 g) PO once, may repeat in 2 weeks
- Albendazole, 400 mg PO once, may repeat in 2 weeks
- Experience is limited in children <2 years of age. Consider risks and benefits before use.
- Caution in treating pregnant individuals with antihelminthic medications because mebendazole, pyrantel pamoate, and albendazole are all category C and are not recommended in pregnancy

ADDITIONAL TREATMENT

General Measures

- Reinfection is common especially if not all close contacts are treated.
- Treat all symptomatic contacts, and consider treating close household contacts, especially if repeated infections have occurred.
- Reinfection can occur if eggs remain on bed linen or clothing.
- Infection may be asymptomatic and transmitted to others.
- Autoreinfection can occur if eggs remain under the nails.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Watch for signs of reinfection.

PATIENT EDUCATION

National Library of Medicine's health information site: <http://www.nlm.nih.gov/medlineplus/pinworms.html>

PROGNOSIS

- Reinfection is common.
- With appropriate treatment, symptoms resolve within a few days.
- Any chronic symptoms are likely due to recurrence rather than chronic infection, because the life cycle of the adult worm is short, with eggs being laid by the adult worm within 5 weeks.

COMPLICATIONS

- Urethritis
- Vulvovaginitis
- Granuloma formation
- Pelvic inflammatory disease
- Bacterial superinfection of perianal excoriations
- Appendicitis (uncommon)

ICD10

B80 Enterobiasis

FAQ

- Q: Could the child have acquired pinworms from a pet dog or cat?
- A: No. Household pets are not involved in the life cycles of pinworms.
- Q: When can an infected child return to day care?
- A: After receiving the 1st treatment dose, the child can return to school or day care. It is prudent to bathe the child and to trim and scrub his or her nails prior to school re-entry.
- Q: Is it necessary to re-evaluate and retest a child once treated?
- A: No. However, reinfection is common.
- Q: Can pinworm eggs survive on bedding, toilet seats, or clothing?
- A: Yes. Eggs can remain infectious in an indoor environment for up to 3 weeks.
- Q: Does pinworm infection cause nocturnal bruxism?
- A: There is no proof of any causal relationship.
- Q: How do the antihelminthic medications work?
- A: They inhibit microtubule function and cause glycogen depletion in the adult worms.

PLAGUE

Genevieve L. Buser
Bruce Tempest (5th edition)
Jonathan Iralu (5th edition)

BASICS

DESCRIPTION

Plague is an enzootic disease transmitted by fleas from wild rodents and caused by *Yersinia pestis*. Humans and their pets can enter this cycle, resulting in human plague. Human plague has 3 forms: Bubonic, septicemic, and pneumonic.

EPIDEMIOLOGY

- > 50% of contemporary cases of plague occur in persons <20 years of age, probably due to behavioral and environmental reasons.
- Worldwide: Enzootic in Africa, Asia, and Americas: 75% of cases are bubonic plague.
- *Y. pestis* is enzootic in the Western U.S., west of 100th meridian (ND to TX).
- In U.S., ~85% cases occur in AZ, NM, CA, CO.
- In U.S., most cases occur in spring/summer.
- 17 cases of plague occurred in the U.S. in 2006 including 5 septicemic, 8 bubonic, and 4 unknown. 2 developed plague pneumonia.
- 20% of U.S. cases with identified mode of transmission are acquired through direct contact with *Y. pestis*-infected animals, not via flea bite.
- No cases of person-to-person transmission of pneumonic plague have been reported in the U.S. since 1925.
- World-wide case fatality rate is 6.7% (WHO, 2010); U.S., 10.9% (estimate, 1987–2009).
- Untreated bubonic plague: > 50% fatal.
- Untreated pneumonic plague: Nearly 100% fatal.

GENERAL PREVENTION

- Reduce rodent shelter and food sources in the immediate vicinity of the home by storing grain and animal food in rodent-proof containers.
- Flea disinfection of cats and dogs, especially in endemic areas
- Hospital isolation precautions:
 - Patients with bubonic or septicemic plague and no evidence of pneumonia: standard precautions; add droplet precautions for 1st 24 hours of therapy, until chest radiograph persistently clear.
 - Patients with pneumonic plague: standard and droplet precautions. Continue droplet precautions until patient has completed 48 hours of appropriate antimicrobial therapy.
- Postexposure management:
 - All persons with exposure to known or suspected plague source in last 6 days:
 - Daily surveillance for fever or symptoms of disease for 7–10 days
 - Offer prophylaxis.
 - Initiate treatment if becomes ill.

– Persons with close (<2 m) contact with a patient with pneumonic plague: Prophylaxis is strongly recommended, but isolation not necessary.

- Chemoprophylaxis ≥ 8 years:
 - Doxycycline (PO), *OR*
 - Ciprofloxacin (PO) at treatment doses for 7 days from last exposure (see “Medications” for dosing)
- Chemoprophylaxis <8 years:
 - Doxycycline or ciprofloxacin (PO) (weigh risks of adverse effects and disease exposure), *OR*
 - Trimethoprim–sulfamethoxazole (PO): TMP 20 mg/kg/d divided q6h, *OR*
 - Streptomycin (IM/IV): 30 mg/kg/d divided q8h, for 7 days from last exposure
- Notify State Public Health authorities of cases of suspected and proven *Y. pestis* infection.
- Vaccination is no longer available and is not considered useful to prevent plague from an enzootic source.

PATHOPHYSIOLOGY

- Skin portal of entry:
 - *Y. pestis* is transmitted from fleas to humans via the regurgitation of the organism into the bite during the flea’s blood meal (*Y. pestis* blocks foregut, causing regurgitation).
 - Rodents, ground squirrels, cats, prairie dogs, marmots, rabbits, and occasionally dogs harbor infected fleas and are reservoirs of infection (enzootic).
 - Direct skin inoculation of organisms from infected animal tissue or blood occurs through breaks in the skin (e.g., cat scratch, skinning quarry).
 - Lymphatic spread of infection to the regional lymph nodes creates a localized inflammatory response (bubo, bubonic).
 - Subsequent hematogenous spread of the organism to other organs results in high levels of circulating bacterial endotoxin (septicemic plague).
 - By hematogenous spread to lungs, both bubonic and septicemic plague can cause secondary pneumonic plague.
- Respiratory portal of entry:
 - Primary pneumonic plague: Acquired via inhalation of respiratory tract droplets from a human or animal (e.g., cat) with pneumonic plague.
- Incubation period:
 - 2–6 days for bubonic or septicemic plague
 - 1–6 days for pneumonic plague

ETIOLOGY

Plague is caused by *Y. pestis*, a pleomorphic, bipolar staining, gram-negative coccobacilli from the Enterobacteriaceae family.

DIAGNOSIS

HISTORY

- A thorough travel history (especially to enzootic areas) is imperative to raise the index of suspicion for diagnosing plague.
- Environmental history should include epizootic deaths (die-offs) of rodents, ground squirrels, or prairie dogs in the patient’s locale.
- In enzootic areas, a sick household cat or dog is an additional risk factor.
- Signs and symptoms:
 - Bubonic plague:
 - Initial symptom: Pain in the groin or axillae prior to lymph node swelling
 - Lymphadenitis (usually inguinal >axillary >cervical)
 - Fever, chills, prostration
 - Septicemic plague:
 - Tachycardia and hypotension
 - Abdominal symptoms
 - Hemorrhage
 - Fever, chills, prostration
 - Bubonic or septicemic plague may progress to secondary pneumonic plague.
 - Pneumonic plague:
 - Cough, dyspnea
 - Systemic manifestations
 - Fever, chills, shock
 - Rapidly progressive and often fatal

PHYSICAL EXAM

- Tachycardic, hypotensive, tachypneic, and toxic-appearing
- Flea-bite lymphadenitis classically affects inguinal nodes; cat-associated plague affects mostly axillary or cervical nodes secondary to handling infected cat.
- GI: Abdominal pain, nausea, and diarrhea are common, secondary to inflammatory mediators.
- Neurologic: Weakness, delirium, and coma, owing to the effects of the endotoxin of *Y. pestis*.
- Heme: Disseminated intravascular coagulation
- Renal: Glomerular parenchymal damage
- Rare: Meningitis, endophthalmitis, endocarditis and pleuritis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total WBC count:
 - Usually 10,000–20,000, but may be as high as 100,000, with immature neutrophils
- Perform Gram, Wayson, Giemsa, or fluorescent antibody staining on specimen (blood, bubo, CSF, sputum) to look for gram-negative, bipolar staining organisms.

- *Y. pestis* culture (notify receiving lab):
 - Suspect bubonic plague: Needle aspiration of the bubo for stain and culture. Puncture center of bubo with a sterile syringe and inject 1 mL of nonbacteriostatic, sterile saline. Withdraw aspirate vigorously until blood-tinged liquid appears in syringe.
 - Suspect pneumonic plague: Sputum for stain and culture.
 - Blood cultures are usually positive, even with bubonic plague, and should always be done prior to therapy.
 - Slow-grower; may be misidentified as *Y. pseudotuberculosis* or *Acinetobacter* sp.
- Serology:
 - Single positive acute serology *OR*
 - At least a 4-fold increase in antibody titers by passive hemagglutination test between acute and convalescent sera taken 4–12 weeks apart
- Comprehensive testing and notification to State Public Health Lab and CDC

Diagnostic Procedures/Other

Pitfalls:

- Patients who present with a nonspecific febrile illness, tachycardia, tachypnea, rather than lymphadenitis, are at higher risk for delayed diagnosis and serious sequelae (e.g., septicemic plague, death).
- Failure to consider septicemic plague in the appropriate epidemiologic setting, and withholding appropriate antibiotics or using an empiric β -lactam regimen.
- Failure to treat suspected bubonic plague with antibiotics while awaiting culture results when needle aspiration of the bubo shows no organisms on direct stain.

DIFFERENTIAL DIAGNOSIS

- Diagnosis of plague follows a high index of suspicion and a thorough review of the patient’s lifestyle, travel history, and recent activities. The appearance of septicemia and endotoxin-mediated shock includes a large differential diagnosis that includes sepsis owing to other bacteria or viruses, as well as distributive shock resulting from toxic ingestion or anaphylaxis.
- Infection:
 - Streptococcal and staphylococcal infections (especially between the toes) can result in tender inguinal lymph nodes, fever, shock.
 - Cat-scratch fever (*Bartonella henselae*) can present with a history of cat scratch or bite, regional lymphadenitis and fever.
 - Hantavirus in humans has a clinical presentation similar to septicemic and pneumonic plague, and occurs in many of the plague enzootic areas.
 - Rickettsial diseases: *Rickettsia*, *Orientia*, *Coxiella*, *Ehrlichia*, *Anaplasma* (e.g., Rocky Mountain spotted fever (*Rickettsia rickettsii*) and relapsing tick fever due to *Borrelia* sp. may mimic septicemic or pneumonic plague.
 - Recent reports of plague-like illnesses have been associated with infections by other organisms, such as *Pseudomonas pseudomallei* (melioidosis) and *Francisella tularensis* (tularemia).

TREATMENT

MEDICATION (DRUGS)

- Use IV/IM forms for acute disease.
- Streptomycin is the drug of choice (IV/IM): Peds: 30 mg/kg/d divided q8–12h. Adult: 15 mg/kg q12h to max 1 gram q12h.
- Gentamicin, equally effective as streptomycin in recent study (IV): Peds: 2.5 mg/kg q8h. Adult: 5 mg/kg q24h.
- Meningitis or severe disease: Consider adding chloramphenicol (IV): 12.5–25 mg/kg q6h (max 4 grams). Monitor for toxicity.
- Alternatives:
 - Doxycycline: Peds <8 years (IV/PO): 2.2 mg/kg q12h. Peds \geq 8 years (IV/PO): 2 mg/kg q12h up to adult dose. Adult: 200 mg IV \times 1, then 100 mg IV/PO q12h. Some experts recommend adding it to gentamicin for severe disease.
 - Ciprofloxacin: Peds (IV/PO): 20–30 mg/kg/d divided q12h. Adults: 400 mg IV q12h; 500 mg PO q12h.
 - Tetracycline: Peds \geq 8 years (PO): 25–50 mg/kg/d divided q6h (max 3 g). Adults (PO): 250–500 mg q6–12h.
- Continue antibiotic therapy for 7–10 days or until several days after lysis of fever.
- Severely ill patients may require a substantially longer course of therapy.
- TMP-SMZ should not be used for 1st-line treatment of bubonic plague or as monotherapy to treat septicemic or pneumonic plague, as some studies have shown higher failure rates and delayed treatment responses.
- Prolonged fever may suggest a pyogenic focus of *Y. pestis* infection (e.g., abscess).
- Foci (e.g., abscess) are infectious until sufficient appropriate antimicrobial therapy is given.

ADDITIONAL TREATMENT

General Measures

For septic patients in shock, initial attention should be given to airway management and fluid resuscitation, then antibiotics.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Resolution of symptoms should begin in the first 3 days after initiation of therapy; however, the rate of clinical improvement depends on the initial severity of illness.

Patient Monitoring

None; most recover without sequelae

COMPLICATIONS

- Hematologic (disseminated intravascular coagulation)
- Renal (glomerular and parenchymal damage)

ADDITIONAL READING

CODES

ICD9

- 020.0 Bubonic plague
- 020.2 Septicemic plague
- 020.9 Plague, unspecified

ICD10

- A20.0 Bubonic plague
- A20.7 Septicemic plague
- A20.9 Plague, unspecified

FAQ

- Q: Can one determine the risks of being exposed to plague during international travel?
- A: Yes. The CDC provides a service that contains updated information for international travel exposures at www.cdc.gov/travel.
- Q: Does persistent fever during treatment for plague warrant altering the antibiotic regimen?
- A: No. Fever can persist for up to 2 weeks despite appropriate 1st-line antibiotic therapy for *Y. pestis*. However, recommend an evaluation for a focus of infection requiring drainage.

PLEURAL EFFUSION

Richard M. Kravitz

BASICS

DESCRIPTION

Accumulation of fluid in the pleural cavity

EPIDEMIOLOGY

- Depends on underlying cause
- Pneumonia (most common cause):
 - *Staphylococcus aureus* (increasing incidence of methicillin-resistant species)
 - *Streptococcus pneumoniae* (increasing incidence of penicillin-resistant species)
 - *Haemophilus influenzae* (decreasing incidence since introduction of *H. influenzae* type B [HiB] vaccine)
 - No identified organisms (all cultures sterile)
- Congenital heart disease
- Malignancy

PATHOPHYSIOLOGY

- Depends on the underlying disease
- 2 types of pleural effusion:
 - Transudate: Mechanical forces of hydrostatic and oncotic pressures are altered, favoring liquid filtration.
 - Exudate: Damage to the pleural surface occurs that alters its ability to filter pleural fluid; lymphatic drainage is diminished.
- Stages associated with parapneumonic effusions (infectious exudates):
 - Exudative stage:
 - Free-flowing fluid
 - Pleural fluid glucose, protein, lactate dehydrogenase (LDH) level, and pH are normal.
 - Fibrinolytic stage:
 - Loculations are forming.
 - Increase in fibrin, polymorphonuclear leukocytes, and bacterial invasion of pleural cavity are occurring.
 - Pleural fluid glucose and pH falls while protein and LDH levels increase.
 - Organizing stage (empyema):
 - Fibroblasts grow.
 - Pleural peel forms.
 - Pleural fluid parameters worsen.

ETIOLOGY

- Normally 1–15 mL of fluid in the pleural space
- Alterations in the flow and/or absorption of this fluid lead to its accumulation.
- Mechanisms that influence this flow of fluid:
 - Increased capillary hydrostatic pressure (i.e., congestive heart failure [CHF], overhydration)
 - Decreased pleural space hydrostatic pressure (i.e., after thoracentesis, atelectasis)
 - Decreased plasma oncotic pressure (i.e., hypoalbuminemia, nephrosis)
 - Increased capillary permeability (i.e., infection, toxins, connective tissue diseases, malignancy)
 - Impaired lymphatic drainage from the pleural space (i.e., disruption of the thoracic duct)
 - Passage of fluid from the peritoneal cavity through the diaphragm to the pleural space (i.e., hepatic cirrhosis with ascites)

DIAGNOSIS

HISTORY

- Underlying disease determines most systemic symptoms.
- Patient may be asymptomatic until the amount of fluid is large enough to cause cardiorespiratory compromise/distress.
- Dyspnea and cough are associated with large effusions.
- Fever (if infectious etiology)
- Pleuritic pain (pneumonia may cause irritation of the parietal pleura, causing pleural pain; as the effusion increases and separates the pleural membrane, the pain may disappear)

PHYSICAL EXAM

- Decreased thoracic wall excursion on the ipsilateral side
- Fullness of intercostal spaces on the ipsilateral side
- Trachea and cardiac apex displaced toward the contralateral side (may produce a mediastinal shift that can reduce venous return and compromise the cardiac output)
- Dull or flat percussion on the ipsilateral side (suggesting the presence of consolidation of pleural effusion)
- Decreased tactile and vocal fremitus
- Decreased whispering pectoriloquy
- Pleural rub during early phase (may resolve as fluid accumulates in the pleural space)
- Decreased breath sounds

DIAGNOSTIC TESTS & INTERPRETATION

- Cytologic exam of pleural fluid:
 - Fresh and heparinized specimen should be refrigerated at 4°C (39.2°F) until it can be processed.
 - Fixatives should not be added.
- Pleural fluid parameters to be routinely measured include:
 - pH
 - LDH
 - Protein
 - Glucose:
 - Note: Glucose of <40 mg/dL suggests a parapneumonic, tuberculosis, malignant, or rheumatic etiology to the effusion.

Lab

Initial lab tests

- Serology values to follow the degree of inflammation and the response to therapy:
 - Erythrocyte sedimentation rate (ESR)
 - C-reactive protein (CRP)

Imaging

- Chest radiograph:
 - Anteroposterior projection can show >400 mL of pleural fluid.
 - Lateral projection can show <200 mL of pleural fluid.
 - Lateral decubitus film to evaluate for free-flowing pleural fluid can show as little as 50 mL of pleural fluid.
- Ultrasound:
 - Reveals small (3–5 mL) loculated collections of pleural fluid
 - Useful as a guide for thoracentesis
 - Aids in distinguishing between pleural thickening and pleural effusion
- CT scan:
 - Clearly reveals effusions/empyemas, abscess, or pulmonary consolidations
 - Useful for defining the extent of loculated effusions

Diagnostic Procedures/Other

- Thoracentesis:
 - Indicated whenever cause is unclear or effusion causes symptoms (e.g., prolonged fever or respiratory distress)
- Pleural biopsy:
 - If thoracentesis is nondiagnostic
 - Most useful for diseases that cause extensive involvement of the pleura (i.e., tuberculosis, malignancies)
 - Confirms neoplastic involvement in 40–70% of cases

DIFFERENTIAL DIAGNOSIS

- Transudate:
 - Cardiovascular:
 - CHF
 - Constrictive pericarditis
 - Nephrotic syndrome with hypoalbuminemia
 - Cirrhosis
 - Atelectasis
- Exudate:
 - Infection:
 - Bacterial effusions (*S. aureus* is most common organism)
 - Tuberculous effusion
 - Viral effusions (adenovirus, influenza)
 - Fungal effusions: Most not associated with effusions; *Nocardia* and *Actinomyces* are most commonly seen.
 - Parasitic effusions
 - Neoplasm: Seen mostly in leukemia and lymphoma; uncommon in children

- Connective tissue disease:
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Wegener granulomatosis
- Pulmonary embolus
- Intra-abdominal disease:
 - Subdiaphragmatic abscess
 - Pancreatitis
- Sarcoidosis
- Esophageal rupture
- Hemothorax
- Chylothorax
- Drugs
- Chemical injury
- Post-irradiation effusion

TREATMENT

MEDICATION (DRUGS)

Antibiotics:

- Used when effusion is caused by a bacterial infection
- Specific antibiotics dictated by organism identified
- If effusion is sterile, broad-spectrum antibiotics are indicated to cover for the usually seen organisms.
- Clinical improvement usually begins within 48–72 hours of therapy.
- Continue IV antibiotics until afebrile.
- Complete remainder of therapy on oral antibiotics.
- Duration of antibiotic therapy depends on the infectious organism and the degree of illness:
 - Total duration is controversial.
 - Usually, at least 2–4 weeks of total IV and PO

ADDITIONAL TREATMENT

General Measures

- Supportive measures:
 - Maintain adequate:
 - Oxygenation
 - Fluid status
 - Nutritional balance
 - Antipyretic agents when febrile
 - Pain control
- Treat the underlying disease:
 - Antibiotics for infections
 - Cardiac medications for congestive heart failure
 - Chemotherapeutic agents for malignancies
 - Anti-inflammatory agents (i.e., steroids) for connective tissue diseases
 - Medium-chain triglycerides and low-fat diet for chylothorax
- Effective drainage of pleural fluid:
 - Thoracentesis
 - Chest tube drainage
 - Surgical drainage
- Duration of chest tube drainage:
 - Discontinue when patient is asymptomatic (afebrile, no distress) and drainage <50 mL/h
 - Thick, loculated empyema requires prolonged drainage (and possibly a video-assisted thoracic surgery [VATS] procedure if effusion not improving).

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Thoracentesis:
 - For diagnosis purposes:
 - To distinguish between a transudate and an exudate
 - For culture material (if infection is suspected)
 - For cytology (if malignancy is suspected)
 - For relief of dyspnea or cardiorespiratory distress

- Chest tube thoracostomy:
 - Reduce reaccumulation of fluid.
 - Drain parapneumonic effusion (before loculations develop which will prevent fluid drainage).
- Intrapleural fibrinolytics:
 - Adjunct to aid in drainage of complicated (i.e., multiloculated empyema) pleural effusions
- Streptokinase and urokinase are agents of choice.

SURGERY/OTHER PROCEDURES

- VATS:
 - Alternative to more invasive procedures (e.g., open thoracotomy/decortication)
 - Débridement through pleural visualization and lysis of adhesions/loculations
 - Useful when:
 - Initial drainage is delayed
 - Loculations prevent adequate drainage by chest tube alone
 - Patient is failing more conservative therapy
- Pleurectomy:
 - Chylothorax
 - Malignant effusions
- Pleurodesis:
 - For recurrent effusions
 - Chemical agents frequently used include talc, tetracycline, doxycycline, and quinacrine.
 - Surgical methods include:
 - Mechanical abrasion
 - Pleurectomy via VATS
 - Open thoracotomy route
 - In cases of malignant effusion:
 - Sclerosing procedures are usually ineffective.
 - Chest tube drainage can create a pneumothorax because the lung is incarcerated by the tumor.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Clinical improvement usually within 1–2 weeks
- With empyemas, the patient may have fever spikes for up to 2–3 weeks after improvement is noted.

DIET

When the effusion is a chylothorax:

- Medium-chain triglycerides
- Nutritional replacement
- At least 4–5 weeks on this regimen

PROGNOSIS

Dependent on underlying disease process:

- Properly treated infectious cause: Excellent prognosis
- Malignancy: Poor prognosis

COMPLICATIONS

- Hypoxia
- Respiratory distress
- Persistent fevers
- Decreased cardiac function
- Malnutrition (seen in chylothorax)
- Shock (secondary to blood loss in cases of hemothorax)
- Trapped lung

CODES

ICD9

- 511.81 Malignant pleural effusion
- 511.89 Other specified forms of effusion, except tuberculous
- 511.9 Unspecified pleural effusion

ICD10

- J11.1 Influenza due to unidentified influenza virus with other respiratory manifestations
- J90 Pleural effusion, not elsewhere classified
- J94.0 Chylous effusion

FAQ

- Q: When will the chest radiograph findings become normal?
- A: They may take up to 6 months (or longer) to return to normal appearance.
- Q: When will the pulmonary function tests normalize?
- A: Depending on extent of effusion, they may take up to 6–12 months.

PNEUMOYSTIC JIROVECI (PREVIOUSLY KNOWN AS PNEUMOCYSTIC CARINII PNEUMONIS)

Danna Tauber

BASICS

DESCRIPTION

Opportunistic lung infection caused by *Pneumocystis jiroveci* (PJ). This organism is currently considered a primitive fungus based on DNA sequence analysis. It has two developmental forms (the cysts contain sporozoites that become trophozoites when excised).

- The acronym PCP is still in use and refers to *Pneumocystis* pneumonia. PCP occurs almost exclusively in the immunocompromised host. Children with congenital or acquired immune deficiency syndrome (AIDS) and recipients of suppressive therapy in the treatment of malignancies or after organ transplantation are at high risk.
- PCP is an AIDS-defining illness. It is the most common opportunistic life-threatening lung infection in infants with perinatally acquired HIV disease.
- PJ causes a diffuse pneumonitis characterized by fever, dyspnea at rest, tachypnea, hypoxemia, nonproductive cough, and bilateral diffuse infiltrates in the roentgenogram. It is a severe condition frequently leading to respiratory failure necessitating intubation and mechanical ventilation.
- Chemoprophylaxis against this microorganism has proven successful. Therefore, early identification of the HIV-infected mother becomes essential.
- Despite advances in therapy, the infection continues to be associated with significant morbidity and mortality.

EPIDEMIOLOGY

- Ubiquitous in mammals worldwide, particularly rodents
- Growth on respiratory tract surfaces
- Mode of transmission is unknown:
 - Airborne person-to-person transmission is possible, but case contacts are rarely identified.
 - Environmentally acquired
- Asymptomatic infection appears early in life; >70% of healthy individuals have antibodies by age 4 years.
- Primary infection is likely to be the mechanism in infants. Reactivation of latent disease with immunosuppression was proposed as an explanation for disease later in childhood; however, animal models of PCP do not support this proposition.
- PCP in the HIV patient can occur at any time, but usually presents during the 1st year of life. The highest incidence is between 3 and 6 months of age.
- In leukemic patients, the incidence of PCP has been directly related to the degree of immunodeficiency resulting from chemotherapy.
- Epidemics of PCP were reported in premature and malnourished infants and children in resource-limited countries and during times of famine.

PATHOPHYSIOLOGY

- In the immunodeficient child, the pathologic changes occur predominantly in the alveoli. Cysts and trophozoites are seen adhering to the alveolar lining cells or in the cytoplasm of macrophages.
- As infection progresses, the alveolar spaces are filled with a pink, foamy exudate containing fibrin, abundant desquamative cells, and a large number of organisms. Alveolar septal thickening with mononuclear cell infiltration is also seen.

DIAGNOSIS

HISTORY

- Malnourishment:
 - Subacute onset with nonspecific manifestations:
 - Poor feeding, weight loss, and restlessness
 - Chronic diarrhea
 - Usually without fever
 - After 1–2 weeks, the patient develops progressive tachypnea, respiratory distress, and cough.
- Sporadic or immunocompromised host:
 - This form has a more abrupt onset, sometimes even fulminant:
 - Fever (>38.5°C)
 - Nonproductive cough
 - Dyspnea at rest
- These subtypes are characterized by general clinical guidelines. Symptoms may be superimposed and can be seen in infants, children, and adolescents.

PHYSICAL EXAM

- Fever and significant tachypnea are characteristic.
- Hypoxemia: Early in the course of disease and disproportionate to the auscultatory findings
- Rapidly progressive respiratory distress with cyanosis: Respiratory failure early in course
- Absence of crackles is a common initial finding.
- Chest auscultation can reveal decreased breath sounds, crackles, and rhonchi.
- Coryza and wheezing have infrequently been reported.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Arterial blood gas:
 - pH is usually increased
 - Reduced PaO₂ in room air (<70 mm Hg)
 - Alveolar–arterial oxygen gradient (>35 mm Hg)
- Chest radiograph:
 - Most common radiologic presentation is diffuse bilateral alveolar infiltrates:
 - Initially a perihilar distribution that spreads to the periphery
 - Apices are the least affected.
 - Interstitial infiltrates and air bronchograms can be seen.
 - Rapid progression to whole lung consolidation
 - Presence of hilar or mediastinal adenopathy may indicate another process such as *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*, fungal infections, cytomegalovirus, or lymphoma.

- Other tests:
 - Lactate dehydrogenase (LDH) can be elevated in patients with AIDS and PCP, but this finding is nonspecific.
 - WBC count is usually normal.

Pathological Findings

- Definitive diagnosis can be obtained by demonstration of PJ in pulmonary specimens:
 - Induced sputum
 - Bronchoalveolar lavage (90% sensitivity), usually through flexible bronchoscopy
 - Open lung or transbronchial biopsy
- Staining (significance):
 - Cysts stain with methenamine-silver, toluidine blue-O stains, calcofluor white, and fluorescein monoclonal antibody.
 - Sporozoites and trophozoites are identified with Giemsa stain, modified Wright-Giemsa stain, and fluorescein-conjugated monoclonal antibody stain.
 - Polymerase chain reaction assays for detecting PJ are experimental. PCR is more sensitive but less specific than microscopic methods but is not US FDA approved for diagnosis.

DIFFERENTIAL DIAGNOSIS

- Viral infections:
 - Common viral respiratory pathogens
 - Cytomegalovirus
 - Epstein-Barr virus
- Bacterial infections:
 - *M. tuberculosis*
 - *M. avium-intracellulare*
- Other:
 - Lymphocytic interstitial pneumonitis

TREATMENT

MEDICATION (DRUGS)

First Line

- Minimum duration of therapy is 2 weeks; 3 weeks of therapy recommended in patients with AIDS.
- Antibiotics:
 - Trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice:
 - TMP (15–20 mg/kg/d) and SMX (75–100 mg/kg/d) IV/PO divided q6h
 - Oral therapy is reserved for patients with mild illness who do not have malabsorption or diarrhea.

Second Line

- Minimum duration of therapy is 2 weeks; 3 weeks of therapy recommended in patients with AIDS.
- Pentamidine isethionate:
 - 3–4 mg/kg/d IV (or IM) given in a single daily dose
 - Used in patients who cannot tolerate TMP-SMX or are unresponsive after 5–7 days of therapy
 - If clinical improvement seen after 7–10 days of IV pentamidine, consider oral regimen to complete the 21-day course.

- Atovaquone:
 - 1–3 months and >24 months: 30 mg/kg/d PO divided into 2 doses
 - 4–24 months: 45 mg/kg/d PO divided into 2 doses
 - Maximum dose: 750 mg b.i.d.
- Dapsone plus trimethoprim
 - Dapsone: 2 mg/kg PO daily to a maximum of 100 mg daily
 - Trimethoprim: 15 mg/kg/d PO divided into 3 doses
- Primaquine plus clindamycin:
 - Primaquine: 0.3 mg/kg PO daily to a maximum of 30 mg PO daily
 - Clindamycin: 40 mg/kg/d PO divided into 4 doses to a maximum of 600 mg q6h.

ADDITIONAL TREATMENT

General Measures

- Supply oxygen as necessary to keep PaO₂ >70 mm Hg.
- Mechanical ventilation must be considered if PaO₂ is <60 mm Hg on FiO₂ of 0.5.
- Corticosteroids:
 - May be beneficial in HIV patients with moderate to severe PCP
 - Not systematically evaluated in children
 - Consider when PaO₂ is <70 mm Hg or the alveolar–arterial gradient is >35 mm Hg.
 - In patients >13 years of age, suggested dose is prednisone 40 mg PO b.i.d. for days 1–5, 40 mg PO once daily for days 6–10, and 20 mg PO once daily for days 11–21 with tapering. Doses of methylprednisolone or prednisone at 1 mg/kg given b.i.d.–q.i.d. for 5–7 days with a taper over the next 5 days have been suggested.

Additional Therapies

During high-risk periods, PCP can be effectively prevented in the immunodeficient host by chemoprophylaxis in the following groups:

- HIV exposed: 4–6 weeks to 4 months
- HIV infected or indeterminate: 4–12 months
- HIV infected: 1–5 years if CD4⁺ T-lymphocyte count is <500 cells/μL or <15%
- HIV infected: ≥6years if CD4⁺ T-lymphocyte count is <200 cells/μL or <15%
- Severely symptomatic HIV patients or those with rapidly declining CD4 counts
- HIV patients who have had previous PCP illness
- Children who have received hematopoietic stem cell transplants (HSCTs)
- All HSCT recipients with hematologic malignancies (e.g., leukemia, lymphoma)
- All HSCT recipients receiving intense conditioning regimens or graft manipulation
- Prophylaxis is initiated at engraftment and administered for 6 months; longer than 6 months in children receiving immunosuppressive therapy or with chronic graft versus host disease

COMPLEMENTARY & ALTERNATIVE THERAPIES

Drug regimen for prophylaxis:

- TMP-SMX is the drug of choice.
 - 150 mg/m² body surface area per day of TMP or 750 mg/m² body surface area per day of SMX PO divided into 2 doses on 3 consecutive days per week
 - TMP-SMX can also be given 7 days a week when prevention against other bacterial infections is sought.
- For patients who cannot tolerate TMP-SMX:
 - Dapsone (>1 month of age): 2 mg/kg (maximum 100 mg) PO daily or 4 mg/kg (maximum 200 mg) PO weekly
 - Aerosolized pentamidine (>5 years of age): 300 mg via Respigard II nebulizer inhaled monthly
 - Atovaquone (1–3 months and >24 months): 30 mg/kg PO daily (4β24 months): 45 mg/kg PO daily

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- After 5–7 days of treatment
- If no improvement, TMP-SMX should be replaced with pentamidine.
- Standard precautions are required. Isolation from other immunodeficient patients is recommended.

PROGNOSIS

- 5–40% mortality in treated patients
- Near 100% mortality if patient is untreated
- ~35% of patients will have recurrence unless lifetime prophylaxis is instituted.

COMPLICATIONS

- High rate of respiratory failure necessitating intubation and mechanical ventilation (~60%)
- HIV-infected patients have a higher rate (40%) of adverse reactions to TMP-SMX than the general population. Rash is most common with fever, neutropenia, anemia, renal dysfunction, nausea, vomiting, and diarrhea occurring as well.
- Prophylactic medication protects the patient as long as the drug is administered. However, this does not eradicate PJ.

FAQ

- Q: Which are the most common side effects of pentamidine?
- A: They include hypoglycemia, impaired renal or liver function, anemia, thrombocytopenia, neutropenia, hypotension, and skin rashes. These side effects can be expected in 50% of patients.
- Q: How frequently is prophylaxis failure seen?
- A: Adequate TMP-SMX treatment has only a 3% failure rate.
- Q: How are adverse reactions to TMP-SMX during PCP therapy managed?
- A: Continuation of treatment, if the reactions are not severe, is recommended.

PNEUMONIA—BACTERIAL

Erica S. Pan

Michael D. Cabana

BASICS

DESCRIPTION

Pneumonia is an acute infection of the pulmonary parenchyma, which is associated with consolidation of alveolar spaces.

EPIDEMIOLOGY

Incidence

Highest incidence in children <5 years of age (annual incidence 3–4%)

RISK FACTORS

- Immune deficiency:
 - Immunocompromised status
 - Sickle cell anemia
- Increased aspiration risk:
 - Altered mental status
 - Tracheoesophageal fistula
 - Cerebral palsy
 - Seizure disorder
- Compromised lung function/anatomy:
 - Cystic fibrosis
 - Congenital pulmonary malformations
 - Bronchopulmonary dysplasia
 - Asthma

ETIOLOGY

- Etiology of bacterial pneumonia differs by age:
 - Neonates: Group B streptococcus, *Enterococcus*, *Listeria monocytogenes*, *Escherichia coli*, *Ureaplasma urealyticum*
 - 1–3 months: *Staphylococcus aureus*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Bordetella pertussis*, *Chlamydia trachomatis*, *U. urealyticum*
 - 4 months to 4 years: *S. pneumoniae*, *S. aureus*, *H. influenzae*
 - >5 years of age: *S. pneumoniae*, *Mycoplasma pneumoniae*, *Mycoplasma tuberculosis*
- Etiology can also differ based on risk factors:
 - Aspiration as etiology increases the risk for oral flora including anaerobes such as *Bacteroides* and *Peptostreptococcus*.
 - Ventilator-dependent patients are at increased risk for *Pseudomonas* or *Klebsiella* infections, and infection with other gram-negative rods.
 - Cystic fibrosis increases the risk for *Pseudomonas* and other more unusual organisms.

DIAGNOSIS

HISTORY

- Fever and/or chills
- Rapid breathing is a sensitive but nonspecific finding in bacterial pneumonia.
- Difficulty breathing or shortness of breath is common and can lead to difficulty feeding in infants.
- Cough is often seen in bacterial pneumonia. *B. pertussis* pneumonia often presents after a catarrhal phase with a paroxysmal cough and posttussive vomiting.
- Pleuritic chest pain
- Abdominal pain and/or vomiting: Lower-lobe pneumonia can present with abdominal pain.
- Irritability, lethargy, and/or malaise
- Poor feeding or apnea in young infants

- Birth history, including maternal infections (e.g., *C. trachomatis* can be transmitted to an infant through a mother's genital tract at delivery)
- Immunization status: In a fully immunized child, *H. influenzae* type B, *B. pertussis*, and *S. pneumoniae* infections are less common.
- Recent history of upper respiratory tract infection (URI) or RSV can predispose to bacterial pneumonia.
- History of repeated bacterial infections suggests immunodeficiency or cystic fibrosis, which are risk factors for bacterial pneumonia.
- Exposure to contacts with pertussis, tuberculosis, or history of recent travel
- Travelers, health care workers, and persons working in prisons or institutional settings are at greater risk for tuberculosis.

PHYSICAL EXAM

- Ill appearance:
 - General examination can range from mildly ill appearing to toxic in appearance.
 - Infants may have a paucity of exam findings disproportionate to their appearance and tachypnea.
 - Patients may be dehydrated or in shock.
- Fever:
 - Most children with bacterial pneumonia have fever.
 - Patients with atypical bacterial pneumonia and pertussis are sometimes afebrile.
- Tachypnea or increased work of breathing: Nasal flaring, grunting, and/or retracting
- Decreased oxygen saturation; therefore, oxygen saturation should be obtained by pulse oximetry in children with tachypnea or other signs of distress.
- Localized rales, rhonchi, decreased breath sounds, or wheezing:
 - These are all significant clinical findings of pneumonia. Crackles suggest the diagnosis of pneumonia.
 - With increasing consolidation, dullness to percussion and decreased breath sounds may be noted.
 - In patients who are actively wheezing, it may be difficult to distinguish rales from other auscultated sounds.

DIAGNOSTIC TESTS & INTERPRETATION

- Not indicated for patients with uncomplicated pneumonia
- In toxic-appearing infants, blood, urine, and CSF cultures (i.e., a sepsis workup) should be considered.

Lab

- Blood culture:
 - Not usually indicated in healthy children with uncomplicated pneumonia
 - Rarely leads to identification of pathogen causing pneumonia
 - Should be obtained in toxic-appearing patients and infants <1 month old
 - Bacteremia has been noted in up to 30% of patients with pneumococcal pneumonia.
- Elevated peripheral WBC or range 15,000–40,000/mm³ is associated with bacterial pneumonia or even higher WBC in pertussis, but should not be relied upon to distinguish etiology of pneumonia.

- Cold agglutinin test:

– A positive test suggests *M. pneumoniae*. This test is usually not indicated because empiric treatment of this pathogen is typically safe and effective.

- Purified protein derivative (PPD) test or an interferon-gamma release assay (e.g., quantiFERON): Should be obtained in all patients in whom *M. tuberculosis* is suspected.

Imaging

- Chest radiograph (CXR), upright:
 - A CXR is not required for diagnosis if clinical symptoms and examination findings are consistent with pneumonia.
 - A CXR is typically obtained if pneumonia is suspected but clinical findings are unclear, if the patient has evidence of respiratory distress and if a complication (e.g., a pleural effusion) is suspected, or if the patient is not responding to treatment.
 - Characteristic CXR patterns include “alveolar or lobar infiltrate” with air bronchograms. “Round” infiltrates may be seen with *S. pneumoniae*. “Diffuse” interstitial infiltrates and hyperinflation may be seen with atypical pneumonia such as *M. pneumoniae* or chlamydial pneumonias.
 - More commonly, CXR cannot be reliably used to distinguish between viral and bacterial disease.
 - An infiltrate may not be seen (negative CXR) if the disease is diagnosed early or if the patient is dehydrated.
- CXR, lateral decubitus: More sensitive than an upright radiograph in detecting pleural effusions or foreign body aspiration
- CT scan: Not recommended as 1st-line imaging for suspected pneumonia. CT is mainly used as adjunct imaging for patients who are worsening (not improving) despite treatment, or have complications.

Diagnostic Procedures/Other

If diagnosis is unclear, consider the following:

- Flexible fiberoptic bronchoscopy with bronchoalveolar lavage or lung biopsy
- Thoracentesis if pleural fluid is present
- For empyema, drainage by aspiration or chest tube may be required.

DIFFERENTIAL DIAGNOSIS

- Infectious:
 - Sepsis
 - Viral pneumonia:
 - In infants: cytomegalovirus (CMV), metapneumovirus, herpes simplex virus (HSV)
 - From 1–3 months: CMV, respiratory syncytial virus (RSV), metapneumovirus
 - From 4 months to 4 years: RSV, adenovirus, influenza, metapneumovirus
 - Bronchiolitis
 - URI
 - Croup (laryngotracheobronchitis)
 - Fungal infection (if immunodeficiency or exposure history)
 - Parasitic infection (if immunodeficiency or exposure history)
- Pulmonary:
 - Asthma
 - Atelectasis
 - Pneumonitis (i.e., chemical)
 - Pneumothorax
 - Pulmonary edema
 - Pulmonary hemorrhage
 - Pulmonary embolism

- Congenital:
 - Pulmonary sequestration
 - Congenital pulmonary airway malformation
- Genetic: Cystic fibrosis
- Tumors:
 - Lymphoma
 - Primary lung tumor
 - Metastatic tumor
- Cardiac: CHF
- GI: Gastroesophageal reflux disease
- Miscellaneous:
 - Foreign body aspiration
 - Sarcoidosis

TREATMENT

ADDITIONAL TREATMENT

General Measures

Outpatient: Empiric Treatment

- Unlike adults, there is no validated tool to identify those patients at low risk who can be treated as outpatients. In general, neonates should be managed as inpatients.
- 2–4 months; if afebrile:
 - Azithromycin 10 mg/kg/d × 1 day then 5 mg/kg/d × 4 days
 - If febrile, hypoxic, or dehydrated, then admit (see “FAQ”)
- 5 months to 5 years:
 - Amoxicillin 80–100 mg/kg/d divided q8–12h
 - Consider for additional coverage of *H. influenzae*, non-type B:
 - Amoxicillin/clavulanate 25–45 mg/kg/d divided b.i.d. or t.i.d.
 - Cefuroxime 30 mg/kg/d divided b.i.d., cefprozil 30 mg/kg/d divided b.i.d., cefdinir 14 mg/kg/d divided daily or b.i.d., or cefpodoxime 10 mg/kg/d divided b.i.d.
 - May consider use of ceftriaxone 50 mg/kg IM to initiate therapy
 - For penicillin-allergic patients, may use macrolide or cephalosporin
 - Age >5 years (unless organism other than atypical pathogen suspected; atypical pathogens are much more common in this age group):
 - Azithromycin 10 mg/kg/d × 1 day (max dose 500 mg) then 5 mg/kg/d (max dose 250 mg) × 4 days
 - May consider doxycycline 4 mg/kg/d divided by 2 doses in patients 9 years of age or older. Not to exceed 200 mg/d
 - May consider fluoroquinolones in patients ≥16 years of age if no other appropriate oral option is available
 - If specific pathogen is known or suspected, use appropriate antibiotic therapy.
 - For patients with more severe disease, may consider combining β-lactam antibiotic and macrolide

Inpatient Management

- Oxygen as needed to keep oxygen saturations >94–95%
- Intubation and positive pressure ventilation, if clinically indicated

- Empiric antibiotic treatment:
 - <1 month: Ampicillin 200 mg/kg/d divided q6–8h
 - Age 1–3 months: Erythromycin: 10 mg/kg IV q6h or azithromycin 2.5 mg/kg IV q12h
 - For infants <6 weeks, consider azithromycin instead of erythromycin owing to the associated increased risk of pyloric stenosis. If febrile, add cefotaxime 200 mg/kg/d divided q8h.
 - Age 4 months to 5 years (if atypical pathogens are not suspected): Ceftriaxone 50–75 mg/kg/d q12–24h or cefotaxime 200 mg/kg/d divided q8h
 - Age ≥5 years: Add macrolide to above therapy. For seriously ill patients, add vancomycin 60 mg/kg/d divided q6h. For antistaphylococcal coverage, add vancomycin 15 mg/kg/dose q6–8h or clindamycin 25–40 mg/kg/d divided q6–8h. If atypical pneumonia also suspected, may add macrolide. May also consider macrolides or clindamycin IV as alternative for cephalosporin-allergic patients.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- If treated as outpatient, consider telephone follow-up within 1–3 days.
- If worsening or not responding to treatment, consider repeated or additional diagnostic studies. For example, persistent fever may be due to loculated pleural fluid or an empyema.
- CXR may be abnormal for up to 10 weeks after successful treatment. Consider follow-up CXR only if indicated for severe disease or complications (e.g., effusion, empyema).
- For children with recurrent bacterial pneumonia, consider an underlying anatomic or immunologic disorder (e.g., abnormal antibody production, cystic fibrosis, tracheoesophageal fistula, pulmonary sequestration).

PROGNOSIS

Otherwise healthy children with uncomplicated pneumonia typically have rapid improvement with treatment (3–5 days).

COMPLICATIONS

- Pleural effusion
- Empyema
- Lung abscess
- Pneumatocoles
- Pneumothorax
- Bacteremia/sepsis

CODES

ICD9

- 482.2 Pneumonia due to *Hemophilus influenzae* [H. influenzae]
- 482.9 Bacterial pneumonia, unspecified
- 482.30 Pneumonia due to *Streptococcus*, unspecified

ICD10

- J14 Pneumonia due to *Hemophilus influenzae*
- J15.3 Pneumonia due to streptococcus, group B
- J15.9 Unspecified bacterial pneumonia

FAQ

- Q: What are the indications for admission and inpatient treatment of pneumonia in children?
- A: Failure of outpatient therapy; hypoxemia; inability to maintain hydration orally or dehydration; respiratory distress; apnea; toxic appearance; presence of complications such as effusion or empyema and risk factors that predispose to complications, such as age <2 months; or immunocompromised status
- Q: What is the most common causative organism of pulmonary abscess, and what is the appropriate treatment?
- A: *S. aureus* is the most common causative organism. Treatment includes IV vancomycin, IV or PO clindamycin, or PO linezolid. If MSSA is confirmed cefuroxime may be used.
- Q: What is the case fatality rate for pneumonia in hospitalized children?
- A: Based on data from 1995–1997, case fatality rates for children differ by age and are as high as 4% for children <2 years of age and 2% for children aged 2–17 years.
- Q: Which children are most likely to have systemic complications from community-acquired pneumonia? Local complications?
- A: An analysis of inpatient data from pediatric hospitals from 1997–2006 suggests that children <1 year of age are more likely to have systemic complications (e.g., sepsis, acute respiratory failure), while patients aged 1–5 years are more likely to have local complications (e.g., empyema, abscess).
- Q: What are risk factors for invasive pneumococcal disease?
- A: Conditions associated with invasive pneumococcal disease include congenital immune deficiency (e.g., B- or T-lymphocyte deficiencies) diseases associated with immunosuppressive therapy or radiation therapy (including malignancies), and solid organ transplantation and chronic cardiac disease.

PNEUMOTHORAX

Richard M. Kravitz

BASICS

EPIDEMIOLOGY

Depends on the underlying lung disease

Incidence

- Spontaneous pneumothorax:
 - Incidence: 7.4–18/100,000
 - Male > Female (6:1)
 - Peak incidence: 10–30 years
- Cystic fibrosis (CF):
 - Overall CF population: 3.5–8%
 - CF patients > 18 years: 16–20%
 - Risk factors:
 - More severe disease
 - Decreased pulmonary function (i.e., forced expiratory volume in 1 second [FEV₁] <30–50%)
 - Colonization with *Pseudomonas aeruginosa*, *Burkholderia cepacia*, or *Aspergillus*

RISK FACTORS

- Asthma
- CF
- Pneumonia
- Collagen vascular diseases

PATHOPHYSIOLOGY

- Air can enter the pleural space via the following:
 - Chest wall (i.e., penetrating trauma)
 - Intrapulmonary (i.e., ruptured alveoli)
- Usually, collapse of the lung on the affected side seals the leak.
- If a ball valve mechanism ensues, however, air can accumulate in the thoracic cavity, causing the development of a tension pneumothorax (a medical emergency).

ETIOLOGY

- Spontaneous (secondary to rupture of apical blebs)
- Mechanical trauma:
 - Penetrating injury (i.e., knife or bullet wound)
 - Blunt trauma
- Barotrauma:
 - Mechanical ventilation
 - Cough (if severe enough)
- Iatrogenic:
 - Central venous catheter placement
 - Bronchoscopy (especially with biopsy)
- Infection: Most common organisms:
 - *Staphylococcus aureus*
 - *Streptococcus pneumoniae*
 - *Mycobacterium tuberculosis*
 - *Bordetella pertussis*
 - *Pneumocystis jiroveci*
- Airway occlusion:
 - Mucus plugging (asthma)
 - Foreign body
 - Meconium aspiration
- Bleb formation (i.e., idiopathic, secondary to CF)
- Malignancy

DIAGNOSIS

HISTORY

- May be asymptomatic (pneumothorax discovered on chest film obtained for other reasons)
- Cough
- Shortness of breath
- Dyspnea
- Pleuritic chest pain that is usually sudden in onset and localized to apices (referred pain to shoulders)
- Respiratory distress
- Underlying medical problems which increase risk for pneumothorax
- Activity prior to developing symptoms that might have caused the pneumothorax:
 - Heavy lifting
 - Increased coughing

PHYSICAL EXAM

- May be normal
- Decreased breath sounds on the affected side
- Decreased vocal fremitus
- Hyperresonance to percussion on the affected side
- Tachypnea
- Tachycardia
- Shortness of breath
- Respiratory distress
- Shifting of the cardiac point of maximal impulse away from the affected side
- Shifting of the trachea away from the affected side
- Subcutaneous emphysema
- Cyanosis
- Scratch sign (heard through the stethoscope): A loud scratching sound is heard when a finger is gently stroked over the area of the pneumothorax.

DIAGNOSTIC TESTS & INTERPRETATION

- EKG:
 - Diminished amplitude of the QRS voltage
 - Rightward shift of the QRS axis (if left-sided pneumothorax)

Lab

- Arterial blood gas:
 - pO₂ can frequently be decreased.
 - pCO₂:
 - Elevated with respiratory compromise
 - Decreased from hyperventilation
- Pulse oximetry:
 - Useful for assessing oxygenation

Imaging

- Chest radiograph:
 - Radiolucency of the affected lung
 - Lack of lung markings in the periphery of the affected lung
 - Collapsed lung on the affected side
 - Possible pneumomediastinum with subcutaneous emphysema
- Chest CT:
 - Useful for finding small pneumothoraces
 - Can help distinguish a pneumothorax from a bleb or cyst
 - Helpful for locating small apical blebs associated with spontaneous pneumothoraces

Diagnostic Procedures/Other

- Pitfalls:
 - Not considering the diagnosis in otherwise healthy patients
 - Confusing the symptoms with those of an underlying lung disease
 - Inserting a needle into a cyst or bleb (can cause a tension pneumothorax with rapid respiratory compromise)

DIFFERENTIAL DIAGNOSIS

- Pulmonary:
 - Congenital lung malformations:
 - Cysts (i.e., bronchogenic cysts)
 - Cystic adenomatoid malformation
 - Congenital lobar emphysema
 - Acquired emphysema
 - Hyperinflation of the lung
 - Postinfectious pneumatocele
 - Bullae formation
- Miscellaneous:
 - Diaphragmatic hernia
 - Infections (i.e., pulmonary abscess)
 - Muscle strain
 - Pleurisy
 - Rib fracture

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Stabilization of the patient
- Evacuation of the pleural air:
 - Should be done urgently if tension pneumothorax is suspected
 - In small asymptomatic pneumothoraces, observation of the patient is indicated.
- Treat the underlying condition predisposing for the pneumothorax:
 - Antibiotics for any underlying infection
 - Bronchodilators and anti-inflammatory agents for asthma attacks
- Oxygen:
 - Used to keep SaO₂ ≥95%
 - Breathing 100% oxygen:
 - Can speed the intrapleural air's reabsorption into the bloodstream hastening lung reexpansion
 - Useful for treating smaller pneumothoraces, especially in neonates

SURGERY/OTHER PROCEDURES

- Needle thoracocentesis: Useful for evacuation of the pleural air in simple, uncomplicated spontaneous pneumothorax
- Chest tube drainage:
 - Used for evacuation of the pleural air in recurrent, persistent, or complicated pneumothoraces, and cases with significant underlying lung disease
 - Chest tube should be left in (usually 2–4 days) until:
 - Most air is reabsorbed
 - No reaccumulation of air is seen on sealing of the chest tube
- Surgical removal of pulmonary blebs:
 - Blebs have a high rate of rupturing with resultant pneumothorax.
 - In patients with established pneumothoraces, the blebs should be removed or oversewn to prevent reoccurrence of the pneumothorax (blebs have a high rate of reoccurrence if not repaired).
 - Thoracotomy versus video-assisted thoracoscopic surgery (VATS)
- Pleurodesis:
 - Used to attach the lung to the intrathoracic chest wall to prevent reoccurrence of a pneumothorax
 - Useful in cases of recurrent pneumothorax or if the pneumothorax is unresponsive to chest tube drainage (i.e., CF, malignancy)
 - Mechanism of action: The surface of the lung becomes inflamed and adheres to the chest wall via the formation of scar tissue.
 - 2 commonly used methods:
 - Surgical pleurodesis:
 - Mechanical abrasion of part of the lung or pleurectomy
 - Advantages: Very effective; low reoccurrence rate; site specific (limits affected area)
 - Disadvantages: Requires surgery and general anesthesia; contraindicated if patient is unstable
 - Chemical pleurodesis:
 - Chemicals are used to cause inflammation.
 - Chemicals commonly used: Talc, tetracycline, minocycline, doxycycline, quinacrine
 - Advantages: Requires no surgery or general anesthesia
 - Disadvantages: Less effective than surgery; generalized inflammation (rather than site-specific; makes future thoracic surgery more difficult; painful)

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

Symptomatic relief within seconds of the air being evacuated

Patient Monitoring

Sign to watch for: Inability to remove the chest tube without reaccumulation of air (suggestive of a bronchopulmonary fistula; requires surgical exploration if no improvement in 7–10 days)

PROGNOSIS

- Depends on the underlying cause of the pneumothorax
- If simple, spontaneous pneumothorax, recovery is excellent
- CF: Development of pneumothorax associated with increased morbidity and mortality (median survival after 1st pneumothorax is 4 years)

COMPLICATIONS

- Pain
- Hypoxia
- Respiratory distress
- Tension pneumothorax:
 - Hypoxia
 - Hypercarbia with acidosis
 - Respiratory failure
- Pneumomediastinum with subcutaneous emphysema
- Bronchopulmonary fistula

**CODES****ICD9**

- 512.81 Primary spontaneous pneumothorax
- 512.82 Secondary spontaneous pneumothorax
- 512.89 Other pneumothorax

ICD10

- J93.0 Spontaneous tension pneumothorax
- J93.1 Other spontaneous pneumothorax
- J93.9 Pneumothorax, unspecified

FAQ

- Q: Can a pneumothorax reoccur?
- A: Reoccurrence depends on the underlying cause of the pneumothorax. Spontaneous pneumothorax reoccurrence rates:
 - Observation alone: 20–50%
 - If thoracocentesis performed: 25–50%
 - If chest tube drainage performed: 32–38%
 - Overall reoccurrence rate: 16–52%
- Chemical pleurodesis reoccurrence rates:
 - Tetracycline: 25%
 - Talc: 8–10%
- Surgical pleurodesis reoccurrence rates:
 - VATS: 13%
 - Thoracotomy: 3%
 - Thoracotomy with pleurectomy: 0–4%
- CF reoccurrence rates:
 - If no drainage attempted: 68%
 - Thoracocentesis alone: 90%
 - Chest tube drainage alone: 72%
 - Chemical pleurodesis:
 - Tetracycline: 42–86%
 - Quinacrine: 12.5%
 - Talc: 8%
 - Surgical pleurodesis: Thoracotomy with pleurectomy: 0–4%

POLYARTERITIS NODOSA

David D. Sherry

BASICS

DESCRIPTION

An inflammatory process of small- and medium-sized muscular arteries resulting in dysfunction of affected organs

EPIDEMIOLOGY

Incidence

Extremely rare in childhood

Prevalence

Prevalence equal in boys and girls

PATHOPHYSIOLOGY

Necrotizing arteritis of small- and medium-sized arteries resulting in segmental fibrinoid necrosis

ETIOLOGY

- Idiopathic
- Postinfectious (streptococcal, hepatitis B)

DIAGNOSIS

HISTORY

- Persistent constitutional symptoms
- Bilateral calf pain
- Abdominal pain
- Weight loss
- Unexplained fever
- Headache
- Arthralgia/Myalgia
- Rashes
- Seizures
- Weakness

PHYSICAL EXAM

- Check skin for livedo reticularis, splinter hemorrhages, erythema nodosum, and necrotic digits.
- Assess BP and pulses.
- Neurologic exam for findings consistent with neuropathy (mononeuritis multiplex)
- Ophthalmologic exam for cotton wool spots
- Check testes for tenderness or swelling.
- Check muscles for tenderness, especially calves.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- ESR:
 - Usually extremely elevated; leukocytosis and thrombocytosis are seen.
- Urine analysis:
 - Proteinuria and hematuria can be present.
- Creatinine and BUN levels:
 - May be elevated
- ANA and rheumatoid factor (RF):
 - Usually negative
- Muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase, and aldolase levels):
 - Muscle involvement is common, especially in those with calf pain.
- Antineutrophil cytoplasmic antibody (ANCA):
 - Detectable in some; usually perinuclear (p) type, rarely cytoplasmic (c) type:
 - pANCA usually associated with anti-MPO, which is associated with microscopic angiitis
 - cANCA usually associated with anti-PR3, which is associated with Wegener vasculitis

– Note: The detection of ANCA, previously thought to be highly specific for vasculitis, now appears to be less so. Hence, it remains important to confirm the diagnosis of polyarteritis nodosa with biopsy or angiography.

- Hepatitis B serologies:
 - Hepatitis B has been associated in some series of patients with polyarteritis nodosa.
- Streptococcal titers:
 - Polyarteritis nodosa may develop after streptococcal infections.

Imaging

- MRI of tender muscles:
 - Short T1 inversion recovery (STIR) images may show edema, so a directed biopsy can be done to avoid false-negative muscle biopsy.
- MRA, CT angiography or angiography:
 - Can demonstrate vessel wall stenoses and aneurysm

Diagnostic Procedures/Other

Biopsy of affected tissue/organ: Usually skin, kidney, nerve, testicle

DIFFERENTIAL DIAGNOSIS

- Infection:
 - Bacterial endocarditis
 - Brucellosis
 - Influenza B (calf pain)
- Tumors:
 - Left atrial myxoma
 - Burkitt lymphoma
- Metabolic:
 - Homocystinuria
- Congenital
- Immunologic:
 - Systemic necrotizing vasculitis
 - Systemic lupus erythematosus

- Kawasaki disease
- Systemic juvenile rheumatoid arthritis
- Wegener granulomatosis
- Takayasu arteritis
- Cryoglobulinemia
- Antiphospholipid antibody syndrome
- Thrombotic thrombocytopenic purpura
- Psychologic:
 - Münchausen syndrome
- Miscellaneous:
 - Degos disease (malignant atrophic papulosis)

TREATMENT

MEDICATION (DRUGS)

- Corticosteroids are mainstay:
 - Usually start at dose of 1–2 mg/kg/d and adjust based on response
 - May initially give methylprednisolone 30 mg/kg up to 1 g/d IV for 3 days.
- Immunosuppressives such as methotrexate, azathioprine, and cyclophosphamide may be necessary.
- Hypertension should be managed aggressively.

ADDITIONAL TREATMENT

General Measures

- Medication
- Diet
- Caution:
 - Do not initiate therapy before efforts to establish the diagnosis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Initiation of steroid therapy may bring response in 1–2 weeks; however, management of specific organs affected during acute stage is essential.
- May require long-term therapy

Patient Monitoring

- Watch for the following:
 - Rising creatinine and BUN levels
 - Abdominal pain
 - Uncontrolled hypertension
- Home testing:
 - May wish to have patients monitor BP periodically if renal involvement suspected

DIET

- If renal system involved, diet low in sodium and potassium
- Possible conflicts with medications

PROGNOSIS

- May be extremely poor over the long term
- Risk is high for renal failure, hypertension, stroke, myocardial infarction, bowel infarction, and death.
- Owing to low incidence/prevalence, precise data are not available.
- Cutaneous polyarteritis nodosa is relatively benign.

COMPLICATIONS

- Hypertension
- Renal failure
- Digital necrosis
- Intestinal infarction
- Stroke

CODES

ICD9

446.0 Polyarteritis nodosa

ICD10

M30.0 Polyarteritis nodosa

FAQ

- Q: What is the difference between polyarteritis nodosa and systemic necrotizing vasculitis?
- A: Polyarteritis nodosa has a strict definition. Many children who clearly have vasculitis of the small- and medium-sized arteries do not fit precisely into the description of polyarteritis nodosa. In most ways, the search for organ involvement and therapy is the same.
- Q: Who should manage the patient with polyarteritis nodosa?
- A: Usually one discipline provides comprehensive management plan (either the pediatrician or rheumatologist). Subspecialist(s) of the affected organ systems provide management guidelines for specific organ issues.

POLYCYSTIC KIDNEY DISEASE

Christopher J. LaRosa

Andres J. Greco (5th edition)

BASICS

DESCRIPTION

- Polycystic kidney disease (PKD) is a heritable disorder with diffuse cystic involvement of both kidneys without other dysplastic elements. The term PKD is generally used to describe 2 genetically distinct syndromes:
 - Autosomal dominant polycystic kidney disease (ADPKD):
 - Saccular, epithelial-lined, fluid-filled cysts of various sizes are derived from all segments of the nephron.
 - Cysts progressively enlarge and become disconnected from the tubule of origin.
 - Usually not clinically apparent until the 3rd or 4th decade of life
 - ~2–5% of patients have early-onset disease.
 - Autosomal recessive polycystic kidney disease (ARPKD):
 - Fusiform dilations arise from the collecting ducts and maintain contact with the nephron of origin.
 - Associated hepatic abnormalities are obligatory such as biliary dysgenesis and periportal fibrosis (congenital hepatic fibrosis), with portal hypertension.
 - Affects both the kidneys and the liver in approximately inverse proportions

EPIDEMIOLOGY

- ADPKD:
 - 1 of the most common human genetic disorders; the most common renal inherited disease
 - A major cause of end-stage renal disease (ESRD) in adults
 - Frequency 1 in 400–1,000
- ARPKD:
 - Incidence of 1 in 20,000–40,000 live births
 - Exact incidence unknown owing to perinatal deaths in severe cases

RISK FACTORS

Genetics

- ARPKD:
 - Mutations in the polycystic kidney hepatic disease 1 gene (PKHD1, chromosome 6)
- ADPKD:
 - Type I ADPKD accounts for 85–90% of cases of ADPKD and is caused by mutations in the PKD1 gene (chromosome 16).
 - Large genomic deletions may encompass PKD1 and TSC2 genes, resulting in early-onset ADPKD with tuberous sclerosis.
 - Type II ADPKD is caused by mutations in the PKD2 gene (chromosome 4) and accounts for 10–15% of the cases.

- Other:
 - Presymptomatic genetic screening for ADPKD is not recommended.
 - Normotensive women with ADPKD usually have uncomplicated pregnancies.
 - Higher risk for maternal/fetal complications if there is preexisting hypertension

PATHOPHYSIOLOGY

- ADPKD is produced by decreased functional polycystins:
 - Polycystin-1 is a membrane mechanoreceptor-like protein that forms multiprotein complexes at focal adhesions, cell–cell junctions, and cilia. It is involved in cell polarity, proliferation, cell–matrix interactions, and secretion.
 - Polycystin-2 is a divalent cation channel involved in calcium signaling and intracellular calcium homeostasis, and is likely critical for cytoskeletal organization, cell adhesion, migration, and proliferation.
- ARPKD is produced by loss of functional fibrocystin/polyductin:
 - Fibrocystin/polyductin is an integral membrane receptor with extracellular protein–interaction sites that transduce intracellular signals to the nucleus.
 - Proteins affected in cystic kidney disease localize to cilia on epithelial cells. Cilia are critical for cell architecture, proliferation, apoptosis, and polarity.

ETIOLOGY

- ADPKD is generally an adult-onset, systemic disorder with cystic and noncystic manifestations. Cysts occur in the kidneys and other epithelial organs (e.g., seminal vesicles, pancreas, and liver):
 - Polycystic liver disease is the most common extrarenal manifestation.
 - Intracranial aneurysms occur in ~8%.
 - Mitral valve prolapse is the most common valvular abnormality (demonstrated in up to 25% of affected individuals).
 - Colonic diverticula in 80% with ESRD
- ARPKD is a renal and hepatic developmental disorder. The hallmark of ARPKD liver diseases is congenital hepatic fibrosis and dilation of intrahepatic bile ducts (Caroli disease).
 - Severely affected infants may have the oligohydramnios sequence at birth, and associated pulmonary hypoplasia and respiratory complications convey a high mortality risk.

DIAGNOSIS

HISTORY

- ADPKD:
 - Detailed family history is essential.
 - Most common presenting complaint in adults is pain.
 - Hypertension, gross hematuria, nephrolithiasis, and UTIs are common.
- ARPKD:
 - Oligohydramnios sequence
 - Postnatal respiratory insufficiency
 - Renal insufficiency
 - Hypertension (may be severe)
 - Hepatobiliary manifestations (cholestasis, cholangitis, liver failure, portal hypertension, hypersplenism) evolve in older patients.
- Signs and symptoms:
 - ADPKD:
 - Older children are often asymptomatic, but may present with hypertension, abdominal pain, abdominal mass, gross hematuria after trauma, proteinuria, UTI/cyst infection, renal calculi, or decreased renal function.
 - ARPKD:
 - Presentation variable
 - Severely affected infants have “Potter” oligohydramnios sequence
 - Pulmonary hypoplasia/respiratory insufficiency a major cause of neonatal mortality
 - Renal insufficiency with neonatal survival
 - Hepatobiliary complications later in course (portal hypertension, hematemesis, hepatosplenomegaly hypersplenism with pallor, petechiae)

PHYSICAL EXAM

- Clinical spectrum variable, particularly in ARPKD
- Hypertension
- Abdominal pain; tenderness at flank or costovertebral angle
- Flank mass or palpable kidneys
- Hepatosplenomegaly, varices, jaundice/icterus, abdominal ascites in ARPKD

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Metabolic panel, to include BUN, creatinine, electrolytes
- Calcium, phosphorus
- Liver function tests
- CBC
- Urinalysis
- Note: Hyponatremia is often present in the neonatal period in ARPKD.

Imaging

- Ultrasonography is the preferred screening method. Should include liver and Doppler to evaluate for portal hypertension in ARPKD
- ARPKD:
 - Kidneys enlarged with increased echogenicity and loss of corticomedullary differentiation
 - The liver may be normal in infants and young children. Over time it becomes enlarged and hyperechoic. Dilated intrahepatic biliary ducts may be seen.
 - Prenatal ultrasound after 24–30 weeks' gestation may show hyperechoic enlarged kidneys, oligohydramnios, and absence of bladder filling.
- Ultrasound diagnostic criteria for ADPKD:
 - <40 years should have at least 2 cysts in 1 of the kidneys and 1 cyst in the other kidney or 3 cysts in a single kidney.
 - ≥40 and ≤59 years should have at least 2 cysts in each kidney.
 - >60 years should have at least 4 cysts in each kidney.
- CT scan with contrast has limited use in young children owing to exposure to ionizing radiation. It is mostly used in adults with ADPKD since it can distinguish between solid and liquid renal masses.
- MRI with gadolinium: Heavy-weighted T2 MRI is the most sensitive method currently available. Can be used in both conditions. Particularly useful to evaluate liver involvement in ARPKD

DIFFERENTIAL DIAGNOSIS

- Multicystic dysplastic kidney (MCDK)
- Glomerular cystic kidney disease (GCKD)
- Acquired cystic disease may occur in patients with ESRD.
- Genetic syndromes with cystic renal dysplasia: Meckel syndrome, Jeune syndrome, Ivemark syndrome, Zellweger syndrome, Bardet-Biedl syndrome, tuberous sclerosis, and others

TREATMENT

MEDICATION (DRUGS)

- Hypertension is common in PKD. Patients respond well to diuretics, ACE inhibitors, or calcium channel blockers. ACE inhibitors or angiotensin-receptor blockers are 1st line.
- In patients with PKD and nephrolithiasis, thiazide diuretics may be used for hypercalciuria, and potassium citrate supplements if hypocitraturia is found.
- Pyelonephritis in patients with PKD may lead to infected cysts. The treatment should include antibiotics that penetrate into the cysts (quinolones, trimethoprim) if cephalosporins and aminoglycosides fail to eradicate the infection.

ADDITIONAL TREATMENT

General Measures

- No currently approved targeted treatments to cure or slow progression
- Medical management is supportive.
- Pain is the most common symptom in ADPKD and can be difficult to treat.

Additional Therapies

Activity: Patients with PKD should not participate in high-contact athletics in which the abdomen may be traumatized repeatedly. Strenuous static exercise should be avoided in hypertensive patients.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

A pediatric nephrologist should be involved in the care of children with PKD.

DIET

In both conditions, dietary changes depend on the degree of renal failure. Sodium restriction is indicated in cases of hypertension and/or edema. Caffeine should be avoided in cases of ADPKD.

PATIENT EDUCATION

- Emotional support and education of patients with PKD and their families can be obtained through the Polycystic Kidney Foundation (www.PKDcure.org) and the PKD Alliance (www.arpkdchf.org).
- As in any genetic condition, genetic counseling is indicated in these disorders

PROGNOSIS

- ADPKD:
 - The probability of being alive and not having ESRD is about 77% at age 50, 57% at age 58, and 52% at age 73 years. Median onset of ESRD 53 years (PKD1) versus 69 years (PKD2).
 - Cystic expansion occurs at a consistent rate per individual, although it is heterogeneous in the population.
 - Larger kidneys associated with more rapid disease progression
 - PKD1 mutation is more severe because more cysts develop earlier, not because they grow faster.
- ADPKD:
 - Neonatal onset is fatal in up to 50% of infants because of pulmonary hypoplasia with associated respiratory failure.
 - Patients who survive the neonatal period have a 50–80% chance of surviving at least to age 15 years.

CODES

ICD9

- 753.10 Cystic kidney disease, unspecified
- 753.19 Other specified cystic kidney disease

ICD10

- Q61.9 Cystic kidney disease, unspecified
- Q61.19 Other polycystic kidney, infantile type

FAQ

- Q: What can be done to slow the progression of renal insufficiency in ADPKD?
- A: Well-controlled BP and rapid treatment of UTIs may decrease the progression of renal failure.
- Q: Should asymptomatic older siblings of an infant with ARPKD be evaluated?
- A: Yes. An older child may have congenital hepatic fibrosis with minimal renal involvement.
- Q: Should one screen ADPKD-affected family members for the presence of cerebral vessel aneurysms if other family members have berry aneurysms?
- A: Although routine screening is not recommended, intrafamilial clustering of aneurysms has been reported and it may be advisable to screen children with MRI or cranial CT in a family with aneurysms.

POLYCYSTIC OVARY SYNDROME

Ernest M. Graham

BASICS

DESCRIPTION

Polycystic ovary syndrome (PCOS) is an endocrinologic disorder characterized by chronic anovulation, excessive androgen production, and noncyclic gonadotropin secretion.

EPIDEMIOLOGY

PCOS is relatively common:

- Usually begins soon after menarche

Genetics

At least 1 group of patients with this condition inherits the disorder, possibly by means of an X-linked dominant transmission.

PATHOPHYSIOLOGY

- The ovaries of most women with PCOS are enlarged as much as 5 cm in diameter, and the ovarian capsule is smooth, white, and thickened:
 - Beneath the capsule are numerous small follicular cysts.
 - For years, it was erroneously believed that the thick sclerotic capsule acted as a mechanical barrier to ovulation.
- Instead of the characteristic picture of fluctuating hormone levels in the normal menstrual cycle, a steady state of gonadotropin and sex steroids is produced in association with persistent anovulation.
- There is increased pulse amplitude of gonadotropin-releasing hormone (GnRH) and tonically elevated levels of luteinizing hormone (LH).
- The polycystic ovary is a sign of these underlying endocrinologic abnormalities, not a disease intrinsic to the ovary.

ETIOLOGY

- The characteristic polycystic ovary emerges when a state of anovulation persists for any length of time.
- Although the ovaries of these women produce excessive amounts of androgens, there is no inherent endocrinologic abnormality in the ovaries.
- The tonically elevated LH levels cause the ovarian stromal tissue to produce more androgens, which in turn produce premature follicular atresia.
- Because there are many causes of anovulation, there are many causes of polycystic ovaries.
- It has been suggested that heredity, central catecholamine abnormalities, psychological stress, insulin resistance, and obesity may be involved.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Hirsutism
- Amenorrhea or oligomenorrhea
- Obesity

HISTORY

- Complete menstrual history
- Amenorrhea or irregular vaginal bleeding
- Infertility

PHYSICAL EXAM

- Hirsutism
- Most patients with this syndrome are obese:
 - Obesity probably enhances the syndrome because of the decrease in sex hormone-binding globulin, but is probably not important in its pathogenesis, because the syndrome occurs in some thin women and because many obese women do not have PCOS.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hormone levels:
 - Because follicle-stimulating hormone (FSH) levels are normal or low, an LH/FSH ratio >3 (provided the LH level is not <8 mIU/mL) may be used to suggest the diagnosis in women with clinical features of PCOS.
- Androgen levels:
 - Elevated
 - Serum testosterone levels are usually between 70 and 120 ng/dL
 - Androstenedione levels are usually between 3 and 5 ng/mL.

DIFFERENTIAL DIAGNOSIS

- Congenital adrenal hyperplasia
- Cushing syndrome
- Adrenal androgen-producing tumors
- Ovarian androgen-producing tumors
- Extragonadal sources of androgens

TREATMENT

ADDITIONAL TREATMENT

General Measures

The best treatment for PCOS is oral contraceptives, unless pregnancy is desired, because these agents inhibit LH, decrease circulating testosterone levels, and increase levels of sex hormone-binding globulin, which binds and inactivates more of the testosterone in the circulation.

MEDICATION (DRUGS)

- Use oral contraceptives that contain <50 mcg estrogen and a progestin other than norgestrel, which is the most androgenic progestin in current use.
- Patients who desire fertility should be treated with ovulation-inducing agents, starting with clomiphene citrate and proceeding to human menopausal gonadotropin or GnRH agonists if unresponsive.
- If adrenal androgens (dehydroepiandrosterones [DHEAs]) are elevated, dexamethasone (0.25–0.5 mg at bedtime) should be given with the oral contraceptive to reduce adrenal androgen levels to normal.
- Patients with amenorrhea or irregular bleeding should be treated with monthly progestins, such as oral medroxyprogesterone acetate 10 mg daily for the 1st 10 days of the month, to prevent the effects of unopposed estrogens.
- Spironolactone 50–100 mg b.i.d. causes regression of the hirsutism in women with PCOS by decreasing androgenic action in the target organs.

SURGERY/OTHER PROCEDURES

Ovarian wedge resection was advocated in the past for treatment of androgen excess, but the decrease in circulating androgens occurred for only a short time, and this therapy should no longer be used.

ONGOING CARE

In the patient who has long-standing anovulation, an endometrial biopsy, with extensive sampling, should be done because of the link between unopposed estrogen and endometrial cancer.

COMPLICATIONS

- The elevated levels of androgens that are produced are associated with hirsutism.
- The lack of a normal menstrual cycle leads to irregular bleeding, amenorrhea, and infertility.

- Because of the increased levels of unopposed estrogens, there is a 3-fold increased risk of endometrial cancer and a 3-fold greater risk of breast cancer appearing in the postmenopausal years.
- PCOS in early adulthood is associated with an increased long-term risk of diabetes and dyslipidemia, independent of body mass index. ref 6

CODES

ICD9

- 256.4 Polycystic ovary syndrome
- 626.0 Absence of menstruation
- 704.1 Hirsutism

ICD10

- E28.2 Polycystic ovarian syndrome
- L68.0 Hirsutism
- N91.2 Amenorrhea, unspecified

FAQ

- Q: Can I still get pregnant if I have this syndrome?
- A: Yes. Although the best treatment for this syndrome is oral contraceptives, those patients who desire to become pregnant can be treated with ovulation-inducing agents.
- Q: I've noticed increased facial hair recently. Is there anything I can do about this?
- A: Yes. In most cases, the oral contraceptives will decrease circulating androgen levels sufficiently so that this will regress, but if increased body hair (hirsutism) persists, another drug, called spironolactone, which blocks the action of androgens, can be added to more effectively treat this.

POLYCYTHEMIA

David F. Friedman

BASICS

DESCRIPTION

Polycythemia is an elevated hemoglobin and hematocrit level caused by an absolute increase in red cell mass. Polycythemia can be divided into subcategories, as follows:

- Primary polycythemia: Primary defect of bone marrow erythropoiesis, resulting in overproduction of red cells
- Secondary polycythemia: Stimulation of red cell production by increased levels of erythropoietin (EPO), which may be appropriately secreted in response to tissue hypoxia or may be inappropriately secreted because of renal disease or from a tumor
- Apparent or relative polycythemia: Increased hematocrit without true increase in red cell mass
- "Erythrocytosis" is another term describing increased red cell mass, which some authors prefer because it avoids confusion with the diagnosis of polycythemia vera (PCV).

EPIDEMIOLOGY

- Secondary causes of polycythemia are unusual:
 - Uncorrected cyanotic congenital heart disease
 - Chronic hypoxia due to lung disease
- Genetic causes of polycythemia are rare:
 - High oxygen-affinity hemoglobins
 - 2,3-Bisphosphoglycerate (2,3-BPG) dismutase deficiency
 - EPO receptor mutations
 - VHL, HIF2, PHD2, JAK2 mutations
 - PCV: <50 reported childhood cases (0.1% of cases of PCV are in children)

RISK FACTORS

Genetics

- High oxygen-affinity hemoglobins: Autosomal dominant
- PFCP:
 - Usually autosomal dominant
 - Finnish clusters described
- VHL gene mutation: Defect of oxygen sensing:
 - Autosomal recessive
 - Chuvash polycythemia
- 2,3-BPG mutase deficiency: Autosomal recessive

GENERAL PREVENTION

- There are no preventive measures for primary conditions such as PCV, hemoglobinopathies, or primary familial and congenital polycythemia (PFCP).
- Treatment of the underlying condition, such as correction of a cyanotic heart lesion or removal from high altitude, will prevent the development of secondary polycythemia.

PATHOPHYSIOLOGY

- Primary polycythemias:
 - PCV: Myeloproliferative disease with abnormal multipotent progenitor cells with abnormally high sensitivity to EPO; EPO levels are normal.
 - Mutation V617F in JAK2 gene found in most PCV but may not be initiating event
 - PFCP: Red cell precursors highly sensitive to EPO; usually autosomal dominant; some families have truncation mutations in the EPO receptor (EPOR), leading to a loss of down-regulation of EPO signaling.
- Secondary polycythemias: Relative tissue hypoxia resulting from reduced oxygen delivery:
 - Chronic lung disease and inadequate oxygenation
 - Cyanotic heart disease: Desaturation of arterial blood due to admixture of oxygen-poor venous blood from right-to-left shunt
 - Circulatory: Right-to-left shunting outside the heart
 - Hemoglobinopathy: Abnormal oxygen transport to tissues because of a mutant hemoglobin with higher than normal oxygen affinity and decreased oxygen delivery
 - At the partial pressure of oxygen of the tissues, high oxygen-affinity hemoglobins release less oxygen than normal, resulting in hypoxia.
 - Tissue hypoxia leads to supernormal secretion of EPO by the kidney and increased production of red cells from the marrow.
 - 2,3-BPG deficiency: Increased oxygen affinity of hemoglobin because of reduced level of red cell 2,3-BPG
 - Genetic defect of the hypoxia-sensing mechanism causes familial polycythemia: VHL—von Hippel-Lindau gene, HIF2—Hypoxia inducible factor, PHD2—prolyl hydroxylase domain
 - Inappropriate EPO secretion associated with kidney disease (not end stage, where EPO is usually deficient)
 - Malignant tumor that secretes EPO

DIAGNOSIS

HISTORY

- Diagnosis of congenital heart disease, uncorrected or partially corrected
- History of cyanosis
- Delivery history
- Baby held below placenta
- Delayed clamping of cord
- Twins of disparate size
- Transfusion history
- Cigarette smoking
- Prolonged time spent at high altitude
- Family history of cyanosis, high hematocrit, need for phlebotomy
- Cobalt poisoning: Homemade beer and magnets may contain cobalt.

PHYSICAL EXAM

Signs and symptoms:

- Central and acral cyanosis
- Signs of dehydration:
 - Dry mucous membranes
 - No tears
 - Poor skin turgor
- Heart murmur
- Clubbing
- Plethora:
 - Conjunctival
 - Mucous membranes
 - Nail beds
- Splenomegaly:
 - Present in 75% of patients with PCV
- Headache, paresthesias, dizziness, syncope
- Transient blindness
- Decreased exercise tolerance, respiratory distress, dyspnea on exertion, oxygen requirement
- Pruritus
- Lethargy

ALERT

- Fingerstick CBC: Squeezing the finger to collect a specimen may give a falsely elevated hematocrit.
- Arterial blood gas: Cannot interpret low pO₂ if specimen is mixture of venous and arterial blood
- Relative polycythemia: Red cell mass normal
- Decreased plasma volume with normal red cell mass: Seen in adult cigarette smokers
- Dehydration: Elevated hematocrit due to hemoconcentration
- Hemoglobin electrophoresis does not identify all high-affinity hemoglobins:
 - Many co-migrate with normal hemoglobins.
 - Hemoglobin electrophoresis cannot be interpreted if the patient has been transfused within the past 3 months.
- Whole-blood P50: Fresh specimen required; normal samples different from red cell lysates, purified hemoglobin

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial:
 - CBC
 - Serum EPO: To distinguish primary from secondary polycythemia, but much overlap in EPO levels
 - Pulse oximetry: To determine percent saturation of hemoglobin
 - Arterial blood gas with co-oximetry: pO₂ low in lung disease or right-to-left shunt
- To investigate high oxygen-affinity hemoglobin:
 - Hemoglobin electrophoresis
 - Whole-blood P50 and red cell 2,3-BPG level
 - Met-hemoglobin level: Apparent cyanosis
- To investigate PCV:
 - Total red cell mass measurement by chromium 51-tagged red cells: Top normal range (adults) is <36 mL/kg in men, <32 mL/kg in women, or <25% above the predicted normal range normalized by body surface area; gold standard test for true polycythemia

- Bone marrow aspirate with chromosomes: Morphologic evidence of myelodysplastic syndrome; abnormal clone by karyotype or X-chromosome inactivation studies
- Serum B₁₂, unsaturated B₁₂-binding capacity (UB12BC): Markedly elevated in PCV
- Erythroid progenitor culture studies for burst-forming units–erythroid (BFU-E) that grow independent of EPO
- Genetic testing for V617F JAK2 mutation
- Other testing:
 - Total blood viscosity: Rarely measured
 - Iron studies: Serum iron (Fe), total iron-binding capacity (TIBC), ferritin
- BUN level, creatinine level, and urinalysis: Underlying renal disease

Imaging

- Echocardiography: To evaluate shunting
- Chest radiograph: To evaluate chronic lung disease, lung malignancies
- Abdominal ultrasound: To evaluate renal disease, spleen size, abdominal tumors
- Sleep study: To look for nighttime airway obstruction and desaturation

DIFFERENTIAL DIAGNOSIS

- Primary polycythemia:
 - PCV
 - Myeloproliferative disease
 - Thrombocytosis or leukocytosis
 - PFCP
- Secondary polycythemia:
 - Cyanotic congenital heart disease
 - Eisenmenger syndrome
 - Pulmonary hypertension from long-standing uncorrected congenital heart disease with left-to-right shunting (acyanotic) leads to elevated right-sided pressures and reversal of shunt to flow right to left, leading to cyanosis.
 - Extreme high altitude
 - Compensation for low O₂ pressure includes an increase in red cell mass.
 - Alveolar hypoventilation: Neuromuscular
 - Muscular dystrophy
 - Poliomyelitis
 - Pickwickian syndrome
 - Central hypoventilation
 - End-stage lung disease
 - Abnormal hemoglobins with high O₂ affinity
 - 2,3-BPG mutase deficiency
 - Inappropriate EPO secretion may occur in renal disease, including posttransplantation erythrocytosis after renal allografting; iatrogenic; excessive red cell transfusion, possible in trauma, resuscitations, neonatal blood exchange
 - Excessive exogenous dosing of EPO (blood doping by competitive athletes)
 - Neonatal polycythemia
 - Twin-to-twin or placental transfusion
 - Cobalt poisoning
- Relative polycythemia:
 - May be seen in smokers
 - Dehydration or diuretic use

TREATMENT

MEDICATION (DRUGS)

- Hydroxyurea, alkylating agents, ³²P (in adults) to suppress red cell production in PCV
- Interferon: For PCV

ADDITIONAL TREATMENT

General Measures

- Observation only: Many patients require no therapy.
- Therapeutic phlebotomy:
 - Removal of red cells every 3–4 weeks to maintain hematocrit below threshold for symptoms; usually <50–55%
 - Patients with Eisenmenger syndrome and symptoms of hyperviscosity may not tolerate intravascular volume reduction if a large volume is removed at 1 time.
 - Patients on a chronic phlebotomy program may require iron supplementation.
 - Neonates with polycythemia may require therapeutic phlebotomy removing a series of small volumes of blood and replacing with plasma or albumin to reduce hematocrit while maintaining volume.
- Supplemental oxygen: Helpful for secondary polycythemia from underlying lung disease; may not help in right-to-left shunt

ISSUES FOR REFERRAL

- Persistent high hematocrit that is not clearly related to dehydration or neonatal causes
- Unexplained cyanosis

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Watch for the following:

- Insufficient phlebotomy
- Headache, dizziness, syncope
- Decreased exercise tolerance between phlebotomies
- Progression of myelodysplastic disease
- Thrombocytopenia
- Bleeding or thrombosis
- Stroke
- Severe headache
- Jaundice, ascites

PROGNOSIS

Depends on underlying condition:

- High oxygen-affinity hemoglobinopathies: Very good for normal life
- PCV: Guarded, as may progress to myelodysplastic syndrome
- Eisenmenger syndrome: Poor owing to progressive pulmonary hypertension and cor pulmonale

COMPLICATIONS

- Hyperviscosity:
 - Blood viscosity increases dramatically when hematocrit is >65%.
 - Decreased exercise tolerance, dyspnea, and mental status changes from slowed microcirculation in the CNS
- Thrombosis:
 - Budd-Chiari syndrome from hepatic vein thrombosis, deep vein thrombosis, pulmonary embolus
 - Seen especially in PCV
- Stroke: From hyperviscosity

ICD10

D75.1 Secondary polycythemia

FAQ

- Q: Can a child with uncorrected cyanotic congenital heart disease be supported indefinitely with phlebotomy?
- A: No. Phlebotomy relieves the symptoms of hyperviscosity, but does not stop the progression of pulmonary hypertension.
- Q: When should a child with polycythemia be referred to a pediatric hematologist?
- A: If the high hematocrit is persistent and not clearly related to dehydration or neonatal causes (e.g., placental transfusion), the child should be referred to a pediatric hematologist. Unexplained cyanosis is also a reason for referral. In the case of congenital heart disease, the pediatric cardiologist may be comfortable managing polycythemia without consultation with a hematologist.

POLYPS, INTESTINAL

Steven Liu
Petar Mamula

BASICS

DESCRIPTION

- Intestinal polyps are abnormal tissue growths protruding from the intestinal mucosa into the lumen. They are commonly solitary lesions, but may also be multiple in number and associated with various polyposis syndromes.
- Classification by gross appearance:
 - Pedunculated: Mushroom-like and attached to mucosa with a narrow stalk
 - Sessile: Elevated, flat lesions broadly attached to mucosa
- Types of polyps
 - Single, juvenile polyp
 - Juvenile polyposis syndrome (>3–5 juvenile polyps):
 - Juvenile polyposis of infancy
 - Juvenile polyposis coli (colonic involvement only)
 - Generalized juvenile polyposis
 - Peutz-Jeghers syndrome
 - Familial adenomatous polyposis (FAP)
 - Other polyposis syndromes

EPIDEMIOLOGY

- Juvenile polyps are the most common childhood polyps:
 - Account for >90% of polyps seen in children
 - 1–2% of asymptomatic children are estimated to have juvenile polyps
 - Typically present between 2–5 years of age
 - Twice as common in boys than girls
 - >5 juvenile polyps should raise a suspicion for juvenile polyposis coli.
- Average age at onset of adenomatous polyps in FAP is 16 years.

Prevalence

- Juvenile polyposis syndrome: 1 in 100,000 to 1 in 160,000
- Peutz-Jeghers syndrome: 1 in 25,000 to 1 in 300,000
- FAP: 1 in 5,000 to 1 in 17,000

RISK FACTORS

Family history of polyposis syndrome

Genetics

Different genes and inheritance patterns with various polyposis syndromes:

- Juvenile polyposis syndrome:
 - Autosomal dominant with variable penetrance
 - Mutations in SMAD4 and BMPR1A genes, involved in transforming growth factor- (TGF-) signal transduction
- FAP:
 - Autosomal dominant
 - Mutation in adenomatous polyposis coli (APC) tumor suppressor gene

- Peutz-Jeghers syndrome:
 - Autosomal dominant
 - Mutations in STK11/LKB1 tumor suppressor gene are associated
- Cowden syndrome and Bannayan Riley Ruvacaba syndrome (BRRS)
 - Autosomal dominant
 - Associated with mutations in PTEN gene

PATHOPHYSIOLOGY

Mutations in tumor suppressor genes likely lead to dysregulation of cell proliferation and apoptosis in polyposis syndromes.

COMMONLY ASSOCIATED CONDITIONS

- Juvenile polyposis syndrome, Cowden syndrome, and BRRS all have juvenile polyps as part of their manifestations.
- Peutz-Jeghers syndrome is characterized by multiple GI pedunculated hamartomatous polyps.
- FAP and Turcot syndrome are characterized by multiple adenomatous polyps.

DIAGNOSIS

HISTORY

- Family history of polyps or polyposis syndromes is essential to obtain.
- Presence and amount of blood in stool
- Signs and symptoms:
 - Frequently asymptomatic
 - Painless rectal bleeding is typical presentation
 - Iron deficiency anemia
 - Prolapsing rectal lesion
 - Abdominal pain or obstruction from intussusception
 - Diarrhea

PHYSICAL EXAM

- Digital rectal exam may identify rectal polyp.
- Pigmentation of skin and mucous membranes consistent with Peutz-Jeghers syndrome
- Mucocutaneous lesions such as facial trichilemmoma, oral fibromas, and acral keratosis seen in Cowden syndrome
- Mental retardation, macrocephaly, lipomatosis, hemangiomas, and genital pigmentation seen in BRRS

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool test for occult blood may be positive.
- CBC can assess degree of anemia and also for baseline hemoglobin before polypectomy.
- PT/PTT should be considered before polypectomy due to risk of bleeding.
- Genetic testing can be considered if a polyposis syndrome is suspected.

Imaging

Radiologic studies are not the most effective methods of identifying polyps, but can be used:

- Barium enema may identify colonic polyps.
- Upper GI with small bowel study may locate presence of small bowel polyps.
- Use of CT and MR colonography has been studied mainly in adults.

Diagnostic Procedures/Other

- Full colonoscopy with polypectomy is the preferred test to perform.
- Flexible sigmoidoscopy may miss polyps in proximal colon:
 - 32% of juvenile polyps are located proximal to splenic flexure.
 - 12% of patients with juvenile polyps only had polyps located proximal to splenic flexure.
- Capsule endoscopy may be useful to identify small bowel polyps.

Pathological Findings

- Polyp pathology cannot be determined by gross visualization, hence polyps must be removed for histologic exam.
- Juvenile polyps:
 - Hamartomatous, but occasionally capable of adenomatous changes
 - Potential of malignancy in a solitary juvenile polyp is extremely low, but is increased in juvenile polyposis syndrome.
- Peutz-Jeghers syndrome:
 - Hamartomatous
 - Microscopically have hyperplasia of the smooth muscle layer, extending in an arborizing, tree-like manner
 - Relatively low potential of GI malignancy, but increased potential in other organs such as breast, pancreas, ovary, testicle, and uterus
- FAP:
 - Adenomatous polyps
 - Lifetime risk for colorectal cancer is 100%
 - Increased association with hepatoblastoma and desmoids tumors

DIFFERENTIAL DIAGNOSIS

- Because juvenile polyps often present with rectal bleeding, the differential diagnosis for lower GI bleeding should be considered:
 - Anal fissure
 - Meckel's diverticulum
 - Infectious enterocolitis
 - Inflammatory bowel disease
 - Intussusception
 - Vascular malformation
 - Hemorrhoids
 - Hemolytic uremic syndrome
 - Henoch-Schönlein purpura
 - Rectal trauma
 - Neoplasm

TREATMENT

MEDICATION (DRUGS)

Administration of some NSAIDs may slow progression of adenomatous polyps.

ADDITIONAL TREATMENT

General Measures

Full colonoscopy with polypectomy is an essential diagnostic and therapeutic tool. Removal of GI polyps can help to control symptoms and reduce the risk of malignancy.

ISSUES FOR REFERRAL

Patients suspected of having a polyp or polyposis syndrome should be referred to a gastroenterologist for evaluation. Patients with polyposis syndromes should be referred to a tertiary care center for genetic counseling.

SURGERY/OTHER PROCEDURES

- When adenomatous polyps are identified in FAP, prophylactic colectomy should be considered.
- Colectomy should also be considered in other polyposis syndromes with innumerable polyps or polyps showing premalignant changes.
- The main surgical options include a subtotal colectomy with ileorectal anastomosis (IRA) or a proctocolectomy with ileal pouch–anal anastomosis (IPAA).

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- For solitary juvenile polyps, follow-up with stool guaiac check and CBC 6 months after polypectomy. Repeat colonoscopy is indicated with any abnormalities.
- For polyposis syndromes, screening recommendations differ depending on the syndrome:
 - Typically involve surveillance colonoscopies every 1–3 years depending on findings.
 - Asymptomatic children with an APC mutation for FAP should have annual colonoscopies starting at 10–12 years of age.
 - Published guidelines for follow-up of patients with various polyposis syndromes are available.
- Disposition:
 - Most uncomplicated polypectomies can be performed on an outpatient basis.

CODES

ICD9

- 211.3 Benign neoplasm of colon
- 759.6 Other hamartoses, not elsewhere classified

ICD10

- D12.6 Benign neoplasm of colon, unspecified
- D13.9 Benign neoplasm of ill-defined sites within the digestive system
- Q85.8 Other phakomatoses, not elsewhere classified

FAQ

- Q: What is the potential of developing cancer from a polyp?
- A: Risk of neoplasia is dependent on the type of polyp:
 - Patients with solitary juvenile polyps have essentially no increased risk of colorectal carcinoma.
 - Patients with juvenile polyposis syndrome have been reported to have up to a 65% chance of developing GI cancer, with the risk of malignancy commencing from age 20.
 - Patients with Peutz-Jeghers syndrome have been reported to have almost a 50% chance of developing cancer in the intestinal tract or other organ systems.
 - Patients with FAP have a 100% lifetime risk of developing colorectal cancer.
- Q: Is a flexible sigmoidoscopy sufficient for the detection of polyps?
- A: ~37% of patients with juvenile polyps have polyps proximal to the splenic flexure, and 12% of patients have only proximal colon polyps. A flexible sigmoidoscopy would not identify these polyps, making it necessary to perform a full colonoscopy.
- Q: What is your management recommendation for a patient with painless rectal bleeding that stops on its own?
- A: It is widely believed that pedunculated polyps can auto-amputate after outgrowing their blood supply, although there is no objective evidence supporting this. If there is no family history of a polyposis syndrome, the patient can be followed with stool guaiac checks and a CBC in 6 months. If there is a family history, then referral to a gastroenterologist for full colonoscopy is indicated.
- Q: How many polyps can patients have?
- A: Patients with juvenile polyposis syndrome often have 50–200 polyps distributed throughout the colon. Patients with FAP may have a few to over a thousand polyps in the colon.

PORENCEPHALY CORTICAL DYSPLASIA/NEURONAL MIGRATION DISORDERS—MALFORMATIONS OF CORTICAL DEVELOPMENT

Irfan Jafree

Peter M. Bingham (5th edition)

BASICS

DESCRIPTION

- Developmental brain malformations are associated with epilepsy and mental retardation.
- Associated features may include autism, learning difficulties, hypotonia, spasticity, movement disorders or orthopedic abnormalities.
- Blindness, hearing abnormalities and feeding difficulties may be present.
- Key histologic feature: Structural organization of the cerebral cortex is abnormal.
- Diffuse (lissencephaly, polymicrogyria, hemimegalencephaly) or focal regions of the brain as in focal cortical dysplasia (CD), tuberous sclerosis complex, neurofibromatosis, porencephaly
- General rule: The more extensive the malformation, the greater the degree of neurologic impairment.
 - Malformations of cortical development affecting wide regions of cortex: Etiologic agent likely <20 weeks' gestation.
 - Lissencephaly (smooth brain): Loss of cerebral cortical convolutions (sulci) and cortical laminations. May occur in combination with agyria–pachygyria.
 - Agyria–pachygyria: More heterogeneous pathologic classification in which there are broad regions of cortex without gyri (similar to lissencephaly), but focal areas of thickened cortical gyri also may be present.
 - Hemimegalencephaly: Rare condition in which 1 cerebral hemisphere is enlarged and may exhibit agyric–pachygyric features. Normal-sized hemisphere may also contain subtle, focal abnormalities.
 - Malformations of cortical development affecting focal regions of cortex: Etiologic agent likely >20 weeks' gestation
 - Dysplastic cortical architecture: Focal regions of disorganized cortical architecture and abnormally shaped neurons
 - Heterotopia: Clusters of neurons found within the white matter (where neurons are not typically found) May be nodular and confined to small region in cortex or adjacent to the ependyma (nodular forms) May extend across portions of a hemisphere (laminar heterotopia).
 - Schizencephaly: Nonoculated cavities or clefts (unilateral or bilateral) in the brain that communicate with the system and/or subarachnoid space.
- Recent classification scheme for malformations of cortical development:
- Disorders of cell proliferation: Tuberous sclerosis complex.
 - Focal CD
 - Hemimegalencephaly
 - Microcephaly syndromes.
 - Dysembryoblastic neuroepithelial tumors
 - Ganglioglioma
 - Gangliocytoma.
- Neural migration disorders (NMDs):
 - Lissencephaly type I (classical):
 - Miller–Dieker syndrome
 - X-linked lissencephaly

- Lissencephaly type II (cobblestone):
 - Walker–Warburg syndrome
- Muscle–eye–brain disease: Fukuyama congenital muscular dystrophy
- Subcortical band heterotopia (double cortex syndrome)
- Periventricular nodular heterotopia.
- Disorders of brain organization:
 - Polymicrogyria
 - Schizencephaly
- Taylor type I dysplasia: Microdysgenesis
- Malformations, not otherwise classified:
 - Mitochondrial disorders
 - Peroxisomal disorders (e.g., Zellweger syndrome)

EPIDEMIOLOGY

- Incidence varies according to syndrome.
- Some children die at birth or in early childhood, owing to seizures, respiratory failure.
- Epilepsy may be associated with malformations of cortical development. Malformations of cortical development may underlie infantile spasms (especially tuberous sclerosis complex and lissencephaly).
- Estimated that 20–40% of specimens resected during epilepsy surgery contain malformations of cortical development

PATHOPHYSIOLOGY

- Most characteristic feature: Disruption of normal cerebral cortical architecture
- Lissencephaly:
 - Few cerebral convolutions (sulci and gyri) in the entire brain
 - Layering of cortex abnormal
 - Neurons often abnormally shaped, oriented incorrectly within cortex
- Heterotopias:
 - Clusters of neurons located inappropriately in the subcortical white matter
 - Large bilateral subcortical heterotopia found in patients with double cortex syndrome
 - Clusters of heterotopic neurons line the ventricles in periventricular nodular heterotopia.
- Disruption of the synaptic connections between various brain regions likely accounts for epilepsy and other neurologic problems such as mental retardation or autism associated with cortical malformations.

ETIOLOGY

CD/NMDs result from a variety of in utero causes, including infectious, toxic–metabolic, and ischemic insults. Several cortical malformations result from single gene mutations.

- Genetic:
 - Lissencephaly may occur as a sporadic syndrome, but has been associated with mutations in select genes.
 - Miller–Dieker lissencephaly syndrome: Chromosome 17p13.3
 - Lissencephaly with cerebellar hypoplasia: Chromosome 7q22
 - X-linked lissencephaly: Chromosome Xq22

- Periventricular nodular heterotopia: Chromosome Xq28
- Subcortical band heterotopia: Chromosome Xq22
- Tuberous sclerosis complex: Chromosome 9q34, chromosome 16p13
- Neurofibromatosis (NF) 1 Autosomal dominant, Chromosome 17q11.2 (Von Recklinghausen disease), Neurofibromin protein abnormal.
- NF2 chromosome 22q12.2 Merlin gene, Autosomal dominant, associated with MEN syndromes.
- Fukuyama congenital muscular dystrophy: Chromosome 9q31
- Other lissencephaly-associated syndromes, including the Norman–Roberts, Neu–Laxova, and Walker–Warburg syndromes, are believed to have an autosomal recessive pattern of inheritance.
- The HARD syndrome (hydrocephalus, agyria, retinal dysplasia and encephalocele) is autosomal recessive.
- Cortical abnormalities also occur in trisomy 13, 18, and 21, chromosome 22q deletion syndrome.
- Infectious:
 - Polymicrogyria, pachygyria–agyria, and heterotopias may occur in the setting of toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes virus (TORCH) infections of the CNS during early development. May also occur as a consequence of intrauterine hypoxic–ischemic injury.
- Ischemic/hemorrhagic:
 - Polymicrogyria and heterotopia may occur in the setting of in utero hypoxic–ischemic injury or hemorrhage.
 - Schizencephaly may reflect intrauterine infarction and is characterized by a large cleft in one or both hemispheres.
 - Porencephaly—porencephalic cysts—which may result from intrauterine hypoxic–ischemic injury, are intraparenchymal cavities that communicate with the ventricular system.
- Toxins:
 - Ethanol
 - Ionizing radiation
 - Carbon monoxide
 - Isotretinoin
 - Methyl mercury
 - Antiepileptic drugs (phenytoin/fosphenytoin, depakote)
- Metabolic:
 - CD/NMDs may be associated with Zellweger syndrome, neonatal adrenoleukodystrophy, Menkes disease, GM₂ gangliosidosis, and/or pyruvate dehydrogenase deficiency.
- Miscellaneous:
 - Cortical malformations may occur in syndromes featuring other anomalies: chromosome 22q11 deletion, Smith–Lemli–Opitz, Potter, and Meckel syndromes.

DIAGNOSIS

HISTORY

- Family history of genetic or chromosomal syndromes, family members with mental retardation, neurologic dysfunction or seizures, and infant deaths associated with profound neurologic impairment
- Parental consanguinity; maternal alcohol and drug use
- Subtle manifestations of neurocutaneous syndromes may be identified in family members with skin lesions or, in more overt cases, as individuals with CNS or other cancers, as in tuberous sclerosis or neurofibromatosis.
- Infants: Sudden head or truncal movements (infantile spasms)

PHYSICAL EXAM

- Some children with malformations of cortical developments have no overt signs of dysfunction, whereas others have global neurologic impairment.
- Developmental delay, seizures (especially infantile spasms), and focal neurologic signs may be observed.
- Plot head circumference: Microcephaly or macrocephaly is common.
- Some children will have dysmorphic facies characterized by hypotelorism, malformed skull, and midline deformities.
- Miller–Dieker lissencephaly syndrome: Thin upper lip and microcephaly
- Cutaneous manifestations such as hypomelanotic lesions (ash leaf spots), facial angiofibromas, a shagreen patch, or other regions of hyperpigmentation/hypopigmentation may identify patient with neurocutaneous disorders such as tuberous sclerosis. Neurofibromas, axillary and inguinal freckling, Café au lait spots, plexiform neurofibromas in neurofibromatosis.
- Funduscopic examination may reveal retinal hamartomas in tuberous sclerosis and Lisch nodules in NF1.
- A linear sebaceous nevus on the forehead is associated with hemimegalencephaly.
- Hypomelanosis of Ito: Associated with malformations of cortical development
 - Physical examination tricks:
 - Wood lamp of skin: To identify subtle depigmented areas
 - Tooth enamel pits: Tuberous sclerosis

DIAGNOSTIC TESTS & INTERPRETATION

- Routine blood tests and cerebrospinal fluid usually normal
- Lysosomal enzymopathies characteristic of disorders such as gangliosidoses may be identifiable via blood tests.
- Chromosomal karyotyping/fluorescence in situ hybridization (FISH) analysis: Miller–Dieker, chromosome 22q deletion, trisomies, for diagnosis and genetic counseling
- Screening for select gene mutations is available through several research labs and will become commercially available (<http://www.genetests.org>).

- EEG adjunct in diagnosing seizures. Characteristic findings may be sharp waves, spikes, hypsarrhythmia (in infantile spasms), and slow spike-wave discharges (Lennox–Gastaut syndrome). In children with developmental delay, formal neuropsychiatric assessment may be useful.

Imaging

- Brain MRI is essential to classify cortical malformations. Brain CT may be useful but has lower resolution.
- Research/quaternary epilepsy centers: Functional brain imaging, positron-emission tomography, to assess regional metabolic changes associated with epilepsy

DIFFERENTIAL DIAGNOSIS

- In patients presenting with even subtle neurologic symptoms or signs, consider a structural CNS abnormality.
- Some developmental anomalies may be difficult to distinguish from brain tumors.
- Epilepsy in pediatric patients may be a manifestation of a neurocutaneous disorder such as tuberous sclerosis.
- Tumors, vascular malformations, and in utero ischemic insults also should be considered.

TREATMENT

MEDICATION (DRUGS)

- Neurologic consultation is recommended to help manage children with cortical malformations and epilepsy.
- Virtually all children with malformations of cortical development and seizures will require anticonvulsant drugs for adequate seizure control. Regimens must be tailored to account for drug interactions, potential side effects, and long-term efficacy in seizure control.
- See chapter “Infantile Spasms.”

SURGERY/OTHER PROCEDURES

- A significant proportion of children with cortical malformations and seizures will not respond to medications and will require epilepsy surgery to remove the seizure focus within the malformation of cortical development.
- In some cases, surgery is a small focal resection; in rare cases, removal of an entire hemisphere is indicated.
- Some cases are not amenable to epilepsy surgery; other treatment modalities include the vagal nerve stimulator or the ketogenic diet.

ONGOING CARE

- When to expect improvement:
 - Adequate seizure control may be difficult in these patients.
 - Cognitive, behavioral, and motor deficits may benefit somewhat from education, behavioral interventions, and physical therapy.
 - In children with a cortical malformation and refractory seizures, resective epilepsy surgery can provide a safe and successful alternative when anticonvulsant medications do not help.

- Signs to watch for:
 - Persistent change in mental status, which could indicate status epilepticus.
 - Development of new neurologic symptoms in patients with tuberous sclerosis could indicate tumor progression or hydrocephalus.

PROGNOSIS

Most patients with CD/NMDs will continue to suffer from seizures and cognitive impairment as well as from other neurologic and behavioral abnormalities.

PORTAL HYPERTENSION

Rose C. Graham

BASICS

DESCRIPTION

- Definition: Elevation of portal blood pressure greater than 5–10 mm Hg
- Portal hypertension may be pre-, intra-, or posthepatic in origin.
- A major cause of morbidity and mortality in children with chronic liver disease

PATHOPHYSIOLOGY

- An increase in portal resistance and increased portal blood flow are the main pathogenic factors initiating the process of portal hypertension:
 - Other factors including hyperdynamic circulation, expanded intravascular volume, systemic arteriolar vasodilatation, decreased splanchnic arteriolar tone, and humoral factors (i.e., nitric oxide) contribute to increased portal blood flow and pressure.
- Decompression of the high venous pressure through portosystemic collaterals leads to all the major sequelae of portal hypertension:
 - Splenomegaly
 - Varices (esophageal, gastric)
 - Hemorrhoids
 - Caput medusa (periumbilical varices)
 - Ascites
 - Hepatic encephalopathy

DIAGNOSIS

HISTORY

- History of umbilical catheterization
- History of hepatitis, abdominal trauma, clotting disorder, contraceptive pills, underlying medical problem such as cystic fibrosis, tyrosinemia, Wilson disease
- Ingestion of excessive amounts of vitamin A
- Hematemesis or melena: Upper GI tract bleed from varices may be the 1st sign of long-standing silent liver disease or previously undiagnosed portal vein thrombosis.

PHYSICAL EXAM

- Splenomegaly
- Hepatomegaly may or may not be present.
- Ascites (distension, fluid wave)
- Hemorrhoids
- Prominent vascular pattern on the abdomen (caput medusa)
- Digital clubbing
- Telangiectasia
- Palmar erythema
- Growth failure

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC and smear: Detect hypersplenism, GI tract blood loss, and chronic liver disease
- PT/INR and PTT: Detect coagulation defects
- Hepatic function panel includes liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST]), albumin (measure of hepatic function), alkaline phosphatase, and γ -glutamyl transferase (GGT; may be elevated with cholestasis and bile duct injury)
- Additional laboratory testing to determine the cause of underlying liver disease, depending on clinical scenario (see chapter on “Cirrhosis” for more details)

Imaging

- Doppler ultrasound:
 - Liver size and echogenicity
 - Biliary anatomy
 - Spleen size
 - Renal cysts
 - Presence of ascites
 - Vessel diameter
 - Direction of blood flow
 - Presence of esophageal varices
- Esophagogastroduodenoscopy (EGD): Definitively identifies the presence of esophageal varices and determines if variceal rupture is the cause of GI tract bleeding

Diagnostic Procedures/Other

- Liver biopsy: Identify the underlying cause of the portal hypertension
- Hepatic venous wedge pressure gradient correlates and selective angiography are not used in pediatrics because of a lack of well-documented pediatric measurements and lack of a favorable risk–benefit ratio.

DIFFERENTIAL DIAGNOSIS

- Prehepatic causes:
 - Portal vein thrombosis with cavernous transformation (increased risk with umbilical vein catheterization, sepsis, dehydration, hypercoagulable state)
 - Splenic vein thrombosis
- Intrahepatic causes:
 - Hepatocellular disorders: Viral hepatitis, α_1 -antitrypsin deficiency, chronic hepatitis, autoimmune hepatitis, Wilson disease, glycogen storage disease, tyrosinemia, schistosomiasis, peliosis hepatitis, vitamin A toxicity
 - Biliary tract disorders: Extrahepatic biliary atresia, ductal plate malformation/congenital hepatic fibrosis, intrahepatic cholestasis syndromes, primary sclerosing cholangitis, choledochal cyst, cystic fibrosis
- Posthepatic causes:
 - Budd-Chiari syndrome: Occlusion of suprahepatic inferior vena cava or hepatic veins by congenital web, tumor, or thrombus
 - Congestive heart failure
 - Veno-occlusive disease of hepatic venule

TREATMENT

MEDICATION (DRUGS)

- β -Blockade: Nonselective β -blockers, such as propranolol, have been shown to be effective in preventing both initial and recurrent variceal bleeds in adults. Data are limited on use of β -blockers in children with portal hypertension to prevent primary or secondary variceal bleeding. Use in children for this indication is empiric and mainly based on adult data:
 - Mechanisms include lowering portal blood flow and thus portal pressure by both β_2 -blockade, which increases splanchnic tone, and β_1 -blockade, which decreases cardiac output.
 - Propranolol, specifically, may also decrease collateral circulation.
 - β -Blocker effect on decreasing cardiac output may blunt an adaptive cardiovascular response (elevated heart rate) in the event of a hemorrhage; these medications should not be used in patients with asthma or diabetes.
 - Owing to lack of sufficient data, routine use of β -blockers in children for primary or secondary prevention of variceal bleeding cannot be recommended.
- Diuretic therapy (spironolactone +/- chlorothiazide) when ascites is present

ADDITIONAL TREATMENT

General Measures

Chronic management of varices:

- Surveillance endoscopy and primary prophylaxis in pediatric patients with portal hypertension who have not had a 1st variceal bleed are controversial and not yet recommended.
- Long-term management of patients with portal hypertension who have had a variceal bleed depends on the underlying cause of the portal hypertension and may include endoscopic sclerotherapy or ligation, portosystemic shunts, and liver transplantation.

Additional Therapies

- Endoscopic sclerotherapy: Reduces rebleeding episodes and long-term mortality when initiated after the 1st bleeding episode; it is unclear whether it will prevent occurrence of a 1st bleed.
- Endoscopic band ligation therapy may be as effective as and carry fewer complications compared with sclerotherapy. Endoscopic band ligation is limited in smaller patients by esophageal size.

SURGERY/OTHER PROCEDURES

- Portosystemic shunts:
 - May be helpful in the setting of prehepatic causes of portal hypertension to reduce portal pressure. Specifically, the Rex shunt (mesenteric-left portal bypass) has been used very successfully in the setting of cavernous transformation of the portal vein.
 - Does not improve long-term survival in patients with intrahepatic disease
 - Complications may include thrombosis and worsening of hepatic encephalopathy.
 - TIPS (transjugular intrahepatic portosystemic shunt) procedure may be an effective bridge to liver transplantation in pediatric patients with progressive liver disease and recurrent variceal bleeds.
 - Data in pediatric patients are limited.
- Liver transplantation:
 - The current approach at most institutions is liver transplantation for those patients with life-threatening bleeds not amenable to β -blockade or endoscopic therapies.

IN-PATIENT CONSIDERATIONS**Initial Stabilization**

- Acute management of variceal bleed:
 - Vital signs: Remember that hemodynamic instability can be masked by β -blockers.
 - Fluid resuscitation: Two large-bore IV catheters or intraosseous needles, give crystalloid initially, then RBC transfusion with goal hemoglobin of 10 g/dL
 - Nasogastric tube placement: Lavage with room temperature saline or sterile water until clear; leave tube in place for evaluation and removal of continued or recurrent bleeding
 - Correction of coagulopathy: Parenteral vitamin K, fresh frozen plasma, platelet transfusion if platelets $<50,000/\mu\text{L}$
 - IV antibiotics: Acute variceal hemorrhage increases the risk of spontaneous bacterial peritonitis in the setting of ascites.
 - IV proton pump inhibitor or histamine receptor antagonist to decrease risk of bleeding from ulcers or erosions
 - Pharmacotherapy to control active bleeding:
 - Octreotide (somatostatin analog) decreases splanchnic blood flow via its inhibition of intestinal vasoactive peptide secretion. In turn, portal blood pressure is decreased. Somatostatin can be used but has a shorter half-life compared with octreotide.
 - Vasopressin decreases splanchnic blood flow via its vasoconstriction effects, but its use is limited owing to systemic vasoconstriction and a poor side effect profile. Nitroglycerin, a venodilator, has been used in conjunction to decrease the side effects. This combination is not preferred.
 - Lactulose to prevent hepatic encephalopathy in patients with cirrhosis
 - Endoscopy (after stabilization) to determine source of hemorrhage (variceal rupture or other, such as gastric ulcer) and perform therapeutic procedures such as sclerotherapy or band ligation for varices or electrocautery or clip placement for ulcer.

- Direct tamponade: Sengstaken-Blakemore tube for severe uncontrollable hemorrhage, but high rate of complications
- Surgical intervention: Portosystemic shunt, esophageal devascularization and/or transection, TIPS (transjugular intrahepatic portosystemic shunt)

ALERT

- The site of bleeding needs to be identified and managed appropriately: Not all GI bleeding in a patient with portal hypertension is an upper GI tract source (i.e., hemorrhoids); nasogastric lavage will help to determine if the problem is from the upper tract.
- Be careful not to overestimate the hemoglobin because equilibration may not have taken place at the time of presentation with an acute bleed.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Patients are followed closely for hepatic decompensation.
- Growth failure, recurrent life-threatening bleeds not controllable with prophylactic intervention, refractory ascites, and poor quality of life are indications for liver transplantation.

DIET

Sodium restriction when ascites is present

PROGNOSIS

- The disease course and prognosis depend on the underlying cause.
- Acute variceal bleeding is associated with a 6-week mortality of up to 30% in adults. The mortality rate in children is much lower.
- Variceal bleeding associated with prehepatic causes of portal hypertension such as portal vein thrombosis typically becomes less problematic as the child ages; these patients will most likely not require a shunt and may be easily managed with endoscopic therapy.
- Patients with congenital hepatic fibrosis also do very well, because the underlying disease is not progressive and bleeding may be easily managed with endoscopic therapy.
- Progressive liver disease has a worse prognosis and often requires liver transplantation.

COMPLICATIONS

- Hemorrhage from varices may present as hematemesis, hematochezia, or melena.
- Hypersplenism
- Malabsorption due to congestion of the intestinal mucosa
- Abnormal sodium retention
- Ascites: Presence of ascites increases risk of spontaneous bacterial peritonitis.

- Hepatorenal syndrome
- Hepatopulmonary syndrome (intrapulmonary right-to-left shunting) leads to hypoxemia, shortness of breath, exercise intolerance, and digital clubbing.
- Pulmonary hypertension can be a life-threatening complication of portal hypertension.

572.3 Portal hypertension

ICD10

K76.6 Portal hypertension

FAQ

- Q: What is my child's long-term prognosis?
- A: The disease course and prognosis depend on the underlying cause. Variceal bleeding associated with prehepatic causes of portal hypertension such as portal vein thrombosis typically becomes less problematic as the child ages and may be managed with endoscopic therapy.
- Q: Are there any medications I should avoid?
- A: Avoid aspirin and NSAID-containing products such as ibuprofen.

POSTERIOR URETHRAL VALVE

Shamir Tuchman

BASICS

DESCRIPTION

Valvular obstruction of the posterior urethra that results in variable dysfunction of all segments of the urinary tract, including the bladder, ureters, and renal parenchyma.

EPIDEMIOLOGY

- Most common congenital cause of obstructive uropathy resulting in renal failure in childhood
- Incidence: 1/5,000–8,000 male births
- Most boys with posterior urethral valve (PUV) present in the 1st year of life.
- By adolescence, ~30% of neonatally diagnosed patients will have renal insufficiency.
- There are rare reports of obstructive valves in the female urethra; however, they differ embryologically from those seen in males.

RISK FACTORS

Genetics

- Genetic basis remains unclear.
- Most cases are sporadic, although rare cases in siblings have been reported.

PATHOPHYSIOLOGY

- The embryogenesis is unclear.
- May arise from abnormal integration of the wolffian ducts into the urethra or from persistence of the urogenital membrane.
- The valve is a fold of fibrous connective tissue, extending between the verumontanum and the anterior urethral roof, which usually forms a diaphragm with a slit-like orifice.
- Children with PUV commonly have renal parenchymal dysplasia.
- With flow of urine from the bladder in patients with PUV, the valves balloon into the urethra, causing obstruction. As a result of the increased work of voiding, the bladder hypertrophies, with trabeculation and diverticulum formation. The bladder develops poor compliance, decreased capacity, increased pressure, and spastic hyperreflexia.
- Increased bladder volume and pressure causes incompetence of the ureterovesical junctions, with increased pressure transmitted into the upper urinary tract.
- The segment of the urethra proximal to the obstruction dilates and elongates.

COMMONLY ASSOCIATED CONDITIONS

- Hydronephrosis, vesicoureteral reflux, perirenal urinoma, or urinary ascites may occur.
- Renal parenchymal damage may result.

DIAGNOSIS

HISTORY

- Poor urinary stream
- Unexplained fevers
- Tachypnea from acidosis
- The clinical presentation depends on age of presentation and severity of obstruction:
 - Many severe cases are diagnosed postnatally as the result of evaluation of hydronephrosis detected antenatally on maternal US.
 - Severely affected infants may present with respiratory distress and other sequelae of oligohydramnios, azotemia, sepsis, dehydration, acidosis, and electrolyte disorders.
 - Patients may present with delayed voiding after delivery, a palpable bladder, UTI, abnormal urinary stream, or failure to thrive because of renal failure.
 - Toddlers may present with UTI or voiding symptoms, such as dysuria and a weak urinary stream.
 - Older boys may present with daytime incontinence, nocturnal enuresis, or urinary frequency because of bladder hypertrophy coupled with polyuria secondary to a renal concentrating defect.
 - A strong urinary stream does not exclude the diagnosis of PUV because an adequate flow may be generated by the hypertrophied bladder.

PHYSICAL EXAM

Palpably enlarged bladder and kidneys are the most common physical finding.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Electrolytes: Infants with severe PUV may have UTIs and/or azotemia and fluid and electrolyte abnormalities such as dehydration, acidosis, hyperkalemia, and hyponatremia (type IV RTA).

Imaging

- Voiding cystourethrogram (VCUG):
 - Most important study for diagnosis
 - Will reveal a sharply defined lucency in the posterior urethra and bladder hypertrophy.
 - Bladder trabeculation, diverticuli, and vesicoureteral reflux may also be demonstrated.
- Abdominal US may demonstrate hydronephrosis, evidence of renal dysplasia, dilatation of the posterior urethra with an enlarged, thickened bladder (keyhole sign), and urinary ascites.
- Hydronephrosis is present in 90% of infants with PUV.

Diagnostic Procedures/Other

- Urethroscopy
- Definitive diagnosis requires urethroscopic exam:
 - Caution: When a catheter is passed into the bladder, the valves flatten and are nonobstructive. This may give the misleading impression that there is no obstruction.

DIFFERENTIAL DIAGNOSIS

- Nonobstructive urinary tract dilatation may occur secondary to the following:
 - Vesicoureteral reflux
 - Prune belly syndrome
 - Detrusor sphincter dyssynergia
 - Polyuria
 - UTI
 - Ureteral stenosis
- Other entities that may mimic PUVs include the following:
 - Urethral strictures
 - Primary vesical neck contractures
 - Anterior urethral valves

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Supportive:
 - Initial management in the neonate consists of inserting a fine urethral catheter into the bladder and treating any fluid and electrolyte disturbances and/or UTI.
 - A large postobstructive diuresis may occur, requiring ongoing management of fluids and electrolytes.

SURGERY/OTHER PROCEDURES

- Valve ablation (destruction of the obstructive valve leaflet) is the definitive treatment of the primary lesion. The most common approach is to incise the valves transurethrally through an endoscope.
- In utero drainage of the fetal bladder has yet to show improvement in long-term renal outcome compared to valve ablation after delivery.
- In utero drainage has been used in selected cases in an attempt to ameliorate pulmonary hypoplasia in the setting of oligohydramnios.
- Unless the patient has renal insufficiency that does not improve after fluid resuscitation and catheter drainage, the next step is endoscopic ablation of the valves.

- If the infant's urethra is too small for the endoscope, cutaneous vesicostomy may be necessary.
- If rapid recovery does not occur following placement of the catheter or after valve ablation, vesicostomy or supravescical urinary diversion (such as ureterostomy or nephrostomy) may be required.
- Supravescical diversion may be associated with poorer long-term bladder function.
- The optimal anatomic level of urinary diversion remains controversial.
- Following valve ablation, the posterior urethra will appear less dilated on VCUG. However, improvement in hydroureteronephrosis and vesicoureteral reflux occurs more slowly, over years.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Growth problems, renal insufficiency, and end-stage renal disease can occur at any time during childhood, puberty, or beyond.
- Patients who require extensive urinary diversion, such as vesicostomy, pyelostomy, or ureterostomy, will require long-term reconstruction, including possible bladder reconstruction.
- Delayed obstruction may occur owing to urethral stricture.
- Patients with persistent incontinence require urodynamic evaluation to determine the cause and to dictate individualized therapy.

Patient Monitoring

Careful follow-up through childhood and puberty: Visits should include imaging for renal function and upper tract dilatation and drainage, urodynamic studies of bladder function, assessment of growth, blood pressure, urinary protein, and serum creatinine.

PROGNOSIS

- The prognosis for infants with severe PUV has improved owing to earlier recognition and improved management of pulmonary hypoplasia and fluid and metabolic derangements.
- Pulmonary hypoplasia and renal dysplasia account for most causes of death in infants with PUV.
- Oligohydramnios is a predictor of poor long-term renal function. The earlier and more severe the oligohydramnios occurs during pregnancy, the more guarded the prognosis for long-term renal function.
- Measures of renal function at the time of presentation may not correlate with ultimate outcome. Rather, the rate of improvement following relief of obstruction is more indicative of prognosis. An early nadir creatinine level <1.0 mg/dL does not preclude renal failure, as the child attains greater body mass.

- However, in patients diagnosed and treated in infancy, a creatinine level of <0.8 mg/dL at 1 year of age often portends a better long-term renal prognosis.
- During the course of many years, many children who seem to do well initially will suffer progressive renal failure and require renal transplantation.
- Patients with an abnormal serum creatinine at 2 years of age often develop end-stage renal disease by adolescence or young adulthood.
- Children who develop proteinuria have bilateral renal dysplasia, and/or bladder dysfunction are more likely to eventually develop renal insufficiency and hypertension.

COMPLICATIONS

- Severe cases may suffer the effects of intrauterine oligohydramnios, including Potter syndrome and pulmonary hypoplasia.
- The renal parenchymal damage results in the sequelae of progressive renal failure, such as anemia, acidosis, fluid and electrolyte abnormalities, and failure to thrive.
- UTIs and vesicoureteral reflux are common complications.
- Urinary incontinence may result from uninhibited bladder contractions, bladder noncompliance, and polyuria.

CODES

- ICD9**
- 753.6 Atresia and stenosis of urethra and bladder neck
 - 753.8 Other specified anomalies of bladder and urethra

- ICD10**
- Q64.2 Congenital posterior urethral valves
 - Q64.39 Other atresia and stenosis of urethra and bladder neck

FAQ

- Q: What can be done for children with long-term bladder dysfunction and incontinence?
- A: Voiding dysfunction may occur as the result of myogenic failure, detrusor hyperreflexia, and bladder hypertonia. Patients may require a combination of clean intermittent catheterization, pharmacologic therapy, and bladder augmentation. ~20% of patients with PUVs have secondary bladder pathology that is not reversible by primary therapy of the valve.
- Q: Are patients with PUVs good candidates for renal transplantation?
- A: Patients with valves have a 5-year graft survival rate of only 50%, compared with 75% for patients with other diagnoses. The main adverse factor is poor bladder function. Better results may follow more aggressive correction of the bladder anomalies. Transplantation has been successful in patients with bladder augmentation and in patients using clean intermittent catheterization.
- Q: Do patients with PUVs have impaired sexual and reproductive function?
- A: In a small study, patients had good sexual function and some were fertile. 95% had normal erections and were able to achieve penetration. 34% and 50% had normal and slow ejaculation, respectively. ~50% had normal semen.

PREMATURE ADRENARCHE

Andrew C. Calabria

Andrea Kelly

J. Nina Ham (5th edition)

BASICS

DESCRIPTION

- Appearance of small amounts of pubic hair before age 8 years in girls and age 9 years in boys
- Recent data suggest that the onset of normal sexual development in girls is younger than previously recognized, but lowering of the traditionally accepted limits is subject to debate.
- With premature adrenarche, axillary hair, acne, and apocrine sweat gland secretion are not always present.
- No other signs of sexual development are exhibited. Presence of breast development suggests precocious puberty and not premature adrenarche.
- Occurs independently of hypothalamic–pituitary–gonadal axis.

Genetics

A familial pattern suggesting either recessive or dominant inheritance has been described.

PATHOPHYSIOLOGY

- Levels of dehydroepiandrosterone (DHEA) and dehydroepiandrosterone-sulfate (DHEAS) from the adrenal glands increase earlier than typically seen in normal puberty.
- Zona reticularis of the adrenals normally begins to increase androgen secretion at age 7–8 years.

DIAGNOSIS

HISTORY

- Careful attention to presence of any other signs of sexual precocity as well as rate of progression
- Family history of pubertal development, infertility, irregular menses, hirsutism, polycystic ovarian syndrome, and premature male-pattern balding
- Birth weight that is small for gestational age (SGA) may predispose children to development of premature adrenarche.
- Obesity has been associated with an increased incidence of premature adrenarche.
- Girls with premature adrenarche are at increased risk for the development of polycystic ovarian syndrome.

PHYSICAL EXAM

- Linear growth velocity may be increased.
- The presence of pigmented, curly hairs in the pubic area is consistent with the androgen effect.
- In girls, clitoromegaly suggests congenital adrenal hyperplasia or androgen-secreting tumors.
- The finding of acanthosis nigricans suggests that insulin resistance and the risk of developing ovarian hyperandrogenism (polycystic ovarian syndrome) are present.

ALERT

Be careful to differentiate between true pubic hair (curly and short) and dark lanugo hair (straight, long, fine).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Adrenal steroids: DHEA and DHEAS are often elevated for chronologic age but normal for pubertal stage (usually Tanner 2 or 3). However, testosterone and 17-OH progesterone (17-OHP) should be in prepubertal range.
- Gonadotropin-releasing hormone stimulation test: Not routinely recommended but would have a normal prepubertal response
- Children with systemic signs of virilization (such as a significantly advanced bone age) or elevated adrenal steroids (17-OHP or DHEA) should have adrenocorticotropic hormone (ACTH) stimulation testing to exclude congenital adrenal hyperplasia and other hyperandrogenic syndromes.

Imaging

- Bone age may be advanced by 1–2 years, but correlates with height age.
- Abdominal ultrasound, CT scan, or MRI should be considered if signs of significant virilization are present or if rapid progression has occurred; look for intracranial or intra-abdominal masses, especially if androgens are markedly elevated.

DIFFERENTIAL DIAGNOSIS

- Congenital: Nonclassic (late onset) congenital adrenal hyperplasia
- Tumors: Androgen-secreting tumors can arise in the gonads or adrenal glands.
- Miscellaneous:
 - Central precocious puberty
 - Familial male precocious puberty (testotoxicosis)
 - Exogenous male hormone exposure

TREATMENT

ADDITIONAL TREATMENT

General Measures

- No treatment
- Reassure parents and children that this is a benign process.
- Reassess every 6 months to look for signs of virilization and pubertal progression.

ONGOING CARE

- Regression does not occur.
- Watch for other signs of puberty, such as breast development, testicular enlargement (≥ 4 mL) or growth acceleration, that suggest onset of true precocious puberty.
- Increasing virilization suggests nonclassic congenital adrenal hyperplasia or early polycystic ovarian syndrome.
- Acanthosis nigricans or signs of insulin resistance have been reported in girls with a history of premature adrenarche.
- Monitor for glucose intolerance or early type 2 diabetes. Can check fasting glucose and insulin levels or oral glucose tolerance test if suspicion is high (e.g., obesity, acanthosis nigricans, polyuria, polydipsia).

PROGNOSIS

- Undergo puberty appropriately with normal fertility.
- Development of ovarian or adrenal hyperandrogenism during adolescence (also known as "polycystic ovarian syndrome") is more common in some girls with premature adrenarche. Insulin resistance, a common finding in ovarian hyperandrogenism, has been reported in some children and adolescents with a history of premature adrenarche.
- Final adult height is normal.

COMPLICATIONS

- Can be the first sign of true precocious puberty (i.e., development of breast tissue and advancement of bone age) and thus warrants careful observation.
- Boys with premature adrenarche and precocious puberty are more likely than girls to have an underlying CNS disorder.

CODES

ICD9

259.1 Precocious sexual development and puberty, not elsewhere classified

ICD10

E27.0 Other adrenocortical overactivity

FAQ

- Q: Is there a dietary cause of excess adrenal hormones?
- A: No.
- Q: Does premature adrenarche mean puberty will be early?
- A: The onset of puberty in these children is within the normal range and should follow the familial pattern.
- Q: Can anything be done to reverse the changes?
- A: This is a benign process that does not have long-term sequelae. Antiandrogen drugs are available but are not recommended.

PREMATURE THELARCHE

Andrew C. Calabria

Andrea Kelly

Olga T. Hardy (5th edition)

BASICS

DESCRIPTION

- Breast development <8 years of age in girls with no other signs of pubertal development
- A recent study suggested that African American girls are developing pubertal characteristics as early as age 6 and Caucasian girls as early as age 7. However, physicians should be cautious about using these as normal limits and should evaluate children on an individual basis because signs of puberty at these younger ages may not be normal.

EPIDEMIOLOGY

60–85% of cases noted between 6 months and 2 years of age

PATHOPHYSIOLOGY

- Transient increases in follicle-stimulating hormone levels causing follicular ovarian development
- Low levels of estrogen secretion by normal follicular cysts
- Increased sensitivity of breast tissue to low levels of estrogen

ETIOLOGY

Intermittent estrogen secretion by ovarian cysts or environmental sources of estrogen

DIAGNOSIS

HISTORY

- Careful assessment of onset and progression of breast tissue
- Family history of early puberty
- Exposure to estrogens
- Be sure to ask about ingestion of foods with high estrogen levels.

PHYSICAL EXAM

- Areolar enlargement is usually not present.
- Galactorrhea is not present.
- Palpate carefully to distinguish fat from true breast tissue.
- Look carefully for other signs of puberty:
 - Menstrual blood
 - Dull, gray-pink, or rugose vaginal mucosa (vs. prepubertal appearance: Shiny, bright red, and smooth)
 - Pubic or axillary hair
- Inspect skin for birthmarks suggestive of McCune–Albright syndrome (café au lait spots in a coast of Maine pattern).
- Evaluate for signs of hypothyroidism: Goiter, short stature

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No test is specific.
- Serum follicle-stimulating hormone, inhibin B, and estradiol may be slightly higher than age-matched controls, but are not consistently elevated.
- In isolated premature thelarche, serum ultrasensitive luteinizing hormone is prepubertal.

Imaging

- Bone age is not significantly or is very mildly advanced (<1 year ahead of chronologic age). Useful in guiding the need for more intensive evaluation of true precocious puberty
- Pelvic ultrasonography may demonstrate presence and regression of small ovarian cysts (1–15 mm) and a prepubertal uterus.

DIFFERENTIAL DIAGNOSIS

- Environmental:
 - Exposure to exogenous estrogens in the form of creams or birth control pills
 - Intake of food with high estrogen levels (e.g., chicken liver)
- Tumors: Benign lipomas
- Congenital: Neonatal breast hyperplasia is benign breast enlargement in newborn boys or girls that is apparent shortly after birth and is caused by gestational hormones. This form of breast development usually regresses.
- Other:
 - Severe acquired hypothyroidism: High levels of thyroid-stimulating hormone may cross-stimulate gonadal follicle-stimulating hormone and/or luteinizing hormone receptors.
 - McCune–Albright syndrome: Triad of precocious puberty, café au lait spots, and polyostotic fibrous dysplasia due to gain of function mutations of G proteins
 - Thelarche variant or “exaggerated thelarche”: lies on a spectrum between isolated premature thelarche and precocious puberty; occurs in up to 30% of premature thelarche cases, associated with moderate growth and bone age acceleration and increased uterine size, owing to unsustained estrogen secretion.
 - True precocious puberty

ALERT

- Must distinguish fat from breast tissue in obese girls
- Removal of a breast bud will result in failure of that breast to develop during adolescence

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Observation
- Reassurance that this is a benign process

ONGOING CARE

- Regression often occurs by 2 years but may occur up to 6 years after onset.
- Evidence of pubertal progression should prompt additional evaluation by an endocrinologist:
 - Rapid increase in size of breast tissue
 - Vaginal bleeding
 - Growth spurt
 - Development of pubic and axillary hair

PROGNOSIS

- No known effects on growth or fertility
- Onset after age 2 years may be associated with increased risk of progression to precocious puberty.

COMPLICATIONS

May be the first sign of true precocious puberty

PATIENT EDUCATION

- No data to suggest that premature thelarche increases the risk of breast cancer
- Many newborn male and female infants have breast buds as a result of exposure to maternal estrogen in utero. This neonatal gynecomastia usually resolves quickly.

- Asymmetric breast development is quite common in the early stages of normal pubertal development. Malignant tumors of the breast during childhood are extremely rare. As mentioned earlier, any removal of breast tissue prior to or during puberty must be avoided if possible.

CODES

ICD9

259.1 Precocious sexual development and puberty, not elsewhere classified

ICD10

E30.8 Other disorders of puberty

FAQ

- Q: Does premature thelarche predispose the child to abnormalities in pubertal development?
- A: If onset occurs after age 2 years, the girl may be more likely to enter puberty earlier. However, most girls with premature thelarche will have normal pubertal development and fertility.

PREMENSTRUAL SYNDROME (PMS)

Ann B. Bruner

BASICS

DESCRIPTION

- Premenstrual syndrome (PMS), also called luteal phase disorder, is a disorder characterized by psychologic and physical symptoms that occur cyclically and consistently during the second half (luteal phase) of the menstrual cycle, negatively impact a woman's usual activities of daily living, and remit after the onset of menstruation.
- PMS is diagnosed through prospective symptom charting with symptoms present beginning at approximately day 13 of the cycle and resolving within 4 days of menses for 2 consecutive cycles.
 - At least 1 of the following symptoms must occur within 5 days of menses onset: Breast tenderness, bloating/weight gain, headache, swelling of hands/feet, aches/pains, mood symptoms (depression, anger, irritability, anxiety, social withdrawal), poor concentration, sleep disturbance, or change in appetite.
- Premenstrual dysphoric disorder (PMDD) is the extreme variant of PMS; defined in *DSM-IV-TR* as severe psychologic symptoms causing significant dysfunctions, which are not an exacerbation of symptoms of a chronic condition and are confirmed through prospective daily ratings of 3 consecutive cycles.
- Criteria for PMDD: At least 5 symptoms among the following must be present during most of the luteal phase, with at least 1 of the symptoms being among the first 4:
 - Depressed mood: Feeling sad, hopeless, or self-deprecating
 - Anxiety or tension: Feeling tense, anxious, or "on edge"
 - Affective lability: Fluctuating emotions interspersed with frequent tearfulness
 - Irritability or anger: Increased interpersonal conflicts
 - Decreased interest in usual activities, which may be associated with withdrawal from social relationships
 - Difficulty concentrating
 - Feeling fatigued, lethargic, or lacking in energy
 - Marked changes in appetite, which may be associated with binge eating or craving certain foods
 - Hypersomnia or insomnia
 - A subjective feeling of being overwhelmed or out of control
 - Physical symptoms such as breast tenderness/swelling, headaches, bloating or weight gain, arthralgias, or myalgias

EPIDEMIOLOGY

Prevalence

- 40–75% of women experience some PMS symptoms at some time.
- 15–30% of women report recurrent symptoms suggestive of PMS.
- 2–5% of women have symptoms that interfere with their usual activities (PMDD).
- 14–88% of adolescent girls have moderate to severe PMS; one study demonstrated a 5.8% prevalence of PMDD in young women ages 14–24.

RISK FACTORS

Genetics

Genetic factors may play a role in the development of PMS/PMDD: Twin studies show a 93% concordance rate in monozygotic twins, with only a 44% rate in dizygotic twins.

Age

More severe symptoms of PMDD may be seen in younger women.

Culture

PMS/PMDD appear to be more prevalent in Western cultures, possibly due to differences in socialization and symptom expectations.

Stress

PMS and PMDD may be associated with high levels of day-to-day stress and/or a history of stressful events, including sexual abuse.

PATHOPHYSIOLOGY

- Occurrence of symptoms is related to ovarian function/ovulation:
 - PMS does not occur before menarche, during pregnancy, or after menopause.
 - PMS can occur after hysterectomy, but not after bilateral oophorectomy.
- Research suggests altered cyclic interactions between sex hormones and neurotransmitters (in particular, relationships between sex hormones, prostaglandins, and serotonin): γ -aminobutyric acid (GABA) and opioid neurotransmitter systems have also been studied, along with trace elements, vitamins, and minerals.
- Women with PMS do not have abnormal serum concentrations of estrogen or progesterone or hormonal imbalance; research suggests that women with PMS have abnormal responses to normal variations in sex hormones.

ETIOLOGY

Etiology unknown, but presumed to be multifactorial

DIAGNOSIS

SIGNS AND SYMPTOMS

Many women report that their PMS symptoms are not taken seriously.

HISTORY

- Complete medical history, including use of medications or illicit substances, cigarettes, dietary evaluation
- Gynecologic history: Age at onset of pubertal development, menstrual pattern, sexual activity, contraceptive use, dysmenorrhea
- Psychiatric history: Mental health disorders, medications
- Family history: Mental health and substance use/abuse
- Psychosocial history: Living situation, school/vocational activities and goals, hobbies, peers

- Complete review of systems including both physical symptoms (fatigue, breast tenderness/swelling, bloating, edema, weight gain, headache, arthralgias, myalgias, pelvic discomfort, changes in bowel habit, reduced coordination) and emotional/psychologic symptoms (depression, mood lability, irritability, tension, anxiety, tearfulness, restlessness, reduced concentration, fatigue, altered libido, altered appetite/eating habits, altered sleep)
- Chronologic review to determine if symptoms are recurrent with most menstrual cycles, isolated to luteal phase of cycle, and remit with onset of menses

PHYSICAL EXAM

There are no specific physical findings of PMS.

- Enlarged thyroid gland: May suggest hypothyroidism and need to evaluate for thyroid disease
- Virilization (hirsutism, clitoromegaly): May suggest hyperandrogenism and need to evaluate for adrenal disease, including Cushing syndrome, or other hormonal disorders such as polycystic ovarian syndrome
- Pallor: May suggest anemia
- Orthostatic hypotension: May suggest neurally mediated hypotension

DIAGNOSTIC TESTS & INTERPRETATION

PAF (Premenstrual Assessment Form), PRISM (Prospective Record of Severity of Menstruation), or COPE (Calendar of Premenstrual Experiences): Prospective symptom calendars can help establish diagnosis and provide information about symptom patterns (recurrence and relation to menses). Differences in symptom severity between the follicular and luteal phases (before and after ovulation) may be most diagnostic.

Lab

- CBC: Rule out anemia.
- Thyroid-stimulating hormone (TSH) assay: Rule out thyroid disease.

DIFFERENTIAL DIAGNOSIS

- Psychiatric:
 - Mood disorder, including major depression, dysthymia, bipolar disorder, postpartum depression, anxiety disorder
 - Substance abuse
 - Physical, sexual, or emotional abuse
 - Somatization disorder
 - Eating disorder
- Endocrinologic:
 - Thyroid disease
 - Cushing disease
 - Diabetes mellitus

- Gynecologic:
 - Dysmenorrhea (primary or secondary)
 - Pregnancy
 - Endometriosis
 - Hormonal contraceptive use
 - Perimenopause
- Immunologic/hematologic:
 - Anemia
 - Fibromyalgia
 - Systemic lupus erythematosus (SLE)
 - Chronic fatigue syndrome
- Neurologic:
 - Migraine headache
 - Neurally mediated hypotension

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Treatment goals include reducing both symptom frequency and severity and the impact of symptoms on patients' activities.
- Patient education, counseling, and reassurance may be all that is needed for women with milder symptoms.
- Many pharmacologic and nonpharmacologic modalities have not been formally evaluated.

Diet

- Research supports reducing caffeine and alcohol intake and suggests that reductions in salt and refined sugars may also be beneficial.
- Meta-analyses of research to date have shown that some supplements are beneficial in reducing symptom frequency and severity, including calcium carbonate (1,200 mg/d), pyridoxine/vitamin B₆ (50 mg/d), and possibly magnesium (400 mg/d).
- Many herbal therapies are in use, including evening primrose oil, chaste berry, black cohosh, ginkgo, and St. John's wort. However, there is no strong evidence to support their use in PMS.

Activity

- Increasing physical activity, ensuring adequate and regular sleep, and maintaining a healthy diet are important first steps.
- Mind/body therapies are frequently used including individual psychotherapy, relaxation techniques, guided imagery, yoga, massage, biofeedback, and group therapy; to date, there is no strong evidence to support their use in PMS.

MEDICATION (DRUGS)

First Line

- Many menstrually associated symptoms can be managed with nonsteroidal anti-inflammatory drugs (NSAIDs):
- NSAIDs (e.g., naproxen sodium 275–550 mg b.i.d.) relieve the majority of physical symptoms—premenstrual/menstrual cramping, headaches, and myalgias/artralgias.
 - Side effects include gastrointestinal upset and renal dysfunction.

Second Line

SSRIs are first line for PMDD and severe PMS, especially those with predominantly psychologic symptoms. SSRIs have been shown to improve mood, decrease irritability, ameliorate physical symptoms such as bloating and breast tenderness, and improve psychosocial function. Continuous and intermittent (during luteal phase) dosing can be used, and symptom amelioration can occur during the first cycle of treatment. Intermittent use includes administration during the last 14 days of the menstrual cycle or treatment begun at expected date of symptom onset:

- Fluoxetine (20–60 mg/d), sertraline (50–150 mg/d), paroxetine (10–30 mg/d), and citalopram (5–20 mg/d) are some of the most commonly used SSRIs for PMS/PMDD; side effects include gastrointestinal upset, insomnia, tremor/agitation, fatigue, dry mouth, and sexual dysfunction. SSRIs recently received a US FDA black box warning concerning an increased risk of suicidality among depressed children and adolescents; the warning was for the treatment of depression, not PMS/PMDD.
- Hormonal contraceptives (i.e., low-dose oral contraceptive pills, contraceptive patch) suppress ovulation, which may ameliorate hormonally mediated symptoms such as breast swelling/tenderness and bloating, but may exacerbate mood symptoms.
- Spironolactone (50 mg b.i.d.) is effective for breast tenderness and bloating; potassium levels must be monitored, and spironolactone is contraindicated in patients with abnormal renal function.

ONGOING CARE

- Frequent follow-up and the use of a prospective menstrual/symptom calendar are important.
- After the diagnosis of PMS is established, and after recommending appropriate lifestyle changes (and possibly NSAIDs), the patient should be re-evaluated after 3 months. If there has not been substantial improvement, secondary pharmacologic therapies (SSRIs) may need to be considered. When SSRIs are prescribed as first-line therapy for patients with more severe PMS or PMDD, response to SSRIs and any adverse reactions should be assessed at follow-up and dosage adjusted as needed.

ISSUES FOR REFERRAL

A gynecologist/reproductive endocrinologist can assist in the management of severe PMS/PMDD: Other pharmacologic agents that are used include gonadotropin-releasing hormone (GnRH) analogues, danazol, estrogen implants, and androgens.

COMPLICATIONS

Psychologic morbidity includes difficulty with interpersonal relationships (family and friends) and school absence/failure.

ICD10

N94.3 Premenstrual tension syndrome

FAQ

- Q: Can adolescent girls have PMS and PMDD?
- A: The incidence of PMS and PMDD in adolescents is not well established. Although $\leq 50\%$ of cycles are anovulatory during the first 1–2 years after menarche, younger patients experience many PMS symptoms, and menstrual problems are some of the most common reasons for school absence. Most experts believe that PMS/PMDD will not develop until a regular ovulatory pattern is established, ~ 2 –3 years after menarche.
- Q: Is family history important?
- A: Genetic factors may play a role in the development of PMS/PMDD; twin studies show a 93% concordance rate in monozygotic twins, with only a 44% rate in dizygotic twins.
- Q: Are there any common comorbidities?
- A: The symptoms of PMS/PMDD are also seen with depression, anxiety, and other mood disorders. Psychiatric symptomatology can fluctuate, and symptoms may change in relation to the menstrual cycle. Careful and thorough history taking and prospective symptom diaries can help differentiate PMS/PMDD from another mental health disorder.

PRIMARY ADRENAL INSUFFICIENCY

J. Nina Ham

Lorraine E. Levitt Katz

BASICS

DESCRIPTION

Deficiency in the secretion of cortisol by the adrenal glands

EPIDEMIOLOGY

- Age:
 - Addison disease is uncommon in children and usually presents between the ages of 20 and 50 years. In the pediatric population, it is most often seen in late childhood and adolescence.
 - Adrenoleukodystrophy typically presents late in the 1st decade of life with neurologic symptoms. Signs and symptoms of adrenal insufficiency may be present at any age.
 - Adrenocorticotropic hormone (ACTH) unresponsiveness presents in late infancy or the toddler period.
 - Adrenal hypoplasia congenita presents in infancy or early childhood.
 - Adrenal insufficiency associated with congenital adrenal hyperplasia (CAH) presents in the newborn period.
- Sex:
 - Addison disease is more common in girls.
 - Adrenoleukodystrophy, an X-linked disorder, predominantly affects boys.
 - ACTH unresponsiveness and CAH affect both sexes equally.
 - Adrenal hypoplasia congenita, an X-linked disorder, predominantly affects boys.

RISK FACTORS

Genetics

- Addison disease:
 - Autoimmune adrenal insufficiency may be isolated or part of autoimmune polyglandular syndrome (APS) type 1 or 2. Mutations in the *AIRE1* gene have been identified as the cause of APS type 1. An association exists between idiopathic Addison disease and human leukocyte antigen (HLA)-B8 and DR3.
- Adrenoleukodystrophy:
 - X-linked recessive disorder of very-long-chain fatty acid metabolism due to *ABCD1* gene mutation
 - An autosomal recessive form of the disease exists, with presentation during infancy.
- ACTH unresponsiveness: Autosomal recessive ACTH receptor defect
- Adrenal hypoplasia congenita: X-linked mutation in *DAX1* gene
- CAH: Autosomal recessive inheritance associated with a gene defect in 1 of multiple adrenal steroidogenic enzymes

PATHOPHYSIOLOGY

- Addison disease:
 - Primary hypoadrenalism due to bilateral destruction of the adrenal cortices; this can be due to autoimmune destruction (isolated or associated with APS), tuberculosis, hemorrhage, fungal infection, neoplastic infiltration, or AIDS.
- Adrenoleukodystrophy:
 - Inherited disorders of impaired peroxisomal degradation of very-long-chain fatty acids, resulting in adrenal insufficiency and progressive neurologic deterioration
- ACTH unresponsiveness:
 - Inherited defect in the ACTH receptor, resulting in isolated glucocorticoid deficiency with hypoglycemia in infancy and hyperpigmentation
- Adrenal hypoplasia congenita: A defect in adrenal organogenesis
- CAH: A group of enzymatic disorders of steroid metabolism, of which 21-hydroxylase deficiency is the most common
- Waterhouse-Friderichsen syndrome: Bilateral adrenal gland hemorrhage classically associated with fulminant meningococemia, but also reported with *Staphylococcus aureus* and *Streptococcus pneumoniae*

COMMONLY ASSOCIATED CONDITIONS

- Deficiencies of other hormones, including aldosterone and adrenal sex steroids
- Adrenal hypoplasia congenita (*DAX1* mutation) is associated with hypogonadotropic hypogonadism.
- APSs are associated with other autoimmune disorders:
 - APS type 1: Mucocutaneous candidiasis, hypoparathyroidism
 - APS type 2: Autoimmune thyroid disease, type 1 diabetes
- Both types can also present in conjunction with multiple other autoimmune disorders (e.g., pernicious anemia, vitiligo, autoimmune hepatitis)

DIAGNOSIS

HISTORY

The symptoms of primary adrenal insufficiency are nonspecific and similar to those found in many disease processes. The electrolyte picture of adrenal insufficiency can be seen in renal disorders, obstructive uropathy, and isolated aldosterone deficiency:

- Weakness and fatigue
- Anorexia, weight loss
- Headache
- Nausea, vomiting, diarrhea, abdominal pain
- Orthostatic symptoms
- Muscle or joint pains
- Emotional lability
- Salt craving
- Hyperpigmentation
- Decreased axillary or pubic hair in females due to lack of adrenal androgens
- Amenorrhea in females

PHYSICAL EXAM

- Hyperpigmentation, especially on lip borders, buccal mucosa, nipples, and over skin creases
- Weight loss
- Hypotension
- Evaluate for other signs of autoimmune disease (e.g., thyromegaly, vitiligo).
- Pubertal staging
- Signs of virilization in females

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Specific:
 - Cosyntropin (Cortrosyn) stimulation test:
 - Administer cosyntropin (synthetic ACTH) 250 mcg IV and measure cortisol at 30 and 60 minutes. A normal response is a final cortisol >18 mcg/dL. An insufficient cortisol response is diagnostic of adrenal insufficiency:
 - A baseline ACTH >200 pg/mL with inadequate cortisol is seen in primary adrenal insufficiency.
 - Serum adrenal antibodies may be positive in autoimmune Addison disease.
 - Very-long-chain fatty acids are elevated in adrenoleukodystrophy.
 - Low gonadotropin and sex steroid levels suggesting hypogonadotropic hypogonadism may be seen with adrenal hypoplasia congenita.
 - Adrenal steroid precursors will be elevated in CAH.

- Nonspecific:
 - Electrolytes:
 - Hyponatremia: Result of the mineralocorticoid defect and glucocorticoid deficiency; combination sodium loss from kidneys, and the inability to excrete a water load
 - Hyperkalemia and acidosis: Chronic mineralocorticoid deficiency with the inability to excrete potassium and acid
 - Hypercalcemia: Most likely a result of increased calcium absorption due to the lack of glucocorticoid effect on the gut
 - Hypoglycemia: Glucocorticoids have permissive effects on gluconeogenesis.
 - Renin levels are elevated when a mineralocorticoid deficiency is present.

DIFFERENTIAL DIAGNOSIS

- Autoimmune adrenal cortical destruction
- Infectious adrenal cortical destruction:
 - Tuberculous
 - Fungal
 - HIV
- Adrenal hemorrhage
- Neoplastic adrenal infiltration
- Adrenoleukodystrophy
- ACTH unresponsiveness
- Adrenal hypoplasia congenita
- CAH
- Withdrawal of chronic exogenous steroids

TREATMENT

MEDICATION (DRUGS)

- Acute adrenal crisis:
 - Hydrocortisone (HC): Stress dosage of hydrocortisone: 100 mg/m² followed by 100 mg/m²/24 hours of hydrocortisone divided q4-6h. Taper steroids rapidly to a physiologic replacement dosage when acute illness has resolved.
 - Mineralocorticoid replacement: Florinef 0.1 mg daily when able to take PO
- Chronic adrenal insufficiency:
 - Hydrocortisone 10–12 mg/m²/d PO divided as t.i.d. Triple the dose for stress of fever, illness, or vomiting. For major stress (surgery, significant illness), give hydrocortisone 50–100 mg/m² IV/IM followed by 50–100 mg/m²/24 hours IV divided q4-6h. IM hydrocortisone is recommended for emergency home use.
 - Florinef 0.1 mg PO daily

ADDITIONAL TREATMENT

General Measures

Chronic adrenal insufficiency:

- Daily maintenance HC replacement
- Increased HC dose for stress of fever, illness, vomiting
- Fludrocortisone acetate (Florinef): Mineralocorticoid agent
- Patient education on stress dosing in the event of illness

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Acute adrenal crisis:
 - An intercurrent illness or surgical procedure may provoke an episode of hypotension, tachycardia, and shock. Electrolytes reveal decreased serum sodium, elevated potassium, metabolic acidosis, and a decreased or normal glucose. Serum should be drawn and saved to aid in diagnosis, but emergent treatment should not be delayed for a diagnostic ACTH stimulation test.
- Treatment:
 - 5% dextrose in normal saline solution (D5NS) for volume repletion and treatment of salt wasting and hypoglycemia
 - HC or other glucocorticoid
 - Mineralocorticoid replacement

IV Fluids

D5NS for volume repletion and treatment of salt wasting

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

An acute adrenal crisis usually improves rapidly with the administration of fluids and glucocorticoids. Once the acute phase of illness has resolved, steroids can be resumed at physiologic replacement doses.

Patient Monitoring

- Clinical status
- Reduction in hyperpigmentation
- Electrolytes, ACTH, and renin levels
- Screen for polyautoimmune disorders.
- Growth
- Very-long-chain fatty acid levels and neurologic function in adrenoleukodystrophy
- Pubertal development

PATIENT EDUCATION

- Stress dosing
- Importance of seeking medical attention for significant illness, persistent vomiting, or the inability to take fluids by mouth
- MedicAlert bracelet

PROGNOSIS

- Long-term prognosis of isolated adrenal insufficiency is good, provided adequate hydrocortisone is administered, particularly in times of illness.
- Adrenoleukodystrophy carries a poor prognosis.

COMPLICATIONS

- If not diagnosed and/or treated properly, a significant physical stress such as surgery or illness may result in a life-threatening adrenal crisis.
- Adrenoleukodystrophy results in severe neurologic impairment and death.
- Unrecognized ACTH unresponsiveness is associated with recurrent hypoglycemia, seizures, mental retardation, and death.
- Pubertal delay or hypogonadotropic hypogonadism is seen with adrenal hypoplasia congenita due to *DAX1* mutations.
- CAH can cause virilization/ambiguous genitalia in female infants with the disease and can cause salt-wasting crises in infants of both sexes.

- 277.86 Peroxisomal disorders
- 759.1 Anomalies of adrenal gland

ICD10

- E27.1 Primary adrenocortical insufficiency
- E71.529 X-linked adrenoleukodystrophy, unspecified type
- Q89.1 Congenital malformations of adrenal gland

FAQ

- Q: What are the indications for stress dosing and how rapidly can the stress hydrocortisone dose be tapered?
- A: Patients will require stress dosing of hydrocortisone for surgical procedures, fever (>37.7°C [100°F]), vomiting, diarrhea, and particularly vigorous exercise. The stress dose is typically given for 24 hours, after which the usual dose is resumed. Should it be necessary to administer the stress dosage for a more prolonged period, the dosage can usually be tapered rapidly to physiologic dosage, once the patient's clinical condition has improved.

PRION DISEASES (TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES)

Jason Y. Kim

BASICS

DESCRIPTION

- Transmissible spongiform encephalopathies (TSEs) or prion diseases are a family of progressive neurodegenerative diseases of humans and animals that cause irreversible cumulative brain damage and are uniformly fatal.
- Prions are the infectious agents that cause TSE. The term *prion* was coined to denote "a small proteinaceous infectious particle resistant to inactivation by most procedures that modify nucleic acids."
- Prion proteins (PRP) are normal cellular glycoproteins (PRP^C) encoded by the *PRNP* gene, and are found on neurons and white blood cells.
- The infectious particles that cause TSEs are protease-resistant conformers of PRP^C (PRP^{RES} or PRP^{SC} for protease-resistant or scrapie-causing PRPs, respectively).
- Human TSEs include Creutzfeldt–Jakob disease (CJD), the more recently identified variant CJD (vCJD), kuru, Gerstmann–Sträussler–Scheinker syndrome, and fatal familial insomnia syndrome.
- Six TSEs in animals have been described: Bovine spongiform encephalopathy (BSE, also known as mad cow disease), scrapie in sheep and goats, feline spongiform encephalopathy, transmissible mink encephalopathy, exotic ungulate encephalopathy, and chronic wasting disease of cervids.

EPIDEMIOLOGY

- CJD:
 - CJD is the most prevalent form of TSE in humans and occurs as either a sporadic or a familial disease.
 - ~85% of cases are sporadic because there is no family history and no known source of transmission. Sporadic CJD occurs throughout the world at a rate 1/1,000,000 people.
 - Familial CJD (fCJD) cases are associated with a gene mutation in PRNP and account for ~10–15% of cases. fCJD shows an autosomal dominant inheritance, with >50 mutations in PRNP identified.
 - ~1% of CJD cases are iatrogenic, resulting from accidental transmission of the causative agent via contaminated surgical equipment, as a result of cornea or dura mater transplants, or administration of human-derived pituitary growth hormones.
 - No evidence confirms person-to-person transmission among family members via direct contact, droplet, or airborne spread.
 - Disease is characterized by progressive dementia, myoclonus, visual or cerebellar disturbance, pyramidal/extrapyramidal dysfunction, and/or akinetic mutism
 - Classic sporadic CJD most often occurs between the ages of 50–70 and affects both sexes equally; whites have about a 2-fold higher rate than blacks.
 - Death usually occurs within 1 year of onset of symptoms.

- Variant CJD (vCJD):
 - New form of CJD, 1st reported in 1994; has unique clinical features
 - In contrast to CJD, affects younger patients including adolescents (average age, 29 years) and has a longer duration of illness with median of 14 months as opposed to 4.5 months with CJD
 - Strong epidemiologic evidence links vCJD to BSE:
 - BSE is a TSE that affects cattle; it was 1st reported in the U.K. The most likely route of exposure is through bovine-based foods derived from BSE-infected cattle.
 - The highest incidence of vCJD is seen in the U.K., the country with the largest potential exposure to BSE.
 - 3 cases of vCJD have been confirmed in the U.S. (although each were likely to have been contracted outside the U.S.).
 - Clinical features, found early in the illness, include:
 - Prominent psychiatric symptoms (e.g., depression, schizophrenia-like psychosis) and ataxia
 - Other neurologic signs (e.g., paresthesia/dysesthesia, chorea, dystonia, myoclonus, and akinetic mutism) develop as the disease progresses.
 - Recently, clinical criteria for the diagnosis of vCJD were validated in the U.K. by autopsy/biopsy proven cases compared to non-cases
- Fatal familial insomnia (FFI):
 - An autosomal-dominant disorder, caused by mutation at codon 178 of PRNP, also identified in fCJD. If there are homozygous alleles at codon 129 encoding methionine in conjunction with the codon 178 mutation, FFI ensues. If codon 129 encodes valine in conjunction with the codon 178 mutation, then fCJD develops.
 - Clinical features include insomnia, dysautonomia, ataxia, myoclonus, and late dementia.
 - Pathology reveals minimal vacuolization and no plaques.
- Gerstmann–Straussler–Scheinker syndrome:
 - A disorder with autosomal-dominant inheritance
 - Clinical features include ataxia and dementia.
 - Pathology reveals amyloid plaques.

PATHOPHYSIOLOGY

- TSE arises when exogenous or endogenous PRP^{RES} cause PRP^C to misfold into the abnormal protease-resistant form associated with TSE.
- Progressive accumulation of PRP^{RES} in the CNS disrupts function, leading to vacuolization and cell death. There is no host-adaptive immune response beyond microglial cell activation involved in the pathologic process.
- Neuropathologic findings include neuronal loss, atrophy, vacuolization or spongiform change, reactive astrogliosis, and cell death.
- PRP^{RES} also accumulate in the reticular endothelial system, mucosa-associated lymphoid tissues, and areas of chronic inflammation throughout the body.

ETIOLOGY

- Prions are infectious proteins lacking nucleic acids that are believed to cause TSE.
- Infection arises when normal protease-sensitive host proteins, involved in neuronal function, undergo spontaneous misfolding to yield the abnormal protease-resistant form associated with infectivity.
- Newly formed host PRP^{RES} recruit neighboring cellular PRP^C and convert it to the infectious conformer. The exact molecular and cellular mechanisms surrounding propagation of PRP^{RES} remains unknown.
- Although the presence of PRP^C is necessary for the migration of PRP^{RES} to the RES, the mechanism for migration to the CNS remains unknown.
- Prions reproduce by recruiting neighboring normal cellular PRP and stimulating its conversion to the infectious form.
- Whether PRP^{RES} reproduce without any genetic material, thus bypassing the central dogma, is still hotly debated.
- Not all scientists believe the prion hypothesis, and some have argued that the causative agent is virus-like and possesses nucleic acids although none has ever been isolated from TSE pathologic specimens.

DIAGNOSIS

HISTORY

- Evidence of a familial form of TSE
- Potential iatrogenic exposures such as administration of human-derived pituitary growth hormones, implantation of dura mater or corneal grafts from humans, epilepsy surgery, or other CNS surgery involving stereotactic electrodes
- Duration of symptoms >6 months
- Afebrile illness
- In vCJD, progressive neuropsychiatric symptoms including:
 - Depression, anxiety, apathy, withdrawal, or delusions
 - Painful sensory symptoms including pain and/or dysesthesia
 - Ataxia
 - Myoclonus, chorea, or dystonia
 - Dementia

PHYSICAL EXAM

- Afebrile
- Abnormal mental status exam with defects in memory, personality, and other higher cortical functions, or psychosis
- Neurologic signs include unsteady gait and the presence of involuntary movements.
- Late findings include mutism and complete immobility.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Most laboratory tests are of little value in the diagnosis of TSE. Exam of CSF fluid may reveal a mild elevation of protein, but otherwise the cerebrospinal fluid is normal.
- EEG:
 - In CJD, generalized slowing is seen early in the disease with progression to periodic burst of biphasic or triphasic sharp-wave complexes.
- In vCJD, the EEG does not show the waveforms characteristic of sporadic CJD. Although EEG abnormalities are seen in most patients, these findings are not specific.

Imaging

MRI:

- In patients with vCJD, abnormally high T2 signal in the bilateral pulvinar regions of the thalamus may be seen.
- In CJD, hyperintense signals in the basal ganglia are often seen.
- In later stages of CJD and vCJD, imaging studies such as MRI or CT scan reveal generalized atrophy with large ventricles.

Diagnostic Procedures/Other

- Diagnosis of TSE in humans can be confirmed only following pathologic exam of the brain.
- Microscopic exam of patients with all types of human TSEs reveals spongiform change accompanied by neuronal loss and gliosis.
- Amyloid plaques or immunohistochemical demonstration of abnormal PRP in the brain may also be seen.
- “Florid” plaques (amyloid plaques encircled by holes or vacuoles resulting in a daisy-like appearance) are consistently present in patients with vCJD.
- Tonsil biopsy revealing accumulation of PRP^{RES} may be helpful in confirming suspected cases of vCJD.

DIFFERENTIAL DIAGNOSIS

- Neurodegenerative disorders—mostly seen in older adults with the exception of Alpers disease:
 - Alzheimer disease
 - Parkinson disease
 - Frontotemporal dementia
 - Pick disease
 - Alpers disease (progressive cerebral hemiatrophy)
 - Amyotrophic lateral sclerosis
 - Huntington disease
 - Spinocerebellar ataxia
- Psychiatric disorders—especially when considering vCJD as a diagnosis:
 - Depression
 - Schizophrenia
 - Drug-induced psychosis
- Encephalitis, infectious

- Sydenham chorea
- Subacute sclerosing panencephalitis
- Progressive multifocal leukoencephalopathy
- Toxic encephalopathy
- Inborn errors of metabolism
- Hashimoto thyroiditis
- CNS vasculitis
- CNS tumors

TREATMENT

ADDITIONAL TREATMENT

General Measures

- No treatment is effective in slowing or stopping the progression of disease. Appropriate supportive care should be provided. Prognosis for patients with human TSEs is uniformly poor.
- Several compounds and methods have undergone testing in cell-free, tissue, and animal models of TSE. Some decrease the rate of PRP^{RES} accumulation and allow animals to reach their expected lifespan. None reverses the damage seen in the CNS after plaques have formed.
- Infection control:
 - Standard universal precautions are indicated for infection control.
 - Strict isolation is not necessary.
 - Caution should be used in obtaining cerebrospinal fluid and handling tissues obtained at autopsy.
 - Equipment contaminated by high-risk tissue should be soaked in ≥1 N sodium hydroxide solution for at least 1 hour and then autoclaved at 134°C for at least 1 hour.

FAQ

- Q: Is transmission of TSEs from human blood possible?
- A: There have been 3 verified cases of vCJD attributed to transfusion of blood products in the U.K. There have been no cases of transfusion related vCJD in the U.S.
- Q: Is our food supply safe?
- A: No cases of BSE have been recognized in North America. The incidence in the U.K. has been low and is not increasing rapidly. Measures have been taken by the World Health Organization and the U.S. FDA to reduce the risk of TSE, including a ban on the use of ruminant tissues in animal feed and surveillance systems to detect TSE in animals and to prevent any part or product of an animal with suspected TSE to enter the human or animal food chain. The FDA has banned biologic agents of bovine origin produced in countries at risk of BSE. There have been 3 cases of vCJD in U.S. citizens, but each case was likely contracted outside the U.S. (U.K. and Saudi Arabia).

PROBIOTICS

Andi L. Shane

Michael D. Cabana

BASICS

DESCRIPTION

- Probiotics are defined by the World Health Organization as “live micro-organisms, which when administered in adequate amounts, confer a health benefit to the host.”
- Just because a product contains “live cultures” does not make it a probiotic product. There has to be sufficient numbers of colonies, as well as a proven health benefit.
- Specific probiotic strains are generally regarded as safe. The Center for Food Safety and Nutrition (CFSAN) provides guidelines for the manufacture of probiotic products are not directly regulated as biologic drug products by the FDA, clinicians must carefully evaluate the agent selected.
- Probiotic strains are similar to the bacteria commonly found in fermented food products, such as yogurt, sour cream, sauerkraut, and buttermilk.
- Several formulations of probiotic products are available both in single-strain and multistrain preparations:
 - Probiotic organisms may be consumed as fermented dairy products or as supplements in the form of a capsule, tablet, liquid, or powder formulation.
 - Supplements theoretically provide a more consistent dose of colony-forming units (CFUs) of probiotic organisms than probiotics consumed in food products.
- Commonly used probiotic supplements contain single organisms, including the following strains:
 - *Bifidobacterium bifidum* strain YIT 4002
 - *Lactobacillus rhamnosus* ATCC 53103
 - *Lactobacillus delbrueckii* subsp. *bulgaricus*
 - *Streptococcus salivarius* subsp. *thermophilus*
 - *Escherichia coli* Nissle 1917
- Yeast, including *Saccharomyces boulardii*, is an alternative to bacterial probiotic formulations.
- Multistrain probiotics incorporate a combination of organisms in varying quantities.

PATHOPHYSIOLOGY

- Probiotics are hypothesized to exert their primary effects on the gut by re-establishing the intestinal microbiota balance, competing for receptor sites in the intestinal lumen and competing with pathogens for nutrients.
- The proposed immunomodulatory functions of probiotics include enhancing host immune defenses via strengthening tight junctions between intestinal enterocytes, increasing immunoglobulin A production, stimulating cytokine production, and producing substances (e.g., arginine, glutamine, and short-chain fatty acids) thought to secondarily act as protective nutrients.

DIAGNOSIS

- The selection of a single-strain versus a multistrain probiotic product, or a bacterial probiotic versus a yeast probiotic, should be based on the underlying indication and whether the probiotic is administered for treatment or prophylaxis.
- The following probiotics have been shown to be efficacious for the treatment and/or prevention of the following conditions:

Probiotic	Indication
<i>L. rhamnosus</i> GG	Infectious diarrhea, especially of viral etiology
<i>S. boulardii</i>	Antibiotic-associated diarrhea
Combination therapy with lactobacilli, bifidobacteria, streptococci, <i>S. boulardii</i>	<i>Clostridium difficile</i> -associated diarrhea
<i>Lactobacillus reuteri</i> DSM 17938	Colic

- Efficacy with a probiotic strain or species does NOT imply that other strains will be equally efficacious. Host factors, dosing, and indication must be considered in formulating recommendations.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- The unit of dosing for oral probiotic supplements is the colony forming unit (CFU).
- Currently, there are no established dosing guidelines based on pharmacokinetic data for children.
- Studies, to date, in adults have used oral doses of 1–10 billion CFUs per dose, with administration frequency ranging from 3 times daily to weekly.
- Practitioners have used 1/2 of the adult dose for children of average weight and 1/4 of the adult dose for infants.

- There are no known reports of “toxicity” associated with probiotics in adults or children.
- The optimal dosing regimen with respect to timing of antimicrobials and probiotic supplements is not known. Currently available data suggest that temporal separation of probiotic and antimicrobial is not essential for efficacy. Furthermore, coadministration may improve compliance. For the treatment of antibiotic-associated diarrhea, there is no need to administer a probiotic at a different time from the administration of the antibiotic.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- The use of probiotics for the treatment and prevention of disease and maintenance of health is a developing field. Specific probiotics may be beneficial for certain indications and hosts, but not for all.
- The American Academy of Pediatrics (AAP) has issued a clinical report summarizing the evidence for use of probiotics and supports their use on a case-by-case basis in children who may benefit from supplementation.
- Probiotics have been shown to be efficacious in randomized, double-blind, placebo-controlled studies for the following indications:
 - Decreasing the duration of infectious diarrheal episodes in hospitalized children, childcare attendees, and children with enteric viral infections in resource-poor areas
 - Reducing antibiotic-associated diarrhea in children receiving oral and intravenous antibiotics
 - Treating and preventing pouchitis, inflammation of a surgically created distal small bowel reservoir, and irritable bowel syndrome in children and adults
 - Treating atopic dermatitis (eczema)
- Probiotic applications currently being evaluated include:
 - Prevention of necrotizing enterocolitis
 - Maintenance of remission in persons with ulcerative colitis
 - Treatment and prevention of atopic disease including rhinitis and asthma
 - Improving tolerance of *Helicobacter pylori* eradication therapy
 - Prevention of genitourinary infections, such as urinary tract infections and candidiasis
 - Prevention of dental caries

- Future investigations to evaluate the efficacy and safety of probiotics in large-scale, multicenter trials; to monitor the potency and composition of probiotic formulations; to develop *in vitro* and *in vivo* systems to understand the molecular mechanisms of action; and to understand the balance among infection, immunity, and probiotics are in progress.
- The selection of a probiotic for pediatric use requires an understanding of the indication, the optimal formulation (single strain vs. multistrain), delivery system, and the host.

Patient Monitoring

- Currently available probiotic formulations are viable microorganisms and therefore have the potential to cause invasive infections in hosts who may have compromised mucosal epithelia.
- A recent review (2008) suggests that probiotics should be used with caution in children with major risk factors or multiple minor risk factors:
 - Major risk factors include immune compromise or prematurity.
 - Minor risk factors include the presence of a central venous catheter, impaired intestinal epithelial barrier, administration of a probiotic by jejunostomy, concomitant administration of a broad-spectrum antibiotic to which the probiotic organism is resistant, use of probiotic strains with high mucosal adhesion or known pathogenicity, and the presence of cardiac valvular disease (*Lactobacillus* strains only).
- An extremely low incidence of bacteremia has been observed with widespread use of probiotics in Finnish adults.
- To date, there have not been any adverse effects attributable to probiotic consumption in pregnant women consuming a probiotic supplement to prevent atopic dermatitis in their infants.
- HIV-infected adults taking a probiotic supplement to prevent diarrhea and improve tolerance of antiretroviral agents have not experienced adverse effects attributable to the probiotic supplement.

FAQ

- Q: Can children receive an adequate amount of probiotics by consuming yogurt?
- A: Although probiotic organisms are found in some foods such as yogurt, the dosage of active organisms provided via routine consumption may be inadequate for a therapeutic benefit. Food processing may result in variable viability and CFUs of probiotic organisms in food products. The availability of CFUs in commercially prepared probiotic formulations is theoretically more precise. Probiotic supplements may offer a higher dose of organisms in a more concentrated form. The volume of yogurt that one would need to ingest to match the CFUs of a nonfood probiotic supplement usually exceeds what an adult or child could consume in a single serving.
- Q: What is the difference between probiotic and prebiotic supplements?

- A: Probiotic supplements contain live microorganisms, while prebiotic supplements are substances that promote the growth of probiotic organisms. The most common prebiotic supplements are fructo-oligosaccharides and galacto-oligosaccharides, which are present in human milk.
- Q: What other factors should a clinician consider when recommending use of a probiotic supplement?
- A: The rate of adherence will affect the clinical effectiveness of probiotic supplementation. The addition of a probiotic supplement may complicate a treatment or maintenance regimen. “Per protocol” analyses of studies evaluating probiotic supplementation demonstrate statistical significance, while an “intention to treat analysis” may not. These results have implications regarding the importance of patient adherence for effectiveness.
- Q: What is the standard dose for a probiotic supplement?
- A: There are no uniform dosing recommendations for probiotics. The optimal dose depends on the indication, the host, and the species and strain of the probiotic being utilized.

PROLONGED QT INTERVAL SYNDROME

Ronn E. Tanel

BASICS

DESCRIPTION

Prolonged QT interval syndrome, also known as *congenital long QT syndrome* (LQTS), is characterized by prolongation of the QT interval on the surface ECG, syncope, and sudden death as a result of malignant ventricular arrhythmias. The electrical instability is due to an abnormality of ventricular repolarization associated with a cardiac ion channelopathy.

EPIDEMIOLOGY

Incidence

Extrapolation from sudden death data suggests that the frequency may be ~1 in 2,500.

Prevalence

Exact prevalence of LQTS is not known, but it may be a relatively common cause of syncope and sudden unexplained death in children and young adults.

RISK FACTORS

Genetics

- Autosomal dominant (Romano-Ward syndrome)
- Autosomal recessive, sometimes associated with congenital nerve deafness (Jervell and Lange-Nielsen syndrome)
- Genetic linkage analysis studies have demonstrated that >400 genetic mutations among 12 cardiac channel genes account for nearly 3/4 of LQTS.
- Genotype-phenotype-based research studies have identified gene-specific electrocardiographic profiles, gene-specific arrhythmia triggers, gene-directed treatment strategies, and gene-specific risk stratification.

GENERAL PREVENTION

- Preventive measures focus on screening for the electrocardiographic abnormality, especially in individuals who appear to be at risk of having the diagnosis.
- Patients who have been diagnosed are advised to avoid exposure to stimulants, medications that are known to prolong the QT interval or provoke ventricular arrhythmias and situations that may aggravate the cardiac rhythm or induce torsades de pointes.

PATHOPHYSIOLOGY

2 hypotheses have been proposed to explain the pathogenesis of congenital long QT syndrome:

- An abnormality or imbalance in sympathetic innervation to the heart, which helps explain the findings of sinus bradycardia, abnormal repolarization, adrenergic dependence of arrhythmias, and response to adrenergic antagonist medications associated with the syndrome.
- Intrinsic cardiac ion (potassium and sodium) channel gene defects appear to be the mechanism responsible for cardiac repolarization abnormalities. Because some identified gene mutations that result in congenital long QT syndrome occur at loci that also encode a cardiac ion channel protein, ion channels have been proposed as the intrinsic abnormality that is responsible for abnormal repolarization.

DIAGNOSIS

HISTORY

- Notable findings include:
 - Palpitations
 - Presyncope
 - Syncope
- These symptoms may be related to provocative stimuli, especially emotional or physical stress. Any use of medications known to prolong the QTc interval should be noted.
- Most importantly, a thorough family history for arrhythmia, syncope, epilepsy, or sudden unexplained death should be obtained.

PHYSICAL EXAM

Findings are usually normal, but bradycardia may be present.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The Bazett formula: $QTc = QT / (\text{square root of } RR \text{ interval})$. Generally, a $QTc > 480$ msec is considered abnormal, although some clinicians allow a slightly longer QTc for infants <6 months of age.
- Some clinicians believe that the QTc should not be corrected at heart rates <60 beats per minute (bpm). The measurement should be taken in lead II without significant sinus arrhythmia.
- Children frequently have a prominent U wave. It should generally be included in the measurement of the QTc if it exceeds 1/2 the amplitude of the T wave.

- A single measured prolonged QTc interval does not confirm the diagnosis of long QT syndrome.
- Since 2004, genetic testing has been available as a commercial diagnostic test. Unfortunately, only 2/3–3/4 of all genetic causes of LQTS have been identified, so false-negative genetic testing is possible.
- Clinical scoring systems may help stratify patients into high, moderate, and low probability of having the diagnosis, based on symptoms, family history, and ECG findings.

Imaging

ECG:

- Atrioventricular block can be seen on the ECG in infants with relatively rapid heart rates and P waves that occur during the prolonged repolarization period (QT interval) of ventricular refractoriness.
- The echocardiogram should demonstrate normal cardiac structure and function.

Diagnostic Procedures/Other

- Other tests that may help confirm the diagnosis include 24-hour ambulatory Holter monitoring:
 - This recording may disclose asymptomatic ventricular ectopy or arrhythmias, T-wave alternans, or variability in the QTc interval during different periods of the day.
- Exercise stress testing may also be helpful in identifying ventricular arrhythmias or prolongation of the QTc interval, particularly during the early recovery phase.

DIFFERENTIAL DIAGNOSIS

- Congenital LQTS is most commonly misdiagnosed as vasovagal syncope or a seizure disorder. All patients who have a syncopal event or who are diagnosed with epilepsy should have a baseline screening ECG. Sudden infant death syndrome (SIDS) may be related to congenital long QT syndrome. Some studies have demonstrated that mutations of ion channel proteins that cause LQTS have been found in SIDS victims. QT interval prolongation may be subtle, such that ~10% of affected patients may have a normal result on routine ECG and ~40% may have borderline prolongation of the QT interval.
- Acquired forms of LQTS should be differentiated from the congenital and inherited form. Acquired LQTS may be due to the following:
 - Electrolyte abnormalities: Hypokalemia, hypocalcemia, hypomagnesemia, and metabolic acidosis
 - Toxins: Organophosphates
 - CNS trauma
 - Malnutrition: Anorexia

- Primary myocardial disease: Myocarditis, ischemia, cardiomyopathy
- Medication:
 - Cardiac medications: Quinidine, procainamide, disopyramide, sotalol, and amiodarone
 - Antibiotics/Antifungals: Erythromycin, trimethoprim–sulfamethoxazole, pentamidine, ketoconazole, and fluconazole
 - Psychotropic medications: Tricyclic antidepressants, phenothiazines, and haloperidol
 - Antihistamines: Terfenadine, astemizole, diphenhydramine
 - GI: Cisapride

TREATMENT

MEDICATION (DRUGS)

- The primary therapy is β -blockade, most commonly with propranolol, atenolol, or nadolol.
- Class Ib antiarrhythmic medications (e.g., mexiletine) are also used in patients with congenital LQTS, especially in those with documented ventricular arrhythmia.
- Medications do not generally help treat patients with acquired LQTS.

ADDITIONAL TREATMENT

General Measures

Patients are usually treated based on symptoms and the clinical severity of the disease.

Additional Therapies

Automatic implantable cardioverter-defibrillators (ICDs) are usually reserved for older children and adolescents who have significant symptoms, documented ventricular arrhythmias, or other significant risk factors for sudden death.

SURGERY/OTHER PROCEDURES

- Occasionally, implantation of a permanent pacemaker is indicated based on the theory that the tachyarrhythmias (e.g., torsades de pointes) are dependent on bradycardia and/or pauses. Pacemaker implantation may be necessary to support the low heart rate that is a result of β -blocker therapy. Newborns and infants with a very prolonged QT interval, atrioventricular block, and low ventricular rates are historically treated with a pacemaker.
- An ICD may be recommended for patients thought to be at higher risk of developing ventricular arrhythmias.
- Left stellate ganglionectomy is controversially performed to eliminate the hyperactive left sympathetic ganglion output that has been proposed as a mechanism of ventricular arrhythmias.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Most clinicians treat diagnosed asymptomatic children with medications because of a high incidence of sudden death that occurs as the 1st symptom.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow-up outpatient appointments should review new or recurrent symptoms, including palpitations, near syncope or syncope, and the efficacy and adverse effects of medical therapy.
- ECG may demonstrate a normal or prolonged QTc.
- Follow-up 24-hour ambulatory Holter monitor recordings and exercise stress tests may help assess the adequacy of β -blocker therapy and identify ventricular arrhythmias.
- All family members of the patient should have an ECG, as a minimum screening measure.

PROGNOSIS

- Children have a higher incidence of sudden death than adults, which may reflect an inherent bias because adult patients have already survived childhood. The risk of cardiac events is higher in boys before puberty and in women during adulthood.
- Pediatric patients with greatest risk for sudden death are those with QTc >600 msec. Gender, environmental factors, genotype, and therapy are other factors that influence the clinical course.
- A particular clinical phenotype may be caused by different genetic substrates, while a single gene can cause very different phenotypes, even within the same family, by acting through different pathways.
- β -blocker therapy has been shown to reduce the incidence of sudden death.
- Current research may lead to the development of therapy specific to the precise ion channel defect.

COMPLICATIONS

- Complications, especially in untreated patients, include:
 - Ventricular tachyarrhythmias, specifically torsades de pointes
 - Syncope
 - Sudden death
- In patients with the congenital and inherited form of the condition, asymptomatic family members may be affected.

FAQ

- Q: Should activity be restricted in patients with congenital LQTS?
- A: Because sudden rises in serum catecholamine levels may precipitate symptoms, it is appropriate to restrict competitive and vigorous athletics. Symptomatic patients may require greater restrictions. Documentation of appropriate β -blockade by a lower maximal heart rate at peak exercise on follow-up exercise stress test may be helpful.
- Q: If someone is identified as having LQTS, should family members be evaluated?
- A: Yes, with a high degree of suspicion. Most cases of congenital LQTS are inherited in an autosomal-dominant pattern, so that each child of an affected parent has a 50% chance of having the gene. This does not predict severity of symptoms, but parents, all siblings, and children of patients should be examined with an ECG. Holter monitor and exercise stress test. These studies may help reveal an abnormal QTc interval in suspected family members.

PROTEIN-ENERGY MALNUTRITION (KWASHIORKOR)

Robert D. Karch
Teena Sebastian

BASICS

DESCRIPTION

- The term “protein-energy malnutrition” (PEM) describes a general state of undernutrition and deficiency of multiple nutrients and energy.
- There are three clinical presentations of severe PEM: Kwashiorkor, marasmus, and marasmic kwashiorkor.
- Kwashiorkor results from protein deficiency and is characterized by hypoproteinemia, pitting edema, varying degrees of wasting and/or stunting, dermatosis, and fatty infiltration of the liver.
- Marasmus results from both energy and protein deficiency and is characterized by wasting, fatigue, and apathy.
- Marasmic kwashiorkor is caused by acute or chronic protein deficiency and chronic energy deficit and is characterized by edema, wasting, stunting, and mild hepatomegaly.
- The distinction between kwashiorkor and marasmus is frequently blurred and many children present with features of both.
- Severe PEM covers a broad clinical spectrum ranging from frank kwashiorkor to severe marasmus when the body’s protein and energy requirements are not adequately met:
 - Primary:
 - Inadequate dietary intake
 - Secondary:
 - Result of other disease processes that limit food ingestion or reduce nutrient absorption, or those that increase nutrient requirements or losses
- Cicely Williams introduced the name “kwashiorkor” in 1935 in a classic description of her observations of the Ga tribe on the Gold Coast of Africa (currently Ghana).
- Kwashiorkor in the US:
 - In developed nations, symptoms of kwashiorkor have been described in chronic malabsorptive conditions such as cystic fibrosis.
 - In the US, few cases of kwashiorkor unrelated to chronic illness have been described.
 - Common reasons for the consumption of a protein-deficient milk alternative, sugar water or fruit juice, are nutritional ignorance, perceived milk or formula intolerance, or food fads.
 - Consumption of a low-protein health food milk alternative, such as rice milk, secondary to a history of chronic eczema and perceived milk intolerance, has occurred in the United States.
 - Symptoms like “flaky paint dermatitis,” edema, and lab abnormalities suggestive of kwashiorkor have been seen in such cases.

EPIDEMIOLOGY

- Malnutrition underlies 55% of childhood mortality worldwide.
- Kwashiorkor may occur at any age, but is seen most frequently in children 1–3 years of age.
- Kwashiorkor is seldom seen in the 1st year of life. It is usually seen in the 2nd year or beyond, when the toddler is fully weaned or only partially breastfed and may have a low intake of dietary protein.

PATHOPHYSIOLOGY

- Temperature regulation is impaired, leading to hypothermia in a cold environment and hyperthermia in a hot environment.
- Increase in total-body sodium and decrease in total-body potassium
- Hypophosphatemia is associated with malnutrition and results in high mortality.
- Protein synthesis is reduced, particularly albumin, transferrin, and apolipoprotein B. Hypertriglyceridemia leads to fatty infiltration of the liver.
- Gluconeogenesis is reduced, which increases risk of hypoglycemia during infection.
- Reduced cardiac output leads to low blood pressure, compromised tissue perfusion, and a reduction in renal blood flow and glomerular filtration rate.
- Diminished inspiratory and expiratory pressures and vital capacity
- Reduction of gastric and pancreatic secretions
- Reduced intestinal motility
- Intestinal mucosa atrophy resulting in malabsorption of carbohydrates, fats, fat- and water-soluble vitamins
- Low circulating insulin levels
- Growth hormone secretion is increased while somatomedin activity is reduced.
 - Glucagon, epinephrine, and cortisol levels are increased.
 - Serum T₃ and T₄ levels are reduced.
- Immune system:
 - All aspects of immune function are diminished in malnutrition, thereby increasing susceptibility to infection.
 - Delayed wound healing may be seen owing to nutritional deficiencies.

ETIOLOGY

- There are two principal theories regarding the etiology of kwashiorkor: The classical theory of protein deficiency and the newer theory of free radical damage.
- Both theories emphasize different aspects of the environment: In the classical theory, nutrients, and in the free radical theory, oxidative stresses.
- The classical theory of protein deficiency was supported by Williams’ original description of kwashiorkor developing in children who were weaned onto starchy gruels after being deposited from the breast and being cured by milk:
 - The free radical theory of kwashiorkor proposes that kwashiorkor results from an imbalance between the production of toxic free radicals and their safe disposal.
 - Golden and colleagues argue that inadequate diet leads to a state of impaired antioxidant defense.

- The free radical theory attempts to explain the entire spectrum of clinical findings in kwashiorkor by implicating a wide range of nutritional deficiencies, as well as environmental oxidative stressors (noxae):
 - Important noxae include infections and exogenous toxins such as aflatoxin and its metabolites.
 - Aflatoxin, from the fungus *Aspergillus flavus*, has been found in greater concentrations in the serum and urine of children with kwashiorkor than in controls.
 - There is a hierarchy of causes of PEM operating at different levels and interacting with one another; from food scarcity, infection, malabsorption, and neglect, to poverty and social disadvantage, to drought, war, or civil disturbance.
- The multiplicity of causes of PEM necessitates a multidisciplinary approach to its treatment and prevention.

DIAGNOSIS

HISTORY

- Dietary history:
 - Diet before current illness episode
 - Adequacy of protein and total calories
 - Food and fluids taken in past few days
 - Assess whether parents and children adhere to special diets or whether health food milk alternatives, such as rice milk, are given.
- Determine duration and frequency of emesis or diarrhea.
- Loose stools with evidence of malabsorption are common. Stools may be watery and/or tinged with blood.
- Any death of siblings
- Cultural beliefs and practices regarding infant and childhood feeding
- Growth records: Decreased growth velocity commensurate with poor protein intake

PHYSICAL EXAM

- Weight and length/height:
 - Growth failure always occurs to some extent.
 - Wasting is also typical, although it may be masked by the presence of edema.
- Affected child is usually apathetic and irritable.
- Child is usually unsmiling and prefers to remain in one position.
- Hypothermia or hyperthermia
- There is some degree of edema in all cases of kwashiorkor:
 - Peripheral edema usually begins in the feet and ascends up the legs.
 - Pitting of the skin above the ankle is diagnostic.
 - The hands and face may become edematous.
 - Facial edema gives the characteristic “moon facies.”

- Hair lacks luster and color may change to brown or reddish-brown.
- Hair is easily pluckable.
- Bands of discolored hair, representing periods of malnutrition, are termed the “flag sign.”
- Dermatitis often develops in areas of friction or pressure.
- Hypo- or hyperpigmented patches may appear, which subsequently desquamate in scales or sheets, exposing atrophic ulcers resembling burns.
- Additional clinical signs of PEM:
 - Signs of B-vitamin deficiency, such as perioral lesions
 - Signs of vitamin A deficiency, such as xerosis and/or xerophthalmia
 - Pale, cold, and cyanotic extremities: Decreased vascular volume secondary to decreased protein concentration
 - Abdomen is frequently protuberant secondary to poor peristalsis, leading to distended stomach and intestinal loops.
 - Respiratory: Looks for signs of pneumonia or heart failure.
 - Enlargement of liver and jaundice may also be seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum protein
- Prealbumin and serum transferrin may be useful in determining severity of kwashiorkor.
- Retinal binding protein may be reduced.
- Hemoglobin and hematocrit are usually low.
- Ratio of nonessential to essential amino acids in plasma is elevated in kwashiorkor and usually normal in marasmus.
- Increased serum elevation of free fatty acids
- Low serum and urine carnitine levels
- Stool exam to rule out infectious cause of chronic diarrhea
- Chest radiograph and PPD to rule out TB

DIFFERENTIAL DIAGNOSIS

- Nephrotic syndrome
- Hookworm anemia:
 - May cause edema alone. Commonly seen in association with kwashiorkor. It is not associated with the kwashiorkor-related dermatologic findings.
- Chronic dysentery
- Protein-losing enteropathy (PLE)
- Pellagra: Dermatitis of pellagra and kwashiorkor are similar. However, the dermatosis of pellagra is often seen in sun-exposed areas, not in areas such as the groin, as commonly seen in kwashiorkor. Kwashiorkor dermatosis is often described as “flaky paint” dermatosis.

TREATMENT

WHO Guidelines

- Prevent and treat:
 - Hypoglycemia
 - Hypothermia
 - Dehydration
 - Electrolyte imbalances
 - Infection
 - Micronutrient deficiencies
- Provide special feeds for:
 - Initial stabilization
 - Providing catch-up growth
 - Providing loving care and stimulation
- Where guidelines have been fully implemented, mortality has been reduced by at least half.
- Management of the child with severe protein-energy malnutrition is divided into 3 phases: Initial treatment, rehabilitation, and follow-up.

ADDITIONAL TREATMENT

General Measures

- Whenever possible, a dehydrated child with malnutrition should be rehydrated orally or by nasogastric tube.
- IV infusion should be avoided except for when it is essential (e.g., severe dehydration and shock).
- Hypoglycemia is an important cause of death in the 1st 2 days of treatment.
- Suspected hypoglycemia should be treated with oral rehydration salts solution (ORS) or 10% glucose by mouth or nasogastric tube.
- Severely malnourished children have high levels of sodium and are deficient in potassium. Standard WHO ORS does not meet the special electrolyte requirements of the severely malnourished child.
- ReSoMal is a modified ORS that contains less sodium and more potassium than the standard WHO ORS and is the recommended ORS for severely malnourished children.
- Breastfeeding should not be interrupted during rehydration.

ONGOING CARE

PROGNOSIS

- Treatment corrects the acute signs of the disease, but catch-up growth in height may never be achieved.
- Mortality rate in kwashiorkor can be as high as 40%, but adequate treatment can reduce it to <10%.
- Some of the factors that indicate poor prognosis:
 - Age <6 months
 - Infections
 - Dehydration and electrolyte abnormalities
 - Persistent tachycardia, signs of heart failure
 - Total serum protein <3 g/100 mL
 - Elevated serum bilirubin
 - Severe anemia with hypoxia
 - Hypoglycemia and/or hypothermia

- Several longitudinal studies have demonstrated associations between early childhood stunting and later cognitive function and academic attainment. Behrman et al. demonstrated that stunting at 72 months was related to cognition between 25 and 42 years of age.

- E41 Nutritional marasmus
- E61.8 Deficiency of other specified nutrient elements

FAQ

- Q: What are the signs and symptoms of kwashiorkor and how do these change over the course of the clinical spectrum of severe protein-energy malnutrition, from kwashiorkor to marasmus?
- A: Signs and symptoms of kwashiorkor:
 - Growth failure, wasting
 - Edema that is peripheral in onset and ascending
 - Hair changes including color change, “flag sign,” and easy pluckability; “flaky paint” dermatosis of skin
 - In addition to above signs and symptoms child may also develop vitamin A and B deficiency, decreased peripheral circulation, and decreased peristalsis with distended bowel loops. Hepatomegaly/splenomegaly may also be observed. The child is at higher risk for developing other conditions such as pneumonia or congestive heart failure.
- Q: What are some common causes of severe undernutrition in the US that may present as kwashiorkor?
- A:
 - Chronic malabsorptive conditions such as cystic fibrosis
 - Consumption of protein-deficient milk substitutes such as rice milk, fruit juices, etc.

PROTEINURIA

Matthew G. Sampson

Andres J. Greco (5th edition)

BASICS

DEFINITION

- Protein may be found in the urine of healthy children. The term proteinuria is used to indicate urinary protein excretion beyond the upper limit of normal (100 mg/m²/d or 4 mg/m²/hr in children and 150 mg/d in adults).
- Proteinuria >40 mg/m²/hr is considered as nephrotic range.
- Classification:
 - Transient proteinuria: Often associated with high fever, cold stress, dehydration, and exercise. It is not associated with underlying renal disease and by definition is absent on subsequent urine examinations.
 - Orthostatic or postural proteinuria: Elevated protein excretion when the subject is upright and ambulating, but normal during recumbent position. It most commonly occurs in school-aged children and adolescents and rarely exceeds 1 g/m²/d.
 - Persistent or fixed proteinuria: Urinary dipstick ≥1+ in the first morning urine specimen on multiple occasions for a period >3 months. Requires prompt referral to nephrology.
 - Glomerular proteinuria: The amount of proteinuria may range from <1 to >30 mg/d. It is usually found in the context of edema and hypoalbuminemia. If there is a mixed nephritic/nephrotic picture, there may be associated, hypertension, abnormal glomerular filtration rate, and hematuria. The major urinary component is albumin.
 - Tubular proteinuria: Rarely >1 g/d and is not associated with edema. It may be associated with other defects of proximal tubular function (e.g., glucosuria, phosphaturia, aminoaciduria) and tubular interstitial processes. The major marker is beta-2-microglobulin.

PATHOPHYSIOLOGY

- ~50% of the normally excreted protein consists of Tamm-Horsfall protein, a glycoprotein secreted by the ascending loop of Henle.
- Proteinuria may be the result of an increased permeability of the glomeruli to the passage of serum proteins (glomerular proteinuria) or decreased reabsorption of low molecular weight proteins by the renal tubules (tubular proteinuria).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Idiopathic nephrotic syndrome**
 - Minimal change nephritic syndrome
 - Mesangial proliferation
 - Focal and segmental glomerulosclerosis
 - Membranous nephropathy
- **Nephrotic syndrome due to genetic causes**
 - Finnish-type congenital nephrotic syndrome
 - Familial focal and segmental glomerulosclerosis
 - Diffuse mesangial sclerosis
 - Denys-Drash syndrome (nephropathy, Wilms tumor, and genital abnormalities)
- **Chronic kidney disease**
- **Acquired glomerular disease**
 - Idiopathic glomerulonephritis (membranoproliferative glomerulonephritis)
 - Lupus-associated nephritis
 - IgA nephropathy
 - Systemic vasculitides
 - Subacute bacterial endocarditis
 - Diabetes mellitus
 - Hypertension
 - Hemolytic uremic syndrome
 - Hyperfiltration secondary to nephron loss (with or without sclerosis)
- **Genetic disorders**
 - Nail-patella syndrome
 - Alport syndrome
 - Fabry disease
 - Glycogen storage disease
 - Cystic fibrosis
 - Hurler syndrome (mucopolysaccharide type-1)
 - α-1-antitrypsin
 - Mitochondrial disorders (usually tubular proteinuria)
 - Gaucher disease
 - Dent disease (X-linked nephrolithiasis)
 - Cystinosis
 - Wilson disease
- **Oncologic/hematologic**
 - Sickle cell disease
 - Renal vein thrombosis
 - Leukemia
 - Lymphoma

• Infectious

- Poststreptococcal glomerulonephritis
- HIV-associated nephropathy
- Hepatitis B and C virus infection
- Malaria
- Syphilis (can present as congenital nephrotic syndrome)
- Pyelonephritis

• Drugs/toxins

- Bee sting
- Food allergens
- Antibiotic-induced interstitial nephritis
- Penicillamine
- Gold salts
- NSAIDs
- Heavy metals (e.g., mercury, lead)

• Miscellaneous

- Tubular interstitial nephritis
- Acute tubular necrosis
- Reflux nephropathy
- Hypothyroidism

• Congestive heart failure

 - Hepatosplenomegaly
 - Abdominal masses/organomegaly
- Genitalia:
 - Scrotal edema
 - Ambiguous genitalia (Denys-Drash syndrome)
- Skin:
 - Purpuric or petechial rash (leukemia, lymphomas)
 - Pallor (malignancies, chronic renal failure, HUS)
 - Angiokeratomas (Fabry disease)
- Extremities:
 - Pitting edema
 - Arthralgias/arthritis
- Dystrophic nails

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** Dipstick testing
- **Significance:**
 - Always to be performed in a first morning urine sample
 - A negative or trace result in a concentrated urine specimen (specific gravity > 1.020) is normal.
- **Test:** 24-hour collection of urine for protein

- **Significance:**
 - It is indicated for quantification of proteinuria and to confirm the diagnosis.
 - Normal range: < 100 mg/m²/d or < 4 mg/m²/hr
- **Test:** Spot ratio for protein/creatinine
- **Significance:**
 - Always to be performed in a first morning urine sample
 - Normal values are < 0.2 in children > 2 years of age and < 0.5 in children 6–24 months old.
 - It is the simplest method to quantitate proteinuria

ALERT

- Most patients with proteinuria will have orthostatic proteinuria that is identified with an early morning test for protein and a second test several hours later.
- It is important to check the urine sediment for red cell casts; this indicates a glomerular involvement and requires additional studies for nephritis and chronic renal disease.

 - R80.2 Orthostatic proteinuria, unspecified
 - R80.9 Proteinuria, unspecified

FAQ

- Q: When to refer to nephrology?
- A: Patients with one of the following: Fixed proteinuria, associated hypertension, associated hematuria, clinical evidence of nephritic syndrome and patient with family history of renal diseases with proteinuria.
- Q: When are imaging studies indicated?
- A: Patients with abnormal renal function, hematuria, or nephrolithiasis. The best initial study is renal and bladder ultrasound.

PRUNE BELLY SYNDROME

Shamir Tuchman

BASICS

DESCRIPTION

- Rare congenital disorder characterized by the triad of:
 - Deficiency of abdominal musculature
 - Bilateral cryptorchidism
 - Dilated, anomalous development of the bladder and upper urinary tract
- It presents with a broad-spectrum of severity, from mild hydroureter with an enlarged bladder and normal renal function to severe renal dysplasia and pulmonary hypoplasia.
- Also known as Eagle-Barrett syndrome

EPIDEMIOLOGY

- Incidence: 1/35,000–50,000 live births
- Most patients are detected during the neonatal period or prenatally during maternal ultrasound.
- Prune belly syndrome is much more common in males (>95%).

RISK FACTORS

Genetics

- The genetic basis of prune belly syndrome remains unclear.
- Most patients have normal karyotypes.
- Most cases are sporadic, although rare cases in sibs have been reported.

PATHOPHYSIOLOGY

The bladder in prune belly syndrome is large, irregularly shaped, and thick walled. Many patients have poor urinary flow and high residual volumes:

- Ureters are usually markedly dilated, tortuous, and elongated. Peristalsis is ineffective, and the distal ureters are most severely affected.
- Renal involvement is variable; the most severe dysplasia occurs in patients with extensive dilation of the urinary tract. Dysplastic changes are usually symmetric.
- Usually, the bladder neck is wide and the prostatic urethra is dilated and triangular.

ETIOLOGY

The cause of the prune belly syndrome remains unclear. 2 theories have been proposed:

- The triad of congenital defects may result from a primary mesodermal defect in development with congenital deficiency of smooth muscle in the bladder, ureter, and renal pelvis.
- Outflow obstruction of the bladder in utero may result in dilation of the bladder and upper urinary tract with subsequent renal injury. The expanded bladder may block the route of the descending testicles and may cause abdominal distention and abdominal wall muscle atrophy.

COMMONLY ASSOCIATED CONDITIONS

Many patients have associated anomalies:

- GI anomalies: Affect up to 30% of patients (e.g., imperforate anus and increased risk of volvulus)
- Musculoskeletal anomalies (e.g., talipes equinovarus, congenital hip dislocation, pectus excavatum, scoliosis).
- Respiratory (e.g., chronic respiratory tract infections due in part to impaired coughing, reactive airway disease, respiratory difficulty after general anesthesia)
- Genital anomalies in females (e.g., genital sinus, urethral atresia, vesicovaginal fistula, vaginal atresia, and bicornuate uterus). Ovaries in affected female patients are typically normal.
- Cardiac anomalies: Effect up to 10% of patients (e.g., patent ductus arteriosus [PDA], atrial septal defect [ASD], ventricular septal defect [VSD], tetralogy of Fallot [TOF])

DIAGNOSIS

HISTORY

In patients with mild involvement of the abdominal wall that is not detected in the neonatal period, evaluation of UTIs may reveal the dilated urinary tract.

PHYSICAL EXAM

- Dilated urinary tract
- Abdominal wall is characterized by multiple wrinkles and redundant skin.
- A large, distended bladder creates a suprapubic mass.
- Ureters and kidneys are readily palpable.
- Intestinal loops and peristalsis may be observed.
- Testes are undescended.
- Myopathy results in difficulty in sitting up from a supine position.
- Abnormal gait secondary to congenital hip dislocation and abdominal muscular hypoplasia.
- Chronic constipation from abdominal muscular hypoplasia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum levels of creatinine and BUN may be elevated.
- Renal failure may result in anemia and elevated levels of potassium, phosphorus, hydrogen ion, and uric acid, and decreased concentrations of sodium, calcium, and bicarbonate.

Imaging

- Ultrasound will demonstrate dilatation and redundancy of the upper urinary tract.
- When considering a voiding cystourethrogram, assess possible risk of introducing infection into dilated, poorly draining urinary tract.
- Renal function and drainage of the dilated tract can be assessed by radioisotope renal scan or an excretory urogram.

Diagnostic Procedures/Other

Initial evaluation should include assessment of renal function.

DIFFERENTIAL DIAGNOSIS

- Distinctly abnormal findings of physical exam of the affected infant results in an early, accurate diagnosis in most cases.
- Pseudo-prune belly syndrome (e.g., prune belly syndrome uropathy, normal abdominal wall exam, and incomplete or absent cryptorchidism)

TREATMENT

SURGERY/OTHER PROCEDURES

- Some clinicians advocate minimal surgical intervention, based on lack of functional obstruction and that the dilated system has a low pressure owing to the deficient smooth musculature. If renal function deteriorates, urinary tract dilation progresses, or the patient develops a UTI despite antibiotic prophylaxis, cutaneous vesicostomy is recommended to facilitate drainage.
- Other physicians advocate extensive surgical remodeling. Possible procedures include, as indicated:
 - Internal urethrotomy, reduction cystoplasty
 - Excision of the redundant ureter with reimplantation of the remaining segment
 - Cutaneous ureterostomy
 - Pyelostomy
- Reconstruction of the abdominal wall has yielded good cosmetic results but only questionable improvements in physical function.
- Bilateral orchiopexy is indicated.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Basic principles of supportive care and management of renal failure apply.
- Antibiotics in the neonatal period and antibiotic prophylactic of indefinite duration are indicated to prevent infection.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Regardless of how patients are managed, affected patients require long-term follow-up, with meticulous attention to renal function, pulmonary function, and urine bacteriology.

PROGNOSIS

- Patients with the most severe renal dysplasia and pulmonary hypoplasia (e.g., sequelae of severe, early oligohydramnios) succumb as neonates.
- Associated with a mortality rate of up to 20% in the neonatal period.
- ~25% of patients with prune belly syndrome who survive the neonatal period will progress to end-stage renal disease (ESRD).
- Those with a milder form do not require urinary tract surgery; renal function is usually stable and prognosis excellent.
- For patients with moderate involvement, the degree of renal dysplasia and insufficiency determines outcome. In addition, upper urinary tract stasis, poor bladder emptying, vesicoureteral reflux, and bacteriuria are factors that may combine to worsen the long-term prognosis.

COMPLICATIONS

- Pulmonary hypoplasia
- Frequent UTIs secondary to upper urinary stasis, vesicoureteral reflux, and bacteriuria
- Sequelae of progressive renal insufficiency

CODES

ICD9
756.71 Prune belly syndrome

ICD10
Q79.4 Prune belly syndrome

FAQ

- Q: Are patients with prune belly syndrome candidates for renal transplantation?
- A: Yes. However, special pretransplantation consideration should be given to patients with a dilated urinary tract to optimize function.
- Q: How does the urinary tract function in older children?
- A: A tendency for bladder tone and ureteral peristalsis to improve with age has been noted.
- Q: Are such patients infertile?
- A: Normal sexual activity has been described. However, there are no reports of fertility, and the patients usually have azoospermia.
- Q: What is the usual cause of morbidity in the newborn period?
- A: Respiratory failure.

PRURITUS

Mark L. Bagarazzi

BASICS

DEFINITION

Itching—an unpleasant cutaneous sensation that provokes the desire to rub or scratch the skin to obtain relief

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Congenital/anatomic**
 - Cholestasis secondary to biliary obstruction (e.g., Alagille syndrome)
- **Infectious**
 - Pinworms (*Enterobius vermicularis*):
 - Pruritus that is worse at night is seen with scabies or pinworm.
 - Swimmer's itch (due to fresh water mammalian or avian schistosomes):
 - If the child was recently swimming in fresh water, consider swimmer's itch, caused by fresh water mammalian or avian schistosomes.
 - Seabather eruption (affects swimmers and divers in marine waters off Florida, in the Gulf of Mexico, and the Caribbean, attributed to various organisms but more recently to the larvae of the thimble jellyfish), *Linuche unguiculata*
 - Herpes virus: Primary varicella infection or herpes zoster; herpes simplex
 - *Borrelia burgdorferi*: Erythema chronicum migrans lesion associated with Lyme disease
 - *Streptococcus pyogenes*: Sandpaper rash of scarlet fever
 - Tinea corporis
 - *Toxocariasis canis*
- **Toxic**
 - Contact dermatitis (see Table 1):

Table 1. Potential contact irritants

Medications (see below)	Plants (e.g., rhus dermatitis—poison ivy/oak, cacti)
Allergens	Foods
Cosmetics	Capsaicin in hot peppers*
Chemicals (e.g., soaps and detergents)	Animals
Dyes (for hair, etc.)	Clothing (e.g., wool)
Jewelry (nickel)	Shoes
Fiberglass	Diapers
Excrement	

*Acts as an irritant on first contact but may actually decrease pruritus if applied repeatedly over weeks

- **Environmental**
 - Papular urticaria: Bites of fleas, mosquitoes
 - Pediculosis (lice)
 - Mites: Scabies (*Sarcoptes scabiei*), chiggers (*Trombicula alfreddugesi*)
 - Subcutaneous foreign body
 - Phytophotodermatitis occurs when skin is exposed to sunlight after contact with an offending plant.
 - **Drugs**
 - Systemic use of medications (e.g., aminophylline, aspirin, barbiturates, chloroquine, erythromycin, gold, griseofulvin, iodine contrast dyes, isoniazid, opiates, phenothiazines, vitamin A)
 - **Allergic, inflammatory**
 - Atopic dermatitis (eczema)
 - Psoriasis (pruritus is often persistent)
 - Seborrheic dermatitis
 - **Miscellaneous**
 - Burns
 - Nonspecific urticaria
 - Pityriasis rosea
 - Asteatotic eczema (“winter itch”)
 - Xerosis (dry skin) due to excess bathing with or without strong detergents or low humidity; idiopathic
- APPROACH TO THE PATIENT**
- Determine severity and if pruritus is isolated or due to an underlying systemic illness, primarily by assessing the presence or absence of associated signs and symptoms, especially rash.
- **Phase 1:** Assess severity of illness. Pruritus rarely constitutes a medical emergency except in cases of anaphylaxis or erythema multiforme major (i.e., Stevens–Johnson syndrome).
 - **Phase 2:** A thorough review of potential precipitating events and the duration of symptoms will help determine if the itch is isolated or if there are any associated signs or symptoms. Pruritus is most frequently associated with rash. Pruritus with or without rash may be a manifestation of systemic illness. Underlying states may range from hepatic or renal diseases to pregnancy or psychiatric disease. As always, differential diagnosis should consider common causes first, then entertain less common and even rare causes.
 - **Phase 3:** A thorough history and physical exam should narrow the differential diagnosis considerably, enabling the clinician to determine the underlying cause of the complaint in most cases. Laboratory tests may be indicated in cases where the diagnosis remains unclear.

HISTORY

- **Question:** New or recurrent problem?
- **Significance:** If it is new, one should ask if there is anything new in the child's life that may be associated with the onset of pruritus (with or without rash). This is often the most revealing question as one may find that the child recently came in contact with a new item, which is known to be a contact irritant.
- **Question:** How severe is the pruritus? On a scale of 1–10? Compared with a mosquito bite? Is it severe enough to interfere with the daily routine of the child (e.g., wakes the child from sleep)?
- **Significance:** Answers will provide some measure of the true severity of the problem. Waking from sleep may suggest a more severe form resulting from systemic disease.
- **Question:** Introduction of anything new or different, especially anything that comes in contact with the child's skin?
- **Significance:**
 - Frequency of baths and types of products used to bathe the child
 - Different soaps or detergents contain additives that may be allergenic. Changes in soaps may be important. Some soaps cause excessive dryness or contain heavy fragrances. Children who are bathed frequently with anything more than water may develop dry and irritated (pruritic) skin.
- **Question:** Hiking or camping in a wooded area?
- **Significance:** May be a clue to common skin irritation (rhus dermatitis) from contact with certain plants
- **Question:** Any underlying illness(es) or associated symptoms?
- **Significance:** Pruritus associated with night sweats and fever may point to hematopoietic malignancy. Many illnesses are associated with pruritus.
- **Question:** Complaints about itching from anyone who has frequent contact with the child?
- **Significance:** May identify a common source of a contact irritant. For example, one will often see multiple family members affected by scabies or lice.
- **Question:** Is the pruritus accompanied by rash or other signs and symptoms?
- **Significance:** This general question is meant to elicit additional signs and symptoms of any systemic disease. For instance, arthritis and arthralgias are seen in systemic lupus erythematosus and juvenile rheumatoid arthritis, and jaundice in the cholestatic disorders.
- **Question:** Itching has happened before?
- **Significance:** Atopic dermatitis will present as chronic or recurrent pruritic skin lesions.

PHYSICAL EXAM

- **Finding:** If rash is present, appearance of rash?
- **Significance:**
 - Lesions appear in crops with varicella zoster, scabies, and insect bites.
 - Lesions are in groups of 3 or 4 with a central punctum in scabies.
 - Papular lesions result from insect bites, chiggers, pediculosis, contact dermatitis, pityriasis rosea, urticaria (wheal), and atopic dermatitis.
 - Lichenification (i.e., plaque and scale formation) occurs with psoriasis, xerosis, tinea, and atopic dermatitis.
 - Serpiginous lesions occur with cutaneous larva migrans and myiasis (or maggots).
 - Vesicular lesions occur in varicella (generalized), scabies, poison ivy (linear), and atopic dermatitis.
 - Dry skin (xerosis) occurs in atopic dermatitis.
 - Christmas tree pattern occurs in pityriasis rosea.
- **Finding:** Location of the itch and/or rash?
- **Significance:**
 - Generalized distribution: Consider varicella
 - Anus: Consider pinworms
 - Back: Consider pityriasis rosea
 - Axillae and/or genital/diaper area: Consider seborrheic dermatitis and scabies
 - Dorsal foot: Consider shoe dermatitis from rubber or tanning agents
 - Exposed surfaces: Consider schistosomal dermatitis and poison ivy
 - Finger, earlobe, wrist, or necklace distribution: Consider irritant contact dermatitis (e.g., nickel)
 - Nipples: Consider scabies (burrows)
 - Interdigital areas and ulnar borders: Consider tinea pedis, scabies (burrows)
 - Palms and/or soles: Consider biliary cirrhosis
 - Plantar foot: Consider cutaneous larva migrans
 - Scalp: Consider pediculosis (nits found cemented to hair shaft) and tinea capitis
- **Finding:** Abnormal affect or mood?
- **Significance:** If after an exhaustive search there appears to be no physiologic basis for the itch, one must consider whether the complaint is a conversion disorder or due to neurotic excoriation, especially in cases of abnormal affect or mood.
- **Finding:** Enlargement of liver, spleen, or lymph nodes?
- **Significance:** Pruritus may be the initial manifestation of lymphoma.

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** Complete blood count with differential
- **Significance:** Presence of eosinophilia suggests atopy or parasitic infections.
- **Test:** Wood lamp examination, potassium hydroxide preparation
- **Significance:** Screen for tinea infections
- **Test:** Serum for hepatic and renal function
- **Significance:** Screen for underlying disease
- **Test:** Urinalysis for β -human chorionic gonadotropin
- **Significance:** Investigate presence of cholestasis associated with pregnancy

**TREATMENT****ADDITIONAL TREATMENT****General Measures**

Antihistamines are the mainstay of symptomatic treatment of pruritus.

- Systemic and topical corticosteroids and topical pramoxine and doxepin have been shown to be effective in placebo-controlled trials.
- Some anecdotal references to other agents that are effective for pruritus include ursodeoxycholic acid in liver disease, opiate antagonists (e.g., naloxone and naltrexone), propofol at subhypnotic doses, cholestyramine, rifampin, gabapentin in burn-related pruritus, and serotonin antagonists (e.g., ondansetron).
- Tacrolimus and pimecrolimus have been used as second-line therapy for the short-term and noncontinuous chronic treatment of mild-to-moderate atopic dermatitis in non-immunocompromised children 2 years of age and older, who have failed to respond adequately to other topical prescription treatments, or when those treatments are not advisable. These drugs carry a "black box" warning about a possible risk of cancer and a Medication Guide. The Medication Guide is to be distributed with each prescription to help ensure that patients using these prescription medicines are aware of this concern.
- Exploratory studies of virtual reality immersion (VRI), an advanced computer-generated technique, show reduction of pruritus intensity before and during VRI.

Initial Stabilization

Pruritus due to anaphylaxis will require initial management of circulation, breathing and airway (CABs) followed by sympathomimetics (e.g., epinephrine), antihistamines (e.g., diphenhydramine), corticosteroids, and possibly fluid resuscitation.

ISSUES FOR REFERRAL

- Identification of an underlying disorder or state
- Some severe cases of atopic dermatitis or psoriasis may require dermatologic referral.
- Identification of pubic pediculosis may require investigation for child sexual abuse.

**CODES****ICD9**

698.9 Unspecified pruritic disorder

ICD10

L29.9 Pruritus, unspecified

FAQ

- Q: Does the time course of a pruritic rash give any clue in identifying the offending agent?
- A: Yes, certain plants cause an immediate welt on the skin, but the urticaria is short-lived (immediate contact dermatitis). Skin that is traumatized mechanically (e.g., cactus spine) or chemically (e.g., capsaicin as found in hot peppers) produces more persistent skin reactions. Poison ivy or rhus dermatitis is a type of allergic contact dermatitis that only occurs in those previously sensitized. It is due to a cellular immune response and may persist for several weeks.
- Q: Are some antihistamines better than others for pruritus?
- A: Possibly; evidence is conflicting, but several studies have shown that older systemic antihistamines that cause greater somnolence are actually more effective at alleviating pruritus than newer, longer-acting antihistamines (e.g., astemizole, loratadine, terfenadine, cetirizine).
- Q: Do topical antihistamines alleviate pruritus?
- A: Not usually, except for widespread pruritus seen with insect bites and urticaria. Use of topical antihistamines for pruritus or rash that is widespread should be discouraged, because toxicity may result from systemic absorption.
- Q: Does scratching make the pruritus better or worse?
- A: Worse; scratching leads to the release of the mediators of inflammation including histamine which, in turn, leads to more pruritus, thus creating a vicious cycle.
- Q: Are there any useful adjuncts to reduce pruritus?
- A: Yes, keeping skin moist with moisturizers and avoiding dry environments. Avoid overwashing, especially with hot water and/or alkaline soaps.

PSITTACOSIS

Nicholas Tsarouhas

BASICS

DESCRIPTION

- An acute febrile disease characterized by pneumonitis and other systemic symptoms. The name is derived from the Greek for parrot, *psittakos*.
- Also known as *ornithosis*.

EPIDEMIOLOGY

- Birds (e.g., pigeons, parrots, parakeets, turkeys, chickens, ducks) are the major reservoir.
- Infecting agent present in bird nasal secretions, urine, feces, feathers, viscera, and carcasses.
- Inhalation of aerosols of feces, urine, and secretions of infected birds is the most common route of infection.
- Bird bites and mouth-to-beak contact also spread infection.
- Birds may be healthy or sick.
- Most reported cases (70%) are the result of exposure to pet caged birds (especially parrots, parakeets).
- Most common mammalian source of infection is sheep.
- Occupational hazard of workers in poultry plants, pet shops, zoos, farms
- Rarely transmitted person-to-person

Incidence

- Only 100–200 total cases reported in U.S. each year
- Very rare disease in young children

RISK FACTORS

Close human contact with birds, and in some cases, sheep

GENERAL PREVENTION

- Epidemiologic investigation is indicated in all suspected cases.
- Birds suspected to be infected should be killed, transported, and analyzed by qualified experts.
- Potentially contaminated living areas where bird was kept should be disinfected and aired.
- *Chlamydophila psittaci* is susceptible to most household disinfectants (rubbing alcohol, Lysol, bleach).

PATHOPHYSIOLOGY

- Inhalation of aerosolized organisms into the respiratory tract
- Incubation period 5–21 days
- Spreads via bloodstream to lungs, liver, and spleen
- Lymphocytic inflammatory alveolar response

ETIOLOGY

- Infection produced by *C. psittaci*, an obligate intracellular parasitic bacterium
- Antigenically and genetically different from *Chlamydia* species

COMMONLY ASSOCIATED CONDITIONS

Pneumonitis (with a severe headache) is a common presentation.

DIAGNOSIS

HISTORY

- Mandatory to question parents about exposure of the patient to any type of bird—wild or domestic
- Signs and symptoms:
 - Abrupt onset of symptoms
 - Fever, headache, cough, weakness, chills, muscle aches, and joint pain
 - Nonproductive cough
 - Vomiting, confusion, and photophobia are less common findings.

PHYSICAL EXAM

- Ill-appearance, tachypnea, rales, and splenomegaly are common.
- A relative bradycardia is found in some cases.
- Rash, meningismus, pharyngeal injection, cervical adenopathy, hepatomegaly, and mental status changes are less common findings.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Routine laboratory studies are rarely helpful.
- Complement fixation titers (see “FAQ”)
- Microimmunofluorescence studies and polymerase chain reaction assays are more specific than complement fixation studies.
- Isolation of the organism is diagnostic.
- Complement fixation titers do not, however, distinguish between chlamydial infections (*C. trachomatis*), and the various chlamydophilal infections (*C. psittaci*, *C. pneumoniae*, and *C. pecorum*).

Imaging

- Chest x-rays are abnormal in 90% of hospitalized cases.
- Chest x-rays often demonstrate diffuse interstitial infiltrates, but may also have unilateral lower lobe consolidation.

DIFFERENTIAL DIAGNOSIS

- Psittacosis should be considered in all fevers of unknown origin or atypical pneumonitis.
- *Mycoplasma* and *Chlamydophila pneumoniae*, *Legionella* spp., *Coxiella burnetii* (i.e., Q fever), tuberculosis, viral and fungal pneumonitis, as well as pneumococcal pneumonia

**TREATMENT****MEDICATION (DRUGS)****First Line**

- Tetracycline (40 mg/kg/d) or doxycycline (100 mg b.i.d.) in children >8 years of age
- Erythromycin (40 mg/kg/d) in children <8 years of age.
- Antibiotics should be continued for at least 10–14 days after defervescence.

Second Line

Azithromycin, clarithromycin, and chloramphenicol are additional options.

**ONGOING CARE****PROGNOSIS**

- Although complete recovery is the rule (even without antibiotic use), fatality rates as high as 15–20% have been reported.
- Resolution of fever and most other systemic symptoms can be expected within 48 hours of antibiotic therapy.
- Untreated patients may have severe pulmonary symptoms for 1–3 weeks.

COMPLICATIONS

- Hepatitis
- Anemia
- Thrombophlebitis
- Pulmonary embolus
- Adult respiratory distress syndrome
- Arthritis
- Keratoconjunctivitis
- Endocarditis
- Myocarditis
- Pericarditis
- Encephalitis: Agitation, delirium, confusion, stupor

**CODES****ICD9**

- 073.0 Ornithosis with pneumonia
- 073.8 Ornithosis with unspecified complication
- 073.9 Ornithosis, unspecified

ICD10

- A70 *Chlamydia psittaci* infections
- J17 Pneumonia in diseases classified elsewhere

FAQ

- Q: In children with pneumonia who have a pet bird, how is the diagnosis confirmed?
- A: An IgM titer of 1:16 or greater by microimmunofluorescence (MIF) assay, a 4-fold rise in IgG antibody titers by complement fixation or MIF assay (acute and convalescent specimens; 2–3 weeks apart); a single IgG titer of 1:32 or higher, or a positive culture.
- Q: Does the source bird usually exhibit signs of disease?
- A: No. The bird is often asymptomatic; it may, however, show some signs of illness (e.g., anorexia, ruffled feathers, depression, or watery green droppings).

PSORIASIS

Leslie Castelo-Soccio
Albert Yan (5th edition)

BASICS

DESCRIPTION

Skin disease characterized by a chronic relapsing nature and, most commonly, clinical features of scaly, erythematous papules, and plaques with thick white scale, usually involving elbows, knees, and scalp (i.e., psoriasis vulgaris). Other variants include guttate, erythrodermic, and pustular psoriasis (see “Physical Exam” for details).

EPIDEMIOLOGY

- No gender predilection
- Onset of psoriasis is bimodal, commonly presenting in the 3rd decade with a smaller 2nd peak of onset in the 6th decade; however, it can present at any age, with a mean age of onset in children of 8.1 years.
- Earlier onset is associated with more severe disease.

Prevalence

Psoriasis is universal in occurrence, but the prevalence varies in different populations. The average prevalence in the U.S. is estimated at 1–3%

RISK FACTORS

Genetics

- Although psoriasis has a strong genetic influence, mode of transmission is not defined. It is likely multifactorial with more than one gene involved and is modified by environmental influence.
- 1/3 of patients with psoriasis report a relative with the disease.
- In family studies, 8.1% of children develop psoriasis when 1 parent is affected.
- When both parents have psoriasis, the affected percentage increases to 41%.
- In twin studies, 65% of monozygotic twins are concordant for the disease, whereas only 30% of dizygotic twins are concordant.

PATHOPHYSIOLOGY

- Plaque-type psoriasis is characterized by a thickened parakeratotic epidermis with an absent granular layer above dermal papillae containing dilated tortuous capillaries.
- Collections of polymorphonuclear leukocytes extend from the dermal papillae into the epidermidis stratum corneum (i.e., Munro microabscesses).
- A mixed perivascular infiltrate is confined to the papillary dermis.

ETIOLOGY

The pathogenesis is unknown. Well-defined trigger factors include:

- Trauma to normal skin, producing psoriasis in the area (i.e., isomorphic response, sometimes called the Koebner phenomenon)
- Infections (e.g., upper respiratory infections, *Streptococcus pyogenes*, human immunodeficiency virus)
- Stress
- Winter in colder climates in northern hemisphere
- Some drugs (i.e., systemic corticosteroids, lithium, β -adrenergic blockers, NSAIDs, and antimalarials)

COMMONLY ASSOCIATED CONDITIONS

Leukocytosis and hypocalcemia are associated with pustular psoriasis.

DIAGNOSIS

HISTORY

- 1st appearance of eruption
- Area involved
- Recent illness, particularly sore throat
- Recent medications, particularly systemic steroids
- Any appearance of lesions with trauma to skin
- Joint pain
- Previous treatments and response
- Improvement with sun exposure
- Family history of psoriasis
- Signs and symptoms:
 - Thick, flaky scales on skin
 - In psoriasis vulgaris, sharply demarcated erythematous plaques with white scale are located most commonly on the elbows, knees, scalp, lumbar area, and umbilicus, but they can cover any surface and large areas of the body. Intertriginous regions are often involved, but scale is absent.
 - Guttate psoriasis is a form that more often presents in children and young adults as small papules (0.5–1.5 cm), with limited scale over the trunk and proximal extremities, and is frequently associated with streptococcal infection.
 - Erythema with variable scale involving the majority of the body accompanied by chills is characteristic of erythrodermic psoriasis.
 - Generalized pustular psoriasis is the most serious variant, with sterile pustules as large as 23 mm arising on erythematous skin over large areas of the body. Usually, such appearance is accompanied by high fever.

- A chronic and localized variant of pustular disease, however, involves only the palms and soles.
 - Note: Classic plaque psoriasis is easily diagnosed, but variants and less virulent cases require careful exam for physical clues.
- Nails are frequently involved, with pinpoint pits, hyperkeratosis, and oil spots.
- Areas where disease is hidden are the retroauricular portion of the scalp and the perianal region.
- Swollen or deformed joints suggest associated psoriatic arthritis.

PHYSICAL EXAM

- A complete cutaneous exam is necessary.
- Removal of scale on plaques produces bleeding points, a feature known as the Auspitz sign.
- The Koebner phenomenon may produce linear or geometric lesions corresponding to areas of trauma.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Common finding: Elevated uric acid level.
S. pyogenes infection is frequent in guttate disease, and throat culture is appropriate.
- Other laboratory values are generally within normal ranges. However, in more severe variants, anemia, elevated ESR, and decreased albumin levels may be found.

DIFFERENTIAL DIAGNOSIS

- Classic plaque psoriasis is easily diagnosed. Variants of psoriasis, including guttate, erythrodermic, and pustular disease, are more difficult to recognize.
- The differential diagnosis varies with the type of psoriasis and includes:
 - Nummular eczema
 - Cutaneous T-cell lymphoma
 - Tinea corporis
 - Pityriasis rosea
 - Pityriasis lichenoides et varioliformis acuta
 - Secondary syphilis
 - Atopic dermatitis
 - Drug eruption
 - Candidiasis
 - Seborrheic dermatitis

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Phototherapy:
 - UVB:
 - Administered between 3–7 times weekly in a booth with bulbs that emit the appropriate wavelength of UV radiation
 - Effective for guttate and plaque psoriasis
 - Average treatment time: 3 months, with gradual increases in time of exposure. Sunscreen should be used on the face.
 - Narrow-band UVB represents a form of monochromatic UVB, using 311 nm wavelengths; appears to be a somewhat more effective form of delivering UVB phototherapy

- PUVA (psoralen and UVB):
 - PUVA and oral medications (e.g., methotrexate, acitretin) should be reserved for severe cases and carefully monitored by a dermatologist.

ALERT

- Possible conflicts with other drugs: Photosensitizing medication (e.g., tetracyclines, sulfa derivatives, phenothiazines, among others) should be avoided with phototherapy.
- Topical:
 - Topical corticosteroids
 - Mid- to high-potency topical corticosteroid ointments are applied b.i.d.
 - Mid-potency preparations (e.g., 0.025% fluocinolone ointment, 0.1% triamcinolone acetone) are preferred in children.
 - Low-potency corticosteroids (e.g., 1.0% and 2.5% hydrocortisone) are used on the face and intertriginous regions to prevent atrophy.
 - Agents can also be found in shampoos (e.g., Derma-Smoothie FS and Capex).
 - Anthralin:
 - Anthralin, applied to plaques for a 30-minute application, should be carefully washed off.
 - Lower concentrations used initially (e.g., 0.1%, 0.25%) are increased gradually as tolerated (e.g., 0.5%, 1.0%).
 - Irritation and staining are common, so that the face and intertriginous regions cannot be treated with this approach.
 - Calcipotriene:
 - Calcipotriene ointment is a vitamin D₃ derivative often used to treat disease in adults.
 - It is applied b.i.d., avoiding the face and intertriginous regions.
 - Maximum weekly dosage in adults is 100 g.
 - Rare cases of hypercalcemia have been reported.
 - Although effective in children, safety guidelines have not been established.
 - Tazarotene gel:
 - A topical retinoid (i.e., 0.05% and 0.1%)
 - Can be mildly to moderately irritating when used as monotherapy
 - Often combined with topical steroids as adjunctive therapy applied once daily or b.i.d.
 - Coal tar:
 - A weak therapeutic agent as monotherapy
 - More effective when combined with UVB phototherapy
 - Used in various shampoo preparations, as well as in solution that can be added to the bath.
 - Systemic agents:
 - May be considered when the psoriasis is especially severe, or when joint symptoms are prominent. In these instances, consultation with a rheumatologist may be advisable.
 - Methotrexate
 - Isotretinoin or acitretin
 - Cyclosporine
 - Biologic agents, such as etanercept
 - Systemic corticosteroid should be avoided since withdrawal from steroid may be accompanied by a pustular psoriasis flare.

ISSUES FOR REFERRAL

- Pustules, a significant increase in degree or extent of erythema, or fever suggest progression of the disease to more serious variants and may require hospitalization and systemic therapy.
- Erythrodermic psoriasis may require hospitalization to address issues of impaired skin integrity, such as fluid–electrolyte imbalances, hypothermia, and sepsis.
- New evidence suggests that adult patients with psoriasis have an increased prevalence of cardiovascular disease and an increased risk for myocardial infarction. Patients should be monitored for increased cardiovascular risk factors and have blood pressure, glucose, weight and lipids under good control to decrease risk.

IN-PATIENT CONSIDERATIONS**Initial Stabilization**

- Therapy is delivered by topical medications, phototherapy, or systemic medications.
- Localized disease is treated with topical therapy and more diffuse disease with phototherapy.
- Systemic medications are reserved for resistant cases.
- Except in the most severe cases, therapy for children should be limited to topical medication and UVB phototherapy.
- General skin care should include gentle washing, soaking to remove scale, and application of emollients, preferably ointments and creams.

**ONGOING CARE****FOLLOW-UP RECOMMENDATIONS**

- Topical therapy is administered chronically, with breaks to minimize side effects.
- Remissions occur in summer with sun exposure, and medications may often be discontinued.
- The average treatment course with UVB therapy is 3 months; if the patient's skin clears, treatment may be followed by an average remission period of 5 months.

PROGNOSIS

- Once psoriasis appears, it generally persists throughout life.
- Spontaneous remissions of variable length and frequency occur but are unpredictable.
- Response depends on potency of medication and frequency of treatment.
- Improvement with topical medication is obvious at 2 weeks, and usually peaks at 2 months.
- 1 month of UVB therapy may produce a decrease in disease.
- If therapy is too aggressive, disease may worsen, due to irritation.
- Scrubbing by the patient to remove scales also irritates the disease.
- Psychologic aspects of the disease, particularly in children, should be addressed.

- L40.4 Guttate psoriasis
- L40.9 Psoriasis, unspecified

FAQ

- Q: Will my disease get worse?
- A: It is impossible to predict the course of any patient's disease, because it is influenced by both heredity and everyday factors in the environment. Although there is no cure, with treatment the disease can be kept under control. Remissions do occur and may be for prolonged periods of time.
- Q: When my disease is in remission, what can I do to prevent it from returning?
- A: Avoiding trauma and keeping skin moist are important. In the summer, controlled sun exposure is helpful. You may have to continue other treatments at less frequent intervals. Any cases of sore throat should be cultured and treated if streptococcal disease is present. However, frequently, it is impossible to prevent recurrence of the disease.
- Q: Will my other children get psoriasis?
- A: If neither parent has psoriasis, the chances are <10% that another child will develop the disease; if 1 parent is affected, the chances increase to 15%; if both parents are affected, the chances are 50%. Therefore, unless both parents are affected, it is more likely that other children will not get psoriasis.
- Q: Does stress make psoriasis worse?
- A: Some studies have suggested that flare-ups of psoriasis are associated with increased stress. It is difficult to evaluate whether stress is the cause or the result of the disease. Do all you can to reasonably relieve stress, but do not focus on this as the cause of your psoriasis.

PUBERTAL DELAY

Daniel H. Reirden

Kenneth R. Ginsburg (5th edition)

BASICS

DESCRIPTION

- Pubertal delay is the absence of secondary sexual characteristics by an age $>2-2.5$ standard deviations (SD) of the population mean. In the US, this is considered to be ~ 13 years of age for girls and 14 years of age for boys.
- Pubertal delay may also occur if progression through puberty stalls or takes longer than $2.5 SD$ from the mean time of the population.
- $\sim 2.5\%$ of healthy teens will meet criteria for pubertal delay.
- Most cases of pubertal delay can be ascribed to constitutional delay of growth and maturity (CDGM); however, missing the presentation of an underlying disease should be avoided.
- CDGM:
 - Likely an extreme normal variant of pubertal development
 - Children usually grow at or near the 5th%ile for most of childhood, enter puberty late, and usually reach normal adult height.
 - More common in boys than in girls
 - Strong familial component

GENERAL PREVENTION

- Begin conversations about pubertal development with both patients and parents in late childhood. Realistic expectations regarding timing can avoid undue stress and unnecessary testing.
- Examination of growth charts at routine visits can alert providers to potential problems or changes in growth.
- Children with chronic health conditions should receive counseling regarding the effect their illness may have on their puberty. For example, children with cystic fibrosis generally have delayed puberty.

EPIDEMIOLOGY

- By definition, delayed puberty will occur in 2.5% of the population.
- CDGM explains 90–95% of pubertal delay.
- $>60\%$ of patients with constitutional delay of puberty have a positive family history.

Genetics

- Pubertal timing is highly influenced by genetic factors. This is evidenced by high correlation within ethnic groups, families, and monozygotic twins.
- 50–80% of variation in timing can be explained by genetics
- Pubertal delay as a result of an underlying medical condition is influenced by the pathophysiology of each disorder.

ETIOLOGY

Deficiency of gonadal sex steroids, estrogen in girls or testosterone in boys, is the underlying cause of delayed puberty. Several pathways to the common etiology exist:

- Hypogonadotrophic hypogonadism: Delayed puberty as a result of a deficiency in secretion of gonadotropin-releasing hormone (GnRH):
 - Functional: Delay or transient decrease in GnRH secretion. Describes CDGM, hypothyroidism, chronic illness
 - Permanent: Irreversible deficiency of GnRH, such as in Kallman syndrome or panhypopituitarism
- Hypergonadotrophic hypogonadism: Generally failure of the gonad, as seen in Turner syndrome, Klinefelter syndrome, and anorchia

DIAGNOSIS

HISTORY

- A thorough history of past medical conditions, past growth patterns, and family history is essential.
- A complete review of systems to uncover an underlying chronic disorder, such as inflammatory bowel disease, is necessary.
- Request and examine a long-term growth chart:
 - CDGM will generally exhibit a consistent low percentile of growth throughout childhood.
 - Gonadotropin or gonadal causes will generally present with normal growth in childhood, but no increase in growth during the expected pubertal spurt.

- Obtain history of progression of secondary sex characteristics:
 - Adolescents with complete gonadal or gonadotropin deficiencies will not enter puberty unless initiated by exogenous or adrenal hormones, whereas those with constitutional delay will progress at a normal rate after initiation of puberty.
 - Adolescents with partial deficiencies may reach pubarche at a normal time, but will fail to progress.
- Medication history may be useful (e.g., use of glucocorticoids or cytotoxins).
- Assess nutrition and socioeconomic history: Rule out chronic malnutrition or eating disorder.

PHYSICAL EXAM

A thorough physical exam is essential. Pay particular attention to the following elements:

- Thyroid examination
- Neurologic and fundoscopic examinations to check for intracranial pathology
- Genital examination and sexual maturity rating (Tanner staging):
 - External examination for all patients
 - Breast exam for girls
 - Pubic hair
 - Penis/testicle exam for boys
 - Internal gynecologic examination for girls with amenorrhea may be indicated.
- The first sign of puberty in boys is when testicular size is >2.5 cm. Find which one of your finger segments is ~ 2.5 cm, and use it as a gross measure.
- As a means of screening size, using a finger is more subtle than using an orchidometer. However, when a clinician needs to follow pubertal progression closely, an orchidometer is necessary to establish testicular size accurately.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial workup: routine screening tests for chronic or systemic disease:
 - CBC
 - Urinalysis
 - ESR
 - Electrolytes, renal function
 - Thyroid-stimulating hormone
 - Gonadotropin levels, follicle-stimulating hormone (FSH), and luteinizing hormone (LH)
 - Low levels suggest pre-puberty or hypothalamic-pituitary failure
 - High levels suggest gonadal failure or absence
 - If hypergonadotropic, obtain karyotype:
 - XX is suggestive of ovarian failure.
 - XO or abnormal X could be indicative of Turner syndrome or gonadal dysgenesis.
- If all of the aforementioned studies are normal, and there is no evidence to support constitutional delay, re-evaluation for cryptic chronic illness, substance abuse, eating disorder, or ongoing psychosocial stress should occur until puberty progresses or the underlying cause of delay becomes clear.

Imaging

- Bone age: Generally, an essential step in primary workup:
 - Plain film of the epiphyseal growth centers in the hand. Epiphyses change in response to growth hormone, thyroxine, and steroids of adrenal or gonadal origin.
 - Comparison to chronologic age can help to differentiate CDGM from organic disorders. A bone age that is > 2 years delayed from chronologic age is consistent with CDGM but not specific, and can be found with any hypogonadotropic cause of delayed puberty.
- Pelvic ultrasound: Can be useful in locating intra-abdominal testicular structures or in determination of the presence or absence of Müllerian structures. Indicated when testes cannot be detected in patients with a male phenotype or when Müllerian structures cannot be confirmed on physical examination in patients with a female phenotype.
- CT or MRI of the head: Useful in assessing pituitary or hypothalamic structures, mass lesions, pathologic calcifications, or increased intracranial pressure if a central cause of delayed puberty is suspected

DIFFERENTIAL DIAGNOSIS

- Increased serum gonadotropins (LH/FSH):
 - Chromosomal abnormalities
 - Turner syndrome (gonadal dysgenesis)
 - Klinefelter syndrome
 - Bilateral gonadal failure
 - Cytotoxic therapy
 - Castration
 - Irradiation
 - Primary testicular failure
 - Vanishing testes syndrome
 - Trauma

- Normal or low serum gonadotropins:
 - CDGM
 - Hypothalamic dysfunction
 - Chronic illness
 - Strenuous exercise
 - Malnutrition
 - Eating disorders
 - CNS tumors
 - Hypopituitarism
 - Panhypopituitarism
 - Kallman syndrome
 - Hypothyroidism
 - Hyperprolactinemia
 - Pituitary adenoma
 - Drug associated

ALERT

- No test can make a definitive diagnosis of constitutional delay.
- Consultation with a specialist or experienced laboratory personnel is recommended before obtaining pituitary stimulation tests, as they may require special conditions.

TREATMENT

ADDITIONAL TREATMENT

General Measures

Most patients with pubertal delay do not require drugs, but all need psychological and social support.

MEDICATION (DRUGS)

- In cases of presumed constitutional delay, hormones can be used to affect hypothalamic maturation, thereby initiating endogenous puberty.
- Referral to an endocrinologist or adolescent specialist is usually recommended before the initiation of hormonal therapy to aid in diagnosis and management.

ONGOING CARE

In cases of permanent hypogonadism, because of gonadal absence, failure, or gonadotropin deficiency, long-term hormonal therapy is necessary.

CODES

ICD9

- 253.4 Other anterior pituitary disorders
- 256.39 Other ovarian failure
- 259.0 Delay in sexual development and puberty, not elsewhere classified

ICD10

- E23.0 Hypopituitarism
- E28.39 Other primary ovarian failure
- E30.0 Delayed puberty

FAQ

- Q: As ~5% of pubertal delay is constitutional or physiologic, when can I avoid an expensive workup and just observe the patient?
- A: Unfortunately, only the spontaneous onset of puberty confirms the diagnosis of constitutional delay. Anxiety from delayed puberty may preclude waiting. To make a presumptive diagnosis of constitutional delay, pathology must be ruled out:
 - Physical examination, including genital anatomy and smell sense, must be normal.
 - There should be no signs or symptoms consistent with chronic disease.
 - History, including nutritional history and review of systems, must be negative.
 - Screening blood work must be negative.
 - Growth must progress ≥ 3.7 cm/yr.
 - Bone age must be delayed ≤ 4.0 years compared with chronologic age.
- Q: When should patients with pubertal delay be seen by an endocrinologist or adolescent specialist?
- A: Often, the initial workup of pubertal delay can be completed by the primary care provider. For complex stimulation tests, or if help is needed in interpreting test results, referral to an experienced specialist is warranted. If a specific chronic disease is suspected as the underlying cause, then referral should be made to the appropriate subspecialist.
- Q: Do racial differences affect pubertal onset and development?
- A: Several recent studies indicate that the mean ages for onset of breast development and menarche are younger for African American females than for Caucasian females. These differences are rarely, if ever, clinically relevant.

PULMONARY EMBOLISM

Akinyemi O. Ajayi

BASICS

DESCRIPTION

- Occlusion of a pulmonary vessel by a thrombus
- Pitfalls:
 - Failure to make the diagnosis is the most common mistake.
 - Pulmonary embolism must be suspected in critically ill children who have a central venous catheter in place and subsequently develop sudden respiratory failure. Because the symptoms of severe lung disease and pulmonary embolism are similar, the diagnosis might be missed if the index of suspicion is low.

EPIDEMIOLOGY

- Pulmonary embolism is seen more frequently in adults and tends to occur in postsurgical situations, especially when patients have been bedridden.
- ~10% of adults who present with an acute pulmonary embolus die within 1 hour of onset.
- Death occurs with 85% obstruction of the pulmonary artery.
- Risk factors vary according to age groups and gender.

Incidence

- Pulmonary embolism is rarely recognized in children; the incidence in children is 3.7%.
- Increasing incidence is secondary to increased central catheter use.
- Mortality rate can be as high as 30% if diagnosis is delayed.

RISK FACTORS

- In children:
 - Presence of a central venous catheter
 - Lack of mobility
 - Congenital heart disease
 - Ventriculoatrial shunt
 - Trauma
 - Solid tumors or leukemia
 - After surgical procedures (especially reparative intervention for scoliosis repair)
 - Hypercoagulable condition
- In adults: Most commonly due to the presence of a deep vein thrombosis, usually in the legs or pelvis.

PATHOPHYSIOLOGY

- Thromboemboli may develop anywhere in the systemic venous system.
- Pulmonary embolism is characterized by the triad of hypoxemia, pulmonary hypertension, and right ventricular failure.
- Diminished pulmonary perfusion causes a ventilation/perfusion (VQ) mismatch, resulting in hypoxemia.
- Hyperventilation occurs secondary to stimulation of proprioceptors in the lung.

- Hypercapnia is seen with severe occlusion of the pulmonary artery (often not seen with smaller emboli).
- Pulmonary infarction is uncommon owing to the presence of collateral pulmonary and bronchial arteries along with the airways providing additional sources of oxygen to the tissues.

ETIOLOGY

Blood clots appear as a result of deep vein thrombosis or other disease states.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Pulmonary embolism should be suspected in children who present with:
 - Pleuritic chest pain
 - Shortness of breath
 - Hemoptysis
 - Cough
 - Acute respiratory distress
 - Apprehension or anxiety
 - Syncope
 - Cardiovascular shock
- Symptoms may be nonspecific and indicative of other disorders.

HISTORY

Ask about chest symptoms: The clinician must have a high index of suspicion and recognize risk factors to establish the correct diagnosis.

PHYSICAL EXAM

- Findings on physical examination are nonspecific.
- General:
 - Fever
 - Diaphoresis
 - Nervousness or apprehension (altered mental status is uncommon)
- Cardiovascular:
 - Increased intensity of the pulmonic component of S₂
 - Tachycardia
 - Gallop rhythm
 - New murmur
- Pulmonary:
 - Tachypnea
 - Rales
 - Cyanosis (present with 65% obstruction of the pulmonary artery)
 - Pleuritic chest pain
 - Dyspnea
 - Cough
 - Hemoptysis
 - Wheezing (uncommon)
- Extremities:
 - Deep venous thrombosis is frequently found in the adult population.
 - Phlebitis
 - Edema

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In general, blood tests are nonspecific and of no significant value in making the diagnosis of a pulmonary embolus.
- Arterial blood gases:
 - Decreased PaO₂ and PaCO₂
 - Increased alveolar-arterial (A-a) gradient

Imaging

- EKG:
 - Useful in ruling out other conditions
 - May show sinus tachycardia or nonspecific ST-T wave changes
- Echocardiogram:
 - Useful for identifying:
 - Abnormalities of cardiac anatomy
 - Thrombi on catheter tips
 - If emboli are seen on echocardiogram, mortality rate is 40–50%. Additionally, if signs of right ventricular dysfunction are noted (e.g., right ventricular dilatation, abnormal right ventricular wall motion, or increased tricuspid regurgitation jet velocity), risk of poor outcome is greater.
- Spiral CT:
 - New diagnostic modality
 - Greater sensitivity than ventilation/perfusion scan in the diagnosis of pulmonary embolism, due to the ability to image abnormal pulmonary pathology.
- Chest x-ray:
 - May be abnormal in 70% of patients with pulmonary embolus
 - Most frequent findings:
 - Parenchymal infiltrates
 - Atelectasis
 - Pleural effusions: Seen in 33% of cases, mostly unilateral
 - Hampton hump (pyramidal shape pointing toward the hilum)
- Ventilation/Perfusion scan
 - Results of a ventilation/perfusion scan performed to rule out a pulmonary embolus are reported in 1 of 5 categories, ranging from high probability to normal.
 - An abnormal ventilation/perfusion scan with normal ventilation and decreased perfusion in the appropriate clinical setting is 90% specific for a pulmonary embolus.
 - A normal result on ventilation/perfusion scan does not completely rule out pulmonary embolus, although if the patient is at low risk, a pulmonary embolus is highly unlikely.

- Pulmonary angiography:
 - Most sensitive and specific test
 - Not done as frequently in children as in adults because of complications of the procedure
 - With the introduction of newer, improved catheters and safer contrast solutions, this test can now safely be performed in the pediatric population.
- Indicated for cases:
 - Intermediate-probability ventilation/perfusion scans
 - High-probability scans in patients who are: Poor candidates for anticoagulation, hemodynamically unstable, or require an embolectomy

Diagnostic Procedures/Surgery

- Pulmonary function testing:
 - Results are nonspecific.
- Evaluation of the lower extremities:
 - Diagnosing deep vein thrombosis via:
 - Impedance plethysmography
 - Doppler technology
 - Venography

DIFFERENTIAL DIAGNOSIS

- Cardiac:
 - Cardiac tamponade
 - Constrictive pericarditis
 - Restrictive cardiomyopathy
- Pulmonary:
 - Chronic cough
 - Status asthmaticus
 - Pneumonia with empyema
 - Pneumothorax

 **TREATMENT**

ADDITIONAL TREATMENT

Initial Stabilization

- Stabilize patient before anticoagulation or thrombolytic therapy is begun:
 - Improve oxygenation.
 - Correct acidosis
 - Stabilize BP
 - Analgesia for severe pleuritic chest pain. Avoid prescribing opiates in cases of cardiovascular collapse.
- Goal of therapy is anticoagulation and/or thrombolysis.
- In patients with an intermediate or high suspicion, begin anticoagulation before investigations.

MEDICATION (DRUGS)

- Anticoagulation therapy to prevent further thrombus formation
 - Heparin:
 - Bolus dose: 100–200 U/kg
 - Maintenance dose: 10–25 U/kg/hr
 - Keep PTT at 55–60 seconds
 - Should be given for 7–10 days

- Coumadin:
 - Coumadin should be started 24–48 hours after heparin therapy is begun.
 - Maintenance dose: 2.5–10 mg/d
 - Keep PT twice normal and maintain the International Normalized Ratio between 2.0 and 3.0.
 - Should be continued for 36 months
- Thrombolytic therapy:
 - Agents available:
 - Streptokinase: No difference in outcome has been found using streptokinase over urokinase.
 - Urokinase
 - TPA (tissue plasminogen activator): Same efficacy as streptokinase and lower incidence of allergic reactions
 - Indications:
 - Hemodynamically unstable
 - Large embolus
- Low-molecular-weight heparin has been used as prophylaxis or as treatment for preexisting conditions in both adults and children.
 - A synthetic, nonthrombocytopenic heparin pentasaccharide with pure antifactoxa activity is currently being tested.
- Ticlopidine and clopidogrel have been used successfully to prevent thrombotic strokes and arterial thrombotic syndromes.
- Contraindications to anticoagulation therapy:
 - Active internal bleeding
 - Recent cerebrovascular accident
 - Major surgery
 - Recent gastrointestinal bleed

SURGERY/OTHER PROCEDURES

- Embolectomy:
 - Indicated when hemodynamic instability persists; reserved for patients who have failed thrombolytic therapy or in whom medical treatment is contraindicated.
 - Late results are excellent if the patient has not suffered from a perioperative cardiac arrest, which is associated with early mortality.
- Percutaneous caval filtration:
 - Indicated if commencement or continuation of anticoagulation is strongly contraindicated, or if full anticoagulation has failed to prevent recurrent emboli.
 - This should be considered in patients undergoing venous thrombolysis, because up to 20% may develop embolization during treatment.

 **ONGOING CARE**

Patients receiving Coumadin therapy should have the usual follow-up for those receiving an anticoagulant.

PROGNOSIS

- If treated promptly, prognosis is good
- If treatment is delayed, especially if the patient is hemodynamically unstable, prognosis is poor.

FAQ

- Q: Is it safe for children on Coumadin to play contact sports?
- A: The general recommendation is that no contact sports should be allowed while children are on Coumadin therapy, because of the increased risk of bleeding.

PULMONARY HYPERTENSION

Richard M. Kravitz

BASICS

DESCRIPTION

Increased pulmonary vascular resistance

EPIDEMIOLOGY

Incidence

Incidence in children is unknown.

PATHOPHYSIOLOGY

- Structural alterations in pulmonary vessel architecture (remodeling)
- Smooth muscle hypertrophy
- Extension of blood vessel's smooth muscle into smaller vessels
- Inflammation

ETIOLOGY

- Hypoxemia-induced pulmonary hypertension
- Chronic lung disease:
 - Cystic fibrosis
 - Bronchopulmonary dysplasia
 - Interstitial lung disease
 - Diaphragmatic hernia with secondary pulmonary hypoplasia
- Upper airway obstruction:
 - Tonsillar and/or adenoid hypertrophy
 - Obesity
- Hypoventilation:
 - Neurologically mediated process
 - Secondary to muscular weakness
- High pulmonary blood flow secondary to left-to-right shunting (seen in congenital heart disease):
 - Patent ductus arteriosus
 - Atrial septal defect
 - Ventricular septal defect
- Left-sided cardiac disorders that increase pulmonary venous pressure:
 - Left ventricular failure
 - Mitral valve stenosis
 - Obstructed anomalous pulmonary veins
- Occlusion of pulmonary vessels:
 - Sickle cell disease
 - Veno-occlusive disease
 - Thromboembolism
- Pulmonary vasculitis:
 - Systemic lupus erythematosus
 - Rheumatoid arthritis
 - Scleroderma
- Persistent pulmonary hypertension of the newborn
- Idiopathic cases (primary pulmonary hypertension)

DIAGNOSIS

HISTORY

- Dyspnea (usually earliest complaint reported)
- Fatigue:
 - Seen early in course of illness with exercise or exertion (but not at rest)
 - Seen at rest in the later stages of the illness or in severe cases
- Exercise intolerance
- Feeding intolerance
- Failure to thrive
- Excessive sleeping
- Diaphoresis
- Chest pain
- Syncope
- Palpitations (late finding)
- Signs and symptoms pitfalls:
 - Signs and symptoms of pulmonary hypertension are not specific and can easily be missed.
 - Consider obstructive sleep apnea as a possible cause of pulmonary hypertension (ask about snoring if suspecting pulmonary hypertension in the absence of overt cardiac or pulmonary disease).

PHYSICAL EXAM

- Typically governed by the signs and findings related to underlying lung or heart disease
- Tachypnea
- Arrhythmias
- Narrowed splitting of S2 heart sound
- Increased P2 heart sound
- Presence of S3 and/or S4 heart sounds
- Murmur of pulmonary or tricuspid insufficiency; tricuspid insufficiency more common
- Jugular venous distention
- Peripheral edema
- Hepatomegaly

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Arterial blood gases:

- Measurement of pO₂ assesses degree of hypoxia.
- Evaluation of pCO₂ determines presence or absence of hypoventilation.

Imaging

Chest x-ray:

- Will vary according to the underlying disorder and extent of pulmonary hypertension
- Degree of pulmonary hypertension correlates poorly with chest x-ray findings.
- In primary pulmonary hypertension:
 - Cardiomegaly
 - Enlarged pulmonary artery
 - Peripheral lung appears underperfused ("pruning" of pulmonary vessels)

Diagnostic Procedures/Other

- EKG:
 - Can be normal if cor pulmonale has not yet developed
 - If cor pulmonale present, EKG can demonstrate:
 - Right QRS axis deviation
 - Right ventricular hypertrophy
 - Right atrial hypertrophy
- Echocardiogram with Doppler flow:
 - Increased pulmonary artery pressure
 - Right ventricular hypertrophy
 - Paradoxical movement of the intraventricular septum
 - Pulmonic and tricuspid valve regurgitation
 - Right-to-left shunting via an open foramen ovale
- Cardiac catheterization:
 - Most accurate measurement of pulmonary artery pressure is accomplished by right heart catheterization.
 - Criteria for pulmonary hypertension in children:
 - Mean pulmonary arterial pressure >25 mm Hg (at rest)
 - Mean pulmonary arterial pressure >30 mm Hg (with exercise)
 - Pulmonary vascular resistance >3 U/m²
 - Systolic pulmonary artery pressure > 1/2 systolic systemic pressure
 - Pressures should be measured before and after various vasodilators to assess potential reversibility of pulmonary hypertension.
 - Caution: In patients with severe disease, catheterization is associated with increased risk of complications.

DIFFERENTIAL DIAGNOSIS

- Pulmonary:
 - Asthma
 - Cystic fibrosis
 - Chronic obstructive pulmonary disease
 - Emphysema
 - Pulmonary arteriovenous malformations
- Miscellaneous:
 - Congestive heart failure (CHF)
 - Noncardiogenic pulmonary edema
 - Fatigue
 - Syncope

TREATMENT

MEDICATION (DRUGS)

- Oxygen:
 - Acts as a vasodilator
 - Keep SaO₂ ≥95%
 - Supplemental O₂ may prove useful even with normal resting SaO₂ (supplemental O₂ will cover for desaturations associated with exertion, exercise, or illness).
 - Caution: Supplemental oxygen can sometimes cause hypercapnia by blunting the hypoxia-driven respiratory drive.
- Anticoagulation therapy (i.e., Coumadin):
 - Prevents clot formation in the narrowed pulmonary vessels
 - Helpful even in the absence of thromboembolic disease
- Vasodilators:
 - Methods of action:
 - Decreases pulmonary arterial pressures
 - Improves right-sided cardiac function
 - Available agents:
 - Oxygen
 - Calcium-channel blocker (i.e., nifedipine)
 - Nitric oxide (continuous inhalation)
 - Prostacyclin (continuous IV infusion) (i.e., epoprostenol)
 - Endothelin receptor antagonist, PO (i.e., bosentan)
 - Phosphodiesterase inhibitor PO (i.e., sildenafil)
 - Caution: Vasodilators should be used under close supervision because of their effect on systemic BP (systemic hypotension can be a significant problem).

ADDITIONAL TREATMENT

General Measures

- Provide for patient stabilization.
- Treat the primary disease process.
- Treat underlying hypoxia (supplemental O₂).
- Treat underlying hypoventilation:
 - Useful for correcting hypoxia and hypercarbia secondary to hypoventilation
 - Available methods:
 - Noninvasive positive pressure ventilation (bi-level ventilation)
 - Mechanical ventilation (tracheostomy with mechanical ventilation)

SURGERY/OTHER PROCEDURES

- Tonsillectomy and/or adenoidectomy if obstructive sleep apnea is the underlying etiology
- Atrial septostomy may be considered when inadequate right-to-left shunting is present with syncopal episodes and/or right-sided heart failure
- Transplantation (lung or heart-lung transplantation): Reserved for patients with refractory, severe pulmonary hypertension

ONGOING CARE

PROGNOSIS

- Depends on underlying disease, but generally poor
- In cases of primary pulmonary hypertension, improvement of pulmonary hypertension with administration of vasodilators during initial catheterization is associated with a better survival rate than if no response occurs.
- 10–40% mortality in treated patients
- Near 100% mortality if patient is untreated
- Treatment can be lifelong unless the primary cause of the pulmonary hypertension can be corrected.
- In acute pulmonary hypertension, response to most treatment modalities is almost immediate.
- Oxygen has been shown to reverse hypoxia-related remodeling of the airways after 1 month of therapy.

COMPLICATIONS

- Chronic hypoxia
- Exercise intolerance
- Right-sided heart failure (cor pulmonale)
- Death

CODES

ICD9

- 416.0 Primary pulmonary hypertension
- 416.8 Other chronic pulmonary heart diseases
- 747.83 Persistent fetal circulation

ICD10

- I27.0 Primary pulmonary hypertension
- I27.2 Other secondary pulmonary hypertension
- P29.3 Persistent fetal circulation

FAQ

- Q: How many hours per day should supplemental oxygen be used?
- A: Studies have shown decreased mortality in patients using oxygen 24 hours per day compared with patients using supplemental oxygen for only part of the day.
- Q: Should the dosage of oxygen be adjusted during the day according to the patient's activity?
- A: Increasing supplemental oxygen should be considered for activities that require increased oxygen consumption (i.e., exercise, eating, sleeping).
- Q: Can an echocardiogram replace the need for a cardiac catheterization?
- A: No. Although an abnormal echo can confirm the presence of pulmonary hypertension, it does not inform one of its severity or the (acute) response to therapy. Furthermore, a normal study does not rule out pulmonary hypertension (especially mild cases).

PURPURA FULMINANS

David F. Friedman

BASICS

DESCRIPTION

- Congenital, acquired, or idiopathic condition of rapidly progressive microvascular hemorrhage into the skin
- Associated with an underlying acquired or congenital disorder of coagulation
- May lead to skin necrosis as well as acral amputations

EPIDEMIOLOGY

Incidence

- Neonatal purpura fulminans related to homozygous protein C deficiency: 1 in 2–4 million births
- Clinical protein C deficiency: 1 in 20,000 individuals
- Homozygous protein S deficiency is more rare.

Prevalence

Purpura can be seen in bacterial sepsis with meningococcus and other pathogens, as well as other causes of disseminated intravascular coagulation.

RISK FACTORS

Genetics

- Deficiencies of protein C and protein S are autosomally inherited with variable penetrance.
- Over 150 different genetic mutations of protein C have been described, leading to both qualitative and quantitative defects of the proteins.
- Heterozygous protein C and S deficiency states usually cause a hypercoagulable condition, with increased risk of venous or arterial thrombosis throughout life.
- Homozygous protein C or S deficiency states lead to severe deficiency (<1% of normal factor activity) and neonatal purpura fulminans and are often fatal.
- Factor V Leiden:
 - Known risk factor for thrombosis
 - May predispose to infection-associated purpura fulminans
 - May also predispose to purpura fulminans in patients who are heterozygotes for protein C or S deficiency
- Other genetic predispositions to thrombosis, such as prothrombin mutations, may also contribute to risk for purpura fulminans.

PATHOPHYSIOLOGY

Common features of purpura fulminans:

- Inflammation: Endothelial injury from bacterial endotoxin or other trigger may initiate secretion of inflammatory cytokines or activation of coagulation and complement proteins.
- Purpura: Extravasation of formed elements of the blood from injured capillaries into the skin
- Dermal vascular thrombosis: Formation of microthrombosis in blood vessels of the skin, leading to hemorrhage in the skin (purpura), necrosis of skin, and gangrene

ETIOLOGY

- Infection-associated purpura fulminans:
 - Overwhelming sepsis, usually bacterial; *Neisseria meningitidis* most common
 - May be a complication of varicella infection
 - Disseminated intravascular coagulation: State of sustained activation of coagulation cascade and fibrinolytic mechanisms, leading to consumption of platelets, fibrinogen, and often formation of microthrombosis
- Inherited defect of coagulation presenting as neonatal purpura fulminans:
 - Deficiency of protein C: Loss of important inhibitory regulation of coagulation and uncontrolled clotting
 - Protein C slows (“brakes”) the coagulation cascade at two steps: By degrading activated coagulation factor Va in the common part of the coagulation pathway and by degrading factor VIIIa in the intrinsic pathway
 - Also plays a role in inflammatory cascade
 - Protein S is a cofactor for protein C.
- Idiopathic:
 - Postinfectious complication: Formation of antibodies to protein S causing protein S deficiency has been described as a postinfectious autoimmune phenomenon.
 - Complication of warfarin (Coumadin) therapy
 - Other unknown mechanisms

DIAGNOSIS

HISTORY

- Current bacterial sepsis: Fever, weakness, dizziness, nausea, vomiting, onset of petechial rash:
 - Family history suggestive of hypercoagulable state
 - Blood clots or thromboses at an early age, such as stroke, deep vein thrombosis, pulmonary embolism
 - Family members taking warfarin (Coumadin) or low-molecular-weight heparin or other anticoagulation
- Previous affected child with purpura fulminans or hypercoagulable state
- Prior exposure to heparin, therapeutically or via IV Hep-Lock
- Medications, including anticoagulation

PHYSICAL EXAM

- Signs of sepsis:
 - Fever
 - Hypotension
 - Tachycardia
 - Poor perfusion
 - Cool extremities
 - Decreased pulses
 - Shock
- Nonblanching purpura
- Acral purpura and necrosis: Check fingers, nose, toes, and penis for black areas.
- An erythematous border may surround purpuric areas.
- Bullae may form over purpuric skin.
- Oozing at sites of venipuncture

- Pain, ischemia, and edema of extremities or internal organ dysfunction may result from deep vein thrombosis or arterial thrombosis, depending on location and severity.
- Physical exam trick: Depress the purpuric area with a glass slide to determine whether it blanches.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Screening:

- CBC:
 - Platelet count may be low.
 - Hemoglobin may be low.
- Prothrombin time and INR: Prolonged as in disseminated intravascular coagulation
- Partial thromboplastin time: Prolonged as in disseminated intravascular coagulation
- Fibrinogen: Decreased with consumption and fibrinolysis
- D-Dimer: Increased fibrinolysis as in disseminated intravascular coagulation
- Etiologic:
 - Protein C activity in patient and parents
 - Protein S antigen (total and free) in patient and parents
- Test for antiphospholipid antibodies: Usually lupus anticoagulant or anticardiolipin antibody
- Factor V Leiden mutation assay
- False positives:
 - Protein C and S levels may decrease because of consumption during a thrombotic episode that is not related to an underlying deficiency. Low measurements often need to be repeated at baseline after recovery. Protein C and S levels may be below adult normal ranges for the first 3–6 months of life in healthy infants.

Imaging

To document presence and extent of suspected large-vessel thrombosis: The most useful imaging strategy depends on location and clinical situation:

- Ultrasound with Doppler flow study
- CT scan
- MRI: Better for visualization of vessels
- Angiography: Most invasive, requires vascular injury for access
- Imaging is potentially useful to:
 - Distinguish thrombosis from other pathology
 - Judge age of thrombus (based on collateralization)
 - Assess clot size prior to anticoagulant or thrombolytic therapy
 - Distinguish baseline old clot from new thrombosis

DIFFERENTIAL DIAGNOSIS

- Infection:
 - *N. meningitidis*, most common infectious cause of purpura fulminans
 - Streptococci
 - *Haemophilus* species
 - Staphylococci
 - Gram-negative bacteremia: *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*
 - Rickettsia: Rocky Mountain spotted fever
 - Varicella

- Environmental:
 - Warfarin-induced skin necrosis: 1 in 500–1,000 individuals starting warfarin therapy develops necrosis in subcutaneous fat.
 - Thought to be caused by relative depletion of anticoagulant protein C (a vitamin K–dependent factor) during the initial phase of warfarin effect
- Tumor: Myeloid leukemia
- Congenital: Inherited deficiencies of protein C and protein S:
 - Only severe, homozygous (<1% activity) deficiencies of proteins C and S are associated with purpura fulminans.
 - Milder, heterozygous deficiencies of protein C and protein S as well as deficiency of antithrombin III, dysfibrinogenemias, the carrier state for factor V Leiden, and other prothrombotic defects all give rise to hypercoagulable states, but usually not neonatal purpura fulminans.
 - Patients with 1 or more risk factors for thrombosis may be more likely to develop purpura fulminans with an environmental stimulus.
 - Immune: Heparin-induced thrombocytopenia: Antibody to heparin–platelet complex causes platelet activation, thrombocytopenia, and microthrombosis, including dermal vessels.
- Antiphospholipid antibody syndrome: Predisposition to thrombosis can include skin necrosis.
- Miscellaneous:
 - Thrombotic thrombocytopenic purpura
 - Paroxysmal nocturnal hemoglobinuria
 - Hensch-Schönlein purpura

TREATMENT

MEDICATION (DRUGS)

Contraindications, precautions, and significant possible interactions:

- Many drugs can affect warfarin metabolism.
- Chronic protein C concentrate infusion therapy for neonates may run into access problems.

First Line

- Anti-infective agents depending on underlying cause
- Fresh frozen plasma q12h to replace proteins C and S in acute disseminated intravascular coagulation of purpura fulminans
- Periodic fresh frozen plasma infusions for chronic replacement
- Prothrombin complex concentrates also have thrombogenic potential.
- Protein C concentrates are available and probably of benefit in meningococemia.
- Protein C has half-life of 6–10 hours in circulation.
- Protein C replacement by periodic infusion of protein C concentrate
- Oral warfarin therapy indefinitely usually recommended for documented severe protein C or S deficiency with thrombosis
- Low-molecular-weight heparin given subcutaneously is also a commonly used option for long-term anticoagulation therapy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- When to expect improvement: Related to underlying cause of purpura fulminans
- Signs to watch for:
 - Spread of purpura
 - Hypotension
 - Gangrene
- Pitfalls:
 - Individuals with protein C and protein S deficiency may have increased risk of warfarin-induced skin necrosis when starting warfarin. Patients should be heparinized for several days prior to the start of oral anticoagulation.
 - Management of an infant on oral anticoagulation is difficult because of the practical problem of obtaining reliable measurements of PT, the increased risk associated with deep venipunctures for blood samples, and difficulty in establishing a stable warfarin dose. Low-molecular-weight heparin by injection is usually the preferred anticoagulant therapy in infants.

DIET

Patients on warfarin therapy may need to avoid foods with high vitamin K content, especially if there is variation in the dose of warfarin required to maintain adequate anticoagulation.

PROGNOSIS

- Related to underlying cause of purpura fulminans
- Overall, poor for homozygous deficiencies of proteins C and S

COMPLICATIONS

- Skin necrosis and gangrene
- Scarring
- Acral amputations, from tips of digits to whole limbs
- Thrombosis in internal organs
- Death

ICD9

286.6 Defibrination syndrome

ICD10

D65 Disseminated intravascular coagulation [defibrination syndrome]

FAQ

- Q: What is the risk of a 2nd affected child with protein C or S deficiency?
- A: If the diagnosis is confirmed by family studies that show both parents to be carriers of the deficiency and the affected child to be homozygous, there is a 25% chance that each subsequent infant would have purpura fulminans and a 50% chance that each child would be a carrier. However, other hypercoagulable states have been described that may be risk factors for purpura fulminans.
- Q: Should a child with purpura fulminans be followed by a specialist?
- A: Generally yes, with a pediatric hematologist, to assist in acute management of purpura, establishment of diagnosis, and management of long-term anticoagulation.

PYELONEPHRITIS

Shamir Tuchman
Kevin E. C. Meyers

BASICS

DESCRIPTION

Acute pyelonephritis (upper urinary tract infection [UTI]) is defined clinically by fever, a positive urine culture, and urinary symptoms (e.g., dysuria, frequency/urgency, and/or flank pain) and histologically by acute renal parenchymal (interstitial) inflammation secondary to bacterial invasion.

EPIDEMIOLOGY

- UTIs are more likely to involve the upper renal tracts in children <3 years of age.
- UTIs are more common in females, except in uncircumcised males <3 months of age.

Incidence

Cumulative incidence of UTIs (1st 6 years of life):

- 6.6% for girls
- 1.8% for boys

Prevalence

- 5–7% of febrile infants <8 weeks of age
- 1% of all school-aged children
- 1–3% of girls between 1–5 years
- 0.03% in school-aged boys

RISK FACTORS

- Previous history of UTI
- Sibling with a history of a UTI
- Female sex
- Indwelling urinary catheter
- Structural abnormalities of the kidneys and lower urinary tract
- Vesicoureteral reflux (VUR): Present in ~30–40% of children with febrile UTIs.
- The majority (>95%) of VUR associated with febrile UTIs is low-moderate grade (grade I–III). Although, there is a stronger statistical association of febrile UTI with high grade (grade >IV) VUR.

PATHOPHYSIOLOGY

Specific factors related to development of pyelonephritis:

- Host related:
 - Anatomic abnormalities (e.g., obstruction, fistula)
 - Functional abnormalities (e.g., dysfunctional voiding, vesicoureteral reflux)
- Pathogen related:
 - Adherence factors (P and type 1-fimbriae, adhesins)
 - Virulence factors (e.g., lipopolysaccharide, capsular antigen)
- Adhesion of bacteria to uroepithelium induces cytokine release and a subsequent inflammatory response.
- Patchy infiltration of the medullary parenchyma by polymorphonuclear leukocytes and lymphocytes leads to degradation of extracellular matrix, tubular disruption, and interstitial edema.
- Parenchymal scarring may result as a consequence of the infection.

ETIOLOGY

- Enterobacteriaceae: *Escherichia coli* most frequent cause (90% of initial infections and in up to 66% of recurrent infections); *Proteus*, *Klebsiella*, *Enterobacter* spp. are also implicated.
- Gram-positive organisms cause 10–15% of cases: *Staphylococcus aureus*, *S. epidermidis*, *S. saprophyticus*, *Enterococci* spp.
- Other organisms: *Pseudomonas*, *Haemophilus influenzae*, *Streptococcus* group B

COMMONLY ASSOCIATED CONDITIONS

- Struvite kidney stones: Associated with urease-producing bacteria (e.g., *Proteus* sp.)
- Anatomic or physiologic abnormality of the collecting system: Found in up to 50% of infants with pyelonephritis

DIAGNOSIS

HISTORY

- A fever of 38.5°C may be the only presenting complaint.
- In the neonate, inquire of caregivers about vomiting, lethargy, poor feeding, irritability, fever, hypothermia, and jaundice.
- Older children are more likely to present with flank pain, dysuria, frequency, urgency, and incontinence.
- Important factors that predispose to the development of UTI that should be specifically inquired about:
 - Constipation
 - Incorrect toilet training
 - Perineal skin irritation
 - Antibiotic exposure
 - Uncircumcised males
 - Previous UTIs
 - Investigations already performed
 - A family history of UTIs or reflux nephropathy
 - A history of structural abnormalities of the kidneys and/or lower urinary tract
 - Symptoms suggestive of dysfunctional voiding, such as that the bladder always feels full, infrequent use of the toilet, double-voiding, and urgency incontinence
 - Previous surgery or trauma to the lower back
- Lower-motor milestones
- Signs and symptoms:
 - Fever
 - Chills
 - Flank pain
 - Urination problems: Dysuria, frequency, urgency

PHYSICAL EXAM

- Findings may be nonspecific.
- Fever, irritability, rigors, lethargy
- Flank tenderness:
 - May be related to an underlying renal tract abnormality, such as flank mass due to obstruction with hydronephrosis or cystic kidney disease, spina bifida apparent or occult (as evidenced by a dimple), pilonidal sinus, or hemangioma
- Gentle posterior punch test will reveal tenderness at the costovertebral angle.
- Bimanual palpation of kidneys to assess tenderness and size
- Careful neuromuscular exam of lower limbs and back to evaluate for the presence of a neurogenic bladder
- Assess rectal tone.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Collect urine using sterile methods (e.g., midstream in toilet-trained children, catheter or suprapubic for infants).
- Urine dipstick for measurement of leukocyte esterase and nitrites as a rapid screen for infection.
- WBC casts on urine microscopy are diagnostic.
- As a screening test, an unspun clean-catch urine specimen with bacteria on stained microscopic exam correlates (80–90%) with culture results exceeding 100,000 colonies/mL.
- Urine for culture and sensitivity: A positive culture result is defined by the growth of a single pathogenic organism of clean-catch 100,000 colonies/mL, catheter 1,000 colonies/mL, and by any growth in a suprapubic specimen.
- CBC with an elevated WBC count
- ESR and C-reactive protein (CRP) levels are often increased.

Imaging

- Renal ultrasound to rule out obstruction and assess renal size and parenchyma
- Voiding cystourethrogram (VCUG) to rule out anatomic anomalies including obstruction (e.g., posterior urethral valves) and vesicoureteric reflux
- ^{99m}Tc-dimercaptosuccinic acid (DMSA) test can be done to confirm the presence of acute pyelonephritis and to look for renal scarring. This is a sensitive and specific test that some clinicians believe to be the imaging study of choice for diagnosing acute pyelonephritis and renal scarring.

Diagnostic Procedures/Other

- Imaging evaluation of the urinary tract after a UTI should be individualized based on the child's clinical presentation and clinical judgment.
- All children <36 months of age should have an ultrasound and VCUG.
- A VCUG should be done in all males with a confirmed 1st pyelonephritis and a VCUG or nuclear cystogram in all females ≤7 years of age.

- After the urine is sterile, a VUCG can be performed; there is no need to wait 4 weeks.
- Administer antibiotic prophylaxis before the VUCG.

ALERT

- False-positive test results:
 - May be due to nonsterile collection techniques (bagged urine specimen) or allowing urine to stand unrefrigerated.
- False-negative test results:
 - The rapid test for nitrites requires urine to stay in the bladder for several hours and is therefore not useful in infants who do not store urine in the bladder.
 - Pre-collection antibiotic exposure

DIFFERENTIAL DIAGNOSIS

- Cystitis
- Sterile pyuria:
 - Vulvovaginitis
 - Balanitis
 - Systemic viral illness
 - Post-vaccination
 - Pregnancy
 - Appendicitis
 - Cystic renal disease
 - Tuberculosis
- Lower-lobe pneumonia
- Acute appendicitis

TREATMENT

MEDICATION (DRUGS)

- Give IV antibiotics (especially in children who appear toxic, are dehydrated, or vomiting) until afebrile for at least 24 hours, then change to an oral formulation.
- In total, 7–14 days of antibiotic therapy are required.
- Patients with 1st-time urinary infections should receive low-dose antibiotic prophylaxis until their workup is completed.
- Children with frequent symptomatic recurrences of UTI and those with high-grade vesicoureteric reflux require long-term antibiotic prophylaxis.
- Antibiotics such as co-trimoxazole (Bactrim), amoxicillin–clavulanate (Augmentin), and the 2nd-generation cephalosporins
- Familiarity with local antibiotic patterns of resistance is particularly important in treating hospital-acquired infections.
- Antipyretics (e.g., acetaminophen)

ALERT

- Removing struvite calculi during active infection may precipitate bacteremia/urosepsis.
- High index of suspicion is required for pyelonephritis associated with cystic renal disease as urine cultures may be negative when the infection is intracystic.

IN-PATIENT CONSIDERATIONS

IV Fluids

- May be necessary when children are hospitalized with fever and vomiting, to maintain hydration and urine output.
- Underlying anatomic or functional urinary collecting system abnormality should be evaluated/treated by a urologist.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Requirements for testing: Educate caregivers in the use and interpretation of the dipstick, and about the symptoms and signs of UTI.

PROGNOSIS

- Fever usually resolves in 3–5 days.
- Ongoing fever or persistent flank pain requires further evaluation to exclude a drug-resistant organism, kidney stone, kidney abscess or another unrecognized urinary tract obstruction.
- Diagnosis and treatment of any underlying voiding dysfunction and constipation are required for successful management of UTIs in children.
- Outcome of acute pyelonephritis is usually good but may result in parenchymal scarring.
- Pyelonephritis associated with struvite renal stones requires removal of the infectious stones after antibiotic treatment is completed.
- Risk factors for renal damage include obstruction, reflux with dilation, young age, delay in treatment, number of episodes of pyelonephritis, and bacterial virulence factors.

COMPLICATIONS

- Acute:
 - Reduced concentrating ability, hyperkalemic renal tubular acidosis
 - Bacteremia: Highest risk in young infants (23% of children <2 months)
 - Perinephric abscess formation
- Chronic:
 - Focal renal scarring, hypertension, proteinuria, azotemia, xanthogranulomatous pyelonephritis

CODES

ICD9

- 590.10 Acute pyelonephritis without lesion of renal medullary necrosis
- 590.80 Pyelonephritis, unspecified

ICD10

- N10 Acute tubulo-interstitial nephritis
- N12 Tubulo-interstitial nephritis, not specified as acute or chronic

FAQ

- Q: Should a DMSA scan be used to help diagnose acute pyelonephritis?
- A: Routine use of the DMSA scan to diagnose acute pyelonephritis is controversial because disagreement exists about the therapeutic implications of a positive test result, and such routine testing is expensive. Children with hypertension and previous UTIs require a DMSA scan to look for renal cortical scarring.
- Q: Does renal parenchymal scarring occur *without* reflux?
- A: Yes. The causal relationships among reflux, acute pyelonephritis, and renal parenchymal scarring are complex.

PYLORIC STENOSIS

Joy L. Collins

BASICS

DESCRIPTION

Hypertrophy of the muscular layers of the pylorus with elongation and thickening, leading to obstruction of the gastric outlet

EPIDEMIOLOGY

- Exceedingly rare in newborns, as well as in patients >6 months of age
- More common in Caucasians

Incidence

~1 in 950 live births

PATHOPHYSIOLOGY

- Diffuse hypertrophy and hyperplasia of the pylorus lead to narrowing of the gastric antrum.
- The antrum becomes thickened, elongated, and firm.
- Hypergastrinemia associated with hyperactivity, elevations of prostaglandins, and deficiency of nitric oxide as a smooth muscle neurotransmitter have been suggested as etiologic factors.

ETIOLOGY

- Unknown
- No specific pattern of inheritance established
- Multifactorial inheritance likely
- Neonatal hypergastrinemia and gastric hyperacidity are involved.
- An association between infantile hypertrophic pyloric stenosis and the administration of oral erythromycin given for postexposure prophylaxis for pertussis has been described.

COMMONLY ASSOCIATED CONDITIONS

Increased occurrence of esophageal atresia and malrotation was noted in 5% of infants with pyloric stenosis.

DIAGNOSIS

HISTORY

- The infant is typically a "hungry vomiter," refeeding immediately, only to vomit yet again.
- Signs and symptoms:
 - Nonbilious vomiting, classically projectile in an otherwise well and hungry child between 2–8 weeks of age
 - Possible weight loss
 - Varying degrees of dehydration and lethargy

PHYSICAL EXAM

- Visible peristalsis may be appreciated just after the infant feeds, which is seen as a waveform proceeding from the left upper quadrant toward the pylorus in the right upper quadrant.
- A palpable, hard, mobile, and nontender mass in the epigastrium to the right of the midline, referred to as an "olive"
- Best confirmed by palpation after the stomach has been emptied and with the infant quiet and comfortable

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hypochloremia and alkalosis
- Hyponatremia
- Hypokalemia
- 1–2% of infants have indirect hyperbilirubinemia associated with jaundice.

Imaging

- Ultrasound:
 - Ultrasonography identifies the hypertrophic pyloric musculature as a broad ring with low echo density and an inner layer of high echo density corresponding to the mucosa.
 - To confirm the diagnosis, muscle thickness should be >4 mm or pyloric length >15 mm.
- GI studies:
 - An upper GI study can differentiate antral webs, pylorospasm, and other obstructive lesions.
 - Vigorous gastric peristalsis with little or no gastric emptying is seen in association with pyloric stenosis.
 - An elongated, narrow pyloric anal canal can be seen as a single or sometimes a double tract of barium, commonly known as the "string sign."
 - A pyloric bulge into the distal antrum, producing an umbrella appearance, also may be seen.

DIFFERENTIAL DIAGNOSIS

- Gastroesophageal reflux
- Gastroenteritis
- Pyloric atresia
- Antral or duodenal web

TREATMENT

SURGERY/OTHER PROCEDURES

- Pyloromyotomy (Ramstedt procedure): Longitudinal incision of the antropyloric muscle
- Laparoscopic pyloromyotomy is a minimally invasive version of pyloromyotomy and is favored by many surgeons over an open approach.
- Pyloric stenosis is a medical emergency, but not a surgical emergency.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

- Early identification of electrolyte abnormalities and correction with appropriate IV fluids
- Correction of metabolic abnormalities by replacing (i.e., maintaining levels of) sodium, chloride, and potassium
- Postoperative vomiting is well recognized and is most likely caused by persistent local edema.
- Most patients can resume feedings 6–8 hours after surgery.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Vomiting may persist for several days after surgery.

ALERT

- Do not fail to appreciate that chloride loss is the most significant electrolyte disorder when replacing fluids and electrolytes.
- Do not fail to appreciate that this disorder occurs in girls as well as boys.

PROGNOSIS

Morbidity and mortality rates are low; surgery is curative.

COMPLICATIONS

- Dehydration
- Electrolyte abnormalities, primarily hypochloremic metabolic alkalosis that results from loss of hydrochloric acid caused by persistent vomiting
- Postoperative complications:
 - Incomplete pyloromyotomy
 - Mucosal injury; may lead to leak and sepsis if not immediately recognized and repaired

CODES

ICD9

- 537.0 Acquired hypertrophic pyloric stenosis
- 750.5 Congenital hypertrophic pyloric stenosis

ICD10

- K31.1 Adult hypertrophic pyloric stenosis
- Q40.0 Congenital hypertrophic pyloric stenosis

FAQ

- Q: Can ultrasound help make the diagnosis?
- A: Yes. Many clinicians order this test 1st, to avoid possible aspiration of contrast material.
- Q: Why is so much chloride lost?
- A: The chloride loss occurs with the loss of gastric acid, which contains hydrochloric acid.
- Q: What plan should I follow when replacing electrolytes?
- A: Correct the deficiency of fluids with twice maintenance fluid volumes. Correct chloride loss with normal saline, and correct potassium loss with potassium chloride.

RABIES

Edmund A. Milder

Louis M. Bell (5th edition)

Suzanne Dawid (5th edition)

BASICS

DESCRIPTION

Viral infection of CNS transmitted from animals to humans

EPIDEMIOLOGY

- Although the current annual incidence of reported human rabies in the U.S. is ~1–2 cases per year, incidence rates elsewhere in the world are much higher.
- In addition, thousands of infected animals are identified each year in the U.S.
- Endemic regions of the U.S. include the mid-Atlantic, southeast, south central, and north central areas, and the state of California.
- Common vectors: 7 species of animals account for 98% of all reported animal rabies cases in the U.S.: Skunk (38–43%), raccoons (28–31%), bats (14%), cats (4%), foxes (4%), cattle (4%), dogs (3%), and all other (2%).

Prevalence

- From 2000–2007, there were 20 cases of rabies acquired in the U.S. 17 of these were associated with bat rabies strains.
- Despite widespread infection of raccoons, there has been only 1 documented human death.

RISK FACTORS

- Travel to areas where canine rabies is endemic
- Exposure to a wild animal, typically through a bite. In the U.S., bats, raccoons, skunks, foxes, and coyotes are the principal reservoir.
- Exposure to an unimmunized domestic animal, especially through a bite.
- Transmission from transplanted corneas and organs has occurred.
- Working with animals (e.g., veterinarians), or working in a laboratory with the virus.

GENERAL PREVENTION

- Immunoprophylaxis: Preexposure vaccines are offered to those at high risk (e.g., veterinarians, animal handlers).
- Because wild animals account for 90% of new rabies cases in the U.S. today, avoiding unnecessary contact is helpful.
- Attempts are being made in several areas of the U.S. to vaccinate wild animals orally by using vaccine-baited food.
- Pets should be vaccinated.

PATHOPHYSIOLOGY

- Except for rare cases, the rabies virus enters the body through a bite that breaks the skin and introduces infected saliva:
 - From there, the virus gains access to muscle, where it is sequestered.
 - The virus then enters the peripheral nerves, where it moves centripetally to the CNS at a rate of ~3 mm/h.
 - Once in the CNS, infection spreads rapidly to involve nearly all neurons.
 - This state, if untreated, leads to cardiopulmonary arrest and death shortly thereafter, as a result of still poorly understood mechanisms.
- The incubation period is typically 4 weeks but can be days to years, with the longest documented incubation being 6 years.

ETIOLOGY

Rabies virus is a rhabdovirus containing single-stranded RNA.

DIAGNOSIS

HISTORY

- Behavior of animal: Although signs of rabies in animals vary greatly, atypical behavior for the animal is the norm (e.g., passive animals become aggressive, nocturnal animals roam in daylight).
 - Foaming at the mouth and lack of coordination may be present.
- A few humans with rabies have no identifiable preceding animal exposure.
- Type of animal inflicting the bite (domestic vs. wild)
- Location of the animal and availability for observation
- History of previous rabies vaccination of the animal and patient
- Signs and symptoms:
 - Prodrome: 2–10 days with vague and insidious symptoms (e.g., sore throat, malaise, anxiety, depression, fever, nausea). A fairly specific prodromal symptom is itching, pain, or tingling at the site of the bite.
 - Acute neurologic phase: Furious (80%) vs. paralytic (20%) rabies:
 - Furious rabies: Agitation, hyperactivity, bizarre behavior, nuchal rigidity, sore throat, and hoarseness. The pathognomonic sign is hydrophobia and, at times, aerophobia.
 - Paralytic rabies: Initial finding is flaccid paralysis in the limb that was bitten; subsequently spreads to other limbs. Cranial nerve involvement can give complete lack of facial affect.
 - Coma: Onset follows acute neurologic phase; may persist up to 2 weeks and is followed by death almost universally.

PHYSICAL EXAM

- Although neurologic findings can vary, cranial nerve paralysis (e.g., palate, vocal cords) is common. Therefore, hoarseness and stridor can be seen.
- Meningismus is also fairly common, along with involuntary movements. Beyond this, findings depend on type of presentation (furious vs. paralytic).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- There are no known methods for identification of rabies virus infection before onset of clinical signs. However, after signs appear, laboratory diagnosis is now possible as early as day 5 of illness by several techniques:
 - Enzyme-linked antibodies stain of brain tissue from captured animal
 - Fluorescent antibody stain of corneal epithelial cell smears or a section of skin from the neck at the hairline of patient
 - Serologic diagnosis is possible if the patient survives beyond the acute period. A rise in virus-neutralizing antibody will be seen.
 - Viral isolation in suckling mice or tissue culture from saliva, CSF, urine sedimentation, and brain is, at times, possible between days 4–24.
- Postmortem diagnosis is made by the presence of pathognomonic cytoplasmic inclusions (i.e., Negri bodies) in brain tissue (sensitivity, 80%).

DIFFERENTIAL DIAGNOSIS

- Other causes of encephalitis (e.g., herpes simplex virus, enterovirus) can mimic rabies.
- Paralytic rabies can present much like Guillain-Barré syndrome or poliomyelitis.
- Pseudorabies is conversion-related (hysteria) in someone who believes she or he has rabies but does not. In such patients, however, normal blood gases and lack of variation in bizarre behavior are diagnostic for no finding of rabies.

TREATMENT

MEDICATION (DRUGS)

- Immunization: Both passive and active immunization should be initiated concurrently
- Passive:
 - Human rabies immune globulin derived from the plasma of volunteers hyperimmunized with rabies vaccine should be given to anyone bitten by any species of wild animal known to be at high risk for rabies infection (e.g., skunk, raccoon, fox, coyote, bat) and any domestic dog or cat not in good health and in the custody of someone able to observe the animal for a 10-day period. Local health departments can advise about the risk of specific animal exposures.
 - The present recommendation for human rabies immune globulin vaccination is 20 IU/kg instilled locally into the tissue at the site of the bite.
 - Remaining vaccine can be given IM.
 - In cases of multiple wounds, to ensure that all wounds receive an injection of human rabies immune globulin, dilution in saline (2–3-fold) is acceptable.
 - Using more than the recommended dosage is contraindicated because it may interfere with the immune response to the active vaccine.
- Active:
 - 2 forms of rabies vaccine are commercially available. These include human diploid cell rabies vaccine (HDCV) and purified chicken embryo cell vaccine (PCEC). These should be administered by the same criteria given above for passive immunization. In addition, preexposure vaccination is recommended for those at high risk for exposure (e.g., veterinarians, animal handlers, trappers).
- Dosage: 1 mL IM in the deltoid region on days 0, 3, 7, 14, and 28 postexposure. The anterolateral thigh can be used in infants or young children. Discontinue the vaccine series if fluorescent antibody testing of the animal is conducted and result is negative.

IN-PATIENT CONSIDERATIONS

Initial Stabilization

Local wound care:

- The 1st step in preventing infection is washing out the virus mechanically or inactivating it before it has a chance to attach to and enter a neuron.
- The wound should be flushed with copious amounts of soap and water or saline solution.
- For puncture wounds, insertion of a catheter (i.e., angiocatheter) and irrigation with fluid by means of an attached syringe should be performed. If irrigation is too painful, infiltration of the area with local anesthetic can help.

ONGOING CARE

PROGNOSIS

- After the patient is infected with the rabies virus, prognosis is poor. There is no medical therapy available once the nervous system is infected
- Without postexposure rabies immunization, the disease is uniformly fatal.
- 1 patient survived following intensive care and induced coma (see www.mcw.edu/rabies). 2 other patients survived the acute illness using this regimen, but died of complications during rehabilitation.

FAQ

- Q: Does a wild squirrel or rabbit bite necessitate rabies prophylaxis?
- A: In general, rodents (e.g., squirrels, rats, mice, hamsters, gerbils), lagomorphs (e.g., rabbits and hares), and opossums are not known to serve as natural rabies reservoirs. They should not be considered rabid unless they exhibit unusual behavior.
- Q: Is there any evidence of human-to-human spread?
- A: No. However, health care workers or others exposed to a patient with known or suspected rabies should receive vaccination if they have suffered a bite wound or if mucosal surfaces or open wounds have been exposed to the patient's body fluids.
- Q: Are there any countries that require routine rabies vaccination?
- A: Yes, Nepal.
- Q: What if a severe allergic reaction occurs during postexposure rabies prophylaxis?
- A: The reaction should be treated at the time, as you would any systemic anaphylactic reaction. Subsequently, the rabies vaccine adsorbed (RVA), produced in rhesus diploid cells, can be given on the same schedule as human diploid cell rabies vaccine.
- Q: If a bat is found in the house, should the family members receive immunoprophylaxis?
- A: If a bat is found in the room of a sleeping person, previously unattended child, or mentally disabled person, prophylaxis should be considered. The injury inflicted by a bat bite or scratch may not be noticed in the above situations.
